Many strategies to reduce the need for allogeneic RBC transfusion in premature infants have been developed and have resulted in a marked decrease in the number of transfusions and number of donor exposures for most premature infants. Reducing phlebotomy losses by use of noninvasive monitoring techniques has been of only limited usefulness (Strauss, 1991). Donor exposures can be reduced by assigning a specified bag of adult donor blood to a sick neonate for multiple transfusions (Cook et al, 1993), particularly because it has been shown that blood stored for up to 35 days in CPDA-1 (Liu et al, 1994) or AS-3 (Goldman et al, 2001; Strauss et al, 2000) is safe for use in this setting. Defining strict criteria for RBC transfusions also can reduce the number of donor exposures in routine nursery practice (Batton et al, 1992; Maier et al, 2000). Traditionally, RBC transfusions have been given to replace phlebotomy losses or in the presence of symptoms thought to reflect hypoxia (e.g., tachycardia, tachypnea, dyspnea, apneic spells, poor feeding) (Oski and Naiman, 1982; Wardrop et al, 1978). However, studies to validate such practices have yielded conflicting results. Stockman and Clark (1984) showed a beneficial effect of transfusion on weight gain, but no benefit was found by Blank et al (1984). Similarly, apneic spells were reduced in frequency following RBC transfusion in some studies (Joshi et al, 1987; Ross et al, 1989) but not others (Bifano et al, 1992; Blank et al, 1984; Keyes et al, 1989). Lachance et al (1994) measured oxygen consumption, myocardial function, resting energy expenditure, and other physiologic variables before and after RBC transfusions. They concluded that in asymptomatic anemic premature infants, oxygenation was well maintained without RBC transfusions when the hemoglobin level was 6.5 g/dL or more. Nelle et al (1994) studied a similar group of asymptomatic anemic premature infants and found that RBC transfusion improved systemic oxygen transport as well as transport in the cerebral and gastrointestinal arteries. When clinical features of hypoxia are absent or findings are equivocal, an elevated blood lactate level may predict a need for transfusion (Izraeli et al, 1993) but in the experience of Frey and Losa (2001) adds little value to the decision-making process in the individual patient. At present, most neonatal intensive care units have abandoned earlier practices of automatically replacing phlebotomy losses in favor of transfusing for clear-cut symptoms of hypoxia or for significant anemia unaccompanied by evidence of an adequate erythropoietic response (Alagappan et al, 1998; Engelfriet and Reesink, 2001).

The question of optimum guidelines for transfusion in preterm infants has been studied in two important prospective randomized clinical trials comparing liberal (high) and restrictive (low) transfusion thresholds (Table 77-8). The Iowa study enrolled 100 infants with birthweights of 500 to 1300 g, using either liberal or restricted transfusion thresholds, with thresholds depending on need for respiratory support (Bell et al, 2005). The PINT Canadian study enrolled 451 infants under 1000 g; transfusion thresholds were different for infants requiring respiratory support or not, and changed for 1st, 2nd, and 3rd to 4th weeks of life (Kirpalani et al, 2005).

In the Iowa study, only 10% to 12% of patients required transfusions. The restrictive group received fewer transfusions (3.3±2.9) as compared to the liberal group (5.2±4.5), but the number of donor exposures was similar (2.8±2.5 for liberal group, 2.2±2.0 for restrictive group). There was more apnea in the restricted transfusion group. In addition, although the study was not designed to detect a difference in CNS outcome, there was a higher rate of grade IV intraventricular hemorrhage (IVH) and periventricular leukomalacia in the restricted group.

In the Canadian study, 89% to 95% of infants received at least one transfusion, and the number of transfusions per infant was not significantly different, 4.9 versus 5.7. There was no difference between groups for primary endpoint

for the PINT study, which was a composite of death before discharge or survival with bronchopulmonary dysplasia, severe retinopathy, or brain injury on cranial ultrasound. This study had smaller, sicker infants with 70% to 74% suffering the composite primary endpoint, so it was difficult to discern possible differences between the liberal and restrictive groups. In a follow-up report (Whyte et al, 2009), an assessment of preplanned secondary neurologic outcomes did not show a difference between groups, though the liberal transfusion group had a lower rate of cognitive delay when redefined as a Mental Development Index <85 in post hoc analysis.

A recent analysis of these two studies (Strauss, 2008) noted that the lack of difference in number of RBC transfusions in the Canadian trial likely reflected the relatively small differences in transfusion triggers between the two groups, and also that transfusions for clinical indications, rather than hematocrit thresholds, made up 16% of all transfusions in that study. However, the apparent higher rate of IVH and periventricular leukomalacia in the restrictive group in the Iowa study certainly raises the potential impact of a low transfusion threshold and resulting low hematocrit on the immature central nervous system. In a study of 25 preterm infants (Kissack, 2004), high cerebral fractional oxygen extraction was associated with intraventricular hemorrhage and/or hemorrhagic parenchymal infarction. The potential for a higher blood hemoglobin content and/or blood volume and cardiovascular stability to improve oxygen delivery to tissues and decrease rates of IVH is supported by the lower rate of IVH (14%) in infants <32 weeks undergoing delayed umbilical cord clamping as compared with 35% in those undergoing immediate clamping (Mercer et al, 2006).

Thus, the optimum transfusion threshold for preterm infants remains uncertain, especially with respect to neurologic sequelae. Strauss concludes that the potential risk of using very restrictive transfusion guidelines may be greater than the risk of more frequent transfusions, especially given the availability of "single-donor" transfusion practices that limit exposures to multiple blood donors (Strauss, 2008). He thus recommends following conventional transfusion guidelines, which are generally liberal, while stressing the need to continue to study these questions. In particular, there is a need for a prospective clinical trial of transfusion thresholds that is designed to determine whether liberal RBC transfusions may have a neuroprotective effect.

Despite controversies, there is agreement that the optimum approach to the anemia of prematurity includes delayed clamping of the umbilical cord (at least 30 seconds) (Rabe et al, 2009); limiting blood loss by phlebotomy; use of dedicated red blood cell units to minimize donor exposure; optimizing nutrition including protein, iron, folate, vitamin B_{12}, and vitamin E; and use of standardized transfusion guidelines.

POLYCYTHEMIA

Neonatal polycythemia usually is caused by one of two conditions: increased intrauterine erythropoiesis or fetal hypertransfusion (Table 77-9). Other causes seen in older children, such as arterial hypoxemia (cyanotic heart disease, pulmonary disease), abnormal hemoglobins, or hypersecretion of erythropoietin by tumors, are rare, and primary polycythemia or polycythemia vera is virtually nonexistent. In normal term infants, delayed clamping of the cord leading to an increased transfer of placental blood to the infant is the most common cause of polycythemia. In the setting of acute intrapartum hypoxia, increased placental transfusion also may account for the observed increase in fetal RBC mass, according to animal studies by Oh et al (1975). Placental insufficiency and chronic intrauterine hypoxia, as seen typically in small-for- gestational-age infants, most commonly underlie increased intrauterine erythropoiesis.

As the hematocrit increases, blood viscosity increases exponentially (Figure 77-15). Blood flow is impaired by hyperviscosity at hematocrits of 60% or more. Oxygen transport, which is determined by both hemoglobin levels (i.e., oxygen-binding capacity) and blood flow, is maximal in the normal hematocrit range. At low hematocrits, oxygen transport is limited by reduced oxygen-binding

TABLE 77-8 Comparison of Iowa and Canadian Prospective Randomized Trials for Premature Infants: Transfusion Thresholds (Triggers)

		Iowa Trial		Canadian Trial (PINT)	
		Liberal*	Restrictive*	Liberal†	Restrictive†
Mechanical ventilation	≤7 days	46%	34%	41%	35%
	8–14 days			36%	30%
	≥15 days			30%	26%
CPAP or nasal O_2	≤7 days	38%	28%	41%	35%
	8–14 days			36%	30%
	≥15 days			30%	26%
No respiratory support	≤7 days	30%	22%	36%	30%
	8–14 days			30%	26%
	≥15 days			26%	23%

CPAP, Continuous positive airway pressure; *Hct*, hematocrit; *RBC*, red blood cell.
*Hct threshold prompting RBC transfusion.
†Hct threshold, calculated as 3 × the hemoglobin in g/dL, prompting RBC transfusion.

capacity, whereas at higher hematocrits, reduction in blood flow secondary to hyperviscosity may similarly limit oxygen transport. At any given hematocrit, expansion of the blood volume beyond the normal level (hypervolemia) distends the vasculature, decreases peripheral resistance, and increases blood flow and, ultimately, oxygen transport. These physiologic observations have implications for therapy of polycythemia.

Most polycythemic infants have no symptoms, particularly if the polycythemia becomes apparent only on routine neonatal screening. Symptoms, when present, usually are attributable to hyperviscosity and poor tissue perfusion or to associated metabolic abnormalities such as hypoglycemia and hypocalcemia. Common early signs and symptoms include plethora, cyanosis (resulting from peripheral stasis), lethargy, hypotonia, poor suck and feeding, and tremulousness. Serious complications include cardiorespiratory distress (with or without congestive heart failure), seizures, peripheral gangrene, necrotizing enterocolitis, renal failure (occasionally resulting from renal vein thrombosis), and priapism. Because the elevated RBC mass increases the catabolism of hemoglobin, hyperbilirubinemia is common and gallstones occasionally occur.

In the symptomatic infant, a venous hematocrit of 65% or more (or a hemoglobin greater than 22 g/dL) confirms the presence of polycythemia. In screening apparently healthy newborns for polycythemia, however, account must be taken of a number of physiologic variables that influence the hematocrit during the first 12 hours of life:

1. Time of cord clamping—immediate clamping (within 30 seconds) minimizes placental transfusion.
2. Age at sampling—values increase from birth to a peak at 2 hours, gradually decreasing to cord levels around 12 to 18 hours (Ramamurthy and Berlanga, 1987; Shohat et al, 1984).
3. Site of sampling—values from blood extracted by the heelstick method exceed those from venous blood (the difference can be minimized by prewarming the heel).
4. Method of hematocrit determination—spun values are higher than those obtained by electronic cell counter and show better correlation with blood viscosity (Villalta et al, 1989).

One way to standardize and simplify screening for polycythemia is as follows: At birth, clamp the cord at about 30 to 45 seconds; at 4 to 6 hours of age, obtain a blood sample from a warmed heelstick and perform a spun hematocrit determination. If the result is greater than 70%, repeat the test on a venous sample. A venous hematocrit of 65% or more indicates polycythemia. By this approach, 1% to 5% of newborns are polycythemic; the range largely reflects differences in altitude at which the study population resides. Because the hematocrit is lower with increasing prematurity, polycythemia is seen less frequently in preterm infants than in term babies.

Following diagnosis, an attempt should be made to determine the cause of polycythemia (see Table 77-9). The condition is particularly common in infants of diabetic mothers or those with Down syndrome (Mentzer, 1978) and may also occur in the setting of maternal hypertension (Kurlat and Sola, 1992) or, rarely, fumaric aciduria (Kerrigan et al, 2000). However, no apparent cause is found in most cases. Studies to determine the effects of polycythemia are dictated by the clinical findings but should usually

TABLE 77-9 Etiology of Neonatal Polycythemia

Active (Increased Intrauterine Erythropoiesis)	Passive (Secondary to Erythrocyte Transfusions)
Intrauterine hypoxia	Delayed cord clamping

include serum bilirubin, glucose, calcium, urea nitrogen, and creatinine levels.

Treatment by isovolumetric partial exchange transfusion (PET) is recommended to reduce the RBC mass without inducing hypovolemia. However, the precise indications for PET and the impact of the procedure on outcome have been questioned. In a review of randomized or quasirandomized studies of infants with symptomatic or asymptomatic polycythemia (Dempsey and Barrington, 2006), there was no evidence of difference in either long-term neurodevelopmental outcome or short-term neurobehavioral scores. There was a trend toward an earlier improvement in symptoms, but an apparent increase in risk of necrotizing enterocolitis (relative risk 8.68, 95% confidence interval 1.06 to 71.1), although several of the studies used fresh frozen plasma. The general finding that polycythemic infants have a poorer outcome than concurrent infants without polycythemia has been thought to be related to the underlying cause of the polycythemia; in one study, perinatal risk factors other than polycythemia were best correlated with outcome and thought to underlie both the polycythemia and the developmental delay (Bada et al, 1992).

Many neonatal intensive care units use PET for symptomatic infants with hematocrits greater than 60% to 65%, and for asymptomatic infants with hematocrits greater than 65% to 70%. However, the Committee on the Fetus and Newborn of the American Academy of Pediatrics acknowledged in their 1993 statement that "there is no evidence that exchange transfusion affects long term outcome. ... Universal screening for polycythemia fails to meet the methodology and treatment criteria and also, possibly the natural history criterion." Thus, Schimmel et al (2004) made the following recommendations based on the available evidence, until such time as systematic studies can be conducted directly measuring blood viscosity to allow development of objective criteria for PET in polycythemia:

- In symptomatic patients with hematocrit >65%, PET with normal saline should be used to reduce possible ongoing injury to tissues by enhancing blood flow.
- In asymptomatic polycythemic infants with presumed normal or increased blood volume, careful monitoring (glucose, cardiorespiratory) is adequate.
- In infants with presumed reduced plasma or blood volume status, treat with early feeding or intravenous fluids.
- For asymptomatic polycythemic infants with presumed normal blood and plasma volume, consider PET only if repeated venous hematocrits are >75%.

Systematic reviews of several studies comparing the use of crystalloid or colloid for PET have concluded that crystalloid solutions are as effective as colloid solutions (Dempsey and Barrington, 2005; de Waal et al, 2006). Thus, normal saline, as an inexpensive product that carries no risk of transfusion-associated infection or reaction to plasma proteins, should be used. Withdrawal of blood for a partial exchange transfusion is most easily done using an umbilical artery catheter. Any vessel may be used for blood withdrawal, and all but arterial lines can be used to infuse volume. An umbilical venous catheter inserted into the right atrium also provides acceptable access, but if correct placement cannot be achieved, the catheter should be inserted just far enough into the vessel to allow blood to be withdrawn. Calculation of the total volume of blood to be exchanged for diluent uses the following formula (Oski and Naiman, 1982):

$$\text{Exchange volume} = \frac{\text{observed Hct} - \text{desired Hct} \times \text{BV (mL/kg)} \times \text{weight (kg)}}{\text{observed Hct}}$$

where blood volume (BV) usually is 100 mL/kg but in infants of diabetic mothers may be lower (80 to 85 mL/kg).

Example: A 3-kg dyspneic infant with an 80% hematocrit requires a partial exchange transfusion.

$$\text{Blood volume} = 3\ \text{kg} \times 100\ \text{mL/kg} = 300\ \text{mL}$$

$$\frac{\text{observed Hct} - \text{desired Hct}}{\text{observed Hct}} = \frac{80 - 55}{80} = 0.31$$

Therefore, volume of exchange = 300 mL × 0.31 = 93 mL.

Because coexisting hypoglycemia is an important determinant of adverse neurologic outcome, careful monitoring and maintenance of adequate glucose levels and hydration are essential.

METHEMOGLOBINEMIA

Methemoglobin (metHb) is an oxidized derivative of hemoglobin in which heme iron is in the ferric (Fe^{3+}) or oxidized state rather than the ferrous (Fe^{2+}) or reduced state. Because methemoglobin is unable to bind (or release) oxygen, the presence of significant amounts of metHb adversely affects oxygen transport. Small amounts of methemoglobin normally are formed daily, associated with the release of oxygen from hemoglobin (auto-oxidation). The metHb that is formed rapidly is reduced through the action of RBC NADH-methemoglobin reductase (also known as cytochrome b_5 reductase), so that in normal persons, levels of metHb seldom exceed 1%. A second methemoglobin reductase, dependent on NADPH as cofactor, also is present in RBCs. This enzyme has little function under normal physiologic conditions, but it is greatly activated by the presence of certain redox compounds such as methylene blue, forming the basis for the clinical treatment of methemoglobinemia.

Acquired methemoglobinemia can occur in normal individuals following exposure to chemicals that oxidize hemoglobin iron. Newborns are particularly susceptible because fetal hemoglobin is more readily oxidized to the ferric state than is hemoglobin A and because RBC NADH-methemoglobin reductase activity is low during the first few months of life. Merely marking the diapers of newborns with aniline dyes has caused methemoglobinemia. Drugs such as prilocaine, administered before birth to provide local anesthesia, can produce methemoglobinemia in both mother and infant. Although in most infants, no increase in methemoglobin levels follows the use of lidocaine-prilocaine cream (Emla Cream) to provide analgesia during circumcision (Taddio et al, 1997), a few case reports of visible cyanosis due to methemoglobinemia

in infants treated with this cream have appeared (Couper, 2000; Tse et al, 1995). Perhaps the best-known agent that may cause methemoglobinemia is nitrite, either present de novo in ingested material or generated by administering nitric oxide to term babies in high concentrations for treatment of persistent pulmonary hypertension (Davidson et al, 1998). Nitrates can be converted to nitrite by the action of intestinal bacteria. It is for this reason that well water or foods with a high nitrate content (e.g., cabbage, spinach, beets, carrots) can produce methemoglobinemia in infants (Keating et al, 1973). Accumulation of nitrate in the intestinal tracts of infants with diarrhea and acidosis (Kay et al, 1990; Yano et al, 1982) or symptomatic dietary protein intolerance (Murray and Christie, 1993) is thought to underlie the transient methemoglobinemia that occurs in these conditions.

Congenital methemoglobinemia is due to inherited disorders of hemoglobin structure or to a severe deficiency of NADH methemoglobin reductase activity. The inherited abnormalities of hemoglobin structure that give rise to methemoglobinemia, known collectively as the hemoglobin M disorders, are rare autosomal-dominant defects caused by point mutations that alter a single amino acid in the structure of normal globin. The altered conformation that ensues favors the persistence of the ferric rather than the ferrous form of heme iron. The normal methemoglobin reductive capacity of the RBC cannot compensate for such instability of ferrous heme. Two of the mutations affect the alpha globin chain, three affect the beta globin chain, and two affect the gamma chain. Only the alpha and gamma globin chain mutations are associated with neonatal methemoglobinemia, because these are the globins that form hemoglobin F. Neonatal methemoglobinemia is transient when produced by one of the two gamma chain mutations, hemoglobin FM–Osaka (Hayashi et al, 1980) or hemoglobin FM–Fort Ripley (Priest et al, 1989), because the normal developmental switch from fetal to adult hemoglobin eliminates all but a trace of the mutant hemoglobin. Hemoglobin M heterozygotes inheriting alpha or beta globin mutations have lifelong cyanosis, but they are usually asymptomatic. No therapy is needed (and none is possible). The homozygous state is incompatible with life. Diagnosis of the hemoglobin M disorders is made by special tests in RBC diagnostic laboratories.

NADH-methemoglobin reductase deficiency is a rare autosomal recessive disorder. Heterozygotes are asymptomatic and do not have methemoglobinemia under normal circumstances. However, if challenged by drugs or chemicals that cause methemoglobinemia, heterozygous deficient patients may become cyanotic and symptomatic at doses that have no effect in normal persons. Homozygotes have lifelong methemoglobin levels of 15% to 40% and are cyanotic but otherwise asymptomatic unless exposed to toxic agents. Diagnosis of NADH-methemoglobin reductase deficiency is by assay of RBC enzyme activity, a procedure available only in specialized hematology laboratories.

The cardinal clinical manifestation of methemoglobinemia is cyanosis not resulting from cardiac or respiratory disease. Cyanosis present at birth suggests hereditary methemoglobinemia, whereas that appearing suddenly in an otherwise asymptomatic infant is more consistent with acquired methemoglobinemia (Box 77-3). The blood is dark and, unlike deoxygenated venous blood, does not turn red when exposed to air. Rapid screening for methemoglobinemia can be done by placing a drop of blood on filter paper and then waving the filter paper in air to allow the blood to dry. Deoxygenated normal hemoglobin turns red, whereas methemoglobin remains brown. Methemoglobin levels of 10% or more can be detected (Harley and Celermajer, 1970). More accurate determination of methemoglobin levels is accomplished in the blood gas laboratory by co-oximetry or in the clinical laboratory using a spectrophotometer. Cyanosis is first clinically evident when methemoglobin levels reach approximately 10% (1.5 g/dL), but symptoms attributable to hypoxemia and diminished oxygen transport do not appear until levels increase to 30% to 40% of total hemoglobin. Death occurs at levels of 70% or greater. Methemoglobinemia is not associated with anemia, hemolysis, or other hematologic abnormalities.

Treatment with intravenous methylene blue (1 mg/kg as a 1% solution in normal saline) is indicated when methemoglobin levels are greater than 15% to 20%. Doses greater than 1 mg/kg should be avoided, because they may be toxic (Porat et al, 1996). The response to methylene blue is both therapeutic and diagnostic. Methemoglobin levels decrease rapidly, within 1 to 2 hours, if methemoglobinemia is caused by a toxic agent or by a deficiency of NADH-methemoglobin reductase. In contrast, the hemoglobin M disorders do not respond to methylene blue. Reappearance of methemoglobinemia after an initial response to methylene blue suggests a deficiency of

BOX 77-3 Approach to Infants With Cyanosis and Methemoglobinemia

CYANOSIS WITH RESPIRATORY AND CARDIAC ABNORMALITIES:

Blood turns red when mixed with air
Decreased arterial Po_2
Consider pulmonary, cardiac, or central nervous system disease

CYANOSIS WITH OR WITHOUT RESPIRATORY OR CARDIAC ABNORMALITIES:

Blood turns red when mixed with air
Normal arterial Po_2
Consider polycythemia syndromes

CYANOSIS WITHOUT RESPIRATORY OR CARDIAC ABNORMALITIES:

Blood remains dark after mixing with air
Normal arterial Po_2
Consider methemoglobinemia syndromes

1. With rapid clearing of methemoglobin following methylene blue:
   - **a.** Consider toxic methemoglobinemia (look for environmental oxidants)
   - **b.** Consider NADH-methemoglobin reductase deficiency (perform enzyme assay)
2. With reappearance of methemoglobinemia after initial response to methylene blue:
   - **a.** Consider NADH-methemoglobin reductase deficiency
3. With no change in methemoglobin following methylene blue:
   - **a.** Consider hemoglobin M disorders (perform hemoglobin electrophoresis)
   - **b.** Consider associated glucose-6-phosphate dehydrogenase deficiency (perform enzyme assay)

NADH-methemoglobin reductase or the persistence of an occult oxidant. A poor response to methylene blue also is seen in G6PD-deficient persons because this disorder is characterized by suboptimal generation of NADPH, a required cofactor in the reduction of methemoglobin by methylene blue in deficient persons. In general, most infants with hereditary methemoglobinemia are asymptomatic and require no therapy.

Controversy Box

1. The use of erythropoietin in premature infants. Given the use of dedicated RBC-unit strategies, a modest rHuEPO effect is less likely to decrease the chance of exposure to multiple blood donors. There is wide variation in the use of rHuEPO for very low-birthweight infants in the United States, and disagreement regarding the cost-benefit ratio of rHuEPO therapy.
2. The optimum transfusion threshold for premature infants. Recent prospective randomized studies comparing liberal (high) and restrictive (low) transfusion thresholds were designed differently and came to different conclusions regarding outcomes. However, concerns were raised regarding the potential impact of a restrictive threshold and low hematocrit on the developing central nervous system.
3. The appropriate indications for partial exchange transfusion for infants with polycythemia. In a review of randomized or quasirandomized studies of infants with symptomatic or asymptomatic polycythemia, there was no difference in either long-term neurodevelopmental outcome or short-term neurobehavioral scores.

CHAPTER 78

Neonatal Leukocyte Physiology and Disorders

Evan B. Shereck, Carmella van de Ven, and Mitchell S. Cairo

This chapter presents an overview of neonatal leukocyte physiology and quantitative and qualitative disorders of leukocytes. Topics include the normal physiology and defects associated with neonatal hematopoiesis, neutrophils, lymphocytes, monocytes, dendritic cells, and natural killer cells. Novel therapeutic approaches also are discussed.

HEMATOPOIESIS

Hematopoiesis is a complex process that begins with an uncommitted pluripotent hematopoietic stem cell that progresses through a series of steps to development of a single-lineage progenitor cell. The final result of this physiologic process is a mature, lineage-restricted effector cell that circulates either in the bloodstream or within tissue. In 1961, Till and McCulloch demonstrated that when bone marrow cells were transfused into lethally irradiated mice, separate colonies of hematopoietic cells could be identified in the spleen of the recipient. Each colony, containing neutrophils, monocytes, erythrocytes, megakaryocytes, eosinophils, and basophils, was derived from an individual cell, and many of the colonies contained cells that were capable of such colony formation when transplanted into a second irradiated animal. Such cells, which are capable of unlimited self-renewal, have been referred to as *pluripotent stem cells*.

FETAL AND NEONATAL HEMATOPOIESIS

In human ontogeny, the process of hematopoietic maturation involves the orderly shift of hematopoiesis from extramedullary organs to the bone marrow (Nathan, 1989). Hematopoietic cells are derived from the mesodermal layer of the blastula in embryogenesis. This layer contains undifferentiated, self-renewing cells that will migrate to different tissues, including blood. The first step towards hematopoietic maturation occurs when these hematopoietic cells migrate to the blood islands formed by the yolk sac by embryo day 15 (Zon, 1995). The erythrocytes are the predominant lineage during this time. Yolk sac erythrocytes are large nucleated cells, expressing the products of certain genes that are unique to this phase of development. Shortly after, the yolk sac develops single and multilineage myeloerythroid progenitor cells (Gekas, 2005). Although the yolk sac greatly expands the hematopoietic progenitor pool, these cells do not differentiate into mature blood cells (Palis et al, 1999). These progenitor cells then migrate from the yolk sac to the fetal liver (Zon, 1995). There are studies suggesting that hematopoietic progenitor cells from the aorto-gonado-mesonephron and placenta also contribute to fetal liver seeding (Gekas, 2005; Zon, 1995). The fetal liver then becomes the main site of hematopoiesis until hematopoiesis relocates to the bone marrow perinatally (Ema and Nakauchi, 2000).

Granulocyte-macrophage colony-forming units (CFU-GMs) have been identified in the fetal liver as early as 5 weeks' gestation. However, their number is low compared with that of cells of the erythroid lineage. Myelopoiesis increases fourfold once hematopoiesis relocates to the bone marrow of the fetus at 14 weeks' gestation, but the myeloid cells remain comparatively limited (Kelemen et al, 1979). Myeloid cells (neutrophil progenitor cells) constitute less than 5% of nucleated marrow cells in the fetus, compared with 31% to 69% in term neonates and 25% to 52% in adults.

HEMATOPOIETIC GROWTH FACTORS

The regulation of hematopoiesis is a complex biologic process involving multifactorial mechanisms. As reported by our group (Abu-Ghosh et al, 2000), in vitro culture of hematopoietic progenitor cells has enabled the categorization, functional analysis, and definition of the growth factor requirements of the various committed progenitor cells (Figure 78-1).

The hematopoietic pluripotent stem cell (PPSC) that expresses CD34 represents an early and primitive hematopoietic stem cell that can be identified by immunophenotyping. This cell can either undergo self-renewal or proliferate and differentiate into any of the hematopoietic blood lineages depending on its exposure to individual and combinations of hematopoietic growth factors (HGFs). Primitive progenitor cells maintain their multipotent potential, whereas more mature progenitor cells become committed as they differentiate into specific lineages. A relatively small and common set of pluripotent stem cells gives rise to large numbers of functionally diverse mature cells.

Cell proliferation and differentiation is regulated and controlled by highly specific protein factors, affecting single- and multiple-lineage hematopoiesis. These growth-promoting factors are named colony-stimulating factors (CSFs). CSFs are a group of glycoproteins with molecular masses of 18 to 90 kDa, defined by their abilities to support proliferation and differentiation of hematopoietic cells of various lineages (see Figure 78-1).

GRANULOCYTE COLONY-STIMULATING FACTOR

Human granulocyte colony-stimulating factor (G-CSF) was first purified to homogeneity from a medium conditioned by the bladder carcinoma cell line 5637 (Welte

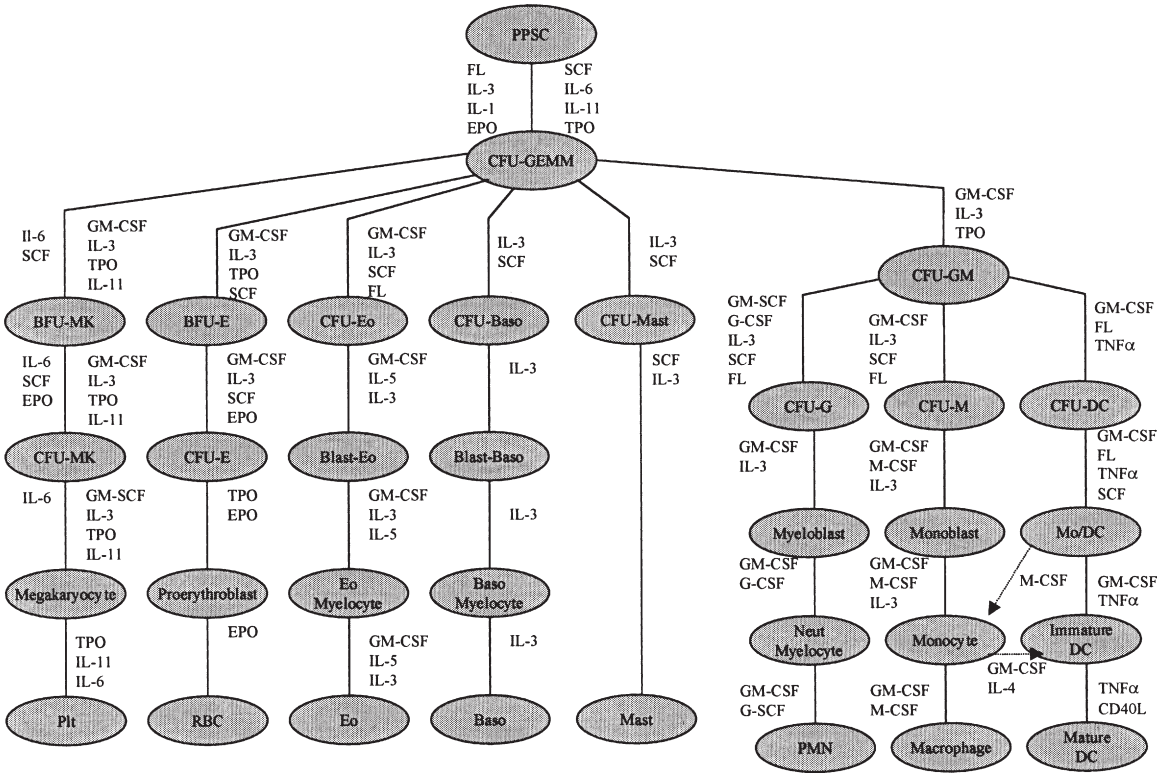

FIGURE 78-1 Hematopoiesis and hematopoietic growth factors. *Baso*, Basophil; *BFU*, burst-forming unit; *CFU*, colony-forming unit; *CSF*, colony-stimulating factor; *DC*, dendritic cell; *E*, erythroid; *Eo*, eosinophil; *EPO*, erythropoietin; *FL*, Flt 3 ligand; *G*, granulocyte; *GEMM*, granulocyte, erythrocyte, macrophage, and megakaryocyte; *GM*, granulocyte-macrophage; *IL*, interleukin; *M*, macrophage; *MK*, megakaryocyte; *Mo*, monocyte; *Neut*, neutrophil; *Plt*, platelet; *PMN*, polymorphonuclear neutrophil leukocyte; *PPSC*, pluripotent stem cell; *RBC*, red blood cell; *SCF*, stem cell factor; *TNFα*, tumor necrosis factor-α; *TPO*, thrombopoietin.

et al, 1985). The molecular mass of this glycoprotein is between 18 and 20 kDa, and the gene has been localized to chromosome 17q11-21. It has been identified in the 15-to-17 chromosomal translocation commonly found in acute promyelocytic leukemia. G-CSF is produced primarily by mature macrophages, endothelial cells, fibroblasts, and mesothelial cells. Its production can be stimulated in these cells by tumor necrosis factor, lipopolysaccharide (LPS), and the interleukins IL-1, IL-3, and IL-6 and also stem cell factor (SCF) (Lieschke and Burgess, 1992). G-CSF stimulates the proliferation of committed myeloid progenitor cells and has specific activity toward granulocyte colony formation with pure neutrophil colony proliferation. G-CSF affects mature neutrophil effector function in that it primes neutrophils to increase expression of chemotactic receptors and to enhance bactericidal and phagocytic activity, superoxide generation, antibody-dependent cellular cytotoxicity, and antiapoptotic prosurvival (Molloy et al, 2005).

Clinical studies have shown that G-CSF therapy results in a dose-dependent increase in the circulating neutrophil count in children and adults with congenital and acquired neutropenia syndromes as well as chemotherapy-induced neutropenia (Bonilla et al, 1989; Hammond et al, 1989). Significant differences in G-CSF production, G-CSF gene expression, and circulating G-CSF level exist between adults and newborns (Cairo et al, 1993). Gessler et al (1995) reported G-CSF serum levels at birth with respect to neutrophil count, infection, and gestational age. Serum concentrations of G-CSF in term and preterm neonates without infection reached peak levels within the first 7 hours of life (mean values of 261 pg/mL and 126 pg/mL in term and preterm infants, respectively). Levels decreased to normal adult range (<50 pg/mL) between 4 and 7 days of age and were unchanged at 2 to 3 weeks of age.

From neonatal animal model studies, it appears that the administration of recombinant human G-CSF (rhG-CSF) has significant effects on neonatal rat hematopoiesis, with a marked increase in the circulating neutrophil count, bone marrow myeloid progenitor pool, and neutrophil storage pool (NSP) (Cairo et al, 1990a). Combining G-CSF with earlier-acting cytokines such as SCF, IL-6, and IL-11 further enhances these effects on neonatal rat hematopoiesis (Cairo et al, 1991a, 1992a, 1993, 1994).

G-CSF acts synergistically with antibiotics to improve survival during neonatal sepsis, but only if given before or at the start of experimental sepsis (Cairo et al, 1990a, 1992b). Additionally, improved survival during experimental sepsis in neonatal rats has been demonstrated following prophylactic use of G-CSF in combination with antibiotics and either SCF or IL-11 (Cairo et al, 1992a, 1994; Chang et al, 1994).

G-CSF has been used in clinical trials for both prevention and therapy of neonatal sepsis. One study investigated the safety, pharmacokinetics, and biologic efficacy of administration of G-CSF to newborn infants with sepsis (Gillan et al, 1994). Forty-two newborn infants, both term

and preterm, with presumed sepsis during the first 3 days of life were randomized to receive either placebo or varying doses of rhG-CSF. The growth factor was given for 3 days at doses of 1, 5, or 10 μg/kg every day or 5 or 10 μg/kg twice a day. The half-life of rhG-CSF was 4.4 ± 0.4 hours. Intravenous rhG-CSF was well tolerated at all gestational ages and was not associated with any recognized acute toxicity. RhG-CSF induced a significant increase in the absolute neutrophil count (ANC) within 24 hours following doses of 5 and 10 μg/kg given either every 24 hours or divided every 12 hours. The increased neutrophil count was maintained for 96 hours, 48 hours after the last rhG-CSF dose. Bone marrow aspirates demonstrated a dose-dependent increase in NSP following treatment with rhG-CSF. In addition, polymorphonuclear neutrophil (PMN) C3bi expression was significantly increased at 24 hours following administration of 10 μg/kg of rhG-CSF every 24 hours. The enhancement of neonatal neutrophil C3bi expression indicates that rhG-CSF may induce functional maturation of neonatal neutrophils. A 2-year follow-up analysis in these patients has shown that rhG-CSF therapy for presumed neonatal sepsis was not associated with long-term hematologic, immunologic, or developmental adverse effects (Rosenthal et al, 1996).

Several other clinical studies have evaluated the efficacy of G-CSF in neonates with presumed sepsis or neutropenia. A randomized, placebo-controlled trial of G-CSF administration to infants with neutropenia and clinical signs of early-onset sepsis was recently reported (Schibler et al, 1998). Twenty infants, term and preterm, were given G-CSF (10 μg/kg/day) or placebo for 3 days. Absolute neutrophil count (ANC), ratio of immature to total neutrophils (I/T ratio), bone marrow NSP, bone marrow neutrophil proliferative pool (NPP), and plasma concentration of G-CSF were evaluated and found to be similar in treated and control infants. No significant differences were found in outcome measures such as severity of illness and mortality.

Ahmad et al (2004) studied the outcome of 14 neutropenic very low-birthweight (VLBW) and preeclamptic neutropenic versus nonseptic neonates (gestational ages 24 to 30 weeks) similarly treated with G-CSF (10 μg/kg/day) for 3 days. They also assessed phagocytic and oxidative burst activity before and after treatment with rhG-CSF. Following rhG-CSF treatment the neutropenic neonates increased their ANC by >12-fold, whereas the nonneutropenic group increased their ANC by 2.6-fold. Further, septic neutropenic neonates showed greater oxidative burst activity but a lower phagocytic response compared to nonseptic neutropenic neonates (Ahmad et al, 2004).

A recent multicenter randomized placebo-controlled study evaluated prophylactic rG-CSF treatment of neutropenic premature neonates with recombinant G-CSF (Kuhn et al, 2009). Twenty-five neonatal intensive care units participated, treating neutropenic (<1500 neutrophils/mm^3) premature infants (≤32 weeks' gestation). The results of the study confirm that prophylactic rG-CSF had a modest effect on the reduction of the incidence of nosocomial infections. Although survival free of confirmed infection did not differ significantly between the rG-CSF and control groups, rG-CSF treated neonates had significantly greater survival without confirmed infection (84% vs. 71%, p = 0.028, respectively), and survival free of any type of infection was also significantly greater in the rG-CSF treated group (69%) versus placebo controls (55%), p=0.049 (Kuhn et al, 2009).

GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR

Granulocyte-macrophage colony-stimulating factor (GM-CSF) was purified from a medium conditioned by the human T-cell lymphotropic virus-II (HTLV-II)-infected T-lymphoblast cell line MO. Characterization of the purified material showed that GM-CSF is a glycoprotein of 22 kDa, and the gene is located on chromosome 5q21-32 (Huebner et al, 1985). Potential physiologic sources for GM-CSF are T and B lymphocytes, macrophages, fibroblasts, mast cells, endothelial cells, mesothelial cells, and osteoblasts.

GM-CSF acts as a potent growth factor both ex vivo and in vivo by stimulating proliferation and maturation of myeloid progenitor cells, subsequently giving rise to neutrophils, eosinophils, and monocytes. GM-CSF has direct and indirect effects on human neutrophils. Direct effects include inhibition of neutrophil migration, enhanced degranulation, induction of adhesion, and changes in cytoskeleton and cell shape. Indirect actions enhance the ability of the neutrophil to respond to triggering stimuli. Among these effects are increased superoxide generation, Ca^{2+} fluxes, and production of inflammatory mediators such as leukotriene B_4.

Administration of GM-CSF in clinical trials results in an immediate and transient decrease in circulating neutrophils, eosinophils, and monocytes, followed by a recovery to baseline within 2 hours. A second phase follows in which the number of leukocytes increases, with a marked "shift to the left" as a result of demargination from the bone marrow NSP and increased myeloid production in the marrow.

The effect of GM-CSF on the incidence of sepsis in human neonates has also been evaluated. A phase I/II trial determined the feasibility, safety, and biologic response of GM-CSF in VLBW (≤1500 g) neonates. Twenty neonates (500 to 1500 g) were randomized in the first 3 days of life to receive GM-CSF at 5 μg/kg/day, 5 μg/kg/twice a day (or 10 μg/kg/day) or placebo. The study demonstrated that GM-CSF was well tolerated with no toxic acute effects. GM-CSF induced a significant increase in ANC, absolute monocyte count (AMC), bone marrow NSP, and neutrophil C3bi expression (Cairo et al, 1995).

A phase III multicentric, randomized, prospective, double-blind, placebo-controlled trial was performed to determine whether prophylactic administration of GM-CSF would reduce nosocomial infections in VLBW neonates. Infants (264, weighing 500 to 1500 g) were randomized in the first 3 days of life to receive either GM-CSF (8 μg/kg/day) for 7 days and then every other day for 21 days or placebo. No toxicity was recorded. The ANC was significantly elevated in the GM-CSF group on days 7, 14, and 21, and the absolute eosinophil count (AEC) on days 7 and 28. However, there was no difference in the incidence of confirmed nosocomial infections between the two groups (Cairo et al, 1999).

A recent single-blind, multicenter, randomized controlled trial was conducted in 26 centers in the United Kingdom (Carr et al, 2009). Infants (≤31 weeks, <10th percentile birthweight) were randomized to receive either GM-CSF (10 μg/kg/day) for 5 days or standard management and monitored for 28 days. Neutrophil counts after treatment were significantly higher in infants treated with GM-CSF than in control infants in the first 11 days. However, there was no significant difference in sepsis-free survival between the groups (Carr et al, 2009).

NEONATAL NEUTROPENIA

Manroe et al (1979) established reference values for ANCs in term and preterm infants during the first 28 days of life for both healthy infants and those with perinatal complications. Mouzinho et al (1994) studied serial white blood cells counts in healthy preterm VLBW infants to investigate whether this patient cohort had different neutrophil counts from those found in previous studies in which cohorts consisted mostly of term infants. They found that there was a wider range of the absolute total neutrophil count, mostly resulting from a downward shift of the lower boundary, especially during the first 60 hours of life. However, there was no difference in absolute total immature neutrophil counts or in I/T ratio. Schmutz et al (2008) demonstrated that the ANC reached its peak value at 6 to 8 hours for those neonates born at ≥28 weeks' gestation, but at 24 hours for those delivered at <28 weeks. The 5th and 95th percentiles for ANCs at 72 to 240 hours among neonates born at >36 weeks were 2700/μL and 13,000/μL, respectively; for neonates born at 28 to 36 weeks were 1000/μL and 12,500/μL, respectively; and for neonates born at <28 weeks were 1300/μL and 15,300/μL, respectively (Christensen et al, 2009). Another factor that contributes to the ANC at birth is the amount of labor the mother experienced. There are higher ANCs in neonates whose mothers had labored significantly versus those whose mothers who had not. Also, female newborns' ANC averages about 2000 cells/μL more than their male counterparts (Christensen et al, 2009).

The pathophysiologic mechanism responsible for neonatal neutropenia may be exhaustion of myeloid committed progenitor cells, inadequate response of progenitor cells to proliferative or maturational signals, and increased usage and destruction. In a series of studies, Christensen and Rothstein (1984) documented significant differences in myeloid progenitor pools and cell kinetics in fetal and neonatal rats compared with adult rats. In the newborn rat, the myeloid progenitor pool, consisting of CFU-GMs in the bone marrow, is only 25% of that of adult animals and requires 4 weeks of maturation to reach adult levels. Additionally, despite a lower number, the CFU-GM of the newborn rat is in a state of near-maximal proliferative capacity, the maximal rate of proliferation being 75% to 80%, whereas that of the adult CFU-GM is only 25% (Christensen and Rothstein, 1984). Concomitantly with reduced numbers of myeloid progenitor cells (lower numbers of CFU-GMs) and lower expansion capacity (already near maximal proliferative rate), the neonatal rat also possesses reduced numbers (25% of adult) of NSP, defined as the percentage of metamyelocytes, bands, and mature neutrophils in the bone marrow. The NSP reaches adult levels in the neonate rat at 4 weeks of age. These factors make it difficult for the neonatal rat to compensate when there is an increased demand.

SEPSIS-INDUCED NEUTROPENIA

Neonates with overwhelming sepsis often develop neutropenia, which illustrates some of the differences between adult and neonatal neutrophils. Neonates have fewer neutrophil progenitors and a diminished precursor storage pool so that neutrophils are easily depleted in stress conditions (Levy, 2007). Following experimental sepsis with group B streptococci (GBS), adult rats respond with a transient decrease in circulating neutrophil counts followed by significant neutrophilia associated with a two- to threefold increase in the progenitor pool (CFU-Meg) and an increase in the proliferative rate to 75% of the maximal capacity (Christensen et al, 1982, 1983). In contrast, neonatal rats under the same conditions had a decrease of 50% of their progenitor pool and failed to increase their myeloid proliferative rate, which, as discussed previously, was already at near-maximal levels. Most important, during experimental sepsis, neonatal rats had further depletion of their already reduced NSP reserves by almost 80%, compared with a decline of 33% in adult rats.

ALLOIMMUNE NEONATAL NEUTROPENIA

Alloimmune neonatal neutropenia occurs as a result of maternal sensitization to neutrophil antigens present on the infant's neutrophils (paternally acquired) that are not present on the maternal neutrophils, with subsequent production of immunoglobulin G (IgG). Neutrophil-specific antibodies are found in the maternal and infant sera, but the mother has a normal neutrophil count. It is estimated to occur at a frequency of 3% of live births (Curnette, 1993). The most common antigens involved in the United States are HNA-1a, HNA-1b, and HNA-2a. Because the antibodies are IgG, which crosses the placenta, peripheral blood counts show profound neutropenia and often demonstrate a monocytosis and eosinophilia. The condition is self-limiting and typically lasts for 6 to 7 weeks, during which time the neonate is susceptible to infections, mostly cutaneous in nature. Although most infections are typically mild, occasionally life-threatening infections may occur necessitating intensive support. Therapeutic interventions that have been attempted include antimicrobials, granulocyte colony stimulating factor, intravenous immune globulin (IVIG) infusions, and granulocyte transfusions that lack the disparate antigen (Maheshwari et al, 2002).

AUTOIMMUNE NEUTROPENIA OF INFANCY

This disorder is analogous to autoimmune hemolytic anemia or immune thrombocytopenic purpura. In this case, however, the infant develops antibodies directed toward its own neutrophils. The etiological mechanism is not yet understood. The incidence is estimated at 1 in 100,000 in children between infancy and 10 years of age (Hartman et al, 1994), though there may be many more children who remain undiagnosed because they lack any clinical

characteristics to prompt a complete blood count to be drawn. Although it is most commonly diagnosed from 3 to 30 months, it can occur during the neonatal period (Maheshwari et al, 2002). The most common antigenic targets include HNA-1a,-1b,-2a, FCγ receptor IIB, leukocyte adhesion molecule b, and the C3b complement receptor CR1 (Bux et al, 1997; Rios et al, 1991). If an infection does occur, it is typically mild, although there are some cases of pneumonia, sepsis or meningitis. The vast majority of children will recover by 4 years of age (Bux et al, 1998; Conway et al, 1987).

NEONATAL AUTOIMMUNE NEUTROPENIA

This is a disorder where antineutrophil antibodies are passively transferred to the fetus from a mother with autoimmune disease. Unlike autoimmune neutropenia of infancy, both mother and neonate have neutropenia. The neutropenia is transient and depends on the time needed to clear the maternal IgG antibody, but typically lasts a few weeks to a few months. The majority of neonates will be asymptomatic (Maheshwari et al, 2002).

Rh HEMOLYTIC DISEASE OF THE NEWBORN

Neutropenia has been demonstrated in neonates with Rh hemolytic disease of the newborn and seems to correlate with the severity of disease. This phenomenon can be explained by decreased production of neutrophil progenitors in the bone marrow. Koenig and Christensen (1989a) demonstrated that patients with severe hemolytic disease of the newborn had lower concentrations of granulocyte-macrophage progenitors and decreased proliferative rates of these progenitors, and they lacked a left shift as would be expected if the decrease was due to neutrophil consumption.

MATERNAL HYPERTENSION-ASSOCIATED NEUTROPENIA

One of the most common and well-described causes of transient neonatal neutropenia is maternal hypertension. Infants of hypertensive mothers seem to have decreased production of neutrophils, but the cause is uncertain. Several studies have demonstrated a decrease in neutrophil progenitor cells, decreased cycling of these cells, a relatively normal NPP and NSP, and the absence of a "left shift" (Koenig and Christensen, 1989b). In fact, many investigators have documented an increased incidence of nosocomial infections if neutropenia is associated with maternal hypertension (Doron et al, 1994). In a prospective study, Mouzinho et al (1994) analyzed the incidence of neonatal neutropenia in relation to birthweight, gestational age, and severity of maternal hypertension. They concluded that the neonatal neutropenia was inversely related to the birthweight and gestational age and directly related to the severity of the hypertension. The incidence was nearly 80% among neonates born at less than 30 weeks' gestation and was statistically different from that in similar infants born to normotensive mothers. In most cases, the neutropenia resolves within 72 hours; it almost always resolves by day 5 of life, but may persist even longer (Koenig and Christensen, 1991; Tsao et al, 1999).

DRUG- OR CHEMICAL-INDUCED NEUTROPENIA

Drug (nonchemotherapy)-induced neutropenia is one of the most common causes for neutropenia in the newborn period and may result in a high rate of infectious complications. There are several mechanisms by which this can occur. Some cases are immune mediated with antineutrophil antibodies present, as is seen with penicillin (Salama et al, 1989). In some cases, the drugs can damage the myeloid precursors directly, as is seen with ibuprofen and indomethacin. Other cases may be due to hypersensitivity that leads to direct damage of the precursors, as is seen with phenothiazines and sulfasalazine. It is also important to evaluate not only the newborn's drug history, but the mother's as well. Some drugs are capable of crossing the placenta and causing neutropenia in the neonate. The management for drug-induced neutropenia includes removing the offending agent and possibly starting G-CSF, especially if the patient develops a severe infection (Andres et al, 2002).

CONGENITAL DISORDERS ASSOCIATED WITH NEONATAL NEUTROPENIA

There are several congenital disorders associated with neutropenia. Please see Table 78-1 for a summary.

Severe Congenital Neutropenia

Severe congenital neutropenia (SCN) is a group of heterogenous disorders that characteristically manifest within the first few months of life with severe, persistent neutropenia, with ANCs of less than 500/mm^3 and often less than 200/mm^3. Bone marrow examination typically demonstrates a maturational arrest at the promyelocyte stage (Kostmann, 1956). Affected children have frequent infections, especially of the skin and oral mucosa, as well as recurrent fevers and early life-threatening infections. Until recently, these were all grouped under the name of Kostmann's syndrome, but they are now believed to be separate entities.

Dale et al (2000) described the occurrence of mutations of the gene encoding neutrophil elastase (ELA2) in 22 patients with severe congenital neutropenia. Autosomal dominant mutations of this same gene are responsible for cyclic neutropenia (Horwitz et al, 1999), which is typically diagnosed in later infancy. Eighty percent of patients with severe congenital neutropenia have autosomal dominant heterozygous mutations, and of these, 50% to 60% are caused by mutations of ELA2 (Bellanne-Chantelot et al, 2004; Boxer et al, 2006; Skokowa et al, 2007). Neutrophil elastase is a serine protease exclusively found in the neutrophil and monocyte that is synthesized and packaged in promyelocytes at early stages of development. The pathogenic role of the elastase mutation in causing neutropenia, in both congenital and cyclic neutropenia, may be linked to the poor survival of early myeloid precursor cells and/or aberrant differentiation.

TABLE 78-1 Selected Neutropenic Syndromes

Syndrome	Inheritance	Gene	Clinical Features
Severe congenital neutropenia	Autosomal dominant	*ELA2*	Static neutropenia MDS and AML
	Autosomal dominant	*GFI1*	Static neutropenia Lymphopenia
	X-Linked	*WASP*	Neutropenia No Wiskott-Aldrich syndrome
Kostmann's syndrome	Autosomal recessive	*HAX1*	Neutropenia No MDS or AML
Cyclic neutropenia	Autosomal dominant	*ELA2*	Periodic oscillations (typically every 21 days) of neutrophil count
Shwachman-Diamond syndrome	Autosomal recessive	*SBDS*	Neutropenia Exocrine pancreatic insufficiency Metaphyseal chondrodysplasia Bone marrow failure
Barth syndrome	X-linked	*TAZ*	Neutropenia Cardiomyopathy Growth deficiency 3-Methylglutaconic aciduria
WHIM syndrome	Autosomal dominant Autosomal recessive	*CXCR4*	Warts Hypogammaglobulinemia Immunodeficiency Myelokathexis

AML, Acute myeloid leukemia; *MDS*, myelodysplastic syndromes.

Other mutations have been implicated in SCN. Klein et al (2007) recently discovered the gene responsible for classical autosomal recessive severe congenital neutropenia, first described by Kostmann (1956). The defect is in a gene responsible for an antiapoptotic molecule called HCLS1-associated protein X-1 (HAX1) (Klein et al, 2007).

There have been a few patients with mutations in the WAS gene, which is the same gene that is responsible for Wiskott-Aldrich syndrome, who have developed Kostmann's syndrome, which is distinctive from Wiskott-Aldrich. Recently the growth factor-independent protein 1 (GFI1) gene has been implicated in some cases of SCN (Person et al, 2003). There are still some patients with SCN who do not have any one of the known mutations.

It had been known for some time that patients with SCN are at high risk for leukemic transformation. Recently, this risk has been linked to acquired mutations for the CSF3R gene, responsible for the intracytoplasmic domain of the G-CSF receptor, that are not present from birth (Ancliff et al, 2003). The mechanism for how these mutations are acquired and how they predispose to leukemia is still under investigation.

G-CSF has been used with success for increasing the ANC and decreasing the number of infections in patients with severe congenital neutropenia (Bonilla et al, 1989; Welte et al, 1990). Dale et al (1993) have described the successful use of G-CSF in the treatment of infants, children, and adults with either congenital neutropenia or cyclic neutropenia, with significant laboratory and clinical responses. Although there is great benefit from G-CSF in that children with SCN can now live into adulthood, it must be used with caution. There is an 8% risk per year of developing leukemia after G-CSF has been used for 12 consecutive years (Rosenberg et al, 2006). Also, despite having the neutrophil count increased by G-CSF, there remains a 0.9% risk per year of dying from a serious infection (Rosenberg et al, 2006). Bone marrow transplantation has been used for those patients in whom medical therapy fails and who have a human leukocyte antigen (HLA)-identical unaffected sibling.

Glycogen Storage Disease Type Ib

Glycogen storage disease type Ib (GSD Ib) is a rare autosomal recessive disorder caused by a deficiency of glucose-6-phosphate translocase, which plays a pivotal role in converting glucose 6-phosphate to glucose. This deficiency results in accumulation of glycogen in the liver, kidneys, and intestines. Patients also have severe fasting hypoglycemia. In addition, these patients may also have neutropenia and neutrophil dysfunction that may lead to severe infections and inflammatory bowel disease (IBD). Although patients with GSD Ib typically present at a median of 4 months, there have been patients identified as early as 1 day of life. Presenting features may consist of any of the following: acute metabolic derangement, failure to thrive, recurrent infections, muscular hypotonia, and delayed psychomotor development (Rake et al, 2002). Lack of transport of glucose 6-phosphate may impair cellular function and lead to apoptosis (Hiraiwa et al, 1999; Kilpatrick et al, 1990). GSD Ib patients have been successfully maintained on GCSF with doses anywhere between 0.5 and 10 μg/kg given on varied schedules from daily to 2 to 4 times per week to intermittent with reduction in infections and IBD (Visser et al, 2002).

Cartilage-Hair Hypoplasia

Cartilage-hair hypoplasia (CHH), inherited as an autosomal recessive trait common among Amish populations, is characterized by short-limbed dwarfism, fine hair, and

increased susceptibility to infections. Immunologic and hematologic investigations in patients with recurrent infections revealed the presence of chronic noncyclic neutropenia and lymphopenia. Neutropenia may be due to an arrest of myeloid maturation, with underproduction of mature neutrophils and diminished bone marrow storage pools. Lymphopenia, decreased delayed hypersensitivity, and impaired in vitro responsiveness of lymphocytes to mitogens suggest functional dysfunction of small lymphocytes (Lux et al, 1970).

Shwachman-Diamond Syndrome

Shwachman-Diamond syndrome (SDS) is a rare multiorgan disease characterized by metaphyseal chondrodysplasia, dwarfism, pancreatic exocrine insufficiency, neutropenia, and bone marrow failure. Clinical manifestations begin in neonates with diarrhea, weight loss, failure to thrive, eczema, otitis media, and pneumonia. By 2 years of age, dwarfism is evident; later, gait disturbances result from metaphyseal chondrodysplasia. Neutropenia is severe (ANC of 200 to 400/mm^3) and leads to recurrent infections. Aplastic anemia occurs in about 25% of the cases, and leukemic transformation has been described. Homozygous mutations in a novel gene, the *SBDS* gene, appear to be responsible for SDS (Boocock et al, 2003; Lai et al, 2000). The exact function of the *SBDS* gene is not known, but studies suggest that it may have a role in ribosome biogenesis and RNA processing (Koonin et al, 2001; Rujkijyanont et al, 2009; Wu et al, 2002). In vivo administration of G-CSF has been reported to increase the neutrophil count to normal levels. Allogeneic bone marrow transplantation is the only cure for this bone marrow failure syndrome.

Reticular Dysgenesis

Reticular dysgenesis is characterized by extremely severe neutropenia, leukopenia, agammaglobulinemia, and presence of rudimentary thymic, lymphoid, and splenic tissue. In the bone marrow, erythroid and megakaryocyte elements are normal, but myeloid cells are absent or sparse, possibly owing to a maturation defect in a progenitor cell (Roper et al, 1985). Use of GM-CSF or G-CSF has been ineffective. Allogeneic bone marrow transplantation remains the only available curative option.

Barth Syndrome

Barth syndrome is an X-linked recessive disorder characterized by neutropenia, cardiomyopathy, skeletal myopathy, growth deficiency, and 3-methylglutaconic aciduria. The disorder has been linked to a mutation in taffazin gene (TAZ) at Xq28 that leads to severe cardiolipin deficiency in the mitochondrial membrane. A recent study demonstrated neutropenia in 25% of patients, but normal hematocrit and platelets (Spencer et al, 2006).

WHIM Syndrome

WHIM syndrome is characterized by warts, hypogammaglobulinemia, immunodeficiency, and myelokathexis. Myelokathexis is identified by hypersegmented neutrophils with increased apoptosis (Zuelzer, 1964). Heterozygous mutations in CXCR4, a chemokine receptor gene, have been implicated as the cause of WHIM syndrome (Hernandez et al, 2003; Kawai et al, 2007; Sanmun et al, 2006).

QUALITATIVE DEFECTS (DYSFUNCTION) OF NEONATAL PHAGOCYTIC IMMUNITY

The immaturity of the neonatal phagocytic immune system in both humans and animals predisposes the neonate to greatly increased morbidity and mortality during bacterial sepsis. This impairment is attributed to both the inadequacies of the neonatal adaptive immune response characterized by the lack of established memory cell mechanisms and decreased Th1-type responses and also the impairment of the innate immune system (Figure 78-2). Neutrophils and macrophages play vital roles as effector cells in the phagocytic system. The efficient function of the phagocyte system depends on several factors, including the presence of adequate numbers of phagocytes in the peripheral blood, the ability to respond to signals from the sites of inflammation, the ability to migrate to these sites, and the capability to ingest and kill invading microorganisms.

Toll-like receptors (TLRs) play a critical role in the detection and recognition of microbes in the innate immune response. TLRs are highly conserved components of the innate immune system and are involved in the recognition of microbial pathogen antigen molecular patterns. These receptors are essential in initiating and orchestrating the immune response. TLR activation triggers intracellular signaling cascades resulting in production of inflammatory mediators that modulate the primary immune response and instruct the adaptive immune system (Belderbos et al, 2009). Humans express 10 TLR proteins that facilitate the recognition of microbial products and initiate intercellular signaling resulting in the nuclear translocation of nuclear factor (NF)-κB and consequent expression of genes mediating the inflammatory response. Some TLRs are positioned at the cell surface, and others are located in the endoplasmic reticulum. TLR2 and TLR4 are expressed at the cell surface and are involved in recognition of the cell wall components of gram-positive and gram-negative bacteria, respectively. TLR2 recognizes the receptor of gram-positive peptidoglycan and bacterial lipopeptides, and TLR4 is part of a receptor complex recognizing gram-negative bacteria LPS and lipoteichoic acid. Cytoplasmic TLRs (TLR3, 7 8, 9) recognize nucleic acids, with TLR3 sensing dsRNA, TLR7 and 9 sensing ssRNA, and TLR9 unmethylated DNA (Marodi, 2006).

TLRs mediate intracellular signals that trigger inflammatory gene responses through an IL-1 receptor–like pathway that uses the MyD88 protein, IL-1 receptor associated kinase (IRAK), and tumor necrosis factor receptor-associated factor (TRAF)-6 signaling to activate NF-κB and mitogen-activated protein kinase dependent signaling pathways (Viemann et al, 2005).

Several studies have reported differences in the expression of TLRs on granulocytes and monocytes in neonates and adults. Results have shown that the levels of TLR2 and TLR4 expression in healthy adult and full-term neonate phagocytes appeared to be similar (Levy, 2007). However,

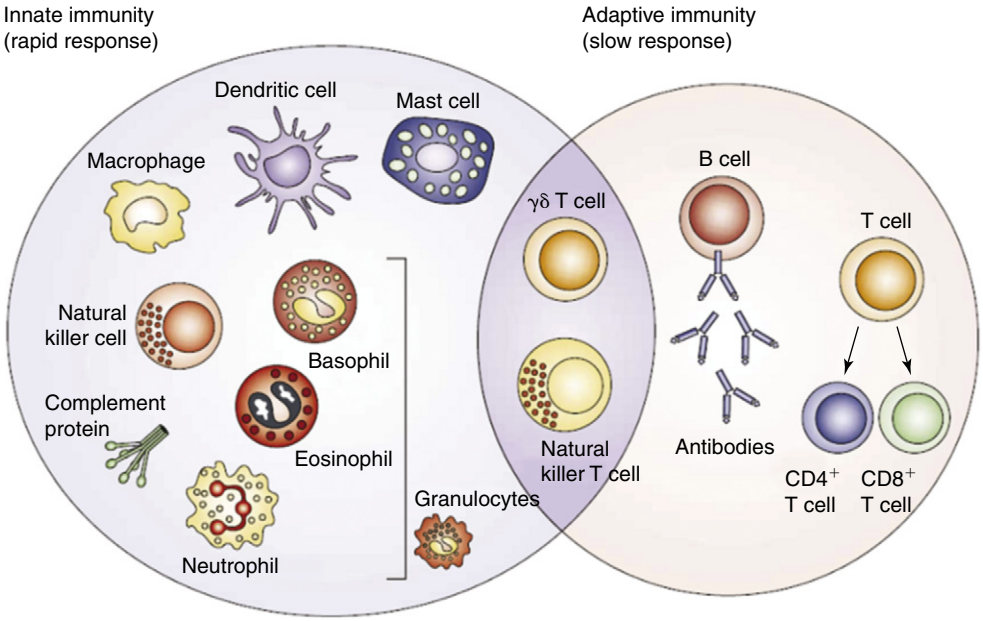

FIGURE 78-2 The innate and adaptive immune response. The innate immune response functions as the first line of defense against infection. It consists of soluble factors, such as complement proteins, and diverse cellular components, including granulocytes (basophils, eosinophils, and neutrophils), mast cells, macrophages, dendritic cells, and natural killer cells. The adaptive immune response is slower to develop but manifests as increased antigenic specificity and memory. It consists of antibodies, B cells, and $CD4^+$ and $CD8^+$ T lymphocytes. Natural killer T cells and γδ T cells are cytotoxic lymphocytes that straddle the interface of innate and adaptive immunity. *(Reprinted with permission from Macmillan Publishers Ltd:* Nature Reviews Cancer. *Dranoff, G. 4:11-22, copyright 2004.)*

neonates with clinical sepsis showed a significant increase of TLR2 expression on granulocytes and monocytes compared to healthy controls. During the course of sepsis, the expression of TLR4 on granulocytes remained low with no significant changes, but on monocytes the expression level was higher compared to granulocytes (Viemann et al, 2005). Age-related monocyte TLR4 expression and LPS-induced cytokine secretion was compared in VLBW infants, newborns (>30 weeks), and healthy adults. In the VLBW group, expression of TLR4 surface protein and TLR4-specific messenger RNA (mRNA) was significantly reduced in comparison to mature infants and adults. TLR4 expression was accompanied by significantly diminished ex vivo LPS stimulated IL-1β, IL-6, and tumor necrosis factor (TNF)-α release (Forster-Waldl et al, 2005). Other studies have shown that stimulation of newborn monocytes with LPS produced a significant decrease in the expression of MyD88, supporting the premise of impaired TLR4-mediated signaling (Marodi, 2006). Recent studies compared TLR agonist-induced cytokine production from cord blood (CB) from healthy neonates, neonatal venous blood at the age of 1 month, and adult venous blood. CB demonstrated similar TLR3 and TLR7 or increased TLR4 and TLR9 levels of agonist-induced IL-10. However, CB production of IL-12p70 and interferon (IFN)-α in response to TLR3, TLR4, and TLR7 was decreased compared to adults. Neonatal responses to TLR3, TLR7, and TLR9 producing IL-12p70 and IFN-α rapidly increased to adult levels within the 1st month of life, although TLR4-mediated production of IL-12p70 and IFN-α remained significantly decreased compared to adults (Belderbos et al, 2009).

The immaturity of neonatal host defense is also characterized by profound deficiencies in quantitative and qualitative phagocytic effector cell function. Stressed and septic neonates exhibit significant dysfunction of the phagocytic process. Chemotaxis is the initial step in the inflammatory response. Chemotaxis is a process that involves numerous changes in cellular motility and mobility, followed by intracellular biochemical changes. It begins with stimuli from the invading microorganism and continues with the directed migration of neutrophils to the site of invasion, ingestion of the pathogen, and killing by oxygen-dependent and -independent mechanisms. Qualitative abnormalities of neonatal neutrophils include decreased deformability and impaired functions including chemotaxis, phagocytosis, adherence, bacterial killing, aggregation, and oxidative metabolism (Cairo et al, 1990b).

GM-CSF increases adult neutrophil oxidative metabolism by augmenting *N*-formyl-L-methionyl-L-leucylphenylalanine (FMLP)-, C5a–, and leukotriene B_4–induced superoxide anion production. Additionally, GM-CSF increases FMLP-stimulated chemotaxis, promotes phagocytosis of *Staphylococcus aureus*, and augments neutrophil aggregation by the increased expression of surface adhesion (Gasson et al, 1984; Weisbart et al, 1985). Our laboratory investigated the biologic effects of GM-CSF on CB neutrophil oxidative metabolism, bacterial killing, and chemotaxis (Cairo et al, 1989). We determined that GM-CSF is not a direct stimulant of in vitro neonatal neutrophil function; however, when CB was preincubated with GM-CSF and stimulated with FMLP or opsonized zymosan particles, a significant increase in superoxide production was observed. Priming with GM-CSF and subsequent stimulation with phorbol myristate acetate (PMA) did not evoke a significant difference in superoxide release when CB neutrophils were compared with unprimed controls. Furthermore, when CB was compared with adult

neutrophils, an earlier but less maximal superoxide generation was seen in CB.

The diminished inflammatory response of CB neutrophils results in a high incidence of microbial invasion. Significant defects in the upregulation of surface-active glycoprotein receptors (C3bi) and reduced aggregation also predispose the neonate to impaired response to bacterial infection. C3bi expression has been compared in adult blood and CB neutrophils and found to be significantly less in CB when stimulated by FMLP- or zymosan-activated serum (Cairo et al, 1990b). However, CB neutrophils incubated with GM-CSF demonstrated a significant induction of C3bi expression. Also, a significant increase in C3bi expression was seen when CB neutrophils were pretreated with GM-CSF and subsequently stimulated with calcium ionophore A23187. The upregulation of C3bi receptor by GM-CSF also appears to correlate with enhancement of CB neutrophil aggregation. GM-CSF also primes CB neutrophils for increased neutrophil aggregation following agonist (FMLP) stimulation.

G-CSF and TNF-α also have been reported to modulate the function of adult and CB neutrophils in a manner similar to that for GM-CSF. Priming CB neutrophils with G-CSF or TNF-α and subsequent stimulation with FMLP induces the expression of C3bi receptors and enhances bacterial and phagocytic activity and superoxide generation.

MONOCYTE PHYSIOLOGY AND DYSFUNCTION

GRANULOCYTE COLONY-STIMULATING FACTOR

Our laboratory has demonstrated a significant reduction in G-CSF mRNA transcript expression as well as decreased production of G-CSF protein in stimulated CB versus adult peripheral blood (APB) mononuclear cells (MNCs) (Cairo et al, 1992b). Furthermore, we have determined that circulating serum G-CSF levels, measured by enzyme-linked immunosorbent assay (ELISA), in CB from term infants are low but similar to healthy adult levels (50 pg/mL). However, we found that G-CSF levels are approximately threefold higher in CB from healthy preterm infants than in CB from 1- to 3-day-old term infants. G-CSF production in the first days of life is associated with peak values at 7 hours of life, followed by a peak neutrophil count approximately 6 hours later.

GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR

On stimulation of mononuclear cells with phytohemagglutinin and phorbol-12-myristate-6-acetate (PMA), we have observed a sevenfold decrease of GM-CSF protein production in CB versus APB (Table 78-2). Additionally, a fourfold decrease in the expression of GM-CSF mRNA and a threefold lower GM-CSF half-life were measured in CB versus APB stimulated MNCs. Although no difference in rate of transcriptional activation from activated CB and APB MNCs was noted, actinomycin D transcriptional decay studies demonstrated reduced GM-CSF half-life in activated CB compared with APB mononuclear cells (Cairo et al, 1991).

TABLE 78-2 Cytokine Production in Stimulated Adult versus Neonatal Mononuclear Cells

Cytokine	Adult	Neonate
G-CSF	↑	↓
GM-CSF	↑	↓
M-CSF	↑	↓
IL-12	↑	↓
IL-15	↑	↓
IL18	↑	↓

We thus established that the decrease in GM-CSF mRNA expression and protein in activated CB versus APB MNCs is due to a decrease in posttranscriptional mRNA stability and not to alterations in GM-CSF gene transcription. The cytoplasmic instability of GM-CSF mRNA is regulated in part by adenosine + uridine-rich elements in the 3′-untranslated region of the cytokine transcript. We have previously investigated the molecular basis for the differential stability of GM-CSF mRNA in CB and APB MNCs using electrophoretic mobility-shift assays. We demonstrated that the destabilization of GM-CSF mRNA in CB MNC is translation dependent and that increased levels of the specific RNA binding protein AUF-1 isoforms in the CB MNC may target transcripts for increased degradation and contribute to the dysregulation of phagocytic immunity (Buzby et al, 1996).

MACROPHAGE COLONY-STIMULATING FACTOR

Macrophage colony-stimulating factor (M-CSF) is a hematopoietic growth factor that regulates the proliferation, differentiation, and functional activation of monocytes. Normally detected in human serum, M-CSF plays an important role in enhancing the effector functions of mature monocytes and macrophages. M-CSF serum levels are increased in CB and further increased in the neonate. Our laboratory studied the regulation of the M-CSF gene expression under basal and activated conditions and the transcriptional and posttranscriptional regulation of M-CSF in CB versus APB. Both CB and adult blood MNCs constitutively express M-CSF mRNA on adhesion to tissue culture flasks. However, when GM-CSF was added as a costimulator, CB MNCs produced two- to threefold less M-CSF protein compared with APB MNCs, and a fourfold decrease in M-CSF mRNA expression was shown in both unstimulated and GM-CSF-induced CB versus APB MNCs (see Table 78-2). Furthermore, we determined that M-CSF mRNA expression peaked between 16 and 24 hours after stimulation and fell to normal levels by 48 hours in both CB and APB (Suen et al, 1994). This study also demonstrated that the transcriptional rates of the M-CSF gene were similar in CB and APB even after stimulation with rhGM-CSF. However, actinomycin D decay studies showed that the half-life of M-CSF mRNA in CB MNCs was significantly lower, and the induction of M-CSF mRNA after cycloheximide

administration in CB compared with APB MNCs was significantly increased, suggesting that one or more labile proteins may be involved in regulating M-CSF transcript stability (Suen et al, 1994).

INTERLEUKIN-12 AND INTERLEUKIN-15

IL-12 is a critical cytokine regulating many of the biological functions of natural killer (NK) and T cells. IL-12 is a heterodimer of 70 kDa (p70) formed by two covalently linked glycolated chains of 40 kDa (p40) and 35 kDa (p35). The heterodimeric form of IL-12 is produced by activated monocytes, B cells, and macrophages in response to TLR signaling from bacteria or parasites or their products (Lee et al, 1996). IL-12 enhances Th1 development and suppresses Th2 development in humans. IL-12 is a potent inducer of IFN-γ production but also stimulates the production of other inflammatory agonists, including TNF-α, GM-CSF, MCSF, IL-3, IL-8, and IL-2 from NK and T cells. In addition, IL-12 enhances the cytolytic activity of resting and activated NK and lymphocyte activated killer (LAK) cells (Satwani et al, 2005a). IL-15 is a cytokine that has biological properties similar to IL-2. IL-15 induces the proliferation of T cells, B cells, and notably NK cells. IL-15 enhances nonspecific NK and LAK cytotoxic activity and induces NK cell production of IFN-γ, TNF-α, TNF-β, and GM-CSF.

Our laboratory compared the expression and production of IL-12, the regulatory mechanisms associated with IL-12 expression in CB MNC. We reported a three- to fourfold decrease in IL-12 mRNA and protein production in activated CB versus APB MNC, but no differences in the basal levels of transcription or transcriptional activation of the IL-12 gene (see Table 78-2). Further, we demonstrated that IL-12 is a significant inducer of IFN-γ in CB and APB MNCs, although levels of IFN-γ were lower in stimulated CB versus APB. Our studies show that IL-12 can significantly enhance CB NK cytotoxicity to comparable levels of APB and in combination with low doses of IL-2 can further enhance NK CB cytotoxicity (Lee et al, 1996). Additionally, IL-12 significantly enhanced CB NK and LAK in vitro activity against a broad range of tumor cell lines (Lee et al, 1998).

Similar to IL-12, we demonstrated that IL-15 mRNA and protein production is significantly decreased in activated CB MNCs compared to APB MNCs (see Table 78-2). The discrepancy in IL-15 production is secondary, in part, to altered posttranscriptional regulation. IL-15 also significantly enhanced CB NK and LAK activity in vitro against several tumor lines and also induced the production of IFN-γ and TNF-α in CB MNC. Further, the combination of IL-12 and IL-15 produced additive and synergistic augmentation in CB NK and LAK cytotoxic activity (Qian et al, 1997).

INTERLEUKIN-18

IL-18 has a similar structure to IL-1 and is considered to be a member of the IL-1 superfamily because it binds to the IL-1 receptor. IL-18 induces the production of multiple cytokines including IFN-γ, IL-13, IL-4, IL-8, and GM-CSF and both Th1 and Th2 lymphokines. Additionally, IL-18 upregulates the expression of Fas ligand on both NK and T cells and facilitates target cell killing (Satwanti et al, 2005b).

Our laboratory compared the regulation of IL-18 gene expression and protein production in activated CB and APB MNCs. Constitutive levels of IL-18 produced by APB MNCs were significantly higher compared with CB MNCs (see Table 78-2). Upon stimulation with Staphylococcus endotoxin, IL-18 production was increased in both CB and APB MNCs; however, IL-18 levels were significantly higher in APB versus CB MNCs. Further, IL-18 mRNA expression in both activated MNCs was seen, but mRNA expression was significantly lower in CB compared to APB MNCs. IL-18 stimulation of CB MNCs showed no significant increase in IFN-γ production; however, IFN-γ secretion was significantly induced in similarly stimulated APB MNCs. Interestingly, the combination of IL-18 + IL-12 for stimulation of APB and CB MNCs induced a significant increase in IFN-γ production. However, IFN-γ production from CB stimulated with IL-18 or IL-18 + IL-12 was significantly less than from APB stimulated cells (Satwanti et al, 2005b).

NEGATIVE REGULATORS OF HEMATOPOIESIS

Cytokines also play a predominant role as negative regulators of hematopoiesis. These negative growth factors regulate early hematopoiesis with suppressive effects on the proliferation of early myeloid and lymphoid progenitors. The most notable negative regulators of hematopoiesis are transforming growth factor-β1 (TGF-β1), macrophage inflammatory protein-1α (MIP-1α), and IL-8. TGF-β1 induces a wide range of responses, including the inhibition of lymphocyte, thymocyte, and epithelial cell proliferation as well as the suppression and proliferation of early progenitor cells. MIP-1α and IL-8 also have suppressive effects on early progenitors, similar to TGF-β1. Our laboratory measured the protein levels of TGF-β1 and MIP-1α in the conditioned media of phytohemagglutinin and PMA-stimulated CB and APB MNCs. Both TGF-β1 and MIP-1α levels were significantly less in CB supernatants compared with APB supernatants. Furthermore, the mRNA expression of TGF-β1, MIP-1α, and IL-8 in stimulated CB and APB MNCs was found to be significantly less in CB MNCs; yet no significant difference was seen in the transcription rate of either the TGF-β1 or MIP-1α genes in CB compared with APB. These results suggested that the reduced mRNA of the negative regulators, TGF-β1 and MIP-1α, may be secondary to alterations in posttranscriptional regulation, and that the altered expression of both positive and negative regulators may be involved in the immaturity of host defense in the neonate (Chang et al, 1994).

MONOCYTES

Ontogeny

Embryonic macrophages are found among hematopoietic cells in the yolk sac at 3 to 6 weeks' gestation. After 6 weeks, the fetal liver becomes the primary site of

hematopoiesis for the next 6 to 22 weeks of gestation, when the bone marrow becomes the lifelong center of blood cell production (Palis et al, 2001). Monocytes are present in high proportions in the early hematopoietic tissues, with approximately 70% of hematopoietic cells at 4.5 weeks' gestation morphologically identifiable as monocytes. This proportion decreases to 1% to 2% over the next 6 weeks as erythroid cells become predominant. The precursors of monocytes, monoblasts, and promonocytes continue to be present in the fetal liver; however, intravascular monocytes are not observed until the 5th month of gestation. Circulating monocytes do not appear with regularity until hematopoiesis is first established in the bone marrow after the 10th week of gestation.

At birth, the number of circulating granulocyte-monocyte progenitor cells (CFU-GMs), the committed progenitor precursor to monocytes, are increased in CB before 32 weeks, but levels fall shortly after birth. The estimated total bone marrow cellularity of the term neonate at birth is approximately 1.36×10^{11} cells/L, and the total cell numbers decline over the first 1 to 2 weeks to 3.5×10^{10}/L. These levels remain low through the neonatal period, in which circulating monocyte counts are highest in the 1st week of life, ranging from 1340 to 2200 cells/μL, and gradually fall in successive weeks to 700 cells/mm^3 at 3 weeks and 450 cells/mm^3 by 6 years of age.

Morphology

Immunophenotyping using fluorescent conjugated monoclonal antibodies also has been used to identify monocyte cell subpopulations and give insight to cell activation and function. During ontogeny, macrophages in the fetal liver express CD11b as early as 12 weeks' gestation. The classic monocyte marker, CD14, does not appear until about 15 to 21 weeks' gestation. CD14 expression on circulating MNCs is equivalent in CB and APB. CD11a, CD11b, and CD11c are expressed in lower densities on CB monocytes than on adult cells. There is also lower expression of class II major histocompatibility complex (MHC) antigens HLA-DR, HLA-DP, and HLA-DQ on neonatal monocytes compared with adult monocytes. HLA-DR expression also is significantly lower in CD14$^+$ populations in CB compared with APB CD14$^+$. The density of these class II MHC antigens has been correlated with antigen-presenting capacity of monocytes in vitro; however, it has not been determined whether this deficiency affects neonatal host defense. Other important monocyte markers are the receptors for the Fc moiety of IgG (FcγR)) and the TLRs. FcγR receptors are important in the process of monocyte and macrophage phagocytosis of microbes and antibody-dependent cytotoxicity. Monocytes constitutively express the high- affinity receptor FcγRI (CD64) and FcγRII (CD32). FcγR-III$^+$ monocytes in adult blood are significantly higher compared with CB samples. Despite the difference in the FcγR-III$^+$ populations, the intensity of FcγR-III expression is higher in CB than in APB. TLRs play a critical role in the recognition of microbial pathogens. Full-term neonatal monocytes express normal basal levels of TLR2 and TLR4 at both the protein and mRNA levels, but reduced TNF-α release in response to stimulation to a range of TLRs (Levy, 2005; Sadeghi et al, 2007; Viemann et al, 2005). CB monocytes of preterm neonates, however, have diminished basal TLR4 expression but normal TLR2 expression compared with APB monocytes (Forster-Waldl et al, 2005).

TABLE 78-3 Characteristic Function and Phenotype of Adult versus Neonatal Mononuclear Cells

Cell	Function/Phenotype	Adult	Neonate
Monocyte	Chemotaxis	↑	↓
	Phagocytosis	↑	↓
	Adhesion	≈	≈
	Respiratory burst	≈	≈
Dendritic cells	Expression CD83, CD86	↑	↓
	Mixed lymphocyte reaction	↑	↓
	IL-12 (p40) production	↑	↓
	IL-12	↑	↓
	IL-10	↓	↑
Natural killer cells	Expression CD8, CD57	↑	↓
	Expression ICAM-1, CD161	↑	↓
	Cytolytic activity	↑	↓

↑, Increased; ↓, decreased; ≈, similar.

Function

Monocytes exhibit the characteristic properties of phagocytosis—namely, movement, adherence, endocytosis, and microbial activity. Monocytes are capable of directed movement (chemotaxis) in response to substances (chemokines) produced by bacteria or by accessory cells at the site of injury or invasion. Chemotactic capabilities of neonatal and adult peripheral blood monocytes have been compared, and chemotaxis was found to be less pronounced in neonates than in adults (Table 78-3).

The cascade of reactions within the immune response to infection involves monocyte upregulation and adherence via CD11b/CD18 receptors followed by cell activation and the release of cytokines (TNF, IL-1, and IL-6) and bactericidal products—superoxide radicals, nitric oxide, and granule contents released in the process of degranulation. Adherence requires the interaction of monocytes and the endothelium. Activated monocytes migrate from circulation into the tissues by firmly adhering to endothelial surfaces through the interaction of the integrins (CD11a-c and CD18) expressed on the monocyte cell membrane and the intercellular adhesion molecule-1 (ICAM-1) or ICAM-2 on the endothelial surface. Finally, the activated monocyte moves through the endothelium to the site of inflammation or infection. Preliminary studies demonstrate that levels of monocyte adhesion molecule expression are comparable in neonate and adult peripheral blood (Schibler, 2000). The β-2 integrin, CR3, plays a major role in the migration to sites of infection by mediating the binding to ICAM-1 and also is responsible for mediating the recognition of opsonized microbial pathogens. Neonatal monocytes express approximately 85% as much CR3 as is expressed by adult monocytes.

Antimicrobial activity of monocytes includes oxygen-dependent mechanisms such as the respiratory burst, which through a complex series of reactions forms highly reactive hydroxyl radicals that damage host and microbial membranes. The ability of monocytes of fetal and neonatal monocytes to kill pathogens (*Staphylococcus aureus*, *S. epidermidis*, *Escherichia coli*, and *Candida albicans*) is shown to be equivalent to that of APB monocytes (see Table 78-3). However, a recent study of isolated CB plastic adherent monocytes from preterm and full-term infants revealed a significant decrease in superoxide production and degranulation in preterm compared with full-term monocytes.

Activated monocytes and macrophages in response to the recognition of microbial antigens by collaborative actions of soluble recognition proteins including CD14, bacterial lipopeptides and TLRs produce several cytokines and chemokines contributing to the inflammatory process. IL-1, IFN-α, and TNF-α are synthesized at similar levels in adults and neonates. Kaufman et al (1999) found a significant decrease in the secretion of TNF-α by LPS-stimulated adherent monocytes from preterm infants compared with full-term infants; however, no difference was seen in the production of IL-1β or IL-6. They showed a significant decrease in the expression of CD11b and CD18 adhesion receptor subunits in monocytes collected from preterm infants compared with that in full-term infants. Further, whereas TLR expression of full-term neonatal monocytes is similar to that in adult monocytes, the functional response is quite different. Levy et al reported a 1–3 log decrease in sensitivity to the induction of TNF-α by multiple TLR ligands in CB monocytes compared to APB, and the differences in TNF-α release correlated with the ligand-induced changes in monocyte TNF-α mRNA levels (Levy et al, 2004). A more recent study reported that the innate immune responses of neonatal monocytes to microbial TLR agonists are biased toward a high IL-6 but low TNF-α levels in vitro due to distinct neonatal cellular (monocyte) and humoral (serum) factors, and such a pattern was also evident postnatally in vivo (see Figure 78-2) (Angelone et al, 2006).

Our laboratory has compared the differential gene expression basal and LPS (TLR4)-stimulated profiles of APB versus CB monocytes. Genes whose basal expression were significantly higher in APB versus CB monocytes included cytokines/cytokine receptors, chemokines, immunoregulators, genes for signal transduction, and cytoskeleton/cell structure regulatory genes. Genes with expression higher in CB compared to APB monocytes include several adhesion molecules (CD9, integrin-αM, cyclin-dependent kinase inhibitor 1C). Following stimulation with LPS (TLR4), CB monocytes exhibited increases in cytokine/cytokine receptor, chemokine, immunoregulatory, apoptosis, signal transduction, and cytoskeleton/cell structure regulation genes. Further analysis revealed 82 genes whose expression was significantly increased in LPS-activated APB versus CB monocytes, including cytokine/cytokine receptor, chemokine, and immunoregulatory genes. Conversely, gene expression increased in CB versus APB monocytes including genes regulating apoptosis/cell cycle regulation, growth factor/ligand/receptor, and cytoskeleton structure regulation (Jiang et al, 2004).

DENDRITIC CELLS

Dendritic cells (DCs) are specialized mononuclear cells with highly developed antigen-presenting capabilities that play a pivotal role in humoral and cellular immunity by initiating primary and secondary T cell responses. DCs can be categorized into several types: follicular, lymphoid, and circulating blood DCs. Follicular DCs are located in the paracortical areas of the spleen and lymph nodes and express receptors for immunoglobulin and complement. Their role is to present antigen to B lymphocytes. Lymphoid DCs are highly motile, low-density cells found in several locations. These DCs express high levels of costimulatory molecules and class II MHC and function to present antigen to T cells. Circulating blood DCs constitute from 0.1% to 1.0% of peripheral blood mononuclear cells and migrate to the lymph nodes. The function of circulating DCs is similar to that of the lymphoid DCs—stimulating T cells by the presentation of antigen. DCs are derived from pluripotent hematopoietic stem cells ($CD34^+$) that differentiate along myeloid or lymphoid lineages. Recent studies have suggested that DCs derived from a novel population of progenitors ($CD34^+/CD7^+/CD45RA^+$) in CB represent an original lymphoid DC population. These DCs produce two- to fourfold higher levels of IL-6, IL-12, and TNF-α on stimulation with CD40L and demonstrate a higher allogeneic T-lymphocyte reactivity. Two classes of dendritic cells have been characterized on the basis of expression of CD8a. $CD8a^+$ DCs are derived from lymphoid tissue, and $CD8a^-$ DCs are derived from myeloid tissue.

Caux et al (1997) generated DCs in vitro from CB $D34^+$ hematopoietic stem cells stimulated with GM-CSF plus TNF-α. Two subsets of DCs were generated: one expressing CD1a and the other, CD14 surface antigens. These subsets further differentiated along two independent DC pathways, with cells expressing either the $CD1a^+$ or $CD14^+$ membrane antigen. $CD1a^+$ cells differentiated into Langerhans cells, characterized by Birbeck granules, the Lag antigen, and E-cadherin. $CD14^+$ progenitors matured into $CD1a^+$DCs that expressed CD2, CD9, and CD 68 and could be induced to differentiate into circulating blood DCs. CD40 activates CB $CD34^+$ cells to proliferate and differentiate independently of GM-CSF into a cell population with prominent DC characteristics. DCs generated with CD40 are able to prime allogeneic T cells and express high levels of HLA-DR but lack the characteristic CD1a and CD40 surface molecules (Flores-Romo et al, 1997).

Mature DCs express high levels of CD80 and CD83 on the cell membrane. Several agents have been shown to increase CD80 and CD83 expression on DCs, including TNF-α, bacterial LPS, and monocyte-conditioned media. Interactions with other cells also can induce activation and maturation of DCs, as demonstrated by the crosslinking of CD40 that is mediated by T cells.

We have demonstrated the ability to generate CB DCs ex vivo in serum-free media with GM-CSF, IL-4, Flt-3 ligand, TGF-β, and TNF-α. We found that the ex vivo–generated CB DCs from plastic adherent MNCs exhibit morphology and immunophenotypic characteristics similar to those of APB DCs; however, CB adherent MNC-derived DCs have differential potency in stimulating

allogeneic mixed leukocyte reaction when compared with adult adherent MNC-derived DCs (Bracho et al, 2000).

Morphology

The cardinal properties of DCs include the ability to take in, process, and present antigen and the ability to migrate selectively through tissues and interact with, stimulate, and direct T-cell responses. DCs have a distinct morphology and are noted for their irregular shape with veil-like ruffled cell membranes (lamellipodia) that include many pseudopods and numerous membrane processes. Microscopic examination of DCs reveals prominent mitochondria and endosomes and lysosomes within the cytoplasm, which are necessary for the processing of antigen. The morphology of DCs in CB and APB is identical; however, the mean percentage of DCs is lower in CB (0.5%) than in adult blood (1%).

Immunophenotyping studies have shown that DCs express numerous surface molecules commonly found on mononuclear cells, MHC molecules, CD4, CD45 isoforms, adhesion molecules (ICAM-1, -2, -3 and leukocyte function-associated antigen-1 [LFA-1]), and Fc receptors (FcγI [CD64], FcγII [CD3]). Maturation of DCs is commonly associated with high expression of CD80 and CD83. On stimulation, DCs upregulate costimulatory molecules CD40, CD80, and CD86. Flow cytometric studies, however, show levels of ICAM-1 (CD54), MHC class I (HLA-ABC) and II (HLA-DR), CD80, and CD40 antigens to be significantly lower on CB DCs (Goriely et al, 2001; Hunt et al, 1994). Liu et al (2001) compared the phenotypic and functional characteristics of monocyte-derived DCs in CB versus APB. After 7 days of culture with GM-CSF plus IL-4, CB monocytes generated fewer $CD1a^+$ cells than those generated by APB monocytes, and the cultured CB DCs had a reduced intensity of CD1a expression and MHC class II molecules. These investigators further reported that both the endocytotic ability and ability to stimulate $CD3^+$ T cells was reduced in CB DCs compared with APB DCs.

Function

The activation of TLR pathways are shown to mediate DC maturation. Krutzik et al (2005) demonstrated that TLR activation of monocytes induces rapid differentiation to $CD1b^+$ DCs that could be expanded by TLR-mediated upregulation of GM-CSF, promoted T cell activation and secreted proinflammatory cytokines (IFN-γ). A more recent study found that exposure to TLR4 or TLR8 alone induced upregulated expression of CD80, CD83, and CD86 in APB monocyte-derived dendritic cells (MoDCs), whereas CB MoDC showed lower expression of CD83 and CD86 (see Table 78-3). When TLR3-ligand was combined with TLR8 ligand, CB MoDC showed a synergistic increase in the expression of CD83 and CD86, but no further upregulation of CD80, CD83, and CD86 in APB MoDC (Krumbiegel et al, 2007).

Our laboratory compared gene expression between APB and CB immature (iDC) and mature DC (mDC) populations. Surface molecules, transcription regulator genes, cell adhesion, and structure regulators were more significantly expressed (twofold or more) in APB versus CB iDCs. Following maturation induced by LPS (TLR4) and comparing APB to CB mDCs, significantly higher expression of chemokine genes, cytokine and cytokine receptor genes, IFN-inducible genes, TNF-α-induced protein, and expression of cell surface MHC class II molecules. Additionally, apoptotic regulator genes were significantly amplified, as well as the expression of several signaling genes, TLR signaling pathway family genes, and transcription and structure regulator genes. Conversely, a group of cell cycle regulator and transcription factor genes were significantly decreased in APB versus CB mDCs (Jiang et al, 2009).

Cytokine production by stimulated neonatal DCs can provide insight into the defect of their impaired immune response. IL-12 plays a critical role in the stimulation of T cells by mature DCs. Goriely et al (2001) reported comparable levels of IL-6, IL-8, TNF-α, and IL-10 in newborn and adult DCs after stimulation with LPS or CD40 ligand. However, IL-12 (p40) levels secreted by neonatal DCs were significantly lower on stimulation with LPS but not with CD40 ligand. Also, after either LPS or CD40 ligand stimulation, neonatal DCs produced lower levels of IL-12 (p70) than adult DCs. CB DCs stimulated with LPS, CD40 ligand, or poly(I;C) showed a selective defect in the synthesis of IL-12. Furthermore, when stimulated with poly(I;C), neonatal DCs produced deficient levels of IL-12 (p70), but their production of IL-12 (p40) was similar to that of adult DCs. Neonatal DCs were also placed in mixed leukocyte culture with adult $CD4^+$ T cells, and neonatal DCs induced significantly lower levels of IFN-γ but higher levels of IL-10 than did adult DCs (see Table 78-3). Analysis of IL-12 (p35) mRNA from LPS stimulated neonatal and adult DCs by real-time polymerase chain reaction assay revealed significantly lower levels in neonatal versus adult DCs; however, the addition of rIFN-γ to LPS-stimulated newborn DCs restored the expression of and synthesis of IL-12 to adult levels.

TLRs are also integral in initiating and directing the response of MoDCs. Several studies have demonstrated TLR-mediated responses in human cord blood dendritic cells to be impaired. A recent study reported the significant increase of IL-12p70 production in APB but not CB MoDC on simultaneous stimulation with TLR3 and TLR8. However, stimulation with TLR4/TLR8-ligands in CB DC induced adult-like levels of IL-12p40 and upregulation of IL-12p70, but not to the levels seen in APB DC (Krumbiegel et al, 2007). Another study demonstrated a skewed pattern of cytokine production in CB MoDCs in response to TLR4. MoDC stimulated in vitro with TLR4 showed a significantly lower expression of activation markers CD40 and CD80 and decreased production of IL-12 p70 and IFN-β compared to adult MoDCs (Belderbos et al, 2009).

Functional differences between neonatal and adult DCs have been examined by several investigators. CB DCs have been found to be poor stimulators of T cells in a mixed leukocyte reaction when either adult-blood or CB mononuclear cells or T cells were used as responder cells (Bracho et al, 2001) (see Table 78-3). In contrast, CB T cells and mononuclear cells responded normally to allogeneic adult DCs. Furthermore, CB DCs performed poorly as accessory cells for T-cell mitogenic responses (Hunt et al,

1994). Recent studies of the ontogeny of DCs have shown that DCs from 3- and 7-day-old mice were severely defective in presenting tetanus toxoid to antigen-specific T-cell clones. However, the ability of the neonatal DCs to present antigen improved with age, reaching adult levels by 4 weeks of age.

NATURAL KILLER CELLS

NK cells are an essential part of the innate immune system. They have the ability to lyse target cells and secrete immunomodulatory cytokines (Robertson and Ritz, 1990). NK cells make up 10% of peripheral blood lymphocytes and are characterized by lack of CD3, but expression of CD56 (Farag et al, 2002). NK cells can be further divided based on the surface density of CD56 into $CD56^{bright}$ (high density) and $CD56^{dim}$ (low density). The $CD56^{dim}$, which are the more cytotoxic NK cells, usually represent 90% of the NK population. The $CD56^{dim}$ have high expression of CD16, which is the Fcγ receptor III responsible for antibody-dependent cellular cytotoxicity (Leibson, 1997). The $CD56^{bright}$ have less expression of CD16 and are known to produce immunoregulatory cytokines.

NK cells develop from the HSCs that are found in the aorto-gonado-mesonephron and later within the fetal liver (Godin and Cumano, 2002). However, committed NK cell lineage cells are first identified in the fetal thymus by embryonic day 15.5 (Carlyle and Zuniga-Pflucker, 1998). As the bone marrow starts to develop, NK cell development eventually relocates there. The bone marrow then remains the primary site of maturation (Miller et al, 1992; Shibuya et al, 1993). Human NK cell development occurs in two phases. First, after exposure to early growth factors (flt-3 ligand or kit ligand),the NK progenitor cell ($CD34^{+}Lin^{-}$) develops into the NK precursor intermediate with the phenotype of $CD34^{+}IL\text{-}15R^{+}$. On exposure to IL-15, the NK cell becomes a mature NK cell that is $CD56^{bright}$. This cell can then undergo further differentiation to become a $CD56^{dim}$ NK cell.

NK cells express a repertoire of classes of receptors (NKRs) that bind to MHC class I or class I–like molecules or targets that regulate whether NK cells will be activated or inhibited (Farag et al, 2002; Moretta et al, 2001). When NK cells fail to interact with the MHC class I molecule and the activating receptor is activated, NK-mediated cell lysis will ensue, as occurs in the case of infection. Viral infections, such as with cytomegalovirus, downregulate the MHC class I molecule, which when expressed would inhibit cell lysis (Moretta et al, 2005). After activation, lysosome-like vesicles containing perforin, serine esterases, and sulfated proteoglycans are secreted toward the target cell. Perforin forms pores in the target cell, leading to osmotic lysis. The serine esterases, including granzymes, induces apoptosis. TNF-α activates a target cell endonuclease which degrades genomic DNA. Proteoglycans protect the granzymes from inactivation by protease inhibitors (Berthou et al, 1995; Moretta et al, 2005; Pao et al, 2005; Robertson and Ritz, 1990; Spaeny-Dekking et al, 2000). After stimulation with cytokines, the $CD56^{bright}$ NK cells are able to produce positive feedback by secreting IFN-γ, TNF-α, and granulocyte macrophage stimulating factor. These cytokines help to recruit macrophages and other antigen-presenting cells for more efficient control of the infection (Cooper et al, 2001a, 2001b).

Neonates appear to have immature NK cells, which leads to an impaired immune system. Cord-blood NK cells have lower expression of CD8 and CD57, which are surface markers that confer maturity (Dalle et al, 2005) (see Table 78-3). Cord-blood NK cells also had lower expression of ICAM-1 and CD161, adhesion and activating molecules, respectively, when compared to their adult counterparts (Dalle et al, 2005). Cord-blood NK cells have been demonstrated to have less spontaneous cytolytic activity when compared to adult NK cells (Dalle et al, 2005). This leads to impaired clearance of intracellular pathogens (Wynn et al, 2009). Interestingly, the cytolytic potential of NK cells can be increased to adult levels after exposure to IL-15 (Dalle et al, 2005).

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

Hemophagocytic lymphohistiocytosis (HLH) can appear anytime between fetal life and adulthood. NK cell dysfunction can result in HLH. HLH presents as a multisystem disorder characterized by prolonged fever, hepatosplenomegaly, and occasional neurologic symptoms. Laboratory analysis reveals cytopenias, liver dysfunction, hypofibrinogenemia, hypertriglyceridemia, hypoalbuminemia, and hyponatremia. Several genes have been linked to this disorder. The first gene linked was that for perforin and accounts for 15% to 20% of HLH cases. Another cause is a mutation in MUNC13-4, which is necessary for cytolytic granule fusion with the cytoplasmic membrane during the process of degranulation. MUNC 13-4 mutations account for another 15% to 20% of HLH cases. In Turkish families, a mutation in syntaxin 11 has been demonstrated to cause HLH. Syntaxin 11 is important in facilitating membrane trafficking events. Untreated HLH is almost uniformly fatal. Treatment may include chemotherapy and/or hematopoietic stem cell transplant (Filipovich, 2008).

HERMANSKY-PUDLAK SYNDROME TYPE 2

Although Hermansky-Pudlak syndrome (HPS2) is characterized by congenital neutropenia, oculocutaneous albinism, and prolonged bleeding, it is also associated with defects in NK cells. Unlike other severe inherited neutropenias, there are mature neutrophils present in the bone marrow. The defect caused by a mutation in the AP3B1 gene, prevents trafficking proteins to transport to the lysosomes. Recent studies have demonstrated that HPS2 also causes decreased NK cytotoxicity and reduced perforin expression (Fontana et al, 2006).

SUMMARY

Immaturity of neonatal neutrophils, monocytes, lymphocytes, dendritic cells, and NK cells predisposes the newborn to an increased incidence and/or severity of infectious complications. An increased understanding of the genetic mechanisms responsible for these defects will provide insight regarding future treatment strategies to prevent and/or treat serious or overwhelming infection in the newborn.

CHAPTER 79

Neonatal Indirect Hyperbilirubinemia and Kernicterus

Jon F. Watchko

Hyperbilirubinemia is the most common clinical condition requiring evaluation and management in the newborn. Bilirubin is a breakdown product of hemoglobin and other heme proteins. Heme oxygenase converts heme to biliverdin, producing an equimolar amount of carbon monoxide with biliverdin subsequently reduced to bilirubin by biliverdin reductase. Bilirubin is transported in plasma bound to albumin and there is rapid and selective uptake of bilirubin from blood into hepatocytes where it is conjugated with glucuronic acid by the uridine diphosphate glucuronosyl transferase 1A1 (*UGT1A1*) isoenzyme. Conjugated bilirubin is actively transported into bile and bilirubin eliminated via stool passage.

Neonatal hyperbilirubinemia reflects the interplay of developmentally modulated changes in bilirubin production, metabolism, and excretion characterized by (1) an increased bilirubin load on hepatocytes and (2) decreased hepatic and enteric bilirubin clearance. The increased hepatic bilirubin load is the result of bilirubin overproduction reflective of the newborn's large red cell mass, an overall reduced red cell life span, and in a subset of neonates, hemolytic conditions known to accelerate red cell turnover. Decreased neonatal bilirubin clearance results primarily from limited hepatic bilirubin uptake and conjugation. In addition, an increased reabsorption of bilirubin from the intestinal tract (i.e., enterohepatic bilirubin circulation) limits bilirubin clearance and thereby enhances the hepatic bilirubin load. The following equation reflects the complexity of interactions among the rates of bilirubin production (a), the enterohepatic circulation of bilirubin (b), and bilirubin elimination (c) in determining the total serum bilirubin (TSB) levels at any postnatal time point t, where TSB_0 is the cord blood TSB (Valaes, 2001).

$$TSB_t = TSB_0 + \sum [a(t) + b(t) - c(t)^{\Delta t}]$$

A variety of specific clinical factors can increase bilirubin load and/or decrease bilirubin clearance and thereby contribute to neonatal indirect hyperbilirubinemia in any given infant (Box 79-1), although quantifying the individual contribution of each may not be possible. In a small fraction of neonates, a constellation of conditions may lead to hazardous levels of hyperbilirubinemia that pose a neurotoxic risk.

INCREASED HEPATIC BILIRUBIN LOAD: ENHANCED ENTEROHEPATIC CIRCULATION

Intestinal absorption of bilirubin excreted into the intestine is enhanced by several features of newborn physiology, thereby adding to the tendency for newborns to become jaundiced. Conjugated bilirubin, as either the mono- or diglucuronide, is unstable and can be spontaneously or enzymatically (via β-glucuronidase) hydrolyzed back to unconjugated bilirubin, which is easily reabsorbed through the intestinal mucosa. In addition, absorption is enhanced by the sterility of the intestinal contents. Older children and adults have intestinal flora, which can metabolize conjugated bilirubin to the water-soluble and readily excretable breakdown products urobilin and stercobilin. Newborns have no such advantage; instead, the neonatal intestinal mucosa has a greater concentration of β-glucuronidase than is found in the adult. This enzyme can deconjugate bilirubin to form more unconjugated bilirubin, which can be absorbed via the enterohepatic circulation, adding further to the hepatic unconjugated bilirubin load. Two other factors accelerating the deconjugation of bilirubin glucuronides in the newborn intestine are the mildly alkaline pH of the proximal intestine, which facilitates nonenzymatic hydrolysis, and the predominance of monoglucuronides as the main excretion form of bilirubin in the first few days of life.

INCREASED HEPATIC BILIRUBIN LOAD: HEMOLYTIC DISEASE

The reduced erythrocyte life span of normal newborn red cells (70 to 90 days as opposed to 120 days in the adult) (Pearson, 1967; Vest et al, 1961) contributes to an enhanced level of bilirubin production. It follows that an increase in red cell mass, that is, polycythemia, and factors known to accelerate red cell turnover, that is, hemolytic disorders, are clinically important conditions that increase the risk for developing neonatal hyperbilirubinemia. Of these, hemolysis is the most potent contributor to the genesis of marked hyperbilirubinemia and merits special consideration. The causes of hemolysis in the neonatal period are many but can be broadly grouped into three major categories: (1) heritable defects in red cell metabolism, membrane structure, or hemoglobin; (2) acquired disorders; and (3) immune mediated mechanisms (see Box 79-1).

HERITABLE CAUSES OF HEMOLYSIS: RED CELL MEMBRANE DEFECTS

Of the many red cell membrane defects that lead to hemolysis, only hereditary spherocytosis, elliptocytosis, stomatocytosis, and infantile pyknocytosis manifest themselves in the newborn period (Caprari et al, 1997; Oski, 1993a; Tuffy et al, 1959). Establishing a diagnosis of these disorders is often difficult because newborns normally exhibit a marked variation in red cell membrane size and shape (Oski, 1982, 1993a; Stockman, 1988; Zipursky et al, 1983). Spherocytes, however, are not often seen

BOX 79-1 Causes of Indirect Hyperbilirubinemia in Neonates

A. INCREASED HEPATIC BILIRUBIN LOAD

1. Hemolytic disease—red blood cell membrane defects
   - **a.** Hereditary spherocytosis
   - **b.** Elliptocytosis
   - **c.** Stomatocytosis
   - **d.** Pyknocytosis
2. Hemolytic disease—red blood cell enzyme abnormalities
   - **a.** Glucose-6-phosphate dehydrogenase deficiency
   - **b.** Pyruvate kinase deficiency
3. Hemolytic disease—hemoglobinopathies
   - **a.** Alpha-thalassemia
   - **b.** Gamma-thalassemia
4. Hemolytic disease—immune mediated (positive direct Coombs' test)
   - **a.** Rh isoimmunization
   - **b.** ABO incompatibility
   - **c.** Minor blood group incompatibility
5. Enhanced enterohepatic bilirubin circulation
   - **a.** Intestinal obstruction, pyloric stenosis
   - **b.** Ileus, meconium plugging, cystic fibrosis
   - **c.** Breast milk feeding
6. Extravascular blood (e.g., cephalhematoma)
7. Polycythemia

B. DECREASED HEPATIC BILIRUBIN CLEARANCE

1. Prematurity including late-preterm gestation
2. Hormonal deficiency
   - **a.** Hypothyroidism
   - **b.** Hypopituitarism
3. Impaired hepatic bilirubin uptake
   - **a.** Patent ductus venosus
   - **b.** *SLCO1B1* gene polymorphisms
4. Disorders of bilirubin conjugation—*UGT1A1* gene variants
   - **a.** Crigler-Najjar syndrome type I
   - **b.** Crigler-Najjar syndrome type II (Arias disease)
   - **c.** Gilbert disease
5. Enhanced enterohepatic circulation
   - **a.** Intestinal obstruction, pyloric stenosis
   - **b.** Ileus, meconium plugging, cystic fibrosis
   - **c.** Breast milk feeding

SLCO1B1, Solute carrier organic anion transporter 1B1; *UGT1A1*, uridine diphosphate glucuronosyltransferase 1A1.

on red cell smears of hematologically normal newborns, and this morphologic abnormality, when prominent, may yield a diagnosis of hereditary spherocytosis in the immediate neonatal period. A mean corpuscular hemoglobin concentration of ≥36.0 g/dL can also be used to alert neonatal caregivers to the possible presence of hereditary spherocytosis (Christensen and Henry, 2010). Given that approximately 75% of families affected with hereditary spherocytosis manifest an autosomal-dominant phenotype, a positive family history can often be elicited and provide further support for this diagnosis. The diagnosis of hereditary spherocytosis can be confirmed using the incubated osmotic fragility test, which is a reliable diagnostic tool in neonates after the first weeks of life when coupled with fetal red cell controls. One must rule out symptomatic ABO hemolytic disease by performing a direct Coombs' test, because infants so affected may also manifest prominent microspherocytosis (Becker et al, 1993). Moreover, hereditary spherocytosis and symptomatic ABO hemolytic disease can occur in the same infant and result in severe anemia and hyperbilirubinemia (Trucco et al, 1967).

Hereditary elliptocytosis and stomatocytosis are rare but reported causes of hemolysis in the newborn period (Oski, 1993a). Infantile pyknocytosis, a transient red cell membrane abnormality manifesting itself during the first few months of life, is more common. The pyknocyte, an irregularly contracted red cell with multiple spines, can normally be observed in newborns, particularly premature infants where up to approximately 5% of red cells may manifest this morphologic variant (Tuffy et al, 1959). In newborns affected with infantile pyknocytosis, up to 50% of red cells exhibit the morphologic abnormality, and this degree of pyknocytosis is associated with jaundice, anemia, and a reticulocytosis. Infantile pyknocytosis can cause hyperbilirubinemia that is severe enough to require control by exchange transfusion (Tuffy et al, 1959). Red cells transfused into affected infants become pyknocytic and have a shortened life span, suggesting that an extracorpuscular factor mediates the morphologic alteration (Ackerman, 1969; Keimowitz et al, 1965; Tuffy et al, 1959). Whatever the mechanism underlying infantile pyknocytosis, the disorder tends to resolve after several months of life. Pyknocytosis may also occur in other conditions including glucose-6-phosphate dehydrogenase (G6PD) deficiency and hereditary elliptocytosis, and these must be excluded before a diagnosis of infantile pyknocytosis is made.

HERITABLE CAUSES OF HEMOLYSIS: RED CELL ENZYME DEFICIENCIES

The two most common red cell enzyme defects that can lead to hyperbilirubinemia in the neonatal period are G6PD (Beutler, 1994; Kaplan et al, 1998, 2004; Luzzatto, 1993; MacDonald, 1995; Valaes, 1994) and pyruvate kinase deficiency (Luzzatto, 1993). G6PD deficiency is an X-linked enzymopathy affecting hemizygous males, homozygous females, and a subset of heterozygous females (via X chromosome inactivation) and remains a noteworthy cause of hazardous hyperbilirubinemia and kernicterus worldwide including the United States. G6PD is critical to the redox metabolism of red blood cells, and G6PD deficiency may be associated with acute hemolysis in newborns following exposure to oxidative stress. Reported hemolytic triggers in G6PD deficiency are outlined in Box 79-2. Severe hemolysis and marked hyperbilirubinemia may occur in this context and result in kernicterus (Kaplan et al, 1998, 2004; Valaes, 1994). Another important hemolytic trigger in G6PD-deficient newborns is infection. Hemolysis in G6PD-deficient neonates, however, is often self-limited and overt anemia not necessarily noted, masked by other factors that modulate hemoglobin concentration in the immediate newborn period (Valaes, 1994). Indeed, severe jaundice rather than anemia may predominate in the clinical presentation. Moreover, severe neonatal jaundice can develop in the absence of significant hemolysis in some G6PD-deficient babies (Kaplan et al, 2008). In other neonates, the combination of G6PD deficiency with the hepatic bilirubin conjugation defects of Gilbert syndrome significantly increases

Box 79-2 Agents Triggering Hemolysis in Patients With Glucose-6-Phosphate Dehydrogenase Deficiency

ANTIMALARIALS
Pamaquine
Pentaquine
Plasmoquine
Primaquine
Quinacrine
Quinine
Quinocide

SULFONAMIDES
Sulfacetamide
Sulfamethoxazole

SULFANILAMIDE
Sulfamethoxypyridazine
Sulfapyridine
Sulfisoxazole
Trisulfapyrimidine

SULFONES
Nitrofurans
Furaltadone
Furazolidone
Nitrofurantoin
Nitrofurazone
Thiazolesulfone

ANTIPYRETICS AND ANALGESICS
Acetophenetidin
Acetylsalicylic acid
Aminopyrine
Antipyrone
p-Aminosalicylic acid

OTHERS
Ascorbic acid
Chloramphenicol
Chloroquine
Aniline dyes
Dimercaprol (BAL)
Fava beans
Methylene blue

NALIDIXIC ACID
Naphthalene* (used in mothballs)
Naphthoquinones* (used in mothballs)
Paradichlorobenzenes (moth repellent, car freshener, bathroom deodorizer)
Phenylhydrazine
Probenecid
Quinidine

TOLBUTAMIDE
Vitamin K, water-soluble analogues
Menadione diphosphate
Menadione sodium disulfate

*Associated with most severe and numerous hemolytic episodes.

the risk of hyperbilirubinemia (Kaplan et al, 1997). Details regarding this icterogenic genetic interaction and other aspects of G6PD deficiency in neonates are described later under hyperbilirubinemia risk factors.

Pyruvate kinase deficiency is an autosomal recessive disorder that is less prevalent than G6PD deficiency and typically presents with jaundice, anemia, and reticulocytosis (Mentzer, 1993; Oski, 1982). Such jaundice may be severe; in one historical series, a full third of affected infants required exchange transfusion to control their hyperbilirubinemia (Matthay et al, 1981), and kernicterus in the context of pyruvate kinase deficiency has been described (Oski et al, 1964). The diagnosis of pyruvate kinase deficiency is often difficult because the enzymatic abnormality is frequently not simply a quantitative defect, but in many cases involves abnormal enzyme kinetics or an unstable enzyme that decreases in activity as the red cell ages. The diagnosis of pyruvate kinase deficiency should be considered whenever jaundice and a picture of nonspherocytic, Coombs'-negative hemolytic anemia is observed, particularly in newborns from tightly inbred communities as in the case of the Amish and Mennonites .

HERITABLE CAUSES OF HEMOLYSIS: HEMOGLOBINOPATHIES

Defects in hemoglobin structure or synthesis are disorders that infrequently manifest themselves in the neonatal period. Of these, the alpha-thalassemia syndromes are the most likely to be clinically apparent in newborns. Each human diploid cell contains four copies of the alpha-globin gene, and thus, four alpha-thalassemia syndromes have been described reflecting the presence of defects in 1, 2, 3, or 4 alpha-globin genes. Silent carriers have one abnormal alpha-globin chain and are asymptomatic. Alpha-thalassemia trait is associated with two alpha-thalassemia mutations and in neonates is not associated with hemolysis. Alpha-thalassemia trait, however, is common in African American populations and can be detected by a low mean corpuscular volume of <95 μm^3 (normal infants 100 to 120 μm^3) (Schmaier et al, 1973). Hemoglobin H disease results from the presence of three thalassemia mutations and can cause hemolysis and anemia in neonates (Pearson, 1982). Homozygous alpha-thalassemia (total absence of alpha chain synthesis) results in profound hemolysis, anemia, hydrops fetalis, and almost always stillbirth or death in the immediate neonatal period.

The pure beta thalassemias do not manifest themselves in the newborn period and the gamma thalassemias are (1) incompatible with life (homozygous form), (2) associated with transient mild to moderate neonatal anemia (if one or two genes are involved) that resolves when beta chain synthesis begins, or (3) in combination with impaired beta chain synthesis, associated with severe hemolytic anemia and marked hyperbilirubinemia (Oort et al, 1981).

ACQUIRED CAUSES OF HEMOLYSIS

Acquired causes of hemolysis comprise a miscellaneous group of disorders that include among others (1) the microangiopathic hemolysis associated with disseminated intravascular coagulation or hemangiomas and (2) infection (bacterial sepsis or congenital infections) (Oski, 1982). The mechanism(s) underlying the hemolytic process in the latter is not fully understood but may also serve as a hemolytic trigger in the context of G6PD deficiency.

IMMUNE-MEDIATED HEMOLYTIC DISEASE

Immune-mediated hemolysis encompasses the fetomaternal incompatibilities of the Rhesus (Rh), ABO (major), and minor blood group systems. Historically Rh incompatibility has been viewed as the most clinically important immune-mediated hemolytic disorder. The incidence of isoimmunization to the Rh D antigen, however, has declined since the introduction of Rh_o(D) immune globulin in 1968 and is now estimated at approximately 1 case per 1000 live births (Bowman, 2000; Chavez et al, 1991). Most instances of Rh isoimmunization are due to the Rh D antigen (Bowman, 2000; Gottvall et al, 1994). The severity of hemolysis varies in the context of Rh isoimmunization, but almost half of Rh-positive infants born to Rh-sensitized mothers will have moderate or severe disease. Affected infants develop significant hyperbilirubinemia that frequently requires exchange transfusion, in addition

to intensive phototherapy. Isoimmunization secondary to minor blood group antigens, such as Kell, Duffy, and Kidd, can also lead to significant hemolysis in utero and postnatal hyperbilirubinemia, although these antigens are far less potent in inducing antibodies than Rh D. The incidence of clinically significant sensitization to the minor blood group antigens as determined by metaanalysis approximates 1 in 330 pregnancies (Solola et al, 1983).

Hemolytic disease related to ABO incompatibility is generally limited to infants of blood group A or B whose mothers are blood group O (Naiman, 1982; Ozolek et al, 1994). Although this association exists in approximately 15% of pregnancies, only a fraction of infants born in this context will develop significant hyperbilirubinemia (Naiman, 1982; Ozolek et al, 1994). Defining which infants will become so affected is difficult to predict using laboratory screening tests. Ozolek et al observed that of type A or B infants born to mothers who are blood group O, only one third had a positive direct Coombs' test, and of those with a positive direct Coombs' test, only approximately 15% had peak serum bilirubin levels ≥12.8 mg/dL (Ozolek et al, 1994). Thus, evidence of symptomatic ABO hemolytic disease was found in only 4% of such incompatible mother-infant pairs and was not strongly predicted by the Coombs' test. Similarly, group A or B infants born to respectively incompatible group B or A mothers are not likely to manifest symptomatic ABO hemolytic disease or have a positive direct Coombs' test (<1%) (Ozolek et al, 1994). Infants born of ABO-incompatible mother-infant pairs who have a negative direct Coombs' test as a group appear to be at no greater risk for developing hyperbilirubinemia than their ABO-compatible counterparts, regardless of the indirect Coombs' test status (Ozolek et al, 1994).

Despite the difficulty in predicting its development, symptomatic ABO hemolytic disease does occur and in individual instances may develop even in the absence of a positive direct Coombs' test (Naiman, 1982; Voak et al, 1969). The latter may reflect a paucity of A and B antigens on newborn red cells and/or the absorption of serum antibody by A and B antigen epitopes throughout the body tissues and fluids (Naiman, 1982). The diagnosis of symptomatic ABO hemolytic disease should be considered in infants who develop marked jaundice in the context of ABO incompatibility that is generally accompanied by a positive direct Coombs' test and prominent microspherocytosis on red cell smear (Naiman, 1982). The hyperbilirubinemia seen with symptomatic ABO hemolytic disease is often detected within the first 12 to 24 hours of life (i.e., icterus praecox) (Halbrecht, 1944) and is usually controlled by using intensive phototherapy alone (Naiman, 1982). Only a few affected infants develop hyperbilirubinemia to levels requiring exchange transfusion (Mollison, 1983). Nevertheless, in hyperbilirubinemic newborns with ABO hemolytic disease, TSB should be followed during phototherapy to ensure that the TSB does not rise to levels that merit exchange transfusion. Routine screening of all ABO-incompatible cord blood has been recommended in the past (Hubinont, 1960) and remains common practice in many nurseries (Leistikow et al, 1995). More current literature (Leistikow et al, 1995; Quinn et al, 1988; Ozolek et al, 1994), however, suggests that such routine screening is not warranted given the low yield and cost, consistent with the tenor of recommendations of the American Association of Blood Banks (Judd et al, 1990). A blood type and Coombs' test are indicated, however, in the evaluation of any newborn with early and/or clinically significant jaundice.

DECREASED HEPATIC BILIRUBIN CLEARANCE

HEPATIC BILIRUBIN UPTAKE

During intrauterine life, fetal bilirubin is removed by the placenta, metabolized, and excreted by the maternal liver, and thus the bilirubin in cord blood is virtually entirely unconjugated. At birth, blood supply to the newborn right liver lobe changes from the high oxygen content of the umbilical vein to the low oxygen content of the portal vein. Blood flow through the hepatic arteries develops only in the 1st week of extrauterine life, and the ductus venosus may remain partially patent for several days, allowing blood to bypass the liver. These factors can contribute to a delay in the plasma clearance of bilirubin. In addition, recent evidence suggests that unconjugated bilirubin may be a substrate for the solute carrier organic anion transporter *SLCO1B1*, a sinusoidal transporter that facilitates the hepatic uptake of a broad range of endogenous substrates and xenobiotics in an ATP-independent fashion (Cui et al, 2001). It follows that the developmental expression of *SLCO1B1* (Daood et al, 2006) and nonsynonymous *SLCO1B1* gene variants may affect hepatic bilirubin uptake kinetics and bilirubin metabolism of neonates (Huang et al, 2004).

HEPATIC BILIRUBIN CONJUGATION

The bilirubin conjugating capacity of infants is dependent on the activity of hepatic uridine diphosphate-glucuronosyltransferase 1A1 (*UGT1A1*). UGT1A1 isoenzyme expression is modulated in a developmental manner such that its activity is 0.1% of adult levels at 17 to 30 weeks' gestation, increasing to 1% of adult values between 30 and 40 weeks' gestation and reaching adult levels by 14 weeks of postnatal life (Coughtrie et al, 1988; Kawade et al, 1981). This graded upregulation of hepatic UGT1A1 activity over the first few days of life may be induced by the TSB itself and is noted following birth regardless of the newborn's gestational age. Induction of *UGT1A1* is also enhanced by certain drugs. Phenobarbital is known to have this effect, and a phenobarbital responsive enhancer module (PBREM) in the *UGT1A1* gene promoter element has been identified. Indeed, a polymorphism of the *UGT1A1* PBREM (T–3279G) is associated with an increased risk of hyperbilirubinemia (Sugatani et al, 2002).

In addition to the developmentally modulated postnatal transition in hepatic bilirubin *UGT1A1* activity, there are congenital inborn errors of *UGT1A1* expression, commonly referred to as the indirect hyperbilirubinemia syndromes (Valaes, 1976). These include the Crigler-Najjar type I and II (Arias) syndromes, and Gilbert syndrome

TABLE 79-1 Congenital Nonhemolytic Unconjugated Hyperbilirubinemia: Clinical Syndromes

Characteristic	Severity		
	Marked (Crigler-Najjar Type I)	**Moderate (Crigler-Najjar Type II, Arias)**	**Mild (Gilbert Syndrome)**
Steady-state total serum bilirubin	>20 mg/dL	<20 mg/dL	<5 mg/dL
Range of bilirubin values	14–50 mg/dL	5.3–37.6 mg/dL	0.8–10 mg/dL
Total bilirubin in bile	<10 mg/dL (increased with phototherapy)	50–100 mg/dL	Normal
Conjugated bilirubin in bile	Absent	Present (only monoglucuronide)	Present (50% monoglucuronide)
Bilirubin clearance	Extremely decreased	Markedly decreased	20–30% of normal
Hepatic bilirubin uptake	Normal	Normal	Reduced
Bilirubin *UGT1A1* activity	None detected	None detected	Decreased
Genetics	Autosomal recessive	Heterogeneity of defect distinctly possible	Genetic polymorphisms: 1. Thymine-adenine $(TA)_7$ and $(TA)_8$ repeats in the *UGT1A1* promoter region 2. G211A (Gly71Arg) *UGT1A1* coding sequence mutation identified in Asian populations 3. Linkage disequilibrium between $(TA)_7$/$(TA)_7$ and T–3279G PBREM *UGT1A1* promoter polymorphisms

UGT1A1, Uridine diphosphate glucuronosyltransferase 1A1 isoenzyme.

(Table 79-1). Crigler and Najjar first described a clinical syndrome of severe chronic nonhemolytic unconjugated hyperbilirubinemia in 1952 (Crigler et al, 1952). Affected infants have complete absence of bilirubin *UGT1A1* activity and are at significant risk for hyperbilirubinemic encephalopathy and its neurodevelopmental sequelae. Although inherited in an autosomal recessive pattern, the type I syndrome has marked genetic heterogeneity (Clarke et al, 1997). Currently, more than 30 different genetic mutations have been identified in Crigler-Najjar type I syndrome, and defects common to both the *UGT1A1* exon and those comprising the constant domain (exons 2 to 5) (Clarke et al, 1997) underlie most cases. Such gene defects are typically nonsense or "stop" mutations in nature.

Phototherapy is the mainstay of treatment for infants and children with Crigler-Najjar type 1 syndrome, although neonates may develop hazardous levels of hyperbilirubinemia necessitating exchange transfusion. Liver transplantation is the only current definitive therapeutic intervention for this disorder (Shevell et al, 1987). Human hepatocyte transplantation holds promise to enhance hepatic *UGT1A1* activity as an alternative approach that could obviate the need for liver transplantation. The ultimate treatment for this inborn error of bilirubin *UGT1A1* expression will reside in the development of an effective gene therapy strategy (Roy-Chowdhury et al, 2001).

In contrast, the Arias syndrome, typified by more moderate levels of indirect hyperbilirubinemia as well as low but detectable hepatic bilirubin *UGT1A1* activity, appears in the majority of cases to be mediated by missense mutations in the *UGT1A1* gene (Clarke et al, 1997). Phenobarbital can be trialed to induce residual *UGT1A1* activity. These rare but important clinical syndromes must be included in the differential diagnosis of prolonged marked indirect hyperbilirubinemia.

Gilbert syndrome, originally described at the turn of the previous century (Gilbert et al, 1901), is far more common and characterized by mild, chronic, or recurrent unconjugated hyperbilirubinemia in the absence of liver disease or overt hemolysis (Gourley, 1994). Hepatic *UGT1A1* activity is reduced at least 50% in affected subjects and more than 95% of their total serum bilirubin is unconjugated (Gourley, 1994). Typically, the indirect hyperbilirubinemia associated with Gilbert syndrome is seen during fasting associated with an intercurrent illness. Interestingly, in about half of patients there is also an unexplained, shortened red cell life span and increased bilirubin production (Powell et al, 1967).

Gilbert syndrome affects ~9% of the population and a genetic basis for this disorder has been defined (Bosma et al, 1995). The start site on the *UGT1A1* gene where transcription of messenger RNA begins, that is, the promoter element is abnormal. More specifically, the variant promoter for the gene encoding *UGT1A1* contains a two base-pair addition (TA) in the TATAA promoter element giving rise to 7 ($A[TA]_7TAA$) rather than the more usual 6 ($A[TA]_6TAA$) repeats and is known as *UGT1A1*28*. This extra TA repeat ($A[TA]_7TAA$) impairs proper message transcription and accounts for a reduced *UGT1A1* activity (Bosma et al, 1995). Indeed, as the repeat number increases, *UGT1A1* activity decreases (Beutler et al, 1998). Subjects with Gilbert syndrome are homozygous for the *UGT1A1*28* variant promoter providing a genetic marker for this disorder. The expanded $A[TA]_7TAA$ promoter motif is expressed in the heterozygous form in 40% of the population (Bosma et al, 1995).

Although Gilbert syndrome is most commonly diagnosed in young adulthood, investigators have long speculated that this disorder might contribute to indirect hyperbilirubinemia in the newborn period (Odell, 1980; Oski, 1984; Valaes, 1976). Identification of a molecular

marker for Gilbert syndrome has provided investigators with an important tool to study the role of Gilbert syndrome in the pathogenesis of neonatal jaundice. Bancroft et al reported that newborn infants with the $A(TA)_7TAA$ *UGT1A1* promoter polymorphism have accelerated jaundice and decreased fecal excretion of bilirubin mono- and diglucuronides. Roy-Chowdhury et al 2002 in an analogous study demonstrated that the $A(TA)_7TAA$ variant is associated with modestly higher postnatal TSB levels. Others have failed to demonstrate a clinically significant effect of $A(TA)_7TAA$ alone on peak TSB. However, the coupling of $A(TA)_7TAA$ with icterogenic conditions such as G6PD deficiency and hereditary spherocytosis markedly increases a newborn's risk for hyperbilirubinemia (Iolascon et al, 1998; Kaplan et al, 1997). Others have clearly demonstrated that the $A(TA)_7TAA$ promoter variant is prevalent in breastfed infants who develop prolonged neonatal indirect hyperbilirubinemia (Maruo et al, 1999; Monaghan et al, 1999; Roy-Chowdhury et al, 2002). In Asian populations, the nucleotide 211 guanine-to-adenine mutation (G71R) in the coding sequence of *UGT1A1 (UGT1A1*6)* appears to underlie the Gilbert phenotype and contribute to neonatal hyperbilirubinemia risk (Huang, 2005; Huang et al, 2002a, 2004). Taken together, these studies demonstrate that Gilbert syndrome is a significant contributing factor to neonatal jaundice. The role of Gilbert syndrome in the genesis of extreme hyperbilirubinemia remains unclear, although (1) the low direct bilirubin fractions and (2) evidence of poor feeding and prominent weight loss (i.e., a state resembling fasting) reported in several of the published cases of extreme neonatal hyperbilirubinemia (Bhutani et al, 2004; Maisels et al, 1995) suggest that Gilbert syndrome might contribute to some cases of marked jaundice.

CLINICAL RELEVANCE

All of the aforementioned physiologic phenomena have the combined effect of increasing TSB levels in the healthy term newborn. The late-preterm and premature newborn are even more susceptible to these influences. Because individual variation in the maturation of these systems is great, TSB levels in a normal neonatal population vary widely. Slight perturbations in any of these processes can result in increased TSB levels. For example, through studies of production of carbon monoxide (CO), an index of heme breakdown produced in equimolar amounts to biliverdin by heme oxygenase, it has been determined that the infant of a diabetic mother has an increased propensity for jaundice because of enhanced production as well as impaired elimination of bilirubin. Any pathologic process that increases the production or impairs the elimination of bilirubin can exacerbate the normally occurring physiologic jaundice in newborns.

Certain demographic, environmental, and genetic risk factors, among a myriad of icterogenic contributors, merit special clinical attention. These are characterized as major risk factors for the development of severe hyperbilirubinemia in the 2004 American Academy of Pediatrics (AAP) clinical practice guideline on hyperbilirubinemia management in infants of 35 or more weeks' gestation (Box 79-3) (AAP, 2004). Although each holds the potential to be a singularly important, even sole, contributor to an infant's hyperbilirubinemia, more often one risk factor is observed in combination with others (Huang et al, 2004; Newman et al, 2000; Watchko et al, 2009), particularly in the genesis of marked hyperbilirubinemia. Indeed, in infants with peak TSB levels ≥25 mg/dL (428 μmol/L), 88% had a least two and 43% had three or more identified risk factors in one recent report (Newman et al, 2000), and 58% with peak TSB ≥20 mg/dL (342 μmol/L) had at least two risk factors in another (Huang et al, 2004). Data derived from risk instruments that incorporate several factors support the potential multifactorial etiopathogenesis of marked hyperbilirubinemia; albeit genetic contributors may go undetected and individual factors confer different degrees of risk (Newman et al, 2000, 2005). These instruments further highlight the clinical importance of two specific risk factors in particular, namely (1) late preterm gestational age and (2) exclusive breastfeeding (Keren et al, 2008; Newman et al, 2000, 2005). These two contributors and six others of notable clinical impact—(1) glucose-6-phosphate dehydrogenase (G6PD) deficiency, (2) ABO hemolytic disease, (3) East Asian ethnicity, (4) jaundice observed in the first 24 hours of life, (5) cephalhematoma or significant bruising, and (6) history of previous sibling treated with phototherapy—are reviewed in further detail.

BOX 79-3 Major Risk Factors for Development of Severe Hyperbilirubinemia in Infants of 35 or More Weeks' Gestation

- Gestational age 35–36 weeks
- Exclusive breastfeeding, particularly if nursing is not going well and weight loss is excessive
- Blood group incompatibility with positive direct antiglobulin test, other known hemolytic disease (e.g., G6PD deficiency)
- East Asian race
- Jaundice observed in the first 24 hours
- Cephalhematoma or significant bruising
- Previous sibling received phototherapy
- Predischarge TSB or TcB level in the high-risk zone

LATE-PRETERM GESTATION

Late preterm ($34^{0/7}$ to $36^{6/7}$ weeks' gestation) and full-term infants become jaundiced by similar mechanisms, including (1) an increased bilirubin load on the hepatocyte as a result of decreased erythrocyte survival, increased erythrocyte volume, and the enterohepatic circulation of bilirubin and (2) defective hepatic bilirubin conjugation (Watchko, 2006b). Late preterm infants evidence a similar degree of red blood cell turnover and heme degradation as their term counterparts, but demonstrate lower *UGT1A1* enzyme activity as compared to their term counterparts (Kaplan et al, 2005; Kawade et al, 1981). Moreover, although there is a marked postnatal increase in *UGT1A1* enzyme activity in newborns, such maturation appears to be slower in late preterm neonates during the 1st week of life (Kawade et al,

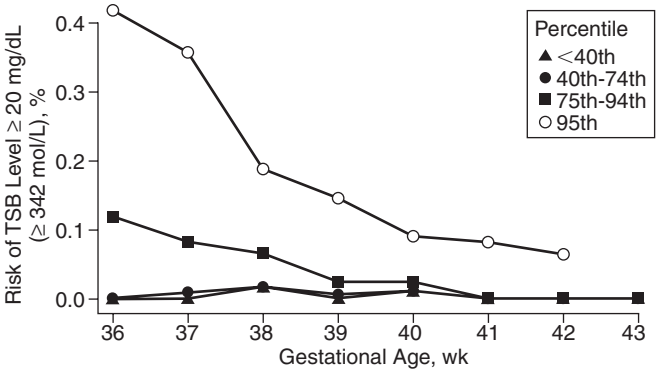

FIGURE 79-1 Risk of developing a TSB ≥20 mg/dL (342 μmol/L) as a function of gestational age (weeks) and percentile-based TSB measured at <48 hours using the Bhutani nomogram. *(Modified from* Arch Pediatr Adolesc Med *159:117, Copyright 2005, American Medical Association. All rights reserved.)*

1981). This exaggerated hepatic immaturity contributes to the greater prevalence, severity, and duration of neonatal jaundice in late preterm infants.

Underscoring the importance of late preterm gestational age is the ≈8-fold increased risk of developing a TSB of ≥20 mg/dL (342 μmol/L) in infants born at 36 weeks' gestation (5.2%) as compared to those born at 41 or ≥42 weeks' gestation (0.7% and 0.6%, respectively) (Newman et al, 1999). This gestational age effect is even more evident when examined as a function of hour-specific TSB risk zones using the percentile-based nomogram described by Bhutani et al (1999) as shown in Figure 79-1 (Newman et al, 2005). It can be seen, for example, that coupling 36 weeks' gestation with a high risk zone (≥95%) TSB is associated with a >40% chance of developing a TSB of ≥20 mg/dL (342 μmol/L) (Newman et al, 2005). Even a high intermediate risk zone (75% to 94%) TSB in a 36-week-gestation late preterm neonate is associated with >10% chance of developing a TSB ≥20 mg/dL (342 μmol/L), a risk greater than that for a full-term newborn with a TSB level ≥95% (Newman et al, 2005). The reported difficulty in visually assessing the degree of jaundice in late preterm newborns (Keren et al, 2009) suggests that birth hospitalization TSB or transcutaneous bilirubin screening before discharge is warranted to more fully ascertain hyperbilirubinemia risk as recently recommended (Maisels et al, 2009b).

Late preterm infants are disproportionately overrepresented in the U.S. Pilot Kernicterus registry, a database of voluntarily reported cases of kernicterus (Bhutani et al, 2004, 2006). Moreover, the registry demonstrates that late preterm neonates show signs of bilirubin neurotoxicity at an earlier postnatal age than term newborns, indirectly suggesting a greater vulnerability to bilirubin-induced brain injury (Bhutani et al, 2006). Clinical hyperbilirubinemia management guidelines for late preterm infants therefore recommend treatment at lower TSB thresholds than term newborns, a distinction that is an important component of the 2004 American Academy of Pediatrics practice guideline on neonatal jaundice (AAP, 2004). In this regard it is important to note that (1) the management of late preterm newborns born between $34^{0/7}$ and $34^{6/7}$ weeks' gestation is not addressed by the 2004 AAP guideline, and (2) infants born between $37^{0/7}$ and $37^{6/7}$ weeks' gestation, although strictly defined as term, are characterized in the 2004 AAP guideline as medium to higher risk and are to be managed as "late preterm" regarding phototherapy and exchange transfusion thresholds (AAP, 2004).

Of the other clinical factors observed in conjunction with late preterm gestation hyperbilirubinemia risk, breast milk feeding has been identified most consistently, indeed almost uniformly, and therefore appears to be of paramount importance (Bhutani et al, 2004, 2006). Late preterm neonates, because of their immaturity, often demonstrate less effective sucking and swallowing and may have difficulties achieving consistent nutritive breastfeeding (Wang et al, 2004), phenomena that may predispose to varying degrees of lactation failure. Suboptimal feeding was the leading reason for discharge delay during birth hospitalization in late preterm neonates in one recent study (Wang et al, 2004). Pediatricians, therefore, need to be alert to the potential of suboptimal breast-milk feeding in late preterm neonates and not be misled by the seemingly satisfactory breastfeeding efforts of late preterm newborns during the birth hospitalization when limited colostrum volumes make it a challenge to adequately assess the effectiveness of breast-milk transfer (Neifert, 2001). Late preterm infants who are breastfed merit timely post birth-hospitalization discharge follow-up and lactation support (Bhutani et al, 2006; Watchko, 2006b). Lactation support coupled with regular neonatal weight checks is helpful in averting lactation difficulties and in the early identification of those mother-infant pairs prone to lactation failure. Parental education (written and verbal) about neonatal jaundice and when to call the pediatrician are also important (AAP, 2004). A shortened hospital stay (<48 hours after delivery), although permitted for selected healthy term neonates, is not recommended for late-preterm neonates (AAP, 2007).

EXCLUSIVE BREAST MILK FEEDING

It is likely no coincidence that almost all reported cases of kernicterus over the past two and one-half decades have occurred in breastfed infants (Bhutani et al, 2004). As such, exclusive breast milk feeding, particularly if nursing is not going well and weight loss is excessive, is listed as a major hyperbilirubinemia risk factor in the 2004 AAP practice guideline. What does the association between exclusive breast milk feeding and kernicterus imply with respect to the etiopathogenesis of marked neonatal jaundice? Numerous studies have reported an association between breastfeeding and an increased incidence and severity of hyperbilirubinemia, both during the first few days of life and in the genesis of prolonged neonatal jaundice (Hansen, 2001; Kivlahan et al, 1984; Linn et al, 1985; Maisels et al, 1986; Schneider, 1986). A pooled analysis of 12 studies comprising more than 8000 neonates showed a threefold greater incidence in TSB of ≥12.0 mg/dL (205 μmol), and a sixfold greater incidence in levels of ≥15 mg/dL (257 μmol) in breastfed infants as compared with their formula-fed counterparts (Schneider, 1986). Others, however, report that if adequate breastfeeding is established and sufficient lactation support is in place, breastfed infants should be at no greater risk for

hyperbilirubinemia than their formula-fed counterparts (De Carvalho et al, 1982; Nielsen et al, 1987; Rubaltelli, 1993; Yamauchi et al, 1990). The latter studies suggest that many breastfed infants who develop marked neonatal jaundice do so in the context of a delay in lactation or varying degrees of lactation failure. Indeed, an appreciable percentage of the breastfed infants who develop kernicterus have been noted to have inadequate intake, and variable but substantial degrees of dehydration and weight loss (Bhutani et al, 2004; Johnson et al, 2002; Maisels et al, 1995).

Inadequate breast milk intake, in addition to contributing to dehydration, can further enhance hyperbilirubinemia by increasing the enterohepatic circulation of bilirubin and resultant hepatic bilirubin load. The enterohepatic circulation of bilirubin is already exaggerated in the neonatal period, in part because the newborn intestinal tract is not yet colonized with bacteria that convert conjugated bilirubin to urobilinogen, and because intestinal β-glucuronidase activity is high. Earlier studies in newborn humans and primates suggest that the enterohepatic circulation of bilirubin may account for up to 50% of the hepatic bilirubin load in neonates (Gartner et al, 1977; Poland et al, 1971). Moreover, fasting hyperbilirubinemia is largely due to intestinal reabsorption of unconjugated bilirubin, an additional mechanism by which inadequate lactation and/or poor enteral intake may contribute to marked hyperbilirubinemia in some newborns. In the context of limited hepatic conjugation capacity in the immediate postnatal period, any further increase in hepatic bilirubin load will likely result in more hyperbilirubinemia. Recent studies confirm that early breastfeeding jaundice is associated with a state of relative caloric deprivation (Bertini et al, 2001) and resultant enhanced enterohepatic circulation of bilirubin (Bertini et al, 2001; Maisels, 2000a). Breastfeeding-associated jaundice, however, is not associated with increased bilirubin production (Stevenson et al, 1980).

Lactation failure is not uniformly present in affected infants, suggesting that other mechanism(s) may be operative in breastfeeding-associated jaundice, a finding that merits further clinical study. Breast-milk feeding may act as an environmental modifier for selected genotypes and thereby potentially predispose to the development of marked neonatal jaundice (Watchko, 2005, 2004). A recent report lends credence to this possibility, demonstrating that the risk of developing a TSB ≥20 mg/dL (342 μmol/L) associated with breast-milk feeding was enhanced 22-fold when combined with expression of either a coding sequence gene polymorphism of (1) the bilirubin conjugating enzyme *UGT1A1* (the nucleotide 211 guanine to adenine [G211A] missense mutation *UGT1A1*6*) or (2) the solute carrier organic anion transporter 1B1 (*SLCO1B1*; also known as organic anion transporter polypeptide 2 [*OATP-2*]; the A388G missense variant *SLCO1B1*1b*) (Huang et al, 2004). SLCO1B1 is a sinusoidal membrane protein putatively involved in facilitating the hepatic uptake of unconjugated bilirubin (Cui et al, 2001). This hyperbilirubinemia risk increased to 88-fold when breast-milk feedings were combined with *both UGT1A1* and *SLCO1B1* variants (Huang et al, 2004). Others have previously reported an association between prolonged (>14 days) breast-milk jaundice and expression of the *UGT1A1* gene promoter variant allele $A(TA)_7TAA$ (*UGT1A1*28*) (Maruo et al, 1999; Monaghan et al, 1999). Although the relationship between breast-milk feeding and jaundice must be recognized, the benefits of breast-milk feeds far outweigh the related risk of hyperbilirubinemia. Cases of severe neonatal hyperbilirubinemia with suboptimal breast-milk feedings underscore the need for effective lactation support and timely follow-up exams.

G6PD DEFICIENCY

G6PD deficiency is an X-linked enzymopathy affecting hemizygous males, homozygous females, and a subset of heterozygous females (via nonrandom X chromosome inactivation); it is an important cause of severe neonatal hyperbilirubinemia and kernicterus worldwide (Beutler, 1994; Kaplan et al, 1998, 2004; Valaes, 1994, 2000). Although most prevalent in Africa, the Middle East, East Asia, and the Mediterranean, G6PD deficiency has evolved into a global problem as a result of centuries of immigration and intermarriage (Beutler, 1994; Kaplan et al, 1998, 2004; Valaes, 1994, 2000). It is a noteworthy contributor to endemic rates of bilirubin encephalopathy in several developing countries (e.g., Nigeria where approximately 3% of neonatal hospital admissions evidence bilirubin encephalopathy) (Oguniesi et al, 2007) and accounts for a substantial and disproportionate number of neonates with kernicterus in the U.S. Pilot Kernicterus registry (20.8% of all reported cases) (Bhutani et al, 2004). Although the majority of the latter cases are African American males, other U.S. population subgroups at risk for G6PD deficiency include African American females and newborns of East Asian, Greek, Italian (especially Sardinia and Sicily), and Middle Eastern descent (Kaplan et al, 2004).

Current G6PD deficiency prevalence rates in the United States are 12.2% for African American males, 4.1% for African American females, 4.3% for Asian males, and 2.0% for Hispanic males (Table 79-2) (Chinevere et al, 2006). Even the ethnicity subset characterized as unknown or other in this large U.S.-based cohort showed a G6PD deficiency prevalence of 3.0% in males and 1.8% in females (Chinevere et al, 2006). In this regard, *G6PD* is remarkable for its genetic diversity (more than 370 variants have

*Number tested (percent deficient).

been described) (Beutler, 2008) and those mutations seen in the United States include, among numerous others, (1) the *African A*-variants, a group of double site mutations, all of which share the A376G variant (also known as G6PD A+ when expressed alone; a nondeficient variant), coupled most commonly with the G202A mutation (G202A;A376G), but on occasion with the T968C variant (T968C;A376G; also known as G6PD Betica) or the G680T mutation (G680T;A376G); (2) the *Mediterranean* (C563T) mutation; (3) the *Canton* (G1376T) mutation; and (4) the *Kaiping* (G1388A) variant (Beutler, 1994; Lin et al, 2005).

Two modes of hyperbilirubinemia presentation have classically been reported in *G6PD*-deficient neonates (with overlap between the two on occasion): (1) an acute, often sudden, unpredictable rise in TSB to potentially hazardous levels precipitated by an environmental trigger (e.g., naphthalene in mothballs or infection) (Beutler, 1994; Kaplan and Hammerman, 2004a; Kaplan et al, 1998; Valaes, 1994, 2000); this mode is difficult to foretell and therefore anticipate or prevent, and it is often a challenge to ascertain the trigger; and (2) low-grade hemolysis coupled with genetic polymorphisms of the *UGT1A1* gene that reduce *UGT1A1* expression and thereby limit hepatic bilirubin conjugation. These include the $(TA)_7$ dinucleotide repeat TATAA box promoter element (*UGT1A1*28*) (Kaplan et al, 1997, 2004a; Valaes, 1994, 2000) and the G211A coding sequence (UGT1A1*6) (Huang et al, 2002b) variants; the former underlies the Gilbert's syndrome phenotype in Caucasians (Bosma et al, 1995), whereas the latter underlies the Gilbert's syndrome phenotype in East Asians (Huang et al, 2002a, 2005). Kaplan et al were the first to demonstrate dose-dependent genetic interactions between the *UGT1A1*28* promoter variant and G6PD deficiency that enhance neonatal hyperbilirubinemia risk (1997). Others have subsequently confirmed that coupling of (1) G6PD deficiency and (2) other genetically determined hemolytic conditions (e.g., hereditary spherocytosis) *with* hepatic gene variants that adversely affect bilirubin clearance (i.e., hepatic bilirubin uptake [*SLCO1B1*] and/or conjugation [*UGT1A1*]) increases the risk of significant neonatal hyperbilirubinemia) (Huang et al, 2002b, 2005; Iolascon et al, 1998; Watchko et al, 2009). Coexistent nongenetic factors may also impact hyperbilirubinemia) risk in G6PD-deficient African American male neonates as shown in those who are also late preterm and breastfed (Kaplan et al, 2006). Sixty percent of this subgroup demonstrate bilirubin levels >95% (high risk zone) on the bilirubin nomogram of Bhutani et al (odds ratio 10.2 [1.35 to 76.93 95% confidence interval]) (Kaplan et al, 2006).

African Americans as a group have a lower incidence of neonatal hyperbilirubinemia: odds ratio 0.43 for bilirubin level that exceeded or was within 1 mg/dL [17 μmol/L] of 2004 AAP hour-specific phototherapy treatment threshold (Keren et al, 2008) and odds ratio 0.56 for TSB ≥20 mg/dL [342 μmol/L] (Newman et al, 1999) than the rest of the population; as a result, numeric instruments designed to predict hyperbilirubinemia risk in newborns deduct points for African American race (Newman et al, 2000, 2005). This lower overall hyperbilirubinemia incidence, however, may belie the hyperbilirubinemia risk for G6PD-deficient African American newborns, leading some to caution that African American neonates with overt jaundice (male or female) merit special attention and follow-up because such infants represent exceptions to this general pattern, a subset of which might be G6PD deficient. It may be that once an African American infant develops notable jaundice, he/she is at equal or perhaps even greater risk, if G6PD deficient, for marked hyperbilirubinemia. Consistent with this assertion, Kaplan and Hammerman, (2004a) have reported that 48.4% of G6PD-deficient African American neonates developed a TSB level ≥75% and 21.9% a TSB level ≥95%. In contrast, Keren et al (2008) report that neither the presence of a G6PD mutation nor overt clinical jaundice was associated with the development of significant hyperbilirubinemia in African American infants or African American male infant cohorts. This matter merits further clinical study and clarification (Watchko, 2010).

Although there has been discussion on the potential utility of screening for G6PD deficiency in the United States, no consensus has emerged on whether or how best to screen for this condition in America, and point-of-care testing during birth hospitalization is not routinely practiced. Reports from abroad (e.g., Israel, Singapore, Taiwan) (Kaplan et al, 2008; Padilla et al, 2007) show that various point-of-care G6PD screening strategies, some that target specific at-risk population subgroups, others that screen population-wide, are associated with reductions in the prevalence of severe hyperbilirubinemia and kernicterus.

ABO HEMOLYTIC DISEASE

Hemolytic disease related to ABO incompatibility is noted to be a major risk factor for severe hyperbilirubinemia in the 2004 AAP practice guideline and for all intents and purposes is limited to infants of blood group A or B born to mothers who are blood group O as detailed earlier in this chapter. Although this association exists in approximately 15% of pregnancies, only a small fraction of such infants will develop significant hyperbilirubinemia. The diagnosis of symptomatic ABO hemolytic disease should be considered in infants who develop marked jaundice in the context of ABO incompatibility with a positive direct Coombs' test, often accompanied by microspherocytosis on red cell smear (Hershel et al, (2002); Naiman, 1982; Ozolek et al, 1994). Underscoring the importance of a positive direct Coombs' test in support of the diagnosis of ABO hemolytic disease, Herschel et al (2002) recently concluded that in direct Coombs'-negative newborns of ABO incompatible mother-infant pairs with significant hyperbilirubinemia, a cause other than isoimmunization should be sought.

Despite the difficulty in predicting its development, symptomatic ABO hemolytic disease does occur, often with clinical jaundice detected within the first 12 to 24 hours of life. The early rapid rise in TSB during the first 24 hours of life to the 10 to 15 mg/dL range or slightly higher is typically followed by a plateau at 15 to 20 mg/dL on the 2nd day of life (Cashore, 1990; Naiman, 1982). Hyperbilirubinemia secondary to ABO hemolytic disease was recognized decades ago to be controllable with phototherapy in most cases (Cashore,

1990; Naiman, 1982), and even more so using current intensive phototherapy strategies with special blue fluorescent lamps (Maisels et al, 2008). The addition of intravenous immune globulin (IVIG) to the therapeutic armamentarium against immune-mediated (positive direct Coombs') hyperbilirubinemia has proven effective in reducing hemolysis and the need for exchange transfusion in ABO hemolytic disease (number needed to treat 2.7) (Gottstein et al, 2003; Hammerman et al, 1996). The mechanism of IVIG action is not clear but is thought to inhibit hemolysis by blocking antibody receptor sites on red blood cells. Few affected infants with ABO hemolytic disease ever develop hyperbilirubinemia to levels requiring exchange transfusion (Naiman, 1982), although preparations for possible double volume exchange should be made when exchange thresholds are approached (AAP, 2004).

EAST ASIAN ETHNICITY

Neonates of East Asian ethnicity encompassing the populations of mainland China, Hong Kong, Japan, Macau, Korea, and Taiwan evidence a higher incidence of hyperbilirubinemia than others and an overall increased risk for a TSB of ≥20 mg/dL (342 μmol/L) (odds ratio 3.1 [1.5 to 6.3 confidence interval]) (Newman et al, 2000). Therefore, East Asian ancestry is listed as a major risk factor for severe hyperbilirubinemia in the 2004 AAP clinical practice guideline. Investigators have speculated as to the nature of this phenomenon invoking potential population differences in the incidence of ABO hemolytic disease and G6PD deficiency as well as environmental exposures to Chinese materia medica, among others (Ho, 1992). There is little doubt that G6PD deficiency is an important contributor to hyperbilirubinemia risk in East Asian newborns. Innate ethnic variation in hepatic bilirubin clearance (Ho, 1992) also contributes to the biologic basis of hyperbilirubinemia risk in Asian newborns as revealed by genetic analysis of enzymatic variants that modulate bilirubin metabolism. Four different *UGT1A1* coding sequence variants—G211A (*UGT1A1*6*), C686A (*UGT1A1*27*), C1091T (*UGT1A1*73*), and T1456G (*UGT1A1*7*)—have been described in East Asian populations, each associated with a Gilbert's syndrome phenotype (Huang et al, 2000, 2004). Of these, the *UGT1A1*6* variant is predominant, with an allele frequency of 11% to 13% in East Asians (Huang et al, 2000) (as high as 30% in neonates with hyperbilirubinemia ≥15 mg/dL [257 μmol/L]) (Huang et al, 2002a) and an associated significant decrease in UGT1A1 enzyme activity (Yamamoto et al, 1998). Hepatic *SLCO1B1* gene variants are also prevalent in East Asian populations (Huang et al, 2004; Kim et al, 2008), and the *SLCO1B1*1b* variant has been demonstrated to enhance neonatal hyperbilirubinemia risk (Huang et al, 2004). As noted in the section on breastmilk feeding, coupling *UGT1A1* and *SLCO1B1* variants together enhances hyperbilirubinemia risk, which is further increased when that infant is also exclusively breastfed (Huang et al, 2004). The high incidence of neonatal hyperbilirubinemia in East Asian populations appears to be at least partly attributable to the prevalence of these hepatic gene polymorphisms.

JAUNDICE OBSERVED IN THE FIRST 24 HOURS OF LIFE

Jaundice appearing in the first 24 hours of life has long been regarded as an abnormal clinical finding and an indication for obtaining a serum bilirubin measurement (AAP, 2004). Approximately 2.8% of newborns will evidence jaundice within 18 hours and 6.7% within 24 hours of age (Newman et al, 2002). As contrasted with nonjaundiced newborns on the first postnatal day, newborns with overt jaundice in the first 24 postnatal hours are more likely to receive phototherapy (18.9% vs. 1.7%; relative risk, 10.1; 95% confidence interval 4.2 to 24.4) and to develop a TSB ≥25 mg/dL (428 μmol/L) (odds ratio 2.9; 95% confidence interval 1.6 to 5.2) (Newman et al, 2002). Hemolytic disease, immune mediated and otherwise, should be a diagnostic consideration in any infant with early clinical jaundice.

CEPHALHEMATOMA OR SIGNIFICANT BRUISING

Internal hemorrhage, ecchymoses, and other extravascular blood collections will enhance the bilirubin load on the liver. Extravascular red cells have a markedly shortened life span, and their heme fraction is quickly catabolized to bilirubin by tissue macrophages that contain heme oxygenase and biliverdin reductase (Odell, 1980). Thus, cephalhematoma, subdural hemorrhage, massive adrenal hemorrhage, and marked bruising can be associated with increased serum bilirubin levels, typically manifest 48 to 72 hours after the extravasation of blood (Odell, 1980). This temporal pattern is consistent with the evolution of ecchymoses and bilirubin formation in situ and also accounts for why extravascular blood can cause prolonged indirect hyperbilirubinemia (Odell, 1980). An unusual but dramatic example of how extravascular blood can contribute to the genesis of hyperbilirubinemia is found in reports of marked jaundice associated with the delayed absorption of intraperitoneal blood in infants who received fetal intraperitoneal red cell transfusions (Rajagopalan et al, 1984; Wright et al, 1982). In one such case, 13 exchange transfusions were necessary to control the hyperbilirubinemia that resolved only when approximately 87 mL of packed red cells were evacuated from the intraperitoneal cavity (Wright et al, 1982). In this instance, the intraperitoneal blood hematocrit of 60% had the potential to contribute up to approximately 600 mg of bilirubin to the infant's bilirubin load over time. Although other causes of extravasation generally are not associated with such large amounts of sequestered blood and resultant bilirubin load, they can nevertheless contribute to the development of jaundice.

PREVIOUS SIBLING TREATED WITH PHOTOTHERAPY

A history of a previous sibling treated with phototherapy is an identified risk factor for hyperbilirubinemia (Gale et al, 1990; Newman et al, 2000) and most notable with a higher TSB in the index case (>15 mg/dL [257 μmol/L]) (Khoury et al, 1988). This relationship may reflect recurrent ABO or Rh hemolytic disease (Maisels,

1982) or exposure to a common environmental factor in addition to a shared genetic background (Gale et al, 1990). It is known that the recurrence rate of ABO hemolytic disease is high—88% in infants of the same blood type as their index sibling, with almost two thirds of the affected infants requiring treatment (Katz et al, 1982). However, an excess risk in siblings independent of other hyperbilirubinemia risk factors expected to recur in sibships (including breastfeeding, lower gestational age, and hemolytic disease) suggests that genetic rather than environmental effects are responsible (Gale et al, 1990; Khoury et al, 1988). Consistent with this hypothesis, there is a higher concordance level in TSB between monozygotic (identical) as opposed to dizygotic (fraternal) twins when controlled for confounders known to modulate neonatal bilirubinemia (Ebbesen et al, 2003). Regardless of the etiopathogenesis, a previous sibling treated with phototherapy is a risk factor for neonatal hyperbilirubinemia (AAP, 2004).

COMBINING CLINICAL RISK FACTOR ASSESSMENT WITH PREDISCHARGE BILIRUBIN MEASUREMENT

Several clinical studies suggest that combining clinical risk factor analysis with a birth hospitalization predischarge measurement of TSB or TcB improves the prediction of subsequent hyperbilirubinemia risk (Keren et al, 2008; Maisels et al, 2009a; Newman et al, 2005). Indeed, an hour-specific predischarge TSB or TcB level in the high risk zone (>95%) using the percentile-based bilirubin nomogram described by Bhutani et al (1999) (Figure 79-2) is itself a major risk factor for severe hyperbilirubinemia (Bhutani et al, 1999, 2000) (see Box 79-3). Not surprisingly, the clinical factors most predictive of hyperbilirubinemia risk when combined with the risk zone characterization are lower gestational age and exclusive breastfeeding (Keren et al, 2008; Maisels et al, 2009a; Newman et al, 2000, 2005). On the basis of these recent reports, the authors of a commentary that provides clarifications on the 2004 American Academy of Pediatrics clinical practice guideline on the management of hyperbilirubinemia in the newborn infant 35 or more weeks' gestation recommend universal predischarge bilirubin screening to help assess the risk of subsequent severe hyperbilirubinemia (Maisels et al, 2009b). Recently published data further suggest that predischarge bilirubin screening is associated with a reduction in the incidence of TSB ≥25 mg/dL (428 μmol/L) (Eggert et al, 2006; Kuzniewicz et al, 2009), possibly by increasing the use of phototherapy (Kuzniewicz et al, 2009). The efficacy and cost effectiveness of a combined percentile based risk zone–clinical risk factor analysis in preventing bilirubin encephalopathy is unknown (Maisels et al, 2009b).

CLINICAL EVALUATION OF JAUNDICE

Jaundice is the visible manifestation in the skin of elevated serum concentrations of bilirubin. Although most adults are jaundiced when total serum bilirubin (TSB) levels exceed 2.0 mg/dL (34 μmol/L), neonates characteristically do not appear jaundiced until the TSB exceeds 5.0 to 7.0 mg/dL (86 to 120 μmol/L). Some degree of jaundice develops in approximately 60% of neonates, and chemical hyperbilirubinemia, defined as a TSB ≥2.0 mg/dL (34 μmol/L), is virtually universal in newborns during the 1st week of life. Jaundice in neonates becomes evident first on the face and progresses in a cephalocaudal fashion with increasing hyperbilirubinemia as classically characterized by Kramer (1969). Recent studies, however,

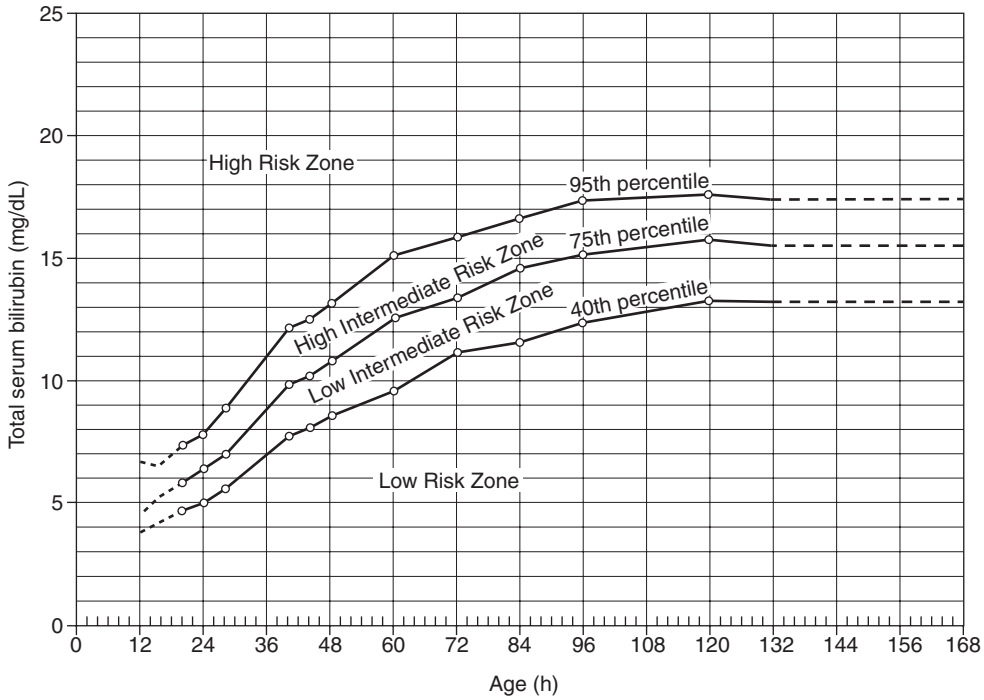

FIGURE 79-2 Nomogram for designation of hyperbilirubinemia risk based on hour-specific bilirubin value. *(Adapted from Bhutani V, Johnson L, Sivieri EM, et al: Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns*, Pediatrics *103:6-14, 1999.)*

suggest that the pattern and intensity of jaundice during the birth hospitalization may not be as reliable an indicator of degree of hyperbilirubinemia as previously thought (Keren et al, 2009; Moyer et al, 2000). Therefore, the AAP (2004) cautions that "visual estimation of bilirubin levels can lead to errors". Nevertheless, the absence of jaundice has excellent negative predictive value (99%) for developing a TSB that merits phototherapy (Keren et al, 2009); also, jaundice limited to the face and upper chest likely predicts a TSB <12.0 mg/dL (Moyer, 2000). It is currently recommended that a transcutaneous (TcB) or TSB measurement complement the clinical assessment for jaundice in every neonate during the birth hospitalization to assist in hyperbilirubinemia detection and neonatal management (Maisels et al, 2009b).

KERNICTERUS: CHRONIC BILIRUBIN ENCEPHALOPATHY

The clinical focus on neonatal hyperbilirubinemia derives from the neurotoxic risk hazardous bilirubin levels pose. Acute bilirubin encephalopathy may develop during hazardous hyperbilirubinemia and evolve into the chronic adverse neurodevelopmental sequelae of kernicterus. Kernicterus is a devastating, disabling neurologic disorder classically characterized by the clinical tetrad of (1) choreoathetoid cerebral palsy, (2) high-frequency central neural hearing loss, (3) palsy of vertical gaze, and (4) dental enamel hypoplasia, the result of bilirubin-induced cell toxicity (Perlstein, 1960). The central nervous system (CNS) sequelae reflect both a predilection of bilirubin toxicity for neurons (rather than glial cells) (Notter and Kendig, 1986), and the regional topography of bilirubin-induced neuronal injury that is characterized by prominent basal ganglia, cochlear, and oculomotor nuclei involvement (Ahdab-Barmada, 1983, 2000; Ahdab-Barmada and Moossy, 1984). Originally described in the context of severe hyperbilirubinemia secondary to Rh hemolytic disease (Evans and Polani, 1950; Vaughan et al, 1950), kernicterus has also been reported in other hemolytic conditions (e.g., hereditary spherocytosis and pyruvate kinase deficiency) (Watchko, 2000b), G6PD deficiency (MacDonald, 1995; Valaes, 1994, 2000), premature neonates (Ahdab-Barmada et al, 1984; Watchko et al, 1994) and in otherwise healthy term ($\geq 37^{0/7}$ weeks) and late preterm ($34^{0/7}$ to $36^{6/7}$ weeks) gestation breastfed infants without hemolysis (Bhutani et al, 2004; Maisels et al, 1995). The pediatric community's recent decades' experience with kernicterus is notable for the number of reported cases in the United States (Bhutani et al, 2004; Johnson et al, 2009; Maisels and Newman, 1995) and abroad (Ebbesen, 2000; Hansen, 2002; Kaplan and Hammerman, 2004b), a phenomenon that arose during the mid-to-late 1980s in conjunction with a striking sustained increase in breastfeeding initiation at birth (Ryan et al, 2002) and concurrent progressive decline in birth hospitalization length of stay (Curtin and Kozak, 1998) (Figure 79-3). These factors have combined to unmask a previously underappreciated potential to develop extreme hyperbilirubinemia among a select number of neonates, the biological basis of which appears to be in part genetically determined. Recent population-based kernicterus incidence estimates for term neonates in developed countries range from approximately 1 per 30,000 (Sgro et al, 2006) to 1 per 100,000 (Manning et al, 2006); higher rates have been reported for (1) preterm newborns (Watchko, 1994) and (2) infants born in developing countries where kernicterus is a serious endemic problem (e.g., Nigeria, where approximately 3% of neonatal hospital admissions evidence bilirubin encephalopathy) (Oguniesi et al, 2007; Zipursky, 2009).

Bilirubin toxicity usually does not become overt until high TSB levels have been established for several hours. Acute bilirubin encephalopathy typically progresses through three stages. Stage 1 occurs during the first few days, with the infant having decreased activity, poor sucking, hypotonia, and a slightly high-pitched cry. If the TSB level is rapidly decreased (e.g., by way of exchange transfusion), these nonspecific abnormalities can be reversed.

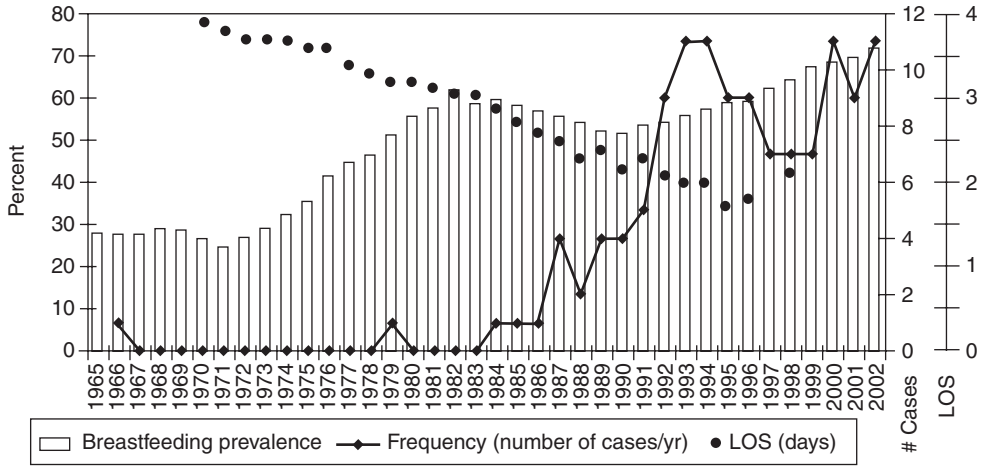

FIGURE 79-3 Number of reported kernicterus cases by birth year from 1965 to 2002 *(solid diamonds)* (Bhutani et al, 2004) shown in relation to annual prevalence of breastfeeding at birth hospitalization *(open bars as percentage)* (Ryan et al, 2002) and birth hospitalization length of stay *(solid circles in days)* (Curtin et al, 1998). An increase in reported cases of kernicterus is seen in conjunction with a sustained resurgence of breastfeeding initiation prevalence during birth hospitalization and concurrent decreased birth hospitalization length of stay (LOS). *(Adapted from Springer Science+Business Media:* Neuromolecular Medicine, *Volume 8, 2006: Kernicterus and the molecular mechanisms of bilirubin-induced CNS injury in newborns, Jon F. Watchko, page 515,* Figure 1.*)*

In stage 2, the infant demonstrates the features of stage 1 and also rigid extension of all four extremities, tight-fisted posturing of the arms, crossed extension of the legs, and a high-pitched, irritable cry. Sometimes these changes are accompanied with seizure activity, backward arching of the neck (retrocollis) and trunk (opisthotonos), and fever. Stage 3 is evidenced by hypertonia with marked retrocollis and opisthotonos, stupor, coma, and a shrill cry. The preponderance of evidence in the medical literature suggests that once an infant demonstrates signs of opisthotonos, some damage to the central nervous system has occurred. Van Praagh (1961) reported that all infants with definite opisthotonos (20 of 20 infants in his review) proved to have kernicteric sequelae on follow-up, although he did not comment on the extent of the adverse neurodevelopmental findings. Jones et al (1954) reported that the presence of definite abnormal signs, such as opisthotonos, in the neonatal period was associated with the development of handicap(s) but was not necessarily predictive of the severity of that handicap(s) (although most infants experienced moderate to severe neurodevelopmental sequelae). In contrast to these earlier reports, Harris et al (2001) follow-up experience in six neonates with marked hyperbilirubinemia showed that transient neurologic abnormalities may not correlate with long-term prognosis. In their study, however, only two infants demonstrated opisthotonos; one recovered without sequelae (peak serum bilirubin 30.6 mg/dL [523 μmol/L] on readmission on day 5 of life), whereas the other (peak serum bilirubin 36.9 [631 μmol/L] on readmission on day 6 of life) had profound long-term adverse neurodevelopmental deficits despite aggressive treatment with phototherapy and exchange transfusion. Most recently, Hansen et al (2009) reported a cohort of six extremely jaundiced neonates (TSB range 27.9 to 46.3 mg/dL [477 to 792 μmol/L]) with signs of intermediate to advanced phase acute bilirubin encephalopathy (e.g., seizures, opisthotonos, retrocollis) who were treated with rapid and aggressive intervention and demonstrated normal neurologic development. These more recent findings support the potential clinical utility of the AAP recommendation for immediate exchange transfusion in any infant who is jaundiced and manifests the signs of intermediate to advanced stages of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever) even if the TSB level is falling (AAP, 2004).

Magnetic resonance imaging (MRI) offers a tool by which to assess possible bilirubin-induced brain damage in neonates with marked hyperbilirubinemia (Figure 79-4). The first MRI showing such damage was done in a full-term neonate with G6PD deficiency (Penn et al, 1994). The MRI at 8 days of age showed abnormally high signal intensity on T1-weighted images of the basal ganglia, thalamus, and internal capsule. A similar but less intense signal was seen on T2-weighted images. Subsequently there have been several reports of abnormalities seen in the globus pallidus on MRI in infants with bilirubin encephalopathy, typically with increased signal intensity of T1-weighted images early and that of T2-weighted images later. Although these findings often correlate with adverse long-term neurologic outcome, there have been reports of exceptions to this rule, including both infants with abnormal MRI who are subsequently normal on follow-up and infants with normal MRI who evidence long-term neuromotor sequelae characteristic of bilirubin-induced brain damage.

The ongoing occurrence of kernicterus has rekindled an interest in its molecular pathogenesis (Tiribelli and Ostrow, 2005; Watchko, 2006a) and in efforts to identify potential novel strategies to protect the CNS against bilirubin-induced injury. Although no one disputes the

neurotoxic potential of bilirubin, the cellular and molecular events attendant on bilirubin-induced neurotoxicity have been only partially characterized, and there is little agreement as to which, from a mechanistic standpoint, may be the most clinically relevant. Almost without exception, kernicterus has occurred during extreme unconjugated hyperbilirubinemia (UCB), and it is the UCB fraction not bound to albumin, that is, free bilirubin (B_F), that can cross the blood-brain barrier and prove neurotoxic. The concentration of this unbound bilirubin fraction is believed to dictate the biologic effects of bilirubin in jaundiced newborns, including its potential neurotoxicity. The full-term newborn infant has a significantly lower plasma albumin level than the adult and, correspondingly, fewer bilirubin binding sites. The albumin level is inversely correlated with gestational age, so this lack of binding sites is more pronounced in preterm infants. Bilirubin-albumin binding may also be modified by clinical conditions and the presence of competing compounds. It is notable that susceptibility for bilirubin-induced neurotoxicity is enhanced by prematurity (Gartner et al, 1970; Govaert et al, 2003); by drugs that displace bilirubin from albumin, thereby increasing B_F (Silverman et al, 1956); and possibly by concurrent marked conjugated bilirubinemia (Ebbesen, 1982; Grobler et al, 1997; Merhar et al, 2005).

BILIRUBIN-INDUCED CNS INJURY IN NEONATES LESS THAN 35 WEEKS' GESTATION

Hyperbilirubinemia in preterm infants is more prevalent and its course more protracted than in term neonates as a result of exaggerated neonatal red cell, hepatic, and gastrointestinal immaturity. The postnatal maturation of hepatic bilirubin uptake and bilirubin conjugation may also be slower in premature infants (Cashore, 2000). In addition, the delay in the initiation of enteral feedings that is so common in the clinical management of sick premature newborns may limit intestinal flow and bacterial colonization, resulting in a further enhancement of bilirubin enterohepatic circulation (Cashore, 2000). These developmental and clinical phenomena contribute to the greater degree and duration of neonatal jaundice in premature infants.

Despite the near-universal finding of clinical jaundice in the very low-birthweight infant, kernicterus has virtually disappeared in postmortem series of premature neonates (Jardine, 1989; Perlman, 1978; Watchko, 1994), and postkernicteric bilirubin encephalopathy and central neural hearing loss related to neonatal hyperbilirubinemia have not emerged as important clinical sequelae in neurodevelopmental follow-up of premature infants (Cashore, 2000). Yet kernicterus has occurred in preterm infants at low bilirubin levels and in the absence of acute neurologic signs (Gartner et al, 1970; Harris et al, 1958; Okumura et al, 2009; Sugama et al, 2001), and investigators have suggested that moderate hyperbilirubinemia (total serum bilirubin levels higher than 10 to 14 mg/dL [170–239 μmol/L]) may be associated with milder forms of central nervous system dysfunction and sequelae (Naeye, 1978; Scheidt et al, 1977; van de Bor et al, 1989). Recent studies report that hyperbilirubinemic extremely low-birthweight premature neonates may evidence athetotic cerebral palsy with features similar to term infants with kernicterus (Okumura et al, 2009) and further suggest an association between peak total serum bilirubin and long-term adverse neurodevelopmental sequelae in this high-risk group (Oh et al, 2003). However, there remains considerable debate regarding the risk that neonatal hyperbilirubinemia poses for neuronal injury in the premature neonate, how to quantify that risk, and when to intervene with phototherapy or exchange transfusion (Hansen, 1996; Maisels and Watchko, 2003; NICHD, 1985). As a result, the framing of guidelines for the use of phototherapy and exchange transfusion in these infants is a capricious exercise at best and one for which no claim of an evidence base can be made (Maisels et al, 2003). Tables 79-3 to 79-5 illustrate a range of TSB levels for intervention in varying circumstances. These guidelines are provided by various experts, none of whom would likely make any claim for the greater validity of one approach versus another. A recent report from the United Kingdom showing a wide range of treatment

thresholds for phototherapy and exchange transfusion in premature neonates further underscores this uncertainty (Rennie et al, 2009).

The recent NICHD Neonatal Network study on aggressive versus conservative phototherapy for infants with extremely low birthweight (<1000 g) has shed some new insight on hyperbilirubinemia risk and treatment options in the tiniest of preterm neonates but has also raised important new questions (Morris et al, 2008). Table 79-6 outlines the aggressive and conservative phototherapy treatment guidelines and exchange transfusion thresholds used in the Network study. Their data suggest that aggressive phototherapy may be preferred for infants of 751 to 1000 g birthweight because of significant neurodevelopmental benefit including a reduction in athetosis and severe hearing loss (Morris et al, 2008). However, their findings also raised concerns for aggressive phototherapy use in infants with birthweight of 501 to 750 g because of a higher mortality rate in that subgroup—that is, increased mortality may offset any potential neurologic benefits of aggressive treatment in these smallest of infants (Morris et al, 2008). Although it is unclear why phototherapy might increase mortality in this birthweight cohort, speculation focuses on greater light penetration deep into subcutaneous tissues via thin gelatinous skin and possible oxidative injury to cell membranes (Maisels, 2009; Vreman et al, 2004). Few neonates required exchange transfusion, confirming again the broad efficacy of phototherapy in preterm neonates. However, additional clinical study is needed to further clarify the hyperbilirubinemia risk of premature neonates and frame guidelines for phototherapy and exchange transfusion in preterm infants that are evidence based (Maisels et al, 2003).

CLINICAL EFFORTS AT KERNICTERUS PREVENTION

The key elements to preventing kernicterus in term and late preterm neonates are (1) hyperbilirubinemia risk assessment, (2) appropriate and timely birth-hospitalization follow-up, and (3) timely and effective treatment of marked hyperbilirubinemia with phototherapy and/or exchange transfusion when it occurs. Support of successful breastfeeding is also an important part of hyperbilirubinemia control. Recent clinical evidence suggests that a TSB or TcB measured ≥18 hours after birth combined with assessment of hyperbilirubinemia risk factors significantly improves the prediction of subsequent hyperbilirubinemia (Keren, 2008; Maisels, 2009; Newman, 2005), and a group of experts now recommends the approach outlined in Figure 79-5 (Maisels et al, 2009b). In this approach, the predischarge TSB or TcB is plotted according to the infant's age in hours using the Bhutani hour-specific nomogram (see Figure 79-2). The bilirubin risk zone, gestational age at birth, and hyperbilirubinemia risk factors (see Box 79-3) are then combined to assess the risk of subsequent hyperbilirubinemia and formulate a plan for management and timely post–birth-hospitalization follow-up (see Figure 79-5). Critical in the effort are the characterization of the birth-hospitalization TSB/TcB bilirubin risk zone (Bhutani et al, 1999), accurate knowledge of the infant's gestational age in weeks, and details regarding the presence of other hyperbilirubinemia risk factors. Coupling the gestational age with knowledge of hyperbilirubinemia risk factors will determine which portion of the algorithm is operative for a given neonate. Using the predischarge TcB/TSB determined risk zone, the algorithm will provide direction regarding further evaluation and management, including timing of post-discharge follow-up and whether additional TSB/TcB measurements are indicated. The AAP has developed a resource kit for hospitals and clinicians to help provide breastfeeding support and manage the jaundiced newborn (www.aap.org/bookstore) and a Web-based program developed at Stanford, accessible at www.bilitool.org, is a practical instrument for plotting hour-specific TSB/TcB measurements.

TREATMENT CONSIDERATIONS

Phototherapy and exchange transfusion are the staples of intervention for the hyperbilirubinemic newborn, and current AAP phototherapy and exchange transfusion treatment

TABLE 79-6 Guidelines for Initiating Phototherapy and Exchange Transfusions—NICHD Neonatal Research Network Trial*

	Aggressive Management		Conservative Management	
Birthweight	Phototx Begins	Exchange Transfusion	Phototx Begins	Exchange Transfusion
501–750 g	ASAP after enrollment	≥13.0 mg/dL	≥8.0 mg/dL	≥3.0 mg/dL
751–1000 g	ASAP after enrollment	≥15.0 mg/dL	≥0.0 mg/dL	≥15.0 mg/dL

From Morris BH, Oh W, Tyson JE, et al: Aggressive vs. conservative phototherapy for infants with extremely low birth weight, *N Engl J Med* 359:1885-1896, 2008.
*Enrollment is expected within the period 12 to 36 hours after birth, preferably between 12 and 24 hours.

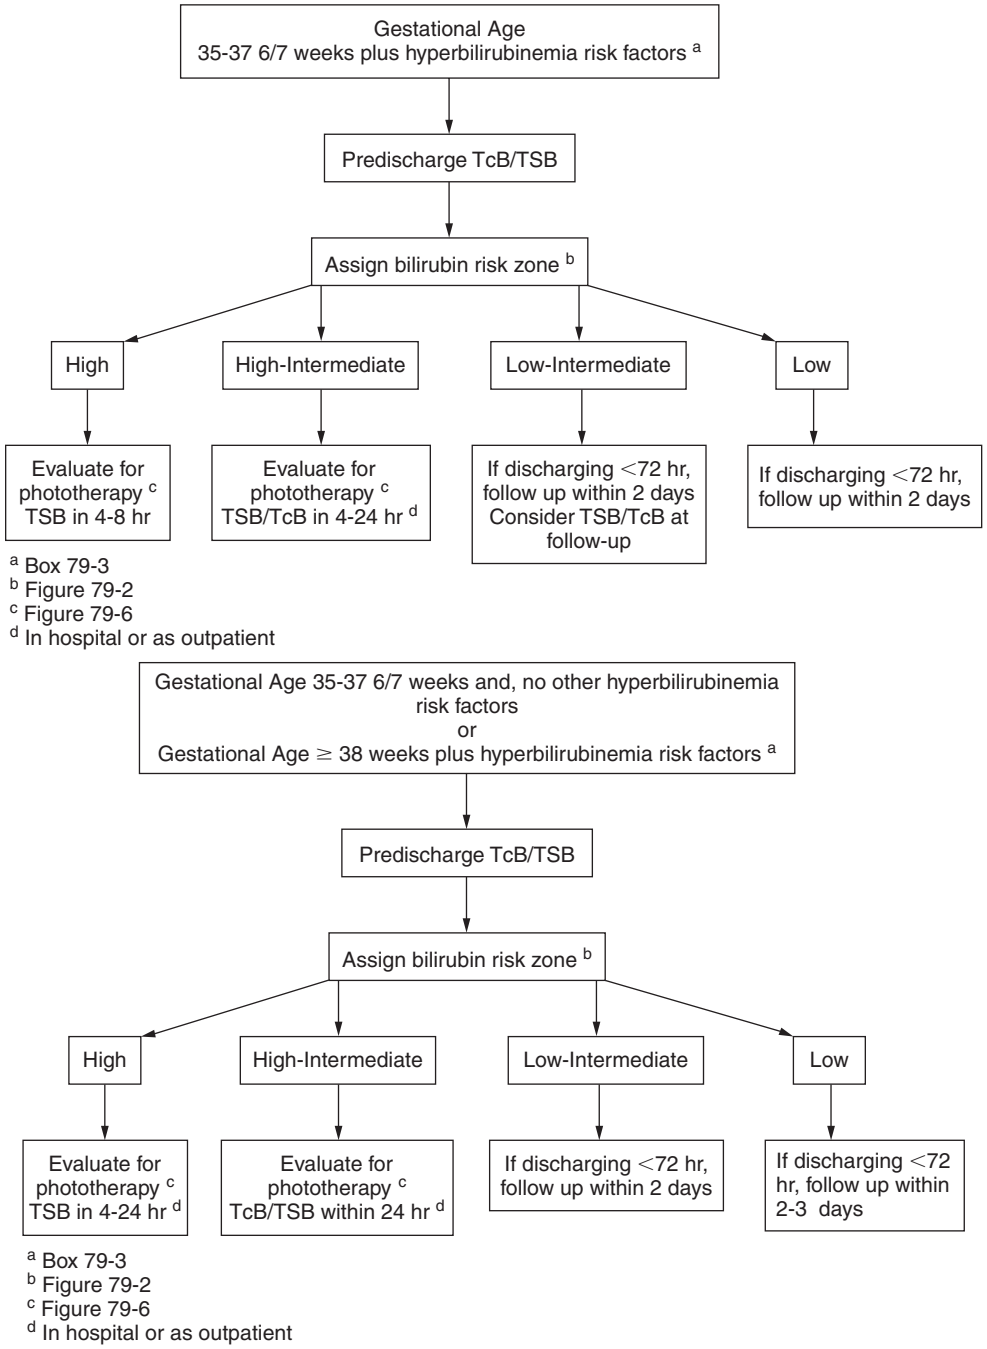

FIGURE 79-5 Algorithm providing recommendations for management and follow-up according to predischarge bilirubin measurements, gestational age at birth, and other risk factors for subsequent hyperbilirubinemia.

thresholds for infants ≥35 weeks' gestation are shown in Figures 79-6 and 79-7, respectively (AAP, 2004). Tables 79-4 to 79-6 illustrate a range of TSB levels for intervention in varying circumstances for preterm neonates. Phototherapy was first introduced at the Rochford (Essex) General Hospital by Cremer et al (1958) and has proven to be exceedingly successful. Just how effective phototherapy has been can be gauged by the impact it has had on the number of exchange transfusions performed for hyperbilirubinemia (Maisels, 2001; O'Shea et al, 1992), particularly in the neonatal intensive care unit population of infants weighing <1500 g. Certainly phototherapy, if used appropriately (Maisels, 1996), is capable of controlling the bilirubin levels in almost all low-birthweight infants, with the possible exception of the occasional infant with severe erythroblastosis fetalis or marked bruising. In a similar fashion, phototherapy has proven effective in controlling bilirubin levels and preventing the need for exchange transfusion in most term and late-preterm neonates as well—exceptions on occasion being infants with severe hemolysis. Indeed, a rising TSB on phototherapy should raise the concern that the neonate has significant hemolysis, and preparations for exchange should be made in anticipation of the TSB possibly rising to the exchange threshold.

[c] Figure 79-6
[d] In hospital or as outpatient
[e] Follow-up recommendations can be modified according to level of risk for hyperbilirubinemia. Depending on the circumstances, in infants at low risk, later follow-up can be considered

FIGURE 79-5—cont'd For legend see facing page.

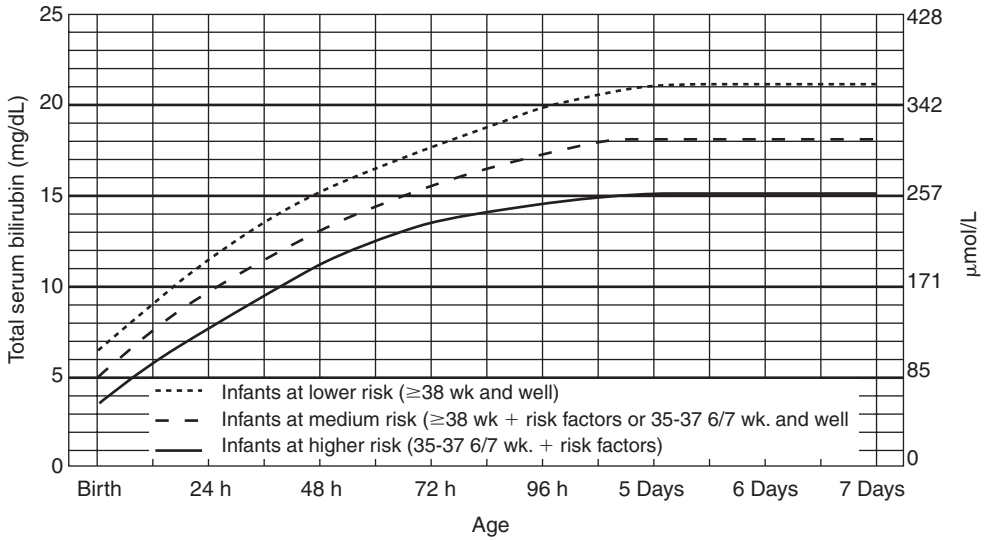

FIGURE 79-6 Guidelines for phototherapy in hospitalized infants ≥35 weeks' gestation.

- Use total bilirubin. Do not subtract direct reading or conjugated bilirubin.
- The lines for lower, medium, and higher risk refer to risk for neurotoxicity.
- Risk factors for neurotoxicity—isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis or albumin <3.0 g/dL (if measured).
- For well infants 35 to $37^{6/7}$ wk can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wk and at higher TSB levels for those closer to $37^{6/7}$ wk.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2 to 3 mg/dL (35 to 50 mmol/L) below those shown, but home phototherapy should not be used in any infant with risk factors.

These guidelines refer to the use of intensive phototherapy, which should be used when the TSB exceeds the line indicated for each category. Infants are designated as "higher risk" because of the potential negative effects of the conditions listed on albumin binding of bilirubin, the blood-brain barrier, and the susceptibility of the brain cells to damage by bilirubin.

"Intensive phototherapy" implies irradiance in the blue-green spectrum (wavelengths of approximately 430 to 490 nm) of at least 30 µW/cm2 per nm (measured at the infant's skin directly below the center of the phototherapy unit) and delivered to as much of the infant's surface area as possible. Note that irradiance measured below the center of the light source is much greater than that measured at the periphery. Measurements should be made with a spectroradiometer specified by the manufacturer of the phototherapy system.

If the total serum bilirubin does not decrease or continues to rise in an infant who is receiving intensive phototherapy, this strongly suggests the presence of hemolysis. *(Adapted from American Academy of Pediatrics: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation*, Pediatrics *114:297-316, 2004.)*

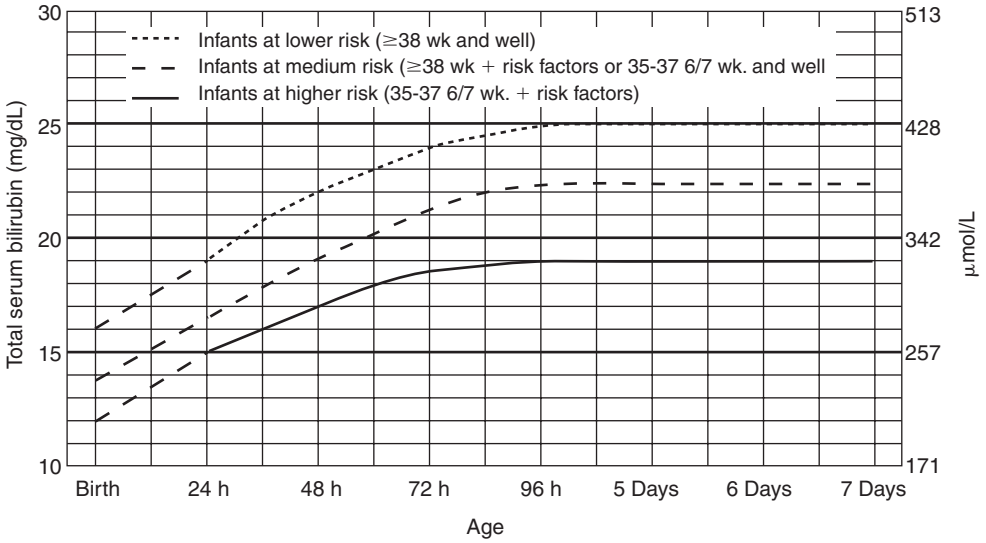

FIGURE 79-7 Guidelines for exchange transfusion in infants ≥35 weeks' gestation.

- The *dashed lines* for the first 24 hours indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high-pitched cry) or if TSB is ≥5 mg/dL (85 μmol/L) above these lines.
- The lines for lower, medium, and higher risk refer to risk for neurotoxicity.
- Risk factors for neurotoxicity: isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate B/A ratio (see legend).
- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- If infant is well and 35 to $37^{6/7}$ wk (median risk), can individualize TSB levels for exchange based on actual gestational age.
- During birth hospitalization, exchange transfusion is recommended if the TSB rises to these levels despite intensive phototherapy. For readmitted infants, if the TSB level is above the exchange level, repeat TSB measurement every 2 to 3 hours and consider exchange if the TSB remains above the levels indicated after intensive phototherapy for 6 hours.
- The following B/A ratios can be used together with but in not in lieu of the TSB level as an additional factor in determining the need for exchange transfusion (Ahlfors, 1994).

	B/A Ratio at Which Exchange Transfusion Should Be Considered	
Risk Category	**TSB mg/dL/Alb, g/dL**	**TSB μmol/L/Alb, μmol/L**
Infants ≥$38^{0/7}$ wk	8.0	0.94
Infants $35^{0/7}$–$36^{6/7}$ wk and well or ≥$38^{0/7}$ wk if higher risk or isoimmune hemolytic disease or G6PD deficiency	7.2	0.84
Infants $35^{0/7}$–$37^{6/7}$ wk if higher risk or isoimmune hemolytic disease or G6PD deficiency	6.8	0.80

If the TSB is at or approaching the exchange level, send blood for immediate type and crossmatch. Blood for exchange transfusion is modified whole blood (red cells and plasma) crossmatched against the mother and compatible with the infant. *(Adapted from American Academy of Pediatrics: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation*, Pediatrics *114:297-316, 2004.)*

PHOTOTHERAPY

The most effective phototherapy units deliver output in the blue-green region of the visible spectrum including the commercially available special blue fluorescent tubes (Ennever, 1990). These tubes are labeled F20 T12/BB or PL52/20W, and they provide much greater irradiance than regular blue tubes (labeled F20T12/B). Special blue tubes are particularly effective because they provide light with wavelengths that penetrate the skin well and are absorbed maximally by bilirubin (Ennever, 1990). Phototherapy effectiveness can be further enhanced by increasing the irradiance and the surface area exposed (Maisels, 1996, 2001; Maisels et al, 2008). Irradiance increases dramatically as the distance between the light source and the infant decreases, and this effect is most significant when special blue tubes are used (Maisels et al, 2003). If bilirubin levels are rising in spite of conventional phototherapy (e.g., severely bruised infants or those with hemolytic disease), a free-standing bank of special blue fluorescent tubes may be placed about 10 cm above the infant (Maisels et al, 2003). This proximity is accomplished by placing the fluorescent bank of lights between the radiant warmer and the infant and cannot be achieved when the infant is in an incubator. If halogen spot phototherapy lamps are used, they must not be positioned closer to the infant than recommended by the manufacturer because of the risk of a burn (Maisels et al, 2003). In addition, if two or more halogen lamps are used, they should never be focused on the same area of the infant's skin, as this might also cause a burn. The efficacy of phototherapy is also closely related to the surface area of the infant exposed to the phototherapy lights, and the simplest way of increasing the surface area exposed is to place fiberoptic pads below the infant with phototherapy lamps above (Maisels et al, 2003). Clinical studies comparing intermittent vs. continuous phototherapy have produced conflicting results, but in many circumstances, phototherapy does not need to be continuous. As long as

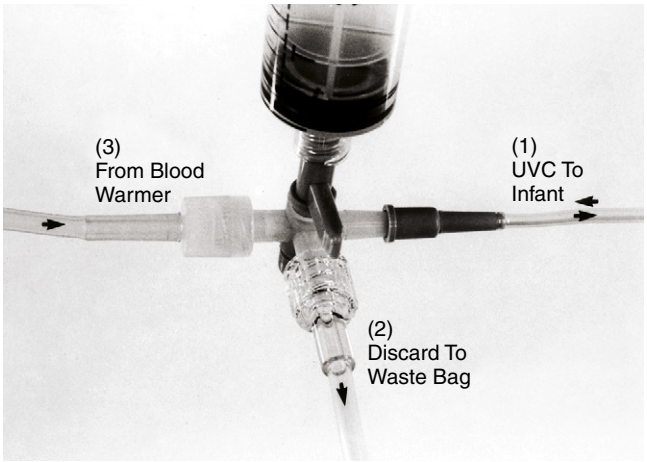

FIGURE 79-8 Special four-way stopcock assembly. *(1)* Male adapter to umbilical venous line; *(2)* female adapter to waste container; and *(3)* attachment to blood bag and warmer. The stopcock handle points to the port that is open to the syringe, and stopcock handle is rotated in a clockwise fashion when correctly assembled (e.g., first, withdraw aliquot from infant; second, discard to waste container; third, draw fresh blood from bag; and then fourth, infuse into infant to complete one cycle). *(From Watchko JF: Exchange transfusion in the management of neonatal hyperbilirubinemia. In Maisels MJ, Watchko JF, editors:* Neonatal jaundice, *Amsterdam, 2000c, Harwood Academic, pp 169-176.)*

the serum bilirubin level is being controlled, phototherapy can be interrupted during feeding or short parental visits.

Some studies suggest that phototherapy significantly increases insensible water loss, particularly in preterm infants (Kjartansson et al, 1992; Wu and Hodgman, 1974), but more recently it has been shown that as long as skin temperature is kept constant (by servo-control) and infants are not subjected to heat stress, phototherapy does not lead to an increase in oxygen consumption or insensible water loss through the skin or the respiratory tract (Fok et al, 2001; Kjartansson et al, 1992). Because we have effective means of monitoring newborn hydration (such as a daily weight and measurements of serum electrolytes), there is no reason to provide additional fluids routinely to infants who are receiving phototherapy. They should, of course, be kept adequately hydrated, not because phototherapy produces dehydration but because adequate urine output is important for effective phototherapy. The bilirubin isomer, lumirubin, is excreted in the bile and the urine, and lumirubin excretion appears to be an important element in the bilirubin-lowering function of phototherapy (Ennever, 1990).

Significant complications associated with phototherapy are exceptionally rare. Perhaps the most important clinical complication encountered during the use of phototherapy is that associated with the presence of direct hyperbilirubinemia or cholestatic jaundice. When infants with direct hyperbilirubinemia are exposed to phototherapy, they may develop a dark, grayish-brown discoloration of the skin, serum, and urine (i.e., bronze baby syndrome) (Rubaltelli et al, 1983, 1996). The pathogenesis of this syndrome is unknown but is possibly related to the accumulation of porphyrins or other pigments in the plasma in the presence of cholestasis (Onishi et al, 1982; Rubaltelli et al, 1983, 1996). Although few deleterious consequences of the bronze baby syndrome have been described, two infants with this syndrome who died were shown to have kernicterus at autopsy (Clark et al, 1976; Rubaltelli et al, 1996). With the exception of these case reports, there are no other reports of significant complications in infants who develop the bronze baby syndrome, although impaired binding of bilirubin to albumin has been detected in three infants with this syndrome and in infants with cholestasis (Ebbessen, 1982; Kopelman et al, 1972). If there is a need for phototherapy, the presence of direct hyperbilirubinemia should not be considered a contraindication to its use, particularly in the sick newborn, and, as a rule, the direct serum bilirubin level should not be subtracted from the total bilirubin concentration when decisions are made about initiating phototherapy or an exchange transfusion. In infants who develop the bronze baby syndrome, exchange transfusion should be considered if phototherapy does not lower the total serum bilirubin. Because of the paucity of data, however, firm recommendations cannot be made. Rarely, purpuric bullous eruptions have also been described in infants with severe cholestatic jaundice receiving phototherapy.

EXCHANGE TRANSFUSION

Exchange transfusion occupies a unique place in the history of neonatal jaundice because it was the first intervention to permit effective control of severe hyperbilirubinemia and to have the potential to prevent kernicterus. In addition to immediate control of hyperbilirubinemia, an exchange transfusion in immune-mediated hemolytic disease also achieves: (1) the removal of antibody-coated red blood cells (a source of "potential" bilirubin), (2) the correction of anemia (if present), and (3) the removal of maternal antibody. A "double volume" exchange refers to an exchange of twice the neonate's blood volume or approximately 170 to 200 mL/kg and removes approximately 110% of circulating bilirubin (extravascular bilirubin enters the blood during the exchange), but only 25% of total body bilirubin. The exchange transfusion is much less efficient in the removal of total body bilirubin compared to circulating bilirubin because the majority of the infant's bilirubin is in the extravascular compartment (Valaes, 1963). Postexchange bilirubin levels are approximately 60% of preexchange levels, but the rapid (approximately 30 min) reequilibration of bilirubin between the vascular and extravascular compartments produces a rebound of serum bilirubin levels to 70% to 80% of preexchange levels (Brown, 1957).

Exchange transfusions are most readily performed via the umbilical vein using a 5 or 8 French umbilical catheter inserted just far enough to obtain free flow of blood (usually no more than the distance between the xiphoid process and umbilicus). The push-pull method with a single syringe and special four-way stopcock assembly permits a single operator to complete the procedure (Figure 79-8) (Watchko, 2000c). Fresh citrate-phosphate-dextrose preserved blood (<72 hours old, and devoid of the offending antigen in the case of immune-mediated hemolytic disease) crossmatched to the infant should be used. Although the risk for graft-versus-host disease following an exchange transfusion is extremely rare, blood for exchange transfusion should be irradiated if possible. The blood should be warmed to body temperature by a blood/fluid warmer. The actual exchange should be performed

slowly in aliquots of 5 to 10 mL/kg body weight with each withdrawal-infusion cycle approximating 3 minutes' duration (Aranda, 1977). Using this approach, a double volume exchange should take approximately 1.5±0.5 hours. This rate has been demonstrated to be both safe and efficient (Forfar, 1958) and avoids deleterious hemodynamic changes (Aranda, 1977).

During the exchange, the infant's vital signs should be monitored closely, including heart rate/rhythm respiration, oxygen saturation, temperature, and blood pressure. Symptomatic hypocalcemia in early studies was reported in up to 5% of healthy infants, but supplemental calcium gluconate administration during the exchange transfusion has little effect on serum ionized calcium (Ellis, 1979; Maisels, 1974; Wieland, 1979), and too rapid infusion of calcium may cause bradyarrhythmias or cardiac arrest. If symptomatic hypocalcemia develops, temporary cessation of the procedure will allow recovery toward normal calcium levels as the citrate (which binds calcium) is metabolized by the liver. Postexchange studies should include bilirubin, hemoglobin, platelet count, ionized calcium, serum electrolytes, and serum glucose.

The unintended consequences of exchange transfusion include cardiovascular, hematologic, gastrointestinal, biochemical, and infectious hazards, among others (Watchko, 2000c). Previously reported overall mortality rates associated with exchange transfusion ranged from 0.3 to 0.95 per 100 procedures (Hovi et al, 1985; Keenan et al, 1985), and significant morbidity (apnea, bradycardia, cyanosis, vasospasm, thrombosis) was observed in 6.7% of infants who received exchange transfusion in the NICHD collaborative phototherapy study (Keenan et al, 1985). These rates, however, may not be generalizable to the current era if, as with most procedures, frequency of performance is an important determinant of risk and experience with exchange transfusion is decreasing (Newman e al, 1992). It is quite possible that the mortality (and morbidity) for this now infrequently performed procedure might be considerably higher than previously reported. On the other hand, none of the reports before 1986 included contemporary monitoring capabilities such as pulse oximetry. Jackson (1997) reported a 2% overall mortality rate (2 of 106) associated with exchange transfusions between 1980 and 1995 and a 12% risk of serious complications attributable to exchange transfusion in ill infants. Moreover, in infants classified as ill with medical problems in addition to hyperbilirubinemia, the incidence of exchange transfusion related complication leading to death was 8%. There were no procedure-related deaths in 81 healthy infants. Symptomatic hypocalcemia, bleeding related to thrombocytopenia, catheter-related complications, and apnea-bradycardia requiring resuscitation were common serious morbidities observed in this study, suggesting that exchange transfusion should be performed by experienced individuals in a neonatal intensive care unit with continuous monitoring (including pulse oximetry) prepared to respond to these adverse events (Jackson, 1997). Finally, although the risk of blood transfusion is now very low, transfusion always carries some infection risk (Schreiber et al, 1996). The risk estimates (risk per tested unit) for transfusion-transmitted viruses in the United States for the period 1991 through 1993 were as follows: for the human immunodeficiency virus (HIV), 1:493,000 (95% confidence interval, 202,000 to 2,778,000); for the human T cell lymphotropic virus (HTLV), 1:641,000 (256,000 to 2,000,000); for the hepatitis C virus (HCV), 1:103,000 (28,000 to 288,000); and for the hepatitis B virus (HBV), 1:63,000 (31,000 to 147,000) (Schreiber et al, 1996).

PART XVI

NEOPLASIA

CHAPTER 80

CONGENITAL MALIGNANT DISORDERS

Elizabeth Robbins, Mignon L. Loh, and Katherine K. Matthay

Neonatal malignancies differ in incidence, clinical behavior, and heritable features from cancers seen in older children. Whereas acute leukemia is the most common malignancy in young children, the majority of neonatal tumors are solid tumors, many of which are detected prenatally during routine ultrasonography. Some childhood malignancies that carry excellent prognoses, such as acute lymphoblastic leukemia, are often fatal in neonates. In contrast, neuroblastoma, which responds poorly to treatment in older children, often spontaneously regresses in newborns.

Treatment of cancer in the neonatal period presents special challenges. Among these are differences in drug metabolism in newborns, the sensitivity of rapidly growing normal tissues to chemotherapeutic agents and radiation, and the increased possibility of late effects including neurocognitive sequelae, impaired reproductive capacity, growth disturbances, and secondary malignancies. The epidemiology, etiology, and diagnosis of neonatal malignancy are reviewed here, followed by a discussion of commonly encountered malignancies.

EPIDEMIOLOGY, ETIOLOGY, AND DIAGNOSIS OF NEONATAL MALIGNANCY

EPIDEMIOLOGY: INCIDENCE AND MORTALITY

Neonatal tumors are rare, with an incidence of approximately 1 per 12,500 to 27,500 live births; they make up 2% of childhood malignancies (Gurney et al, 1997; Moore et al, 2003). Although trend analyses suggest that the incidence of malignancy in the pediatric population may be increasing (Linabery and Ross, 2008), a number of factors affect incidence rates, including improvements in molecular methods of diagnosis, changes in population characteristics, screening fetal ultrasound practices, and case ascertainment by cancer registries (Spector and Linabery, 2009).

The most common malignancy in infants is neuroblastoma, followed by leukemia, central nervous system tumors, retinoblastoma, and germ cell tumors (Linabery and Ross, 2008). Female and male infants have similar cancer incidence rates, but white infants have significantly higher rates than those reported in African American infants for all histologic types. The distribution of the major types of cancers in newborns, infants, and children is depicted in Table 80-1. Incidence rates for the most common types of malignancy in infants are shown in Table 80-2.

The mortality rates for infants with cancer exceed those for older children, even among similar histologic groups (Ries et al, 1999). Despite cure rates exceeding 75% for children older than 1 year who are diagnosed with acute lymphoblastic leukemia (ALL), newborns with ALL experience cure rates of less than 25% (Bresters et al, 2002). This is likely due to biologic differences in the leukemias afflicting infants: infants with leukemia, but not older children, often harbor rearrangements of the *MLL* (mixed lineage leukemia) gene, which confer a poor prognosis. Poorer survival patterns for infants are also seen with rhabdomyosarcoma and central nervous system (CNS) tumors, including primitive neuroectodermal tumor (PNET) and ependymoma (Ries et al, 1999). Two notable exceptions are neuroblastoma, for which 5-year survival in newborns with disseminated disease is >90%, and infantile fibrosarcoma, for which cure rates often exceed those achieved in older children or adults.

ETIOLOGY

Genetic Predisposition Syndromes and Congenital Defects

The etiology of cancer in children is multifactorial, involving both genetic and environmental factors; in neonates, predisposing genetic factors frequently play an important role. An acquired or inherited abnormality of a cancer-predisposing gene that is critical during embryogenesis underlies many cases of neonatal cancer. Malignant transformation of normal cells results from the activation or suppression of these cancer-predisposing genes. The retinoblastoma gene at 13q is an example of a constitutional chromosomal abnormality that results in a high risk of malignancy.

A number of well-defined hereditary conditions are associated with an increased incidence of specific neoplasms; these are listed in Table 80-3. Except for retinoblastoma, hepatoblastoma, and Wilms' tumor, the neoplasms associated with these syndromes seldom manifest in the neonatal period, but the associated abnormalities may be recognized early, allowing for regular screening. A lack of family history should not dissuade the clinician from investigating these syndromes, because both spontaneous germline mutations and parental mosaicism occur. The genetic

TABLE 80-1 Percent Distribution of the Major Types of Cancer in Newborns, Infants, and Children

Malignancy	Newborns <30 d (%)	Infants <1 yr (%)	Children <15 yr (%)
Leukemia	13	14	31

*Incidence rate per 1 million person-years, age-adjusted to the 2000 U.S. Standard population.

defect in many of these neoplasms has been identified. For example, the NF1 gene, located at 17q11.2, encodes a protein, neurofibromin, that normally acts as a guanosine triphosphatase activating protein that downregulates the Ras signaling pathway. Children with NF1 are at increased risk of developing juvenile myelomonocytic leukemia (JMML), a rare but aggressive myeloproliferative neoplasm that is currently only cured with hematopoietic stem cell transplant (Niemeyer and Kratz, 2008). In children with NF1 and JMML, the hematopoietic cells display loss of the wild type *NF1* gene and duplication of the mutant allele, thus resulting in the complete loss of the normal neurofibromin protein in the leukemia cells (Stephens et al, 2006). This promotes cell growth because there is no functional off switch.

A large number of childhood tumors occur in association with congenital defects. For instance, children with congenital aniridia have an increased incidence of Wilms' tumor. Although aniridia is found in only 1 of 75,000 persons, it is found in as many as 1 in 75 children with Wilms' tumor. Children with abnormalities of the Wilms' tumor 1 gene (*WT1*), located on chromosome 11p13, also have an increased risk of developing Wilms' tumor (Scott et al, 2006). Most patients with constitutional *WT1* defects have associated phenotypic syndromes that include combinations of genitourinary abnormalities, renal dysfunction, and mental retardation. The Beckwith-Wiedemann syndrome (BWS) and hemihypertrophy syndromes are associated with Wilms' tumor as well as several other childhood neoplasms. These syndromes are typified by macroglossia, gigantism, and abdominal wall defects; patients may also have visceromegaly, flame nevus, neonatal hypoglycemia, microcephaly, and retardation (Scott et al, 2006). Approximately 8% of infants with either the complete or partial syndrome develop neoplasms including Wilms' tumor, adrenal cortical carcinoma, and hepatoblastoma—tumors of the same organs in which visceromegaly develops. Also reported are rhabdomyosarcoma, neuroblastoma, ganglioneuroma, and adenomas and hamartomas. BWS is linked with abnormalities of 11p15; this is the location of the insulin-like growth factor II gene (*IGF-2*) and the tumor suppressor gene *H19* (Rahma, 2005).

Transplacental Tumor Passage

A rare cause of cancer in neonates and infants is the transplacental passage of tumor cells from the mother. Fewer than 20 cases of transplacentally transmitted cancer have been reported (Walker et al, 2002). Malignancies transmitted include leukemia, melanoma, lymphoma, hepatic carcinoma, and lung cancer. Transplacentally acquired neoplasm is usually apparent at birth or shortly thereafter, but diagnosis has been reported as late as age 8 months (Maruko et al, 2002).

The frequency of malignancy in pregnant women is estimated at 1 per 1000 pregnancies (Greenlund et al, 2001; Maruko et al, 2004; Pavlidis, 2002). That transplacental transmission is so rare is attributed to the protective function of the placenta.

Twin-to-Twin Transmission

The risk of development of leukemia is increased in a monozygotic twin. If one monozygotic twin has leukemia, the co-twin has an approximately 25% chance of developing leukemia, usually within weeks or months of the diagnosis of the sibling. A dizygotic twin has only a slightly increased risk of developing leukemia. Growing evidence suggests that this increased incidence is likely due to in utero twin-to-twin transmission of a preleukemic clone rather than to the simultaneous development of a shared germline mutation facilitating the later development of leukemia (Greaves et al, 2003; Mahmoud et al, 1995).

Environmental Factors

Environmental factors are probably less important in the development of neonatal cancer compared with their role in the development of cancer in older children and adults. Nonetheless, there is evidence that environmental

influences including radiation exposure, maternal medication use, and various environmental exposures may affect the incidence of neonatal cancer (Moore et al, 2003).

Exposure to ionizing radiation during pregnancy is known to increase the risk of a number of tumors, including acute leukemia, in exposed offspring. There appears to be a dose-response relationship between the dose of ionizing radiation received by the fetus in utero and the subsequent development of cancer in childhood, with doses on the order of 10 mGy sufficient to produce an increase in risk (Doll and Wakeford, 1997).

Maternal exposure to drugs during pregnancy has been associated with the subsequent development of cancer in offspring. Maternal use of diethylstilbestrol has been strongly associated with the development of clear cell adenocarcinoma of the vagina and cervix in daughters born from those pregnancies (Herbst et al, 1971). A number of substances known to be teratogenic also may be carcinogenic to offspring. In utero exposure to phenytoin or other antiepileptic drugs can result in the fetal hydantoin syndrome; some infants with this syndrome have developed neuroblastoma (Ehrenbard and Chaganti, 1981). Excessive maternal alcohol consumption may be linked to an increased risk of developing cancer in the newborn period, particularly acute myeloid leukemia (Shu et al, 1996). The use of fertility drugs does not appear to increase the risk of cancer in the exposed offspring (Basatemur and Sutcliffe, 2008).

Environmental exposures of the mother or father to hydrocarbons, dyes, and other chemicals and solvents may be related to the development of neonatal tumors, but there is only a weak association for most of the risk factors identified. The association of neoplasms with other environmental factors, such as maternal use of tobacco, has not been conclusively proven (Shu et al, 1996).

DIAGNOSIS AND EVALUATION

The diagnostic evaluation of a newborn infant suspected to have cancer is guided by the signs and symptoms of the disease. Symptoms of malignancy in neonates can be nonspecific, such as irritability, poor feeding, failure to thrive, and fever. Table 80-4 lists clinical features associated with the more common malignancies found in the neonatal period. Most neonatal tumors present as a mass

at birth; often the mass has previously been identified by prenatal ultrasonography. Postnatal imaging with magnetic resonance imaging (MRI) or computed tomography (CT) is usually required to better delineate the lesion.

Laboratory and pathologic evaluations should be directed at making the diagnosis efficiently, sparing the newborn unnecessary procedures that can result in acute and chronic morbidity. Routine laboratory studies including a complete blood cell count (CBC) and liver and renal function tests should be obtained. Urine catecholamine excretion should be measured when neuroblastoma is being considered. Serum alpha-fetoprotein (AFP) and beta human chorionic gonadotrophin (hCG) levels should be obtained in infants suspected of having a germ cell tumor or teratoma; these can serve as tumor markers, although the normally elevated levels in infancy can complicate the interpretation of these values. Consultation with a pediatric oncologist should be obtained for help in making the initial diagnosis. Surgeons and pathologists should submit biopsy tissue for histologic examination, immunoperoxidase staining, flow cytometry, cytogenetic analysis, and tumor banking.

TABLE 80-4 Differential Diagnosis of Malignant and Nonmalignant Conditions in Infancy

Feature	Malignancy	Nonmalignant Condition
Skin nodules	Neuroblastoma Acute leukemia Reticuloendotheliosis	Congenital viral infections Vasculitis Fibromatosis Neurofibromatosis Xanthoma

SPECIFIC NEOPLASMS

NEUROBLASTOMA

Neuroblastoma is the most common malignant tumor in infants, accounting for about 27% of cancers diagnosed in infants less than age 1, and about 54% of cancers diagnosed in neonates less than 1 month of age. The small round blue cell neoplasm originates from neural crest cells that normally give rise to the adrenal medulla and sympathetic ganglia (Figure 80-1). In infants, the first clinical manifestations in more than half of cases result from the presence of metastatic disease rather than the primary tumor. However, despite the occurrence of widespread disease, neuroblastoma in newborn infants is almost always associated with biologically favorable features and carries a remarkably good prognosis.

Etiology

The etiology of neuroblastoma is largely unknown. Neuroblastoma usually occurs sporadically, likely following random genetic mutations; environmental factors do not appear to play a significant role. There are rare familial cases, accounting for 1% to 2% of patients. These cases may result from a hereditary-predisposition locus now attributed to multiple different genetic aberrations. Chromosome 16p12-13 was identified as a likely predisposition locus, though no causal gene has been identified (Kushner et al, 2005; Maris et al, 2002). More recently, multiple groups have identified the anaplastic lymphocyte kinase gene (*ALK*) as a predisposition gene in familial neuroblastoma (Janoueix-Lerosey et al, 2008). Familial neuroblastoma is inherited in an autosomal dominant mendelian fashion with incomplete penetrance. Affected children

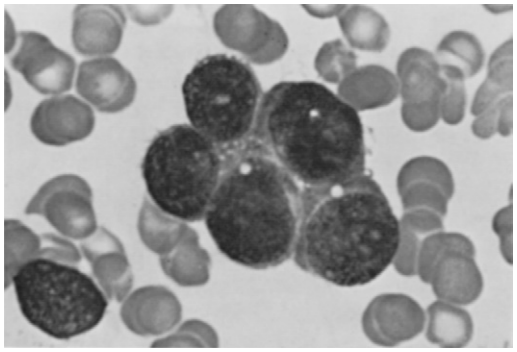

FIGURE 80-1 Clump of neuroblastoma cells found in bone marrow aspirate.

differ from those with sporadic disease in that they are often diagnosed at an earlier age (usually infancy) and/or they have multiple primary tumors.

Neuroblastoma has also been seen in several patients with constitutional chromosomal rearrangements, including deletions overlapping putative tumor suppressor loci at chromosome bands 1p36 and 11q14-23. Additionally, neuroblastoma has been reported in patients with other neural-crest disorders such as Hirschsprung's disease and central hypoventilation syndrome; these cases are associated with a germline mutation at chromosome band 4p12 (the *PHOX2B* gene) (Raabe et al, 2008).

Clinical Manifestations

Neuroblastoma may manifest as a tumor mass anywhere sympathetic neural tissue normally occurs. The clinical presentation can range from an asymptomatic newborn with an incidentally noted mass on prenatal ultrasound to a critically ill infant with massive hepatomegaly and respiratory distress. In the newborn, neuroblastoma most commonly manifests by enlargement of the liver alone, seen in 65% of cases, followed with subcutaneous metastases, seen in 32%. These percentages differ strikingly from those for older infants and children (Table 80-5). Metastases to lungs, bones, skull, and orbit are rare in the newborn, although clumps of tumor cells are often found in the bone marrow.

The most common site for the primary tumor is within the abdomen, arising in the adrenal medulla or a sympathetic ganglion. The tumor may also arise in the posterior mediastinum with resultant bronchial obstruction or invasion of the neural foramina, with neurologic symptoms. Increasing dyspnea, cough, wheezing, or pulmonary infection may be the presenting sign or symptom. Metastatic lesions, especially of the skin and liver, are common presenting features in the neonatal period; in the newborn, the primary site often cannot be discovered. Rapidly progressive hepatic involvement from multiple foci of neuroblastoma can cause abdominal distention, coagulopathy, and life-threatening respiratory distress (Figure 80-2). In some cases hepatomegaly at birth causes dystocia. Massive liver involvement in newborns with disseminated neuroblastoma is responsible for the higher mortality rate in newborns compared with older infants (Nickerson et al, 2000). Subcutaneous skin nodules, which may be present at birth, are typically bluish in color. On palpation, the skin nodules may become erythematous for 2 to 3 minutes, followed by blanching of the lesion. The blanching is presumably due to vasoconstriction caused by release of catecholamines from the tumor cell and may be a diagnostic sign of subcutaneous neuroblastoma.

The neoplasm may also arise in the neck or pelvis. Involvement of the stellate ganglion may result in Horner's syndrome, which includes ptosis of the upper eyelid, slight elevation of the lower lid, miosis, narrowing of the palpebral fissure, anhidrosis, and enophthalmos (Figure 80-3). Neuroblastoma arising from a paravertebral sympathetic ganglion has a tendency to grow into the intervertebral foramina, causing spinal cord compression and resultant paralysis. Careful periodic neurologic evaluation should be performed on a child with a neuroblastoma arising in this location, because the onset of cord compression may necessitate emergency intervention with chemotherapy, surgery, or irradiation.

Unusual Presentations

Intractable diarrhea can be the sole presenting manifestation of neuroblastoma. Secretion of vasoactive intestinal peptide by the tumor has been postulated to be the cause of the diarrhea, which resolves following surgical removal of the tumor (Bourdeaut et al, 2009).

Opsoclonus and myoclonus (i.e., dancing eyes, dancing feet) is associated with neuroblastoma, although this presentation is only rarely seen in the neonatal period (Rudnick et al, 2001). Patients have rapid multidirectional eye

movements (opsoclonus), myoclonus, and truncal ataxia (OMA) in the absence of increased intracranial pressure. The condition may be due to an autoimmune reaction, because the presence of antineuronal antibodies has been shown to be significantly more common in children with neuroblastoma and OMA than in case-control neuroblastoma patients (Antunes et al, 2000). Removal of the tumor usually results in a decrease in neurologic signs and symptoms, but the use of steroids is frequently required for complete resolution. In general, the prognosis for survival of children with opsomyoclonus is excellent, although long-term neurologic deficits and learning delays are common and can be quite debilitating.

Maternal symptoms such as sweating, pallor, headaches, palpitations, hypertension, and tingling in the feet and hands during the 8th and 9th months of pregnancy may be a sign of neuroblastoma in the fetus (Newton et al, 1985). The symptoms, which disappear postpartum, are likely caused by fetal catecholamines entering the maternal circulation. Newborns with neuroblastoma whose mothers have experienced these symptoms are typically diagnosed with neuroblastoma shortly after birth or during the first few months of life.

Erythroblastosis with hepatosplenomegaly, severe jaundice, and an increase in nucleated red blood cells is occasionally seen in newborns with neuroblastoma. Congenital neuroblastoma with metastases to the liver and placenta can be clinically indistinguishable from hydrops fetalis.

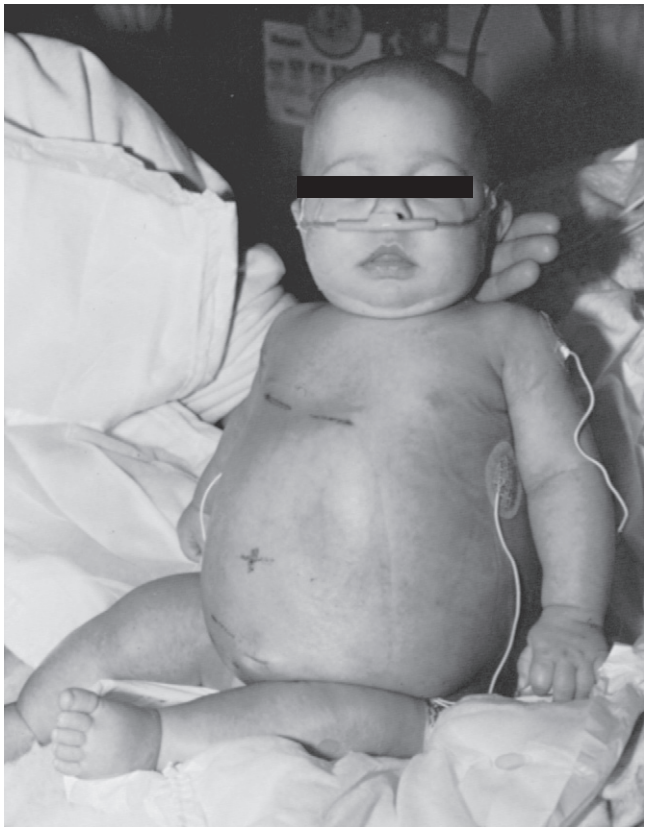

FIGURE 80-2 Stage 4S neuroblastoma causing abdominal distention and respiratory distress secondary to hepatic infiltration.

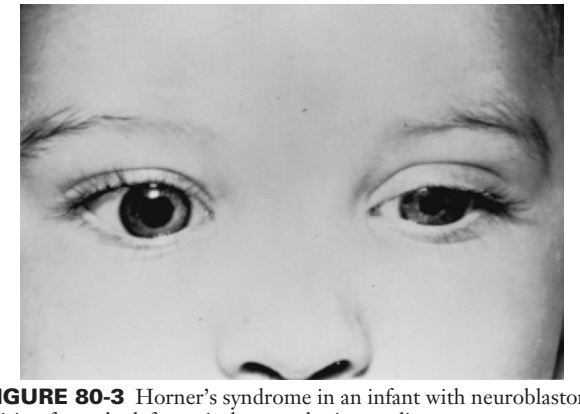

FIGURE 80-3 Horner's syndrome in an infant with neuroblastoma arising from the left cervical sympathetic ganglion.

Catecholamine Secretion

A hallmark of neuroblastoma cells is the ability to store and secrete catecholamines. Patients with neuroblastoma usually have elevated urinary levels of norepinephrine as well as its biochemical precursors and their metabolites. More than 90% of patients have an elevated urinary excretion of vanillylmandelic acid (VMA) or homovanillic acid (HVA), or both. VMA and HVA determinations can be made on random urine samples when values are normalized for creatinine concentration. In the occasional case with no elevation of catecholamines, a 24-hour urine collection is necessary. Urine catecholamines must be measured before surgical removal of the tumor or before initiation of therapy. Catecholamine secretion can be used not only as a diagnostic aid but also as a means to assess the response to therapy and to detect tumor recurrence.

Diagnosis

Clinical evaluation should include a physical examination with particular attention paid to detecting an abdominal mass, hepatomegaly, lymphadenopathy, Horner's syndrome, and skin lesions; a baseline neurologic exam is also performed. Laboratory evaluation should include a CBC, urine for VMA and HVA, and serum ferritin and lactate dehydrogenase. Although the initial imaging study in an infant is often an abdominal ultrasound, additional imaging to better delineate the tumor and to evaluate for metastatic disease is needed; this should include CT or MRI of the primary lesion. MRI of the spine should be obtained for paraspinal and posterior mediastinal lesions. An ^{123}I-metaiodobenzylguanidine (MIBG) scan is particularly important for diagnosis and follow-up. MIBG, a norepinephrine analogue specifically taken up by neuroblastoma in bone and soft tissue, serves as a sensitive modality for disease localization (Taggart et al, 2008). Bilateral bone marrow aspiration (along with bilateral bone marrow biopsy in patients over age 6 months) is also part of the initial evaluation.

Histologic evidence provides confirmation of the diagnosis of neuroblastoma. Tissue may be obtained from a primary lesion or a metastatic site. Because tumor-specific biologic information plays a critical role in risk classification and treatment recommendations, obtaining adequate tissue for biologic studies is essential.

Pathologic Classification

The histopathologic appearance of neuroblastoma ranges from undifferentiated neuroblasts, to more mature ganglioneuroblastoma, to fully differentiated and benign ganglioneuroma. The most widely used morphologic classification system is based on that proposed by Shimada, in which tumors are classified as favorable or unfavorable (Sano et al, 2006; Shimada et al, 1999). Classification is dependent on age, the degree of differentiation of the neuroblasts, the cellular turnover (mitosis-karyorrhexis) index, and the presence or absence of Schwannian stromal development.

Genetic Prognostic Factors: Tumor Biology

In addition to clinical factors and histology, a number of biologic factors have been shown to correlate with prognosis (Table 80-6). Genomic data currently used in risk classification schemes includes status of the *MYCN* oncogene; tumor cell DNA content (ploidy); and the allelic status of chromosomes 1p, 11q, 14q, and 17q (Ambros et al, 2009).

Amplification of the *MYCN* oncogene is present in 25% of primary neuroblastomas and has been shown to correlate with poor prognosis independent of age, stage, and other genetic alterations (Schneiderman et al, 2008). Patients with stage 1, 2, or 4S disease demonstrate *MYCN* amplification only rarely; when present, it has been associated with rapid disease progression in these usually favorable stages (Perez et al, 2000). In a Children's Cancer Group study of stage 4 neuroblastoma in infants, the progression-free survival rate after 3 years was less than 10% in infants with tumors that demonstrate *MYCN* amplification, compared with 93% for those with single-copy tumors (Schmidt et al, 2000).

Total cellular DNA content also predicts response to therapy in infants with neuroblastoma (Look et al, 1991). Diploid DNA content is an unfavorable prognostic factor, particularly in infants less than 12 months of age. Infants with hyperdiploid tumors have a significantly better response to therapy than those with diploid tumors (Bourhis, 1991). Diploidy often correlates with tumor *MYCN* amplification, although in rare cases of hyperdiploidy with *MYCN* amplification, the *MYCN* amplification portends an unfavorable outcome.

TABLE 80-6 Features That Affect Prognosis in Neuroblastoma

Feature	Favorable	Unfavorable
Age at diagnosis	<1.5 years	>1.5 years
INSS stage	Stage 1, 2, or 4S	Stage 3, 4
MYCN status	Nonamplified	Amplified
Shimada histology	Favorable	Unfavorable
DNA ploidy (DNA index)	DI >1 or <1	DI = 1
Allelic status of 11q	Normal	11q deletion or LOH at 11q

INSS, International Neuroblastoma Staging System.

Tumor karyotype also influences outcome. Common genomic aberrations found in neuroblastoma include deletion at the chromosomal region 1p36.3 or 11q23; deletion of 14q32; and unbalanced gain of the long arm of chromosome 17 (17q21 to 17qter) (Ambros et al, 2009). Loss of heterozygosity (LOH) of 1p occurs in up to 36% of primary tumors, and is associated with *MYCN* amplification. LOH at 11q23 is seen in 44% of primary neuroblastomas, and rarely is associated with *MYCN* amplification (Guo et al, 1999). Comprehensive genome-wide approaches such as comparative genomic hybridization are becoming increasingly useful in refining the prognostic accuracy of chromosomal alterations (Schleiermacher et al, 2007).

Staging

Neuroblastoma has traditionally been staged according to the International Neuroblastoma Staging System (INSS) summarized in Table 80-7 (Brodeur et al, 1993). Staging is based on age, disease site(s), and degree of surgical resection. New guidelines for a pretreatment risk classification system have been developed by the International Neuroblastoma Risk Group (INRG) Task Force and are being used in addition to the INSS system (Montclair et al, 2009); this system will facilitate the comparison of risk-based clinical trials. INRG stages include L1, localized tumor not involving vital structures (corresponds to INSS stages 1 and 2); L2, locoregional tumor with one or more image-defined risk factors (corresponds to INSS stage 3); M, metastatic disease (corresponds to INSS stage 4); and MS, metastatic disease in children younger than 18 months with metastases confined to skin, liver, or

TABLE 80-7 International Staging System for Neuroblastoma

Stage	Definition
Stage 1	Localized tumor confined to the area of origin; complete gross excision, with or without microscopic residual disease; identifiable ipsilateral and contralateral lymph nodes negative microscopically (adherent nodes may be positive)
Stage 2A	Localized tumor with incomplete gross excision; identifiable ipsilateral and contralateral lymph nodes negative microscopically
Stage 2B	Localized tumor with complete or incomplete gross excision, with positive ipsilateral nonadherent regional lymph nodes; identifiable contralateral lymph nodes negative microscopically
Stage 3	Unresectable tumor initiating across the midline with or without regional lymph node involvement; or unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral regional lymph node involvement; bilateral extension by infiltration
Stage 4	Dissemination of tumor to distant lymph nodes, bone, bone marrow, and liver and/or other organs (except as defined in stage 4S)
Stage 4S	Localized primary tumor as defined for stage 1 or 2 with dissemination limited to liver, skin, and bone marrow in infant <1 year of age

Data from Brodeur GM, Pritchard J, Berthold F, et al: Revisions of the international criteria for neuroblastoma diagnosis, staging and response to treatment, *J Clin Oncol* 11:1466, 1993.

bone marrow (corresponds to INSS stage 4S). Two important differences in the INRG system compared to the INSS are that it is a radiologic rather than a surgical staging system, and that the upper age limit for stage MS has been extended from 12 to 18 months.

Stage 4S (MS) comprises a unique group of patients with disseminated disease but a good prognosis, a combination that occurs exclusively in infants younger than 12 months of age. In this special group of children, typical findings include a small primary tumor that does not cross the midline and remote spread involving the liver, skin, or bone marrow (less than 15% of marrow replacement by tumor), without roentgenographic evidence of skeletal metastases. The primary tumor may be unidentifiable. There is lack of *MYCN* oncogene amplification in stage 4S tumors, in contrast to stage 4 tumors (Seeger et al, 1985). Infants with stage 4S disease have a very good prognosis despite having disseminated disease; spontaneous regression occurs without cytotoxic therapy in approximately 50% of cases.

Treatment

Treatment modalities for neuroblastoma include observation alone, surgery, chemotherapy, and radiation therapy. Factors that affect outcome include the age at diagnosis, stage of disease, histology, and tumor biology (see Table 80-6). Patients with stage 1 and stage 2 neuroblastoma have a 96% to 100% survival rate with surgery alone (Perez et al, 2000). Observation alone is justified in well infants with congenital, small, localized neuroblastoma without *MYCN* amplification; in these infants spontaneous regression occurs in about half the cases (Hero et al, 2008). Infants with stage 3 and stage 4 disease have a poorer survival, even with aggressive chemotherapy, although the outcome, with better than 70% surviving overall, is far better than the 10% to 20% reported for older children with these stages (Schmidt et al, 2000). Infants with stage 4S disease have a very good prognosis, with a 5-year survival >90%, despite having disseminated disease.

The unpredictable course of neuroblastoma, with its occasional spontaneous maturation or regression, not only makes this tumor unusual but also causes difficulty in planning therapy. The type and intensity of treatment is determined by identifying infants with relatively good, intermediate, and poor prognoses based on stage, international pathology classification, Shimada histology, ploidy, and *MYCN* amplification. Patients who have localized disease (stage 1 or 2) without amplification of *MYCN* have a 90% to 100% survival with surgery alone, even if the tumor is not completely resected. Such patients should undergo surgical resection or partial resection, but they likely will not derive any additional benefits from postoperative chemotherapy or radiation therapy. An exception to this rule is in the case of spinal cord compression, in which prompt decompression with chemotherapy, laminectomy, or local irradiation may be used to preserve function. There is an increasing trend to use chemotherapy first, given the exquisite sensitivity of the tumor to chemotherapeutic agents, but a rapid deterioration in neurologic function should prompt alternative interventions. A neurosurgeon should be consulted early in the diagnosis. The combination of extensive laminectomy with postoperative irradiation should be avoided because later spinal deformity is almost inevitable. Infants with stage 3 and stage 4 disease usually are treated with combination chemotherapy and local surgery, with radiation therapy given only as necessary to eradicate residual disease. Active drugs that are most commonly used include cisplatin, etoposide, doxorubicin, cyclophosphamide, vincristine, and ifosfamide. Infants with stage 4 disease with amplification of the *MYCN* oncogene have a very unfavorable prognosis; standard chemotherapy regimens are not usually sufficient for cure. In these high-risk patients, intensive chemotherapy followed by myeloablative therapy and stem cell support may offer additional benefit (Canete et al, 2009). In addition, the use of the differentiation agent *cis*-retinoic acid has been shown to improve survival in patients with advanced-stage, high-risk neuroblastoma (Matthay et al, 2009).

Infants with stage 4S disease have a highly favorable prognosis and may require minimal or no therapy. Because many patients undergo spontaneous regression without chemotherapy and the overall disease-free survival rate is 85% to 90%, therapy should be directed toward supportive care, with use of chemotherapy and surgery restricted to relieving symptoms (De Bernardi et al, 2009). The main cause of death in these patients is massive hepatic involvement resulting in respiratory insufficiency or compromise of renal or gastrointestinal function. Symptomatic patients are treated with chemotherapy. When there is a risk of organ impairment due to tumor bulk not responding to initial chemotherapy, low-dose radiotherapy can be administered (450 cGy given in three fractions). No benefit has been shown to result from resection of the primary tumor.

Prenatal Diagnosis

Neuroblastoma is increasingly being detected prenatally by screening ultrasonography. Newborns with adrenal or other mass lesions detected prenatally should be evaluated with urine catecholamines and follow-up ultrasonography. Careful observation may be adequate for infants with localized tumors, which frequently regress.

Newborn Screening

Newborn screening for neuroblastoma by measuring urine catecholamines has been studied in Japan and a number of other countries (Hiyama et al, 2008). It was hoped that early diagnosis of neuroblastoma would reduce the frequency of cases with poor prognosis from advanced-stage disease. Screening, however, has shown no impact on survival; neuroblastomas detected by screening almost always have favorable biologic features (Schilling et al, 2002). Thus, routine screening of infants for neuroblastoma is not currently recommended.

CONGENITAL LEUKEMIA

Epidemiology

Although leukemia is the second most common malignancy in infants, congenital leukemia, defined as leukemia diagnosed in the first 4 weeks of life, is quite rare. The incidence of leukemia in the first 3 months is approximately

5 cases per million (Bajwa et al, 2004). Two thirds of congenital leukemia cases arise from the myeloid lineage, in contrast to older infants and children in whom acute lymphoblastic leukemia predominates. Congenital leukemia is associated with a high mortality with an overall survival at 24 months of only 23% (Bresters et al, 2002); this is due to the aggressive biology of these leukemias and to treatment complications.

The etiology of leukemia is unclear. In infants and older children, a number of factors are associated with the development of leukemia; these include genetic factors, environmental influences, viral infections, and immunodeficiency. Genetic epidemiologic studies of infant leukemia indicate that many cases, if not all, are initiated in utero and involve genetic rearrangements; chromosome 11q23 (*MLL* rearrangement) is frequently involved (Greaves et al, 2003). Leukemia-associated gene rearrangements have been retrospectively identified in archived newborn blood spots of children who subsequently developed leukemia (Hjalgrim et al, 2002; Taub et al, 2002; Wiemels et al, 2002). Intrauterine exposure to topoisomerase 2 inhibitors may be responsible for some cases of infant leukemia (Pui and Evans, 1999; Ross, 2000). The Children's Cancer Group has reported a higher incidence of acute myeloid, but not lymphoid, leukemia in infants of mothers who consumed larger amounts of naturally occurring topoisomerase 2 inhibitors, such as those in foods high in flavonoids and phytates (Ross et al, 1996). Nucleotides involved in the breakpoint of the 11q23 locus may be particularly susceptible to topoisomerase 2–induced breaks (Strick et al, 2000).

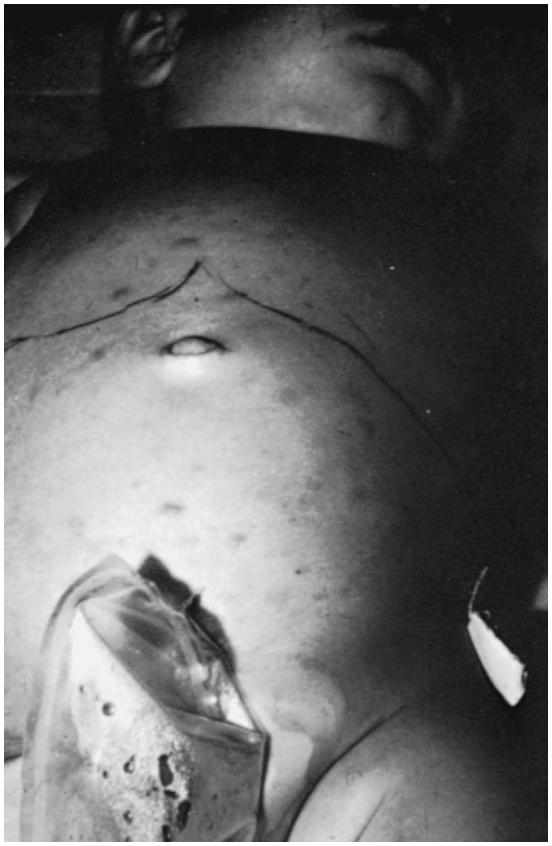

FIGURE 80-4 Leukemia cutis in a newborn infant.

Clinical Manifestations

Clinical signs of leukemia may be evident at birth and include hepatosplenomegaly, petechiae, and ecchymoses. Myeloid leukemic cell infiltration of the skin (i.e., leukemia cutis) is present in 25% to 30% of patients with congenital leukemia; a skin nodule may be the first clinical sign of leukemia (Figure 80-4). Patients typically have multiple nodules that are freely movable over the subcutaneous tissue (Resnik and Brod, 1993). There is usually a greenish-blue discoloration of the overlying skin due to the abundance of myeloperoxidase—hence the name *chloroma*. Lesions can also be pink or bluish. It is important to perform cytogenetic studies, in addition to flow cytometry, on the skin biopsy specimen; infants found to have an 11q23 rearrangement have a poor prognosis even in the absence of marrow involvement and should be treated aggressively (Zhang et al, 2006). When chloromas are present on the head or neck, imaging studies should be obtained to assess for the presence of intracranial or skull involvement. At birth, many infants have respiratory distress from leukemic infiltration in the lungs. Severe respiratory difficulty may develop soon after birth from pulmonary hemorrhage secondary to thrombocytopenia. Some infants with leukemia may appear somnolent or have periodic apnea as a result of CNS leukostasis, caused by sludging of leukemic cells in blood vessels.

In those infants in whom signs of the disease develop within the 1st month but in whom no detectable signs of leukemia were noted at birth, presenting symptoms and signs are nonspecific, including lethargy, diarrhea, hepatomegaly, and poor feeding with failure to gain weight. In addition, affected infants can present with fever due to bacterial infections or hemorrhagic manifestations due to thrombocytopenia.

Laboratory Manifestations

Hemoglobin levels may be normal initially, but anemia soon develops as the normal postnatal decrease in red cell production is combined with the expansion of the leukemic clone in the marrow. Total white blood cell count may be normal or decreased, but leukocytosis is more often present. White blood cell counts of 150,000 to 250,000/mm^3 or higher are common, and counts as high as 1.3 million/mm^3 have been recorded. There is usually a predominance of blast cells and immature granulocytes. Auer rods, intracellular inclusions composed of lysosomes, may be present; they are pathognomonic of acute myelogenous leukemia (AML) (Figure 80-5).

Differential Diagnosis

A number of conditions can mimic congenital leukemia. Leukocytosis, organomegaly, and thrombocytopenia can be seen in congenital infections caused by syphilis, cytomegalovirus (CMV), herpes simplex, toxoplasmosis, and bacteria. Thrombocytopenia and a leukemoid reaction can be seen in infants with congenital amegakaryocytic thrombocytopenia; the absence of radii, commonly seen in these

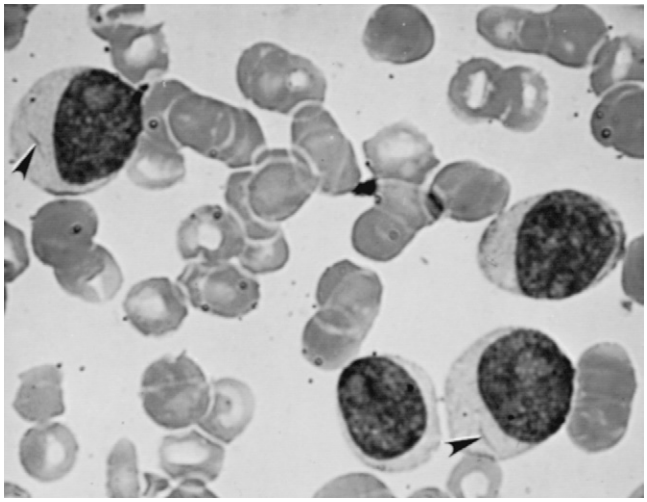

FIGURE 80-5 Malignant blast cells with Auer rods *(arrowheads)* present in cytoplasm. This finding is diagnostic of acute myelogenous leukemia.

children, provides a clue to the correct diagnosis. A transient leukemoid reaction (i.e., transient myeloproliferative disorder [TMD]) occurs in many infants with trisomy 21. The leukemoid reaction usually resolves, but these infants are at higher risk for the subsequent development of acute leukemia (see later discussion).

Severe erythroblastosis fetalis can mimic leukemia. Affected infants usually have hepatosplenomegaly, large numbers of nucleated erythroblasts in the peripheral blood, and occasionally, thrombocytopenia. Small infiltrates of extramedullary erythropoiesis may appear in the skin, resembling leukemia cutis. Infants with neonatal neuroblastoma may have symptoms similar to those of congenital leukemia, with hepatomegaly and discolored tumor nodules in the subcutaneous tissue. Blood counts are usually normal, without circulating blasts. Bone marrow aspirate sometimes shows clusters of neuroblastoma cells (see Figure 80-1). Increased excretion of catecholamine metabolites, the presence of an abdominal mass or other primary lesion, and the presence of neuroblastoma cells in the bone marrow are clues to the diagnosis of neuroblastoma.

Congenital human immunodeficiency virus (HIV) infection may rarely be confused with leukemia. Clonal B-cell expansions in such patients may cause lymphadenopathy. Thrombocytopenia, usually immune-mediated in HIV, has been reported (Voelkerding et al, 1988). A marked but transient leukemoid reaction may occur in the newborn following in utero exposure to betamethasone (Calhoun et al, 1996). History of prenatal exposure to corticosteroids and lack of the usual clinical and laboratory findings of leukemia usually excludes the diagnosis of leukemia.

Cellular Morphology and Immunophenotype

The bone marrow of a newborn with leukemia shows extreme hypercellularity and a marked predominance of immature cells, either myeloid or lymphoid. AML and ALL are differentiated on the basis of typical morphologic characteristics, such as the presence of granules or Auer rods (in AML) and nuclear and cytoplasmic morphology, cytochemical stains, immunophenotyping, and chromosome analysis. Terminal deoxynucleotidyl transferase, a DNA polymerase that catalyzes the polymerization of deoxynucleotides in thymocytes, is usually present in lymphoblasts, but is only rarely present in myeloblasts. Myeloblasts are usually positive for myeloperoxidase, whereas lymphoblasts are not. Both types of leukemia are subclassified according to an international French-American-British (FAB) classification based on morphology and histochemistry (Table 80-8). The most common FAB morphology in neonatal and infant AML is monocytic (FAB M5) or myelomonocytic (FAB M4), whereas the most common subtype in ALL is the FAB L1 variety (Sande et al, 1999). The traditional FAB classification system is being replaced by the World Health Organization classification system, which incorporates additional

TABLE 80-8 Morphologic and Immunophenotypic Classification of Childhood Acute Leukemia

FAB System	Morphology	Antigen Expression*
ALL		
L_1	Small cells, homogeneous Regular nuclei, scant cytoplasm Inconspicuous nucleoli	Pre=B: HLA-DR, CD10, CD19, CD20, CD24
L_2	Large cells, heterogeneous, irregular or cleft nuclei May be multiple large nucleoli Moderate cytoplasm	T: CD2, CD5, CD7
L_3	Large cells, homogeneous Regular nuclear shape Prominent nucleoli Moderately abundant, deeply basophilic cytoplasm with vacuolation	B: HLA-DR, CD10, CD19, CD20, CD24, Slg*
ANLL System		
M0	Minimal myeloid differentiation (MPO^-)	CD13, CD33, CD34
M1	Poorly differentiated myeloblasts (MPO^+)	CD13, CD33, CD34
M2	Myeloblastic with differentiation (MPO^+)	CD13, CD33, CD34
M3	Promyelocytic (MPO^+)	CD11b, CD13, CD33, CD34
M4	Myelomonoblastic (MPO^+, NSE^+)	CD11b, CD13, CD14, CD15, CD33, CD34
M5	Monoblastic (NSE^+)	CD11b, CD13, CD14, CD15, CD33, CD34
M6	Erythroleukemic (MPO^+, PAS^+)	Glycophorin CD34
M7	Megakaryoblastic (PPO^+)	CD41, CD42, CD34, CD61

ALL, Acute lymphocytic leukemia; *ANLL*, acute nonlymphocytic leukemia; *FAB*, French-American-British; *MPO*, myeloperoxidase; *NSE*, nonspecific esterase; *PPO*, platelet peroxidase; *Slg*, surface immune globulin.
L_1 or L_2 may show either pre-B or T antigens.
*The indicated FAB type may express some or all of the indicated antigens.

information including genetics, immunophenotype, and clinical features (Vardiman et al, 2009).

The immunophenotype, determined using a panel of fluorescent-labeled monoclonal antibodies against cluster differentiation (CD) antigens, is critical for differentiating myeloid from lymphoid leukemia (Craig and Foon, 2008). Myeloid leukemia cells usually react with antibodies to the CD13/CD33 antigens, present on cells of myeloid and monocytic lineage. The only exception is the FAB M7 category, acute megakaryoblastic leukemia, which expresses the CD41/CD42 platelet glycoprotein and CD61. Acute megakaryoblastic leukemia is most commonly seen in patients with trisomy 21. Most neonatal and infant acute lymphoblastic leukemia cells exhibit an early precursor B-cell phenotype and often are CD1a, CD19, CD24, and CD15 positive and CD10 negative (Pui et al, 1995; Pui and Evans, 1999). In addition, coexpression of myeloid antigens is often present. Frequently there are rearrangements of the immune globulin heavy-chain gene and occasionally the light-chain gene, but almost never the T-cell receptor gene (Felix et al, 1987; Ludwig et al, 1989). Surface antigen expression in acute leukemia is summarized in Table 80-8.

Genetics and Prognosis

A number of cytogenetic abnormalities have been found in association with congenital leukemia; many of these abnormalities are independent prognostic indicators. The most frequent abnormalities involve disruptions of the mixed lineage leukemia (*MLL*) gene at 11q23. Abnormalities of 11q23 are found in approximately 65% of infant AML and 93% of infant ALL cases (Chowdhury and Brady, 2008; Pui et al, 2003; Van der Linden, 2009). These are nonhereditary, nonconstitutional abnormalities that occur in utero (Ford et al, 1993). The *MLL* gene is the human homologue of the trithorax gene in Drosophila melanogaster (Ziemin-van der Poel et al, 1991). In mice and in humans, the MLL protein positively regulates *HOX* genes, which are critical for hematopoietic development (Armstrong et al, 2002). Rearrangements in the *MLL* gene confer a poor prognosis, which worsens with decreasing age (Chen et al, 1993).

The t(4;11)(q21;q23) gene rearrangement, detected in up to 48% of infants with acute lymphoblastic leukemia, is the most prevalent subtype of 11q23/*MLL* rearrangements (Van der Linden, 2009). It confers a particularly poor prognosis in infants younger than 6 months of age (Heerema et al, 1999; Pui et al, 2003). It is usually associated with hyperleukocytosis, CNS leukemia, and a precursor B-cell immunophenotype with $CD19^+/CD15^+/CD10^-$. Interestingly, older children harboring this same rearrangement do not have the same dismal prognosis as infants. Studies in gene expression analysis demonstrate unique genetic signatures that distinguish infant ALL with *MLL* rearrangements from ALL and AML in older children (Armstrong et al, 2002).

Approximately 35% of infants with AML have 11q23 rearrangements. Half of the patients have t(9;11) abnormalities; t(11;19) and t(10;11) are also common (Chowdhury and Brady, 2008). AML in infants is commonly associated with hyperleukocytosis and extramedullary involvement. Spontaneous resolution without chemotherapy has occasionally occurred in leukemia cutis and rarely in infant leukemia without bone marrow involvement; in general, these leukemias lack 11q23 rearrangements (Mora et al, 2000). When 11q23 rearrangements are present, systemic disease usually develops.

Treatment

The course of congenital leukemia is usually characterized by rapid deterioration and death from hemorrhage or infection. Although survival has been significantly prolonged in older children with leukemia, success has been limited in newborns; survival at 2 years is only 23% (Bresters et al, 2002). Infants with leukemia frequently present with hyperleukocytosis (blast cell count in excess of $100{,}000/mm^3$), which may result in sludging of blast cells in capillaries with resultant intracranial hemorrhage, respiratory distress, or tumor lysis syndrome (hyperkalemia, hyperphosphatemia, hypocalcemia, hyperuricemia, and renal failure). Disseminated intravascular coagulation is another common complication, especially when monocytic subtypes are suspected. Monoblasts release procoagulants, causing a consumptive coagulopathy; this may be exacerbated by further cell lysis induced with chemotherapy.

Initial supportive care includes correction of metabolic and hemorrhagic complications. Transfusion of platelets and fresh frozen plasma is frequently required. Exchange transfusion is sometimes undertaken in infants to lower the white blood cell count and to correct metabolic abnormalities. Rasburicase, a recombinant urate oxidase enzyme, has been safely used in infants with hyperuricemia (McNutt et al, 2006).

In infants with AML, intensive chemotherapy regimens have resulted in an improved rate of remission induction (Bresters et al, 2002; Chessells et al, 2002; Kawasaki et al, 2001). More than half of infants with myelomonocytic or monocytic subtypes obtain complete remission with chemotherapy. Chemotherapy regimens used in infants with myeloid leukemia are identical to those used in older children and usually include daunomycin, cytosine arabinoside, and etoposide. Because CNS involvement is common in infants with AML and ALL, intrathecal chemotherapy is a routine part of treatment. Radiation therapy, indicated in older children with CNS leukemia, is deferred in most instances until 1 year after diagnosis to limit potential late effects (which include neurocognitive sequelae and secondary malignancies).

Young infants with ALL fare significantly worse than do older children with ALL, in whom chemotherapy produces disease-free survival in more than 80%. Studies of infant leukemia have reported only 5% to 20% survival for infants younger than 6 months of age at diagnosis (Chessells et al, 1994; Heerema et al, 1994; Pui et al, 2003). However, outcomes for infants may be improving with the addition of high-dose cytarabine and high-dose methotrexate (Silverman et al, 1997). The use of cytarabine, which is used in the treatment of AML, may address the more primitive nature of the *MLL*-rearranged ALL cell, with its frequent coexpression of myeloid antigens and lack of CD10 positivity. The use

of stem cell transplantation has not been shown to be of benefit in the treatment of congenital leukemia (Pui et al, 2003).

Transient Myeloproliferative Disorders and Leukemia in Patients with Down Syndrome

The incidence of acute leukemia in children with Down syndrome (DS) is 20-fold higher than in the general population. In DS children younger than 3 years, the rare megakaryoblastic subtype (M7) predominates and the prognosis is usually favorable (Pui, 1995). In older DS children, both AML and ALL occur; about one third of cases are AML. Neonates with DS frequently present with a TMD that mimics acute leukemia. Although it usually resolves without treatment, it is considered to be a preleukemic syndrome: approximately 20% of neonates with TMD develop acute megakaryoblastic leukemia within 4 years (Malinge et al, 2009). Neonates with DS and TMD should have careful follow-up.

Transient Myeloproliferative Disorder

TMD, which occurs in 4% to 10% of neonates with DS, is clinically indistinguishable from acute myelocytic leukemia (Malinge et al, 2009). Although the majority of cases of TMD occur in DS patients, TMD rarely can be seen in patients with no constitutional chromosomal abnormalities or with trisomy mosaicism. TMD is a clonal disorder typically manifested by hepatomegaly, splenomegaly, and circulating myeloblasts. There may or may not be associated anemia and thrombocytopenia. In general, the blast count of the peripheral blood exceeds that of the marrow. Blast cells often have cell surface antigens characteristic of megakaryoblasts (Zipursky et al, 1997). Somatic mutations in the *GATA1* transcription factor have been detected in nearly all cases of TMD and acute megakaryoblastic leukemia in patients with DS (Mundschau et al, 2003; Wechsler et al, 2002).

Most neonates with DS and TMD experience complete clinical and hematologic recovery without systemic therapy, usually within 3 months. The blast count slowly decreases over 2 to 3 weeks, and the hemoglobin and platelet counts normalize. In some cases, however, spontaneous resolution does not occur, and the neonate may experience clinical deterioration manifested by progressive hepatosplenomegaly, hepatic dysfunction, coagulation disorder, ascites, and pleural or pericardial effusions. Approximately 20% of DS patients with TMD die, usually from hepatic or cardiopulmonary failure (Muramatsu et al, 2008). Treatment with low-dose cytarabine can benefit high-risk neonates with TMD. Indications for starting treatment vary, but generally include WBC >50,000, platelet count <100,000, or signs of cholestasis or liver dysfunction (conjugated bilirubin ≥15, increase of transaminases >2 times the standard deviation of normal, or hepatomegaly with liver size >3 cm above normal, as measured by ultrasound) (Klusmann et al, 2008). In some instances, complications from TMD occur in utero, and varying degrees of hydrops fetalis can result. CNS involvement is rare in neonates with TMD.

GERM CELL TUMORS

Germ cell tumors are neoplasms derived from primordial germ cells. They are a heterogeneous group of tumors, varying in site, age at presentation, histopathology, and malignant potential. They can occur in both gonadal and extragonadal sites. The etiology is unknown; they are thought to arise from sporadic genetic mutations (Horton et al, 2007).

Most germ cell tumors in the fetus and newborn are benign and are classified as either mature or immature teratomas (Isaacs, 2004). However, one or more of the germ-layer derivatives may develop malignant characteristics. Extragonadal germ cell tumors may arise in a variety of locations in the body, usually along the axial midline. Common sites in children include the pineal gland, neck, mediastinum, retroperitoneum, and sacrococcygeal region. In the neonatal period, a majority of teratomas occur in the sacrococcygeal region, followed next by tumors in the neck. After puberty, teratomas most frequently occur in the gonads, particularly the ovary.

Yolk sac tumor (endodermal sinus tumor) is the most common malignant germ cell tumor in neonates and young children. In the neonate it most often occurs with a teratoma, often in the sacrococcygeal region (see later discussion).

Pathology

Teratomas are composed of tissues arising from all three layers of the embryonic disk. Ectodermal components, including glial tissue, are a major component of teratomas presenting at birth—in particular, sacrococcygeal tumors. There are often skin, hair, and teeth elements. Mesodermal components, including fat, bone, and muscle, also are present. Less commonly seen are endodermal components such as digestive tract tissue. Occasionally, less mature elements coexist within the teratoma and are typified by higher grade histologic features including nuclear atypia, mitotic activity, and hypercellularity. Hormonal markers, including serum AFP and hCG, often are elevated in the presence of malignant tissue within the teratoma and are useful to follow as therapy progresses. Elevated serum AFP indicates the presence of immature endodermal sinus tissue or yolk sac elements, whereas elevated hCG indicates the presence of embryonal carcinoma. Choriocarcinoma, which is rarely seen in newborns, manifests with an elevated hCG.

Evaluation

MRI or CT imaging of the primary tumor is indicated to evaluate the extent of disease. Sacrococcygeal tumors should be imaged using MRI because of the possible involvement of the spinal cord. The entire abdomen is included in the imaging study to assess the extent of any local invasion, particularly involvement of the rectal wall. A CT scan of the chest is performed to rule out metastasis. Baseline levels of serum AFP and hCG, which are normally elevated in newborns, are measured. Because of the variation in levels at birth and the variation in rates at which levels decline to normal, these tumor markers can

be difficult to interpret as measures of residual disease or recurrence. The half-life of AFP is 5 to 7 days; that of hCG is 24 to 36 hours.

Sacrococcygeal Teratomas

Sacrococcygeal teratomas are the most common solid tumors in newborns. The estimated incidence is 1 in 27,000 live births (Swamy et al, 2008). A minority are malignant: 10% to 17% of sacrococcygeal teratomas contain yolk sac tumor (Isaacs, 2007). Females are affected 2 to 4 times more frequently than males. Half of sacrococcygeal teratomas are diagnosed prenatally by ultrasonography. Polyhydramnios, nonimmune fetal hydrops, and dystocia have all been described in association with sacrococcygeal teratomas. Congenital anomalies, including genitourinary, hindgut, and lower vertebral malformations, are present in 15% of patients (Isaacs, 2007). In most cases, the tumor manifests as a mass protruding between the coccyx and rectum; the mass may be quite large (Figure 80-6). About 10% of these tumors are only found by rectal examination. Nearly all arise at the tip or inner surface of the coccyx.

Differential Diagnosis

Sacrococcygeal teratomas may be confused with meningomyelocele, rectal abscess, pelvic neuroblastoma, pilonidal cyst, and a variety of very rare neoplasms that may occur in the sacral region. Most benign teratomas in this area produce no functional difficulties, even when marked intrapelvic extension is present. Bowel or bladder dysfunction, painful defecation, and vascular or lymphatic obstruction suggest that the lesion is malignant.

Treatment

Treatment of sacrococcygeal tumors is primarily surgical if age-adjusted AFP and hCG levels are normal (Horton et al, 2007). The tumor should be radically excised as soon as possible because small, undifferentiated foci may proliferate and become aggressive. Removal of the entire coccyx is required. Failure to remove the coccyx carries a 30% to 40% risk of local recurrence, which is sometimes accompanied by malignant elements. The survival rate for neonates with sacrococcygeal teratoma is 85% (Isaacs, 2007).

Sacrococcygeal teratomas diagnosed prenatally by ultrasound (approximately 50% of cases) are associated with a worse outcome; the survival rate is only 53% (Isaacs, 2004). Fetal hydrops and prematurity are the main factors contributing to the poor survival rate. If hydrops occurs before fetal pulmonary maturity, fetal surgical intervention to debulk and devascularize the tumor may be an option (Adzick, 2010).

Infants with sacrococcygeal teratoma containing malignant yolk sac elements are treated with surgery followed by chemotherapy with cisplatin, etoposide, and bleomycin. Acute and late complications of this regimen can be significant and include hearing loss, pulmonary fibrosis, and secondary malignancy.

FIGURE 80-6 Large sacrococcygeal teratoma in a newborn girl.

RENAL NEOPLASMS

Approximately two thirds of intraabdominal masses in the neonatal period arise from the kidney. The vast majority of these neoplasms are nonmalignant and are generally due to congenital defects such as polycystic or dysplastic kidneys or other conditions causing hydronephrosis. The most common intrarenal neoplasm manifesting at birth is congenital mesoblastic nephroma, followed by Wilms' tumor. Less common intrarenal neoplasms seen in the newborn period are rhabdoid tumor, nephroblastomatosis, clear cell sarcoma of the kidney, cystic renal tumors, renal cell carcinoma, rhabdomyosarcoma, hemangiopericytoma, and lymphoma. The typical clinical manifestation is an asymptomatic abdominal mass detected on physical examination or by ultrasonography.

Congenital Mesoblastic Nephroma

Congenital mesoblastic nephroma (CMN), or fetal mesenchymal hamartoma, is the most common intrarenal neoplasm in the neonate. It usually behaves as a benign neoplasm, but the histopathologic subset, cellular CMN, is associated with an increased incidence of recurrence and metastases. The typical clinical presentation is an asymptomatic abdominal mass detected on physical examination or by ultrasonography. Occasionally patients present with complications including respiratory distress, fetal hydrops, and circulatory problems caused by the size of the mass. The tumor infiltrates into normal renal parenchyma and is not encapsulated (Figure 80-7). Specific sonographic features can help to differentiate CMN from Wilms' tumor

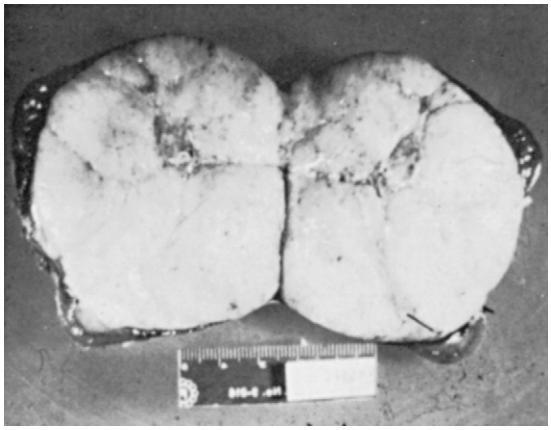

FIGURE 80-7 Congenital mesoblastic nephroma compressing and nearly totally replacing the kidney.

(Chan et al, 1987). The tumor may be diagnosed prenatally with ultrasonography, which reveals a greatly enlarged kidney distorted by the tumor. There is an increased incidence of polyhydramnios (71%) and premature labor (Glick et al, 2004).

Two histologic subtypes of congenital mesoblastic nephroma have been identified: the "classic" subtype and the cellular variant. The classic histologic subtype, which represents about one third of cases, has a preponderance of interlacing bundles of spindle-shaped cells, within which dysplastic tubules and glomeruli are irregularly scattered. Extrarenal infiltration is common. The cellular or atypical variant demonstrates increased cellularity, focal hemorrhage, necrosis, and a high mitotic index. The cellular variant usually manifests at an older age (3 months) than the classic type (mean age at presentation 1 month). Cytogenetic analysis of the cellular variant shows a translocation t(12;15)(p13;q25) that results in a ETV6-NTRK3 fusion protein that is identical to that found in infantile fibrosarcoma (Bavindir et al, 2009; Glick et al, 2004).

Complete surgical resection is usually an effective treatment for the classic form of CMN. Patients with the cellular variant are also treated with complete resection, but local and distant recurrences, for example to lung or brain, can be problematic. Positive surgical margins or tumor rupture during resection are risk factors for recurrence, which usually occurs within the 1st year following surgery. Resection and chemotherapy can successfully treat recurrent disease (Glick et al, 2004). Overall survival for CMN is 95% to 98% (Isaacs, 2008).

Wilms' Tumor

Wilms' tumor, or nephroblastoma, is the most common intraabdominal tumor of childhood, affecting 1 in 8000 children, but it is relatively rare in the neonatal period. In subsets of children with aniridia, the incidence is much higher.

Clinical Manifestations

The tumor lies deep in the flank, is attached to the kidney or is part of it, and is usually firm and smooth. It seldom extends beyond the midline, even though it may grow downward beyond the iliac crest. In 5% to 10% of all cases, tumors involve both kidneys. Most children with Wilms' tumor present with an abdominal or flank mass or an increase in abdominal size. Gross hematuria is a rare presenting symptom, but microscopic hematuria is found in approximately 25% of cases. Hypertension, occasionally noted in older infants and children, has not been observed in the newborn. The tumor may sometimes manifest with abdominal pain and be discovered at laparotomy, and occasionally acute hemorrhage into the tumor may result in a rapidly enlarging mass, usually associated with anemia and fever.

Wilms' tumor is seldom diagnosed at birth or during the neonatal period. Characteristics associated with an earlier presentation include bilaterality and associated aniridia or hypospadias (Pastore et al, 1988) and a positive family history. Rare cases of Wilms' tumor associated with polycythemia have been reported; this finding is secondary to an increased production of erythropoietin by the neoplasm.

Hereditary Associations and Congenital Anomalies

Although most cases of Wilms' tumor are sporadic, a number of conditions are associated with an increased risk of developing the tumor. These include *WT1*-associated phenotypes caused by deletions and mutations of the *WT1* gene (11p13), familial Wilms' tumor, overgrowth syndromes, and constitutional chromosomal disorders (Scott et al, 2006). The WAGR syndrome (*W*ilms' tumor, *a*niridia, *g*enitourinary abnormalities, mental *r*etardation) is found in approximately 0.8% of individuals with Wilms' tumor; the Wilms' tumor predisposition is due to a deletion in *WT1*, and the aniridia is due to a deletion of *PAX6* (Breslow et al, 2003). From a clinical perspective, if an infant has aniridia, chromosome analysis should be undertaken. If a deletion of chromosome band 11p13 is found, the child should be monitored for the development of Wilms' tumor with serial ultrasonographic studies of the kidneys. Wilms' tumor develops in approximately half of these patients. Hemihypertrophy, which either can be isolated or associated with various genetic syndromes, is associated with an increased risk of the development of Wilms' tumor. Beckwith-Wiedemann syndrome (BWS), an overgrowth disorder caused by dysregulation of imprinted genes at chromosome 11p15, is also associated with an increased risk of Wilms' tumor, particularly bilateral disease. Between 1% and 8% of individuals with BWS develop Wilms' tumor (Scott et al, 2006). Other heritable disorders may predispose a patient to Wilms' tumor. Denys-Drash syndrome, caused by a variant mutation at 11p13, includes Wilms' tumor, genital anomalies, and nephropathy. Bloom syndrome, an autosomal recessive disease, and Li-Fraumeni syndrome, an autosomal dominant tumor predisposition syndrome, are both associated with an increased incidence of Wilms' tumor. Patients with Fanconi anemia with biallelic *BRCA2* mutations are also at higher risk of developing Wilms' tumor. Between 1% and 2% of Wilms' tumor cases occur within families, but the underlying cause of familial Wilms' tumor is currently unknown (Scott et al, 2006).

Prognostic Factors

Important prognostic factors include the histologic pattern, the extent of disease, and chromosomal abnormalities. Well-differentiated tumors with glomeruloid and tubular formation have a better prognosis than those with anaplastic and sarcomatous morphology. Absence of tumor-specific loss of heterozygosity for chromosomes 1p and 16q is associated with a better prognosis (Grundy et al, 2005). Patients younger than 2 years of age have fewer relapses, especially to distant sites, than older children.

Evaluation and Staging

The most common staging system in use is that of the National Wilms Tumor Study (NWTS) (Table 80-9). Clinical staging, which includes a CT scan of the abdomen and chest, is an important factor in predicting survival; tumors with more extensive spread carry a poorer prognosis. The most common sites of metastasis are the liver and lungs (Figure 80-8). Tumor thrombus is occasionally noted in the inferior vena cava. Other sites of

TABLE 80-9 Wilms' Tumor Staging

Stage I	Tumor limited to kidney, completely resected. Renal capsule is intact. No evidence of tumor at or beyond the margins of resection. No rupture or prior biopsy.
Stage II	Tumor is completely resected. No evidence of tumor at or beyond the margins of resection. The tumor extends beyond the kidney, for example, penetration of the renal capsule, presence of tumor cells within blood vessels of the renal sinus. No rupture or prior biopsy.
Stage III	Residual nonhematogenous tumor present following surgery, including peritoneal implants or tumor spillage before or during surgery.
Stave IV	Hematogenous metastases (lung, liver, bone, brain, etc.), or lymph node metastases outside the abdominopelvic region.
Stage V	Bilateral renal involvement.

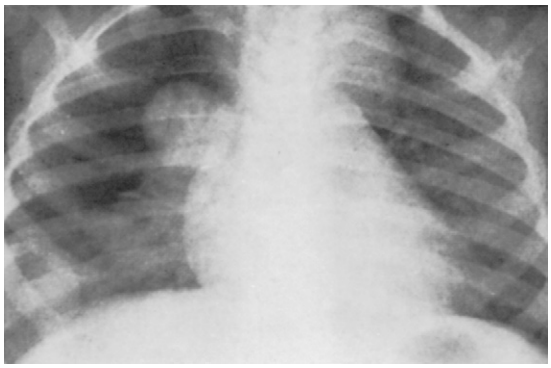

FIGURE 80-8 Pulmonary metastases from Wilms' tumor.

metastatic spread are the retroperitoneum, peritoneum, mediastinum, and pleurae. Approximately 10% of patients will have disease in both kidneys. A bone scan is necessary if histologic studies show clear cell sarcoma because of the possibility of bone metastases. CT or MRI of the brain is necessary in patients with rhabdoid tumors (which may be confused radiologically with Wilms' tumor) because they frequently metastasize to brain.

Treatment

Patients with low-stage Wilms' tumor have a cure rate of >90%. Patients with small tumors limited to the kidney can be cured with surgery alone. Follow-up involves periodic screening with abdominal ultrasonography, chest x-ray, and urinalysis. Patients with intermediate-stage Wilms' tumor are treated with a short course (12 weeks) of chemotherapy with vincristine and dactinomycin. More extensive disease requires the addition of doxorubicin. Radiation therapy is indicated in children with diffuse abdominal disease or nonresponsive pulmonary metastases. Even patients with metastatic disease have a good prognosis, with 70% long-term survival. Recurrent disease, which can be local or may involve metastases to the lungs or brain, is treated, often successfully, with additional chemotherapy and radiation.

Infants younger than 12 months of age have experienced significant toxicities to the hematopoietic system, liver, and lungs from dactinomycin, vincristine, and doxorubicin. Drug doses for infants are approximately 50% of the usual per kilogram dose for older children; this has not affected the very favorable cure rate.

Rhabdoid Tumor of the Kidney

Rhabdoid tumor of the kidney (RTK) is an uncommon tumor of children that is one of the most lethal neoplasms of early neonatal life, with a mortality rate exceeding 80%. RTK is the second most common malignant neoplasm of the kidney in neonates, after Wilms' tumor. It has a predilection for males, with a male-to-female ratio of 1.5:1, and for infants, with median age at diagnosis of 11 months. It is often widely metastatic at diagnosis; metastatic sites include lung, abdomen, lymph nodes, liver, bone, skin, and brain. Renal rhabdoid tumors occasionally manifest simultaneously with brain tumors, which are usually in the midline cerebellum. Although the brain tumors have been classified histologically as medulloblastoma or primitive neuroectodermal tumors, they show the same chromosome 22 abnormalities seen in RTK. Homozygous inactivating deletions or mutations of the *INI1* gene, located in chromosome band 22q11.2, are responsible for a majority of rhabdoid tumors (Jackson et al, 2007). *INI1* functions as a tumor suppressor gene; loss of expression in RTK can be detected immunohistochemically.

The prognosis for infants with RTK is extremely poor. Survival at 4 years for infants diagnosed before 6 months of age is less than 10% (Tomlinson et al, 2005). Virtually all patients with distant metastases will have a fatal outcome. Treatment modalities have included surgical resection, chemotherapy, and radiation therapy.

Persistent Renal Blastema and Nephroblastomatosis

Accumulations of immature renal tissue are not normally found beyond 36 weeks' gestation, the time at which nephrogenesis normally ceases. Nodular renal blastema is characterized by microscopic nests of primitive cells in the subcapsular renal cortex; these cells resemble the blastemal cells of Wilms' tumor but lack mitoses. Although benign, these nodules are believed to have the potential for neoplastic transformation. They are found in 1 of every 200 to 400 postmortem examinations of infants dying from other causes before 4 months of age. When nodular renal blastema becomes massive and confluent and replaces the cortex, it is referred to as *nephroblastomatosis*. Children with massive bilateral involvement often respond to therapies used for Wilms' tumor. Although persistent renal blastema is not a true malignancy, it probably has been confused with Wilms' tumor in the past, and it appears in many instances to be a precursor of this malignancy (Beckwith, 1993).

Cystic Partially Differentiated Nephroblastoma

This renal neoplasm is known by a variety of names: polycystic nephroblastoma, benign multilocular cystic nephroma, well-differentiated polycystic Wilms' tumor, and cystic partially differentiated nephroblastoma. It is a cystic encapsulated tumor occurring before 2 years of age.

The cysts are lined by epithelium and show a mixture of partially differentiated and undifferentiated metanephrogenic blastemas, a finding that differentiates this lesion from multilocular cysts of the kidney. The tumor appears to have a benign course, and nephrectomy is the treatment of choice. These neoplasms probably represent a differentiated form of nephroblastoma (van den Hoek et al, 2009).

RETINOBLASTOMA

Retinoblastoma is a malignant ocular tumor that arises from embryonic retinal cells. It occurs in the setting of hereditary and nonhereditary disease. The incidence of retinoblastoma is approximately 1 in 18,000 live births; between 250 and 350 cases are diagnosed in the United States each year (Kiss, 2008). Bilateral involvement, which occurs in the setting of heritable disease, is observed in 20% to 35% of patients. Whereas the incidence of heritable retinoblastoma is constant among various population groups, the incidence of sporadic, nonheritable, unilateral retinoblastoma is increased in poorer, tropical, and subtropical regions (Kiss, 2008).

Genetics

Approximately one third of patients have hereditary disease, which is often bilateral. Patients with hereditary disease have a germline mutation in the retinoblastoma gene, *RB1*, a tumor suppressor gene located on chromosome band 13q14. The mutation either is inherited from a parent or occurs during embryonic development. There is autosomal transmission with high penetrance, approximately 90%. Patients with nonhereditary disease, about 60% of cases, have unilateral retinoblastoma. Their disease is the result of acquired somatic mutations in both *RB1* alleles.

Approximately 5% of retinoblastoma patients are born with a constitutional deletion of chromosome 13, 13q–. These patients have associated constitutional anomalies including micrencephaly, macrognathia, malformed ears and thumbs, hypertelorism, microphthalmia, ptosis, short stature, cleft palate, and developmental delay.

Children with the bilateral and hereditary form often are diagnosed at an earlier age, in part because the family history leads to screening starting early in the postnatal period. In rare instances, family history of the disorder may be lacking; hereditary bilateral retinoblastoma may be the result of germline mosaicism in the parent.

Clinical Manifestations

Patients with retinoblastoma commonly present with leukocoria (i.e., cat's eye), with squinting, or with strabismus caused by loss of vision in the affected eye. Multifocal retinal involvement is common, occurring in 84% of the cases. Intraocular spread may fill the vitreous body by extension or seeding, whereas exophytic tumors arise from the outer retinal layer and cause retinal detachment. Extraocular spread is seen in less than 15% of patients, usually occurring by direct invasion of the optic nerve and eventually leading to subarachnoid involvement and intracranial spread. In such cases the cerebrospinal fluid may contain tumor cells. Rarely, tumors may spread by invasion of the orbit or by hematogenous dissemination to bone and bone marrow. Children with bilateral retinoblastoma are at risk for tumor dissemination to the pineal gland, a condition known as trilateral retinoblastoma; these children should be evaluated periodically by brain MRI.

The diagnosis is made by funduscopic examination performed with the patient under general anesthesia. CT or MRI of the eye is useful to determine tumor extent and optic nerve involvement. A lumbar puncture for cerebrospinal fluid cytology is performed if there is optic nerve invasion, but more extensive evaluation with bone marrow biopsy or bone scan is not usually necessary. Tumors are staged according to the International Classification of Retinoblastoma, based on tumor size and location and the extent of vitreous and subretinal seeding (Kiss, 2008).

Treatment

Because extraocular spread and death from dissemination are rare, the main goal of treatment is local control and preservation of vision. Surgical enucleation is used only when there is no chance for useful vision, if glaucoma is present, or if conservative measures fail to control the tumor. Small tumors confined to the retina often can be controlled with focal consolidative therapies such as cryotherapy and laser photocoagulation. Systemic chemotherapy with agents such as carboplatin, vincristine, and etoposide is frequently used concurrently with cryotherapy and laser therapy. External beam radiation therapy is an effective treatment, but because of the late effects of radiation on bone growth and the potential for second tumor induction, aggressive local therapy and chemotherapy are preferable.

Prognosis

The prognosis for children with unilateral retinoblastoma is excellent, with cure rates of 85% to 90%. However, patients with bilateral disease have a much lower long-term survival rate because of the high incidence of second malignancies, which may occur at any point in the life span. Patients with hereditary disease can develop secondary sarcomas in the area treated with radiation therapy; they are also at increased risk of developing sarcomas in other, nonirradiated areas. Local extension of retinoblastoma confers a poor prognosis, with survival rates of less than 10% with orbital extension or distant dissemination.

CENTRAL NERVOUS SYSTEM TUMORS

Incidence and Epidemiology

Congenital brain tumors are rare, with an incidence of approximately 1 to 3 per million live births (Lasky, 2008). Most brain tumors in infants are supratentorial. Half are gliomas, including astrocytomas. PNETs and medulloblastomas also occur. Atypical teratoid or rhabdoid tumor of the CNS is associated with a high mortality rate (Packer et al, 2002). In general, brain tumors manifesting in the perinatal period carry a very poor prognosis.

Clinical Manifestations

Macrocephaly is often the first sign of a congenital CNS tumor. Signs and symptoms of increased intracranial pressure (ICP) may be present. In infants these include a bulging fontanel, split sutures, or rapidly enlarging head size. Poor feeding, vomiting, lethargy, and irritability also can be symptoms of increased ICP. Funduscopic examination may or may not show papilledema. Loss of developmental milestones may be detected in older infants and children. Specific neurologic abnormalities include Parinaud's syndrome (impaired upward gaze secondary to increased pressure in the dorsal midbrain), cranial nerve palsies, and nystagmus. Head tilting can occur in patients with posterior cerebellar masses secondary to cervical root irritation.

Congenital brain tumors are sometimes detected prenatally by ultrasound. CT scan is often the initial imaging study performed, but MRI provides more detailed information.

Treatment

The optimal therapy is surgical resection of the tumor. The degree of surgical resection is the single most important predictor of survival (Lasky, 2008). Complete resection is often not possible. Tumors in infants tend to be large, highly malignant, and invasive. They are also highly vascular, making it difficult to remove the tissue without significant morbidity.

Radiation therapy, a backbone of treatment for older children with malignant brain tumors, is avoided if possible in young infants because they experience devastating late effects including neurocognitive deficits and growth impairment. Adjuvant chemotherapy can play a role in treatment; this may allow necessary radiation therapy to be delayed until the child is older. Conformal stereotactic techniques that target the tumor and minimize radiation to normal brain structures may help lessen late complications.

SARCOMAS

Soft tissue sarcomas are rarely seen in newborns. The most commonly diagnosed soft tissue sarcoma in the neonatal age group is infantile or congenital fibrosarcoma, which is classified as a low-grade nonrhabdomyosarcoma soft tissue sarcoma. The incidence in infants between age 1 and 12 months is 5 cases per 1 million infants (Ries et al, 1999). In general, infantile fibrosarcoma is treated by complete surgical excision, although neoadjuvant chemotherapy with a variety of agents has been successfully used for tumor shrinkage, with subsequent reduction in the morbidity related to radical surgical procedures (Russell et al, 2009). The cure rates for infantile fibrosarcoma, with surgery alone or with chemotherapy and surgery, approach 100% (Kurkchubasche et al, 2000; Loh et al, 2002).

The initial evaluation of a patient with a congenital fibrosarcoma includes imaging of the primary tumor by MRI or CT, and a chest CT scan. Diagnosis is made by biopsy of the lesion. Chemotherapy regimens used successfully for treatment of this tumor include vincristine, actinomycin D, and cyclophosphamide, as well as etoposide and ifosfamide. Doxorubicin, although efficacious, is generally avoided because of the risk of cardiac toxicity. Duration of therapy depends on the size, location, and response of the tumor, but the general goal is to reduce the tumor size to maximize chances of surgical local control. Radiation therapy is usually avoided to spare the infant the associated late effects of poor growth and secondary cancers.

Rhabdomyosarcoma (RMS), the most common soft-tissue sarcoma in children, is rarely seen in neonates: fewer than 1% of RMS cases are diagnosed in the 1st month of life (Lobe et al, 1994). Congenital rhabdomyosarcoma often involves the genitourinary tract and is frequently of the embryonal subtype. Congenital embryonal rhabdomyosarcoma appears to be associated with a specific translocation, t(2;8)(q35;q13) (Meloni-Ehrig et al, 2009).

HISTIOCYTOSIS

The histiocytoses are a diverse group of disorders characterized by the accumulation and proliferation of cells derived from the monophagocytic system (Isaacs, 2006). These disorders have been categorized into three classes (Table 80-10). Class I disorders, which are dendritic cell–related, include Langerhans cell histiocytosis (LCH) (formerly known as histiocytosis X), Letterer-Siwe disease, Hand-Schüller-Christian disease, eosinophilic granuloma, and pure cutaneous histiocytosis. Class II disorders, which involve macrophage-derived cells, include familial hemophagocytic lymphohistiocytosis (FHL) and infection-associated hemophagocytic syndrome (IAHS). Class III disorders are malignant disorders of mononuclear phagocytes and include acute monocytic leukemia, malignant histiocytosis, and histiocytic lymphoma. In addition to these three classes, other rare, noncategorized histiocytoses can occur in newborns, in particular, juvenile xanthogranuloma (JXG). The pathophysiology of the histiocytic disorders appears to be related to abnormal regulation of histiocyte activation resulting in cell proliferation and cytokine production (Isaacs, 2006).

The most common histiocytic disease seen in the fetus and neonate is LCH. About half of newborns with LCH have disease confined to the skin; the other half have disseminated disease with resultant organ dysfunction, usually involving bone marrow, liver, or lung. Presenting symptoms of LCH in neonates include skin lesions, hepatosplenomegaly, lymphadenopathy, and respiratory distress. Histologically, both cutaneous and disseminated LCH are characterized by granuloma-like lesions. Diagnosis is made by biopsy; Langerhans cells are positive by immunohistochemistry for CD1A.

The course of LCH is unpredictable. The pure cutaneous form of LCH usually resolves spontaneously in 2 to 3 months, whereas disseminated LCH, which can also manifest with skin lesions, carries a poor prognosis with 52% mortality (Isaacs, 2006). Newborns presenting with skin lesions may not develop the symptoms of disseminated disease for several weeks to months. Disseminated LCH is usually treated with chemotherapeutic drugs including vinblastine and prednisone.

FHL and IAHS are also seen in the newborn period. FHL has an incidence of approximately 1 in 50,000 live-born children (Henter et al, 2007). The overall survival for newborns with FHL is only 9% unless stem cell transplant

TABLE 80-10 Classification of Childhood Histiocytoses

Feature	Class I	Class II	Class III
Diseases included	Langerhans cell histiocytosis Pure cutaneous histiocytosis	IAHS; FEL; grouped together as the hemophagocytic lymphohistiocytoses (HLHs)	Malignant histiocytosis; acute monocytic leukemia; true histiocytic lymphoma
Cellular characteristics	Langerhans cells with cleaved nuclei and Birbeck granules seen by electron microscopy; cell surface antigens include S100 and CD1a; cells mixed with varying proportions of eosinophils; multinucleated giant cells sometimes seen	Morphologically normal, reactive macrophages with prominent erythrophagocytosis; process involves entire reticuloendothelial system	Neoplastic cellular proliferation of cells exhibiting characteristics of macrophages or dendritic cells or their precursors; localized or systemic
Proposed pathophysiologic mechanisms	Immunologic stimulation of a normal antigen-presenting cell—the Langerhans cell—in an uncontrolled manner	Histiocytic reaction secondary to an unknown antigenic stimulation (FEL) or to an infectious agent (IAHS), with erythrophagocytosis possibly reflecting foreign antigens absorbed on erythrocytes or activation of macrophages by excess lymphokine production due to abnormal immunoregulation	Neoplasm; clonal autonomous uncontrolled proliferative process

From Ladisch S, Jaffe ES, in *Principles and practice of pediatric oncology*, Philadelphia, 2006, Lippincott Williams & Wilkins.
FEL, Familial erythrophagocytic lymphohistiocytosis; *IAHS*, infection-associated hemophagocytic syndrome.
Note: Previously known as histiocytosis X and its related syndromes of eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease.

is performed; survival for IAHS is 59% (Isaacs, 2006). Newborns with these disorders commonly present with fever, hepatosplenomegaly, and cytopenias. Other symptoms include liver dysfunction, neurologic symptoms, hypertriglyceridemia, elevated serum ferritin levels, and hypofibrinogenemia. Diagnostic criteria are listed in Box 80-1. Hemophagocytosis is found in the bone marrow in 76% of patients. Natural killer cell and cytotoxic Tcell activity is reduced or absent. Thirty percent of patients with FHL harbor constitutional mutations in the perforin gene, which encodes an essential protein for cellular immune activation (Stepp et al, 1999). Several additional mutations can also cause FHL, including mutations in *UNC13D* on chromosome 17q25 and mutations in *STX11* on chromosome 6q24 (Trizzino et al, 2008). Patients with FHL are usually well at birth, then develop clinical symptoms by age 2 to 6 months. Constant fever, cytopenias, marked hepatosplenomegaly, and progressive cerebromeningeal symptoms characterize the disease course. Progressive disease usually leads to death within 4 months of diagnosis, but hematopoietic cell transplantation can increase 3-year survival to 64% (Jordan and Filipovich, 2008).

Patients with IAHS, whose symptoms are similar to those of patients with FHL, experience a high recovery rate (59%) when appropriate antibiotic treatment is promptly administered (Isaacs, 2006). Leukocytosis is common in IAHS, possibly reflecting the underlying infectious etiology.

JXG, a disorder of dendritic-related cells, is less common in neonates than LCH. Two forms are recognized, cutaneous and extracutaneous. Patients present with one or multiple cutaneous nodules, which are reddish to yellow-brown papules on the head, neck, and extremities. Three fourths of neonates with cutaneous JXG present with a solitary nodule; one fourth present with multiple nodules. Nodules typically resolve spontaneously over approximately 2 years. Survival is excellent for neonates with JXG limited to the skin and subcutaneous tissue, with no deaths reported in one series (Isaacs, 2006). Treatment is not generally indicated. Extracutaneous or disseminated JXG can involve the subcutaneous and soft tissues, liver, lung, spleen, eye, lymph nodes, and brain. Twenty-five percent of neonates with disseminated JXG do not have cutaneous lesions. Jaundice, hepatosplenomegaly, and thrombocytopenia can be seen. Although most cutaneous and extracutaneous lesions resolve spontaneously without treatment, disseminated JXG has an 11% death rate (Isaacs, 2006). Ocular and CNS involvement can cause significant morbidity. Systemic JXG is usually treated with chemotherapy and/or corticosteroids.

HEPATOBLASTOMA

Hepatoblastoma is an embryonal neoplasm composed of malignant epithelial tissue. The incidence in infants is 11.2 cases per million; the incidence is increased as much as 15-fold in premature infants with low birthweights (Feusner and Plaschkes, 2002). The female-male ratio in neonates is 1:6 (Isaacs, 2007). Histologic subtype is associated with outcome, with pure fetal histology having the best prognosis. Hepatoblastoma is associated with a number of genetic abnormalities and malformation syndromes, including Beckwith-Wiedemann syndrome and trisomy 18 (Von Schweinitz, 2003).

Chromosome abnormalities in tumor tissue include trisomy of chromosomes 2 and 20. Chromosomal gains at chromosome 8 and 20 may be associated with an adverse prognosis. Patients with Beckwith-Wiedemann syndrome demonstrate loss of heterozygosity at 11p15.5, the Beckwith-Wiedemann locus.

The most common presenting symptom in neonates is abdominal distention. Even in the absence of distention an abdominal mass can sometimes be palpated. Anemia, fetal hydrops, and respiratory distress are other initial findings. Serum alpha-fetoprotein is elevated in half of patients. Hepatoblastoma is occasionally diagnosed prenatally by

Box 80-1 Diagnostic Criteria for Hemophagocytic Lymphohistiocytosis

The diagnosis can be established if:

I. Patient has a molecular diagnosis consistent with HLH
OR

II. Patient has 5 of the following 8 diagnostic criteria:
- Fever
- Splenomegaly
- Cytopenias (affecting ≥2 of 3 lineages in the peripheral blood)
  - Hemoglobin <9.0 g/dL (<10 g/dL in infants <4 wk)
  - Platelets $<100 \times 10^9$/L
  - Neutrophils $<1.0 \times 10^9$/L
- Hypertriglyceridemia and/or hypofibrinogenemia
  - Fasting triglycerides ≥3.0 mmol/L (i.e., ≥265 mg/dL)
  - Fibrinogen ≤1.5 g/L
- Hemophagocytosis in bone marrow or spleen or lymph nodes; no evidence of malignancy
- Low or absent NK-cell activity (according to local laboratory reference)
- Ferritin ≥500 μg/L
- Soluble CD25 (i.e., soluble IL-2 receptor) ≥2400 U/mL

IL, Interleukin; *NK*, natural killer.
Other findings consistent with the diagnosis include cerebromeningeal symptoms, lymph node enlargement, jaundice, edema, skin rash, hepatic enzyme abnormalities, hypoproteinemia, hyponatremia, elevated very low-density lipoprotein (VLDL), decreased high-density lipoprotein (HDL).
From Henter J-I, Horne A, Arico M, et al: HLH-2004: diagnostic and therapeutic guidelines for hemophagocytic lymphohistiocytosis, *Pediatr Blood Cancer* 48:124-131, 2007.

screening ultrasound. Tumor rupture can occur during birth, resulting in massive hemorrhage.

Ultrasonography is useful to distinguish cystic and solid masses from diffuse hepatic enlargement. CT scan of the abdomen demonstrates the extent of tumor involvement, anatomic landmarks, and operability; MRI most accurately shows tumor margins and vessel involvement.

The goal of therapy is complete surgical resection. Infants with pure fetal histology whose tumors are completely resected have a 92% 24-month survival rate. A lobectomy of the involved portion of the liver is performed if one lobe is free of malignancy and there is no evidence of distant metastases. For unresectable but nonmetastatic tumors, initial treatment consists of chemotherapy with cisplatin and vincristine. If adequate tumor shrinkage results, the tumor is then resected. Orthotopic liver transplant is curative in patients with unresectable, nonmetastatic hepatoblastomas.

HEPATIC HEMANGIOENDOTHELIOMA

Hepatic hemangioendothelioma, also referred to as hepatic hemangioma, is a benign vascular tumor of the liver; it is the most frequent liver tumor of infants (Warmann, 2003). The disease is classified into three subtypes: focal, multiple, and diffuse hepatic lesions. Some patients also present with cutaneous hemangiomas. Although some infants with small tumors are asymptomatic, infants with larger tumors can present with multiple symptoms including abdominal distention, respiratory distress, high-output cardiac failure, and consumptive coagulopathy. The diagnosis is often suspected prenatally when a hepatic mass is detected by ultrasonography. The diagnostic evaluation usually includes an abdominal ultrasound examination and CT or MRI. If imaging studies fail to reveal a diagnosis, then a biopsy is performed. Infants with focal or multifocal disease without evidence of cardiac failure can usually be carefully observed with periodic physical exams and ultrasound examinations. Symptomatic infants are usually treated with corticosteroids. Infants with diffuse hepatic hemangiomas, who are at the greatest risk of morbidity or death, are treated with vincristine in addition to corticosteroids. Embolization or hepatic artery ligation can be considered if pharmacologic intervention is unsuccessful (van der Meijs, 2008). Overall survival in fetal and neonatal focal hemangioma is 86%; overall survival in fetal and neonatal multifocal disease is 71% (Isaacs, 2007).

TREATMENT CONSIDERATIONS IN INFANTS

CHEMOTHERAPY DOSING

Neonates and infants experience more frequent and more severe side effects and late effects from chemotherapy compared to older children and adults. This is likely due to age-related differences in body composition, drug bioavailability, and drug metabolism. Infants have increased total body water; decreased activity of drug-metabolizing enzymes, particularly P450 enzymes; and less efficient renal function. To compensate for these differences, specific chemotherapy dosing protocols have been developed for neonates and infants. Doses for systemic chemotherapy are reduced overall and are frequently calculated by weight instead of by body surface area. Interestingly, the volume of the CSF in relation to body surface area is much greater in young children than in adults; accordingly, doses of intrathecal chemotherapy are adjusted for age to avoid underdosing young infants with leukemia.

RADIATION EFFECTS

The use of radiation therapy in newborn infants is reserved for acute life-threatening situations in which the benefits of radiation clearly outweigh the risks of adverse late effects, which include growth impairment, cognitive impairment, and secondary malignancies. The goal is to use as little radiation as possible to spare the infant potentially morbid side effects.

PAIN MANAGEMENT

Infants experience pain and should be treated with adequate pain medication. Signs of pain in the neonate can be subtle and can include crying, grimacing, poor feeding, tachycardia, and high blood pressure. Acetaminophen can be an effective analgesic in infants, but it must be used judiciously to avoid masking a fever that could signify an infection, particularly if a central line is in place or in the setting of neutropenia. Nonsteroidal antiinflammatory medications are usually avoided in patients with cancer because of the risks of interfering with platelet function. Narcotics can be used as needed provided that adequate monitoring of side effects such as respiratory depression is in place. Narcotics can produce physical dependence when used for more than 1 week, and doses may need to be tapered to avoid symptoms of withdrawal.

NUTRITION

Adequate nutrition is particularly important for neonates and infants. Patients might require supplemental nutrition via nasogastric tube or intravenous parenteral nutrition. A nutritionist should be consulted to help assess the infant's nutritional needs. Breastfeeding can usually be continued in neonates with malignancy.

INTRAVENOUS ACCESS

Most neonates and infants diagnosed with cancer will require a central venous catheter in order to facilitate delivery of chemotherapy, blood product support, and parenteral nutrition. Some chemotherapy agents, such as vincristine and doxorubicin, are vesicants and can cause severe skin and subcutaneous burns if inadvertently infiltrated underneath the skin. The type of central line inserted depends on the size of the infant and the specific needs associated with the chemotherapy regimen.

TRANSFUSIONS

Cancer patients frequently require blood product support for correction of life-threatening cytopenias and coagulopathies. To minimize the risk of transfusion-associated infections and complications, a number of guidelines exist. These include the use of CMV-negative blood to prevent transmission of CMV, which is potentially life-threatening; the use of irradiated blood products to prevent the possibility of graft-versus-host disease in the immunocompromised recipient; and the use of leukocyte-depleted blood products to minimize febrile or allergic reactions. Donor-designated blood is usually discouraged in infants with congenital leukemia, given the possibility of future bone marrow transplantation.

IMMUNIZATIONS

Immunizations generally are avoided until the patient has been off chemotherapy for at least 6 months. In addition, close contacts of the patient should receive the inactivated polio vaccine rather than the live oral polio vaccine. There is no contraindication to immunizing first-degree relatives with the varicella vaccine. However, any person in whom a rash develops after the vaccination should be kept away from the patient.

PSYCHOSOCIAL CONSIDERATIONS

Social services and psychological support are essential for families. These services are usually best coordinated through the efforts of a multidisciplinary team composed of nurses, social workers, and the pediatric oncologist.

LATE EFFECTS

Infants who receive treatment for cancer during the 1st year of life are at risk for many late effects directly related to chemotherapy, surgery, and radiation therapy. Infants in the neonatal period will be particularly susceptible to therapies affecting normal growth and development. Information about late effects of treatment and suggested screening after childhood cancer may be found on the Children's Oncology Group website (www.childrensoncologygroup.org). Infants require follow-up evaluations at routine intervals by a pediatric oncologist (or multidisciplinary cancer survivor team) who can help identify appropriate screening tests and appropriate support.

CONCLUSION

Cancer in the neonatal period is rare, but must be diagnosed and treated promptly, with careful attention to the epidemiologic and clinical features that differ from those in older children with similar malignancies. There are special challenges in treating the neonate with cancer, including the newborn's unique physiologic status, which results in marked susceptibility to acute and late toxicities of treatment. Careful teamwork is necessary among the neonatologist, pediatric oncologist, surgeon, radiation therapist, nurse, and social worker in order to support and treat the patient and family.

PART XVII

Renal and Genitourinary Systems

CHAPTER 81

Renal Morphogenesis and Development of Renal Function

Jean-Pierre Guignard and Endre Sulyok

RENAL MORPHOGENESIS

The fetal kidney develops from three successive mesodermic structures: the pronephros, the mesonephros, and the metanephros. The pronephric tubule extends into the intermediate mesoderm of the mesonephros to form the wolffian duct. The metanephros develops from an outbranch of the wolffian duct called the *ureteric bud* that extends into a mass of undifferentiated metanephric mesenchyme. Reciprocal inductive interactions between the ureteric bud epithelium and the metanephric mesenchyme result in the formation of both the collecting duct system and the nephrons of the permanent kidney. Cells of the metanephric mesenchyme adjacent to the tip of the ureteric bud are induced to aggregate and signal the ureteric bud to grow and branch repeatedly (branching morphogenesis), eventually leading to the formation of the renal collecting system. The ureteric bud also induces the mesenchyme to undergo a mesenchymal-epithelial transformation resulting in the formation of the glomeruli and renal tubules. Ureteric bud outgrowth requires inductive signals derived from the metanephric mesenchyme under the control of transcription factors and signaling molecules including Wilms' tumor gene 1 (WT1) protein and glial cell line–derived neurotrophic factor (GDNF). Normal ureteric bud response to these inductive signals is under the control of several transcription factors such as Pax2 and Lim1 and the *Formin* gene.

Differentiation of the metanephros starts around 5 weeks' gestation, and the first nephrons are formed by week 8. Nephrogenesis continues up to weeks 34 to 35, with the deep nephrons being formed first. From the completion of nephrogenesis around week 35 until birth, the nephrons grow only in size. At birth, juxtamedullary nephrons are more mature than superficial nephrons. The total number of nephrons varies widely ranging from 600,000 to 1.2 million per kidney. Fetal growth retardation and premature delivery are associated with a low number of nephrons, so that a positive correlation exists between birthweight and the final number of nephrons (Merlet-Bénichou et al, 1999). Exposure to drugs (gentamicin, β-lactam antibiotics, cyclosporin, excess glucocorticoid), vitamin A deficiency, hyperglycemia, obstruction in the urinary tract, and deletion of an allele of the *GDNF* gene can also impair nephrogenesis, leading to a permanent nephron deficit (Gilbert and Merlet-Bénichou, 2000).

Mutations in any one of the genes controlling renal morphogenesis result in severe renal developmental defects. The angiotensinogen and angiotensin receptor genes, best known for controlling renal hemodynamics, also play a role in the development of calyces and pelvis. Mutational inactivation of the angiotensin receptor 2 (Agtr2), encoded on the X chromosome, results in a range of anomalies including vesicoureteral reflux, duplex kidney, renal ectopia, ureteropelvic junction stenosis, ureterovesical junction stenosis, renal dysplasia, renal hypoplasia, multicystic dysplastic kidney, and renal agenesis (the CAKUT sequence—*c*ongenital *a*nomalies of the *k*idney and *u*rinary *t*ract) (Winyard and Chitty, 2008; Woolf, 2006).

Major renal malformations resulting from mutations in transcription factors, signaling molecules and gene products are discussed in various reviews (Burrow, 2000; Cooper et al, 2006; Pohl et al, 2002).

The glomerular diameter approximates 110 μm at birth (200 μm in the adult), and the average proximal tubular length reaches 2 mm (20 mm in the adult). Postnatal growth is characterized by accelerated growth of the proximal tubular volume compared with the glomerular filtering area. The glomerular basement membrane, which behaves as a filtration barrier, is thinner in neonates (100 nm) than in adults (300 nm). The size of the apertures in this "barrier" limits the passage of compounds through the capillary wall. In addition, an electrostatic barrier, resulting from the presence of negatively charged glycosialoproteins in the glomerular capillary wall, further restricts the filtration of negatively charged molecules. In the adult, the molecular weight cutoff for the filter is about 70,000. Molecules with a radius less than 1.8 nm are filtered freely. Molecules larger than 3.6 nm are not freely filtered. The permeability of the glomerular basement membrane is greater in newborn animals than in more mature animals.

During the second half of gestation, kidney weight increases proportionally to gestational age, body weight, and body surface area. The kidney and bladder can be visualized by ultrasonography from week 15 of gestation; the precise renal architecture is clearly defined only by week 20. Kidney size as measured by ultrasonography increases proportionally to gestational age (Shin et al, 2007). The ratio between the renal and the abdominal circumferences at the level of the umbilical vein remains constant during gestation, with values ranging from 0.27 to 0.30 (Grannum

et al, 1980). At birth, renal volume approximates 10 mL, and it reaches 23 mL by the third week of life. Each kidney weighs about 12.5 g (approximately 150 g in the adult) and has a length of about 4.5 cm (11.5 cm in the adult) at term birth. The surface of the kidney is lobulated and remains so for months after birth. Fetal bladder volume can also be assessed by ultrasonography. With a maximal capacity of 10 mL at 32 weeks, the bladder can contain up to 40 mL near term.

RENAL FUNCTION IN UTERO

The placenta is the major regulatory organ of the fetus, so that renal growth does not appear to be governed by functional requirements. Urine formation starts around 10 to 12 weeks' gestation. Fetal urine is a major constituent of amniotic fluid, and its production increases with age. Mean hourly urine flow rate is high and approximates 5 mL at 20 weeks, 10 mL at 30 weeks, and 30 mL at 40 weeks of postconceptional age (Chevalier, 2008). Fetal oliguria with a consequent decrease in amniotic fluid results in the oligohydramnios sequence, which includes facial compression (loose skin folds, flattened or beaked nose, large flat ears), positional deformities (asymmetric club feet, major contractures, broad flat hands), and pulmonary hypoplasia.

The fetal urine is hypotonic throughout gestation, with sodium as the major osmotic component. The kidney actively reabsorbs electrolytes and solutes from the glomerular ultrafiltrate. Elevated concentrations of sodium (>100 mmol/L), chloride (>90 mmol/L), and osmolality (>210 mOsm/L) in the urine of a dilated kidney have been considered to be indicators of poor renal prognosis during the postnatal period. However, the sensitivity (40% to 80%) and the specificity (<80%) of these parameters are not ideal.

Fetal renal blood flow (RBF), as measured by Doppler ultrasonography, reaches 20 mL/min at 25 weeks' gestation and 60 mL/min near term (Veille et al, 1993). The low rate of RBF in the fetus is associated with an elevated renal vascular resistance (RVR). Of interest, the fetus appears able to autoregulate RBF within modest limits.

Fetal glomerular filtration rate (GFR) increases rapidly as the number and size of nephrons increase. When the full complement of nephrons is attained, GFR increases in parallel with renal mass, and hence with body weight and body surface area. From 28 to 35 weeks' gestation, GFR (measured by inulin clearance in 1- to 2-day-old neonates) increases proportionally to gestational age and then levels off up to the time of birth (Figure 81-1).

Several vasoactive agents and hormones play a major role in modulating the fetal RBF and GFR, including the renin-angiotensin system, the catecholamines, the prostaglandins, the kallikrein-kinin system, endothelin, nitric oxide, and atrial natriuretic peptide (Table 81-1). Interference with these systems can lead to severe renal dysfunction in the fetus. A clinical example is fetal renal failure after maternal administration of inhibitors of angiotensin-converting enzyme (ACE) or prostaglandin synthesis. In response to ACE inhibition, the decrease in GFR probably results from the attenuated vasoconstriction of the efferent artery by angiotensin II inhibition. Reduced prostaglandin-dependent afferent vasodilation and the unopposed vasoconstrictive effects of angiotensin II and catecholamines may explain the drop in GFR observed in fetuses of mothers given nonselective or cyclooxygenase type 2 (COX-2)-selective nonsteroidal antiinflammatory drugs (NSAIDs) (Guignard, 2002).

POSTNATAL MATURATION OF RENAL BLOOD FLOW

RBF is determined primarily by the mean arterial pressure and the resistance at the level of the renal arterioles. In the adult, physiologic intrinsic autoregulation maintains a constant RBF at varying perfusion pressures ranging from 80 to 200 mm Hg. This means that as perfusion pressure increases, the resistance to flow also increases. Both afferent and efferent arterioles participate in the vasoconstriction. In children and adults, RBF approximates 20% to 25% of cardiac output, and it is around 1200 mL/min × 1.73 m^2 of body surface area. A major part of the blood flow supplies the cortex, with medullary blood flow representing only 10% of the total RBF.

During fetal life, RBF is low, representing only 2% to 4% of the total cardiac output. This proportion increases after birth, from a value of 5% in the first 12 hours of life to 10%

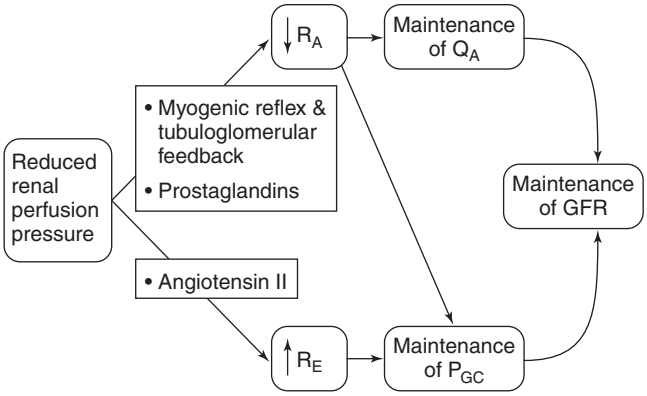

FIGURE 81-2 Mechanisms contributing to the autoregulation of renal blood flow and glomerular filtration rate (GFR). P_{GC}, Glomerular capillary hydraulic pressure; Q_A, glomerular plasma flow rate; R_A, afferent arteriolar resistance; R_E, efferent arteriolar resistance.

at the end of the first week. During the first 5 months, RBF increases rapidly from a value of 250 mL/min × 1.73 m^2 at 8 days of age to approximately 770 mL/min × 1.73 m^2 by 5 months of age. The postnatal maturation of RBF is associated with a striking decrease in RVR and a marked increase in systemic blood pressure. The decrease in RVR occurs along with a decrease in the resistance of both the afferent and the efferent arterioles. Animal studies suggest that autoregulation of RBF is present in the immature kidney but is set at a lower range of blood pressure (Chevalier et al, 1987).

Several autocrine, paracrine, and endocrine factors regulate RBF, intrarenal hemodynamics, and GFR (Seri, 1995) (Figure 81-2; see also Table 81-1). Overactivation of the vasoconstrictive forces that regulate renal hemodynamics in the neonatal period may impair the maturation of RBF and induce renal hypoperfusion. Such activation is seen during respiratory distress, hypoxemia, asphyxia, metabolic acidosis, hypercapnia, hyper- and hypothermia, and positive-pressure ventilation as well as in response to the administration of various medications (Guignard and John, 1986; Tøth-Heyn et al, 2000).

POSTNATAL MATURATION OF GLOMERULAR FILTRATION RATE

DETERMINANTS OF GLOMERULAR FILTRATION RATE

The rate of filtration is governed by the rate at which plasma flows through the glomerular capillaries, the balance of Starling forces across the glomerular capillary walls, the permeability of the basement membrane of the glomerular capillary wall to water and small solutes, and the total surface area of the capillaries. The ultrafiltration coefficient (K_f) represents the product of the permeability of the glomerular membrane and the glomerular filtering area. GFR is proportional to the Starling forces across the glomerular capillaries times the K_f:

$$GFR = K_f \times [P_{GC} - (P_{IT} + \pi_{GC})]$$

where P_{GC} is the hydrostatic pressure in the glomerular capillary, P_{IT} is the proximal intratubular hydrostatic pressure, and π_{GC} is the oncotic pressure in the glomerular capillary. In adults, the average value of P_{GC} probably approximates 60 mm Hg, the pressure in Bowman's capsule 15 mm Hg, and the oncotic glomerular capillary pressure 25 mm Hg. Thus, the average net filtration pressure is probably close to 20 mm Hg at the afferent end of the glomerular capillaries. It decreases to 10 mm Hg at the end of the efferent glomerular capillaries. Because of the very low mean arterial pressure present in neonates, the net transglomerular filtration pressure is probably not greater than 3 to 5 mm Hg (Figure 81-3). The relative state of vasoconstriction of the afferent and efferent arterioles plays a major role in regulating the intracapillary hydrostatic pressure. The factors modulating the state of vascular contraction are listed in Table 81-1.

During the early neonatal period, the factors regulating GFR mature rapidly. Systemic blood pressure and mean transcapillary hydraulic pressure increase, followed by a parallel increase in GFR (Guignard and Gouyon, 2008; Guignard and John, 1986). The plasma oncotic pressure also increases, but at a lower rate than for the transcapillary hydraulic pressure, so that the net ultrafiltration pressure increases. The low glomerular plasma flow rate present at birth is due to elevated afferent and efferent arteriolar resistances. A systemic increase in the ultrafiltration coefficient also occurs during maturation and may be attributed to an increase in both the hydraulic permeability and the glomerular capillary area.

In the fetus and neonate, the low systemic blood pressure and hence the low glomerular capillary hydrostatic pressure are the main factors limiting the rate of filtration. Vasoactive factors modulating the intraglomerular filtration pressure thus play a key role in maintaining filtration (Guignard and Gouyon, 2008). Vasodilatory prostaglandins, the concentration of which is elevated during fetal and early postnatal life, improve filtration by dilating the afferent arteriole. Angiotensin II also increases filtration by preferentially constricting the efferent arteriole (Figure 81-4). Minute-to-minute regulation of the contractile tone also depends on endothelium-released vasoactive factors such as nitric oxide and endothelin. Although endogenous endothelin behaves as a potent constrictor in the adult, it may actually vasodilate the afferent artery in the immature

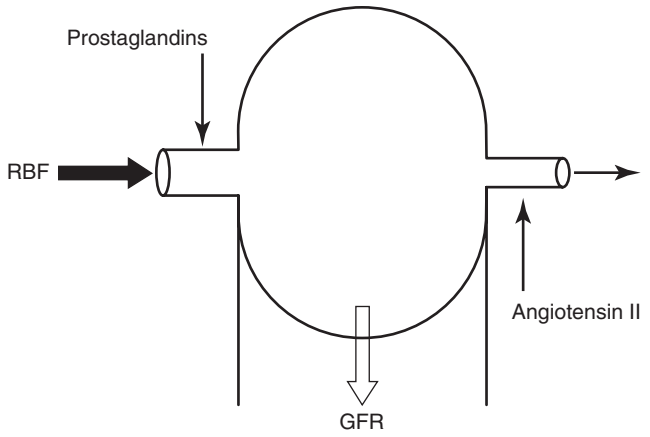

FIGURE 81-4 The physiologic regulation of GFR depends on two main factors: the afferent vasodilator prostaglandins and the efferent vasoconstrictor angiotensin II. *GFR*, Glomerular filtration rate; *RBF*, renal blood flow.

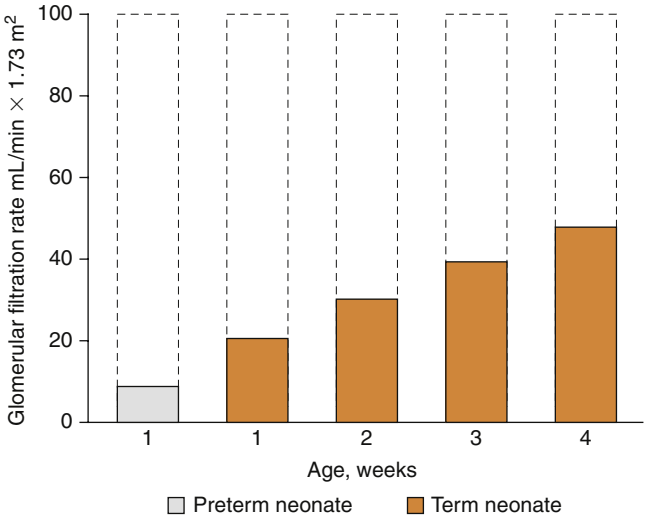

FIGURE 81-5 Glomerular filtration rate during the 1st month of life of preterm and term neonates, compared with adult values (*open columns*). Note that at the end of the 1st month of life, the human neonate is in a state of relative renal insufficiency. *(Adapted from Guignard JP, Torrado A, Da Cunha O, et al: Glomerular filtration rate in the first three weeks of life*, J Pediatr *87:268-272, 1975.)*

kidney (Semama et al, 1993). Atrial natriuretic peptide, the concentration of which also is elevated in the fetus, vasodilates the afferent arteriole (Robillard et al, 1992). Adenosine, a regulator of the tubuloglomerular feedback mechanism, is an efferent vasodilator. When acting in conjunction with elevated levels of angiotensin II, adenosine also vasoconstricts the afferent arteriole (Vallon and Osswald, 2009). Although the overactivation of adenosine plays a critical role in the pathogenesis of the hypoxemia-induced vasomotor insufficiency (Gouyon and Guignard, 1988), the exact physiologic role of intrarenal adenosine in the fetus and neonate is still ill defined.

ASSESSMENT OF GLOMERULAR FILTRATION RATE

Measurement of inulin clearance is the gold standard for assessing GFR in both the immature and the mature kidney. Inulin is freely filtered even in the preterm neonate with a very low gestational age. The postnatal development of GFR has been assessed in premature neonates at different gestational ages and in term neonates. From a value of 20 mL/minute × 1.73 m^2 at birth, GFR doubles in the first 2 weeks of life in term neonates (Guignard et al, 1975; Guignard, 2008) (Figure 81-5). GFR is lower in premature infants and, because of incomplete nephrogenesis, also develops at a lower velocity. GFR reaches mature levels by the first year of life (Figure 81-6).

Creatinine, the most commonly used glomerular marker in mature persons, also is frequently used to assess GFR in neonates. However, the use of creatinine presents several drawbacks. The concentration of creatinine is elevated at birth, reflecting maternal levels. A complete equilibration between the maternal and fetal plasma creatinine levels is achieved throughout pregnancy (Guignard and Drukker, 1999). During the first postnatal week, the highest levels are observed in the most premature neonates (Bueva and Guignard, 1994). In term neonates, serum creatinine decreases rapidly to reach stable neonatal levels close to 0.40 mg/dL (35 μmol/L) by 1 to 2 weeks postnatally. In very premature infants, there is a transient increase in serum creatinine, peaking on postnatal day 4 (Gallini et al,

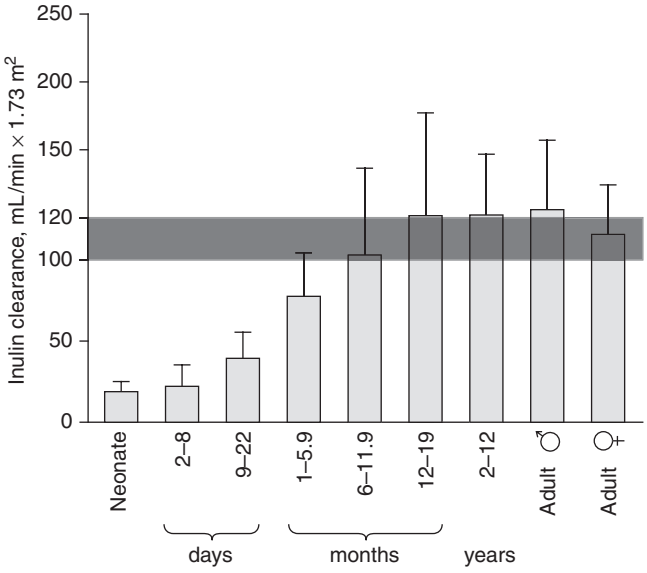

FIGURE 81-6 Maturation of GFR (C_{inulin}) throughout the first year of life.

2000; Miall et al, 1999) (Table 81-2; see also Figure 81-6), followed by a progressive decline toward normal neonatal levels by 3 to 4 weeks of life. The transient increase in plasma creatinine is caused in part by passive reabsorption (back-diffusion) of creatinine across leaky tubules (Matos et al, 1998). The reabsorption of creatinine by the premature infant accounts for the negative correlation between gestational age and the plasma creatinine during the first postnatal week (Bueva and Guignard, 1994), and in very premature neonates, creatinine clearance frequently underestimates inulin clearance. In spite of these drawbacks, creatinine clearance correlates with inulin clearance (Van den Anker et al, 1995), and creatinine clearance studies in neonates have confirmed the rapid development of GFR during the first postnatal week and that GFR develops

TABLE 81-2 Changes in Plasma Creatinine Over Time for Different Gestational Ages.

Gestational Age (weeks)	Birth Creatinine (μmol/L)	Peak Plasma Creatinine (μmol/L)	Time to Peak Plasma Creatinine (hours)*
23–26	67–92	195–247	40–78
27–29	65–89	158–200	28–51
30–32	60–69	120–158	25–40

at a lower velocity in premature infants (Bueva and Guignard, 1994). The differences in GFR among infants with different gestational and postnatal ages explain why the specific dosage recommendations are tailored to the given gestational and postnatal ages for medications eliminated primarily via glomerular filtration (e.g., aminoglycosides, vancomycin, digoxin).

REGULATION OF BODY FLUID TONICITY AND VOLUME

The kidney is responsible for maintaining the extracellular fluid (ECF) volume and osmolality despite large variations in salt and water intake (Ranadive and Rosenthal, 2009). By modulating the renal conservation of water, the antidiuretic hormone (ADH) system plays a central role in the regulation of body fluid tonicity. Sodium chloride, the major osmotically active solute in ECF, determines its volume. The balance between the intake and the renal excretion of sodium thus regulates ECF volume.

SODIUM, CHLORIDE, AND WATER REABSORPTION

Active sodium reabsorption occurs throughout the nephron, driven by the Na^+,K^+-ATPase localized at the basolateral membrane. Two thirds of the filtered Na^+ load is reabsorbed in the proximal tubule via the Na^+-glucose, Na^+-amino acid, Na^+-P_i, and Na^+-lactate cotransporters, and by the Na^+-H^+ antiporter. Because water passively follows Na^+ across the highly water-permeable proximal tubule, the osmolality of the proximal tubule fluid remains isotonic. Twenty percent of the filtered sodium load is reabsorbed in the ascending limb of the loop of Henle, which is relatively impermeable to water. Accumulation of NaCl and recycling of urea into the medullary interstitium lead to the formation of a hyperosmotic medulla. The thick ascending limb also reabsorbs calcium, magnesium, and potassium. The distal tubule and collecting duct reabsorb 10% of the filtered Na^+ and Cl^- load. In the distal tubule, the continuing NaCl reabsorption in the absence of water reabsorption further decreases the osmolality of the tubular fluid, allowing the formation of hypotonic urine. Excretion of solute-free water thus is dependent on Na^+ delivery to and reabsorption at the distal diluting site. The permeability of the collecting duct to water depends on the presence of ADH or arginine vasopressin (AVP). The release of AVP by the posterior pituitary gland is regulated by osmoreceptors located in the supraoptic nucleus of the hypothalamus. By binding to its cell membrane receptors and activating adenylate cyclase, AVP increases the intracellular levels of cyclic adenosine monophosphate (cAMP). This increase ultimately leads to phosphorylation of the aquaporin water channels, which in turn results in insertion of these channels into the luminal membrane of the collecting duct cells, rendering the collecting duct permeable to water. In the absence of AVP, a large volume of hypotonic urine is excreted. In contrast, when elevated levels of AVP are present, water passively diffuses out of the collecting duct into the hyperosmotic interstitium, and a small volume of concentrated urine is excreted.

Water transport depends on the intact function of the aquaporin water channels (AQPs). AQPs, a family of integral plasma membrane proteins, facilitate water permeation across biologic membranes (Nielsen et al, 2000). To date 13 members of the AQP family (AQP0–AQP12) have been identified in mammals with specific expression patterns and distinct roles in given cells and tissues. At least seven AQP isoforms are expressed in different nephron segments (AQP1, 2, 3, 4, 6, 7, 11), where they provide pathways for constitutive- or vasopressin-stimulated water flow (King et al, 2004). AQP2 is the vasopressin-responsive AQP in collecting principal duct cells. Mutations in the AVP V2 receptor gene located at Xq28 are responsible for *X-linked recessive diabetes insipidus*. When inherited as an autosomal recessive or dominant trait, diabetes insipidus usually is caused by various mutations in the *AQP2* gene, located at 12q13.

Sodium

During development, proximal active Na^+ reabsorption increases three- to fourfold, this increase being associated with a threefold increase in Na^+,K^+-ATPase activity in the corresponding segment (Celsi et al, 1986), and with an

increase in the number of cotransporters for glucose and bicarbonate reabsorption (Schwartz and Evan, 1983). The immature proximal tubule has a lower reflection coefficient for mannitol, indicating increased permeability of the proximal tubule to various solutes. The low capacity of the immature thick ascending limb of the loop of Henle to reabsorb Na^+ is associated with a low activity of the tubular Na^+,K^+-ATPase. As a consequence of the reduced Na^+ reabsorption in the loop of Henle, immature nephrons deliver a greater fraction of filtered Na^+ to the distal nephrons. The activity of the Na^+,K^+-ATPase also increases in this segment during development. As a result of the maturational process, the fractional excretion of Na^+ decreases during development, from a value of 13% in the fetus to 3% in premature neonates less than 30 weeks' gestation, and to 1% in term neonates (Bueva and Guignard, 1994). Very low-birthweight (VLBW) infants may be at risk for negative sodium balance around postnatal weeks 2 to 3, when Na^+ retention is required for growth. Partial resistance to aldosterone has been described and ascribed to the low renal mineralocorticoid receptor expression at birth (Martinerie, et al 2009).

The study of the developmental changes in the various tubular epithelial transport mechanisms, the delineation of the molecular basis of such mechanisms, and associated genetic defects have shed new light on a number of rare pediatric renal tubular disorders (Zelikovic, 2001) related to abnormal sodium and water homeostasis. Constitutive activation of the amiloride-sensitive epithelial Na^+ channel (ENaC) is seen in Liddle's syndrome, characterized by salt retention, early-onset hypertension, metabolic alkalosis, and hypokalemia. Autosomal recessive pseudohypoaldosteronism, characterized by renal salt wasting and end-organ unresponsiveness to mineralocorticoids, is due to decreased activity of ENaC. The activity of ENaC is under the tight control of aldosterone and vasopressin (Rossier et al, 2002). ENaC is composed of three subunits: α, β, and γ. The α subunit of ENaC is the most important and is also expressed in other organs such as the lungs. Thus, the α subunit of ENaC is required not only for channel function in the collecting duct of the kidney but also for active lung fluid clearance. Developmental studies on α-ENaC expression in human kidney homogenates from fetuses of 20–36 weeks' gestation have revealed a progressive increase of about 25% in this channel protein abundance during the observational period that corresponds to the improvement in sodium renal conservation (Delgado, et al. 2003).

Experimental evidence suggests that intrauterine growth retardation is associated with upregulation of renal sodium transporters with subsequent sodium retention, suppression of the renin-angiotensin system, and reduction in the number of nephrons. All these changes may contribute to the prenatally programmed hypertension observed later in life. Furthermore, a maternal diet high in sodium is also implicated in fetal programming by inducing oxidative stress, endothelial dysfunction, and restricted nephron number in the offspring (Koleganova et al, 2009).

Chloride

A major fraction of chloride reabsorption in the proximal tubule occurs by paracellular diffusion. Active chloride countertransport with organic anions (formate, oxalate) also takes place in the proximal tubule. In the ascending limb of Henle, the Na^+,K^+-ATPase is the driving force for active NaCl reabsorption and accumulation in the medullary interstitium. Here, Na^+-K^+-$2Cl^-$ cotransporters and Cl^- channels are involved in the transport of chloride. Renal salt wasting with hypokalemic metabolic alkalosis, hyperreninemic hyperaldesteronism, and normal blood pressure are the features of *Bartter's syndrome*. Antenatal Bartter's syndrome, sometimes called hyperprostaglandin E syndrome, is the most severe form of the disease. Congenital defects in genes encoding various chloride transporters, cotransporters, and channels in the thick ascending limb and distal tubule are responsible for the various forms of Bartter's syndrome and Gitelman's syndrome (Rodriguez-Soriano, 1998; Zekikovic, 2001).

Mutations of the chloride channel with gain in function are also associated with Dent's disease, an X-linked renal tubular disorder characterized by low-molecular-weight proteinuria, renal Fanconi syndrome, hypercalciuria, nephrocalcinosis, and nephrolithiasis. Neonatal variants of the disease suggest that the expression and segmental distribution of Cl^- channel proteins is achieved before birth (Ludwig et al, 2006). In fact, during human nephrogenesis, Cl^- channel proteins are identified early in the second trimester, followed by subsequent progressive maturation. It is first distributed in the proximal tubule and appears some weeks later in the principal cells of the collecting duct (Jouret et al, 2004).

BODY FLUID TONICITY

Although the volume of body fluids varies during growth, the tonicity of ECF is maintained constant by the kidneys, which excrete or retain appropriate amounts of water.

Excretion of Free Water

When plasma osmolality decreases, the release of ADH also diminishes, leading to the excretion of dilute urine. The newborn infant, preterm or term, is able to decrease urine osmolality to values as low as 40 mOsm/kg H_2O (Guignard and John, 1986). Because GFR is low in the newborn infant, ability to excrete large amounts of free water and consequently to cope with a hypotonic fluid load is limited. Excessive hypotonic fluid loading leads to hyponatremia.

Hyponatremia also may occur in the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), when the excretion of free water is impaired. This syndrome can occur in term as well as in preterm infants presenting with various cerebral injuries or pulmonary disorders, in infants undergoing mechanical ventilation, and in response to some drugs. Because the renal response to AVP is maturation dependent, the more immature the neonate, the less severe the clinical presentation of the SIADH. Gain-of-function mutation of the AVP V2 receptor gene results in symptoms mimicking SIADH, but with a marked reduction in AVP secretion (Gitelman and Feldman, 2006).

Concentration of Urine

By comparison with adults, who can concentrate urine up to 1400 mOsm/kg H_2O, the concentrating ability is limited in the neonate and matures during the 1st

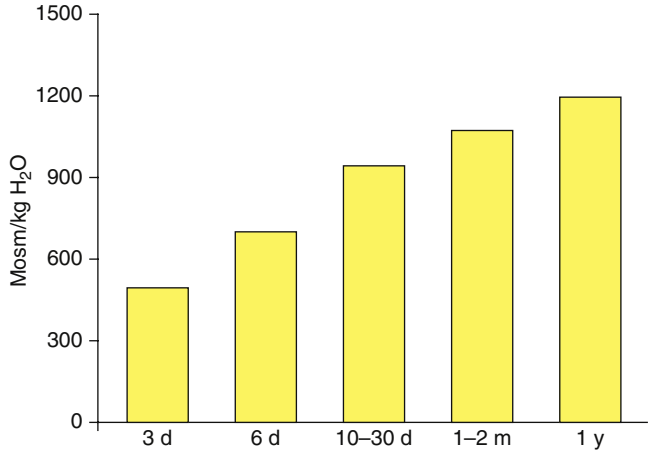

FIGURE 81-8 Maturation of the concentrating ability during the first year of life in term infants. *(Adapted from Polácek E, Vocel J, Neugebauerová L, et al: The osmotic concentrating ability in healthy infants and children,* Arch Dis Child *40:291-295, 1965.)*

year of life (Figure 81-8). The maximal urine osmolality achieved with dehydration or after exogenous vasopressin (DDAVP) administration (10 μg) remains below 430 mOsm/kg H_2O and 630 mOsm/kg H_2O in 1- to 3-week-old and 4- to 6-week-old term infants, respectively. Osmolalities achieved by preterm neonates are slightly lower (Svenningssen and Aronson, 1974). The relative ineffectiveness of the concentrating ability of the neonate is related to several factors including the low corticomedullary solute gradient associated with a limited accumulation of sodium chloride and urea in the medullary interstitium, the decreased formation of cAMP in response to ADH, the shortness of the loops of Henle, and the interference of prostaglandins with the vasopressin-stimulated cAMP synthesis. Low expression of AQP2 mRNA and protein is an additional limiting factor that impairs concentrating ability. The postnatal increase in AQP2 expression parallels that of AVPR2 along with improving concentrating capacity. Of interest, the developmental expression pattern of proximal (AQP1-7-11) and distal (AQP2-3-4) renal AQPs is different. AQP1, AQP3, and AQP4 exhibit a later and more abrupt increase with transient postnatal overexpression. These distinct expression patterns of renal AQPs can be ascribed to structural kidney maturation and vasopressin regulation (Parreira et al, 2009). An additional mechanism for impaired concentrating ability of the immature kidney is the markedly elevated interstitial hyaluronan in the inner medulla/papilla that can antagonize renal tubular water reabsorption (Sulyok, 2008).

NEONATAL REDISTRIBUTION OF BODY WATER COMPARTMENTS

Redistribution of body fluid compartments occurs soon after birth. The early postnatal weight loss observed in the first days of life is usually ascribed to the isotonic contraction of ECW volume and the elimination of excess sodium and water by the kidney. According to a recent hypothesis, cell water rather than extracellular water may be the source of significant neonatal water losses (Sulyok, 2008). The physical compartmentalization and mobility of tissue water could play a significant role in neonatal body fluid redistribution. The term *physical water compartments* designates the physical states of tissue water and assumes interactions between dipole water molecules and tissue biopolymers, including proteins and glycosaminoglycans. Two distinct water fractions should be considered: the free "bulky" water and the relatively slow-motion bound water. Water can be liberated from this latter bound fraction in a regulated manner irrespective of its location in the cellular or extracellular space. The bound water fraction appears to be related to the osmotically inactive body sodium mainly stored in glycosaminoglycan-rich tissues (Titze et al, 2003), which provides a buffer system in the control of physiologic dehydration.

EXTRACELLULAR FLUID VOLUME

The ECF volume is a function of the ECF sodium content. Under normal conditions, plasma volume is closely related to ECF volume. Volume receptors distributed both on the venous (low-pressure receptors) and the arterial (high-pressure receptors) sides of the circulation sense the changes in plasma volume. Arterial sensors perceive the "effective arterial volume." Atrial filling volume is monitored by stretch receptors, which mediate the release of natriuretic peptide (Semmekrot and Guignard, 1991) that promotes diuresis and natriuresis. Effective renal arterial volume also is sensed by baroreceptors located in the juxtamedullary apparatus of the kidney. A decrease in renal perfusion pressure activates the renin-angiotensin-aldosterone system (see Figure 81-2). Angiotensin II, a potent renal and peripheral vasoconstrictor, promotes sodium reabsorption, stimulates thirst, and favors the renal production of prostaglandins and bradykinin, hormones that play a role in sodium homeostasis. Aldosterone increases sodium reabsorption in the distal tubule, leading to further conservation of ECF volume.

The neonatal period is characterized by the rapid physiologic constriction of the expanded ECF volume, as well as by elevated levels of several hormonal systems participating in the regulation of sodium balance. Although angiotensin II induces sodium retention by direct action on the proximal tubule and stimulation of aldosterone secretion, the role of atrial natriuretic peptide in defending the plasma volume is still unclear. The elevated levels of plasma renin activity, which are inversely correlated with gestational age, may be important in maintaining and distributing blood flow to various organs. The integrity of the renin-angiotensin system also appears to be crucial for maintaining renal blood flow and GFR at low perfusion pressure in the neonate (Guignard and Gouyon, 2008). Other factors that may be involved in regulating sodium excretion include atrial natriuretic peptide, bradykinin, dopamine, nitric oxide, endothelin, and adrenomedullin. Dopamine, synthesized by the renal proximal tubule cells, reduces sodium reabsorption by inhibiting the Na^+,K^+-ATPase and decreasing Na^+-H^+ antiporter and sodium-inorganic phosphate (Na^+-P_i) cotransporter activity (Seri, 1995). Agents such as nitric oxide, endothelin, and adrenomedullin can all increase sodium excretion and may participate in sodium homeostasis.

REGULATION OF ACID-BASE BALANCE

The kidneys maintain the acid-base balance by preventing loss of bicarbonate in urine and excreting the daily production of fixed acids. Bicarbonate reabsorption occurs mainly in the proximal tubule (80%) and to a lesser extent in the thick ascending limb of Henle (10%) and the distal nephron (9%). It is mediated by active secretion of hydrogen ions and is closely linked to the tubular reabsorption of sodium. Hydrogen ion secretion occurs through the Na^+-H^+ antiporter (NHE-3) but is also mediated in part by H^+-ATPase. In the tubular lumen, secreted H^+ reacts with filtered HCO_3^- to form H_2CO_3, which quickly dissociates under the influence of the brush border carbonic anhydrase enzyme (CAIV). Luminal CO_2 freely diffuses back into the tubular cells. H_2CO_3 is then formed within the cell by hydration of CO_2, a reaction catalyzed by carbonic anhydrase type 2 (CAII). After crossing the luminal membrane as CO_2, most HCO_3^- exits the tubular cells via a Na^+-HCO_3^- cotransporter (NBC I, II, and III), which couples the transport of 1 Na^+ with 3 HCO_3^-, or in exchange for Cl^- via a Cl^--HCO_3^- antiporter.

The excretion of fixed acids occurs mainly in the distal tubule, where secreted H^+ is buffered by NH_3 and HPO_4^{2-} and excreted as NH_4^+ and $H_2PO_4^-$ (titratable acid). Free H^+ concentration determines the urine pH. The ability of the collecting duct to lower the urine pH is critically important for the excretion of urinary buffers and ammonium. NH_3 is produced by the kidneys; its synthesis and subsequent excretion can be regulated in response to acid-base requirements of the body. To produce NH_3, the kidneys metabolize glutamine, excrete NH_4^+ with the acid salts, and return the generated HCO_3^- to the blood. NH_3 synthesis is upregulated by metabolic acidosis and hypokalemia.

During fetal life, the placenta is responsible for the excretion of H^+. In experimental studies, the fetus responds to an acid load by increasing the excretion of NH_4^+ and titratable acid, and decreasing the urine pH. In early postnatal life, several transporters and enzymes involved in bicarbonate reabsorption are weakly expressed, so that the functioning of the Na^+-H^+ antiporter is clearly impaired (Rodriguez-Soriano, 2000). Consequently, the limited capacity of the immature kidney to excrete H^+ is associated with an obligatory loss of sodium. The maturation of renal acidifying processes with increasing gestational and postnatal ages results in a progressive increase in renal Na^+-H^+ exchange and in a steady decline in urinary sodium excretion (Kerpel-Fronius et al, 1970). The proximal reabsorption of bicarbonate is reduced, resulting in low bicarbonate threshold. This low threshold accounts for the low "physiologic" plasma bicarbonate concentration in neonates: 16 to 20 mmol/L in extremely immature infants and 19 to 21 mmol/L in term infants. In addition to immature carbonic anhydrase activity, the relative expansion of ECF volume at birth may account for the reduced bicarbonate threshold. Immature carbonic anhydrase (CAII and CAIV) enzyme activities may also play an important role in the low bicarbonate proximal reabsorption rate. Maturation of HCO_3^- reabsorption increases proportionally to the increase in proximal tubular basolateral area and Na^+,K^+-ATPase activity (Rodriguez-Soriano, 2000). However, the age-dependent renal expression and segmental distribution of some individual acid-base transporters may be markedly different—for example, the progressive increase of H^+-ATPase expression during fetal development contrasts with the postnatal upregulation of CAII (Jouret et al, 2004; Wang et al, 2009). The functional maturation of renal acidification can be accelerated by glucocorticoids, angiotensin II, catecholamines, thyroid hormones, and metabolic acidosis. The administration of glucocorticoids stimulates the maturation of both the Na^+-H^+ antiporter messenger RNA (mRNA) and activity (Shah et al, 1999). On the other hand, dopamine inhibits NHE-mediated sodium uptake, leading to urinary sodium loss and H^+ accumulation (Gesek and Schoolwerth, 1990).

Distal tubular acidification is more mature than proximal tubular bicarbonate reabsorption. The ability of the neonate to excrete an acid load is fairly well developed. Deficient ammoniagenesis results, however, in low glutamine uptake, decreased NH_3 production and excretion, and, ultimately, impaired ability to excrete an acid load.

Mutations in the various genes encoding the Na^+-HCO_3^- cotransporter (NBC-I), the Cl^--HCO_3^- exchanger (AE1), the H^+-ATPase, and CAII are responsible for the various forms of renal tubular acidosis (Rodriguez-Soriano, 2000, 2002).

Under normal conditions, very little bicarbonate is lost in the urine. The reabsorption of bicarbonate is increased by extracellular volume contraction, hypercapnia, hypokalemia, chloride deficiency, glucocorticoids, angiotensin, aldosterone and alpha-adrenergic stimulation; it is depressed by volume expansion and parathyroid hormone (PTH) (Rodriguez-Soriano, 2000, 2002). The postnatal renal compensation for hypercapnia involves increased bicarbonate reabsorption and excretion of fixed acids, to reduce the decrease in plasma pH. Animal studies and clinical observations indicate that this compensating mechanism is functional in the neonate (van der Heijden and Guignard, 1989).

REGULATION OF POTASSIUM HOMEOSTASIS

Ninety-eight percent of potassium in the body is intracellular, resulting in a high intracellular concentration of potassium. High intracellular concentration of potassium also is required for cell growth and division. Potassium homeostasis depends on an internal balance that maintains a constant potassium concentration in the intracellular and extracellular fluid space. An external balance requires that potassium be absorbed by the gastrointestinal tract in excess of the amount needed for growth that is eventually excreted by the kidneys.

In the proximal tubule, some 70% of filtered potassium is predominantly reabsorbed passively, although active reabsorption against a concentration gradient also occurs. About 20% of filtered potassium is reabsorbed in the ascending limb of the loop of Henle, where reabsorption occurs via both a passive paracellular route and a transcellular route that exploits secondary active Na^+-K^+-Cl^- cotransport. In the cortical collecting duct, K^+ is both reabsorbed by the intercalated cells and secreted by the principal cells. The overall rate of potassium excretion is

determined by the function of the distal tubule and collecting duct (Lorenz, 2008). Plasma potassium concentration and aldosterone are the major physiologic regulators of potassium secretion. Hyperkalemia stimulates the Na^+,K^+-ATPase activity, increases the permeability of the luminal membrane to potassium, and stimulates the secretion of aldosterone by the adrenal cortex. Aldosterone in turn stimulates sodium reabsorption and enhances potassium secretion by stimulating the basolateral Na^+,K^+-ATPase. Elevation of intracellular potassium occurs by increasing the permeability of the luminal membrane to potassium. Aldosterone probably plays a more important role in determining potassium balance than in regulating sodium excretion. The aldosterone-sensitive transport mechanisms for sodium and potassium are largely independent of each other. Other factors favoring potassium secretion by the distal tubule and collecting duct include a rise in tubular flow rate, alkalosis, and an increase in the tubular fluid sodium concentration.

Potassium excretion remains low throughout gestation, and the fetal potassium concentration is maintained at levels exceeding 5 mmol/L. Postnatal growth is associated with an increase in total body potassium from approximately 8 mmol/cm body height at birth to more than 14 mmol/cm body height by 18 years of age (Butte et al, 2000).

In neonatal tissues, K^+ content is significantly higher than in adult tissues. The plasma K^+ concentration is also elevated during the first 3 to 4 postnatal months. The intracellular versus extracellular potassium distribution in infancy may be influenced not only by the expression of the Na^+,K^+-ATPase, potassium transporters, and channels but also by the expression of hormone receptors and intracellular messengers.

Clinical and experimental studies in the newborn demonstrate low rates of urinary K^+ excretion under basal conditions and an inability to efficiently excrete an exogenous potassium load. With advancing gestational and postnatal ages, there is a steady rise in the renal excretory capacity (Aizman et al, 1998). The major cause of impaired potassium excretion by the immature kidney is the low rate of potassium secretion by the principal cells in the collecting duct. It is attributed to the low Na^+,K^+-ATPase activity, low cellular K^+ concentration, and unfavorable electrochemical gradient. Potassium permeability of the apical membrane is also reduced because of low number, low open probability, and low conductivity of the K^+-channel protein. Potassium excretion is further compromised by impaired aldosterone reactivity and limited flow-mediated activation of the K^+ channel. In addition to decreased K^+ secretion, K^+ retention needed for growth can also be ascribed to enhanced apical absorption by Na^+,K^+-ATPase in the intercalated cells of the developing cortical collecting duct (Lorenz, 2008; Sulyok et al, 1979).

In clinical settings , the transtubular potassium gradient (TTKG) is a reliable estimate of distal tubular K^+ secretion, provided that the urine is at least isoosmolar to plasma and the final urine K^+ concentration is equal to or greater than the plasma K^+ concentration. The TTKG is expressed by the following ratio: $TTKG = \{K^+_{urine}/(U/P)_{osm}\}/K^+_{plasma}$ (Kamel et al, 1994), and it has a normal value close to 10. The values observed in healthy neonates are well below the normal range for infants and children, confirming the state of renal unresponsiveness to aldosterone in the neonate.

Transient hyperkalemia sometimes occurs in the early neonatal period in VLBW infants. A lower renal K^+ excretory capacity and a low tissue K^+ uptake due to low Na^+,K^+-ATPase activity are thought to be responsible for this nonoliguric hyperkalemia (Lorenz et al, 1997). In contrast with healthy premature infants, critically ill and stressed premature neonates may develop a negative potassium balance. In sick neonates, potassium losses can be exaggerated by the use of diuretics and volume expansion.

REGULATION OF CALCIUM, PHOSPHATE, AND MAGNESIUM HOMEOSTASIS

The kidney, in conjunction with the gastrointestinal tract and bone, plays a major role in maintaining calcium, phosphate, and magnesium homeostasis.

REGULATION OF CALCIUM HOMEOSTASIS

The blood ionic calcium concentration in plasma is maintained within narrow limits at approximately 1.10 to 1.30 mmol/L. The distribution of calcium between the intracellular (bone) and extracellular compartment is regulated mainly by PTH. The parathyroid gland has the ability to determine the level of blood-ionized calcium by a calcium sensor (CaSR) located on the extracellular site of membrane. The CaSR appears to act via a G protein–coupled signaling system, and its gene has been cloned (Brown, 1999). Loss-of-function and gain-of-function mutations in the CaSR gene are responsible for autosomal dominant familial hypercalcemia with hypocalciuria and autosomal dominant hypoparathyroidism with hypocalcemia (Langman, 2000).

PTH increases plasma calcium concentration by stimulating bone resorption, by activating the synthesis of 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$ or calcitriol), and by increasing calcium reabsorption by the kidney. Normally, 99% of the filtered calcium is reabsorbed by the nephron, mainly by the proximal tubule and the loop of Henle. In the proximal tubule and the thick ascending limb, calcium reabsorption is passive and closely linked to sodium reabsorption. By contrast, in the distal tubule and collecting duct, calcium reabsorption is active and independent of sodium transport, so that net calcium and sodium excretions do not always change in parallel. PTH is the main regulator of the renal excretion of calcium, and it strongly stimulates calcium reabsorption in the distal tubule and collecting duct, resulting in reduced calcium excretion. Volume expansion depresses both sodium and passive calcium reabsorption in the proximal tubule and thus increases calcium excretion. Calcium excretion is increased by acidosis and decreased by alkalosis. Finally, $1,25(OH)_2D_3$ stimulates distal calcium reabsorption and thus decreases its excretion. Whereas the single most important action of PTH is on bone, that of vitamin D_3 is in the intestine.

During weeks 26 to 36 of gestation, the mean intrauterine accumulation of calcium is about 130 mg/kg/day (Forbes, 1976; Wharton et al, 1987). The calcium levels

in fetal plasma are higher than maternal levels (Delivoria et al, 1967), averaging 1.40 to 1.60 mmol/L. Of interest, the fetal kidney also is able to effectively produce $1,25(OH)_2D_3$. The 25-hydroxyvitamin D_3-1α hydroxylase is produced by the renal proximal tubule mitochondria. The $1,25(OH)_2D_3$ binds to an intracellular receptor to stimulate intestinal calcium reabsorption. During the neonatal period, the urinary calcium-to-creatinine ratio is higher in neonates than later in infancy (2.5 vs. 0.7) (Matos et al, 1997). Loop diuretics are potent calciuric agents that may lead to neonatal nephrocalcinosis.

The relatively low efficacy of calcium reabsorption by the developing kidney may be the result of low expression and activity of the epithelial Ca^{2+} channel in the apical membrane and the Ca^{2+}-ATPase and Na^+-Ca^{2+} exchanger in the basolateral membrane of the distal nephron. Maturity-related defective function of the Cl^- channel may also contribute, because gene mutations of this membrane protein are associated with hypercalciuria (Bartter's syndrome, Dent's disease, knockout animals) (Chadha and Alon, 2009; Scheinman, 1998).

REGULATION OF PHOSPHATE HOMEOSTASIS

Plasma phosphate concentration is regulated by the kidney. In the urine, phosphate binds H^+ ions and is eliminated as acid phosphate (a component of titratable acid). Phosphate release from the intracellular stores (mainly bone) is increased by PTH and $1,25(OH)_2D_3$. The proximal tubule reabsorbs approximately 80% of the filtered phosphate load; 10% is reabsorbed by the distal tubule; and 10% is excreted in the urine. Factors that increase the excretion of phosphate include PTH, glucocorticoids, calcitonin, glucagon, volume expansion, dopamine administration, and acidosis. PTH is the main physiologic hormone regulating renal phosphate excretion, and it exerts this effect mainly by the inhibition of the Na^+-P_i cotransporter in the proximal tubule. There are three Na^+-P_i cotransporters: types I, IIa, and IIb. The type IIa cotransporter plays a key role in determining brush border Na^+-P_i cotransport, and thus the overall P_i homeostasis (Mürer et al, 2000). Several genetic defects resulting in isolated renal phosphate wasting include X-linked hypophosphatemic rickets, the autosomal dominant hypophosphatemic rickets without hypercalciuria, and the hereditary hypophosphatemic rickets with hypercalciuria. The X-linked syndrome is caused by mutations in the PHEX gene that indirectly affects the Na^+-P_i cotransporter. Phosphate renal transport is also modulated by changes in dietary intake.

During weeks 26 to 36 of gestation, the mean intrauterine accumulation of inorganic phosphate is close to 75 mg/kg/day (Wharton et al, 1987). At birth, approximately 80% of the phosphorus is in bones (Royer, 1981). During early postnatal life, because of the efficient intestinal absorption and renal retention of phosphate, the neonate is in a positive phosphate balance and presents with elevated plasma concentrations of this anion. The transport rate of Na-Pi is substantially higher in brush-border membrane vesicles obtained from neonates than in those from adults. The high transport capacity is however associated with low adaptability to changes in dietary Pi intake. Of interest, the expression of Na-Pi mRNA in the newborn is similar to or lower than that in the adult, suggesting that the increased protein levels and activity of this cotransporter early in life may be due to posttranscriptional regulation (Spitzer and Barac-Nieto, 2001).

Although fetuses and neonates appear to synthesize PTH in response to hypocalcemia, the phosphaturic response to PTH is attenuated. This phenomenon may be due to decreased sensitivity of the proximal tubule to the hormone. This may reflect homeostatic regulation at a time when phosphate retention is essential for growth. Growth hormone stimulates renal phosphate retention and increases the plasma concentration of phosphate.

REGULATION OF MAGNESIUM HOMEOSTASIS

Magnesium is the second most abundant intracellular cation. It plays a major role in the regulation of protein synthesis and bone formation and regulates potassium and calcium channels in cell membranes. The kidney maintains magnesium balance by excreting in urine the amount of magnesium that is absorbed by the gastrointestinal tract and exceeds that retained for growth. In normal conditions, approximately 3% of the filtered magnesium load is excreted in urine. Magnesium is passively reabsorbed by the proximal tubule and the thick ascending limb. Regulation of magnesium excretion takes place in the thick ascending limb, where approximately 65% of the filtered load is reabsorbed. In this segment, claudin 16, a specific tight junction protein, is necessary for paracellular Mg^{2+} reabsorption. Magnesium reabsorption along the distal convoluted tubule and collecting duct accounts for approximately 10% of the filtered load. Factors that increase magnesium excretion include ECF volume expansion, acidosis, hypercalcemia, and hypermagnesemia. PTH decreases the excretion of magnesium. Most diuretics increase magnesium excretion.

During weeks 26 to 36 of gestation, the mean intrauterine accumulation of magnesium approximates 3.5 mg/kg/day (Wharton et al, 1987). At birth, the urinary excretion of magnesium is low (Chan et al, 1984). Magnesium excretion increases 10-fold during the 1st month of life, reaching values close to 2 mg/kg/day (De Santo et al, 1988). Plasma magnesium levels follow a circadian rhythm, being higher at night (De Santo et al, 1988). Neonatal hypomagnesemia is associated with intrauterine growth restriction, whereas neonatal hypermagnesemia frequently occurs following maternal magnesium administration in the immediate prenatal period. Mutations in the gene encoding the Na^+,K^+-ATPase γ subunit, localized on the basolateral membrane of the distal convoluted tubule, result in magnesium wasting of the so-called isolated renal magnesium wasting syndrome, a rare autosomal dominant disorder.

SUMMARY

Normal renal maturation and adaptive responses at birth play an essential role in the neonate and contribute to the establishment of an intracellular and extracellular milieu necessary for survival and appropriate growth. Renal development and function are regulated by numerous

hormones, paracrine factors, and signaling molecules. Recent advances in the understanding of the molecular basis of renal development and function have provided invaluable insights into the pathophysiology of inherited and acquired renal conditions during development. An understanding of basic principles in renal developmental physiology is essential for successful clinical management of sick preterm and term neonates.

CHAPTER 82

Clinical Evaluation of Renal and Urinary Tract Disease

Carlton M. Bates and Andrew L. Schwaderer

PRENATAL EVALUATION OF RENAL AND URINARY TRACT DISEASE

PRENATAL DIAGNOSIS

Renal anomalies will be frequently encountered in neonatal practice, because they are identified in 0.5% of pregnancies and account for 20% of all anomalies diagnosed with prenatal imaging (Scott, 2002; Scott and Renwick, 1988). Disorders of the renal and urinary tract include a broad spectrum of clinical entities with a wide variation of severity. This variation may result in challenging clinical diagnosis and management scenarios. Thus, an understanding of the clinical evaluation in the prenatal and neonatal periods is an essential component of neonatal clinical practice.

PRENATAL RENAL ULTRASOUND

The primary tool utilized in the diagnosis of disorders of the renal and urinary tract is the prenatal ultrasound. Although the kidneys may be visualized at 10 weeks' gestation, accurate determination of renal anatomy is usually not possible until 16 weeks (Stamilio and Morgan, 1998). Findings on a prenatal ultrasound that suggest renal or urinary tract disease include hydronephrosis, renal cysts, hyperechoic kidneys, renal mass, oligohydramnios, and polyhydramnios. Hydronephrosis (dilation of the renal pelvis) is the most common identified renal anomaly (Dicke et al, 2006). The presence of prenatal hydronephrosis may indicate a variety of renal disorders, including vesicoureteral reflux, upper urinary tract obstruction (ureteropelvic junction obstruction, ureterovesical junction obstruction, and obstructive megaureter), and lower urinary tract obstruction (posterior urethral valves and prune-belly syndrome) (Stamilio and Morgan, 1998; Yiee and Wilcox, 2008). Increasing hydronephrosis is associated with more severe disease, and bilateral hydronephrosis suggests lower urinary tract obstruction, particularly in male fetuses (Yiee and Wilcox, 2008). Prenatal renal cysts can be seen with autosomal dominant polycystic kidney disease (ADPKD), multicystic dysplastic kidneys, and cystic renal dysplasia (Stamilio and Morgan, 1998). Hyperechoic kidneys can result from tubular dilations (autosomal recessive polycystic kidney disease or ARPKD), dysplasia, or multiple microscopic cysts (Bardet-Biedel syndrome, Meckel-Gruber syndrome, and nephrotic syndrome) (Chaumoitre et al, 2006). The etiology of oligohydramnios is not limited to renal disorders; however, its presence can indicate decreased fetal output and renal function (Kemper and Mueller-Wiefel, 2007). Oligohydramnios should prompt an evaluation for severe, bilateral, poorly functioning or absent kidneys as can be seen with renal agenesis, renal dysplasia, ARPKD, and lower urinary tract obstruction (Deshpande and Hennekam, 2008; Kemper and Mueller-Wiefel, 2007). Polyhydramnios is caused by renal anomalies in a small percentage of cases, but can indicate the presence of a renal concentrating defect associated with renal dysplasia, nephrotic syndrome, or inherited renal tubular defects (Cole and Quamme, 2000; Deshpande and Hennekam, 2008; van Eijk et al, 2002). Congenital renal tumors are rare. The most common tumor is the mesoblastic nephroma, which appears as a unilateral, single, solid mass on prenatal ultrasound (Giulian, 1984).

FETAL MAGNETIC RESONANCE IMAGING

An emerging adjunct therapy to ultrasound is fetal magnetic resonance imaging (MRI). The typical indication for fetal urinary tract MRI evaluation is a second- or third-trimester pregnancy with oligohydramnios and an inconclusive prenatal renal ultrasound examination (Poutamo et al, 2000). Fetal MRI lends insight into the evaluation of renal cysts and renal agenesis. Differentiating renal cysts from dilated collecting system is often problematic; the detailed anatomy provided by MRI can help determine if the apparent cysts are limited to the periphery (consistent with cyst) (Figure 82-1) or central in location (consistent with a dilated collecting system) (Hormann et al, 2006). An increase in signal intensity in the renal cortex can differentiate between ARPKD and other polycystic diseases, which have a similar hyperechoic appearance on ultrasound imaging (Liu et al, 2006). When oligohydramnios is present and the kidneys cannot be conclusively identified on ultrasound, MRI is effective at identifying an empty renal pouch, underlying changes (renal dysplasia), or ectopic kidneys (Hormann et al, 2006). In addition to providing more detail of the renal anatomy, MRI studies are also useful in measuring the amniotic fluid, evaluating bladder filling, and assessing lung maturation (Hormann et al, 2006). The aforementioned findings are indirect measures of kidney function that can help define the degree of renal impairment.

AMNIOTIC FLUID AND CHORIONIC VILLUS SAMPLING

The diagnosis of most genetic disease with renal and urinary tract manifestations is based on the characteristic multiorgan findings on imaging. With an increasing number of conditions, analysis of DNA or tissue from amniocentesis or chorionic villus biopsy can be used to confirm a suspected disorder or determine prognosis. Examples are:

1. Molecular testing for the Lamb2 gene, which causes a severe form of infantile nephrotic syndrome, is possible by chorionic villus sampling in fetuses with polyhydramnios and hyperechoic kidneys (Deshpande and Hennekam, 2008).

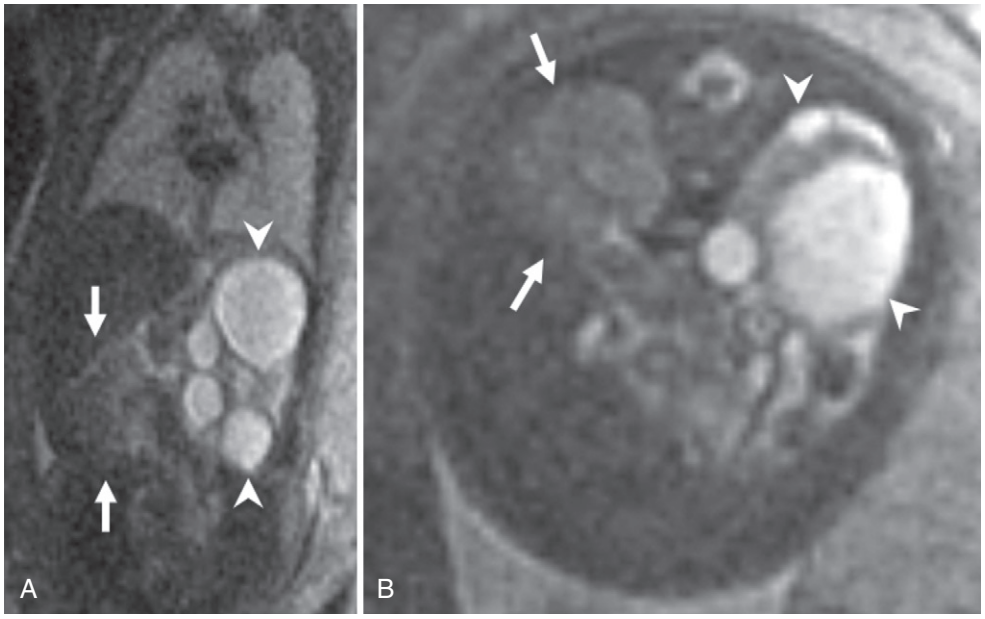

FIGURE 82-1 Coronal **(A)** and axial **(B)** images of the fetal kidneys on T2-weighted MRI. Note the normal right kidney (*arrows*) and large multicystic dysplastic left kidney (*arrowheads*) with the hyperintense peripheral cyst.

2. Fetal karyotyping by amniocentesis or chorionic villus sampling performed when kidney defects occur with anomalies of other organ systems can help identify the precise chromosome anomaly present (Deshpande and Hennekam, 2008).
3. Beckwith-Wiedemann syndrome, which can be associated with Wilms' tumor and other renal anomalies, can be diagnosed by specific 11p methylation studies in amniotic fluid (Deshpande and Hennekam, 2008).
4. Hypotonic fetal urine characterized by a sodium <90 mEq/L, chloride concentration <80 mEq/L, and osmolarity <180 mOsm/L in patients with bilateral hydronephrosis and no evidence of renal dysplasia is associated with a good prognosis, particularly if present on sequential samples taken 48 to 72 hours apart (Johnson et al, 1995; Wu and Johnson, 2009).

PRENATAL MANAGEMENT OF RENAL AND URINARY TRACT DISEASE

GOALS OF MANAGEMENT AND PROGNOSTIC FACTORS

Identification of renal and urinary tract disease on prenatal screening provides the basis for formulating a differential diagnosis, determining prenatal and postnatal risks, and screening for other anomalies. The goals of prenatal intervention include the preservation of renal function and the promotion of lung maturation (Yiee and Wilcox, 2008). Potential management options include parental counseling, follow-up or serial prenatal imaging, postnatal imaging, fetal interventions, and early multispecialty collaboration (Pates and Dashe, 2006; Yiee and Wilcox, 2008). Factors associated with a poor outcome include bilateral involvement of the kidneys and oligohydramnios. If oligohydramnios is severe, the oligohydramnios sequence can occur. This is characterized by pulmonary hypoplasia, "flattened" face, "squashed" nose, and positional limb abnormalities (Deshpande and Hennekam, 2008). When oligohydramnios is present, the prognosis may vary based on the underlying renal diagnosis. Bilateral renal agenesis is considered a lethal disorder, whereas the prognosis is potentially more favorable if the oligohydramnios is secondary to obstruction (Cendron et al, 1994; Kemper and Mueller-Wiefel, 2007; Schwaderer et al, 2007).

INTERVENTIONS

The effectiveness of fetal intervention for hydronephrosis is controversial (Hubert and Palmer, 2007). The primary procedure is placement of a vesicoamniotic shunt with the goal of relieving obstruction (potentially preventing further renal damage) and decreasing oligohydramnios (Wu and Johnson, 2009). This procedure may be considered when bladder outlet obstruction is present, the life of the neonate is at risk, the fetus will likely benefit from bladder decompression, the pregnancy is singleton, and the fetus has a normal karyotype (Hubert and Palmer, 2007). It is a matter of debate whether amnioinfusion prevents or decreases pulmonary hypoplasia. Although some reports have suggested a benefit for oligohydramnios secondary to premature rupture of membranes, prospective data regarding oligohydramnios of renal origin are not yet available (De Carolis et al, 2004; Klaassen et al, 2007).

POSTNATAL EVALUATION OF RENAL AND URINARY TRACT DISEASE

PRENATAL AND PERINATAL HISTORY

As noted earlier, a history of oligohydramnios is often associated with poor urine flow and poor kidney function. Forms that occur in the first trimester (e.g., bilateral renal agenesis or severe dysgenesis) are often associated with poor prognoses, in part from poor pulmonary

development. Other causes, such as obstructive nephropathy, may have a more favorable outcome (Kemper and Mueller-Wiefel, 2007). As noted earlier, polyhydramnios is often idiopathic or secondary to nonrenal problems such as gastrointestinal or central nervous system abnormalities (Deshpande and Hennekam, 2008), but is associated with renal anomalies such as infantile Bartter's syndrome or nephrogenic diabetes insipidus. A large placenta (>25% of birthweight) can be a sign of congenital nephrotic syndrome (Holmberg et al, 1996). Hypoxia/ischemia (e.g., perinatal anoxia, placental abruption), toxin exposure (e.g., pre- or perinatal use of nonsteroidal antiinflammatory agents, aminoglycosides), and shock (e.g., blood loss, sepsis) increase the risk of acute kidney injury (which has an incidence of more than 20 per 100,000 neonatal patients) (Andreoli, 2004; Askenazi et al, 2009).

FAMILY HISTORY

Renal agenesis or severe dysgenesis in parents or siblings increases the risks of congenital kidney disease in newborn patients (Roodhooft et al, 1984; Schwaderer et al, 2007). Some forms of polycystic kidney disease (PKD), vesicoureteral reflux, and medullary cystic kidney disease follow autosomal dominant inheritance patterns; thus, screening should be considered in neonates whose parents have these disorders. Appropriate screening would be indicated in neonates whose siblings have autosomal recessive diseases (e.g., autosomal recessive PKD, cystinosis) or X-linked diseases (e.g., Alport's disease or Lowe syndrome).

PHYSICAL EXAM

Hypertension

As discussed in Chapters 86 and 88, increased blood pressure in the neonatal period is frequently secondary to renovascular and/or parenchymal disorders and should receive appropriate evaluation.

Micturition

Frequently, healthy neonates will not void until 12 hours or later after birth, although nearly all will produce some urine by 24 hours (Clark, 1977). Once voiding commences, it almost never occurs during sleep in term infants, whereas 60% of preterm infants will void when asleep; furthermore, both term and preterm neonates tend to void frequently (often hourly) with quite variable volumes (Sillen, 2001; Sillen and Hjalmas, 2004). Delayed voiding (beyond 24 hours after birth) is often seen after stressful deliveries and has been correlated with enhanced arginine vasopressin and aldosterone secretion (Vuohelainen et al, 2008). Prolonged absence of urine formation should prompt evaluation for acute kidney injury or structural kidney or urinary tract disease.

Abdominal Masses

Palpation of the abdomen for masses is best performed within the first few days after birth, during which there is relative hypotonia of the abdominal musculature (Perlman and Williams, 1976). Palpable abdominal masses, particularly flank masses, in neonates most often originate from the urinary tract (Chandler and Gauderer, 2004). Among three studies that each enrolled more than 10,000 newborn infants, the incidence of renal/urinary tract anomalies detected by deep palpation ranged from 0.2% to 0.6%. The most common urinary tract anomalies detected as abdominal masses are hydronephrotic kidneys, followed by multicystic dysplastic kidneys (Chandler and Gauderer, 2004). Bilateral flank masses may be palpated in patients with ARPKD. Although less common, tumors of renal origin are most often congenital mesoblastic nephromas (usually benign) as opposed to Wilms' tumors, which are most often diagnosed after 6 months of age (Chandler and Gauderer, 2004; Glick et al, 2004). Once an abdominal mass is palpated, imaging such as an abdominal ultrasound or MRI should be obtained (see Imaging, later).

Edema

Edema occurs when there is an imbalance between capillary hydrostatic and interstitial oncotic forces. Neonatal edema is more commonly seen in preterm infants than in term infants and is often transient, resolving a few days after birth (Cartlidge and Rutter, 1986; Griffiths, 1959; Hahn et al, 1997). Most cases of persistent, pathologic edema are extrarenal in origin. The major renal causes include total body fluid overload secondary to a decrease in glomerular filtration rate (GFR) (from acute or chronic renal injury) and low intravascular oncotic pressure from urinary protein losses (from congenital nephrotic syndrome—see Proteinuria, later).

Ascites

As with edema, ascites can arise as an imbalance between hydrostatic and oncotic pressures, but it can also occur secondary to decreased lymphatic drainage. Although neonatal ascites is somewhat rare, urinary tract abnormalities account for a significant number of cases (Aslam et al, 2007; Griscom et al, 1977). The most common urinary tract cause is urinary ascites from perforation of the ureter, renal pelvis, or bladder from obstruction (e.g., posterior urethral valves). Less common conditions leading to ascites are congenital nephrotic syndrome and renal vein thrombosis.

LABORATORY TESTS

Serum Estimates of Glomerular Filtration Rate

Absolute and relative (corrected for body surface area) GFR is much lower in newborns than older children and adults; at day 1 of life, GFR may be as low as 30 mL/min/1.73 m^2 in term infants (and even lower in preterm infants), rising to about 50 mL/min/1.73 m^2 by 1 month of life and 75 mL/min/1.73m^2 by 2 months of life (Arant, 1987; Chevalier, 1996). Because of technical difficulties with 24-hour urine collections for clearance measurements and/or the use of exogenous agents that are freely filtered at the glomerulus,

most often assays of endogenous serum molecules are used to estimate GFR in neonates. Although concentration of cystatin C has been proposed in more recent times as a good way to approximate kidney function (Finney et al, 2000), serum creatinine still remains the most widely used assay. As in adults, serum creatinine is both filtered and secreted in the kidney; however, creatinine also appears to be reabsorbed within the tubules of immature kidneys (with more reabsorption in preterm infants) (Guignard and Drukker, 1999). This likely accounts for the delay in the drop in creatinine level that occurs from the time of birth (at which time serum creatinine reflects the mother's level) until about 7 to 10 days after birth in term infants and which may extend to 3 weeks in preterm infants (tubular reabsorption may also explain creatinine levels slightly greater than the mother's in many preterm infants just after birth). In one study, term infants had a mean serum creatinine of 0.85 ± 0.43 mg/dL at 2 days of age, 0.57 ± 0.40 mg/dL at 7 days of age, and 0.42 ± 0.23 mg/dL at 14 days of age (Rudd et al, 1983). In 28 weeks' gestation preterm infants, the same study reported serum creatinine measurements of 1.31 ± 0.45 mg/dL at 2 days of age, 0.95 ± 0.36 mg/dL at 7 days of age, and 0.81 ± 0.36 mg/dL at 14 days of age. Blood urea nitrogen concentration is also often used as another indirect measure of kidney function, but is less reliable than creatinine because of alterations based on protein intake and hydration status.

Other Serum Chemistry Studies

In addition to GFR, renal tubular function often differs in the neonatal kidney from that of adults, and recently, many of the reasons for the differences between neonatal and adult tubular function have been further clarified. Acidification differs with normal serum bicarbonate levels in the term neonate ranging from 19 to 21 mEq/L and in the preterm infant ranging from 16 to 20 mEq/L (Shaw, 2008). The lower serum bicarbonate is due to a lower threshold at the proximal tubule; the lowered threshold is likely due to the presence of different acid transporter isoforms in maturing kidneys versus adult kidneys as well as to hormonal influences on the abundance and activity of these transporters (Baum, 2008; Baum and Quigley, 1995). Serum potassium is less well excreted in the collecting ducts of neonates compared to older children and adults, with normal newborn levels up to 6.7 mmol/L (Lorenz, 1997). This physiologic increase in potassium (to accommodate vigorous growth over the 1st year of life) is due to a paucity of aldosterone-sensitive secretory potassium channels and an abundance of potassium-reabsorbing transporters on the luminal surface of collecting ducts (Gurkan et al, 2007). Sodium must remain in positive balance for rapidly growing neonates (despite a diet that is typically low in sodium). The ability to excrete less sodium chloride appears to be due to differences in expression of sodium/proton antiporter isoforms and tight junction proteins, called claudins, in neonates versus adults and older children (Baum, 2008; Baum and Quigley, 2004). Serum phosphate levels are also typically higher in newborn infants with serum levels ranging from 5.8 to 9.3 mg/dL on the 1st day of life (with the higher levels typically in preterm infants (Barac-Nieto, 2001; Hellstern et al, 2003; Spitzer and Barac-Nieto, 2001). This physiologic increase in serum phosphate levels compared with older humans (again, to accommodate rapid growth) is due to enhanced capacity of sodium phosphate transport at the proximal tubule in neonates (Spitzer and Barac-Nieto, 2001).

Urine

Urinary Tract Infection

Most frequently urine collections in newborn infants are performed because of suspected urinary tract infection (UTI). Evidence-based guidelines were published regarding evaluation for UTI in patients from 2 months to 2 years of age (American Academy of Pediatrics, 1999). Some of these guidelines indicated that UTI should be considered in all patients with unexplained fever, which is best assessed with a urine culture. Although suprapubic aspiration (SPA) or transurethral catheterization (TUC) is highly recommended, for patients who do not appear to be "so ill as to require immediate antimicrobial therapy" one could consider using a bagged urine collection for a urine analysis and then following up with an SPA or TUC urine culture if the urine analysis or clinical course suggests UTI. For patients under 2 months of age with suspected UTI, one should always collect urine via SPA or TUC for culture.

Concentrating/Diluting

Compared with adults, newborn infants also have a diminished capacity to concentrate their urine based on relative insensitivity to antidiuretic hormone and a less hypertonic medulla due to less sodium chloride and urea transport (Bonilla-Felix, 2004; Quigley et al, 2001). Neonates have less ability to dilute their urine compared with adults and older children, although they can handle the typically hypotonic fluids they receive for nutrition.

Proteinuria

Physiologic and pathologic proteinuria can be seen in newborn infants, particularly in preterm and/or low birthweight infants. Normal preterm and term infants have an average 182 mg/m^2/day and 145 mg/m^2/day of total urine protein, respectively, compared with 91 mg/m^2/day in children 2 to 4 years of age (Loghman-Adham, 1998). A recent study also found that very low birthweight infants had a higher risk of pathologic albuminuria (albumin/creatinine ratio >20 mg/g) than normal infants, particularly in those who developed hypotension after birth (Iacobelli et al, 2007). Another study showed that preterm infants were more likely to develop pathologic tubular proteinuria (α1 microglobulin/creatinine ratio >10 mg/mmol) than term infants (Ojala et al, 2006). Low gestational age enhanced the risk of early tubular proteinuria, the highest α1 microglobulin/creatinine ratios, and delayed normalization of proteinuria.

A more rare but serious pathologic finding is congenital nephrotic syndrome, defined as high-grade proteinuria, low serum albumin, and edema within the 1st year of life. The differential diagnosis includes primary/genetic causes (e.g., Finnish type nephrotic syndrome and diffuse mesangial sclerosis) and secondary causes such as infections (e.g., cytomegalovirus, syphilis, hepatitis), genetic

syndromes (e.g., Denys-Drash, Frasier syndrome), toxins/drugs, hemolytic uremic syndrome, systemic lupus erythematosus, and nephroblastoma (Papez and Smoyer, 2004). Unlike nephrotic syndrome in later childhood, congenital nephrotic syndrome usually portends a poor prognosis, including end-stage renal failure (with the exception of some infectious forms that respond to appropriate therapy). Interestingly, a recent study found that two thirds of all cases of primary/genetic congenital nephrotic syndrome were caused by mutations in 1 of 4 genes, encoding for nephrin (major cause of Finnish type), podocin, Wilms' tumor suppressor gene 1 (found in Denys-Drash, Frasier syndrome), and laminin β2 (a cause of diffuse mesangial sclerosis) (Hinkes et al, 2007).

Other Urinary Findings (Hematuria, Hemoglobinuria, Myoglobinuria, Uricosuria)

Hematuria is a rare finding in neonates and, when present, has a wide differential diagnosis including renal vein thrombosis, polycystic kidney disease, obstructive nephropathy, tumor, congenital malformations, UTI, and acute kidney injury (Emanuel and Aronson, 1974). Hemoglobinuria, another rare finding in newborn infants, occurs secondary to intravascular hemolysis, of which the most common etiology is ABO blood group incompatibility (Murray and Roberts, 2007). Myoglobinuria is even more rarely detected in neonates, but has been reported secondary to rhabdomyolysis from asphyxia and shock (Sirota et al, 1988). Finally, pink or red uric acid crystals are often seen in diapers of otherwise healthy newborn infants; although this has been reported to be a consequence of high urine uric acid levels in normal newborn infants, a recent study challenges that contention (Kupeli et al, 2005).

IMAGING

Renal Ultrasound Examination

The primary indications for renal ultrasound imaging in the neonatal period include a palpable abdominal mass, hypertension, renal failure, and suspected malformations of the renal and urinary tract (McInnis et al, 1982). The neonatal presentation of a renal mass or renal failure is often suggested by the prenatal evaluation (Riccabona, 2006). An abdominal mass of renal etiology might appear as large kidneys, hydronephrotic kidneys, or a renal tumor. Renal ultrasound can be useful to distinguish among intrinsic, prerenal, and postrenal failure. Regarding intrinsic causes of renal failure, neonatal nephrotic syndrome and glomerulonephritis will manifest as large echogenic kidneys; renal vein thrombosis will present as large echogenic kidneys with renal vein color signal missing on veins with thrombosis and increased resistive indices on a duplex exam; and congenital dysplasia will present as small echogenic kidneys (Riccabona, 2006). Postrenal failure is characterized by hydronephrosis, and prerenal failure by echogenic kidneys with decreased flow velocities with elevated resistive index values on duplex exam (Riccabona, 2006). Ultrasound imaging has been recommended as a noninvasive study that should be obtained in all hypertensive infants because it may potentially identify correctable causes of the hypertension, including renal vein thrombosis, aortic/renal artery thrombi, or anatomic renal abnormalities (Flynn, 2000). If a renal ultrasound is planned for follow-up evaluation of prenatal hydronephrosis, it is advantageous to wait until day 3 of life because the initial period of neonatal oliguria might mask renal collecting system dilation (Kennedy, 2002).

Computed Tomography Scan

The risk of ionizing radiation injury from CT is higher in neonates secondary to more radiosensitive tissues and longer life expectancies (Brenner et al, 2001). Further, the CT evaluation of the kidney is limited by reduced contrast uptake by the renal parenchyma (Olsen and Gunny, 2006). Because of the aforementioned factors, CT has limited use in the evaluation of the renal and urinary tract during the neonatal period. Nonetheless, CT does have a role when ultrasound results are inconclusive for complex anomalies of the kidney, abdominal masses, and suspected renal vascular anomalies and when MRI would be problematic because of sedation risk or in the presence of a contraindication to MRI contrast (Gnanasambandam and Olsen, 2006; Grobner and Prischl, 2007; Olsen and Gunny, 2006;).

Magnetic Resonance Imaging

MRI has several advantages in imaging the neonatal kidney and urinary tract. The absence of radiation and detailed anatomy of soft tissue with MRI make it an attractive tool to clearly define normal and abnormal renal anatomy when ultrasound is insufficient. However, MRI has disadvantages because sedation is necessary for infants (Michael, 2008). The risk of MRI contrast (gadolinium)-associated nephrogenic systemic fibrosis in the immature neonatal kidney and gadolinium depositions in the bone marrow are concerns (Michael, 2008). Applications in which MRI is particularly useful include the identification of a suspected ectopic or dysplastic kidney and the identification of renal vascular causes of hypertension in neonates unable to tolerate angiography (Michael, 2008; Mustafa et al, 2006).

Voiding Cystourethrography

Voiding cystourethrography (VCUG) is utilized to evaluate for lower urinary tract obstruction and vesicoureteral reflux. In males, a fluoroscopic as opposed to a nuclear medicine VCUG should be used, because the anatomic details of the male urethra warrant a complete evaluation (Kennedy, 2002).

Nuclear Medicine

The use of nuclear medicine is limited in neonatal practice. Two studies that might be occasionally used include DMSA cortical scintigraphy and the DTPA or MAG3 diuretic renogram. Cortical DMSA cortical scintigraphy can be used to evaluate left and right relative renal function and for evaluation of acute pyelonephritis (Piepsz and Ham, 2006). The diuretic renogram is indicated to evaluate for upper urinary tract obstruction when fetal hydronephrosis has persisted and vesicoureteral reflux has been excluded (Kennedy, 2002; Piepsz and Ham, 2006). It may also be used to identify ectopic renal tissue (Piepsz and Ham, 2006).

SUMMARY

Structural abnormalities are common causes of kidney and urinary tract disorders in the perinatal period of life. Thus, imaging modalities such as renal ultrasonography remain very useful tools in evaluating patients with suspected kidney and/or urinary tract disease. A careful history and physical exam will also offer insights into the underlying causes of kidney and urinary tract disorders. Finally, compared with older children and adults, the neonatal kidney is less efficient at clearance and has reduced tubular function (acidification, potassium secretion, sodium transport), except for phosphate, which is reabsorbed more efficiently in the very young.

CHAPTER 83

Developmental Abnormalities of the Kidneys

Lawrence Copelovitch and Bernard S. Kaplan

The increasing use of prenatal ultrasonography, continuing improvements in ventilator and nutritional support, and progress in dialysis techniques for newborns and in renal transplantation for young children have changed the natural history of cystic and dysplastic kidney diseases. Information gathered from many sources must be evaluated carefully to manage optimally a newborn with a genetic or developmental disorder of the kidneys. Clearly a team approach is needed. Errors occur with insufficient data, inadequate communication, and poor understanding of the natural history of these disorders. Renal tract malformations are, collectively, the major cause of childhood end-stage renal disease, and their contribution to the number of adults on renal replacement therapy is less clear and has possibly been underestimated (Kerecuk et al, 2008). Many newborns who might have died in the past can now be dialyzed from birth and then transplanted when they reach about 10 kg. A precise diagnosis must be made before starting dialysis because some of these problems impose enormous emotional and financial burdens on families. The diagnosis depends on the evaluation of the prenatal history, results of fetal ultrasonography, family history, clinical examination, imaging studies of infants and parents when indicated, laboratory studies (including DNA tests if available), and interpretation of pathology. Several guiding principles are worth keeping in mind. Few genetic renal disorders are confined to kidneys, and many syndromes have renal involvement. Therefore, ultrasonography of kidneys and urinary tract should be done in all newborns with multiple defects. Also, ultrasonographic features can change over time, and in some cases may give erroneous information (Mashiach et al, 2005). Variable expression of congenital renal defects may occur within and among kindreds; this is particularly true in autosomal recessive polycystic kidney disease. There are many classifications of cystic and dysplastic kidneys, but the one shown in Box 83-1 lists conditions that can be seen in newborns.

ECTOPIC KIDNEY, HORSESHOE KIDNEY, AND CROSSED FUSED ECTOPIA

Ectopic kidney, horseshoe kidney, and crossed fused ectopia are abnormalities in the position of the kidney(s), They do not have important long-term effects unless associated with lower urinary tract anomalies, such as reflux or obstruction. In essence, these kidneys are at risk for the same problems as those in normal positions. Horseshoe kidney, however, does occur with increased frequency in Turner and other syndromes. A voiding cystourethrogram should be done to exclude the possibility of reflux, and a technetium-99m–labeled diethylenetriaminepentaacetic acid (DTPA) scan should be done if there is evidence on ultrasonography of an obstruction.

MULTICYSTIC KIDNEY

Multicystic kidney is the second most common cause of a flank mass in the newborn with a prevalence rate of 1 in 4300. Multicystic kidney is almost always a sporadic, nonsyndromal, congenital anomaly. The diagnosis is made by in utero ultrasonography or by detection of an abdominal

BOX 83-1 Cystic and Dysplastic Kidneys in Newborns

- Ectopic kidney, horseshoe kidney, crossed fused ectopia
- Multicystic kidney
- Unilateral renal agenesis
- Bilateral renal agenesis
- Renal adysplasia/dysplasia
  - Isolated adysplasia/dysplasia
  - Hypoplastic kidneys
  - Dysplasia/adysplasia in regional defects
    - Prune-belly syndrome (PBS) [McKusick #100100]
    - Posterior urethral valves (PUV) [McKusick #100100]
  - Adysplasia/dysplasia with multiple-congenital-abnormalities syndromes
    - Branchio-oto-renal dysplasia (BOR syndrome) [McKusick #113650]
    - Mayer-Rokitansky-Küster-Hauser syndrome
    - Kallmann's syndrome (KAL1) [McKusick #308700]
  - Acrorenal syndromes
  - Ectodermal dysplasia, ectrodactyly, cleft lip/palate syndrome
    - Fanconi's pancytopenia syndrome
    - Thrombocytopenia-absent radius syndrome
    - Townes-Brocks syndrome (TBS) [McKusick #107480]
    - Fraser syndrome [McKusick #219000]
    - Fryns syndrome
    - Pallister-Hall syndrome [McKusick #146510]
- Polycystic kidneys
  - Autosomal recessive polycystic kidney disease [McKusick #263200]
  - Autosomal dominant polycystic kidney disease [McKusick #179300]
  - Tuberous sclerosis (TS) [McKusick #191100]
- Cystic kidneys with autosomal recessive inheritance
  - Meckel's syndrome (MKS 1, MKS 2) [McKusick #249000]
  - Jeune asphyxiating thoracic dystrophy syndrome [McKusick #208500]
  - Renal-hepatic-pancreatic dysplasia (Ivemark's syndrome)
- Glomerulocystic kidneys
- Dysgenetic kidneys
  - Congenital hypernephronic nephromegaly with tubular dysgenesis [McKusick #267430]
- Overgrowth syndromes
  - Beckwith-Wiedemann syndrome [McKusick #130650]
  - Perlman syndrome [McKusick #267000]
  - Simpson-Golabi-Behmel syndrome type 1 (SGBS1) [McKusick #312870]
- In utero exposure to teratogens
  - Anticonvulsants; cocaine; indomethacin; lead; phenacetin; salicylate; warfarin; gentamicin
- Inborn errors of metabolism
  - Glutaric aciduria type II (multiple acyl-CoA dehydrogenase deficiencies)
  - Zellweger cerebrohepatorenal syndrome [McKusick #214100]
  - Carbohydrate-deficient glycoprotein syndrome

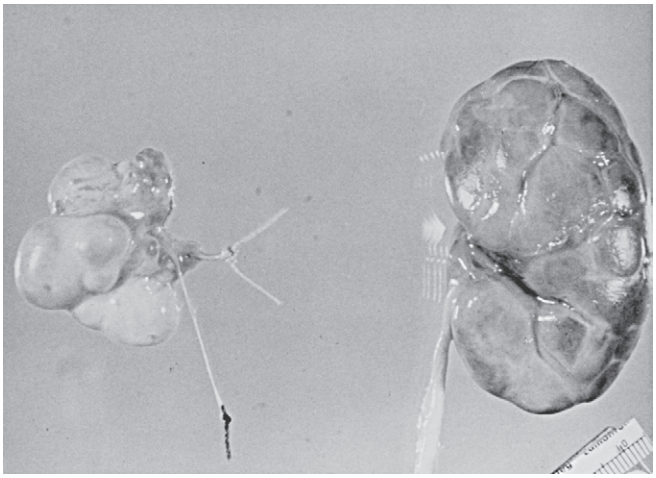

FIGURE 83-1 Multicystic kidney with atretic ureter (*right*). Large cysts with no normal renal tissue.

mass. Multicystic kidney is rarely the cause of symptoms in the newborn. Pathologic findings are ureteropelvic dysplasia or atresia, enlarged kidney, cysts of varying size that do not communicate, and no demonstrable pelvis or calyces (Figure 83-1) (Bernstein, 1991). Multicystic kidney must be differentiated from obstructive cystic renal dysplasia associated with hydronephrosis and other causes of obstructive uropathy by doing a DTPA scan. The multicystic kidney does not function. The contralateral kidney is usually normal, but in up to 33% to 50% of cases it may be absent, hydronephrotic, ectopic, refluxing, and occasionally dysplastic (Ativeh et al, 1992; Schreuder et al, 2009). Reflux may be present in up to 20% of contralateral kidneys, 40% of which are grade 3 or higher. Compensatory hypertrophy of the contralateral kidney is a common finding in childhood (Schreuder et al, 2009). Nephrectomy of the multicystic dysplastic kidney in typical cases is unnecessary (Kuwertz-Broeking et al, 2004). There may be a spectrum, within and among kindreds, of calyceal diverticulum, pyelogenous cyst, ureteropelvic junction stenosis, infundibular stenosis, pelvic stenosis, and multicystic kidney (Kelalis and Malek, 1981). Most patients are followed by ultrasonography, and spontaneous involution often occurs without complications of infection, bleeding, hypertension, or malignancy (Wacksman and Phipps, 1993).

RENAL ADYSPLASIA AND DYSPLASIA

The term *adysplasia* encompasses a spectrum of renal anomalies that include renal agenesis, hypoplasia, dysplasia, and hypodysplasia that occur in a patient (such as unilateral agenesis with contralateral dysplasia) or within a kindred (Buchta et al, 1973). Dysplastic kidneys can be unilateral or bilateral, often contain cysts, are disorganized, and may also contain ectopic cartilage and muscle. They may or may not function. The clinical picture depends on the severity of the renal anomaly, whether it is unilateral or bilateral, and the presence of associated anomalies (Fitch, 1977). The newborn may look normal or may have features of the oligohydramnios sequence, prune-belly syndrome, or malformation syndromes.

Adysplasia and dysplasia can be the result of a single autosomal recessive (Cole et al, 1976) or dominant gene disorder (McPherson et al, 1981). Absent or dysplastic kidneys can also occur by multifactorial inheritance (Holmes, 1989), in chromosomal disorders (Egli and Stalder, 1973), and as a consequence of in utero infections or exposure to toxins. The precise genetics of isolated renal adysplasia remain elusive. Mutations in the SIX6 and BMP4 genes are associated with hypodysplasia (Weber, 2008). Occasionally, PAX2, TCF2, and SALL1 mutations result in isolated adysplasia (Weber, 2006), although they usually occur as part of a global syndrome (see later discussion). Prenatal diagnosis by ultrasonography is possible, especially if there is oligohydramnios or associated anomalies such as limb defects.

UNILATERAL RENAL AGENESIS

Unilateral renal agenesis is usually an isolated (nonsyndromic), sporadic abnormality that is detected during prenatal ultrasonography. Unilateral renal agenesis is an important finding if the solitary kidney is abnormal, is part of a syndrome, or is an expression of hereditary renal dysplasia (Moerman et al, 1994). The incidence is between 1 in 500 and 1 in 800 live births. If the solitary kidney is normal, there is little risk of chronic renal failure in adulthood. The newborn must be examined carefully for additional anomalies—cleft palate, ocular abnormalities, preauricular pits, abnormalities of digits, cardiac and vertebral defects, and mullerian duct aplasia (Tarry et al, 1986). A voiding cystourethrogram should be done to exclude reflux. No further evaluations are needed beyond 1 year of age if renal ultrasonography shows that the kidney is growing normally with appropriate compensatory hypertrophy.

BILATERAL RENAL AGENESIS

Bilateral renal agenesis can occur as an isolated (nonsyndromal), sporadic abnormality detected during prenatal ultrasonography. It can also be a component of a syndrome such as the branchio-oto–renal dysplasia (BOR) syndrome, or an expression of hereditary renal adysplasia. There can be variable expression within a family, and both autosomal recessive and dominant inheritance occur. The incidence is about 1 in 3000 births. Bilateral renal agenesis is an important cause of the oligohydramnios sequence (Potter's syndrome), in which decreased amniotic fluid causes uterine compression of the fetus. This produces the Potter facies with wide-set eyes, a prominent skin fold that extends from medial canthus to cheek, a parrot-beak nose, pliable low-set ears, and receding chin. There are also lower limb deformations and, most importantly, a narrow, small chest with pulmonary hypoplasia. The infant is anuric and dies from pulmonary insufficiency. Bilateral renal agenesis is the most important cause of oligohydramnios, and the diagnosis can be confirmed by prenatal ultrasonography.

ISOLATED DYSPLASIA AND ADYSPLASIA

The incidence of isolated (nonsyndromic) bilateral renal dysplasia is about 15 per 100,000 newborns (Holmes, 1989). Modes of transmission are autosomal dominant

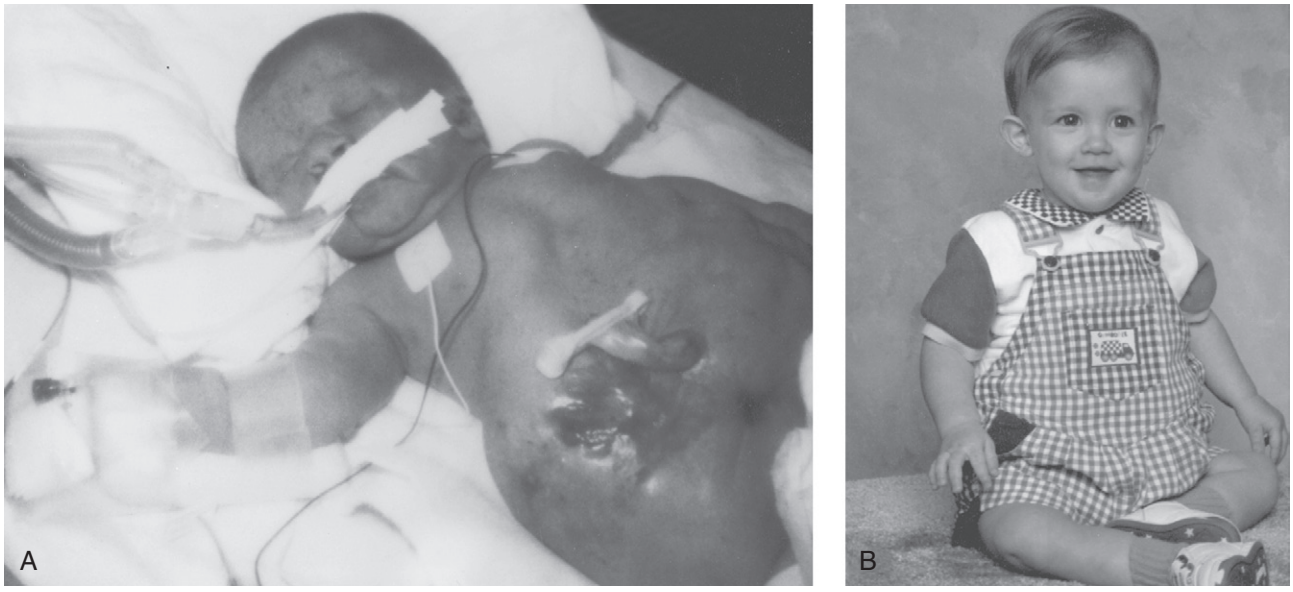

FIGURE 83-2 **A,** Newborn with prune-belly syndrome. The abdomen is protuberant, and the outlines of intestines can be seen. The right ureter ruptured into the amniotic sac, thereby preventing development of features of the oligohydramnios sequence. **B,** The same patient at age 19 months.

inheritance with reduced penetrance and multifactorial inheritance. A parent and/or siblings may be unaffected, have unilateral dysplasia, or have unilateral agenesis. Sporadic adysplasia may be caused by a new mutation or inheritance of gene(s) from a nonmanifesting parent. First-degree relatives should be screened by ultrasonography to provide genetic counseling. The empiric risk of bilateral renal adysplasia for future siblings is 3.5% (Carter, 1970). The recurrence risk increases if two siblings are affected.

HYPODYSPLASIA

Hypoplastic kidneys are small, have fewer calyces, and may be dysplastic. Simple hypoplasia, oligomeganephronia, and renal dysplasia are the types of small kidneys that are seen in newborns. In older children, small kidneys may also be the result of chronic pyelonephritis, chronic glomerulonephritis, renovascular accident, or nephronophthisis. In simple hypoplasia, the renal architecture is normal, but there are a decreased number of reniculi and small nephrons. Oligomeganephronic kidneys are small and have a decreased number of enlarged glomeruli (Royer et al, 1974). This is probably not a specific clinicopathologic entity. Some patients with oligomeganephronic kidneys have chromosome 4 abnormalities (Anderson et al; 1997), and others have heterozygous PAX2 mutations (Salomon et al, 2001).

DYSPLASIA AND ADYSPLASIA IN REGIONAL DEFECTS: PRUNE-BELLY SYNDROME [McKUSICK #100100] AND POSTERIOR URETHRAL VALVES [McKUSICK #100100]

Renal adysplasia occurs in prune belly syndrome (PBS) and posterior urethral valves (PUV), possibly as a result of obstructive uropathy (Bernstein, 1991). The renal pathology ranges from minor anomalies to severe dysplasia with and without cysts. The features of PBS are deficient abdominal wall muscles (Figure 83-2), unilateral or bilateral undescended testes, and urinary tract abnormalities. Females are rarely affected but may have uterine or vaginal anomalies. PBS is also associated with lower intestinal tract malrotation and atresias, lower limb deformations, and cardiovascular defects.

PUV are characterized by urethral valves (either a flap valve or a diaphragm in the prostatic urethra) and features of obstructive uropathy. A dilated prostatic urethra, megacystis, and megaureters can occur in both conditions. The most frequent clinical presentation in the newborn of both conditions consists of features of the oligohydramnios sequence. The survival of newborns with PBS or PUV depends on the severity of pulmonary hypoplasia and severity of renal dysplasia. Both conditions are usually isolated occurrences, although PUV may occur rarely in families and in malformation syndromes.

DYSPLASIA AND ADYSPLASIA WITH MULTIPLE CONGENITAL ANOMALIES

Branchio-oto–renal Dysplasia [McKusick #113650]

The spectrum of renal anomalies in BOR syndrome ranges from unilateral dysplasia to bilateral agenesis. The kidneys may even be normal. Renal function ranges from normal to severe reduction in glomerular filtration rate. Extrarenal manifestations include preauricular pits, branchial clefts, sensorineural deafness, and lacrimal duct atresia. The incidence is 1 in 40,000 newborns. Inheritance is autosomal dominant with high penetrance and variable expression. Mutations in the EYA1 (chromosomal locus 8q13.3), SIX1 (chromosomal locus 14q23.1), and SIX5 (chromosomal locus 19q13.32) genes have been found to be causative (Abdelhak et al, 1997; Hoskins et al, 2007; Kumar et al, 1997; Ruf et al, 2004). The prognosis depends on the severity of the renal disorder.

Renal-Coloboma Syndrome [OMIM 120330]

Renal anomalies in this syndrome include hypoplasia, dysplasia, oligomeganephronia, agenesis, and vesicoureteral reflux. Renal hypoplasia is the most common abnormality. The degree of renal insufficiency is highly variable. Extrarenal manifestations include optic nerve coloboma, sensorineural deafness, joint laxity, mental retardation, and skin anomalies. Heterozygous mutations in the PAX2 gene located on 10q24-25 arising either sporadically or inherited in an autosomal dominant fashion are known to be causative (Sanyanusin, 1995). The PAX2 gene encodes a transcriptional factor that is a member of the paired-box family of homeotic genes that is central to urogenital development.

Hypoparathyroidism-Deafness–Renal Dysplasia Syndrome [OMIM 146255]

Renal manifestations include renal agenesis, renal hypoplasia, renal dysplasia, and vesicoureteral reflux. Extrarenal manifestations include hypoparathyroidism and sensorineural deafness. The degree of hypocalcemia, hearing loss, and renal abnormalities varies. Mutations in the *GATA3* gene on chromosome 10p15 encoding the transacting T-cell-specific transcription factor GATA-3 are causative (Van Esch, 2001). A contiguous gene syndrome with features of a DiGeorge-like phenotype (heart defects and immunodeficiency) and the hypoparathyroidism-deafness–renal dysplasia triad has been reported with terminal chromosome 10p deletions (Daw, 1996).

Mayer-Rokitansky-Kuster-Hauser Syndrome

Females with this syndrome have renal adysplasia and mullerian anomalies of vaginal atresia and bicornuate or septated uterus (Tarry et al, 1986). The fallopian tubes, ovaries, and broad and round ligaments are normal. There is a normal female karyotype and normal secondary sexual development. Rarely, this genetically heterogeneous condition has been associated with mutations in the *WNT4* gene located on chromosome 1p36.12 encoding a member of the frizzled family of seven transmembrane receptors (Philibert et al, 2008).

Kallmann's Syndrome (KAL1) (Hypogonadotropic Hypogonadism and Anosmia) [McKusick #308700]

Males with KAL1 have hypogonadotropic hypogonadism that manifests with delayed puberty and infertility; anosmia caused by agenesis of the olfactory lobes; and renal abnormalities (Colquhoun-Kerr et al, 1999; Deeb et al, 2001; Dissaneevate et al, 1998; Hardelin et al, 1992). Urogenital abnormalities include unilateral renal agenesis, bilateral renal agenesis, multicystic dysplastic kidney, cryptorchidism, testicular atrophy, and micropenis. Males may die at birth as a result of bilateral renal agenesis. Additional features include coloboma of iris, deafness, midline anomalies, oculomotor apraxia (bimanual synkinesis), and Moebius anomalad. The X-linked form is the result of a mutation in the *KAL-1* gene on Xp22.3 encoding the extracellular matrix glycoprotein anosmin-1. The autosomal recessive and dominant forms of Kallman's syndrome are not associated with renal adysplasia. Treatment with testosterone or estrogen for induction of puberty induces appropriate pubertal development.

Acrorenal Syndromes

Radial and renal anomalies occur in many syndromes. In the ectodermal dysplasia-ectrodactyly-cleft lip and/or palate (EEC 1) syndrome [McKusick #128930] there are combinations of urogenital defects, ectrodactyly, ectodermal dysplasia, clefting, lacrimal duct anomalies, and conductive hearing loss (Maas et al, 1996; Roelfsema and Cobben, 1996). Inheritance is autosomal dominant, with variable penetrance and expression. In the VACTERL /VATER association [McKusick #192350] there is variable occurrence of vertebral anomalies, anal atresia, congenital cardiac disease, tracheoesophageal fistula, renal abnormalities, and radial-limb dysplasia. VACTERL is usually sporadic. Neonates with features of VACTERL must be tested for Fanconi's anemia. Congenital malformations occur in 60% of cases of Fanconi anemia (pancytopenia) syndrome (FA). Affected patients may have renal malformations, short stature, café-au-lait spots, radial-ray abnormalities, gastrointestinal, microcephaly, skeletal abnormalities, and, in males, genital anomalies, hypogonadism, and infertility (Giampietro et al, 1993). There is chromosomal instability and mutagen hypersensitivity in cells. Inheritance is autosomal recessive with variable expression and mutations in one of at least seven different genes (Joenje and Patel, 2001). Renal anomalies may occur in thrombocytopenia absent radius syndrome (TAR) [McKusick #274000] and the omphalocele, exstrophy of the cloaca, imperforate anus, and spinal defects (OEIS) complex [OMIM 258040] (Lizcano-Gil, 1995).

The clinical features of Townes-Brocks radial-ear-anal-renal syndrome (TBS) [McKusick #107480] include broad, bifid, or triphalangeal thumb; flat thenar eminences; small, "lop," or "satyr" external ear; preauricular pits or tags; sensorineural hearing loss; and imperforate or stenotic or anteriorly placed anus. Renal and urological anomalies encompass renal hypoplasia, renal dysplasia, unilateral renal agenesis, horseshoe kidney, posterior urethral valves, ureterovesical reflux, and meatal stenosis (Salerno et al, 2000). Inheritance is dominant with a defect in the gene encoding SALL-1 on chromosome 16q12.1. Renal anomalies can occur in association with numerous other abnormalities in Wolf-Hirschhorn syndrome (4p- syndrome) [McKusick #194190] (Grisaru et al, 2000), Fraser syndrome [McKusick #219000] (Schauer et al, 1990), Fryns syndrome [McKusick #229850] (Moerman et al, 1988), De Lange syndrome (Kroes, 2004), Goldenhar syndrome (Kroes, 2004), and Pallister-Hall congenital hypothalamic hamartoblastoma syndrome (PHS) [McKusick #146510] (Killoran et al, 2000).

CILIOPATHIES

The term *ciliopathy* describes a group of genetic conditions with defective cilia. A number of syndromes that had been previously loosely associated due to shared clinical features

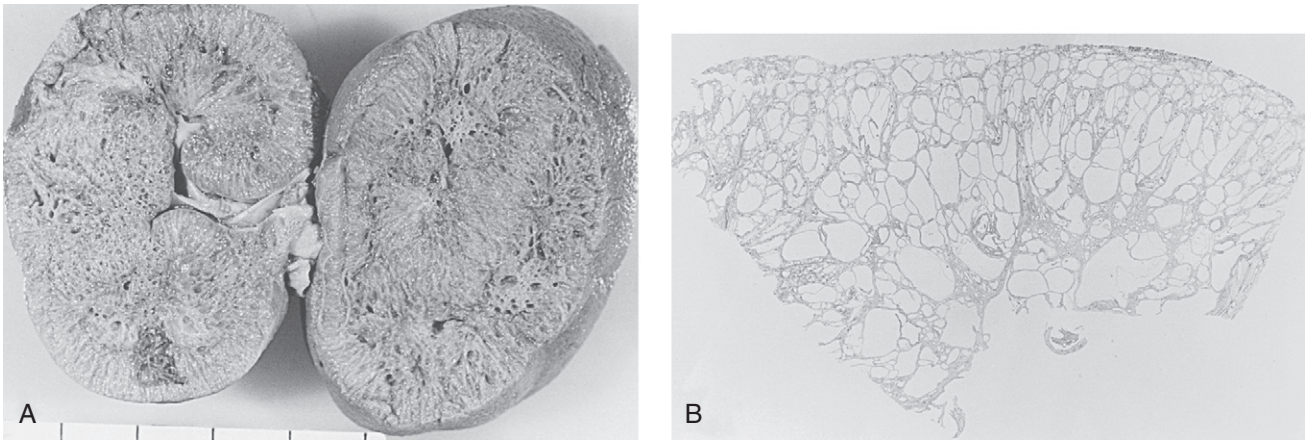

FIGURE 83-3 **A,** Large spongy kidneys (autosomal recessive kidneys). **B,** Photomicrograph of autosomal recessive kidneys with dilated tubules and paucity of glomeruli.

are now grouped under this classification. Most of these conditions display renal cystic and hepatobiliary disease, some have laterality defects and retinal degeneration, and several have polydactyly. The ciliopathies include autosomal recessive and dominant polycystic kidney disease, Bardet-Biedl syndrome, Meckel syndrome (MKS), Joubert's syndrome, nephrophthisis, Senior-Loken syndrome, Jeune's syndrome, oro-facial-digital syndrome type, Ellis-van Creveld syndrome, and Alstrom syndrome. Several of the ciliopathies account for the majority of conditions associated with large fetal echogenic kidneys with or without cysts. Autosomal dominant polycystic kidney disease (ADPKD), autosomal recessive polycystic kidney disease (ARPKD), Bardet-Biedl syndrome, and Meckel-Gruber syndrome are most commonly associated (Chaumoitre et al, 2006). Identifying the primary ciliary defect has contributed to understanding defective cellular processes and potential therapeutic targets. Several agents show promise preclinically and provide hope for effective treatments of the ciliopathies in the future (Harris, 2009).

POLYCYSTIC KIDNEYS

The term *polycystic kidneys* should be applied only to autosomal recessive polycystic kidneys and autosomal dominant polycystic kidneys. In these conditions, there are cysts in both kidneys, there is no evidence of renal dysplasia, and there is continuity of the lumen of the nephron from the uriniferous space to the urinary bladder. Patients with tuberous sclerosis can have cystic kidneys that appear identical by ultrasonography to autosomal dominant polycystic kidneys.

Autosomal Recessive Polycystic Kidney Disease [McKusick # 263200]

The incidence of ARPKD is 1 in 16,000 newborns, inheritance is autosomal recessive, there may be variable expression within a sibship (Kaplan et al, 1988), and the parents are unaffected. Mutations in the PKHD1 gene located on chromosome 6p21 (Guay-Woodford et al, 1995; Ward et al, 2001; Zerres et al, 1998) are causative. The gene encodes for fibrocystin, a hepatocyte growth factor receptor-like protein that functions in the primary cilia of renal and biliary epithelial cells. In the newborn, the kidneys are much more severely affected than the liver, whereas liver disease is more prominent when the disorder is diagnosed in older children. Features of the oligohydramnios sequence occur if there is severe oliguria or anuria in utero. The abdomen is protuberant, and the kidneys are large and easily palpable. Hypertension is often severe, may be caused by volume expansion, and can be difficult to control. Peripheral renin activity and aldosterone excretion are reduced (Kaplan et al, 1989), although intrarenal angiotensin II levels may be high (Loghman-Adham et al, 2005). Hyponatremia is often induced iatrogenically as a result of inappropriate administration of free water and is not associated with increased urinary losses of sodium (Kaplan et al, 1989). Furosemide or metolazone may correct hyponatremia, but additional sodium chloride may be needed. The hypertension often responds to treatment with an angiotensin-converting enzyme inhibitor and a loop diuretic. Renal sonography has superseded excretory urography and histology as the main diagnostic procedure. The sonographic appearances in the newborn are large kidneys, increased echogenicity of the parenchyma, loss of corticomedullary differentiation, and loss of central echo complex (Metreweli and Garel, 1980). Dilated collecting tubules are seen on ultrasonography. The cortex is preserved, and the papillae are echogenic. There may be macrocysts that are less than 2 cm in diameter. The liver is echodense, and biliary ducts are dilated. It is important to note that renal ultrasonography does not always distinguish between autosomal recessive polycystic kidneys and autosomal dominant polycystic kidneys, or between autosomal recessive polycystic kidneys and transient nephromegaly (Stapelton et al, 1981), or between autosomal recessive polycystic kidneys and glomerulocystic kidneys (Fitch and Stapleton, 1986). At postmortem, the kidneys are enlarged, are spongy, and maintain their renal contours (Figure 83-3, *A*). The dilated collecting ducts are arranged perpendicular to the surface of the kidney (Figure 83-3, *B*). There are no dysplastic elements. The liver is always involved; portal areas are expanded by increased numbers of dilated bile ductules surrounded by fibrous tissue. The dilated ductules may become cystic. The liver cells are normal. Autosomal recessive polycystic kidneys can be diagnosed after 24 weeks' gestation by ultrasonographic

demonstration of large hyperechogenic kidneys, oligohydramnios, and an empty bladder (Romero et al, 1984). Most infants who are symptomatic at birth die from respiratory or renal causes. Respiratory and renal function can improve in some cases, and a small number of patients who survive the neonatal period may maintain adequate renal function into adolescence. Massively enlarged kidneys may cause feeding difficulties and respiratory distress by restricting diaphragmatic excursion, and therefore bilateral nephrectomies may improve both ventilation and feeding tolerance (Beaunoyer et al, 2007). Peritoneal dialysis may then be performed until the infant can have a kidney transplant (Sumfest et al, 1993). Seventy-five percent of infants with ARPKD who survive to 1 year of age can live for more than 15 years (Kaplan et al, 1989).

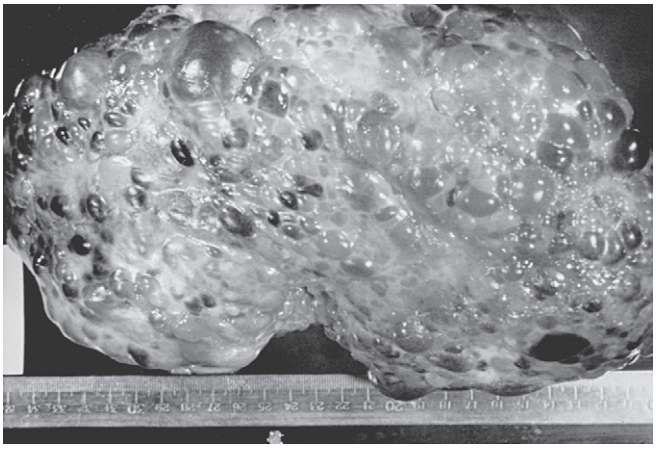

FIGURE 83-4 Autosomal dominant polycystic kidney. The kidney is large, and there are numerous cysts on the surface.

Autosomal Dominant Polycystic Kidney Disease [McKusick #179300]

The incidence of ADPKD in live-born infants is 1 to 3 per 100,000. Although this is the second most common autosomal dominant mutation in humans, with an estimated prevalence in the population of between 1 in 200 and 1 in 1000, ADPKD rarely presents with clinical findings at birth (Fick et al, 1993). The prognosis is favorable in most children with prenatal or neonatal ADPKD throughout childhood (Boyer et al, 2007). The inheritance is autosomal dominant with variable expression. At ages above 10 years, and especially over 30 years, a negative ultrasound examination provides reassurance for persons at 50% risk (Bear et al, 1992). Occasionally an infant may have symptoms before the parent. Prediction by DNA analysis complements ultrasonography for detection, is not age-dependent, and may not be informative in every family. Mutations in at least three genes cause ADPKD. *PKD1*, in 85% of families, is caused by a mutation on chromosome 16p13.3 (Breuning et al, 1987). Patients with *PKD2*, in about 5% of families, have the same phenotype as *PKD1*, and the mutation is at chromosomal locus 4q21 (Peters et al, 1993). Intrafamilial phenotypic variability indicates that both genetic background and environmental factors are important. The specific gene involved is an important factor with end-stage renal disease occurring on average 20 years later in *PKD2* (Rossetti et al, 2007). The location of the third gene *(PKD3)* is unknown. Polycystin-1, the *PKD1* gene product, is a matrix receptor that links the extracellular matrix to the actin cytoskeleton via focal adhesion proteins (Wilson, 2001). The *PKD2* gene encodes polycystin-2, a member of the transient receptor protein polycystin family of calcium-channel proteins (Mochizuki et al, 1996). The two gene products, polycystin-1 and polycystin-2, are thought to form a receptor channel complex that localizes to the primary cilium (Nauli, 2003). The mean age at onset of end-stage renal disease in individuals with *PKD1* is 56.7 ± 1.9 years, as compared with 69.4 ± 1.7 years in those with *PKD2*. Hypertension and renal impairment are less frequent and occur later in the *PKD2* families. The kidneys are enlarged and lobular, and the calyces are stretched and distorted by cysts, which produce smooth or irregular indentations. Numerous cysts of various sizes are seen in the parenchyma of severely affected patients. Post mortem, the kidneys are large with numerous round protuberances on their surfaces (Figure 83-4). Cysts are irregularly dispersed through the parenchyma and arise from many nephron segments. Ultrasonography and computed tomography (CT) scans are more sensitive methods for detecting cysts than intravenous urography. Cysts may be seen in liver, pancreas, and spleen.

ADPKD may be detected prenatally by ultrasonography (Sedman et al, 1987). Some patients have the oligohydramnios sequence, enlarged kidneys, and hematuria. Associated abnormalities reported in infants with ADPKD are endocardial fibroelastosis, an intracerebral vascular anomaly, pyloric stenosis, and hepatic fibrosis (Cobben et al, 1990). The finding of hepatic fibrosis in some patients can make differentiation between ARPKD and ADPKD difficult. In the past, about half the reported patients with ADPKD presenting in utero or in the first few months of life died before 1 year, but more recent studies of larger numbers of patients show a much more optimistic prognosis (Fick et al, 1993). Adult males are also at increased risk for fertility problems including necrospermia, immotile sperm, seminal vesicle cysts, and ejaculatory duct cysts (Vora et al, 2008).

Tuberous Sclerosis [McKusick #191100]

Tuberous sclerosis (TS) is characterized by hamartomata in numerous organs. Rarely, polycystic or unilateral cystic disease is found in a newborn in which a diagnosis of TS is made later (Brook-Carter et al, 1994; Sampson et al, 1997). Renal cysts or polycystic disease in TS are identical to simple cysts or ADPKD in their ultrasonographic, intravenous urogram, and CT scan appearances. Nonsymptomatic renal lesions (cysts and/or angiomyolipomas) occur in about 60% of individuals with TS (Cook, 1996). Other features include skin lesions in 96%, epilepsy, learning difficulties, and behavioral problems. Cardiac rhabdomyoma(s) detected on routine antenatal sonography, cerebral lesions, hydrops, and stillbirth are the major presenting findings in the fetus, whereas respiratory distress, arrhythmias, murmurs, and cardiomegaly are the main signs initially in the neonate. Skin lesions and retinal hamartomas are rarely noted at birth (Isaacs et al,

2009). Ash leaf hypopigmented nevi may be the only skin manifestation of TS in infancy, and babies with polycystic kidneys must be examined for the nevi under ultraviolet light. Shagreen patches and adenoma sebaceum develop before 14 years; nail fibromas appear after 5 years and increase with age. Ventricular rhabdomyomas and seizures may occur in infancy. Patients usually survive to adolescence and adulthood, but those with early-onset polycystic kidneys may develop end-stage renal failure. Inheritance is autosomal dominant with variable expression within a family, nonpenetrance of the gene, or germinal mosaicism. A parent with the gene may appear unaffected, so the parents must also be examined clinically and radiologically for stigmata of TS. TS is linked in half the cases to a gene TSC1 (hamartin) on 9q34. In other patients TS is linked to a marker gene, *TSC2* (tuberin), near the locus for *PKD1* on 16p13.3 (van Slegtenhorst et al, 1998; Kandt et al, 1992). Large deletions can result in *PKD1/TSC2* contiguous gene deletion syndrome.

CYSTIC KIDNEYS WITH AUTOSOMAL RECESSIVE INHERITANCE

Meckel Syndrome (Meckel-Gruber Syndrome) [McKusick #249000]

Polycystic kidneys are an obligatory feature; a consistent feature is hepatic fibrosis with variable reactive ductule proliferation, dilatation, and portal fibrosis. Other features include a sloping forehead, posterior encephalocele, microphthalmia, postaxial polydactyly, ambiguous genitalia, and cleft lip and palate. Complete or partial situs inversus has been reported. Fifty percent of the cases feature oligohydramnios with perinatal death. In Goldston syndrome there are cystic kidneys, hepatic fibrosis, and Dandy-Walker malformation. This, and other syndromes, may be part of the spectrum of MKS or discrete entities (Gloeb et al, 1989). The incidence of MKS is 1 in 9000 newborns. Inheritance is autosomal recessive with variable expression within and among families (Fraser and Lytwyn, 1981). Six gene loci on 17q22-q23 (*MKS 1*), 11q13, (*MKS 2*), 8q24 (*MKS3/TMEM67*), 12q21 (*CEP290/NPHP6*), 16q21 (*RPGRIP1L*), and 4p15 (*CC2D2A/MKS6*) have been associated with MKS (Baala et al, 2007; Delous et al, 2007; Morgan et al, 2002; Roume et al, 1998; Tallila et al, 2008). The *MKS1* and *MKS3* genes encoding the Meckel's syndrome type 1and 3 proteins have recently been identified and appear to affect ciliary function. There is considerable phenotypic overlap among several of the ciliopathies in MKS. *MKS3*, *RPGRIP1L*, and *CC2D2A* gene mutations have also been reported in patients with Joubert's syndrome (Arts et al, 2007; Brancati et al, 2009; Gorden et al, 2008), MKS1 mutations have been seen in patients with Bardet-Biedl syndrome (Leitch et al, 2008), and *CEP290/NPHP6* mutations have been reported in patients with Bardet-Biedl syndrome, Joubert's syndrome, and Senior-Loken syndrome (Brancati et al, 2009; Helou et al, 2007; Leitch et al, 2008). Prenatal diagnosis is possible by ultrasonography and by detection of increased alpha-fetoprotein levels in amniotic fluid.

TABLE 83-1 Genetics of Bardet-Biedl Syndrome

Gene	Chromosome	Protein
BS1	11q13	BBS protein 1
BBS2	16q21	BBS protein 2
ARL6/BBS3	3p12-q13	ADP-ribosylation factor-like protein 6; BBS protein 3
BBS4	15q22.3	BBS protein 4
BBS5	2q31	BBS protein 5
MKKS/BBS6	20p12	McKusick-Kaufman/ Bardet-Biedl syndromes putative chaperonin; BBS protein 6
BBS7	4q27	BBS protein 7
TTC8/BBS8	14q32.11	Tetratricopeptide repeat protein 8; BBS protein 8
PTHB1/BBS9	7p14	Parathyroid hormone-responsive B1 gene protein; BBS protein 9
BBS10	12q	BBS protein 10
TRIM32/BBS11	9p33.1	Tripartite motif-containing protein 32; BBS protein 11

Bardet-Biedl Syndrome (Laurence-Moon-Bardet-Biedl Syndrome) [McKusick #209900]

Bardet-Biedl syndrome (BBS) is a multisystemic disorder characterized by renal disease, mental retardation, obesity, postaxial polydactyly, hypogenitalism, and retinal degeneration. All patients have some abnormalities in renal structure, function, or both. Most have minor functional abnormalities and radiological appearances of calyceal clubbing, calyceal cysts, and medullary or cortical cysts. Other manifestations include diabetes mellitus, heart disease, dental malformations, situs inversus, and hepatic fibrosis. Because of the late onset of symptoms, the diagnosis of BBS is usually made during childhood. Obesity appears around age 2 to 3 years, and retinal degeneration becomes clinically apparent only at age 8 years. The only features that may be present at birth are polydactyly, kidney anomaly, hepatic fibrosis, and genital or heart malformations (Beales et al, 1999). Occasionally, the syndrome manifests in utero with large echogenic or cystic kidneys (Karmous-Benailly et al, 2005). Most cases are autosomal recessive, although triallelic inheritance has been described. Currently, 14 genes (*BBS1 to BBS14*) have been identified (Table 83-1) (Quinlan et al, 2008).

Jeune Asphyxiating Thoracic Dystrophy Syndrome [McKusick #208500]

Jeune asphyxiating thoracic dystrophy syndrome has autosomal recessive inheritance and variable expression. Respiratory distress, dysostoses, renal cystic disease, and congenital hepatic fibrosis characterize the disorder. Dysostoses include short ribs, small and long thoracic cage, small pelvis, trident acetabular margins, short and thick second and third phalanges, cone-shaped epiphyses, handlebar clavicle, and mesomelic shortening of the limbs (Donaldson et al, 1985). Three different

morphologic lesions of the kidneys have been described: (1) dilated proximal and distal tubules and Bowman capsule with interstitial fibrosis, (2) cystic dysplasia and disorganized renal architecture, and (3) chronic tubulointerstitial disease resembling juvenile nephronophthisis. At least three genetic loci have been associated with this genetically heterogeneous condition. One locus has been mapped to 15q13 (Morgan et al, 2003), a second on 3q26.1 in the region encoding the intraflagellar transport protein 80 (IFT80) gene (Beales et al, 2007), and the third on chromosome 11q22.3 in the region of dynein cytoplasmic heavy chain 2 (DNCH2) gene (Dagoneau et al, 2009). The differential diagnosis includes Ellis-van Creveld syndrome, Saldino-Noonan short rib–polydactyly syndrome (type II), and Majewski short rib–polydactyly syndrome, and Naumoff syndrome (type III). Survivors develop metaphyseal dysplasia with short-limb dwarfism. Treatment of renal failure may require dialysis and transplantation. Prenatal diagnosis by ultrasonography is possible by 18 weeks (Elejade et al, 1985).

Renal-Hepatic-Pancreatic Dysplasia (Ivemark's Syndrome)

Inheritance of Ivemark's syndrome is autosomal recessive. Patients may have the oligohydramnios sequence. The kidneys may be dysplastic with peripheral cortical cysts, primitive collecting ducts, glomerular cysts, and metaplastic cartilage (Bernstein et al, 1987). There is fibrosis of the liver and pancreas. Most patients die from respiratory insufficiency in the newborn period. Inheritance is autosomal recessive.

GLOMERULOCYSTIC KIDNEYS

In the purest form of glomerulocystic kidney, there are dilated Bowman spaces, with few or no cysts in the tubule (Bernstein, 1993). The rest of the renal architecture is normal. The kidneys may be large or small. The liver is normal. Glomerular cysts are also seen in obstructive uropathy, in autosomal dominant polycystic kidneys, in association with malformations of other organs, in dysplastic kidneys, and in infants whose mothers received phenacetin or indomethacin during pregnancy. Glomerular cysts are often subcapsular and may contain more than one glomeruloid structure (Figure 83-5). Glomerulocystic kidneys may occur sporadically. Autosomal dominant inheritance of the hypoplastic subtype is found in some kindreds in association with mutations in the gene encoding hepatocyte nuclear factor (HNF)-1β and early-onset diabetes (Bingham et al, 2001).

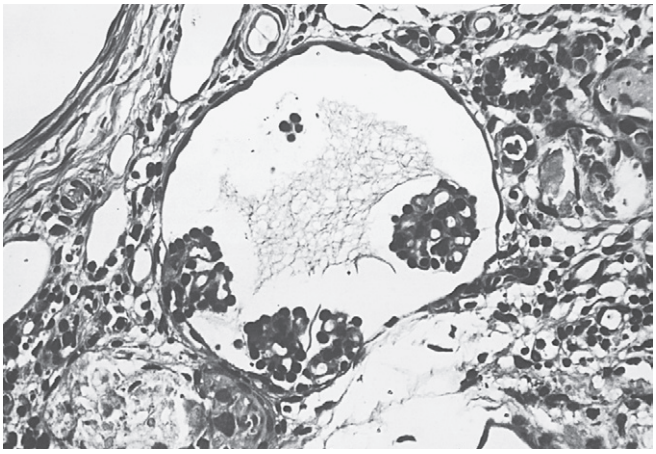

FIGURE 83-5 Glomerulocystic kidneys. Photomicrograph of glomerulus with three glomeruloid structures in a dilated Bowman capsule.

DYSGENETIC KIDNEYS

Renal Tubular Dysgenesis (Congenital Hypernephronic Nephromegaly With Tubular Dysgenesis) [McKusick #267430]

Clinical features of congenital hypernephronic nephromegaly with tubular dysgenesis, an autosomal recessive condition, include late-onset oligohydramnios after 24 weeks of gestation and large nonfunctioning kidneys (Allanson et al, 1992). The calvaria may be underdeveloped with wide sutures. Similar calvarial anomalies occur in patients with the Finnish-type congenital nephrotic syndrome and in infants exposed in utero to angiotensin-converting enzyme inhibitors. The kidneys are enlarged symmetrically by ultrasonography, and the corticomedullary junction is poorly defined. There is an apparent increase in the number of glomeruli and there are immature tubules without proximal convolutions. Prenatal diagnosis is not possible before 20 weeks. Mutations in genes encoding renin, angiotensinogen, angiotensin-converting enzyme, and angiotensin II receptor type 1 have been found (Gribouval et al, 2005). Most patients die in the neonatal period.

OVERGROWTH SYNDROMES

Beckwith-Wiedemann syndrome, Simpson-Golabi-Behmel syndrome, and Perlman syndrome are overgrowth syndromes, with overlapping features including kidneys that may be abnormal at birth (Coppin et al, 1997).

Beckwith-Wiedemann Syndrome [McKusick #130650]

Patients may have nephromegaly, Wilms' tumor, medullary renal cysts, calyceal diverticula, hydronephrosis, and nephrolithiasis (Choyke et al, 1998). The syndrome is caused by mutation of a gene encoding human cyclin-dependent kinase inhibitor p57 (*KIP2*) at chromosomal locus 11p15.5 (Matsuoka et al, 1996). Patients should be screened by renal ultrasound for Wilms' tumor every 3 months for the first 7 years.

Perlman Syndrome With Renal Hamartomas, Nephroblastomatosis, and Fetal Gigantism [McKusick #267000]

Features include polyhydramnios, macrosomia and bilateral nephromegaly with nephroblastomatosis, visceromegaly, cryptorchidism, diaphragmatic hernia, interrupted aortic arch, hypospadias, polysplenia and renal findings of

dysplasia, microcysts, and nephrogenic rests (Greenberg et al, 1988; Schilke et al, 2000). Inheritance is autosomal recessive.

Simpson-Golabi-Behmel Syndrome, Type 1; SGBS1 [McKusick #312870]

Features include pre- and postnatal overgrowth, "coarse" face, hypertelorism, broad nasal root, cleft palate, full lips with a midline groove of the lower lip, grooved tongue with tongue tie, prominent mandible, congenital heart defects, arrhythmias, supernumerary nipples, splenomegaly, large dysplastic kidneys, cryptorchidism, hypospadias, skeletal abnormalities, and postaxial hexadactyly. Inheritance is X-linked. Some cases are caused by mutation in the gene for glypican-3, which maps to Xq26 (Pilia et al, 1996). A second SGB syndrome locus, SGBS2, is located on Xp22 (Brzustowicz et al, 1999).

IN UTERO EXPOSURE TO TERATOGENS

No convincing proof of a cause-and-effect relationship has been provided for associations of in utero exposure to teratogens. Urogenital anomalies are found occasionally in infants exposed in utero to valproic acid and other anticonvulsant agents (Ardinger et al, 1988). Maternal cocaine (and polydrug) use may produce genitourinary abnormalities (Chasnoff et al, 1988). Indomethacin may cause renal dysgenesis in fetal monkeys and possibly in humans exposed early in utero to prolonged high doses (Kaplan et al, 1994). Prenatal lead exposure is incriminated as a possible cause of the VACTERL association (Levine and Muenke, 1991). Glomerulocystic disease was reported in an infant exposed to phenacetin and salicylate in utero (Krous et al, 1977). Unilateral renal agenesis and abnormalities of position were noted in three infants exposed prenatally to warfarin (Hall, 1989).

INBORN ERRORS OF METABOLISM

Several inborn errors of energy metabolism that manifest in the newborn period have morphologic and functional abnormalities of the kidneys. These are all rare conditions.

Glutaric Aciduria Type II (Multiple Acyl-CoA Dehydrogenase Deficiencies)

The clinical features of type IIa neonatal onset form include prematurity, hypotonia, hepatomegaly, nephromegaly, craniofacial anomalies, rocker-bottom feet, anterior abdominal wall defects, and external genital anomalies. An odor of sweaty feet may be present. In affected children there is a high degree of phenotypic variability ranging from milder forms susceptible to decompensation only at times of metabolic stress, to severe forms resulting in congenital anomalies and perinatal death. Within 24 hours there is severe hypoglycemia but no ketosis, a metabolic acidosis with an increased undetermined anion gap, lactic acidosis, and mild hyperammonemia. Elevated levels of organic acids are found in body fluids. Renal cystic dysplasia occurs in many cases (Wilson et al, 1989). The deficiencies in electron transfer flavoprotein or electron transfer ubiquinone oxidoreductase are inherited as autosomal recessive traits. Prenatal diagnosis may be possible by assaying enzyme in amniocytes and/or elevated glutaric acid in amniotic fluid. Ultrasonography in utero may show enlarged cystic kidneys. Treatment with a high-calorie, low-fat, low-protein diet has been tried. Oral supplements of L-carnitine and riboflavin may result in significant improvement.

Zellweger Cerebro-hepato–renal Syndrome [McKusick #214100]

Clinical features are similar to glutaric aciduria type II with profound hypotonia, nystagmus, cataracts (oil droplets), pigmentary retinopathy, optic disc pallor, and stippled epiphyses of patella and acetabulum. Odor is not abnormal. Most cases are associated with mutations in members of the peroxisomal AAA-type ATPase family (*PEX* gene). All peroxisomal functions are abnormal: elevated plasma very long-chain fatty acids, bile acids, pipecolic acid, phytanic acid, and urine dicarboxylic acids, and low cholesterol and triglycerides. Pathologic features are cortical renal cysts, micronodular cirrhosis, brain heterotopias, abnormal brain gyri, and absence of the corpus callosum. Inheritance is autosomal recessive. Prenatal diagnosis is possible by enzyme assays in amniocytes or chorionic villus cells. Most patients die within 6 months, but those with a milder form can survive into adolescence with retardation, deafness, and seizures.

Carbohydrate-Deficient Glycoprotein Syndrome/Congenital Disorders of Glycosylation

Multiple renal microcysts are found in the carbohydrate-deficient glycoprotein syndrome (Strom et al, 1993). There is multisystem involvement with olivopontocerebellar atrophy, retinitis pigmentosa, testicular atrophy, hypothyroidism, and immune deficiency. This is a heterogeneous group of autosomal recessive genetic conditions caused by the abnormal synthesis of glycan moieties or their attachment to glycoconjugates. Several glycoproteins are deficient in their carbohydrate moieties. The prognosis is highly variable.

CHAPTER 84

Developmental Abnormalities of the Genitourinary System

Stephen A. Zderic and Sarah M. Lambert

This chapter reviews the most common clinical presentations that prompt urologic consultation during the neonatal period. Anomalies of the urinary tract and disorders of the external genitalia are reviewed respectively. Advances in imaging technology and the widespread use of screening prenatal sonography have resulted in antenatal detection of many urinary tract anomalies and disorders of the external genitalia. This early detection results in earlier management and intervention, thereby decreasing the number of neonates presenting with urosepsis in the postnatal period. These benefits are tempered by the heightened concern raised and often excessive evaluation that is initiated when anatomic variants or incidental findings are discovered (Thomas, 2008). It must also be remembered that not all urologic conditions will be revealed by prenatal sonography. Additionally, these technologic advances only benefit expectant mothers with access to medical care.

PRENATAL DIAGNOSIS

The widespread use of ultrasonography in screening for fetal anomalies has profoundly changed neonatal urology within the past two decades. In optimal circumstances, prenatal consultation was obtained and the urologist and family have already discussed the relevant urologic issues affecting the fetus. These families have the potential for a greater understanding of the clinical parameters and are able to plan for evaluation and management in the postnatal period. Two decades ago, most children with congenital anomalies of the urinary tract presented with urosepsis. In contrast, prenatal ultrasonography now identifies patients at risk; if indicated, in utero decompression of an obstructed urinary tract (i.e., from posterior urethral valves or ureterocele) may be performed, or antibiotic prophylaxis may be initiated in the immediate postnatal period. Additionally, intervention can occur at an earlier date. Prenatal diagnosis has also led to a decrease in the incidence of several severe congenital anomalies, such as prune-belly syndrome, posterior urethral valves, and spina bifida, because some parents decide to terminate the pregnancy (Cromie et al, 2001).

Primarily because of the high fetal urine output, most prenatally discovered cases of hydronephrosis will be benign and self-limiting in nature. Therefore, it is important to give realistic advice and reassurance in cases of functional hydronephrosis. With severe congenital anatomic obstructions, fetal intervention may be considered (Biard et al, 2005). Recent studies suggest that such interventions offer little benefit to renal function (Coplen et al, 1996) but may serve to facilitate pulmonary development. In addition to the obstructive uropathies, disorders of sexual differentiation and other disorders of the external genitalia are being detected with prenatal sonography (Rintoul and Crombleholme, 2002).

HYDRONEPHROSIS

As mentioned earlier, most patients with prenatally diagnosed hydronephrosis have transient dilatations of the urinary tract that may reflect a more distensible fetal urinary tract and large volumes of dilute fetal urine. With the cardiovascular and hormonal changes in the immediate postnatal period, urine output per kilogram of body weight decreases, resulting in the resolution of prenatally detected "functional" renal and ureteral dilatation. In addition, the ureter may contain small kinks or folds that normalize with time. The potential explanations for spontaneous improvement in these systems is seemingly endless. Even though most dilatations of the fetal urinary tract prove to be of no long-term significance, a small subset of affected patients will prove to have anatomic obstructions requiring surgical correction (Lee et al, 2006).

The neonatal evaluation of antenatal hydronephrosis is influenced by gender, the presence or absence of hydronephrosis, and laterality of hydronephrosis. The rigor of the initial evaluation varies considerably (Estrada, 2008; Estrada et al, 2009; Yerkes et al, 1999) (Figure 84-1). Bilateral hydroureteronephrosis in a boy should raise concerns regarding the presence of posterior urethral valves (PUVs). PUVs can be diagnosed by performing an ultrasound examination and voiding cystourethrogram (VCUG) within 24 hours of birth. Unilateral hydronephrosis in a boy or girl can be evaluated by performing an ultrasound of the kidneys and bladder at 2 to 5 days of age. Performing an ultrasound study too early in the first postnatal hours may show minimal to no hydronephrosis, resulting from the significant and physiologic decrease in urine output during the period of transition to extrauterine life. In these cases, a follow-up study should be performed to ensure that, with the ensuing increase in the urine output over the first few days, the collecting system remains unobstructed (Dejter and Gibbons, 1989). For patients with persisting unilateral hydronephrosis, a VCUG and mercaptoacetyltriglycine (MAG3) or renal diethylenetriaminepentaacetic acid (DTPA) renal scan should be performed at about 1 month of age. In the interim, antimicrobial prophylaxis is essential, usually one dose of amoxicillin (12.5 mg/kg) at bedtime. The algorithm presented in Figure 84-1 represents one such approach to the management of neonatal hydronephrosis, which seeks to maximize safety while avoiding exposures to invasive studies and radiation exposures in situations that are deemed to be low yield.

Ample controversy exists concerning some of the fine points of this management algorithm. Because 20% of children with prenatal hydronephrosis have reflux, should all children get a VCUG irrespective of their first ultrasound findings? If results on their initial ultrasound examination are negative, should these children then be placed on antimicrobial prophylaxis until their next ultrasound

study is done and judged to be normal? Yerkes et al (1999) have suggested that for patients with mild pelviectasis and no caliectasis or hydroureter, the diagnostic yield of the VCUG is low, and the study may be deferred. Other authors argue in favor of a VCUG for all patients with a prenatal diagnosis of hydronephrosis (Estrada et al, 2009; Herndon et al, 1999). In support of more aggressive screening for these patients, Walsh et al (2007), using a Washington state registry, have shown that infants with an antenatal diagnosis of hydronephrosis have a 12-fold higher risk of being hospitalized for pyelonephritis within the 1st year of life. Further outcome studies are essential to help drive refinement of such algorithms (Estrada, 2008). It is important to remember that while the urologic issues are being sorted out, antibiotic prophylaxis is cost-effective and protects against urosepsis. Therefore, when the diagnosis is unclear, the clinician should provide empiric antibiotic prophylaxis.

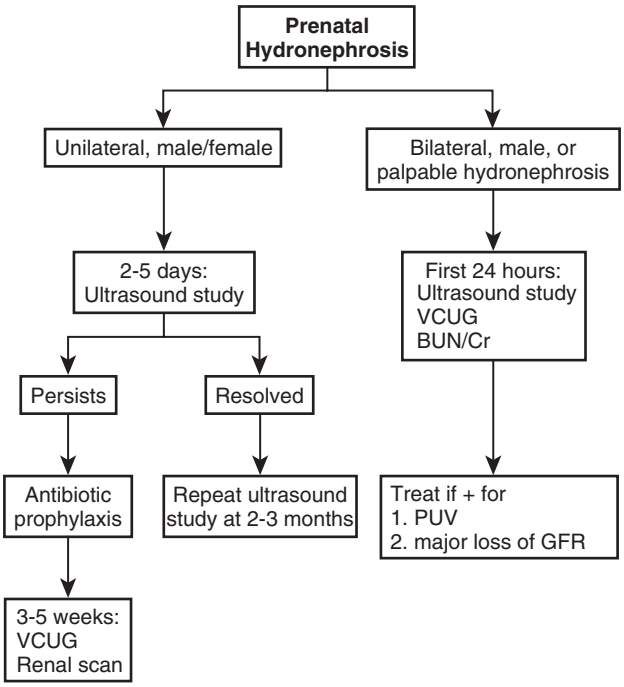

FIGURE 84-1 An algorithm for the approach to the work-up of a patient with antenatally diagnosed hydronephrosis. With further experience and clinical outcome studies, it may be possible to better select which patients require a voiding cystourethrogram *(VCUG)* and renal MAG3 on DTPA scan. *BUN*, Blood urea nitrogen; *Cr*, serum creatinine; *GFR*, glomerular filtration rate; *PUV*, posterior urethral valve.

OBSTRUCTIVE UROPATHY

URETEROPELVIC JUNCTION OBSTRUCTION

Ureteropelvic junction (UPJ) obstruction is the most common obstructive uropathy in children. Ultrasonography will reveal a dilated renal pelvis with or without caliectasis, and the absence of ureteral dilatation (Figure 84-2). Conversely, a dilated distal ureter can be observed with ureterovesical junction obstruction, megaureter, vesicoureteral reflux, or ureteral ectopia. The sonographic appearance of a UPJ obstruction is not always predictive of function. Many infants with fairly impressive dilatation of the renal pelvis in the neonatal period demonstrate partial or complete resolution of their hydronephrosis with preservation of renal function (see Figure 84-2). Functional imaging is often obtained before any surgical repair. Although any kidney with an anteroposterior diameter greater than 2 cm has a greater risk of functional compromise (Ransley et al, 1990), many patients demonstrate stable renal function over time (Ulman et al, 2000). DTPA or MAG-3 renal scans allow for careful selection of those patients with a loss of function as defined by a decrease in glomerular filtration rate. The degree of functional impairment necessary to prompt surgical intervention remains controversial. Some authorities advocate intervention only if the differential function in the affected kidney falls below 35% (Cartwright et al, 1992), whereas others recommend intervention at 40% differential function (Chertin et al, 2006). Magnetic resonance imaging (MRI) urogram represents a newer imaging modality that provided functional and anatomic information in one study. Although many centers still rely on the use of a carefully performed diuretic renogram with furosemide washout curves to identify those patients whose urinary tract is truly obstructed or wide open (Conway and Maizels, 1992), there is a tendency toward the use of the MRI urogram in situations that are equivocal or complex (McMann et al, 2006). Given the expense of MRI as well as the need for sedation, this may be a reasonable approach.

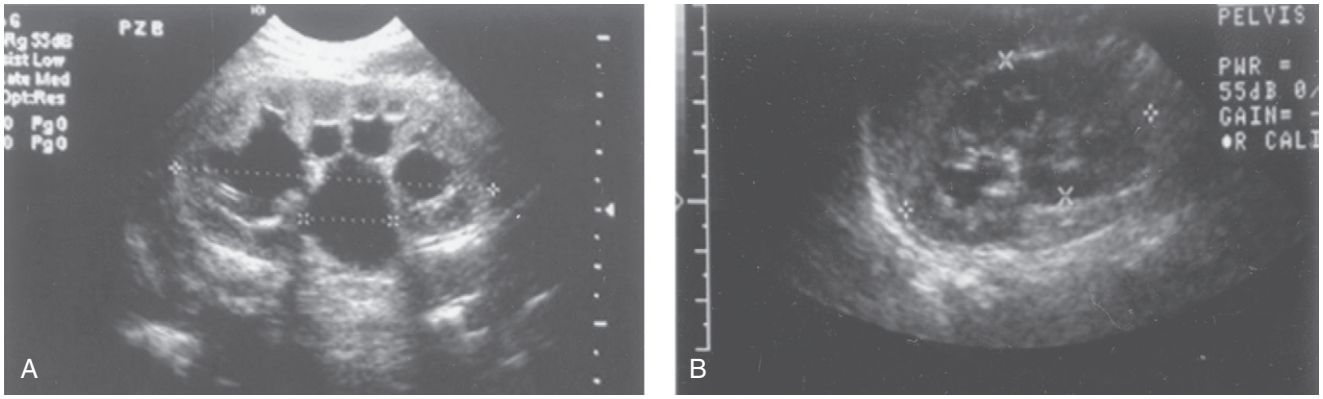

FIGURE 84-2 An example of antenatal hydronephrosis consistent with a partial ureteropelvic junction obstruction **(A)** that spontaneously resolved over a 6-month interval **(B)**.

Many patients will demonstrate good function and rapid washout curves despite a significant degree of hydronephrosis (Figure 84-3). For those patients in whom a UPJ obstruction is diagnosed by sonography, and in whom the renal scan shows diminished function, pyeloplasty is indicated. Antimicrobial prophylaxis is not effective in children with a poorly functioning kidney because the affected kidney will not deliver enough antibiotic into the collecting system. As a result, the child remains at risk for urosepsis. It is important to note that with most severe UPJ obstructions, the kidney does not recover normal function following surgical correction. In addition, infection in the presence of a UPJ obstruction further increases the risk of permanent renal damage. Unfortunately, no preoperative test will predict recovery of renal function following relief of obstructive uropathy.

Finally, few prenatally diagnosed cases of UPJ obstruction require immediate repair. These cases rarely result in palpable hydronephrosis, and most affected infants will have good renal function. Therefore, a nonemergent evaluation and surgical repair if necessary can be performed at 3 to 6 weeks of life. This group of patients may be divided into three subgroups (Homsy et al, 1990). One third will demonstrate severe obstruction and require intervention, one third will have a normal postnatal evaluation, and the remaining one third may be observed with serial sonograms and renal scans. Of this observed group, up to one third of the patients may ultimately need surgical correction. The postnatal evaluation and treatment of prenatally diagnosed hydronephrosis must contain two key elements: (1) antimicrobial prophylaxis and (2) thorough follow-up evaluation. Although expectant management may eliminate unnecessary surgical procedures that may offer little benefit, this advantage mandates careful follow-up evaluation (Cordero et al, 2009). This aspect of management must be made clear to the family in no uncertain terms.

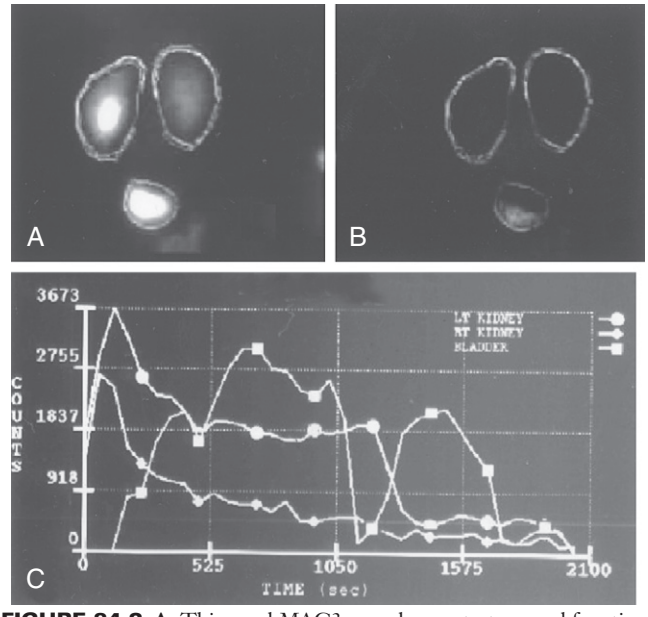

FIGURE 84-3 **A,** This renal MAG3 scan demonstrates equal function in the right and left kidneys but marked stasis in the left kidney. **B** and **C,** Following administration of furosemide, stasis in the left renal pelvis cleared quickly.

MULTICYSTIC DYSPLASTIC KIDNEY

The diagnosis of multicystic dysplastic kidney (MCDK) is applied to a kidney that on ultrasound examination consists of multiple cysts of roughly equal size, which results in a classic "bunch of grapes" pattern and no function on a DTPA renal scan (Figure 84-4). The contralateral kidney is often hypertrophied with an increased length and width. If the MCDK has one large, centrally located cyst, it may appear similar to a severe UPJ obstruction. In these rare instances it may prove necessary to explore the kidney to see if there is any salvageable renal function that might be amenable to relief of the obstruction. In most cases of MCDK, the cysts will involute completely without intervention. There is considerable debate regarding the follow-up and indication for surgical intervention in patients with MCDK. Ultrasound imaging of the contralateral kidney is also recommended because metachronous contralateral obstruction has been reported (Weiser et al, 2002). Concerns have been raised about the occasional case reports of malignancy in MCDK. It has been estimated that 80,000 nephrectomies would have to be performed to save one patient with MCDK from developing a malignancy. In practice, if involution fails to occur by 1 to 2 years of age, simple nephrectomy is often recommended. Increasingly, surgical extirpation is performed using the techniques of modern minimally invasive surgery.

URETEROVESICAL JUNCTION OBSTRUCTION: MEGAURETER

Primary megaureters account for 15% of prenatally diagnosed cases of hydronephrosis and are characterized by pelviectasis, caliectasis, and ureteral dilatation. Ureteral dilatation is usually visualized posterior to a distended bladder. A VCUG is indicated to eliminate concomitant vesicoureteral reflux. Reflux into a partially obstructed system can occur, creating the paradoxical refluxing obstructed megaureter. Often times a VCUG reveals a

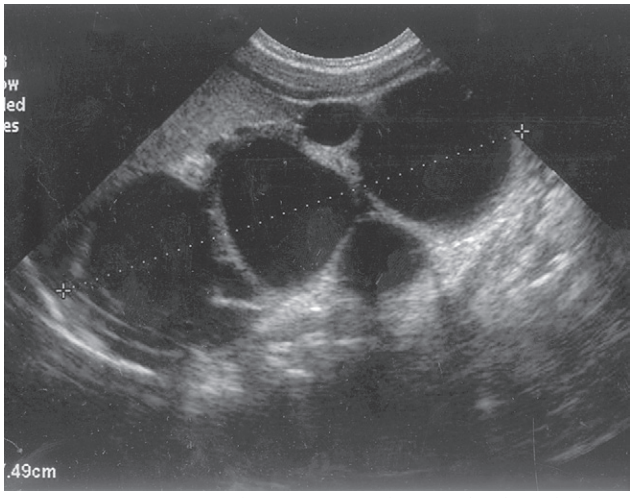

FIGURE 84-4 Sonographic view of a multicystic dysplastic kidney in which multiple cysts that do not communicate with one another are grouped together, giving the typical "bunch of grapes" appearance. No function was noted on the patient's renal scan, confirming this diagnosis.

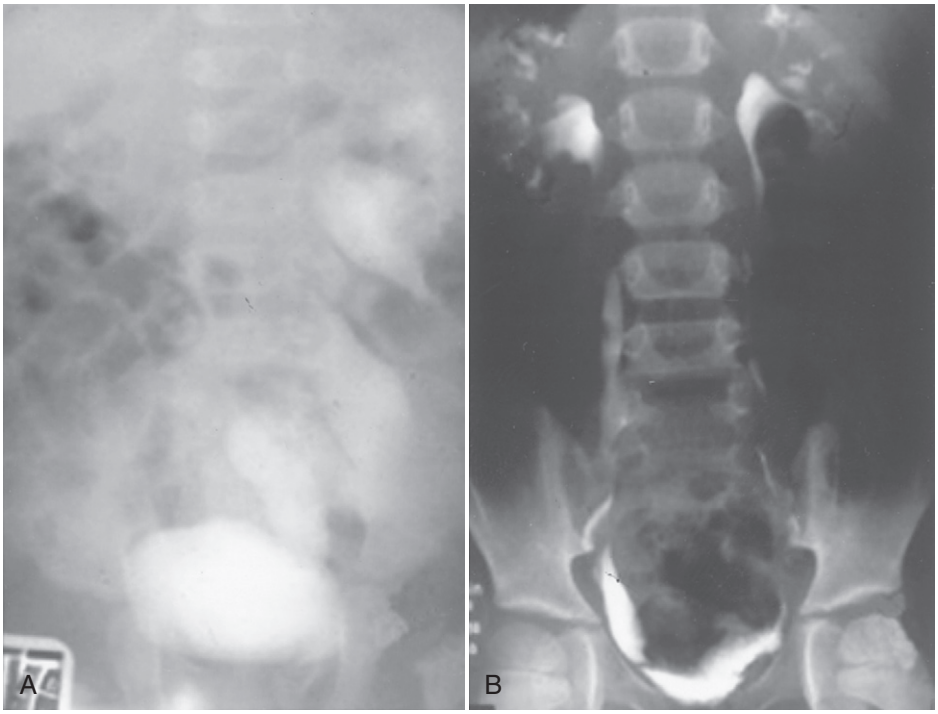

FIGURE 84-5 **A,** This radiograph shows significant hydroureteronephrosis that was diagnosed by antenatal sonography and was shown to be consistent with bilateral primary megaureters. Renal function was normal despite the abnormal morphologic appearance. **B,** With time, the radiographic findings showed marked improvement.

dilutional effect due to urinary stasis within the dilated ureter in comparison with the bladder. Furthermore, on the postvoid images, the contrast will often be retained within the ureter. Some investigators believe that refluxing primary megaureter should be repaired to prevent an infection in a partially obstructed system. Functional imaging such as a MAG3 renal scan or MRI urography is critical for assessing upper tract drainage (Figure 84-5). In systems with good renal function, patients may be safely managed with antimicrobial prophylaxis because of the potential for spontaneous resolution. In a longitudinal study, Shukla et al (2005) demonstrated that renal function is well preserved, and in many instances, the morphologic appearance of the system is substantially improved. However, this series also presented the rare occurrence of late-stage decompensation in a patient who required surgical intervention. It is the potential for later decompensation that prompts long-term surveillance in patients with a megaureter. Certainly if, based on poor function, surgical correction is indicated, excellent results can be obtained (Peters et al, 1989). More recent studies suggest that risk factors for decompensation and loss of function over time include a differential function <30% and ureteral diameters in excess of 1.2 cm (Chertin et al, 2008).

POSTERIOR URETHRAL VALVES

Although most PUVs are detected on prenatal sonography, the clinical manifestations vary across a wide spectrum of disease states. For example, oligohydramnios, pulmonary hypoplasia, and chronic renal insufficiency in a neonate represent a severe manifestation of PUV. In highly selected cases, extracorporeal membrane oxygenation (ECMO) has been used, and long-term survivors have been reported. Most of these survivors, however, ultimately require renal transplantation. At the other end of the spectrum, some PUVs result in minimal functional disturbance. If the abnormality is not detected in utero, patients with PUVs may present with urosepsis. The prenatal diagnosis by ultrasound examination offers the pediatric urologist an opportunity to intervene before the obstructive uropathy is further compromised by the additional burden of infection.

The postnatal evaluation of a child with suspected PUV should begin with a renal and bladder ultrasound (Strand, 2004; Zderic, 2007). The examination should be performed before placement of a urinary catheter to reveal the anatomy of the urinary tract and the degree of distention. There will usually be severe bilateral hydroureteronephrosis. In severe cases, the renal parenchyma will be of extremely poor quality, comprising a thin rim with a highly echogenic appearance. When these findings are associated with a thick-walled bladder in a male infant, the suspected diagnosis is PUV until proven otherwise. Ultrasound examination of the bladder also may reveal a dilated posterior urethra resulting in the classic "keyhole" appearance (Figure 84-6). A catheter should be passed into the bladder and the sonographic examination repeated to document proper placement and decompression of the urinary tract. In some instances, the posterior urethra and bladder are so severely distorted that the catheter cannot pass into the bladder without extensive manipulation.

A fluoroscopic VCUG provides the definitive diagnosis of PUV. This study will demonstrate a dilated posterior urethra, valve cusps at the distal aspect of the prostatic fossa (see Figure 84-6), a heavily trabeculated bladder, and associated high-grade vesicoureteral reflux in many cases. Once the diagnosis is established, endoscopic valve ablation is indicated (Zderic, 2006). In rare instances, the pediatric urologist may opt for a temporizing vesicostomy if the neonate is premature or small for gestational age. A circumcision should be performed at the time of valve

FIGURE 84-6 This voiding cystourethrogram shows a classic posterior urethral valve, with narrowing of the urethra at the most distal end of the prostate. This area corresponds to a flap of tissue that serves as an obstructing valve leaflet.

resection, to minimize the risk of urinary tract infection (Wiswell and Geschke, 1989), because these patients are at high risk.

In severe cases of PUV, decompression may result in postobstructive diuresis. For this reason, neonates with PUVs should remain in the neonatal intensive care unit (NICU) for fluid and electrolyte monitoring after catheter placement. The diuresis may be severe, necessitating hourly records of urine output with appropriate replacement of fluids and electrolytes. Failure to replace fluids and electrolytes may result in hypotension and electrolyte disturbances, thereby further aggravating renal insufficiency. Once the bladder has been decompressed with a catheter, antibiotics should be administered, and the child's medical condition must be optimized before any operative intervention is pursued.

Up to 30% of these patients may require renal replacement therapy during their lifetimes (Smith et al, 1996). In the neonatal period, renal function should be optimized and sterile urine maintained with antibiotic prophylaxis. A subset of patients with PUV present with unilateral reflux and dysplasia. This laterality acts as a "pop-off" valve to lower bladder pressure, sparing the contralateral kidney. Many such pop-off mechanisms have been described and are associated with better long-term renal (Rittenberg et al, 1988) and bladder (Kaefer et al, 1995) function. When bringing the infant home, families must be cautioned that these infants have poor urinary concentrating ability; their additional fluid requirements result in increased susceptibility to dehydration with even mild diarrhea or emesis. The initial follow-up evaluation within 1 month should include a physical examination, renal and bladder ultrasound, and serum creatinine measurement. Antibiotic prophylaxis should be maintained for a long period in these patients.

URETEROCELE

A ureterocele is a cystic dilatation of the distal ureter that protrudes into the urinary bladder and may extend past the bladder neck into the urethra. Ureteroceles are found primarily in duplex systems and are associated with the upper pole renal parenchyma. In a duplex system, the upper pole parenchyma associated with a ureterocele is usually of low volume and may even contain dysplastic elements. The ureterocele creates an obstructed system; accordingly, the prevention of urosepsis in the obstructed system is paramount. Renal-bladder ultrasound examination of a ureterocele demonstrates three characteristic findings (Figure 84-7). First, the upper pole of the duplex system will be dilated and hydronephrotic (although single systems also may contain ureteroceles). Second, significant ureteral dilatation to the level of the bladder will be present. Third, a cystic lesion within the lumen of the bladder adjacent to the bladder base will be demonstrated. A VCUG will complete the evaluation and determine whether vesicoureteral reflux is present in the ipsilateral or contralateral ureter(s). Ureteroceles may prolapse into the urethra and constitute the most common form of bladder outlet obstruction in female neonates. A prolapsed ureterocele appears as a cystic bulge within the labia and must be considered in the differential diagnosis of an introital mass.

Several surgical options exist for the management of the newborn with a ureterocele, including endoscopic puncture (Hagg et al, 2000), ureteroureterostomy (Prieto et al, 2009), upper pole partial nephrectomy, and excision of the ureterocele with ureteral reimplantation. Finally, an additional surgical approach is to perform a cutaneous ureterostomy and defer definitive lower tract reconstruction until the child is 1 to 2 years of age.

ECTOPIC URETERS

Most ectopic ureters today will be detected with prenatal sonography. This prenatal imaging ultimately results in a neonatal evaluation. Physical examination in these patients will often be unremarkable. A boy will never present with incontinence secondary to an ectopic ureter because the ureter enters the urethra proximal to the level of the external sphincter. Girls, in contrast, may present with urinary incontinence because the ureter may be ectopic to the urethra or vaginal vault. In these cases, urinary incontinence is continuous and detectable on physical examination. Addressing ectopic ureters early in life prevents the potential for urosepsis in an obstructed system and allows for normal toilet training in young girls. Historically, ectopic ureters were often diagnosed in young women with refractory and continuous urinary incontinence. The incidence of this delayed presentation has declined as a result of antenatal screening.

Most ectopic ureters occur in duplex systems and are associated with the upper pole moiety. The ultrasound findings in ectopic ureter include the presence of hydronephrosis, usually of an upper pole of a duplex system (although single systems may also be involved); a dilated distal ureter that lies behind the bladder; and extension of this dilated distal ureter distal to the bladder neck. Ultrasonography of an ectopic ureter will not demonstrate a

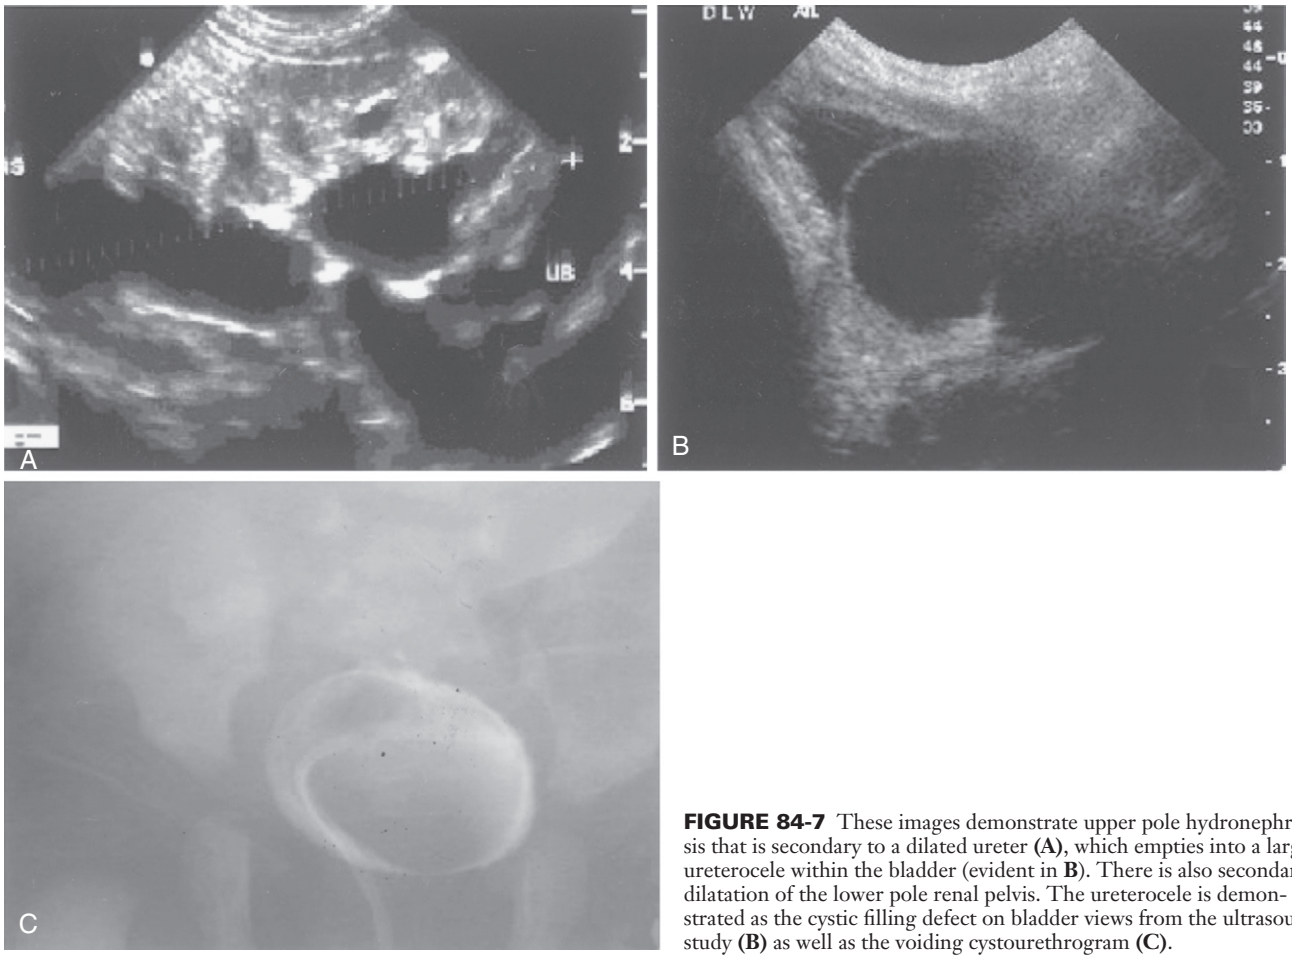

FIGURE 84-7 These images demonstrate upper pole hydronephrosis that is secondary to a dilated ureter **(A)**, which empties into a larger ureterocele within the bladder (evident in **B**). There is also secondary dilatation of the lower pole renal pelvis. The ureterocele is demonstrated as the cystic filling defect on bladder views from the ultrasound study **(B)** as well as the voiding cystourethrogram **(C)**.

cystic lesion within the bladder itself, as is seen with a ureterocele. The VCUG should be included in the evaluation of these patients because 70% of cases may demonstrate reflux into the ectopic ureter. It is important to note that reflux may not be apparent on the first void. Instead, it may be necessary to "cycle" the bladder several times before reflux may be demonstrated. If the ultrasound suggests an ectopic ureter, MRI urography assists in confirming the diagnosis and further evaluating the associated renal function and anatomy (Hanson et al, 2007).

An endoscopic option does not exist for repairing an ectopic ureter. The surgical options include a partial nephrectomy of the upper pole with or without excision of the distal ureter, simple nephrectomy in a nonfunctioning kidney, a cutaneous ureterostomy with delayed reimplantation and excision of the distal stump, and an immediate complete reconstruction with reimplantation and excision of the ectopic stump. The surgical management plan is usually dictated by the amount of renal function in the upper pole segment.

PRUNE-BELLY SYNDROME

Prune-belly syndrome is characterized by a triad of abdominal wall laxity, bilateral undescended testes, and a massively dilated upper urinary tract and bladder (Figure 84-8). The abdominal wall defects impact pulmonary function and development of the diaphragm as well. In severe cases, respiratory insufficiency may mandate temporary mechanical ventilation. Historically, pulmonary complications were a common source of neonatal demise. Currently, the advent of prenatal sonography allows for earlier detection and planned neonatal interventions. These neonates are often born with significant renal dysplasia and ultimately develop end-stage renal disease. Indeed, if the nadir serum creatinine remains above 1.0 mg/dL by 1 year of age, the infant with prune-belly syndrome is more likely to develop end-stage renal disease (Noh et al, 1999). However, this disease manifests across a wide spectrum; some patients may not develop renal insufficiency until adulthood, if at all, despite the massively dilated urinary tracts.

Prune-belly syndrome is a clinical diagnosis that should prompt the initiation of prophylactic antibiotics (Strand, 2004). An ultrasound study to assess the renal parenchyma also is warranted. In contrast, a VCUG is contraindicated because of increased risk of urinary tract infections. Instrumenting a neonate with prune-belly syndrome who is voiding satisfactorily should be avoided. Catheterization procedures increase the risk of urosepsis owing to the presence of the large, distended, and poorly emptying bladder. Furthermore, the diagnosis of vesicoureteral reflux does not affect neonatal management; these infants require antibiotic prophylaxis regardless of the presence or absence of vesicoureteral reflux. The essential tenet of management in boys with prune-belly syndrome is to maintain sterile urine and institute careful follow-up evaluation

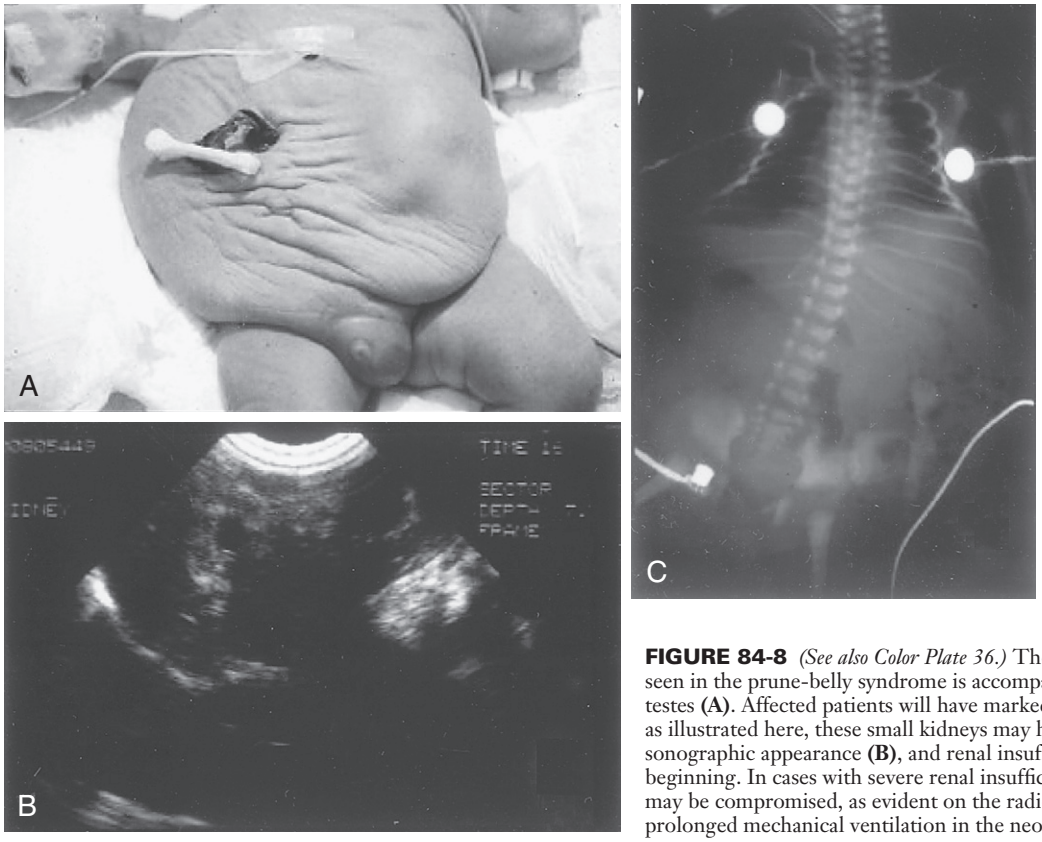

FIGURE 84-8 *(See also Color Plate 36.)* The classic wrinkled abdominal wall seen in the prune-belly syndrome is accompanied by bilateral undescended testes **(A)**. Affected patients will have marked hydronephrosis. In severe cases as illustrated here, these small kidneys may have a markedly dysmorphic sonographic appearance **(B)**, and renal insufficiency may be present from the beginning. In cases with severe renal insufficiency, pulmonary development may be compromised, as evident on the radiograph **(C)**; the patient required prolonged mechanical ventilation in the neonatal period.

(Noh et al, 1999). If the voiding dynamics in the neonatal period are significantly altered, a vesicostomy may safely decompress the urinary tract. Despite tremendous distortions of the urinary tract, the bladder may empty quite adequately, and improvement may occur over time in the quality of the upper tracts. In very rare instances where geography separates patients from specialty care, consideration is given to an aggressive reconstruction of the urinary tract (Denes et al, 2004). In general, reconstructive procedures for these children are limited to bilateral orchiopexies and abdominal wall plication.

THE EXSTROPHIES

Bladder Exstrophy

Classic bladder exstrophy manifests with a bladder plate that protrudes from the abdominal wall in the suprapubic area and extends up to just below the umbilicus (Figure 84-9). In boys, complete epispadias also results. In both male and female neonates, absence of the bladder neck results in urinary incontinence. The prenatal diagnosis of bladder exstrophy is increasingly common; failure to visualize a full bladder on several prenatal sonograms raises the suspicion of exstrophy. Classic bladder exstrophy is not associated with any other anomalies. As a result, many families decide to continue the pregnancy. Children with bladder exstrophy have an excellent prognosis and with proper management can lead nearly normal lives.

The traditional approach to the patient with classic bladder exstrophy included a staged reconstruction beginning with tubularization of the bladder plate within the first 24 hours of life (Kiddoo et al, 2004). These children were left incontinent until the age of 5 to 7 years. At that time, a surgical reconstruction of the bladder neck was performed. This repair was done at 5 to 7 years of age to facilitate self-catheterization, should catheterization be required to empty the bladder and maintain safe storage pressures. In some series, 90% of these children required long-term clean intermittent catheterization (CIC) to achieve continence and maintain stable renal function.

These adverse outcomes associated with staged exstrophy reconstruction led Mitchell and Bagli (1996) to propose a one-stage reconstruction during the 1st month of life. In boys, this procedure includes a deconstruction of the penis with separation of the corporal bodies and urethral realignment. With this method, the bladder neck is reapproximated in an attempt to provide an anatomic closure, thus creating a resistance that stimulates bladder growth; ideally, the one-stage approach will increase the percentage of patients who void spontaneously while maintaining continence.

Cloacal Exstrophy

Cloacal exstrophy manifests with several distinct clinical features (see Figure 84-9), including the presence of two bladder halves fully exposed on the anterior abdominal wall and an abdominal midline that consists of the entire cecal plate allowing for egress of stool. Commonly, a protruding loop of prolapsed distal ileum is visualized within the cecal plate. An omphalocele of variable size is located directly above these structures (Zderic et al, 2002). In addition to these obvious malformations, 50% of these children will

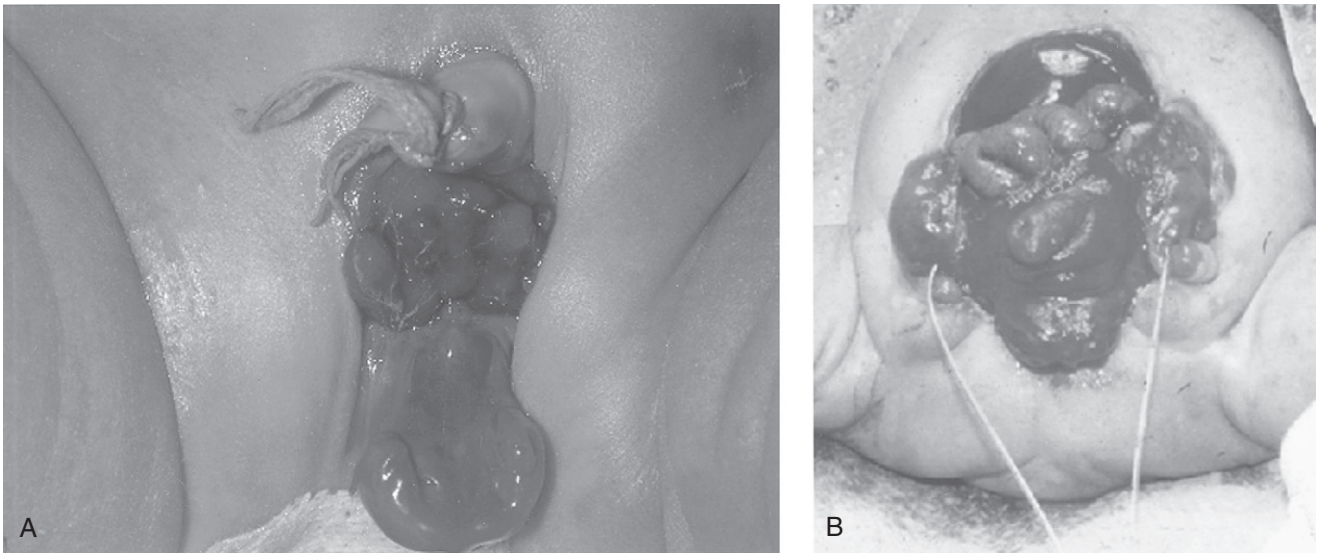

FIGURE 84-9 *(See also Color Plate 37.)* The appearance of classic bladder exstrophy **(A)**, in contrast with the dramatic appearance of cloacal exstrophy **(B)**. In cloacal exstrophy, the bladder halves are separated by the presence of a large cecal plate and a protruding ileal stump. **B,** In this intraoperative photograph, the omphalocele has been removed to expose the small bowel and liver.

have associated spinal dysraphism of various degrees. The risks of fluid loss, hypothermia, and infection from the exposed viscera mandate covering the exposed viscera with plastic wrap and immediately transferring the patient to a NICU with pediatric surgical coverage.

The first stage of reconstruction should be undertaken as soon as the child's condition has stabilized. A central line should be placed, because all of these children will have some degree of short bowel syndrome and require hyperalimentation for varying periods postoperatively. The goals of the initial surgical intervention are to tubularize the cecal plate, create a colostomy, and reapproximate the two bladder halves. In some instances, the limited size of the abdominal cavity requires a staged closure of the cecal plate followed by a closure of the omphalocele. In such an instance, the bladder halves are addressed during a second-stage repair 6 to 12 months later. For most of these children, attainment of urinary continence will require intermittent catheterization because 50% or more have a neural tube deficit.

Male infants with cloacal exstrophy will present with testes and rudimentary corporal bodies. The traditional management of these patients included gender reassignment given the minimal success of reconstructive phalloplasty. Currently, the impact of testosterone imprinting on the fetal brain is recognized and gender reassignment is avoided. These basic science data are corroborated by several reassigned patients reverting to a male role (Reiner and Gearhart, 2004). Indeed, patient dissatisfaction with gender reassignment and the newer surgical techniques available (Mitchell and Bagli, 1996) result in the maintenance of male sex of rearing.

SPINA BIFIDA

The primary goal of the urologist in management of the neonatal patient with spina bifida is the preservation of renal function. In such cases, the main detriment to renal function results from abnormal bladder function. Traditionally, spinal closure occurs in the immediate neonatal period. However, prenatal diagnosis of spina bifida allows for fetal surgical repair in certain patients (Farmer et al, 2003). Evaluating the effects of fetal intervention on bladder function, early urodynamic outcome studies from two centers suggested no improvement in urologic outcomes between the traditional postnatal closure and the fetal repair groups (Holmes et al, 2001; Holzbeierlein et al, 2000). The difficulties encountered in interpreting data from several centers performing a complex surgical procedure under different conditions (Fichter et al, 2008) led to the establishment of an NIH-funded randomized clinical trial comparing outcomes of fetal versus neonatal spina bifida repair. With the impending completion of the MOMS trial, definitive data regarding the long-term outcome for these patients after in utero repair will be available.

Most neonates experience urinary retention after spinal closure. Clean intermittent catheterization in the immediate postclosure period prevents bladder wall overdistention. If the neonate is able to empty his or her bladder, the use of CIC allows for determination of the residual urine. If the urinary volumes on serial catheterizations remain consistently low, clean intermittent catheterization can be discontinued. A baseline renal bladder ultrasound study should be obtained within 1 week of closure to evaluate for hydronephrosis. After discharge from the NICU, a video-urodynamic assessment is performed at 4 to 8 weeks of age. The video-urodynamic studies are then repeated at 6 months of age and thereafter on a yearly basis until 5 years of age. This follow-up is necessary because up to 32% of patients with an initially favorable urodynamic profile demonstrate evidence of deterioration (Bauer et al, 1984). The purpose of the urodynamic studies is to identify early evidence of a hostile bladder. A hostile bladder has poor function that results in compromised renal function if not addressed. Grading scales have been designed to predict those infants at risk of upper urinary tract damage (Bauer et al, 1984). If there is evidence of a hostile

bladder, many pediatric urologists favor the immediate institution of CIC in conjunction with antimicrobial prophylaxis and anticholinergic medications (de Jong et al, 2008; Edelstein et al, 1995; Joseph, 2008). In addition to the known benefits regarding preservation of renal function, recent studies suggest that early institution of CIC and anticholinergic therapy may also improve long-term bladder compliance and decrease the likelihood of bladder augmentation surgery (Kaefer et al, 1999b). Yearly ultrasound examinations must also be performed to ensure that the upper tracts continue to be protected. If the initial ultrasound findings are abnormal, video-urodynamic studies are performed sooner.

An additional option for treatment of a hostile neurogenic bladder is the surgical creation of a vesicostomy. Although CIC offers many benefits, compliance may be difficult with the strict regimen required to maintain safe storage pressures. Vesicostomy is a valid option because the low-pressure drainage preserves the upper urinary tract (Snyder et al, 1983) and can dramatically diminish admission rates for urosepsis. A vesicostomy is especially important in the child with spina bifida and vesicoureteral reflux because it is impossible to maintain sterile urine with use of CIC. Indeed, a child with spina bifida and vesicoureteral reflux who is maintained on CIC is at greater risk of developing pyelonephritis.

The child without evidence of a hostile bladder may be followed with ultrasound examinations every 6 to 12 months. Such children must, however, be evaluated with at least one examination annually, because the bladder may undergo degenerative changes over time, especially within the first 3 years of life. At 3 to 4 years of age, the issues of fecal and urinary continence must be addressed. These children will require fecal training and in most cases a daily enema followed by planned timed evacuation. Urinary continence is rare in these patients; most large series report that fewer than 5% to 10% of patients void to completion without incontinence. For this reason, these children must master the process of CIC. Once compliance with a CIC regimen has been established, further surgical reconstruction of the lower urinary tract may be required in order to achieve complete urinary continence.

IMPERFORATE ANUS

The diagnosis of imperforate anus prompts an immediate general surgical consultation and usually results in a diverting colostomy. It is important to recognize that affected infants often have associated urologic findings. Urologic abnormalities are more common in patients in whom the rectum ends in the supralevator position (30%) as opposed to the infralevator position (15%). Up to 40% of these patients may have an associated lumbosacral lesion such as spina bifida occulta or a tethered cord (Pena and Hong, 2000). These patients must be identified because their bladders are at risk for neurogenic voiding dysfunction even before the rectal pull-through (De Filippo et al, 1999). These patients often require intermittent catheterization to achieve continence.

The urological radiographic evaluation of these patients should include a renal-bladder ultrasound study and VCUG. The renal sonogram will identify those patients with renal agenesis, anomalies of renal fusion, or occasional obstructive uropathy. If the VCUG identifies vesicoureteral reflux, antibiotic prophylaxis should be initiated. In addition, the VCUG may identify signs of a coloprostatic or colovaginal fistula and aid in subsequent anorectal reconstruction. Finally, an MRI study of the lumbosacral spine will identify that subset of patients with a tethered cord or spinal dysraphism. Patients who require detethering should undergo a video-urodynamic assessment postoperatively.

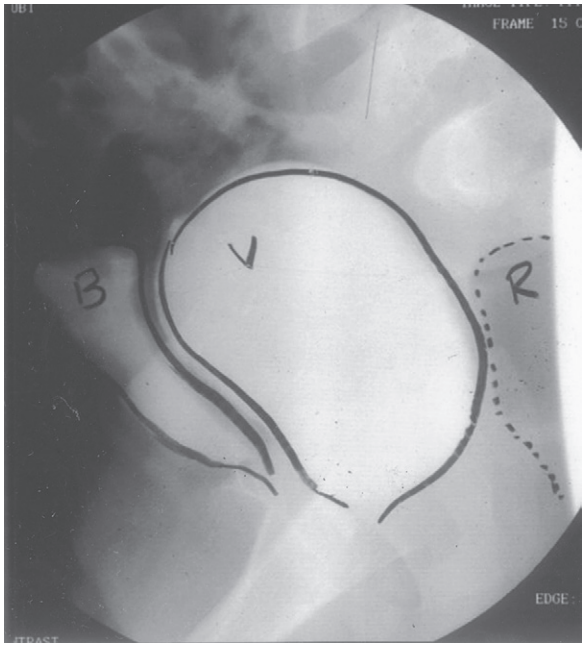

FIGURE 84-10 This genitogram, performed by retrograde injection of contrast into a single sinus anterior to the patient's rectum, demonstrates the anteriorly placed bladder *(B)* and posteriorly placed vagina *(V)*. The vagina and urethra merged into a common sinus, which then traveled a distance of 2 cm before emerging on the perineal body. The rectum *(R)* was normally placed. The vagina distended as a result of urinary entrapment, and the patient presented with a lower abdominal mass.

CLOACAL ANOMALIES

Cloacal anomalies associated with incomplete caudal differentiation manifest as a wide spectrum of clinical abnormalities. The urogenital sinus is a common variant in the female neonate. The term *urogenital sinus* in the setting of cloacal anomalies describes a completely "normal" although anteriorly placed rectum and a common urogenital channel or sinus into which the vagina and urethra merge (Figure 84-10). Such neonates may present with a pelvic mass that is cystic and posterior to the bladder on pelvic sonography. Close inspection of the genitalia reveals one common sinus, which is narrow and offers high resistance to urinary flow. As a consequence, the bladder empties into the vaginal vault, which progressively expands. In severe cases, this dilated vagina may even produce ureteral obstruction and hydronephrosis. The definitive diagnosis is made by a fluoroscopic genitogram or MRI genitogram. The term *cloaca* describes complete fusion of colonic, urinary, and genital systems; urethra, vagina, and rectum empty into the perineum via one common channel. The embryology, anatomy, and complex management of

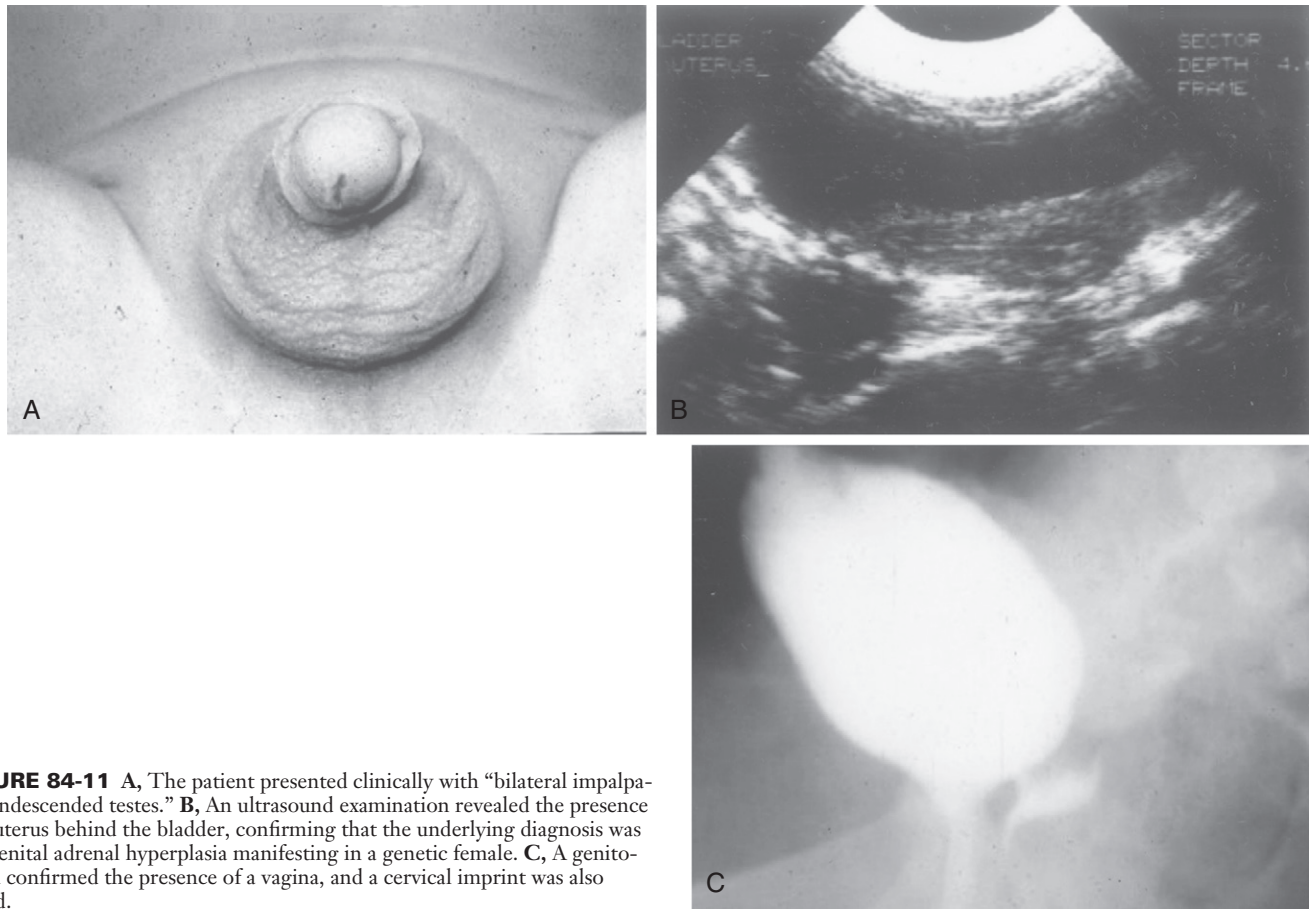

FIGURE 84-11 **A,** The patient presented clinically with "bilateral impalpable undescended testes." **B,** An ultrasound examination revealed the presence of a uterus behind the bladder, confirming that the underlying diagnosis was congenital adrenal hyperplasia manifesting in a genetic female. **C,** A genitogram confirmed the presence of a vagina, and a cervical imprint was also noted.

these rare cases have been reviewed in great detail by Pena et al (2004). These anomalies constitute neonatal surgical emergencies, in which management decisions are highly individualized.

DISORDERS OF THE GENITALIA

UNDESCENDED TESTES

Three percent of full-term boys have an undescended testicle. By 1 year of age, this percentage decreases to approximately 0.8%. Most spontaneous testicular descent will occur by 6 to 9 months of life (Wenzler et al, 2004). Up to 30% of patients with undescended testes present with bilateral undescended testes. The presence of bilateral impalpable undescended testes in a newborn boy warrants a genetic and endocrine evaluation for a disorder of sexual differentiation. In addition, failure to appreciate the significance of bilateral and impalpable undescended testes in the NICU could result in missed diagnosis of congenital adrenal hyperplasia in a virilized female neonate (Figure 84-11). Although in most cases of bilateral impalpable testes the infant proves to be a normal boy, neonates with congenital adrenal hyperplasia often have inadequate cortisol and mineralocorticoid function, leaving the child susceptible to electrolyte imbalances and dehydration. Furthermore, failure to diagnosis a disorder of sexual differentiation delays a decision regarding the sex of rearing. Similar concerns arise if undescended testes are found in the presence of a hypospadias (see later section on ambiguous genitalia).

The neonate with a unilateral undescended testis and a normal phallus may be referred for a urologic follow-up evaluation at 3 to 6 months of age. If at 6 months of age the testis remains out of position, surgical intervention should be undertaken to reposition the testis within the scrotum. The impalpable testis may be a true intraabdominal gonad or a testis that is intermittently in and out of a large patent processus vaginalis; or the testis may be completely absent secondary to an antenatal torsion. If testicular agenesis is present, the contralateral testis usually demonstrates some degree of compensatory hypertrophy. This hypertrophy is recognized on physical examination or manifests with an increased volume by sonographic measurements. The increased contralateral testis volume, however, does not preclude the need for exploration. Parents need to be reminded that in 80% of cases of inguinal exploration for an impalpable testis, the testis is located and a successful orchiopexy is performed. The child who presents at 6 months of age with an undescended testis high in the inguinal canal is also a candidate for surgical intervention, because the testis is unlikely to descend spontaneously. If the testis is near the scrotum, a repeat examination is prudent before pursuing surgical repair.

Long-term issues associated with cryptorchidism include an increased risk of infertility and testicular malignancy. Fertility rates vary greatly depending on whether cryptorchidism is unilateral or bilateral. Long-term follow-up

studies evaluating paternity suggest that 90% of boys with unilateral cryptorchidism report paternity in later years (Cendron et al, 1989; Lee et al, 1996). Furthermore, paternity was not affected by the age at the time of surgery (Lee et al, 1995). However, paternity rate decreased to 50% for patients with bilateral undescended testes who underwent orchiopexy in the first 3 years of life. As age at the time of bilateral orchiopexy increases, the paternity rates decline (Lee et al, 1997). A number of studies have demonstrated that cryptorchidism results in lower sperm counts despite surgical correction, and that the lowest counts are observed in patients with bilateral cryptorchidism. Testicular biopsy at the time of orchiopexy may offer a potential to identify those patients at the greatest risk of infertility 20 and 30 years later; a histologic scoring system allowing the prediction of a high-risk cohort of patients was recently validated with long-term follow-up semen analyses (Rusnack et al, 2003). The ability to predict low sperm counts using biopsy criteria also may allow for early hormonal treatment to enhance future fertility prospects in this select group of patients.

The etiology of cryptorchidism remains poorly understood. A genetic contribution is suggested by the presence of a family history in 5% to 10% of cases (Chacko and Barthold, 2009). Antiandrogen treatment increased the likelihood of cryptorchidism in a rat model offering support for an environmental exposure hypothesis (Spencer et al, 1991). Deletion of the insulin 3 gene in mice results in cryptorchidism that, if untreated, results in infertility; however, microsurgical orchiopexies in this population of mice improved testicular histology and enhanced fertility (Nguyen et al, 2002). This work offers a scientific basis for orchiopexy, which remains one of the more commonly performed pediatric surgical procedures. In human studies of cryptorchidism, mutations in the insulin-3 gene are rare (Baker et al, 2002), suggesting that other pathways or mutations downstream of insulin-3 are responsible for this phenotype.

The relative risk for testicular cancer in patients with an undescended testis increases approximately eightfold over that in the normal population, yet this observation is tempered by the rarity of testicular cancer. Thus, the overall lifetime risk of developing testicular cancer remains low for the individual patient, and in a large Scandinavian series, the incidence of malignancy was further diminished if surgical intervention was performed before puberty (Pettersson et al, 2007). Therefore, orchiopexy is recommended to place the testes in the proper scrotal position and to allow for monthly self-examination once the patient enters puberty.

TESTICULAR TORSION

Torsion of the testes is a rare event in the neonatal period, and its management remains controversial. In determining the proper intervention, it is essential to document the appearance of the scrotum and testes at birth. The newborn who presents in the delivery room with a painless, blue, and edematous hemiscrotum will likely have had an antenatal torsion. In this type of torsion, the entire tunica vaginalis and spermatic vessels twist at the level of the gonadal vessels and occlude the vascular pedicle, thus resulting in testicular ischemia. This event often occurs during the last trimester, and thus the indurated hemiscrotum observed in the delivery room is a late presentation of a terminal process. If the antenatal torsion occurs early in gestation, all inflammation will have resolved, and the neonate presents with an impalpable testis. Surgical findings include blood vessels and a vas deferens that end blindly at a common point where a small nubbin is occasionally located.

Little controversy exists over management of the neonate who was born with a normal scrotal exam but subsequently develops scrotal swelling and erythema; these patients should undergo a Doppler ultrasound and surgical exploration if blood flow cannot be confirmed (Guerra et al, 2008). The persisting controversy surrounds the management of the infant who is born with a clinically apparent torsion. In this setting, immediate exploration in the hours after birth rarely results in testicular salvage, and the risks of anesthesia are elevated. However, multiple case reports have documented bilateral metachronous torsions (Baglaj and Carachi, 2007). Although rare, the potential for bilateral anorchia is devastating given the long-term sequelae of infertility and need for testosterone replacement therapy in puberty and beyond. As the risks of neonatal anesthesia have declined over the years, a growing number of urologists are advocating early exploration with removal of the torsed testes that cannot be salvaged and contralateral orchiopexy to protect the remaining gonad (Guerra et al, 2008). Testes with antenatal torsion may also present as a firm mass in the neonatal period. The use of Doppler ultrasonography will help differentiate testicular torsion from the more rare neonatal yolk sac tumor where testicular blood flow will be demonstrated.

HYDROCELE

A hydrocele is a collection of fluid between the tunica vaginalis and tunica albuginea, which covers the surface of the testes. In the neonate, this fluid originates in the peritoneal cavity that communicates with the scrotum via an evagination or extension of the peritoneum termed a patent processus vaginalis. If the patency is small, peritoneal fluid may become trapped in the scrotum. This unidirectional fluid flow explains the slow and progressive increase in scrotal size that may be observed in some cases. In other cases with a large patency, the fluid may move in and out of the scrotum with ease such that when the urologist arrives to examine the child, the swelling is absent. It is important to reassure families that communicating hydroceles often improve over time. Indeed, the frequency of a patent processus vaginalis in autopsy series of men with no history of hernias or hydroceles was 20%. In addition, hydroceles may present acutely following the placement of ventriculoperitoneal shunts or peritoneal dialysis catheters. In these instances, both sides should be repaired because there is a 30% chance that the contralateral side will also become symptomatic. However, overly aggressive therapy of the neonatal hydrocele should be avoided, because many of these hydroceles will resolve spontaneously, and surgical intervention may damage the vas deferens or testicular vessels, resulting in testicular atrophy. The likelihood of such an iatrogenic injury is increased in the small neonate.

HERNIA

In cases where the patency of the processus vaginalis is large enough, intestines and other viscera (including the bladder) may migrate into the scrotum (Lau et al, 2007). This, by definition, is a hernia, which is often easily reducible and not a surgical emergency. In contrast, a difficult-to-reduce or incarcerated hernia requires urgent repair to preserve the herniated structure. If the hernia becomes strangulated, blood supply to the intestine will be compromised. This represents a surgical emergency.

HYPOSPADIAS

The diagnosis of hypospadias is established when the urethral meatus is not present in the normal glanular position; the meatus may be present anywhere along the ventral penile surface from the glans to the perineum. In addition, there is an asymmetrical or dorsally hooded foreskin, and the penis may be tethered, creating a significant bend (chordee). The etiology of hypospadias remains uncertain, although a genetic contribution is postulated, because a family history is reported in 5% to 10% of cases. More recently, investigators have postulated that environmental exposures to endocrine disruptors provide a significant contribution (Wang and Baskin, 2008). Experimental studies in mice suggest that exposures to high doses of estrogens lead to malformation of the urethral seam in the developing genital tubercle (Yucel et al, 2003), which would provide a mechanism by which endocrine disruptors could lead to hypospadias. Proponents of the endocrine disruptor theory note that the incidence of hypospadias has increased over the past 30 years (Paulozzi et al, 1997); however, other studies have failed to demonstrate such an increase (Fisch et al, 2009).

These infants must not undergo neonatal circumcision; the foreskin is crucial for use in the urethral reconstruction and correction of the chordee. However, up to 10% of patients with a hypospadias may have an intact foreskin, and the diagnosis is determined only after circumcision. These cases constitute the megameatus–intact prepuce variants. In such cases, the loss of foreskin does not compromise the hypospadias repair, which is completed at approximately 6 months of age (Snodgrass and Khavari, 2006). It is important to confirm that both testes are properly descended; hypospadias in conjunction with an undescended testis should raise the possibility of disorder of sexual differentiation (Cox et al, 2008; Kaefer et al, 1999a). This evaluation is critical if both testes are undescended and impalpable, because this phenotype may represent a diagnosis of congenital adrenal hyperplasia in a female neonate (see later section on ambiguous genitalia).

For an infant with hypospadias and bilaterally descended testes, an outpatient urological evaluation should be arranged within 2 to 6 months of age. The greatest chance for an underlying disorder of sexual differentiation being present is seen in proximal hypospadias associated with one or two impalpable testes (Kaefer et al, 1999a). In that setting, urologic consultation should be obtained in the NICU before discharge.

Hypospadias presents with a wide spectrum of severity. The best functional and cosmetic results are obtained in 90% of cases in which the meatus is present anywhere along the penile shaft. Snodgrass and Yucel (2007) have developed a versatile repair that offers high success rates for hypospadias when the meatus is present along the penile shaft. Current hypospadias repairs offer functional improvement in terms of the quality of stream and cosmetic results that are increasingly approaching those seen in normal males. Even the 10% of cases that constitute the most severe penoscrotal hypospadias may be reconstructed with good cosmetic and functional results. The key in all of these cases is the preservation of all genital skin that is to be used in reconstruction—hence the need to avoid circumcision.

CIRCUMCISION

Few topics arouse as much controversy, office visits, phone calls, and annoyance for families, pediatricians, and urologists as the issue of routine circumcision in the newborn boy. Circumcision has been practiced for centuries, and despite efforts to discourage the practice, families have continued to request this surgical procedure. In many parts of the United States, nearly 80% of the male population is circumcised. In fact, the incidence of circumcision appears to be rising in the United States (Nelson et al, 2005). In patients with poor hygiene, a nonretractile foreskin may increase the risk of penile cancer and mask the onset of carcinoma of the penis. Yet, penile carcinoma is a rare malignancy in the United States and a common malignancy in underdeveloped nations where circumcision is not practiced. The risk for penile cancer is associated with limited access to regular bathing, basic hygiene, and the ability to retract the foreskin when sexual activity begins. The etiology of carcinoma of the penis is polyfactorial, and the threat of malignancy is not a mandate for circumcision. Based on recent clinical trials in Africa, it has been demonstrated that circumcision is associated with a significantly lower rate of HIV seroconversion (Siegfried et al, 2009; Tobian et al, 2009). Although the role of circumcision in Africa is expected to increase given these data, educational efforts on behalf of diminished promiscuity, condom use, and basic hygiene are essential to public health.

Parents may cite a significant study reported by Wiswell and Geschke (Wiswell, 1997; Wiswell and Geschke, 1989), that identified a small but very real medical benefit to circumcision. By evaluating discharge data from U.S. Army hospitals worldwide, these investigators correlated the status of the foreskin with subsequent urinary tract infections. Their findings reveal that, within the 1st year of life, although only 20% of males were not circumcised, this 20% accounted for 80% of all urinary tract infections. In other words, these investigators demonstrated that the presence of foreskin increased the risk of a urinary tract infection by approximately fourfold during the 1st year of life. Therefore, circumcision is to be encouraged for any neonate with an underlying congenital anomaly of the urinary tract such as reflux, posterior urethral valves, or megaureters, where the added burden of a urinary tract infection has serious consequences.

The three main techniques for circumcision are those using the Plastibell, the Gomco clamp, and the Mogen clamp. Each has benefits and drawbacks; each physician

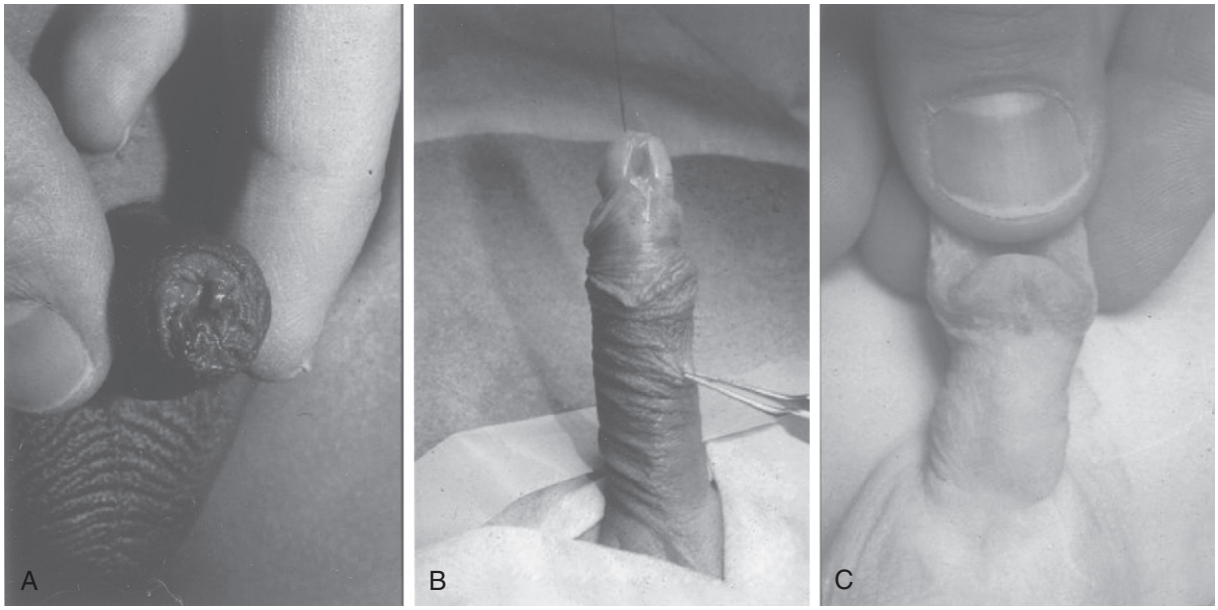

FIGURE 84-12 Hypospadias may not be discovered until the time of circumcision, because the foreskin has such a normal appearance, as in **A** and **B**. These cases represent the megameatus–intact prepuce variant, in which circumcision is not at all detrimental to future reconstruction. **C,** This photograph shows a more typical hypospadias with an asymmetric foreskin and a meatus that is present at the glanular margin. In such cases, circumcision should be deferred because the hooded preputial skin may be required for subsequent reconstruction.

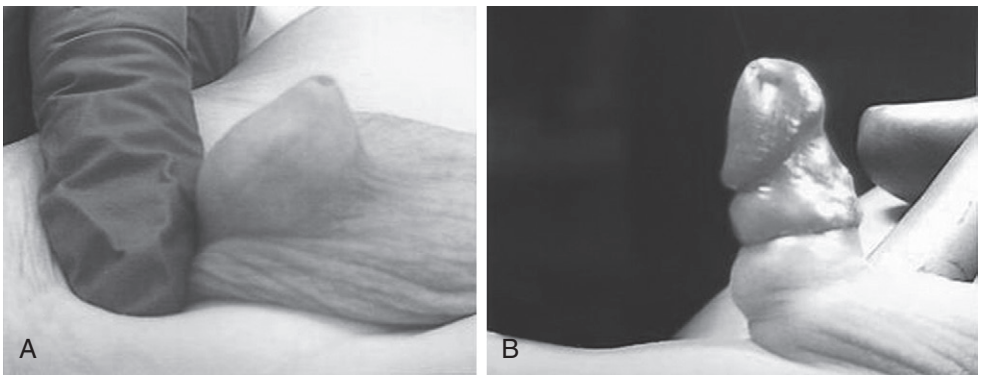

FIGURE 84-13 **A,** This is an example of true penile webbing in which the penile shaft is attached to the scrotal skin for more than 50% of the length of the shaft. This webbing or tethering can only be repaired by a surgical approach **(B)**; such a patient is not a candidate for circumcision done in the neonatal unit.

performing circumcisions will find the method with which he or she feels most comfortable and should use it repetitively. If there is doubt about the penile articular anatomy, the procedure should be terminated and urologic consultation obtained. The use of topical EMLA cream followed by a circumferential penile block is highly effective in minimizing pain associated with the procedure and offers a cost-effective means of providing this service (Jayanthi et al, 1999). Every effort should be made to perform circumcision in the newborn period and thus avoid the use of a general anesthetic in the older child. A study within the Kaiser health plan considered the issue of circumcision from a cost-effectiveness standpoint and came to the conclusion that the system could demonstrate a cost savings of $183 per patient even if routine neonatal circumcision was performed at an average cost of $200 (Schoen et al, 2006).

The leading contraindication to circumcision is medical fragility of the infant. Circumcision in a premature baby may present a technical challenge related to the infant's smaller size. In such instances, circumcision should be deferred until just before discharge from the NICU. In the child with a complex medical course, this timing also offers the physician a chance to perform a circumcision with full cardiovascular and respiratory monitoring that is not available in an office-based setting. Circumcision must never be performed in any child with hypospadias or epispadias (Figure 84-12), because as mentioned earlier, this skin is essential to the urethral reconstruction. In recent years there has been an increase in the diagnosis of penile webbing, which often results in circumcision being deferred to specialty care and performed under a general anesthetic. A case of significant penile webbing is shown in Figure 84-13, and in this instance an operative repair was indicated.

Bleeding after a routine circumcision may be observed in 10% to 20% of cases, and minor bleeding is not cause for alarm. If the bleeding has saturated the dressing and repositioning of the pressure dressing fails to stop the bleeding, the frenulum should be inspected because most bleeding vessels are found in this area. If the bleeding persists, the

clinician should not hesitate to obtain coagulation studies; hemophilia and von Willebrand's disease may manifest in this manner. Rarely, there is injury to the glans and urethra that requires urological intervention. Typically, the most common problem arising after circumcision is the formation of penile adhesions. This complication may be prevented by teaching parents to retract the penile shaft skin and apply petrolatum over the glans. Parents also should be warned that despite a nice skin fit in the neonatal period, the cosmetic appearance of the penis may change as the prepubic fat pad grows. The result may be that a perfect circumcision is obscured as the penis is pulled back into the fat pad; in such cases, reassurance, and not surgical revision, is indicated.

AMBIGUOUS GENITALIA

The diagnosis and management of the child with ambiguous genitalia remain a medical and social emergency; a complete discussion of this topic is beyond the scope of this section. Currently, prenatal diagnosis has allowed discussions about genital ambiguity to begin before delivery (Rintoul and Crombleholme, 2002). The widespread use of ultrasonography and increasing use of amniocentesis have allowed the in utero diagnosis of virilizing congenital adrenal hyperplasia and androgen resistance syndromes. Such diagnosis is possible because the sonographic appearance of genitalia at birth does not correspond to the karyotype obtained at amniocentesis.

The most common presentation is the female neonate with congenital adrenal hyperplasia. Findings on physical examination range from severe clitoromegaly with hypospadias to a fully developed phallus with no palpable gonads (see Figure 84-11). This virilization is caused by enzymatic deficiencies in the pathways of cortisol synthesis, leading to shunting into the androgen biosynthetic pathways (Speiser and White, 2003). Family history is useful, because an older sibling or relative may have been diagnosed with this condition. It is also useful to know if a karyotype was performed during gestation. If a karyotype was not performed or the results are not available, an ultrasound examination of the pelvis should be ordered to evaluate for mullerian structures (see Figure 84-11), and a karyotype should be ordered. Virilizing congenital adrenal hyperplasia is a rare diagnosis, and most neonates with bilateral impalpable testes will prove to be normal males. However, a delay in establishing this diagnosis is dangerous because replacement therapy with cortisol must be initiated. A genitogram (see Figure 84-11) will delineate the extent of surgery required. Whereas 20 years ago, surgery was encouraged in the neonatal period with the idea that it would enable better acceptance of a female gender role by the parents and child, today the timing of surgery is controversial; these issues are addressed in the final paragraph.

Another common presentation is that of the child with androgen insensitivity who is presents as a phenotypic female despite an XY karyotype from an amniocentesis. Mutations in the androgen receptor or in the downstream pathway result in a phenotypic female with bilateral testes. These testes produce the mullerian inhibitory substance—hence, the uterus and the upper two thirds of the vaginal vault will be absent. There are no surgical management or gender assignment issues for these patients in the neonatal period.

Mixed gonadal dysgenesis is diagnosed in the NICU or newborn nursery when neonates present with severe hypospadias and unilateral undescended testis (Rajfer and Walsh, 1976). These patients may have a normal XY karyotype or a mosaic presentation. At exploratory laparotomy, the gonads are biopsied; a testis will be found on one side and a primitive streak on the opposite side. Rudimentary mullerian structures may be seen on the side of the streak gonad and may include a hypoplastic uterus. Streak gonads are removed because of their malignant potential. Historically, female gender assignment was considered, but currently, maintaining a male gender of rearing with advanced hypospadias reconstruction is recommended.

The traditional approach to the diagnosis and management of genital ambiguity has undergone a great deal of criticism and increasing scrutiny over the past decade. With the traditional approach, a heavy emphasis was placed on assigning a sex of rearing as soon as possible and initiating any surgical reconstructions in the neonatal period. In recent years, it has become apparent that this approach is problematic. Physicians and parents assign a sex and gender role to a neonate. However, the long-term question arises as to whether a child's own gender identity will be congruent with the assigned gender role. For years it was believed that gender identity was not fixed until 2 years of age. Given the technical problems encountered in phallic reconstruction, it was believed that if a satisfactory phallus could not be reconstructed, a female sex should be assigned. The recent reports of several patients who, on reaching teenage years, have reverted back to a male gender after early female gender assignment have challenged this practice (Diamond and Sigmundson, 1997; Reiner, 2002). In light of these scientific and clinical concerns, some authors and patients have called for a moratorium on surgery in infancy for patients with genital ambiguity (Diamond, 1999). They propose that all diagnostic tests be performed to allow for a determination of what the appropriate gender assignment will be for the child. However, no irreversible surgery would be performed until the child determines his or her gender identity and pediatric assent is obtained. It is important to note that many patients with an XY karyotype assigned to a female gender have adjusted to their situation (Schober et al, 2002). However, because the brain is a sexually dimorphic organ, many of the structural differences between the two genders exist because of hormonal imprinting in utero (Gorski, 2002; Swaab et al, 2002), and hence such compensatory findings will be variable.

CHAPTER 85

Acute Kidney Injury and Chronic Kidney Disease

David Askenazi, Lorie B. Smith, Susan Furth, and Bradley A. Warady

ACUTE KIDNEY INJURY

DEFINITION

Previously referred to as *acute renal failure*, acute kidney injury (AKI) is characterized by a sudden impairment in kidney function, that results in the retention of nitrogenous waste products (e.g., urea) and alters the regulation of extracellular fluid volume, electrolytes, and acid-base homeostasis. The term *acute kidney injury* has replaced *acute renal failure* by most critical care and nephrology societies, primarily to highlight the importance of recognizing this process at the time of injury as opposed to waiting until failure has occurred (Mehta, 2007). Despite its limitations, serum creatinine (SCr) is the most commonly used measure to evaluate glomerular filtration in the clinical setting and is more specific than blood urea nitrogen (BUN). BUN is an insensitive measure of glomerular filtration rate (GFR) because it can be increased out of proportion to changes in GFR with high dietary protein intake, gastrointestinal bleeding, use of steroids, and hypercatabolic states. If the BUN-to-SCr ratio exceeds 20, increased urea production or increased renal urea reabsorption that occurs in prerenal azotemia should be suspected (Feld et al, 1986).

In the neonatal population, the most common SCr cut-point used to define AKI has arbitrarily been set at 1.5 mg/dL or greater, independent of day of life and regardless of the rate of urine output. Although SCr is the most common method to diagnose AKI, it has significant shortcomings, including

- SCr concentrations may not change until 25% to 50% of the kidney function has already been lost; therefore it may be days after an injury before a significant rise in SCr is seen (Brion, 1986).
- At a lower GFR, SCr will overestimate renal function because of tubular secretion of creatinine (Brion, 1986).
- SCr varies by muscle mass, hydration status, sex, age, and gender.
- Different methods (Jaffe reaction versus enzymatic) produce different values, and medications and bilirubin can affect SCr measured by the Jaffe method (Lolekha, 2001; Rajs and Mayer, 1992).
- Once a patient receives dialysis, SCr can no longer be used to assess kidney function because SCr is easily dialyzed.

Additional problems with using SCr as a measure of AKI specific to neonates include

- SCr in the first few days of life reflects the mother's SCr; thereafter, the normal distribution of SCr values demonstrates variation that is greatly dependent on the level of prematurity and age (Gallini, 2000) (Figure 85-1)
- Normal nephronogenesis in healthy term infants begins at 8 weeks' gestation and continues until 34 weeks' gestation, at which time the number of nephrons (1.6 to 2.4 million) approximates that of an adult (Abrahamson, 1991). Depending on the degree of prematurity, GFR steadily improves from 10 to 20 mL/min per 1.73 m^2 during the first week of life to 30 to 40 mL/min per 1.73 m^2 by 2 weeks after birth, concomitant with alterations in renal blood flow. GFR improves steadily over the first few months of life (Brion, 1986) (Table 85-1).
- Bilirubin levels in premature infants are normal at birth, rise in the first several days, and return to normal after a few weeks; this can have an impact if the Jaffee method of SCr determination is used (Lolekha, 2001).

Other problems with using a threshold cutoff to define AKI is that this approach fails to delineate the severity, timing, and cause of the injury. In the adult and pediatric populations, classification definitions of AKI based on SCr and urine output have gained acceptance. The two most common classification schemes that delineate different severities of AKI are the Risk, Injury, Failure, Loss, and End-Stage Renal Disease (RIFLE) (Bellomo et al, 2004) and the Acute Kidney Injury Network (AKIN) (Mehta, 2007) classifications. These AKIN classification definitions have created commonality in defining AKI, and they clearly show that incremental degrees of AKI independently affect survival after correcting for comorbidities, complications, and severity of illness in pediatric and adult studies (Abosaif et al, 2005; Chertow et al, 1998; Hoste et al, 2006). These data suggest that patients may not only die with kidney failure, but that this dysfunction causes functional and transcriptional changes in the lungs and other organs that ultimately lead to poor outcomes (Bellomo et al, 2004; Elapavaluru and Kellum, 2007; Hoste et al, 2006). These studies have not been reproduced in critically ill neonatal populations.

In children, Akcan-Arikan et al (2007) proposed a modified pediatric RIFLE (pRIFLE) classification that is similar to the adult RIFLE classification except for a lower cutoff of SCr to achieve the F category, thereby reflecting the fact that children have a lower baseline SCr. An SCr of 4.0 mg/dL is not needed to have severe dysfunction. Similar classification definitions of AKI are greatly needed to better describe the incidence and outcomes of AKI in different populations of critically ill neonates. Delineation between the 1st week of life (when the infant has a high SCr level that will slowly fall) and changes in SCr level after the 1st week will be needed in a neonatal AKI classification system.

Despite these working classification systems, the diagnosis of AKI is problematic, because current diagnosis relies on two functional abnormalities: functional changes in SCr (marker of GFR) and oliguria. Both of these

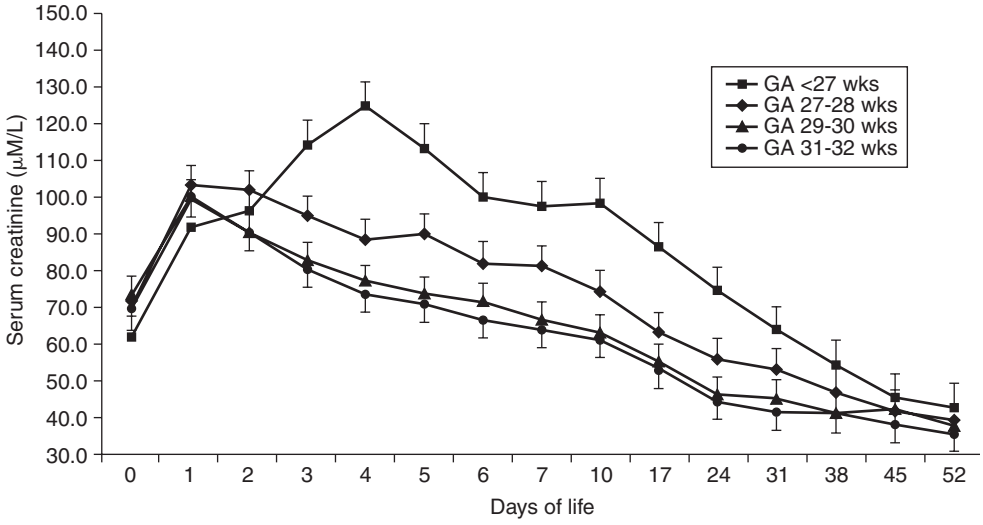

FIGURE 85-1 Serum creatinine concentrations (μM/L) during the first days of life, with values given as means and standard error for infants born at different gestational ages.

TABLE 85-1 Insulin Clearance GFR in Healthy Premature Infants

Age	GFR (mL/min per 1.73 m^2)
1-3 days	14.0 ± 5
1-7 days	18.7 ± 5.5
4-8 days	44.3 ± 9.3
3-13 days	47.8 ± 10.7
1.5-4 months	67.4 ± 16.6

GFR, Glomerular filtration rate.

measures are late consequences of injury and not markers of the injury itself. The ideal marker to detect AKI should be upregulated shortly after an injury and be independent of the GFR (Askenazi, 2009a). Current studies of urinary and serum biomarkers of AKI promise to improve our ability to diagnose AKI early in its disease process. For example, urine and serum neutrophil gelatinase-associated lipocalin, urine interleukin-18, kidney injury marker 1, and others have been shown to predict which neonates undergoing cardiopulmonary bypass will develop a rise in SCr level by greater than 0.5 mg/dL (Mishra et al, 2005; Parekh et al, 2006) (Figure 85-2). Creating AKI definitions using early injury biomarkers, which can ultimately predict morbidity and mortality, is of paramount importance. In addition, well-designed clinical research studies on early noninvasive biomarkers of AKI in different neonatal populations are needed to better characterize AKI and predict outcomes. Once we can reliably identify AKI early in the disease process, preventive and therapeutic interventions can be studied to improve outcomes in neonates with AKI.

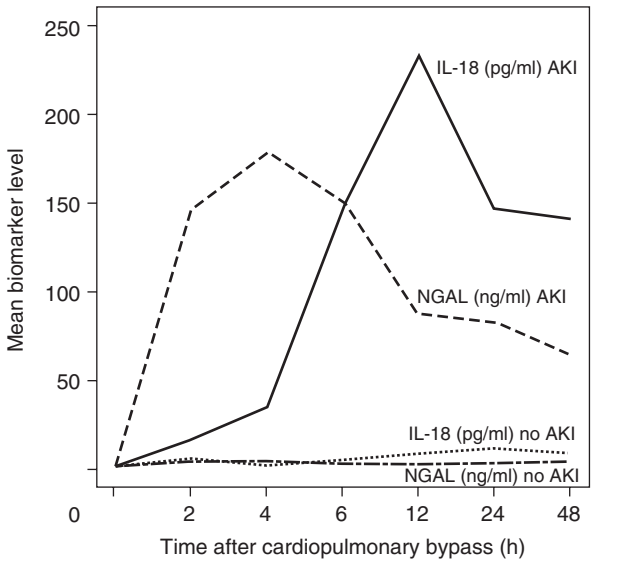

FIGURE 85-2 Mean values of urine interleukin-18 (pg/mL) and neutrophil gelatinase-associated lipocalin (ng/ml) over the first hours after cardiopulmonary bypass in infants who develop acute kidney injury (50% increase in serum creatinine) compared with those who did not develop acute kidney injury.

EPIDEMIOLOGY

Critically ill neonates are at risk of AKI because they are commonly exposed to nephrotoxic medications and have frequent infections that lead to multiple organ failure (Andreoli, 2004). The exact incidence of neonatal AKI is difficult to quantify because infants commonly have nonoliguric renal failure and may therefore not be screened with SCr for AKI. Additionally, most reports define only severe cases of AKI (usually SCr >1.5 mg/dL or need for renal replacement therapy [RRT]) (Agras et al, 2004; Stapleton et al, 1987). Published studies estimate the incidence of neonatal AKI in critically ill neonates between 8% to 24% and mortality rates between 10% to 61% (Andreoli, 2004). Moghal et al (1998) suggested that relative to adult and pediatric critically ill populations, neonates have the highest incidence of AKI.

Infants With Perinatal Hypoxia

Most studies of neonatal AKI describe term infants with asphyxia at the time of birth. Hypoxic-ischemic encephalopathy accounts for 23% of the 4 million neonatal deaths globally and high rates of disability (Lawn et al, 2005).

Three different observational studies describe the incidence of AKI (defined as SCr >1.5 mg/dL) in asphyxiated critically ill newborns. Karlowicz and Adelman (1995) compared term infants with severe asphyxia (according to Portman's asphyxia morbidity scoring system) (Portman et al, 1990) to similar infants with moderate asphyxia scores. They found that AKI occurred in 20 of 33 (66%) of infants with severe asphyxia compared to 0 of 33 (0%) in those with moderate asphyxia. In a case control analysis (matching for gestational age and birthweight in otherwise healthy newborns), Aggarwal et al (2005) observed the incidence of AKI in infants with 5-minute Apgar scores of 6 or less to be 56% versus 4% in controls. Similarly, Gupta et al (2005) found a 47% incidence of AKI and 14.1% mortality in infants with Apgar scores of 6 or less. All these studies report more than 50% of AKI cases to be nonoliguric, which highlights the insensitivity of oliguria in predicting AKI in neonates.

General Neonatal Population

Three recent studies have explored AKI in the general critically ill neonatal population and confirmed the high incidence of AKI and mortality in these infants. In a retrospective analysis, Agras et al (2004) found 25% hospital mortality in neonates with AKI. Many (47%) of their patients had nonoliguric renal failure, and premature infants constituted 31% of the cases. Mathur et al (2006) prospectively studied mostly term neonates with sepsis and found a 26% incidence of AKI. The mortality rate was significantly higher in those with AKI versus those without AKI (70.2% versus 25%; p <0.001). Although this study gives insight into the incidence of AKI in neonates, this study is limited by their choice of the definition of AKI (BUN >20) and their inability to control for gestational age, birthweight, comorbidity, and severity of illness.

To better ascertain the independent role of AKI on survival in premature infants, a recent case-control study (Askenazi et al, 2009b) matching premature infants by gestational age and birthweight found that for every 1 mg/dL increase in SCr, the odds ratio for death increased by a factor of almost 2 (odds ratio [OR], 1.94; 95% confidence interval [CI], 1.13 to 3.32). The OR for death increased even when confounding variables were adjusted (adjusted OR, 3.44; 95% CI, 1.23 to 9.61). Because of study design limitations, caution must be exercised in making inferences about the true incidence and outcomes of neonatal AKI based on these studies. Additional prospective, multicenter studies are needed to determine whether this association exists.

Infants Requiring Cardiopulmonary Bypass

The incidence and outcome data for neonates who require cardiopulmonary bypass are based on single-center experiences, most of which define AKI as a requirement of RRT. Reported incidence of AKI in this population is between 2.7% and 24.6% (Bailey et al, 2007; Picca et al, 1995), with survival rates ranging from 21% to 80% (Picca et al, 1995; Sorof et al, 1999). The causes of AKI in this group are based on preoperative factors, intraoperative changes, and postoperative events. Preoperative risk factors for AKI include hypotension, use of diuretics, angiotensin-converting enzyme inhibitors [ACE-I], indomethacin, hypoxemia, hypothermia, infection, positive pressure ventilation, nephrotoxic medications, and intravenous contrast. Intraoperative changes including hemodynamic changes, aortic clamp time, and inflammatory response to cardiopulmonary bypass influence postoperative AKI. The most important factors that influence the development of postoperative AKI are cardiac performance and sepsis (Picca et al, 2008).

Infants Requiring Extracorporeal Membrane Oxygenation

Several studies of infants and children (Cavagnaro et al, 2007; Meyer et al, 2001; Sell et al, 1987; Shaheen et al, 2007; Weber et al, 1990) who receive extracorporeal membrane oxygenation suggest both AKI and RRT are associated with mortality. To explore the independent role of AKI and receipt of RRT on outcomes, Askenazi et al (2011) performed a retrospective cohort study of 7941 neonates enrolled between 1998 and 2008 in the extracorporeal life-support organization registry. AKI was defined as infants in the registry who had an SCr level greater than 1.5 mg/dL or an International Classification of Diseases code for acute renal failure. Neonatal mortality was 2175 in 7941 (27.4%). Nonsurvivors experienced more AKI (413/2175 [19%] versus 225/5766 [3.9%]; p <0.0001) and more of them received RRT (863/2175 [39.7%] versus 923/5766 [16.0%]; p <0.0001) than survivors. After adjusting for confounding variables, the adjusted OR for the neonatal group was 3.2 (p <0.0001) after AKI and 1.9 (p <0.0001) with RRT. Additional studies to ascertain AKI risk factors, test novel therapies, and optimizing the timing and delivery of RRT can positively affect survival.

One of the most common morbidities of prematurity is the propensity to develop bronchopulmonary dysplasia; it affects 10% and 40% of surviving very low-birthweight and extremely low-birthweight infants, respectively (Eichenwald and Stark, 2008). The pathophysiology of this chronic lung condition involves elevated levels of proinflammatory interleukins, tumor necrosis factor-α, leukotrienes, and increased pulmonary vasculature permeability, which culminate in abnormal lung development and fibrosis. Not only does AKI cause pulmonary edema secondary to volume overload, but evidence in ischemic, nephrotoxic, and bilaterally nephrectomized animal models shows that AKI induces a proinflammatory process highlighted by increase in neutrophils, tumor necrosis factor-α, interleukins, free radicals, endothelial growth factors, and granulocyte colony-stimulating factor (Faubel, 2008; Hoke et al, 2007; Kim do et al, 2006). Clinically it has been recognized that critically ill adults receiving mechanical ventilation with AKI have a dismal prognosis (80% mortality), and they have an impaired ability to wean from mechanical ventilation (Vieira et al, 2007). To date, little is known about the lung-kidney interactions in premature infants, nor the role of AKI on chronic lung disease.

A large prospective cohort study with classification definitions of AKI is greatly needed to better understand the incidence and independent effect of AKI in asphyxiated infants, premature infants, infants undergoing cardiopulmonary

bypass, and the general critically ill newborn population. The role of the kidney in acute and chronic pulmonary disease in premature infants needs to be explored.

PATHOPHYSIOLOGY

Prerenal Azotemia

Prerenal azotemia (sometimes referred to as *pre–kidney failure*, but perhaps better termed *acute kidney success*) occurs in response to decreased renal blood flow (RBF). Causes of prerenal azotemia in neonates include loss of effective circulating blood volume (perinatal blood loss, hemorrhage), dehydration (diarrhea, transepidermal free water losses, poor intake, gastric or chest tube losses), capillary leak (hydrops, infection, or hypoalbuminemia), increased abdominal pressure (necrotizing enterocolitis, ascites, repair or reduction of gastroschisis, omphalocele, or congenital diaphragmatic hernia), and decreased cardiac output (cardiac surgery, heart failure, or the use of extracorporeal membrane oxygenation, which results in a lack of pulsatile flow) (Liem et al, 1995a, 1995b). Nonsteroidal antiinflammatory drugs (NSAIDs), such as indomethacin and angiotensin-converting enzyme inhibitors (ACE-Is), can decrease RBF (Box 85-1).

When low RBF occurs, renal autoregulation preserves GFR by increasing renal sympathetic tone, activating the renin-angiotensin-aldosterone system, and increasing activation of hormones such as vasopressin and endothelin. An increase in filtration fraction (GFR/RBF × 100) increases peritubular oncotic pressure, resulting in enhanced proximal tubular sodium and water reabsorption (Feld et al, 1986) in those with intact tubular function. These renal hemodynamic changes lead to decreased water and sodium losses, so as to maintain systemic volume expansion and blood pressure. Oliguria does not develop in some newborns because of poor vasopressin secretion, weak renal responsiveness to vasopressin (Dixon and Anderson, 1985), poor tubular function in underdeveloped tubular cells, or after prolonged or severe hypoperfusion. In the context of renal hypoperfusion, correction of the underlying condition restores normal renal function unless renal hypoperfusion has been sufficiently severe or prolonged that renal parenchymal damage has already developed. Once parenchymal damage occurs, renal tubular cell damage (acute tubular necrosis) occurs even if renal perfusion is restored.

Intrinsic Acute Kidney Injury

Prolonged or severe hypoperfusion is the most common cause of intrinsic AKI. Other causes of intrinsic AKI include nephrotoxic medications and sepsis, which can cause AKI in both hypodynamic and hyperdynamic blood flow. Approximately 6% to 8% of newborns admitted to NICUs have intrinsic AKI, with severe perinatal asphyxia being the most common cause (Stapleton et al, 1987). Other rare causes of AKI include renal vein thrombosis, renal artery thrombosis, uric acid nephropathy, hemoglobinuria, and myoglobinuria (see Box 85-1). Congenital abnormalities of the kidneys and urinary tract (CAKUT) are discussed further in the section under chronic kidney disease (CKD) of the newborn.

BOX 85-1 Causes of Acute Kidney Injury in the Newborn*

Prerenal Azotemia	Intrinsic Acute Kidney Injury	Obstructive Renal Failure
Loss of effective blood volume	Acute tubular necrosis	Congenital malformations
Absolute loss	Severe renal ischemia	Imperforate prepuce
Hemorrhage	Nephrotoxins	Urethral stricture
Dehydration	Infections	PUV
Relative loss	Congenital infections	Urethral diverticulum
↑ Capillary leak	Pyelonephritis	Ureterocele
Sepsis	Bacterial endocarditis	Megaureter
NEC	Renal vascular causes	UPJ obstruction
RDS	Renal artery thrombosis	Extrinsic compression
ECMO	Renal vein thrombosis	Sacrococcygeal teratoma
Hypoalbuminemia	DIC	Hematocolpos
Renal hypoperfusion	Nephrotoxins	Intrinsic obstruction
Congestive heart failure	Aminoglycosides	Renal calculi
Pharmacologic agents	Indomethacin	Fungus balls
Indomethacin	Amphotericin B	Neurogenic bladder
Tolazoline	Radiocontrast dyes	
ACE inhibitors	Acyclovir	
	Intrarenal obstruction	
	Uric acid nephropathy	
	Myoglobinuria	
	Hemoglobinuria	
	Congenital malformations	
	Bilateral renal agenesis	
	Renal dysplasia	
	Polycystic kidneys	

ACE, Angiotensin-converting enzyme; *DIC,* disseminated intravascular coagulation; *ECMO,* extracorporeal membrane oxygenation; *NEC,* necrotizing enterocolitis; *PUV,* posterior urethral valve; *UPJ,* ureteropelvic junction.

*In many cases, a combination of several causative factors contributes to the development of acute renal failure. For example, absolute hypovolemia, increased capillary leak–induced loss of effective circulating blood volume, and reflex renal vasoconstriction—all can contribute to renal hypoperfusion and ensuing renal injury in newborns with severe forms of shock.

Ischemic Acute Kidney Injury

Despite being the best-oxygenated organ, the kidney is susceptible to hypoxic-ischemic injury because of the redistribution of its blood flow under pathologic circumstances to the vital organs, and because of the unique vascular supply of the renal medulla. The presentation and course of renal damage depend on the severity and duration of the insult. In contrast to prerenal azotemia, renal function abnormalities in intrinsic AKI are not immediately reversible. The severity of intrinsic AKI ranges from mild tubular dysfunction, to acute tubular necrosis, to renal infarction and corticomedullary necrosis with irreversible renal damage (Feld et al, 1986).

Prerenal azotemia and ischemic AKI represent extremes on a continuum of physiologic responses. The main difference between prerenal AKI and ischemic AKI is that in the latter, hypoperfusion induces injury to renal parenchymal cells, particularly to tubular epithelium of the terminal medullary portion of the proximal tubule (S3 segment) and of the medullary portion of the thick ascending limb of the loop of Henle.

The course of ischemic AKI can be subdivided into prerenal, initiation, extension, maintenance, and recovery phases (Sutton et al, 2002) (Figure 85-3). If during prerenal azotemia, restoration of renal blood flow occurs, GFR can return promptly to normal. The initiation phase includes the original insult and the associated events resulting in a

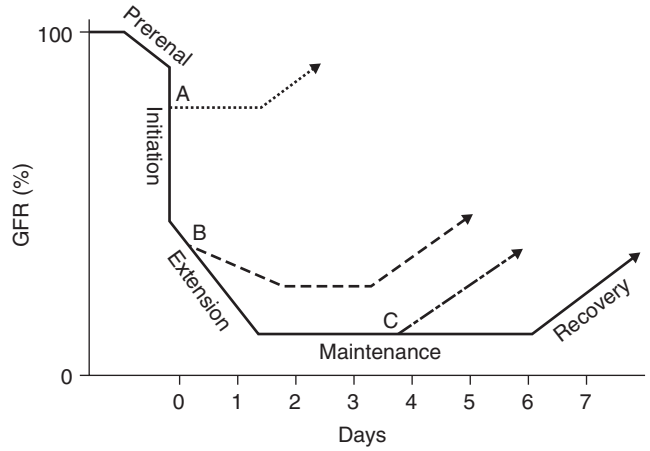

FIGURE 85-3 Schematic representation of stages of the progression in acute kidney injury.

drop in GFR. Tubular dysfunction with low GFR represents the maintenance phase. The duration of the maintenance phase depends, at least in part, on the severity and duration of the initial insult. The recovery phase is characterized by the gradual restoration of GFR and tubular function, which can take months to occur. During the maintenance and recovery phases of AKI, the kidney is susceptible to further damage from additional insults. Recognition of the different phases of intrinsic AKI is helpful in the diagnosis, clinical management, and prognostication of the disorder.

The histologic hallmark of severe ischemic AKI is damage to epithelial tubular cells with a characteristic bleb formation and loss of brush border in the apical portion of the cell, cytoskeleton disruption, and loss of tight junctions between cells. If injury is severe enough, apoptosis and necrosis will occur with resultant desquamation of cells, which lead to tubular obstruction. Tubular epithelial cells are critical in the pathophysiology of ischemic AKI, and damage to the innermost lining of the renal vascular system, endothelial cells, has a critical role in the initiation, extension, maintenance, and recovery phases of ischemic AKI (Basile, 2007; Basile et al, 2001; Molitoris and Sutton, 2004).

When endothelial cell damage occurs, activation of vasoconstriction, impaired vasodilation, and impaired leukocyte adhesion result in capillary obstruction and distorted peritubular capillary morphology. Capillary obstruction and impaired morphology lead to a cycle of increasing ischemia and vascular inflammation. The loss of endothelial cell function may represent an important therapeutic target in which vascular support or endothelial regeneration by progenitor cells can affect the short- and long-term consequences of AKI (Liu and Brakeman, 2008).

Damaged endothelial and tubular cells do not only lead to dysfunction within the kidney; they produce a systemic inflammatory response that has been shown to lead to significant distant organ dysfunction. The inflammatory dysregulation is due, at least in part, to dysfunctional immune, inflammatory, and soluble mediator metabolism. AKI has also been shown to directly affect the brain, lung, heart, liver, bone marrow, and gastrointestinal tract (Awad and Okusa, 2007; Sorof et al, 1999). Mice with AKI (induced by bilateral renal ischemia for 60 minutes) had increased levels of proinflammatory chemokines, keratinocyte-derived chemoattractant, and granulocyte colony-stimulating factor in the cerebral cortex and hippocampus, which results in increased neuronal pyknosis and microgliosis in brain (Liu and Brakeman, 2008). In the lung, mechanistic studies demonstrate that AKI induces increased pulmonary vascular permeability, soluble and cellular inflammation, and dysregulated salt and water channels. Because neurologic and pulmonary morbidity is high in the critically ill neonatal population, the potentially deleterious effects of AKI on these organs need to be explored.

Nephrotoxic Acute Kidney Injury

Pharmacologic agents are the most common cause of nephrotoxic AKI in neonates, although endogenous substances (hemoglobin and myoglobin) may also be toxic to the kidney. These toxins can cause neonatal AKI by decreasing renal perfusion (NSAIDs, diuretics, ACE-Is), direct tubular injury (aminglycosides, cephalosporins, amphotericin B, rifampin, vancomycin, NSAIDs, contrast media, myoglobin–hemoglobin), interstitial nephritis, and tubular obstruction (acyclovir). Although the following discussion is not a comprehensive review, some of the most common nephrotoxic medications in neonates are described.

Indomethacin, a prostaglandin inhibitor used to treat patent ductus arteriosus in premature infants, is one of the most commonly used medications in the neonatal intensive care unit. Severe, although usually transient, nephrotoxicity can occur with indomethacin administration. The primary mechanism of renal action of these drugs is the potentiation of vasoconstrictive and sodium- and water-retaining effects of angiotensin II, norepinephrine, and vasopressin by the indomethacin-induced inhibition of renal prostaglandin production. Because neonatal renal function is more dependent on local prostaglandin production than that of the euvolemic adult—especially when intravascular volume is decreased as a result of fluid restriction, increased capillary leak, and transepidermal water losses in the preterm infant with patent ductus arteriosus—indomethacin administration is commonly associated with elevated SCr concentrations, decreased urine output, and hyponatremia (Cifuentes et al, 1979).

Amphotericin B alters renal function by directly affecting tubular function, resulting in renal tubular acidosis and increasing urinary potassium excretion. Although these nephrotoxic effects are most often reversible, cases of fatal neonatal renal failure caused by amphotericin B toxicity have been reported (Baley et al, 1984). Amphotericin B lipid complex (ABLC), liposomal amphotericin and other lipid formulations of this drug consist of nonliposomal lipid bilayers complexed with amphotericin B. This lipid bilayer causes a higher affinity to fungal rather than mammalian cellular membranes and therefore is less nephrotoxic (Wurthwein et al, 2005). Auron et al (2007) recently showed no differences in blood urea nitrogen or SCr, serum sodium, and serum potassium in 35 premature infants (average birthweight, 764 ± 196 g) compared with similar infants (controlling for gestational age and birthweight). Therefore a 2-week course of amphotericin B complex is likely to be safe in premature infants, although studies to explore longer use of ABLC are needed.

Aminoglycosides are one of the most commonly used medications in the treatment of suspected or proven neonatal sepsis. Aminoglycosides inhibit lysosomal phospholipases, leading primarily to proximal tubule cell damage (Giuliano et al, 1984), although changes in the ultrastructure of the glomerulus also occur (Ojala et al, 2001). A metaanalysis of 11 studies in septic neonates demonstrated that both once-a-day and multiple-dose regimens led to adequate clearance of sepsis. Although rates of ototoxicity or nephrotoxicity were not different among the two groups, pharmacokinetic studies reveal that once-a-day dosing causes less drug accumulation in the kidney's proximal cells, and it usually achieved adequate peak concentrations (>5.0 μg/dL) while avoiding toxic trough levels (<2 μg/dL) (Rao et al, 2006).

Aminoglycosides should be used with caution in any patient with renal dysfunction, concomitant nephrotoxic medication use, or poor renal perfusion owing to volume, hypoalbuminuria, or heart failure. In patients with poor renal dysfunction or risk for impaired aminoglycoside clearance, serial monitoring to assure proper clearance of medication is needed to prevent AKI. Because aminoglycoside toxicity is usually nonoliguric, serial monitoring of SCr values is necessary, especially during prolonged administration of these antibiotics, to detect their potential nephrotoxicity in the newborn.

Acyclovir has replaced vidarabine for treatment of herpes simplex disease because of its ease of use and more favorable side effect profile. High-dose acyclovir (60 mg/kg/day for 21 days) decreased the mortality and CNS disease from sepsis and meningitis associated with herpes simplex virus to 29% and 4%, respectively (Kimberlin et al, 2001). Acyclovir is an antiviral agent that is eliminated rapidly in urine through glomerular filtration and tubular secretion. It is nearly insoluble in urine and may precipitate, particularly in the distal tubular lumen. Intravenous high-dose acyclovir treatment can lead to intratubular crystal precipitation and renal failure. Acyclovir-related nephrotoxicity can be limited by avoiding its use in those with renal insufficiency or intravascular volume depletion, infusing the drug slowly (over several hours), and by assuring adeqaute hydration to maintain high urinary flow rate, which will reduce the likelihood of crystal deposition in tubules (Izzedine et al, 2005).

Finally, medications given to pregnant women can cause combined ischemic and nephrotoxic renal injury in the fetus, resulting in the clinical presentation of AKI after birth. A frequently used class of medications that fall into this category are the NSAIDs prescribed for tocolysis—both nonselective and selective cyclooxygenase inhibitors such as indomethacin or ketoprofen (Bannwarth et al, 1999; Peruzzi et al, 1999)—which can lead to severe AKI in the newborn.

Acute Obstruction

The most common cause for obstruction induced kidney dysfunction in the newborn is congenital malformations, including imperforate prepuce, urethral stricture, prune-belly syndrome, and posterior urethral valves. Other causes of acute obstruction include neurogenic bladder, extrinsic compression (e.g., hematocolpos, sacrococcygeal teratoma), and intrinsic obstruction from renal calculi or fungal balls. Depending on the cause and associated damage to the kidneys, relieving the obstruction will markedly improve renal function.

EVALUATION

The pregnancy history, findings on prenatal tests, vital signs, changes in neonatal body weight, physical examination, interventions, and medications prescribed provide important clues about the cause of neonatal AKI. Serum laboratory values to be monitored in the infant with AKI include serum sodium, potassium, chloride, bicarbonate, calcium, phosphorus, magnesium, urea, creatinine, uric acid, glucose, blood gases, hemoglobin, and platelets. As discussed in the section defining AKI, SCr often does not rise for days after an injury, thus monitoring these values for several days after the inciting event is necessary to determine if AKI occurred. If urine is available, then urinalysis, urine culture, and a spot urine sample for sodium, creatinine, and osmolality can help to differentiate the cause.

One of the major goals in the initial evaluation of neonatal AKI is to determine whether the kidney is hypoperfused. Several laboratory, clinical, and therapeutic interventions can help to delineate prerenal azotemia from intrinsic AKI (Table 85-2). Decreased body weight, tachycardia, dry mucous membranes, poor skin turgor, flattened anterior fontanel, and elevated serum sodium levels can be seen in infants with low intravascular volumes. Measurement of serum albumin will alert the physician if appropriate oncotic pressure is present (serum albumin >2.0, but preferable at 2.5 mg/dL). When the kidney is hypoperfused, it will avidly retain sodium and water to preserve overall intravascular volume. Preservation of urine sodium

TABLE 85-2 Diagnostic Indices Suggestive of Prerenal Azotemia versus Intrinsic Acute Kidney Injury in the Newborn

	Prerenal Azotemia	Intrinsic Acute Kidney Injury
Urine flow rate (mL/kg/h)	Variable	Variable
Urine osmolality (mOsm/L)	>400	≤400
Urine-to-plasma osmolal ratio	>1.3	≤1.0
Urine-to-plasma creatinine ratio	29.2 ± 1.6*	9.7 ± 3.6*
Urine [Na^+] (mEq/L)	10-50	30-90
$FENa^+$ (%)	<0.3 (0.9 ± 0.6)*	>3.0 (4.3 ± 2.2)*
Renal failure index‡	<3.0 (1.3 ± 0.8)*	>3.0 (11.6 ± 9.5)*
Response to fluid challenge	Improved tachycardia, increased UOP	No effect on tachycardia or UOP

‡Renal failure index (RFI) = Urine [Na^+]/(Urine [Cr]/Serum [Cr]).

and water is dependent on intact tubular function. Disturbances of tubular function can occur with diuretic use, ischemic or nephrotoxic tubular injury, or primary tubular diseases. Laboratory markers of prerenal azotemia include low urinary sodium excretion, low fractional excretion of sodium, low renal failure index, and high BUN:SCr ratio. These laboratory studies have important limitations in premature infants. Unfortunately, laboratory tests to determine whether elevated SCr is from prerenal azotemia versus intrinsic AKI are insensitive and nonspecific in premature infants because of underdeveloped tubular function. Normal fractional sodium excretion in preterm infants born before 32 weeks' gestation is usually higher than 3% (Ellis and Arnold, 1982). In addition, because of the developmentally regulated limitation of their concentrating capacity and the effects of low protein intake and urea excretion on urine osmolality, the urine-to-plasma creatinine ratio instead of the urine-to-plasma osmolality ratio should be used in newborns to evaluate their renal tubular reabsorptive capacity (Feld et al, 1986).

If suspicion of renal hypoperfusion is high, an appropriate fluid challenge with 10 to 20 mL/kg of isotonic fluids (usually normal saline) over 30 minutes should be given. Close observation to vital signs and urine output may serve to delineate the presence of intravascular hypoperfusion. Several boluses may be necessary with careful prescription of fluid volume for the next 24 hours. Care to avoid fluid challenges is advised in those with suspected urinary outlet obstruction or congestive heart failure.

A second major goal of AKI evaluation is to detect anatomic causes of AKI, if present. A renal and bladder ultrasound examination should be performed without delay if an obstructive process is suspected and to detect congenital renal abnormalities if present. If hematuria, hypertension, or both are present, the possibility of renal vascular disease should also be considered. Doppler ultrasound examination of renal vessels can be performed if renal vascular thrombosis is suggested.

MANAGEMENT

The approach using fluid boluses (if appropriate) as part of the evaluation of prerenal azotemia also serves as the initial management of this condition. If obstruction of the urinary outflow is discovered, then interventions to eliminate the obstruction should be undertaken followed by plans for surgical correction. Polyuria with electrolyte losses can occur after relief of the obstruction; therefore close monitoring of serum electrolytes, especially bicarbonate, and appropriate replacement of these losses are necessary. Besides these specific management options, there are currently no specific medical therapies to treat AKI. To maximize the chance for survival, the clinician must support the cardiorespiratory system, maintain maximal nutrition, balance homeostasis, and manage the consequences of AKI. Dialysis can provide renal suppport to achieve goal-oriented therapies.

Despite numerous promising therapies in animal studies and many clinical pharmacologic trials, no approved therapies are available to treat AKI in neonates, children, or adults. Only supportive care of the patient (with medications, renal support therapies, or both) is currently available for the care of the infant with AKI (Walters et al, 2009). Several therapies are commonly used in patients with AKI; however, few data are available to support the use of low-dose dopamine, fenoldopam (a selective dopamine-1 receptor agonist), or diuretics for the treatment or prevention of AKI.

Dopamine can increase renal perfusion in the sick preterm and term infant with prerenal azotemia caused by hypoxemia, acidosis, or indomethacin administration (Seri, 1995; Seri et al, 1998, 2002). Although low dose dopamine increases renal perfusion, well-powered randomized controlled studies in adults with AKI have reached the same conclusion (Bellomo et al, 2000; Friedrich et al, 2005; Hoste et al, 2006; Marik, 2002). Compared with placebo, low-dose dopamine does not improve survival, shorten hospital stay, or limit dialysis use. These studies have not been performed in children or neonates.

Diuretics are commonly used to induce diuresis in critically ill neonates; however, no studies in neonates, children, or adults have shown that diuretics are effective in preventing AKI or improving outcomes once AKI occurs (Bellomo et al, 2000). If loop diuretics are to be used in neonates, continuous doses of furosemide may be superior to larger intermittent doses. In neonates with cardiac surgery, continuous doses were shown to be as effective despite smaller total quantities of medications. The authors conclude that those with continuous dosing may have less risk for nephrotoxicity or ototoxicity than occurs with large intermittent doses of this drug (Luciani et al, 1997). The potential toxicity of long-term and aggressive furosemide therapy—including ototoxicity, interstitial nephritis, osteopenia, nephrocalcinosis, hypotension, and persistence of patent ductus arteriosus—should be considered, especially in the preterm newborn (Karlowicz and Adelman, 1992). The mannitol test (used to test whether a patient has renal hypoperfusion) is contraindicated in newborns with a predisposition for intraventricular hemorrhage or periventricular leukomalacia because of a drug-induced, sudden increase in serum osmolality.

Fenoldopam is a selective dopamine-1 receptor agonist whose effects include vasodilation of renal and splanchnic vasculature, increased renal blood flow, and increased GFR. Fenoldopam is approved to treat severe hypertension in adults, but is not clinically approved for the treatment of AKI. Nonetheless, its use in neonates with AKI has been explored in several single-center analyses. Although two separate retrospective single-center analyses (Moffett et al, 2008; Yoder and Yoder, 2009) found increased urine output in a select group of neonates with oliguria, Ricci et al (2008) performed a prospective controlled trial of low-dose fenoldopam (0.1 μg/kg/min) in infants undergoing cardiac surgery with cardiopulmonary bypass. Compared with placebo, low-dose fenoldopam did not show beneficial effects on AKI incidence, fluid balance control, time to sternal closure, time to extubation, or time to intensive care discharge. Because low-dose dopamine, diuretics, and fenoldopam are unlikely to positively affect the outcomes of infants with AKI, efforts should be maximized to support the infant's cardiorespiratory system and to manage and prevent the ill effects of AKI.

If systemic hypotension develops despite adequate volume administration, early initiation of blood pressure

support often establishes appropriate renal perfusion (Seri et al, 1993, 1998). In cases of pressor-inotrope–resistant hypotension and shock, a brief course of low-dose hydrocortisone has been demonstrated to be effective in restoring systemic perfusion and renal function in preterm neonates (Seri, 2001). Other management goals include maintaining blood oxygen content, providing blood products for specific indices, limiting severe acidosis, and maintaining normal serum albuminemia (at least 2.0 mg/dL, but preferably 2.5 mg/dL).

Hypertension is common in neonates with AKI. It can be caused by increased renin release in malformed or damaged kidneys or secondary to increased intravascular volume from a lack of free water clearance. If hypertension is due to fluid overload, inducing free water clearance with diuretics or fluid removal with dialysis will address its cause. Calcium-channel blockers work by selectively causing vasodilatation of the venous system. Short-acting calcium-channel blockers (e.g., isradipine) are reliable, have a quick onset of response, and are well tolerated. Long-acting calcium-channel blockers (e.g., amlodipine) take longer to take effect, but they provide less lability with longer dosing intervals. β-Blockers (propranolol or labetolol) are also commonly used to treat hypertension in neonates. Use of ACE-I in children with ischemic AKI should be avoided, because it can produce further renal hypoperfusion and can alter intrarenal hemodynamics in an already injured kidney. See Chapter 88 for more information on neonatal hypertension.

Managing fluids in the critically ill neonate with AKI can be difficult. These infants may require large volumes of fluid to maintain adequate nutrition and hematologic indices and to provide appropriate medications. However, these fluids can be detrimental in a child with oliguria or anuria, because they can cause congestive heart failure, chest wall edema, and pulmonary failure. Therefore, once adequate intravascular volume has been restored, prevent severe fluid overload (by limiting crystalloid infusions) and maximize nutritional supplements concentration. Severe fluid restriction limiting intake to insensible and gastrointestinal and renal losses is sometimes required, but at a heavy price (inadequate nutrition). Decisions regarding placement of dialysis access should be made early in the course of AKI before severe fluid overload has occurred, because once severe fluid overload occurs, placement of a peritoneal dialysis or a hemodialysis catheter can be significantly more difficult, as is support of the infant with severe pulmonary edema.

Electrolyte abnormalities can vary depending on the cause of AKI. For example, aminoglycoside toxicity is commonly nonoliguric with ongoing potassium and magnesium losses. Alternatively, ischemic AKI causes oliguria–anuria, hyponatremia, hyperkalemia, hyperphosphatemia, and hypocalcemia. Management of electrolyte disorders can usually be managed by attention to electrolyte intake during the initial course of AKI with frequent evalution and specific therapies.

Most cases of hyponatremia are due to water overload and less commonly due to low total body sodium content. Attention to fluid status is critical to determine the cause and proper therapy of hyponatremia. In cases of nonsymptomatic hypervolemic hyponatremia (serum sodium concentrations usually between 120 and 130 mEq/L), restriction of free water intake is recommended. If hyponatremia at this level results in clinical signs and symptoms (e.g., lethargy, seizures) or serum sodium concentration falls to less than 120 mEq/L, use of 3% sodium chloride over 2 hours according to the following formula should be considered:

$$Na^{+}_{\text{Required}}\,(\text{mEq}) = \left([Na^{+}]_{\text{Desired}} - [Na^{+}]_{\text{Actual}}\right) \times \text{Body weight (kg)} \times 0.7$$

Possible complications of hypertonic saline administration include congestive heart failure, pulmonary edema, hypertension, intraventricular hemorrhage, and periventricular leukomalacia. Care should be taken not to increase serum sodium concentration more rapidly than 0.5 mEq/h.

Severe hyperkalemia is a life-threatening medical emergency. Hyperkalemia that is unresponsive to medical management is one of the most common indications for peritoneal and hemodialysis in the newborn (Coulthard and Vernon, 1995; Karlowicz and Adelman, 1992). Signs of progressive hyperkalemia on the electrocardiogram, in order of severity, consist of tall peaked T waves, heart block with widened QRS complexes, U wave formation, the development of sine waves, and finally cardiac arrest. Measures to remove potassium from the body include oral or rectal sodium polystyrene (Kayexalate), loop diuretics to enhance potassium excretion (if not anuric), and dialysis. Several methods to move potassium from the extracellular to the intracellular compartment are available, including albuterol inhalation, sodium bicarbonate, and insulin plus glucose. Adequate ionized calcium levels for cardioprotection should be sought in the context of hyperkalemia (Table 85-3). Vemgal and Olhson (2007) performed a metaanalysis of studies on the management of hyperkalemia in premature infants. Given the limited data available, no firm clinical practice recommendations on which treatment modality was best to treat infants with hyperkalemia are available, except that insulin plus glucose may be better in premature infants.

Hyperphosphatemia is common in AKI and should be treated with low phosphorus intake. Breastmilk and Similac 60/40 both contain low phosphorous and low potassium compared with other neonatal infant formulas. Significant elevations in serum phosphate represent a risk of development of extraskeletal calcifications of the heart, blood vessels, and kidneys in the newborn, especially when the calcium-phosphorus product exceeds 70 (Sell et al, 1987). Calcium carbonate may be used as a phosphate-binding agent in infants whose phosphorous intake exceeds excretion. Although rarely an indication for dialysis without fluid overload or hyperkalemia, severe hyperphosphatemia is best treated with dialysis.

The incidence of hypocalcemia is low in neonates with severe and prolonged AKI, especially in those who develop an inability to convert 25-hydroxy–vitamin D to 1,25-hydroxy–vitamin D. Ionized calcium should be measured when low total calcium levels and concomitant hypoalbuminemia are encountered, because the latter can affect total calcium levels. If ionized calcium is decreased and the newborn is symptomatic, 100 to 200 mg/kg of calcium gluconate should be infused over 10 to 20 minutes and repeated every 4 to 8 hours as necessary. If hypocalcemia

TABLE 85-3 Medical Management of Hyperkalemia in the Newborn

Drug	Dose	Onset of Action	Duration of Action
Calcium gluconate (10%)	0.5-1 mL/kg (IV over 10 min)	1-5 min	15-60 min
Sodium bicarbonate (3.75% solution)	1-2 mEq/kg (IV over 10 min)	5-10 min	2-6 h
Insulin	1 IU/5 g glucose (IV bolus or continuous infusion)	15-30 min	4-6 h
Glucose	≤14 mg/kg/min (IV bolus or continuous infusion)	15-30 min	4-6 h
Furosemide	1 mg/kg dose or as continuous infusion	5-10 min	2-3 h
Sodium polystyrene sulfonate	1 g/kg dose every 6 h as needed (orally/rectally)	1-2 h*	4-6 h
Dialysis	Nephrology will prescribe dialysis treatment	Immediate	Duration of therapy

*Onset of action may take up to 6 hours, and the drug may be ineffective in preterm infants born at less than 29 weeks' gestation.
IV, Intravenous.

is severe, oral or intravenous calcitriol can be administered to increase intestinal reabsorption of calcium.

Normal acid–base homeostasis depends on the kidneys' ability to reabsorb bicarbonate; therefore infants with AKI commonly have a non–anion gap metabolic acidosis. Replacement with bicarbonate or acetate as a base is indicated in infants with AKI to avoid or treat metabolic acidosis. In infants with severe respiratory failure, large doses of bicarbonate should be avoided because they can culminate in increased carbon dioxide retention. Metabolic acidosis should be treated aggressively in infants with severe pulmonary hypertension, because an acidic environment can worsen this condition.

Nutritional goals in infants with AKI are similar to those of infants without AKI. Commonly parenteral nutrition, feeds, or both will need to be concentrated to avoid excessive fluid gains. If nutritional goals are unable to be achieved because of oliguria or ongoing fluid overload, the potential risks of dialysis therapy versus the potential risks associated with inadequate calorie and protein administration should be discussed with the parents. If a neonate is receiving continuous peritoneal dialysis or hemodialysis, an additional 1 g/kg/day of protein is needed to supplement the protein losses that occur with these forms of dialysis (Zappitelli et al, 2008, 2009).

In a neonate with AKI, careful assessment of medication dosing is imperative. Because many drugs are excreted in the urine, impaired metabolism or clearance from the kidneys can cause drug accumulation and adverse side effects. In infants receiving dialysis, pharmacokinetic properties of drugs (e.g., volume of distribution, protein binding, size, charge), dialysis modality (peritoneal dialysis versus hemodialysis), interval of dialysis (intermittent versus continuous) will affect drug availability (Churchwell and Mueller, 2009). Consultation with pharmacists and a nephrologist familiar with drug dosing in renal failure is invaluable.

Dialysis

Decisions to initiate dialysis (especially in infants with severe congenital malformations of the kidney and urinary tract) is a complex decision that requires a multidisciplinary approach to guide the family as they consider very difficult decisions. Access placement and some technical challenges make infant dialysis more difficult than in older children, but this therapy is feasible in experienced programs with dedicated pediatric neonatologists, dialysis nurses, and surgeons.

Indications for Dialysis Initiation

Absolute indications to initiate dialysis include: severe electrolyte abnormalities that are not correctable with medical interventions, life-threatening intoxication by medications that can be cleared with dialysis, inborn errors of metabolism, fluid overload, inability to provide adequate nutritional requirements, and uremia. If renal dysfunction, fluid overload, or both occur, then discussions about dialysis initiation should occur early in the disease process, because prolonged fluid overload or uremia can create worse pulmonary edema and cardiopulmonary instability and make placement of access for dialysis difficult.

The timing of dialysis initiation in infants with AKI is controversial. Several observational studies show a clear advantage in adults receiving dialysis early versus late (Liu et al, 2006; Ronco et al, 1986). In addition, multicenter data show that the degree of fluid overload at the initiation of dialysis is an independent risk factor for survival in critically ill children (Gillespie et al, 2004; Goldstein et al, 2001; Symons et al, 2007) and adults (Gibney et al, 2008; Mehta, 2009). Similar studies in neonates need to be performed. Over the last decade, advocates for early initiation of renal support argue that critically ill patients benefit from early dialysis. Metabolic control is gained faster because of earlier removal of excess fluid, and provision of renal support allows maximal nutrition without progressive fluid overload. Because technical access and machine advances have made neonatal dialysis safer and technically possible, early initiation of dialysis can improve outcomes in critically ill neonates with AKI. Further study is needed before recommendations on the timing of dialysis can be made.

Access

The limiting factor in performing dialysis in the smallest of babies is access to the peritoneal or vascular space for dialysis. Peritoneal dialysis access can be performed with either a straight uncuffed catheter or a curved and tunneled cuffed catheter. The advantage of the straight uncuffed catheter is that it can be placed at the bedside and can be used soon after insertion. However, these catheters are more likely to become infected or leak fluids around the insertion site. The ideal peritoneal dialysis catheter is one with two subcutaneous cuffs and

a downward-facing exit site away from the diaper area and away from a gastrostomy tube (Auron et al, 2007). As with all pediatric surgical procedures, the exact catheter, timing, and location of catheter insertion needs to be tailored to the individual patient (Shaheen et al, 2007). If a hernia is present, it should be repaired at the time of catheter insertion.

Vascular access for hemodialysis requires a large (at least 7F, but preferably 8F) double-lumen catheter that can be placed in the femoral or internal jugular vein. Double-lumen catheters that are smaller than 7F have a much higher chance of developing problems during the dialysis procedure (Symons et al, 2007). Catheterization of the umbilical vessels does not provide sufficient blood flow necessary for conducting hemodialysis. If 7F catheter cannot be placed, two 5F catheters in different sites can be life-saving. If the need for dialysis is likely to last more than 1 week, a cuffed catheter is preferred to decrease the likelihood of infection. The length of the catheter should be chosen such that the tip of the catheter resides in the superior vena cava–right atrium (for internal jugular catheters) and the inferior vena cava for femoral catheters. Unless no other choice is available, use of the subclavian artery should be avoided in infants who are likely to require long-term renal replacement therapy, because in the future the forearm fistula of the ipsilateral arm can fail with mild stenosis of the subclavian vein.

Peritoneal Dialysis

Once a peritoneal dialysis access catheter is placed and the decision to start dialysis has occurred, small-volume continuous cycles (10 mL/kg) are performed. Fluid is filled with dialysate solution, left in the peritoneal cavity to dwell, and drained. Continuous cycles are performed, with each cycle lasting approximately 1 hour. The dextrose concentration in the fluid will determine the amount of net water losses (ultrafiltration). Complications associated with peritoneal dialysis include peritonitis, leakage around the catheter exit site rendering the dialysis virtually impossible, tunnel infection, catheter malfunction, and obstruction by omentum (Coulthard and Vernon, 1995). Fluid leakage into other compartments (including the chest in patients without an intact diaphragm) can occur and if suspected, the fluid composition will reveal high glucose levels if a leak is present. Absolute or relative contraindications to peritoneal dialysis include necrotizing enterocolitis, abdominal wall defects, and the presence of an intraabdominal foreign body, such as a ventriculoperitoneal shunt or diaphragmatic patch.

Hemodialysis

Once reliable access to the vascular space is achieved, the hemodialysis procedure can be performed in neonates. The two types of hemodialysis, intermittent hemodialysis and continuous renal replacement therapy (CRRT), differ mainly on the duration of the procedure. Intermittent hemodialysis is significantly more efficient than CRRT. Because much larger volumes of dialysis are used, the blood flow becomes the limiting factor in the amount of clearance that can be achieved. Even with the smallest dialyzers and neonatal tubing, most infants need blood priming of the extracorporeal circuit for therapy. Skilled pediatric hemodialysis nurses are required at the bedside during the entire procedure, which typically lasts 3 to 4 hours. Achieving adequate fluid removal is sometimes difficult, especially in hemodynamically unstable infants. This approach usually requires systemic heparinization, with activated clotting time usually maintained at 180 to 200 seconds, rendering this approach risky in preterm newborns and others at high risk for intracranial bleeding.

Ronco et al (1986) described the use of CRRT in a critically ill newborn. Before the recent roller pump technology, CRRT used the patient's arterial blood pressure as a pump for the dialysis machine. The advent of newer roller pump technology improved the accuracy of small flows as low as 10 mL/min and provided the option of using the machine to pump blood via a double lumen catheter placed in a major vein. The main advantage of a continuous modality is that lower blood flow and fluid removal rates can be used to accomplish the desired ultrafiltration and clearance goals. Anticoagulation with CRRT is achieved with either systemic heparin or citrate regional anticoagulation. The advantage of regional citrate anticoagulation is that the patient is not anticoagulated; however, this method of anticoagulation has the added risk of hypocalcemia caused from citrate excess (especially in those infants with impaired liver metabolism) and metabolic alkalosis (Tolwani and Willie, 2009).

Outcome data in neonates who require CRRT are scarce. Symons et al (2003) reported a survival rate of 32 in 85 (37.6%) in neonates who received CRRT in five large children's hospitals in the United States. Between 2001 and 2007, the prospective pediatric CRRT group, a multicenter registry of 14 pediatric CRRT programs, reported outcomes for infants in whom CRRT was initiated before 1 month of age (Symons et al, 2007). Approximately 8% (35 neonates) in the registry were dialyzed in the 1st month of life. In this group, the median age was 8 days; the median weight was 3.2 kg, with the smallest infant weighing 1.3 kg. Of the 35 infants in the registry, 24 received dialysis for fluid overload, electrolyte imbalance, or both, and 11 of 35 received dialysis for inborn errors of metabolism. Overall survival was 43%. Infants receiving dialysis for inborn errors had a better survival rate (73%) compared with others (30%).

Several technical issues specific to infants arise when using CRRT for dialysis. The extracorporeal volume can incorporate greater than 50% of the infant's blood volume. For example, a 2.3-kg infant has a blood volume of approximately 184 mL; the Prisma circuit requires 90 mL, which is approximately 50% of the infant's blood volume. Priming the blood circuit with blood will effectively limit this problem. In addition, because standard protocols on citrate regional anticoagulation anticipate normal liver metabolism of citrate, caution must be exercised when performing dialysis in premature infants or newborns with multiple organ failure who may have impaired liver function. Risk for bradykinin reaction that can occur at the initiation of CRRT with AN69 dialyzer membranes can be reduced using several techniques (Brophy et al, 2001; Hackbarth et al, 2005).

ACUTE KIDNEY INJURY AS A CAUSE OF LONG-TERM CHRONIC KIDNEY DISEASE

Total GFR is determined by the filtration rate of a single nephron and the number of nephrons present. When the number of nephrons is diminished, single nephron GFR increases as the kidney works to compensate for low nephron numbers. This compensatory hypertrophy causes glomeruli to function under increased intracapillary hydraulic pressure, which over time causes damage to capillary walls. This abnormal process leads to progressive glomerulosclerosis, proteinuria, hypertension, and CKD (Brenner et al, 1996). The hyperfiltration hypothesis has been applied and confirmed in autopsy data of patients with hypertension (Keller et al, 2003; Ohishi et al, 1995) and has been reported at length in infants with intrauterine growth retardation (Barker and Osmond, 1988; Barker et al, 1989; Manalich et al, 2000; Wadsworth et al, 1985; White et al, 2009). A systematic review and metaanalysis in 2009 concluded that low-birthweight infants (5.5 lb [2.5 kg]) were 70% more likely to develop CKD later in life compared to individuals with normal birthweight (White et al, 2009).

Premature infants (even those born appropriate for gestational age) are born with low nephron numbers. Using computer-assisted morphometry, Rodriguez et al (2004) showed that premature infants have lower numbers of nephrons compared with term infants. Premature infants who had long survival (to at least 36 weeks after conception) had nephron numbers similar to those in premature infants with short survival, suggesting that the extrauterine environment does not allow for proper neoglomerulogenesis. In addition, preterm infants with AKI had fewer nephrons than did similar infants without AKI (Rodriguez et al, 2004).

Animal and epidemiology data suggest that AKI leads to CKD. As discussed in the section on ischemic AKI, tubular and vascular endothelial cellular damage occurs with prolonged hypoperfusion. Animal models suggest that although tubular recovery occurs, damage to vascular endothelial cells remains and leads to interstitial fibrosis and progressive kidney dysfunction (Basile et al, 2001).

Studies on children with AKI show that more than 50% of those with AKI have at least one sign of CKD 3 to 5 years after the inciting event. Large adult studies suggest that after AKI, rates of CKD (low GFR) are 5% to 10%, with approximately 3% to 5% developing end-stage renal disease (ESRD).

The exact prevalence of CKD after neonatal AKI is not known. Stapleton (1987) reviewed the published single-center data and reported a 40% to 88% prevalence of long-term CKD after oliguric renal failure. Since then, other retrospective, small, single-center retrospective studies describe similar tubular and glomerular dysfunction and hypertension in survivors of neonatal AKI (Abitbol et al, 2003; Chevalier et al, 1984; Polito et al, 1998). Data on outcomes of premature infants after AKI are scarce. Rodriguez et al (2004) performed a cross-sectional study on premature infants (birthweight <1000 g) during childhood and found that estimated GFR and tubular function were lower than in similar term children. Despite the limitations of these single-center studies, these data suggest that prematurity, intrauterine growth retardation and AKI lead to a lower number of nephrons, endothelium dysfunction, or both, and an increased risk of long-term renal dysfunction. To further delineate the likelihood and extent of AKI causing CKD, a prospective study is greatly needed to provide guidelines for long-term follow-up. Future studies on interventions (e.g., angiotensin-converting enzyme inhibitors) to decrease the rate of CKD progression in this growing population should be explored.

CHRONIC KIDNEY DISEASE

Neonatal CKD is diagnosed when sustained derangements of glomerular filtration or tubular function occur with minimal to no resolution over time. In many cases CKD follows AKI, and in others the acute phase of the renal compromise has not been detected or has occurred in utero often as a result of anatomic abnormalities (e.g., hypoplasia, dysplasia, malformations), and the diagnosis of CKD is established without documented evidence of preexisting AKI. According to guidelines published by the Kidney Disease Outcomes Quality Initiative, CKD is present if there is evidence of kidney damage for more than 3 months, as defined by structural or functional abnormalities, with or without decreased GFR, or a GFR less than 60 mL/min per 1.73 m^2 for more than 3 months in children older than 2 years with or without kidney damage. GFR increases with maturation from infancy and approaches the adult mean value by 2 years of age. Thus it is important to note that the ranges of GFR that define the stages of CKD apply only to children 2 years and older. The GFR ranges defining CKD do not apply to infants, because they will normally have a lower GFR even when corrected for body surface area. ESRD, the point at which dialysis or kidney transplantation is necessary to ameliorate the physiologic complications of uremia owing to kidney failure, represents the most severe stage of CKD. The pathophysiologic mechanisms leading to the progression of AKI to CKD and ESRD are discussed earlier in this chapter.

EPIDEMIOLOGY

Reports of the regional incidence of neonatal ESRD differ greatly, and the worldwide incidence is unknown. In one study, the estimated incidence of neonatal ESRD in the United States and Canada was 0.32 in 100,000 live births (Carey et al, 2007). Rees (2008) reported that six new infants per 1 million population initiate dialysis per year compared to three per 1 million in the United Kingdom. In a German study, Wedekin et al (2008) estimated the incidence of CKD in infants to be 1 in 10,000 live births and found a male-to-female ratio of 2.8:1. They also found that 53% of these infants were premature, a figure significantly higher than in the total infant population of Germany. The most common causes of renal failure in most studies of neonates are renal dysplasia or obstructive uropathy (Carey et al, 2007; Ledermann et al, 1999; Rees, 2008; Shroff et al, 2003; Wedekin et al, 2008)—specifically, posterior urethral valves (Ledermann et al, 1999).

SEQUELAE AND TREATMENT

Anemia

Anemia is a frequent complication of CKD in infants and children, and there is evidence to suggest that it is an important predictor of patient morbidity and mortality. The anemia of CKD is associated with a number of physiologic abnormalities, including decreased tissue oxygen delivery, increased cardiac output, cardiac enlargement, ventricular hypertrophy, congestive heart failure, and impaired immune responsiveness (Gafter et al, 1994; Mitsnefes et al, 2000). There is also evidence to suggest that the presence of anemia is associated with an increased risk of hospitalization in children with CKD (Staples et al, 2009).

The prevalence of anemia increases with worsening stages of CKD. In a study of the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS), Staples et al (2009) found that the prevalence of anemia increased from 18.5% in CKD stage II to 68% in CKD stage V (Staples et al, 2009).

Guidelines for the evaluation and treatment of anemia in the pediatric patient with CKD have been published as the *KDOQI Clinical Practice Guidelines and Clinical Practice Recommendations for Anemia in Chronic Kidney Disease* by the National Kidney Foundation (National Kidney Foundation, 2006, 2007). According to the guidelines, *anemia* is defined as a hemoglobin (Hgb) concentration less than the 5th percentile of normal for age and sex (Table 85-4). The normative values used to define anemia in children older than 1 year are taken from the third National Health and Nutrition Examination Survey (Astor et al, 2002) database, whereas the norms for infants younger than 1 year are derived from other reference sources (Nathan and Orkin, 2003).

The pathophysiology of anemia in infants and young children with CKD is primarily the result of a decrease in renal production of erythropoietin, iron deficiency, or both (Koshy and Geary, 2008). Other potential contributing factors include a shortened red blood cell life span, secondary hyperparathyroidism, hypothyroidism, folate and vitamin B_{12} deficiency, chronic inflammation and hemoglobinopathies. The etiology of absolute iron deficiency is multifactorial and can be related to poor intake, gastrointestinal blood loss, and repeated phlebotomies for laboratory tests. Functional iron deficiency, defined as occurring when there is a greater need for iron to support Hgb synthesis than can be released from iron stores, may in part be related to the presence of elevated levels of the liver-derived peptide hepcidin—a subject about which further study is needed in the pediatric CKD population (Zaritsky et al, 2009).

The KDOQI guidelines recommend that the initial workup for anemia in children with CKD should include red blood cell indices, reticulocyte count, white blood cell count with differential and platelet count, and iron parameters (serum iron, total iron binding capacity, and serum ferritin) (National Kidney Foundation, 2006, 2007).

Erythropoiesis-stimulating agents (ESAs) such as erythropoietin-alfa (EPO), along with iron supplements, are the key elements of anemia management in CKD. Whereas the average dose of EPO for children with CKD is 150 to 200 units/kg/week given by the subcutaneous route, younger children (<1 year) often require doses as high as 350 units/kg/week. The difference is possibly related to an increased presence of nonhematopoietic binding sites for EPO in younger children that lead to increased clearance (NAPRTCS, 2008; Port et al, 2004). Children receiving peritoneal dialysis (PD) typically require less EPO than patients receiving hemodialysis (HD) as a result of the blood loss that occurs with HD. A recent report on the use of darbepoetin-alfa, an analogue of erythropoietin with a longer half-life, has been conducted in infants with CKD and revealed that the therapy was effective when dosing regimens were individualized (12).

*Data taken from normal reference values.
†Values 2 standard deviations (SD) below the mean are equivalent to <2.5th percentile.

Iron therapy typically consists of the provision of oral elemental iron in doses ranging from 2 to 3 mg/kg/day up to 6 mg/kg/day in two to three divided doses (National Kidney Foundation, 2006). Iron should be taken 2 hours before or 1 hour after all calcium containing phosphate binders to maximize gastrointestinal absorption. Levels of serum ferritin greater than 100 ng/mL and transferrin saturation greater than 20% are believed to reflect adequate iron stores in patients with CKD (National Kidney Foundation, 2006).

In the absence of definitive evidence in pediatrics to support the association of benefit or harm to any given level of Hgb for an individual child, the target Hgb is 10 to 12 g/dL for patients receiving ESAs and iron therapy (National Kidney Foundation, 2006, 2007; Staples et al, 2009). In turn, the rate of rise of the Hgb level should be no more than 1 to 2 g/dL per month. At the initiation of ESA therapy, monitoring of the Hgb level should occur every 1 to 2 weeks; the frequency of monitoring can be decreased once the target Hgb level has been achieved and the patient is receiving a stable dose of ESA.

Acid-Base and Electrolytes

Fluid and electrolyte requirements of individual children with CKD vary according to their primary kidney disease and the degree of residual kidney function. Infants and children normally have a relatively larger endogenous hydrogen ion load (2 to 3 mEq/kg) than do adults, resulting in metabolic acidosis as a common manifestation of CKD in

BMI, Body mass index.

children and an important negative influence on growth. Metabolic acidosis leads to both endogenous growth hormone and recombinant growth hormone resistance. Based on the experience of successfully enhancing the growth of infants and children with isolated renal tubular acidosis with alkalai therapy, it is recommended that children with CKD be treated to achieve a serum bicarbonate level of at least 22 mmol/L (National Kidney Foundation, 2009).

Nutrition

Protein energy malnutrition is a common problem in patients with CKD and is one of the major contributors to poor growth in the first few years of life. The origin of malnutrition in children with CKD is multifactorial; however, an inadequate voluntary intake is considered a major contributing factor, especially in infants. Nausea and vomiting are common in infants and children with CKD, with delayed gastric emptying and gastroesophageal reflux being detected in as many as 75% of patients with these problems (Ruely et al, 1989). In view of the importance of the nutritional status to the outcome of the infant and young child with CKD, frequent monitoring of the patient is mandatory. An age-related schema for parameters and frequency of nutritional assessment for patients with CKD has recently been published (Table 85-5) (National Kidney Foundation, 2009). The World Health Organization Growth Standards of length-for-age, weight-for-age, weight-for-length, body mass index–for-age and head circumference–for-age should be used as the reference for children from birth to 2 years (World Health Organization, 2006). Whereas nutritional intervention is indicated in children with CKD for findings that include an impaired ability to ingest or tolerate oral feedings, a body mass index value less than the 5th percentile of height-for-age, an acute weight loss of 10% or more or a length/height ratio more than 2 standard deviations (SD) less than the mean, neonates with CKD should be considered to be at nutritional risk if they are preterm or have any of the following:

- Low birth weight (<2500 g)
- A birth weight *z* score less than –2 SD for gestational age
- Polyuria and an inability to concentrate urine

TABLE 85-6 Equations to Estimate Energy Requirements for Children at Healthy Weights

Age (mo)	EER (kcal/d) = Total energy expenditure + Energy deposition
0-3	EER = 89 × Weight (kg) – 100 + 175
4-6	EER = 89 × Weight (kg) – 100 + 56
7-12	EER = 89 × Weight (kg) – 100 + 22
13-35	EER = 89 × Weight (kg) – 100 + 20

Modified from National Kidney Foundation: KDOQI clinical practice guideline for nutrition in children with CKD: 2008 update, *Am J Kidney Dis* 53(Suppl 2):S36, 2009.
EER, Estimated energy requirement.

In children with CKD, the spontaneous energy intake decreases with deteriorating kidney function. Energy requirements should, however, be considered to be 100% of the estimated energy requirement for chronologic age (Table 85-6) (Food and Nutrition Board, 2002; Ruely et al, 1989). Because energy intake is the principal determinate of growth during infancy, malnutrition has the most marked negative effect on the growth of children with congenital disorders leading to CKD (Betts et al, 1977). Supplemental nutritional support is indicated when the voluntary intake by the child fails to meet energy requirements and the child is not achieving expected rates of weight gain or growth for age. In infants requiring fluid restriction because of their impaired kidney function, oral intake of an energy-dense diet with a milk formula that has a caloric density greater than 20 kcal/oz, and the appropriate phosphorus content for CKD stage is preferred. If poor appetite or vomiting preclude an adequate oral intake, tube feedings (e.g., nasogastric, gastrostomy, gastrojejunostomy) should be considered and provided by either bolus or continuous infusion. The development of repeated emesis in children fed per nasogastric tube has prompted the use of gastrostomy as the preferred route of therapy (Warady et al, 1996). In infants younger than 1 year, an initial infusion rate of 10 to 20 mL/h or 1 to 2 mL/kg/h is generally well tolerated, to be followed by a daily increase of 5 to 10 mL per 8 hours or 1 mL/kg/h toward achieving the treatment goal. It is imperative that tube-fed

TABLE 85-7 Recommended Dietary Protein Intake in Children with CKD Stages 3 to 5 and 5D

	Dietary Reference Intake (DRI)				
Age	DRI (g/kg/d)	Recommended for CKD Stage 3 (g/kg/d) (100%-140% DRI)	Recommended for CKD Stages 4-5 (g/kg/d) (100%-120% DRI)	Recommended for HD (g/kg/d)*	Recommended for PD (g/kg/d)†
0-6 mo	1.5	1.5-2.1	1.5-1.8	1.6	1.8
7-12 mo	1.2	1.2-1.7	1.2-1.5	1.3	1.5
1-3 y	1.05	1.05-1.5	1.05-1.25	1.15	1.3

AI, Adequate intake; *ND*, not determined.

infants be encouraged to continue some oral intake or have oral stimulation (e.g., pacifier) if persistent feeding dysfunction is to be prevented.

Whereas the spontaneous dietary protein intake (DPI) is reduced in progressive CKD in a manner similar to that of energy intake, the DPI is typically far in excess of the average requirements. At the same time, there is no evidence that strict dietary protein restriction (120% recommended daily allowance) has any nephroprotective effect, nor does this level of intake compromise growth. Because moderate protein restriction reduces the accumulation of nitrogenous waste products and helps to lower dietary phosphorus intake, it is appropriate to gradually lower the DPI toward 100% of the dietary reference intake (DRI) as CKD progresses toward the need for dialysis (Ruely et al, 1989). More specifically, a DPI of 100% to 140% DRI for CKD stage 3, 100% to 120% DRI for CKD stage 4 to 5, and 100% DRI for CKD stage 5D (dialysis) has been proposed (Table 85-7). In patients receiving dialysis, the protein requirements are increased to account for dialysis-related protein losses.

Whereas restriction of sodium and water is often indicated in children with CKD complicated by sodium and fluid retention and systemic hypertension, infants and children with CKD secondary to obstructive uropathy or renal dysplasia often have polyuria and may experience substantial urinary sodium losses despite advanced stages of CKD. This scenario can result in contraction of the extracellular volume, in addition to having an adverse effect on growth and nitrogen retention (Wassner and Kulin, 1990). Infants and children with salt-wasting forms of CKD who do not receive salt supplementation may in turn experience vomiting, constipation, and significant growth retardation (Parekh et al, 2001). The same holds true for infants receiving peritoneal dialysis even if they are anuric, because most patients lose significant quantities of sodium in the dialysate. Sodium depletion in the PD population has resulted in cerebral edema and blindness (Lapeyraque et al, 2003). Individualized therapy can be achieved by first prescribing at least the age-related DRI of sodium and chloride (Table 85-8), with subsequent modification of therapy based on regular assessment of clinical and laboratory data.

Potassium homeostasis in children with CKD is usually unaffected until the GFR falls to less than 10% of normal. However, infants and children with disorders such as renal dysplasia and reflux nephropathy often demonstrate resistance to aldosterone and may experience hyperkalemia, even when the GFR is preserved. The hyperkalemia can be exacerbated by volume contraction, as can be seen in patients with salt-wasting forms of CKD. In patients who remain hyperkalemic despite repletion of salt and water, restriction of dietary potassium intake is critical. For infants and young children, 40 to 120 mg (1 to 3 mmol/kg/d) of potassium may be a reasonable start. Breast milk has a lower potassium content (546 mg/L; 14 mmol/L) than commercial milk–based infant formula (700 to 740 mg/L; 18 to 19 mmol/L) (National Kidney Foundation, 2009). Pretreatment of infant formula with a potassium binder, treatment of constipation, and attention to medications that can exacerbate hyperkalemia (e.g., potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers) may also be necessary in many patients (Bunchman et al, 1991; Fassinger et al, 1998).

Ethics of Initiating or Withdrawing Renal Replacement Therapy

Decisions to withdraw or withhold treatment have to be made for many patients in neonatology units, and for as many as 30% to 58% of patients in pediatric intensive care units. On rare occasions, such decisions pertain to

the infant with ESRD confronted with the prospect of a lifetime of dialysis and transplantation. With the advent of advanced technology in the 1980s that made possible the provision of safe and effective peritoneal dialysis to even the smallest infant came increasing ethical dilemmas and significant variations in practice (Fauriel et al, 2004; Shooter and Watson, 2000; Watson and Shooter, 2004).

In one of the most interesting studies on the topic, Geary (1998) conducted an international survey on the attitudes of pediatric nephrologists regarding the management of ESRD during infancy (Geary, 1998). More than 200 physicians from eight countries replied to a series of questions pertaining to the provision of RRT to infants younger than 1 month of age versus those 1 to 12 months old. The factors that most often influence the decision to initiate or withhold RRT were found to be the presence of coexistent serious medical disorders and the anticipation of significant morbidity for the child. Only 25% of respondents believed it was usually ethically acceptable for parents to refuse RRT in infants beyond the 1st month of life compared with 50% with the same opinion concerning younger infants. Overall, only 41% of respondents offered RRT to all infants younger than 1 month, and 53% offered this therapy to all infants 1 to 12 months old, despite recent evidence supporting the use of this therapy as a reasonable treatment option (Carey et al, 2007). Evidence for this variation in practice has been seen in other surveys as well (Fauriel et al, 2004).

Most clinicians agree that there is more to their skill than the indiscriminant application of technology. Factors to consider when making the decision regarding initiation or withdrawal of RRT during infancy include quality of life concerns, allocation of resources, legal issues, and most importantly the opinions of the hospital team and the parents. The role of hospital ethics committees in the process remains extremely variable. In the end, clinicians and parents often struggle bravely to reach a compassionate decision with as much agreement as possible. Principles of practice that may provide valuable assistance in this process have been published previously (Watson and Shooter, 2004).

Renal Replacement Therapy

End-stage renal disease is an uncommon disorder in children, with an incidence in the United States of approximately 14 patients per 1 million children of a similar age (U.S. Renal Data System, 2008). The incidence varies within the pediatric population with a rate of 29 per 1 million for children 15 to 19 years old, in contrast to a rate of 9 per 1 million for children 0 to 4 years old. In a recent study by the NAPRTCS, Carey et al (2007) estimated the incidence of dialysis-treated neonatal ESRD as 0.045 cases per 1 million population per year (Carey et al, 2007). Although kidney transplantation is the nearly universal goal for children who develop ESRD, approximately 75% of pediatric patients initially receive chronic peritoneal dialysis or hemodialysis before a kidney transplant.

Peritoneal Dialysis

Peritoneal dialysis is the preferred chronic dialysis modality for infants with ESRD. Subsequent to the development of continuous ambulatory PD in 1976, the availability of small dialysate bags resulted in a number of reports of infants receiving continuous ambulatory PD in the middle 1980s. The later emergence of automated cycling machines that were able to deliver fill volumes as low as 50 mL, with incremental adjustments of 10 mL, allowed for the provision of safe and effective PD in neonates and infants. The preference for PD, and specifically automated PD as the chronic dialysis modality in infants and young children, is reflected by data from NAPRTCS in which 93% of patients 0 to 1 year old and receiving dialysis were receiving PD at dialysis initiation (Carey et al, 2007; NAPRTCS, 2008).

Peritoneal dialysis makes use of the peritoneal membrane as a natural dialyzing membrane. Dialysis solution is instilled and dwells within the peritoneal cavity, during which time bloodstream-derived solutes move down a concentration gradient based on diffusion, and fluid is removed as a result of the osmotic gradient created by the dextrose component of the dialysis fluid. The inflow, dwell, and drainage of dialysate characterize a single dialysis cycle or exchange. The peritoneal catheter is the cornerstone of successful PD, and the PD prescription accounts for the dextrose concentration and amount of dialysis solution (initially 600 to 800 mL/m^2 body surface area in infants) during each exchange and the length of the exchange (National Kidney Foundation, 2006).

The infant with ESRD who receives chronic PD is at risk for a variety of treatment-related complications that are ideally either prevented or identified early and treated aggressively if morbidity and mortality are to be minimized. The single most serious complication is peritonitis. The incidence of this infection is greatest during infancy, with a rate of 1 infection every 14.2 patient months reported by the NAPRTCS (2008). Whereas gram-positive organisms account for the majority of infections, gram-negative episodes of peritonitis are common in infants and young children (Zurowska et al, 2008). In turn, when peritonitis is suggested, empiric antibiotic therapy should provide coverage for gram-positive and gram-negative organisms (Warady et al, 2000). In some cases, infants may experience hypogammaglobulinemia in this situation and may benefit from replacement therapy (Neu et al, 1998). Other treatment-related complications that occur most frequently during infancy include anterior ischemic optic neuropathy and sudden blindness secondary to hypovolemia, excessive loss of protein across the peritoneal membrane and hernia formation (Lapeyraque et al, 2003; Quan and Baum, 1996; Warady et al, 2009).

Hemodialysis

The use of HD during infancy is dictated often by the presence of a medical condition that contraindicates use of the peritoneal membrane (e.g., omphalocele, gastroschisis, diaphragmatic hernia, bladder exstrophy). The procedure is complicated, and limited clinical experience has revealed a high incidence of patient morbidity (Al-Hermi et al, 1999; Kovalski et al, 2007; Shroff et al, 2007). Whereas the infrequent use of HD in infants precludes the generation of an evidence base upon which to guide maintenance therapy, there are some key treatment-related principles to consider when conducting the procedure. Despite the

availability of neonatal-sized tubing, the extracorporeal volume usually comprises more than 10% of the patient's blood volume in infants weighing less than 8 kg; this necessitates circuit priming with 5% albumin or packed red blood cells diluted to a hematocrit of 35% (Warady et al, 2009). Blood access is typically in the form of a 7F or 8F dual-lumen catheter, which allows blood pump flow rates of 30 to 50 mL/min. Despite the use of HD machines with volumetric control capability, the accuracy is only to 50 to 100 mL, thus mandating the use of continuous monitoring of the patient's weight with a digital scale when conducting HD on neonates. The complicated nature of the procedure mandates that it be performed only in highly qualified centers.

Transplantation

The topic of kidney transplantation in patients who develop ESRD as neonates or young infants is complicated, and a lengthy discussion is beyond the scope of this chapter. In short, transplantation is a viable alternative for these young patients and is their best hope for long-term survival. In a review of NAPRTCS data, Carey et al (2007) found that 3 years after dialysis initiation, 80% of 63 neonates had undergone transplantation. What is often most important for the neonatologist is recognizing the need to develop a collaborative strategy with members of the pediatric nephrology and urology team for management of congenital structural abnormalities of the urinary tract that are present in the patient with severe CKD/ESRD, the majority of which will ultimately require transplantation (Sarwal and Salvatierra, 2004). Minimizing the use of interventions that greatly increase the risk of central venous thrombosis should also be encouraged. The most recent report of the U.S. Renal Data System reveals that 51 infants younger than 1 year and 89 children aged 1 to 4 years received a kidney transplant in 2006 (U.S. Renal Data System, 2008). The 3-year graft survival for patients who received a living donor transplant in 2003 was 83.9% and 94.6% for patients who were less than 1 and 1 to 4 years old, respectively, at the time of transplant. In the case of deceased donor transplants, the graft survival for those aged 1 to 4 years was 89.7%, while the number of deceased donor transplants performed during infancy was exceptionally small.

OUTCOMES

Growth and Development

Children with CKD often experience some degree of growth failure. This failure is especially concerning when CKD occurs in infancy, a time of rapid growth. By 2 years of age, approximately one third of postnatal growth has occurred (Haffner, 2008); therefore early intervention to address treatable causes of CKD-associated growth failure is essential to maximize the growth of these infants. The disordered growth in patients with CKD is a multifactorial process. Protein-calorie malnutrition, metabolic acidosis, electrolyte disarray, renal osteodystrophy, and changes in the gonadotropic hormone axis in the face of uremia, corticosteroid treatment, or both are factors that contribute to this challenging problem (Geary, 1998; Haffner, 2008). Infants with CKD are especially susceptible to protein-calorie malnutrition because of the high energy demands in this age group.

Several studies have shown that infants have impaired growth at initiation of chronic dialysis. There are conflicting reports regarding improvement in growth with renal replacement therapy. Most studies suggest that young children on dialysis fail to grow well, despite meeting 100% of the recommended daily allowance of caloric intake (Shroff et al, 2003). Growth outcomes may be better after transplantation (Ledermann et al, 1999), and Hijazi et al (2009) report that current growth outcomes of infants with ESRD have improved over time, possibly because of advances in medical and surgical therapies. To continue this trend of improvement, clinicians must address comorbidities including protein-calorie malnutrition in these infants with CKD. Recent reports have described improved longitudinal growth and sustained catch-up growth in infants with chronic renal failure in whom growth hormone treatment was initiated in the 1st year of life. Mencarelli et al (2009) reported 12 infants initiated on recombinant human growth hormone at a median age of 0.5 years had significantly better height SDS scores and change-in-height SDS scores versus a control group not treated with growth hormone, despite similar nutritional intake.

In addition to growth impairments, neurodevelopmental impairments may also be present in children with CKD during infancy and early childhood. Like many children with chronic illnesses, children with CKD may have delayed achievement of many developmental milestones. In addition, delayed cognitive performance especially in regard to general intelligence, attention, executive function, language, visual-spatial abilities, and memory, has been repeatedly reported in children with CKD (Geary, 1998; Gipson, 2008). Whereas some children have renal involvement as part of a larger syndrome that may involve structural or functional abnormalities of the central nervous system, other comorbidities of CKD (e.g., anemia, hypertension, cerebral vascular accidents, adverse effects of therapy) have been implicated in the neurodevelopmental impairments in many patients (Geary, 1998). The brain undergoes rapid growth during infancy, reaching half of its adult weight by 6 months of age (Harris, 2006). Postnatal brain growth includes neuronal differentiation, dendritic branching, and axonal myelination (Gipson, 2008). Renal impairment in infancy, a crucial time of neural development, raises concerns regarding the neurodevelopmental outcomes in these children. In one study, 28 patients initiating chronic peritoneal dialysis by 3 months of age underwent formal neurodevelopmental testing. Only 6 of the 28 patients were functioning below the average level. Nineteen of these patients were retested after their fourth birthday. Fifteen of the 16 school-aged patients were full-time students in age-appropriate classrooms, and all of the children younger than 5 years were in preschool (Warady, 1999). In another longitudinal study of 31 patients with ESRD diagnosed in infancy, 18 were attending regular school, 13 had significant neuropsychologic impairments, 9 required special education classes, and 4 were severely impaired (Hijazi et al, 2009). Eleven patients with ESRD diagnosed before 2 years of age were followed; six had appropriate milestones, whereas five had special education

needs (Shroff et al, 2003). Yet another study followed 16 patients with ESRD diagnosed in infancy and found that 14 achieved age-appropriate developmental milestones (Ledermann et al, 1999). Most recently, Madden et al (2003) reported on the cognitive and psychosocial outcome of 16 infants who began PD during the 1st year of life; a majority (75%) had a functioning transplant at the time of their reassessment at a mean age of 5.8 years. Ten (67%) children had an intelligence quotient in the normal range, whereas 13 of 15 (87%) were within 2 standard deviations of the mean (Madden et al, 2003). Thus, although existing reports are largely case series with relatively small sample sizes, more recent literature suggests improved neurodevelopmental outcomes for children with CKD and ESRD in infancy compared with reports before 2000. It appears that at least 25% of infants and toddlers who have severe renal insufficiency are reported to have developmental delay, whereas the effects of milder forms of CKD on the neurodevelopment of infants remains less clear. Large multicenter longitudinal studies may provide more insight into the developmental outcomes of infants with CKD.

Hospitalization

There is emerging evidence to support the clinical expectation that a majority of neonates and infants with CKD or ESRD require frequent hospitalization throughout childhood. In one study of 18 children requiring chronic hemodialysis by 2 years of age, the median number of hospital admissions while receiving dialysis was 6 (range 3 to 16). Of those hospitalized, the median hospitalization rate per patient was 8.2 admissions per year with the duration ranging from 63 to 399 days (Shroff et al, 2003). Another study divided 698 children requiring chronic dialysis by 2 years old into those initiating dialysis by 1 month of age and those initiating dialysis between 1 month and 24 months of age. Approximately 80% of children in both groups required hospitalization at some point in the 13-year follow-up period. Among children ever hospitalized, those initiating dialysis as neonates were hospitalized more frequently than were children starting dialysis later (mean number of hospitalizations, 54 versus 39; $p < 0.001$) and had longer hospital stays (Carey et al, 2007).

Renal Osteodystrophy

There is a paucity of outcome data in the neonatal and infant populations regarding many of the other comorbidities associated with CKD. There is evidence suggesting that infants with secondary hyperparathyroidism from CKD have improvement with chronic renal replacement therapy. One study followed 17 patients initiating hemodialysis between birth and 2 years of age and found that the percentage of patients with intact parathyroid hormone concentrations less than twice the upper limit of normal increased after 3 months of hemodialysis (41% at initiation versus 69% after 3 months; Shroff et al, 2003). Another study of 20 infants on long-term PD revealed similar results (58% after 6 months of PD versus 100% after 1 year of PD) (Ledermann, 2000). Further study regarding the prevalence of renal osteodystrophy in this population is needed.

Survival

Long-term survival of neonates with CKD or ESRD appears to be similar to that of older infants and young children (Carey et al, 2007, Hijazi et al, 2009, Wedekin et al, 2008). Factors reportedly associated with mortality include African American race, presence of comorbidities such as chronic lung disease, multiorgan dysfunction, diagnosis of a syndrome, and oliguria or anuria (Hijazi et al, 2009). Approximately 25% of neonates died over 18 months of follow-up in one study, which was similar to the mortality rate of older children (Carey et al, 2007). Another study found 22% mortality (Shroff et al, 2003). Yet another study following infants with CKD for 25 years reported 54% mortality, but found a 5-year survival rate of 87% among patients surviving the 1st year (Hijazi et al, 2009). In addition, Wedekin et al (2008) followed 119 infants with CKD and estimated the 1-, 2-, and 5-year survival rates to be 78%, 68%, and 63%, respectively. However, if the patients were receiving renal replacement therapy, survival improved to 91%, 83%, and 83% for 1, 2, and 5 years, respectively. Among the patients who received renal transplants, the 1-, 2-, and 5-year survival rates were greater than 95% (Wedekin et al, 2008). A majority of children with ESRD diagnosed as neonates undergo renal transplantation in the first few years of life. In a study by Carey et al (2007) 80% of neonates with ESRD diagnosed in the neonatal period received a kidney transplant within 5 years of initiating dialysis (Carey). It appears that younger children are receiving transplants more readily in recent years (Carey), which is encouraging in the face of more favorable survival.

CHAPTER 86

Glomerulonephropathies and Disorders of Tubular Function

Lawrence Copelovitch and Bernard S. Kaplan

GLOMERULONEPHROPATHIES

Glomerulonephropathies generally present with features of the nephrotic syndrome and less often with nephritic syndrome. Massive proteinuria, hypoalbuminemia, hyperlipidemia, and edema characterize the nephrotic syndrome. Newborns may have transient proteinuria without apparent glomerular injury, and serum albumin levels can be in the nephrotic range in normal premature infants. Therefore, the diagnosis of nephrotic syndrome should be made only in patients with persistent, massive proteinuria; severe hypoalbuminemia; hyperlipidemia not caused by hyperalimentation; and edema that is not the result of fluid overload, capillary leak, or both. Nephrotic range proteinuria is defined as greater than 4 mg/kg/hour in the neonatal period. Nephritis (hematuria, red blood cell casts, oliguria or anuria, hypertension, and azotemia) is uncommon in newborns.

The nephrotic syndrome can be inherited as an entity isolated to the kidneys (congenital nephrotic syndrome of the Finnish type [CNF] and as isolated diffuse mesangial sclerosis) or as part of a defined malformation syndrome (Denys-Drash syndrome, Galloway-Mowat syndrome, Pierson syndrome, Frasier syndrome, and nail-patella syndrome). Glomerulopathies that occur in newborns and infants can also be divided into primary glomerular conditions with nephrotic syndrome (e.g., CNF) and secondary glomerular conditions (e.g., congenital syphilis). Only CNF and congenital syphilis typically manifest with nephrotic syndrome at birth. Diffuse mesangial sclerosis (DMS), Denys-Drash syndrome, Pierson syndrome, and Galloway-Mowat syndrome infrequently manifest in the neonatal period. Rarely, maternal transmission of antiglomerular antibodies can result in neonatal membranous glomerulonephritis (Debiec et al, 2002). Minimal change nephrotic syndrome, focal segmental glomerulosclerosis (FSGS), primary membranous glomerulonephritis, collagen type III glomerulopathy, and mercury toxicity do not occur in newborns but occasionally are seen in infants. Lupus nephritis and congenital toxoplasmosis have been reported in a neonate (Lam et al, 1999). Renal vein thrombosis can be a consequence of the nephrotic syndrome but is not a cause of the syndrome. There is no convincing evidence that intrauterine infections with cytomegalovirus (Batisky et al, 1993), rubella (Beale et al, 1979), or toxoplasmosis (Shahin et al, 1974) are causes of neonatal nephrotic syndrome. There are reports of *unique* family syndromes in which congenital nephrotic syndrome occurred in association with congenital anomalies, such as buphthalmos. There are reports of congenital glomerular injury that elude classification and reports of spontaneous remission of apparent congenital nephrotic syndrome (Haws et al, 1992).

CONGENITAL NEPHROTIC SYNDROME OF THE FINNISH TYPE (NPHS1) [McKUSICK #256300]

Inheritance is autosomal recessive and the locus is assigned on 19q12-q13.1 (Kestila et al, 1994). The *NPHS1* gene that is mutated in *NPHS1* codes for nephrin, a cell-surface podocyte protein. Two mutations, Fin-major and Fin-minor, are found in more than 90% of Finnish patients (Patrakka et al, 2000). CNF occurs in all population groups, but the highest prevalence is in Finland with an incidence of 12.2 per 100,000 newborns (Huttunen, 1976). There is minor intrafamilial and interfamilial variability in the severity and age of onset of the nephrotic syndrome. Absence of a history of Finnish ancestry does not exclude the diagnosis. Proteinuria is detected within the 1st week of life in 71% of cases and by 2 months in all affected infants (Huttunen, 1976). Early onset of hypertension and renal failure are uncommon. Infants are often premature and small for gestational age. Although there are no typical dysmorphic features, large anterior fontanel, limb deformations, and pyloric stenosis do occur (Sibley et al, 1986). Maternal serum and amniotic fluid alpha-fetoprotein levels are elevated (Seppala et al, 1976), and increased concentrations of albumin are detected in the amniotic fluid of some patients. The diagnosis may be made coincidentally by the finding of a low thyroxine level during screening for hypothyroidism (Finnegan et al, 1980). Most of these patients have a primary form of hypothyroidism characterized by low thyroxine and high thyroid-stimulating hormone levels caused by urinary losses of thyroxine and iodine (McLean et al, 1982). The placenta is large, with a mean placenta–neonatal weight ratio of 0.43 (normal ratio is 0.18).

Echodense kidneys are symmetrically enlarged on ultrasonography. Histologically the glomeruli initially appear normal; proximal tubules are dilated in 74% of cases. Ultrastructural studies show the effacement (*fusion*) of epithelial cell foot processes and, later in the course, interstitial fibrosis, lymphocytic and plasma cell infiltration, periglomerular fibrosis, and glomerular sclerosis (Habib, 1993).

The course is characterized by nephrotic syndrome complicated by failure to thrive, recurrent infections, and eventual chronic renal failure. Renal vein thrombosis may occur in utero and postpartum. The nephrotic syndrome is resistant to treatment. Aggressive feeding by nasogastric or gastrostomy tubes can ensure weight gain. Massive edema is treated with intravenous albumin. Furosemide is added if the patient is not volume-depleted. Hypothyroidism is treated with thyroxine. Bilateral nephrectomies and dialysis are indicated if edema, volume depletion, and

inanition cannot be controlled. Long-term peritoneal dialysis is difficult, but feasible, in small infants. The results of living-relate renal transplantation are encouraging; however, a subset of patients will have recurrence due to the development of anti-nephrin antibodies in response to novel antigen exposure (Patrakka, 2002).

DENYS-DRASH SYNDROME

Early onset of nephrotic syndrome with DMS can occur in the Denys-Drash syndrome. The syndrome consists of overlapping features of ambiguous genitalia in males, nephrotic syndrome with DMS (Habib, 1993), and Wilms' tumor. All 46XY patients have either ambiguous genitalia or female phenotype. Phenotypic females (XX or XY) may go unrecognized. Heterozygous zinc finger mutations in either exon 8 or exon 9 of the *WT1* gene on chromosome 11p are causative (Niaudet et al, 2006; Schumacher et al, 1998). Occasional patients present with nephrotic syndrome in the neonatal period (Gertner et al, 1980). Patients should undergo frequent ultrasound screening to monitor the possible development of Wilms' tumor. Siblings are not affected. Most patients die by 4 years of age unless transplanted. In such cases, bilateral native nephrectomies are performed as soon as possible.

A related condition, Frasier syndrome, is caused exclusively by mutations in the donor splice site in intron 9 of the *WT1* gene. The syndrome is characterized by nephrotic syndrome (FSGS), male pseudohermaphroditism, and gonadal dysgenesis with increased risk of gonadoblastoma and malignant germ-cell tumors. As in DDS, phenotypic females may go unrecognized. Onset of nephrotic syndrome is usually in adolescence but has been described in children as young as 6 months of age (Gwin et al, 2008).

DIFFUSE MESANGIAL SCLEROSIS

DMS can be inherited as an autosomal recessive condition, occur sporadically, or be a component of Denys-Drash (Habib, 1993) or Pierson syndromes (Zenker et al, 2004). DMS has been reported in an 18-week fetus (Spear et al, 1991) and occasionally can present in the neonatal period (Scott and Rochefort, 1992). Recessively inherited DMS can be caused by mutations mapped to 10q23 in the region encoding the phospholipase C epsilon 1 (PLCE1) gene. This phospholipase is a key component in the second messenger pathway and is thought to be involved in growth and development of the podocyte (Hinkes, 2006). Maternal and fetal alpha-fetoprotein concentrations and placental size are usually normal (Scott and Rochefort, 1992). Most patients present with nephrotic syndrome and chronic renal failure between 3 and 6 months and are hypertensive. There are no dysmorphic features. The kidneys are enlarged and echodense by ultrasound examination. The fully developed renal lesion consists of mesangial sclerosis, collapsed tufts, embedded mesangial cells, thick glomerular basement membranes, and tubulointerstitial lesions (Habib, 1993).

There is no specific treatment. Hypertension is treated with angiotensin-converting enzyme inhibitors but often requires several additional agents. Treatment of DMS includes optimal calories, peritoneal dialysis, and transplantation. DMS does not recur after transplantation. All female patients with isolated DMS should undergo karyotype analysis, because Denys-Drash syndrome may go unrecognized in phenotypic females. It is important to determine whether there is a mutation in the *WT1* gene at chromosomal locus 11p to rule out Denys-Drash syndrome. If that cannot be done, renal ultrasound examinations may be warranted every few months to monitor for Wilms' tumor.

GALLOWAY-MOWAT SYNDROME

This rare condition consists of abnormal central nervous system development and nephrotic syndrome (Cooperstone et al, 1993). Inheritance is autosomal recessive, and there may be variable expression in a family (Cohen et al, 1994). Patients may be small for gestational age. The nephrotic syndrome usually manifests before the age of 3 years and often before 3 months of age. There are no consistent glomerular histopathologic changes. The pathogenesis has not been determined. Neurologic findings are microcephaly, wide sulci, abnormal gyral patterns, developmental retardation, and seizures (Kucharczuk et al, 2000). Large floppy ears, a receding forehead, and hiatal hernia are features in some cases (Cooperstone et al, 1993). Death usually occurs before 6 months of age. The nephrotic syndrome does not respond to treatment. Renal transplantation is not encouraged because of the progressive nature of the severe neurologic disorder. Increased maternal serum and amniotic fluid alpha-fetoprotein assays and abnormal renal ultrasonographic findings may prove useful for prenatal diagnosis (Palm et al, 1986).

PIERSON SYNDROME

This syndrome is characterized by microcoria and congenital nephrotic syndrome. Mutations at chromosomal locus 3p21 in the Laminin Beta 2 *(LAMB2)* gene, which encodes an essential glomerular basement membrane protein, have been associated with this condition (Zenker et al, 2004). Inheritance is autosomal recessive. Edema in the newborn period, progressive renal failure within the 1st year of life, and neurocognitive deficits, with ocular maldevelopment, abnormal lens shape, cataracts, retinal abnormalities, and microcoria, are the phenotypic features. The kidneys are enlarged and echodense by ultrasound examination. Diffuse mesangial sclerosis is the hallmark lesion seen on renal biopsy (Zenker et al, 2004), although focal segmental glomerulosclerosis and minor glomerular changes have been described. Occasionally, *LAMB2* mutations are associated with milder clinical involvement of kidneys and/or eyes (Kagan et al, 2008).

CONGENITAL SYPHILIS

Clinical features of nephrotic syndrome predominate over those of nephritis. The diagnosis must be suspected in an infant who has edema, proteinuria, and signs of congenital syphilis (McDonald et al, 1971). The glomerular findings implicate an immune pathogenesis with subepithelial deposits that contain imunoglobulin G (IgG) and *Treponema* antigen (O'Regan et al, 1976). Treatment with penicillin results in permanent remission of the glomerulopathy.

DISORDERS OF RENAL TUBULAR FUNCTION

A diagnosis of a renal tubular disorder cannot be made without an appreciation of normal renal maturation. Premature newborns (and even full-term newborns) can waste sodium and chloride and have variable combinations of aminoaciduria, glucosuria, phosphaturia, impaired potassium excretion, reduced reabsorptive capacity for sodium bicarbonate, and inability to concentrate urine maximally. In healthy newborns, these are transient aberrations that tend to be isolated and do not cause problems except for the low bicarbonate threshold in preterm infants. This can lead to mild metabolic acidosis during the first few months of life. Very low-birthweight newborns may have nonoliguric hyperkalemia, in part secondary to decreased Na^+,K^+-ATPase activity, which increases with maturation. Therefore, except in specific circumstances, it is not necessary to embark on a full-scale evaluation.

Some renal tubular disorders may be suspected and confirmed in utero. A prenatal diagnosis, however, requiring chorionic villus sampling or amniocentesis can be made only after diagnosis of a condition in an older sibling. Postnatally, the possibility of a tubular disorder may arise when abnormal blood gas and electrolyte results are obtained. The initial manifestations of a renal tubular disorder may not include all the findings associated with the disorder.

Three constellations of fluid and electrolyte imbalances should alert a neonatologist to the possibility of a disorder of renal tubular function. The combination of metabolic acidosis, hyperkalemia, and hyponatremia is seen in renal dysplasias, obstructive uropathy (especially if complicated by a urinary tract infection), and pseudohypoaldosteronism. Furthermore, congenital adrenal hyperplasia can present with these abnormalities. Metabolic acidosis, hypokalemia, and hypophosphatemia are the characteristic findings seen in patients with proximal renal tubular dysfunction, the so-called Fanconi's syndrome. Metabolic alkalosis, hypokalemia, and hyponatremia occur in Bartter's syndrome.

Important clinical clues to the presence of a renal tubular disorder are poor feeding, unexplained vomiting, dehydration, failure to thrive, drowsiness, irritability, tetany, seizures, and unexplained icterus. Isolated proximal renal tubular acidosis (RTA) is uncommon, and the need for large quantities of bicarbonate to correct a hyperchloremic metabolic acidosis is a clue to the diagnosis. Fructose intolerance and galactosemia must be considered in a jaundiced newborn with Fanconi's syndrome. Hypophosphatemia and renal phosphate wasting are manifestations of X-linked hypophosphatemic rickets, but it is uncommon for this condition to be diagnosed in a newborn. Hyperchloremic metabolic acidosis with a decrease in the unmeasured anion gap and in the absence of diarrhea raises the possibility of distal RTA. Distal RTA rarely manifests in the neonatal period, however. More commonly, diarrhea with resultant loss of bicarbonate in stool and an inappropriate increase in urine pH may mimic distal RTA. This occurs as a result of decreased sodium delivery to the distal nephron, which is required for normal hydrogen ion excretion (Izraeli et al, 1990). Pseudohypoaldosteronism, Bartter's syndrome, and renal dysplasias must be considered in newborns with severe hyponatremia and renal salt wasting. Infants with Bartter's syndrome are hypokalemic, whereas those with renal adysplasia, pseudohypoaldosteronism, and the renal tubular hyperkalemia syndromes are hyperkalemic. Hematuria, renal calculi, and nephrocalcinosis with hypercalciuria can occur in newborns with prolonged use of furosemide (see Chapter 34). Primary hyperoxaluria type 1 may present in the newborn period with acute renal failure and nephrocalcinosis (Ellis et al, 2001). Nephrocalcinosis in neonates and early infancy is also associated with prematurity, distal RTA, Bartter's syndrome, hypercalcemia, vitamin D intoxication, X-linked hypophosphatemic rickets, and familial hypomagnesemia with hypercalciuria and nephrocalcinosis.

RENAL FANCONI SYNDROME OF PROXIMAL TUBULAR DYSFUNCTION

The renal Fanconi syndrome is characterized by generalized proximal renal tubular dysfunction with impaired net reabsorption of amino acids, bicarbonate, glucose, phosphate, urate, sodium, potassium, and low-molecular-weight proteins. Renal excretion of these solutes and water is increased, and the serum concentrations of some are variably reduced. Hypophosphatemia results in vitamin D–resistant rickets, and bicarbonaturia causes a hyperchloremic metabolic acidosis. In newborns, the clinical manifestations of renal Fanconi syndrome may include polyuria, dehydration, metabolic acidosis, and glycosuria. These features are often asynchronous. Growth retardation and rickets mostly occur later in infancy.

HEREDITARY FRUCTOSE INTOLERANCE [McKUSICK #229600]

Hereditary fructose intolerance presents only in newborns fed sucrose or fructose in formula, antibiotics, fruit juices, or honey. The symptoms are poor feeding, vomiting, and failure to thrive (Gitzelman et al, 1989). The diagnosis can be made by molecular analysis of the aldolase-B gene in blood (Brooks and Tolan, 1993). Inheritance is autosomal recessive. Fructose-containing foods must be withdrawn from the diet as soon as the condition is suspected.

GALACTOSEMIA [MCKUSICK #230400]

Classic galactosemia deficiency can manifest in neonates with vomiting, diarrhea, hyperbilirubinemia with jaundice, hepatomegaly, ascites, and *Escherichia coli* sepsis a few days after starting milk ingestion. Cataracts are occasionally detectable by slit-lamp examination in neonates. This autosomal recessive disease is caused by deficient activity of galactose-1-phosphate uridyl transferase (GALT) as a result of mutations in the *GALT* gene at chromosomal locus 17q (Tyfield et al, 1999). Two other autosomal recessively inherited disorders of galactose metabolism (transferase and epimerase deficiency) occur more rarely. Newborn screening programs include tests for detection of galactosemia. The diagnosis is suggested by demonstrating increased concentrations of galactose in blood and urine and confirmed by demonstrating deficient red blood cell galactose-1-phosphate uridyl transferase (or galactokinase). Milk and milk-containing products must be withdrawn from the diet.

CYTOCHROME *c* OXIDASE DEFICIENCY

A fatal infantile cytopathy with variable manifestations in brain, skeletal and cardiac muscle, liver, and occasionally renal Fanconi syndrome is one of the mitochondrial cytopathy syndromes associated with defects in complex IV of the respiratory chain (cytochrome *c* oxidase) (EC 1.9.3.1). Inheritance appears to be autosomal recessive. Clinical features include neonatal onset of hypotonia; hyporeflexia; respiratory failure; elevated levels of lactic and pyruvic acids in blood, cerebrospinal fluid, or urine; and renal Fanconi syndrome (Lombes et al, 1996). There is no treatment, prognosis is dismal, and most neonates die in infancy.

CYSTINOSIS [McKUSICK #219800]

Affected individuals appear normal at birth and develop manifestations of the renal Fanconi syndrome between 6 and 12 months. The diagnosis should be considered if there are features of the renal Fanconi syndrome in a neonate. Inheritance is autosomal recessive, and there is defective lysosomal transport of cystine. The cystinosis gene, *CTNS*, maps to chromosome 17p13 and encodes an integral membrane protein, cystinosin (Town et al, 1998). Cystinosis can be diagnosed in utero by cystine measurements in chorionic villi by 9 weeks (Smith et al, 1987). Early and adequate treatment with oral cysteamine retards progression to end-stage renal failure (Markello et al, 1993), and administration of 0.55% cysteamine eyedrops from 1 year of age dissolves the corneal cystine crystals (Gahl et al, 2000).

TYROSINEMIA TYPE 1 [McKUSICK #276700]

Type 1 tyrosinemia is caused by deficiency in the gene for fumarylacetoacetate hydrolase at chromosomal locus 15q23-q25. Although type 1 tyrosinemia is an important cause of renal Fanconi syndrome and hepatocellular carcinoma, this rarely manifests in the neonate (Vanden Eijnden et al, 2000).

FANCONI-BICKEL SYNDROME

Fanconi-Bickel syndrome is caused by a homozygous deficiency in the gene for the glucose transporter 2 (GLUT 2) on chromosome 3q26. It is characterized by hepatorenal glycogen accumulation, fasting hypoglycemia, hepatomegaly, proximal tubular dysfunction, rickets, and short stature. The first manifestations usually appear between 3 and 10 months of age but are occasionally present in the newborn period (Riva, 2004).

RENAL GLYCOSURIA

Isolated forms of renal glycosuria rarely manifest in the newborn and are benign. Intermittent or constant renal glycosuria can also be detected in newborns who have the rare, autosomal recessive condition of glucose and galactose malabsorption (Markello et al, 1993).

RENAL TUBULAR ACIDOSIS

Primary RTA is characterized by chronic hyperchloremic metabolic acidosis associated with an inability to either acidify urine or reabsorb bicarbonate. It may be a primary disorder or secondary to acquired renal injury. Primary RTA is not associated with the renal Fanconi syndrome. Primary RTA is separated into three main types: proximal RTA (pRTA or type 2 RTA); distal RTA or *classic* RTA (type 1) and hyperkalemic RTA (type 4).

Primary Proximal Renal Tubular Acidosis

Proximal renal tubular acidosis (pRTA) is an integral feature of the renal Fanconi syndrome, and primary pRTA is extremely uncommon. The primary form may be inherited in autosomal dominant, recessive, or sporadic fashion. The recessive form may be associated with ocular abnormalities such as band keratopathy, glaucoma, and cataracts and is caused by a mutation in 4q21 encoding the apically located Na^+-HCO_3 cotransporter (NBC-1) (Usui et al, 2001). The underlying defect in pRTA is an inability to reabsorb filtered bicarbonate in the proximal tubule with bicarbonate wasting and hyperchloremic metabolic acidosis but normal distal tubular acidification. Therefore, when filtered bicarbonate is reclaimed to maximal renal tubular reabsorptive capacity for a patient with pRTA, the urine pH is appropriate for the severity of metabolic acidosis, with values below 5.3. When pRTA occurs as an isolated defect, it is usually transient (Nash et al, 1972).

Distal Renal Tubular Acidosis

Clinical manifestations of distal RTA (dRTA) are anorexia, failure to thrive, hypotonia, persistently low serum bicarbonate, elevated serum chloride, inappropriately high urine pH, and, in some cases, nephrocalcinosis. Additional findings are decreased urinary excretion of titratable acid, NH_4^+ (ammonium), and citrate. Some patients have congenital high-frequency nerve deafness. Untreated patients develop rickets (Caldas et al, 1992). dRTA is often considered in the differential diagnosis of a neonate with a non-anion-gap acidosis, but there are few reports of dRTA in neonates (Caldas et al, 1992; McSherry et al, 1978). The possibility of dRTA can be inferred from calculating the rate of excretion of NH_4^+. This can be determined indirectly by calculating the urinary net charge or urine anion gap (Goldstein et al, 1986): $Na^+ + K^+ + NH_4^+ = Cl^- + 80$. The kidney is not the cause of acidosis if the Cl^- (chloride) is greater than the sum of Na^+ (sodium) + K^+ (potassium). If $Na^+ + K^+$ is greater than Cl^- (chloride), then the urinary NH_4^+ may be less than 80 mmol per day, in keeping with dRTA (Carlisle et al, 1991). The diagnosis of dRTA is often made erroneously in patients with diarrhea who develop a hyperchloremic metabolic acidosis and have an *inappropriate* urine pH over 6 (Izraeli et al, 1990).

Regardless of whether a transient or permanent form of distal RTA is suspected, adequate amounts of alkali, either as bicarbonate or citrate, in doses of 2 to 3 mEq/kg/day are required to maintain a normal serum bicarbonate concentration (Igarashi et al, 1992). This can be withdrawn after several months to challenge the diagnosis, or the infant can be allowed to outgrow the dose. Challenging with an ammonium chloride loading test is not necessary because the diagnosis can be inferred from indirect tests such as the urine anion gap.

There are at least three autosomal recessively inherited forms of dRTA. In dRTA *without* nerve deafness, a mutation in the gene is located on chromosome 7q33-34; the gene product is the 116-kDa B-subunit of the apical pump (ATP6N1B) (Smith et al, 2000). dRTA *with* nerve deafness (Karet et al, 1999) is caused by mutations in ATP6B1, located on chromosome 2p13, and encoding the B-subunit of the apical proton pump mediating distal nephron acid secretion. Autosomal recessive dRTA without deafness in Asians and autosomal dominant dRTA without deafness in whites are caused by a mutation located on chromosome 17q21-22, which encodes the anion exchanger-1 (AE-1) located in the basolateral membrane of the cortical collecting duct (Sritippayawan, 2004).

Renal Tubular Acidosis Caused by Maternal Sniffing of Toluene

Maternal toluene abuse from paint or glue sniffing during pregnancy causes severe renal tubular acidosis in mother and neonate (Lindemann, 1991).

BARTTER'S SYNDROMES (INHERITED HYPOKALEMIC RENAL TUBULAR DISORDERS)

Bartter's syndrome is a congenital chronic tubular disorder characterized by hypokalemic metabolic alkalosis, polyuria, salt wasting, hyperkaliuria, hyperaldosteronism, resistance to the pressor effect of angiotensin, juxtaglomerular apparatus hyperplasia, increased renal renin production, and, in some patients, hypercalciuria and nephrocalcinosis. Similar features occur with loop diuretic treatment and congenital chloride diarrhea. There are at least three clinical subtypes of Bartter's syndromes with marked phenotypic variations within each subtype. These include *antenatal hypercalciuric variant* (hyperprostaglandin E syndrome, HPS/aBS); *classic Bartter's syndrome* (cBS); and the *Gitelman variant of Bartter's syndrome* (GS). The common characteristics of each subtype are hypokalemic metabolic alkalosis and renal salt wasting.

Antenatal Hypercalciuric Variant (Hyperprostaglandin E Syndrome, HPS/aBS)

This is a life-threatening neonatal disorder. Features include polyhydramnios, premature delivery, hypokalemia, hypercalciuria, metabolic alkalosis, fever, vomiting, diarrhea and failure to thrive, hyposthenuria, and nephrocalcinosis. The inheritance is autosomal recessive with mutations in the gene for either furosemide-sensitive NaK-2Cl cotransporter NKCC2 (*SLC12A1*) on 15q21.1 (Simon, 1996), inwardly rectifying potassium channel, subfamily J, member 1, ROMK (*KCNJ1*) on 11q24 (Jeck et al, 2001), or an essential B-subunit of the CLCNKB channel, Barttin, encoded by the *BSND* gene on chromosome 1p32.3 (Estevez, 2001). Classic Bartter's syndrome may also be caused by mutations in *NKCC2* or *ROMK* genes, suggesting that antenatal and classic forms are different manifestations of severity of the same disorder. Barttin mutations are associated with sensorineural deafness, because the protein is also expressed in stria vascularis of the ear (Estevez, 2001). There is no cure for Bartter's syndrome, but treatment with inhibitors of prostaglandin synthesis improve polyuria, correct biochemical abnormalities, and permit satisfactory growth and development. The nephrocalcinosis, however, may not improve (Mourani et al, 2000).

Classic Bartter's Syndrome [McKusick #241200]

The clinical phenotype varies ranging from episodes of neonatal severe volume depletion with hypotension and hypokalemia to mildly symptomatic patients diagnosed in adolescence. Serum magnesium concentrations are normal. There are several cases involving mutations in one of three genes encoding ascending limb of Henle transporters such as (1) the basolateral chloride channel, CLCNKB, on 1p36; (2) the Na-K-2Cl cotransporter gene, SLC12A1/NKCC2, on 15q13; or (3) the K^+ inwardly-rectifying channel, subfamily J, member 1, ROMK (ROMK1/KCNJ1) on chromosome 11q24. CLCNKB mutations may occasionally manifest with a congenital Bartter's (HPS/aBS) or a Gitelman-like phenotype.

Gitelman Variant of Bartter's Syndrome [McKusick# 263800]

This syndrome usually does not manifest in neonates (Bettinelli et al, 2000). Hypocalciuria and hypomagnesemia are specific clinical features of Gitelman's syndrome. The Gitelman variant is caused by mutations in the gene for the thiazide-sensitive NaCl cotransporter NCCT (SLC12A3) of the distal tubule, located on 16q13.

RENAL TUBULAR HYPERKALEMIA

The causes of neonatal renal tubular hyperkalemia (RTH) are marked prematurity, renal adysplasia, urinary tract obstruction, urinary tract infection, pseudohypoaldosteronism, and congenital adrenal hyperplasia (Rodriguez-Soriano et al, 1995). In RTH, there are inappropriately low urine potassium concentration, renal salt wasting, and metabolic acidosis. The serum creatinine concentration is often increased because of volume depletion (pseudohypoaldosteronism, congenital adrenal hyperplasia), reduced nephron mass (renal adysplasia), and/or obstruction (posterior urethral valves).

PSEUDOHYPOALDOSTERONISM

There are two syndromes of aldosterone resistance: pseudohypoaldosteronism type I and pseudohypoaldosteronism type II (Hanukoglu, 1991). Furthermore, there are two clinically and genetically distinct forms of type I pseudohypoaldosteronism: renal pseudohypoaldosteronism and multiple-organ pseudohypoaldosteronism. Pseudohypoaldosteronism may be inherited as an autosomal dominant or autosomal recessive trait. In the dominant form of pseudohypoaldosteronism type I there are mutations in the gene *MLR*, encoding the mineralocorticoid receptor. In the recessive form of pseudohypoaldosteronism type I, there are mutations in genes *SNCC1A*,

SNCC1B, and *SCNN1G*, which encode subunits of the epithelial Na^+ channel (ENaC) (Rodriguez-Soriano, 2000).

Pseudohypoaldosteronism Type I

Renal pseudohypoaldosteronism usually starts in early infancy and is characterized by diminished renal tubular responsiveness to aldosterone with hyponatremia, hyperkalemia, markedly elevated plasma aldosterone, and hyperreninemia. The clinical expression ranges from severe, with death occurring in infancy, to asymptomatic. Symptomatic patients are treated with sodium supplementation, which they usually outgrow by 2 years of age.

Multiple-Organ Pseudohypoaldosteronism

There is impaired responsiveness to aldosterone in salivary and sweat glands, renal tubules, alveoli, and colonic mucosal cells. The course is protracted, with life-threatening episodes of salt wasting.

Pseudohypoaldosteronism Type II (Gordon Hyperkalemia-Hypertension Syndrome, Familial Hyperkalemic Hypertension)

The features are hyperkalemia, despite a normal glomerular filtration rate, hypertension variable mild hyperchloremia, metabolic acidosis, and suppressed plasma renin activity (Schambelan, 1981). The metabolic abnormalities are corrected by treatment with thiazide diuretics. Mutations in *WNK* (with no lysine kinase) 1 and 4 genes resulting in functional hyperactivity of the thiazide-sensitive Na-Cl cotransporter (NCCT) have been found to be causative (Wilson, 2001). There are no reports of neonatal presentation.

CONGENITAL NEPHROGENIC DIABETES INSIPIDUS

Nephrogenic diabetes insipidus (NDI) can result from congenital or acquired insults to kidneys including electrolyte abnormalities (hypokalemia, hypocalcemia), drugs (aminoglycosides), tubular interstitial inflammation, obstruction, and dysplasia. In congenital or inherited forms of NDI, insensitivity of the distal nephron to the antidiuretic effect of vasopressin results in an inability to concentrate urine, leading to large quantities of hypotonic urine (Bichet et al, 1997; van Lieburg et al, 1999). Affected neonates may be irritable, feed poorly, fail to gain weight, and have unexplained dehydration and fevers. Serum concentrations of sodium, chloride, creatinine, and blood urea nitrogen are elevated, and serum concentrations of vasopressin are normal or increased. There is a blunted response of plasma factor VIII, von Willebrand factor, and plasminogen activator after administration of 1-desamino-8-D-arginine vasopressin. Treatment with hydrochlorothiazide (3 mg/kg/day) and amiloride (0.3 mg/kg/day three times a day) may be preferable to hydrochlorothiazide and indomethacin because indomethacin can cause bleeding. Treatment can prevent dehydration, electrolyte imbalances, cerebral calcification, and seizures and result in normal growth, but patients continue to have polydipsia and polyuria.

About 90% of patients with inherited NDI are males with the X-linked form caused by mutations in the arginine vasopressin receptor 2 gene (*AVPR2*) that codes for the V2 receptor located in chromosomal region Xq28 (Morello and Bichet, 2001). In fewer than 10% of families, the inheritance of NDI is autosomal recessive or autosomal dominant. Mutations have been identified in the aquaporin-2 gene (*AQP2*) on 12q13 that codes for the vasopressin-sensitive water channel (Goji et al, 1998). The reliability of prenatal diagnosis of the X-linked form of NDI is about 96%.

CHAPTER 87

Urinary Tract Infections and Vesicoureteral Reflux

Stephen A. Zderic

This chapter provides an overview of the epidemiology, pathophysiology, radiographic evaluation, and management of urinary tract infections (UTIs) in the neonate. Although the focus is on the management of vesicoureteral reflux as one of the congenital conditions frequently associated with UTI, it can also be the mode of presentation for other congenital urologic anomalies. Of the several key points emphasized in this chapter, one of the most important is that reflux itself does not cause UTI. Many children may have reflux without any symptoms, which has become increasingly apparent during the past 20 years as many newborns with prenatal hydronephrosis were subjected to a voiding cystourethrogram (VCUG). Neonates who develop bladder infections and have reflux will be more likely to present clinically with a febrile UTI. It also is important to remember that biologic susceptibility has a major role in the cause of neonatal UTIs. Finally, it has been recognized that not all damage to kidneys associated with reflux reflects scarring from infection. Some kidneys with high-grade reflux have elements of dysplasia and scarring at the time of initial presentation and in the absence of infection.

URINARY TRACT INFECTIONS

EPIDEMIOLOGY

Within the first several months of postnatal life, UTIs are more common in boys. After the first 6 months, the incidence in girls increases steadily as it declines in boys (Chang and Shortliffe, 2006), such that from 1 to 3 years of age females have a 10- to 15-fold greater risk. Wiswell observed that although only 20% of males were uncircumcised, this group accounted for 80% of all UTIs in boys, thus identifying phimosis as a significant risk factor (Wiswell, 1997; Wiswell and Geschke, 1989). These data suggest that circumcision offers protection against UTIs in the 1st year of life and in particular offers support for encouraging circumcision in males with congenital structural or functional abnormalities that place them at high risk for pyelonephritis and sepsis, such as patients with posterior urethral valves or reflux.

DIAGNOSIS

The diagnosis of a UTI in a young infant is not always straightforward, and a high index of suspicion is required because the symptoms are generalized. Many of the patients will have confounding signs: up to 60% are irritable, 50% show signs of feeding poorly, and up to 40% may have vomiting or diarrhea. In a more recent study of infants with UTI, the best correlates proved to be a body temperature greater than 38° C and uncircumcised males (Shaikh et al, 2007; Zorc et al, 2005). The index of suspicion must rise when these aforementioned symptoms are present with no localizing source. In such instances, obtaining a urine specimen for analysis and culture must be included in the evaluation.

Much has been said and written about the procurement of specimens by the techniques of clean catch (not applicable in neonates), use of a bag, catheterization, or suprapubic puncture (Stamey, 1980). Results of studies on bag or clean-catch specimens are valid only if cultures are truly negative. These collection methods are susceptible to contamination in girls and especially in uncircumcised males (Figure 87-1). Knowledge of the composition of preputial or vaginal flora is of little use in managing the febrile child. What matters most is the composition of urine within the bladder itself. This problem is compounded when bagged specimens are obtained at home and arrive "fresh" at the office to be sent to a central laboratory before plating. Another problem arises with the definition of what a negative urine culture means. In many instances, the reports state that the results are negative only because the presence of 100,000 colony-forming units (CFUs) is used as a cutoff to define a positive culture. Hoberman et al (1994) examined the frequency distribution of voided or bag specimens and compared the findings with those obtained as post-void specimens by catheterization of febrile infants. The authors found that 10,000 to 49,000 CFUs/mL usually represented contamination, whereas counts in excess of 50,000 CFUs/mL were more characteristic of a true positive. Still, there was overlap between these groups; thus numeric quantitation remains an inexact tool.

The standard for specimen collection remains suprapubic aspiration, which is accurate and can be safely performed in a neonate because the bladder is a pelvic organ. A 21-gauge needle can be inserted into the palpable bladder just above the pubic symphysis in the midline to collect an aspirate; however, urologists rarely use this method of collection. A catheterized specimen is easy to obtain and provides accurate results, especially if the first 2 to 3 mL of urine, which can contain urethral contaminants, is discarded. For a febrile child with possible urosepsis in an emergency department, or requiring hospital admission, documentation of a UTI should be established on the basis of a catheterized specimen or a suprapubic aspirate. Voided clean-catch or bag methods can be used early in an evaluation before the urinary tract is considered a source. However, the increased incidence of false-positive findings seen with these collection methods leads to more patients being subjected to antibiotic therapy and a costly and invasive radiographic workup. The greatest diagnostic yield from doing these expensive and invasive studies

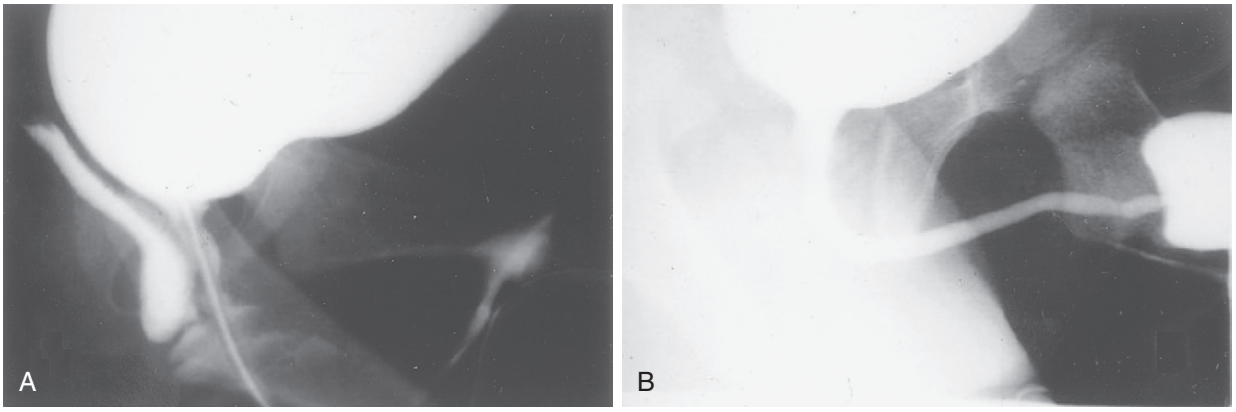

FIGURE 87-1 These voiding cystourethrogram images demonstrate how bagged specimens may lead to false-positive results in infant females or uncircumcised males. Vaginal reflux allows for contaminants in the bagged specimen from an infant female **(A)**. In the uncircumcised male, urine may pool underneath the foreskin and acquire contaminating flora **(B)**.

will be in the population of patients whose UTI was most accurately diagnosed by using catheterized or suprapubic specimens.

TREATMENT

The neonate with suspected urosepsis should receive broad-spectrum antibiotic coverage until the results of sensitivity testing dictate a shift to single-antibiotic coverage. Ampicillin and gentamicin provide excellent treatment for the most common pathogens that are likely to be present. The most likely pathogen is *Escherichia coli*, but there is always a possibility of *Pseudomonas* spp., especially in an infant who was just discharged home after a stay in the neonatal intensive care unit. The duration of intravenous antibiotic therapy for pyelonephritis can be debated, but parenteral therapy at least avoids the concern of compliance issues. Experimental evidence demonstrates that reflux-associated pyelonephritis in piglets confirmed by ^{99m}Tc dimercaptosuccinic acid (DMSA) scan can be successfully treated only with oral nitrofurantoin (Macrodantin; Risdon et al, 1994). In view of given the expense of hospitalization or home-based intravenous antibiotic therapy, the mandatory duration of parenteral therapy will continue to be debated, especially in older children (Hoberman and Wald, 1999). However, in the more susceptible neonate, parenteral therapy should be instituted in a hospital setting and continued until results of a follow-up urine culture become negative (American Academy of Pediatrics, 1999). At that point, oral antibiotic therapy can be started for a total course of 10 to 14 days.

Once the acute infection has been treated, antibiotic prophylaxis should be instituted until the child is ready for radiographic imaging studies. The use of amoxicillin (12.5 mg/kg) in neonates, or trimethoprim-sulfamethoxazole in infants, is acceptable prophylaxis. The use of trimethoprim-sulfamethoxazole in urology patients for suppression is based on the work of Stamey (1980), who demonstrated that low-dose antibiotic treatment does not produce shifts in fecal flora. In contrast, high doses of trimethoprim-sulfamethoxazole, and especially of broad-spectrum antibiotics, have been shown to produce greater and more concerning shifts in fecal flora. This finding is especially significant because feces serve as the origin for most (>90%) bacteria that colonize the perineum and vagina and thus ultimately produce a UTI.

RADIOGRAPHIC WORK-UP

Once a diagnosis of UTI has been established and treated, it is important to initiate a radiographic workup to look for any underlying structural anomalies (American Academy of Pediatrics, 1999). It has been stated that up to 30% of children with a UTI have aberrant urinary tract anatomy or function (Lebowitz and Mandell, 1987). For this reason, a radiographic evaluation of the urinary tract should be undertaken, consisting of an ultrasound study of *kidneys and bladder*, followed by a VCUG. A more contemporary study shows that 15% of hospitalized neonates and infants with a UTI prove to have an underlying anatomic diagnosis (Hsieh et al, 2009). The traditional standard of care has been to obtain a renal bladder ultrasound at the time of hospitalization for a pediatric UTI. Typically, a 2- to 4-week period has been recommended between the infection and the VCUG, but this interval is arbitrary. It is more important to ensure that the urine is sterile before performance of the VCUG. A patient should be maintained on antimicrobial prophylaxis until imaging rules out any urinary tract pathology. On sonography, it is important to obtain both kidney and bladder views, because sometimes the kidneys alone are imaged and shown to be normal and the workup is terminated; several infections later, a bladder ultrasound study shows a stone, ureterocele, or diverticulum. Even if a VCUG is being done on the same day of the renal ultrasound examination, a small ureterocele may be missed at fluoroscopy that would be seen on bladder sonogram.

The VCUG must be done carefully and requires patience on the part of all concerned. Because the act of voiding is required to demonstrate reflux in 20% to 30% of reflux cases, such cases would be missed if the child were anesthetized for a static cystogram. The standard approach is to obtain a classic fluoroscopic study first, define the anatomy, and accurately grade the reflux if it is present. Some groups have advocated that a radionuclide VCUG be used as the initial screening study. However, to appropriately define the anatomy, the contrast VCUG remains the "gold standard". As discussed later in the section on reflux, the cornerstone of accurate management is grading

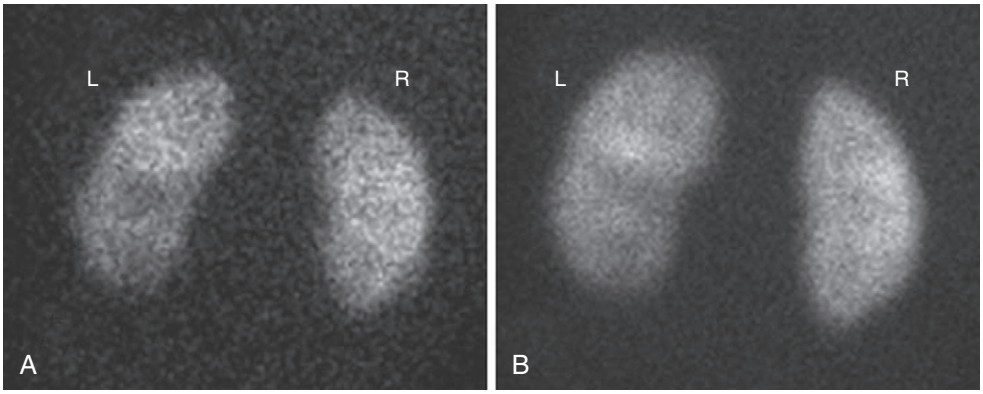

FIGURE 87-2 An example of an acute positive dimercaptosuccinic acid (DMSA) scan taken at the time of hospitalization for a febrile urinary tract infection showing multiple cold spots within a kidney **(A)**. A follow-up DMSA scan done almost 1 year later shows chronic changes after this episode of febrile urinary tract infection **(B)**.

of the reflux, which can be provided only by a well-executed VCUG study.

Within the past 5 years, there has been a growing movement toward limiting the anatomic workup for children with UTIs. There is a growing consensus that many of the radiographic workups done for UTI might be avoided with minimal risk. For example, Hoberman et al (2003) demonstrated that an ultrasound examination done at the time of hospitalization for a febrile UTI had a diagnostic yield of less than 1%. However, it is crucial to note that this study was limited to patients older than 2 months who had all been screened with antenatal sonograms and who had no comorbidities. Understanding these study limitations is critical before trying to apply these criteria to fragile neonates who often have comorbidities. These principles are further illustrated in clinical scenarios presented in this chapter.

In recent years there has been growing support in the literature for the use of DMSA scanning to identify patients with acute pyelonephritis. Hoberman's study demonstrated that only 50% of children with a febrile UTI proved to have a positive DMSA scan (Figure 87-2; Hoberman et al, 2003). Of this subset, 80% had a normal DMSA scan at a follow-up evaluation 6 months later, suggesting that most pediatric patients with a febrile UTI are not prone to renal scarring. Surprisingly, Hoberman's data did not suggest that age (stratified into groups of patients older or younger than 1 year of life) was a risk factor for a positive follow-up scan. It is important to note that other studies based on patients referred to a pediatric urology or nephrology specialty practice reported residual positive DMSA scans in as many as 32% of patients (Biggi et al, 2001; Rushton and Majd, 1992). This finding would suggest that there are critical differences between studies done on a patient population that is drawn on the "first pass" from primary care settings, as opposed to those originating from tertiary care settings. Several studies in the 1990s advocated the use of DMSA scanning to stratify patients into high-risk (positive DMSA scan) or low-risk (negative DMSA scan) groups (Rushton and Majd, 1992), and some have begun to advocate limiting VCUG to the high-risk group alone (Hardy and Austin, 2008; Tseng et al, 2007). However, these studies are all based on older patients and should not be applied to fragile neonates.

PATHOPHYSIOLOGY

UTI has a multifactorial etiology and represents an altered balance between host and pathogen. Abnormal anatomy serves to exacerbate the effects of a UTI (Lebowitz and Mandell, 1987; Shortliffe, 2007). Hematogenous spread of bacteria to the urinary tract can occur but is rare. Most UTIs will start in the bladder and then ascend to produce pyelonephritis. This ascent of infected urine from the bladder to the kidney can take place via two major mechanisms: (1) the bacteria are extremely virulent and produce pili that allow the bacteria to attach themselves to the ureter and migrate upstream or (2) the patient has reflux that showers the renal pelvis, allowing for intrarenal reflux and seeding of the renal parenchyma (Figure 87-3). Once bacteria are injected into the renal parenchyma under high pressures, areas of focal infection and inflammation develop (Figure 87-4), and a series of complex steps in the inflammatory cascade occur. If this process is not interrupted by treatment, it can produce severe renal injury or scarring. Furthermore, if repeated infectious insults such as these continue without adequate therapy, the long-term result is significant renal scarring, which in its extreme produces reflux nephropathy that in turn can lead to end-stage renal disease (ESRD). However, recent advances in understanding embryonic development of the ureter and kidney suggest that infection-induced scarring is a rare mechanism of ESRD in patients with reflux, given today's heightened awareness of urine as a source of fever in pediatric patients (Sreenarasimhaiah and Hellerstein, 1998). As mentioned previously, Hoberman's study suggested that only 50% of patients with a well-documented febrile UTI had a positive DMSA scan, and the positive scans done at the time of acute infection reverted to normal within 6 months in 80% of this subset of patients (Hoberman et al, 2003).

Equally important in the pathogenesis of UTIs is the biology of the patient. Many patients are more susceptible to bacterial UTIs because their bladder mucosa expresses cell surface proteins that have a high affinity for cell surface antigens on the bacterial cell wall. A great deal is known about the bladder mucosal expression of these complex glycoproteins, with some being mannose-sensitive. In these cases, the receptor-ligand interaction between pathogen and host is based on molecular recognition of

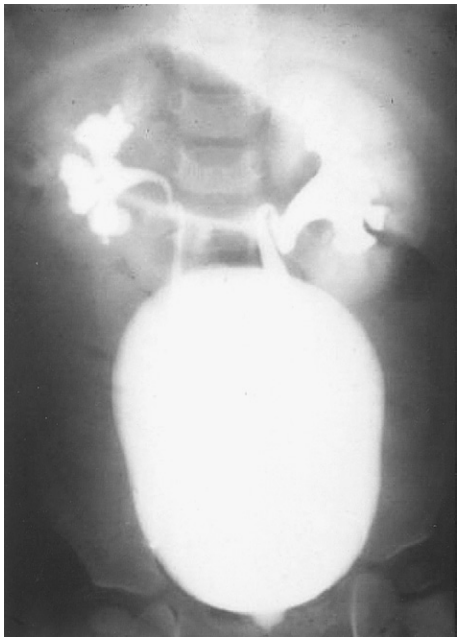

FIGURE 87-3 High-grade bilateral vesicoureteral reflux with evidence of pyelotubular backflow within the left kidney is demonstrated on this voiding cystourethrogram in a neonate.

mannose-6-phosphate. In addition to genetic alterations that increase a patient's susceptibility to bacterial colonization and infection, there may be other differences in a patient's immune system response that affect the individual's propensity for scarring.

URINARY TRACT INFECTIONS COMPLICATED BY OBSTRUCTIVE UROPATHY

An important consideration is what happens when UTIs develop in a newborn with an abnormal urinary tract. It used to be extremely common for obstructive uropathies to manifest after urosepsis had developed. With the widespread use of prenatal sonography, however, most neonates with an obstructive uropathy are identified at birth, and antibiotic prophylaxis is initiated. However, a neonate may still exhibit urosepsis secondary to an obstructive uropathy. In such cases, the obstructive uropathy might have developed after the initial early normal prenatal ultrasound examination, or the problem went undiscovered because of a lack of access to prenatal care, as illustrated in Figure 87-5.

The most common anatomic factor associated with a febrile UTI in a neonate or infant is vesicoureteral reflux. Occasionally an obstructed system will be discovered during the workup. The presence of an obstruction produces a dangerous combination of bacteria, urinary stasis, and a warm environment with a near-ideal culture broth. As a result there is always the possibility of an infection developing in an obstructed system. Keeping this possibility in mind is important because the management may be altered by the use of surgical drainage by either ureterostomy or percutaneous nephrostomy. During treatment for acute pyelonephritis, the patient may not defervesce for 48 to 72 hours; however, beyond 72 hours, underlying obstruction must be suspected if fever persists or the neonate's

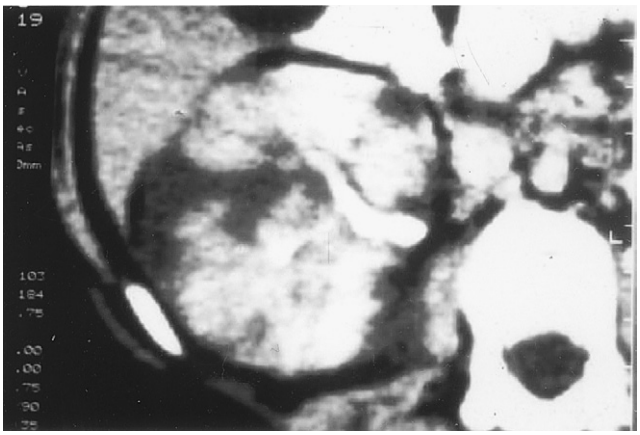

FIGURE 87-4 This computed tomography scan of an infant with right pyelonephritis and associated grade II reflux shows signs of lobar nephronia. Areas within the right kidney function well and excrete contrast, whereas other lobes show signs of poor perfusion.

condition worsens. Under these circumstances, an ultrasound examination to rule out obstruction is warranted. Infections can become established in primary megaureters, ureteroceles, or ectopic ureters (see Figure 87-5) and, on rare occasions, in ureteropelvic junction obstructions. Urine production allows for some antibiotic to reach these bacteria, and a good response may be seen if the patient receives treatment early in the course of infection. In advanced cases, especially in those associated with poor renal function, temporary drainage procedures, such as percutaneous nephrostomy or a cutaneous ureterostomy, will allow for eradication of infection and stabilization of the patient's condition before undertaking definitive surgical repair.

VESICOURETERAL REFLUX

Vesicoureteral reflux exists when urine flows from the bladder back toward the kidney; this reverse flow can occur during bladder filling or emptying (voiding). The etiology of reflux remains debated, but there is growing agreement that reflux constitutes a syndrome. Some patients with reflux have a congenital anatomic basis for the reflux. The normal course of the ureter travels through the bladder wall and underneath the mucosal layer to create a flap valve mechanism, which prevents vesicoureteral reflux. Reflux caused by anatomic malposition of the ureteral insertion into the bladder is referred to as *primary reflux*. In other patients, reflux occurs secondary to increases in bladder pressure, a condition referred to as *secondary reflux*. For example, many patients with posterior urethral valves may have reflux that disappears once the valves are resected. This distinction is important because the rules for primary reflux resolution do not apply to cases of reflux secondary to obstructing lesions, such as posterior urethral valves or the neurogenic bladder seen with spina bifida.

Using contrast VCUG, it is possible to grade primary reflux from I through V (Figure 87-6). Grading reflux allows physicians to communicate findings quickly and to understand what the chances are for the natural resolution of primary reflux. Many additional findings appear on the VCUG images, such as whether there was reflux on filling,

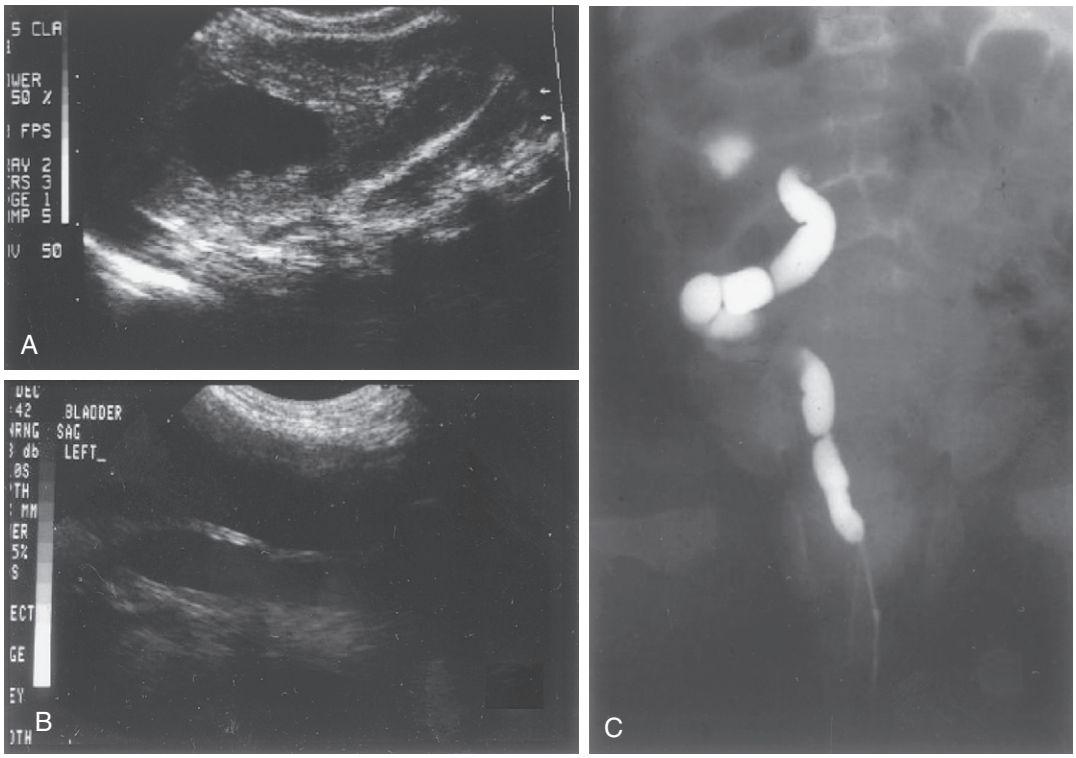

FIGURE 87-5 Ectopic ureter and urosepsis. This 3-month-old infant had a high fever and a positive urine culture that failed to respond to parenteral antibiotic therapy. **A** and **B,** The ultrasound examination showed signs of right hydronephrosis and hydroureter. **C,** A retrograde pyelogram confirmed a diagnosis of ectopic ureter. Most cases are identified by fetal sonography; however, in this instance, the young parents did not seek prenatal care. After cutaneous diversion of this ectopic ureter, the infant became afebrile, and ureteral reimplantation was performed successfully 6 months later.

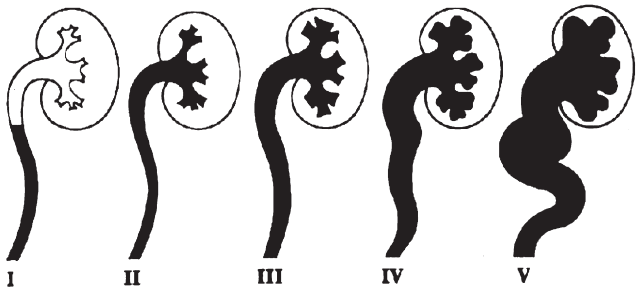

FIGURE 87-6 Grading scale for reflux. The International Reflux Study used this grading scale, which is based on findings of a conventional fluoroscopic voiding cystourethrogram.

whether it started at the beginning or at the end of the filling phase, how much contrast was added to the bladder prior to the initiation of voiding, and whether there was evidence of a pyelotubular backflow (see Figure 87-2). By evaluating the findings in detail, a better understanding of the severity, potential treatment modalities, and outcome can be achieved and used for the benefit of the patient. It is essential to remember that reflux grading for the purposes of calculating the spontaneous resolution applies only to primary reflux; this scale does not apply to secondary reflux such as that seen with posterior urethral valves, or to complex anatomic situations such as ectopic ureters (Figure 87-7). In fact, contrast VCUG is essential in making the diagnosis of an ectopic ureter, because for these patients spontaneous resolution will never occur, and surgery is indicated.

Growing clinical evidence (Sillen et al, 1992, 1996a, 1996b) suggests that voiding pressures are dramatically increased in infants with reflux, especially in boys. These studies have shown that, even in normal males, voiding pressures are elevated in the neonatal period and decline dramatically during the first 2 years of life. The data demonstrate that voiding pressures in boys with high-grade reflux are often threefold to fourfold higher than those seen in older children. In these boys, reflux often resolves in a surprisingly short period of time, implying that the pressures drop with maturation of bladder function. Of interest, female newborns do not fare as well with resolution of neonatal reflux on a grade-for-grade basis, nor are their voiding pressures as elevated. These clinical observations are supported by experimental findings suggesting that there are gender-related differences in bladder neck function. The key concept is that voiding pressures are elevated, especially in male neonates with reflux, and that these pressures diminish over time. These observations have great bearing on how reflux resolution rates should be interpreted in newborns.

Outcomes for reflux resolution in neonates have been studied more extensively over the past 15 years (Sjöström et al, 2004); this was made possible by the increased number of cases detected by prenatal ultrasonography. Evidence from a multicenter study suggests that reflux detected in the first months of life as part of a workup for prenatal hydronephrosis has a better chance for spontaneous resolution, grade for grade, than that diagnosed in the child at 2 to 4 years of age (Herndon et al, 1999). Given this

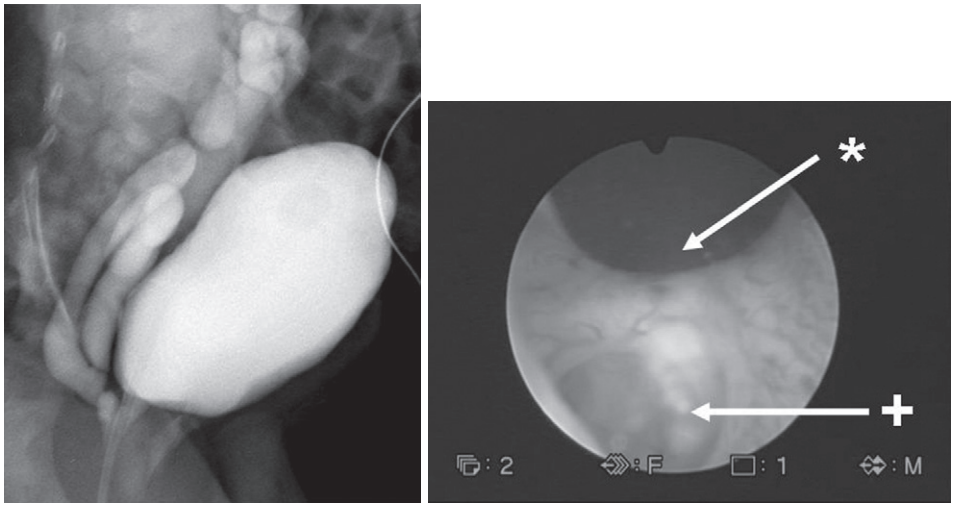

FIGURE 87-7 This voiding phase of the voiding cystourethrogram demonstrates reflux into a Y-type duplex right-sided ureter that has a single opening into an ectopic location within the proximal urethra just below the bladder neck. This radiographic finding was also confirmed at cystoscopy, where the ectopic ureter (+) clearly enters the proximal urethra below the bladder neck (*).

information, recommendations that can be made about neonatal reflux management will be altered by the mode of presentation and social circumstances (compliance issues). For a newborn with prenatally diagnosed grade IV or V reflux, expectant observation with antibiotic prophylaxis seems most reasonable (Sillen, 1999). However, this course of action demands that parents comply with antibiotic prophylaxis and understand that a breakthrough infection rate as high as 20% is possible (Herndon et al, 1999). This series also indicated the benefit of circumcision in males with known reflux (Herndon et al, 1999). The case can be made for a more aggressive surgical approach if a neonate has urosepsis and high-grade (IV or V) reflux; follow-up studies continue to demonstrate that it is in this cohort of patients that the risk of acquired scarring remains high (Sjöström et al, 2009). It is absolutely crucial for any parent and referring physician to understand that successful reimplantation surgery diminishes but does not eradicate the likelihood of pyelonephritis. A child with innate susceptibility will still experience bladder infections despite the absence of reflux.

Several studies have shown that siblings of patients with reflux also have a higher likelihood of having reflux, with an incidence that declines in older siblings. Sibling screening studies in the 1st year of life have shown that 20% to 50% of the siblings will have a VCUG that is positive for reflux (Noe, 1995; Parekh et al, 2002) up to the age of 9 years. Several studies have shown an increased incidence of renal scarring in siblings whose reflux was discovered by screening (Sweeney et al, 2001; Wan et al, 1996). However, Parekh et al (2002) suggest that sibling reflux follows a more benign course, and they noted no renal scarring after antibiotic prophylaxis. On the other hand, would the cohort of patients in this study have done as well without a diagnosis and antibiotic prophylaxis? It is important to remember that many asymptomatic infants have undiagnosed reflux, never develop UTIs, resolve their reflux, and live normal lives. In one metaanalysis of the world literature on screening studies for reflux in asymptomatic siblings, Hollowell and Greenfield (2002) concluded that there was no evidence to support this practice. The extent to which screening averts renal complications or hospital admissions for pyelonephritis will be best answered by prospective trials.

The traditional view was that identifying the pediatric patient with reflux was crucial to allow for antibiotic prophylaxis to be administered to prevent recurrent pyelonephritis and renal scarring. This traditional view has come under closer scrutiny in recent years. The embryologic studies of Mackie and Stephens (1975) suggested that much of the focal hypoplasia seen in kidneys with reflux is present at birth and have been borne out in clinical practice by a 20-year experience of neonatal evaluations for antenatally diagnosed hydronephrosis. Further support has come from newer molecular studies of ureteral bud development in knockout and transgenic mice, showing that aberrant ureteric bud development is associated with abnormal renal morphology. It is becoming clear that most of the renal insufficiency in patients with reflux reflects aberrant embryogenesis and not damage secondary to infection. This case is demonstrated in Figure 87-8, in which a VCUG was done for antenatal reflux and demonstrated massive grade V reflux. In this 3-day-old neonate, there was never a history of UTI, yet serum creatinine was already abnormal and ultrasound examination findings demonstrated increased echogenicity with a loss of corticomedullary differentiation. In this setting, the high-grade reflux was associated with renal dysplasia at the onset, and renal failure was progressive.

Clearly, episodes of pyelonephritis and the resulting renal inflammation (see Figure 87-3) can do harm if left untreated. It is estimated that each episode of febrile UTI can lead to a 5% risk of new renal scar formation per episode, and it is generally agreed that repeated and untreated infection harms the kidney. What is currently being debated is the role of long-term antibiotic prophylaxis in the management of these patients. One recent randomized trial suggested that there is no measurable benefit to prophylaxis (Garin et al, 2006); however, this study was

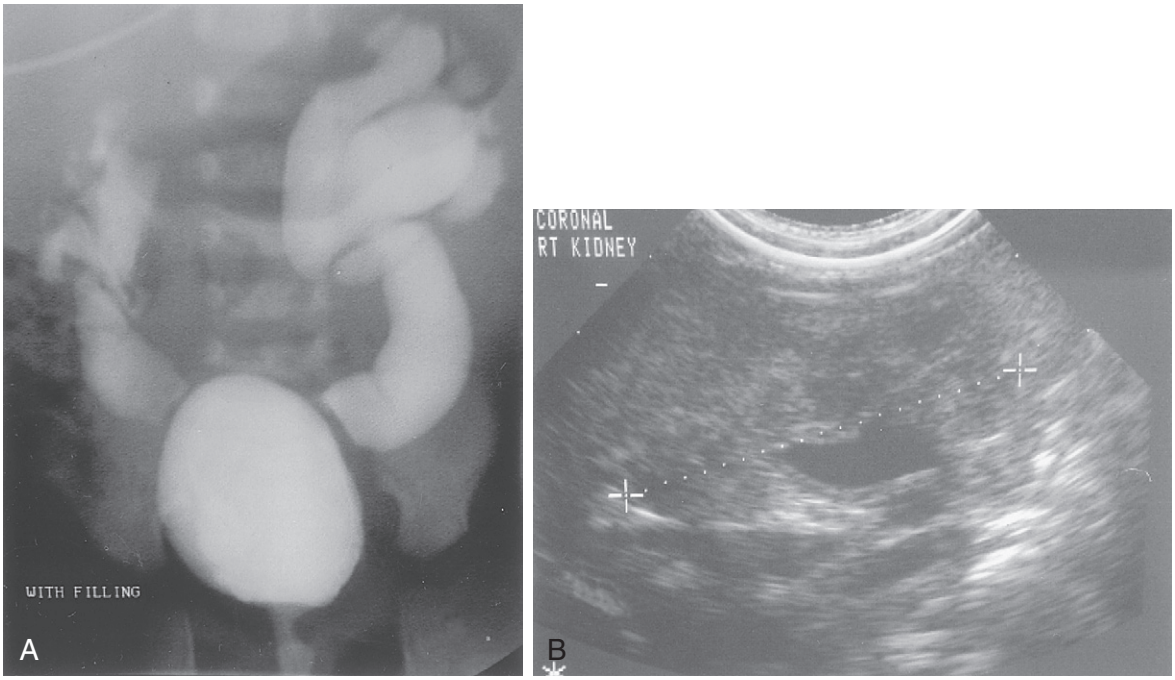

FIGURE 87-8 Dysplasia and high-grade reflux. This case demonstrates the association of bilateral grade V reflux with renal dysplasia. The voiding cystourethrogram **(A)** and ultrasound scan **(B)** shown here were performed within the first 2 weeks of life, and the child had never had a diagnosed urinary tract infection during this interval. Despite sterile urine, the serum creatinine level was elevated, and the renal sonogram showed increased echogenicity and poor corticomedullary differentiation. This case indicates that renal insufficiency associated with reflux often is present at the outset and is not always secondary to infection.

limited by a small sample size and a wide distribution of ages and reflux grades. The National Institutes of Health has currently funded the multicenter Randomized Intervention Vesicoureteral Reflux trial (Mathews et al, 2009) with the goal of obtaining the best data to help settle this debate. However, these studies do not enroll patients younger than 2 months, and they exclude patients with comorbidities. The current standard of care continues to be a full radiographic workup and antibiotic prophylaxis for the neonate with febrile UTI and reflux.

CHAPTER 88

Renal Vascular Disease in the Newborn

Halima Saadia Janjua and Donald L. Batisky

There is a significant risk of neonates developing complications related to thromboembolic phenomena, and the issues related to vessels supplying and draining renal vasculature will be discussed in this chapter. Clearly there are a number of conditions that can result in an imbalance of the delicate homeostasis between bleeding and thrombosis. Some may be genetic, some may relate to underlying stresses during pathologic processes, and some may relate to treatments for the pathologic processes.

RENAL ARTERIAL OBSTRUCTION

INCIDENCE AND ETIOLOGY

Renal artery thrombosis in the neonate is far less common than renal vein thrombosis. A major risk factor for renal arterial obstruction is umbilical artery catheterization. Before the advent of umbilical artery catheterization, only a few cases of renal artery thrombosis were seen. Other significant risk factors are shock, coagulopathy, and congestive heart failure. The reported incidence of umbilical artery–related thromboembolism reflects, in large part, the diagnostic test chosen. Doppler ultrasonography underestimates this incidence. Studies using ultrasound report an incidence of umbilical artery–related thromboembolism from 14% to 35%, whereas studies using angiography document incidences up to 64%. Autopsy studies have shown an incidence of umbilical artery–related thromboembolism between 9% and 28%, although major clinical symptoms of umbilical artery–related thromboembolism occur in 1% to 3% of infants (Andrew et al, 2001). Trauma at the time of insertion of umbilical artery catheter by endothelial injury is postulated to be the cause of aortic thrombus formation which then leads to thrombosis of one or both renal arteries (Box 88-1).

High umbilical artery catheters, placed at the T6 to T10 vertebral level, have been associated with a decreased incidence of clinical vascular complications without a statistically significant increase in any adverse effects (Barrington, 2000b). The chances of umbilical artery catheter occlusion can be decreased by adding heparin to the infusing fluid at a concentration as low as 0.25 unit/mL (Barrington, 2000a).

CLINICAL PRESENTATION

Clinical presentation varies with the extent and severity of thrombosis. Thrombosis of the abdominal aorta or renal arteries can manifest in any of the following ways: signs of congestive heart failure, hypertension, oliguria, renal failure, bowel ischemia or frank necrotizing enterocolitis secondary to superior or inferior mesenteric artery, and decreased femoral pulses with lower limb ischemia. Symptoms of renal arterial thrombosis manifest within the first few postnatal days in a term infant compared with a median age of 8 days in a preterm infant. The symptoms can be classified based on clinical severity; minor thrombosis with mildly decreased limb perfusion, hypertension, and hematuria; moderate thrombosis with decreased limb perfusion, hypertension, oliguria, and congestive heart failure; and major thrombosis with hypertension and multiorgan failure (Box 88-2).

Laboratory findings associated with renal arterial thrombosis are thrombocytopenia, hypofibrinogenemia, elevated fibrin split products, variable prothrombin and thromboplastin times, conjugated hyperbilirubinemia, elevated blood urea nitrogen and creatinine, hyperreninemia, and hematuria.

DIAGNOSIS

Doppler ultrasonography is used as the first line of imaging for diagnosing neonatal thrombosis although it usually fails to detect smaller intraarterial thrombi and some larger asymptomatic venous thrombi (Roy et al, 2002). If ultrasonography is inconclusive, radionuclide imaging could also be used. Angiography is the standard diagnostic modality and should be performed through the umbilical artery line if surgical intervention or intrathrombotic fibrinolytic therapy is being considered.

TREATMENT

For asymptomatic or minimally symptomatic newborns, only supportive care is recommended, such as removal of the umbilical artery catheter and close ultrasonographic monitoring. Most of these thrombi resolve spontaneously.

In newborns with mild signs of organ dysfunction and stable aortic and renal arterial thrombosis, management of hypertension, transient renal insufficiency, and mild congestive heart failure is recommended. Systemic heparin is given for anticoagulation. Close laboratory monitoring is done to avoid excessive heparinization, and clinical response is monitored by Doppler ultrasonography. However, there are age-dependent variations in the mechanism of action of heparin, and activated partial thromboplastin time (APTT) monitoring might not be a reliable marker for therapeutic heparin levels in infants (Ignjatovic et al, 2006; Monagle et al, 2008; Newall et al, 2009). If only APTT is used to titrate the heparin dose in infants, it can result in subtherapeutic levels of heparin; therefore heparin dose should be titrated to both APTT and heparin levels, accounting for the size of the clot and risk of bleeding associated with anticoagulation (Monagle et al, 2008; Newall et al, 2009). Heparin is dosed as an initial loading dose followed by a continuous infusion. The loading dose is 75 to 100 IU/kg over 10 minutes followed by 28 IU/kg/h. Heparin has a larger volume of distribution

BOX 88-1 Risk Factors for Aortic and Renal Arterial Thrombosis

- Systemic infection
- Birthweight <1500 g
- Perinatal asphyxia
- Polycythemia
- Intrauterine cocaine exposure
- Maternal diabetes mellitus
- Maternal lupus
- Congenital heart disease
- Hypercoagulability
- Dehydration
- Infusion of calcium salts
- Hyperalimentation
- Intravenous fat preparation
- Resistance to activated protein C (secondary to mutation of coagulation factor V gene in more than 90% of the cases)
- Homozygous congenital protein C deficiency

BOX 88-2 Clinical Presentation of Aortic and Renal Arterial Thrombosis

- Signs of congestive heart failure
- Hypertension
- Oliguria
- Renal failure
- Bowel ischemia or frank necrotizing enterocolitis secondary to superior or inferior mesenteric artery
- Decreased femoral pulses with lower limb ischemia
- Thrombocytopenia, hypofibrinogenemia, elevated fibrin split products, variable prothrombin and thromboplastin times
- Conjugated hyperbilirubinemia
- Elevated blood urea nitrogen and creatinine
- Hyperreninemia
- Hematuria

in infants and is cleared faster, which leads to higher dose requirements. Bleeding can occur in newborns secondary to heparin, in which case heparin infusion should be stopped. If bleeding is life threatening or needs to be stopped immediately, protamine sulfate is given, 1 mg for every 100 units of heparin given over the last 2 hours (McDonald et al, 1981).

Low-molecular-weight heparins (LMWHs) have some advantages over unfractionated heparin, thereby making them safe and efficacious alternatives to unfractionated heparin therapy. LMWHs have superior bioavailability, a longer half-life, and dose-independent clearance, which gives a more predictable anticoagulant response. The incidences of heparin-induced thrombocytopenia and osteoporosis are rare with LMWHs; they can be used in neonates with poor venous access because they are administered subcutaneously. LMWHs also do not need frequent laboratory monitoring and dose adjustment. Use of subcutaneous catheters for administration, which can remain in place for 7 days, can reduce the number of injections to as few as one per week (Albisetti and Andrew, 2002). In case of clinically significant bleeding, protamine sulfate should be administered intravenously. The dose is based on the amount of LMWH received in the previous 3 to 4 hours; 1 mg protamine sulfate can inactivate 100 units of LMWH (Hirsh et al, 2008).

In case of potential life-threatening complications of aortic or renal thrombosis, fibrinolytic therapy (systemic or intrathrombotic) along with supportive care is indicated. There are limited data on efficacy, dose, and safety of fibrinolytic agents in infants (Manco-Johnson et al, 2002; Monagle et al, 2008). The intrathrombotic infusion of fibrinolytic agent reduces the cumulative dose and possible systemic adverse effects. Close monitoring by ultrasonography or angiography should be done to evaluate the response to this therapy. Fibrinolytic agents act by catalyzing the conversion of endogenous plasminogen to plasmin. The most commonly used agent is recombinant tissue plasminogen activator (tPA).

There are limited data on efficacy, dose, and safety of fibrinolytic agents in infants (Manco-Johnson et al, 2002; Monagle et al, 2008). The tPA is usually administered systemically as a continuous infusion or directly administered into the catheter. For systemic infusion, it can be given with a bolus at its initiation or without it (Gupta et al, 2001; Goldenberg et al, 2007; Wang et al, 2003). The dose for recombinant tPA varies between 0.1 and 0.6 mg/kg/h over a duration of 6 hours (Monagle et al, 2008). A lower dose of recombinant tPA at 0.01 to 0.06 mg/kg/h is associated with decreased incidence of major bleeding (Goldenberg et al, 2007; Wang et al, 2003). Catheter-directed fibrinolysis can be considered, especially if the catheter is already close to the thrombus, in which case a low-dose infusion of recombinant tPA is given (0.01 to 0.2 mg/kg/h for 24 hours). This dosing has advantages such as higher response rate and decreased major bleeding complications. After leaving tPA in the catheter for 2 to 4 hours, catheter patency should be checked by drawing blood. If this dosing level is unsuccessful, a second round of therapy should be started. When fibrinolytic therapy is done for more than 24 hours, its efficacy is reduced because of depleted endogenous plasminogen. This phenomenon is called *plasminogen steal*; it can be overcome by giving supplementary plasminogen if plasminogen levels are low. The major complication of tPA therapy is bleeding. Thrombocytopenia and vitamin K deficiency, if present, should be corrected before the start of treatment. Development of intraventricular hemorrhage or cerebral edema should be monitored closely. Mild bleeding secondary to fibrinolytic therapy can be stopped with local pressure. In the event of major bleeding, tPA should be stopped and intravenous fresh frozen plasma (FFP) or cryoprecipitate should be given. The antifibrinolytic agent aminocaproic acid (Amicar) should be considered if the bleeding is life threatening.

PROGNOSIS

The overall mortality rate with aortic and renal arterial thrombosis is between 9% and 20%, with mortality being higher with major aortic and renal arterial thrombosis (Nowak-Gottl et al, 1997). Renovascular hypertension is the most common long-term complication of renal arterial thrombosis. In most cases, these infants eventually are weaned from antihypertensive medications and remain normotensive. Another consequence of renal arterial thrombosis is chronic renal insufficiency caused by irreversible renal parenchymal damage; this is seen less

frequently but always in cases with severe aortic and bilateral renal arterial thrombosis.

RENAL VEIN OBSTRUCTION

INCIDENCE AND ETIOLOGY

Renal vein thrombosis (RVT) is the most common thrombosis in infancy and occurs primarily in the newborn period. It has an incidence of 2.2 cases per 100,000 live births (Bokenkamp et al, 2000). Renal vein thrombosis has a male predominance of approximately 67%; it is unilateral in more than 70% of patients and more prevalent on the left side (approximately 63%). The thrombus also involved the inferior vena cava in approximately 43% of the cases, and it was associated with adrenal hemorrhage in approximately 15% (Dauger et al, 2009; Lau et al, 2007).

The cause of renal vein thrombosis is unknown, although a number of factors are associated with this disorder. Prothrombotic factors—including lupus anticoagulant, protein C, protein S, plasma antithrombin III activity, lipoprotein(a), factor V Leiden mutation, prothrombin gene mutation, and methylenetetrahydrofolate (*MTHFR*) thermolabile mutation—have a significant role in the pathogenesis of neonatal RVT (Kosch et al, 2004; Lau et al, 2007; Marks et al, 2005). Other associated factors are maternal diabetes, traumatic delivery, prematurity, hyperviscosity, hypovolemia, hemoconcentration, sepsis, birth asphyxia, cyanotic congenital cardiac disease, congenital renal vein defects, and an indwelling umbilical venous catheter (Bokenkamp et al, 2000; Lau et al, 2007; Nowak-Gottl et al, 1997; Proesmans et al, 2005) (Box 88-3).

BOX 88-3 Risk Factors for Renal Vein Thrombosis

INHERITED

- Lupus anticoagulant
- Protein C and protein S deficiency
- Plasma antithrombin III activity
- Elevated lipoprotein (a)
- Factor V Leiden mutation
- Prothrombin gene mutation
- Methylenetetrahydrofolate (*MTHFR*) thermolabile mutation

ACQUIRED

- Maternal diabetes
- Traumatic delivery
- Prematurity
- Hyperviscosity
- Hypovolemia
- Hemoconcentration
- Sepsis
- Birth asphyxia
- Cyanotic congenital cardiac disease
- Congenital renal vein defects
- An indwelling umbilical venous catheter

CLINICAL PRESENTATION

There are three cardinal signs of renal vein thrombosis: macroscopic hematuria, palpable abdominal mass, and thrombocytopenia; these signs have been found in approximately 56%, 45%, and 47% of cases, respectively (Lau et al, 2007). Other signs and laboratory findings associated with renal vein thrombosis are oliguria or anuria, hemolytic anemia, metabolic acidosis, azotemia, and variable prothrombin and partial thromboplastin times (Box 88-4).

BOX 88-4 Clinical Presentation of Renal Vein Thrombosis

- Macroscopic hematuria
- Palpable abdominal mass
- Thrombocytopenia
- Oliguria/anuria
- Hemolytic anemia
- Metabolic acidosis
- Azotemia
- Variable prothrombin and partial thromboplastin times

DIAGNOSIS

Renal ultrasonography is a useful and convenient way of diagnosing RVT. It shows unilaterally or bilaterally enlarged and echogenic kidneys with attenuation or loss of corticomedullary differentiation and little blood flow. In many cases, calcification and thrombus may be seen extending into the inferior vena cava (Proesmans et al, 2005). Doppler studies are useful for detecting resistance or absence of flow in renal venous branches and collateral vessels. Thrombosis in small intrarenal veins can cause increased resistance in renal arteries, even when blood flow in the main renal vein and its branches is normal (Lau et al, 2007). Length of the kidney has been reported to correlate negatively with renal outcomes (Winyard et al, 2006). Ultrasonography may also be used as a prognostic tool.

Although renal ultrasonography is the most commonly used imaging modality for diagnosing renal vein thrombosis, contrast angiography is considered the gold standard. Angiography, however, is invasive and requires exposure to ionizing radiation and can be performed only in a neonate in stable condition. Magnetic resonance imaging has also been reported to give excellent diagnostic findings in RVT, although it should be reserved for those cases in which Doppler findings are inconclusive (Basterrechea Iriarte et al, 2008).

TREATMENT

Treatment of neonatal RVT remains controversial because there is not enough literature to compare supportive therapy with anticoagulation, fibrinolysis, or both. Supportive therapy should be provided to all affected infants in an attempt to correct any abnormalities in fluid, electrolyte, and acid-base balance. Hypertonic solutions, nephrotoxic medications, hyperosmotic radiographic contrast agents, and unnecessary use of diuretics should be avoided. Prophylactic heparin therapy has been recommended in a majority of cases to prevent thrombus extension by some authors (Dauger et al, 2009), whereas others advocate similar renal outcomes between supportive treatment and heparin therapies, including a similar proportion of

atrophic kidneys secondary to RVT in neonates whether they were managed supportively or with heparin (Lau et al, 2007). LMWH is being used more frequently than unfractionated heparin for anticoagulation. Fibrinolysis is usually reserved for more severe cases, such as bilateral thrombosis and systemic effects (Dauger et al, 2009). Whichever the treatment approach, affected neonates must be followed closely for renal complications such as hypertension, chronic renal insufficiency, and renal atrophy.

Surgical interventions such as thrombectomy or nephrectomy have not shown any benefit. Thrombectomy prevents the main thrombus from extending into inferior vena cava or the contralateral kidney, but it does not prevent renal infarction because smaller intrarenal veins are almost always involved.

PROGNOSIS

Renal scarring and atrophy are well-recognized complications of RVT in the affected kidney, which can be assessed with a radionuclide scan. Approximately 19% of patients have persistent elevation of blood pressure (BP), which has been shown to be slightly higher—at 21% for those with bilateral RVT. The mortality rate for neonates with RVT is approximately 3% (Lau et al, 2007). Most of the deaths are due to underlying disease and not RVT or secondary renal dysfunction. Because more than 80% of neonates with RVT have shown persistent abnormalities on renal imaging and there are not enough data on long-term outcome of such neonates, continued follow-up is strongly recommended.

RENAL CORTICAL AND MEDULLARY NECROSIS

INCIDENCE AND ETIOLOGY

Renal cortical and medullary necrosis are uncommon in newborns and are usually encountered in critically ill newborns as a manifestation of perinatal and postnatal stress leading to end-organ injury. It is usually diagnosed on autopsy. The incidence is 5% in infants who die at less than 3 months of age (Lerner et al, 1992). Risk factors associated with renal cortical and medullary necrosis are congenital heart disease, perinatal anoxia, placenta abruption, twin-twin or twin-maternal transfusions, sepsis, infectious myocarditis, vascular malformations, dehydration, prematurity, respiratory distress syndrome, bleeding diathesis, cardiac catheterization, and intravenous contrast agents (Lerner et al, 1992; Nygren et al, 1988).

PATHOPHYSIOLOGY

Medication administration can interfere with compensatory mechanisms to maintain renal perfusion and can lead to acute tubular necrosis that, depending on the severity of the insult, then may lead to vasculature injury and microthrombi formation with subsequent renal cortical and medullary necrosis. Antiinflammatory medications like indomethacin, which are used to close a patent ductus arteriosus, have been shown to worsen renal ischemia in the setting of hypoperfusion, potentially leading to renal cortical and medullary necrosis. When renal perfusion is decreased, it results in increased catecholamine secretion, activation of the renin-angiotensin system and the generation of prostaglandins. The intrarenal generation of vasodilatory prostaglandins mediates vasodilation of renal microvasculature to maintain renal perfusion. In this scenario, nonsteroidal antiinflammatory drugs can inhibit this compensatory mechanism and cause acute renal insufficiency during renal hypoperfusion, leading to renal cortical and medullary necrosis (Andreoli, 2004; Badr and Ichikawa, 1988).

In the same way that renal perfusion pressure is low as in renal artery stenosis, increased intrarenal generation of angiotensin II works to increase efferent arteriolar resistance in order to provide the necessary intraglomerular pressure for filtration (Badr and Ichikawa, 1988). Administration of angiotensin-converting enzyme inhibitors in this setting can precipitate acute renal failure and eventually renal cortical necrosis.

CLINICAL PRESENTATION

The clinical manifestations include hematuria, oliguria, and renal enlargement, which are nondiagnostic and associated with many other common neonatal renal abnormalities. Because renal cortical and medullary necrosis usually develops in critically ill newborns in the setting of shock, diagnosis of renal cortical and medullary necrosis is usually delayed or never considered.

DIAGNOSIS

In renal cortical and medullary necrosis, laboratory features may be present, such as hematuria, elevated blood urea nitrogen and creatinine, and thrombocytopenia. Renal ultrasound examination results are normal initially, but may show renal atrophy with substantially decreased size of kidneys later in the course. A radionucleotide renal scan shows decreased to no perfusion with delayed or no function (Andreoli, 2004).

MANAGEMENT AND PROGNOSIS

Infants with cortical necrosis may have partial recovery or no recovery at all. Typically they need renal replacement therapy, short-term or long-term, but those who recover enough renal function to be managed without dialysis are at risk for late development of chronic renal failure.

ADRENAL HEMORRHAGE

INCIDENCE AND ETIOLOGY

The incidence of neonatal adrenal hemorrhage is approximately 0.2% (Avolio et al, 2002). The actual incidence is difficult to ascertain because most cases are asymptomatic. Bilateral hemorrhages are seen in 5% to 15% of cases (Khuri et al, 1980). The right side is involved in 70% of unilateral cases (Fang et al, 1999). Factors involved in neonatal adrenal hemorrhage include anoxia or hypoxia during delivery, being large for gestational age, prolonged labor, trauma during delivery, shock or sepsis, bleeding

disorders, and renal vein thrombosis (Fang et al, 1999; Velaphi and Perlman, 2001).

PATHOPHYSIOLOGY

The adrenal gland in an infant is significantly larger than that in an adult and regresses in size during the 1st year of life. The cortex of the gland loses approximately one third of its weight in the first 3 weeks of life. Mechanical trauma and changes in BP easily cause hemorrhage in the adrenal gland, which is more susceptible because of its large size, vascularity, and relative hyperemia. The right adrenal gland is trapped between the liver and spine, which makes it an easy target for mechanical trauma (Velaphi and Perlman, 2001), and its direct venous drainage into the inferior vena cava makes it more susceptible to changes in central venous pressure.

CLINICAL PRESENTATION

Clinical signs and symptoms are usually nonspecific and depend on the volume of bleeding. Smaller bleeds may be asymptomatic or result in unexplained persistent jaundice or mild anemia (Adorisio et al, 2007). Larger bleeds can cause abdominal distention associated with an abdominal mass. Adrenal hemorrhage can also manifest with a scrotal mass that could be confused with testicular torsion (Avolio et al, 2002). Severe hypovolemic shock and hypoglycemia can occur with larger or bilateral bleeds.

DIAGNOSIS

The differential diagnosis of prolonged anemia and jaundice will include hemolysis, liver dysfunction, inborn errors of metabolism, and other forms of jaundice. In case of an abdominal mass, neuroblastoma, mesoblastic nephroma, teratoma, or other masses such as adrenal, hepatic, ovarian, pancreatic, and choledochal cysts should be considered (Fang et al, 1999). Testicular torsion, incarcerated hernia, epididymitis, hematocele, tumor, or orchitis should be considered in patients with a scrotal mass (Bor et al, 2000). In case of shock, sepsis should be evaluated and empirically treated along with BP support and volume replacement.

Laboratory tests that help in the diagnosis are complete blood cell count, serum bilirubin, serum glucose, urinary catecholamines, and their metabolites. Ultrasonography is the most commonly used diagnostic modality (Perl et al, 2007); it can also identify features of evolution of adrenal hemorrhage that follows hemorrhage, such as fibrosis and calcification. Calcification is usually identified 2 weeks after adrenal hemorrhage. Computed tomography scans and magnetic resonance imaging have also been used to identify adrenal hemorrhages, although the former is associated with concerns about radiation exposure and the latter is more accurate than other modalities for identifying adrenal hemorrhages but is not readily available and is time-consuming (Abdu et al, 2009). Laparotomy is needed only rarely for diagnosis.

MANAGEMENT AND PROGNOSIS

Adrenal hemorrhage is usually managed with supportive care, such as volume expansion, administration of blood products, and BP support. Serial imaging can guide changes in the adrenal size and consistency, which can be helpful in identifying certain tumors. Most infants recover completely. Adrenal insufficiency can occur but is rare and usually occurs with bilateral adrenal involvement (Perl et al, 2007; Ruminska et al, 2008).

HYPERTENSION IN THE NEWBORN

DEFINITION

BP measurements in the newborn infant are an important indicator of appropriate circulation. Determining whether a neonate is hypotensive or hypertensive requires normative BP values. In the pediatric population, *hypertension* is defined as systolic or diastolic BP in the 95th percentile or higher (or more than two standard deviations above the mean values). Hypertension is considered stage 1 if the BP is at the 95th percentile to less than the 99th percentile, and stage 2 if the BP is 99th percentile or greater plus 5 mm Hg (National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents, 2004).

NORMAL BLOOD PRESSURE IN NEWBORN

An Australian study of 406 term infants showed a median systolic BP of 65 mm Hg (range, 46 to 94 mm Hg), diastolic BP of 45 mm Hg (range, 24 to 57 mm Hg), and a mean BP of 48 mm Hg (range, 31 to 63 mm Hg) at 12 to 24 hours of life. Blood pressure was seen to increase over the next four days by 1 to 2 mm Hg per day. This study did not show any significant difference in BP depending on birthweight or length (Kent et al, 2007), although in another larger study there was a significant difference in gestational age, birthweight, and length between infants with and without systemic hypertension (Seliem et al, 2007) (Figures 88-1 to 88-3).

EPIDEMIOLOGY

In an Australian study of 2572 newborn infants born between 2001 and 2005, the incidence of hypertension was 1.3% (Seliem et al, 2007). In another study of 3179 infants admitted to the neonatal intensive care unit over a 6-year period, the incidence of hypertension was reported as 0.81% (Singh et al, 1992). Factors associated with hypertension included lower gestational age, lower birthweight, decreased length, maternal antenatal steroid administration, maternal hypertension, umbilical arterial catheterization, postnatal acute renal failure, patent ductus arteriosus, and bronchopulmonary dysplasia (Seliem et al, 2007; Singh et al, 1992).

BLOOD PRESSURE MEASUREMENT

Invasive (Direct) Measurement

Invasive measurement of BP is used in critically ill newborns and is the preferred method of measurement in severely ill and preterm neonates. Direct intraarterial measurement through a catheter placed in the aorta or radial artery is the most accurate technique and provides continuous readings. The degree to which radial measurements correlate with aortic pressures is uncertain. In

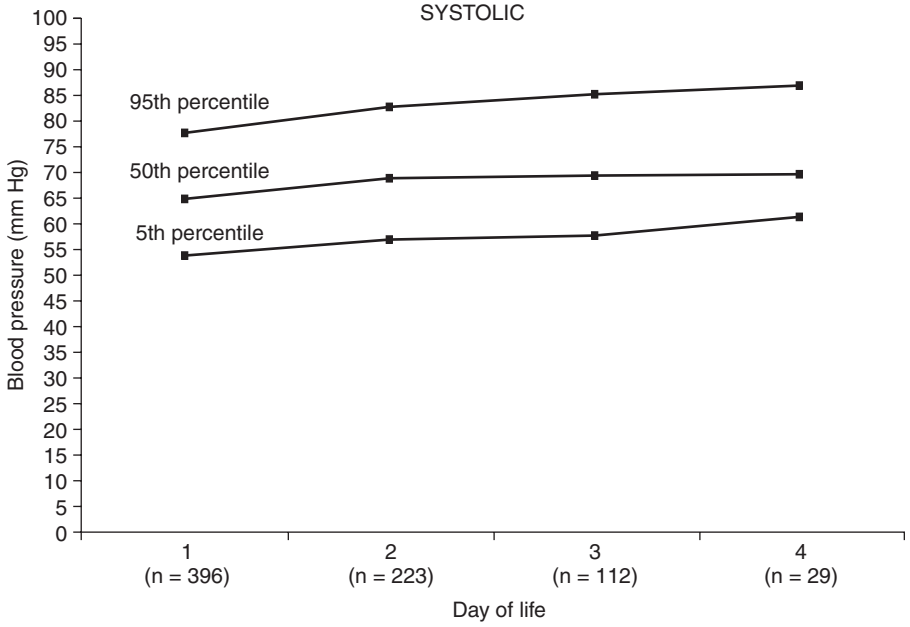

FIGURE 88-1 Systolic blood pressure percentiles (5th, 50th, and 95th) at 1 to 4 days old. *(Reproduced with permission from Kent AL, Kecskes Z, Shadbolt B, et al: Normative blood pressure data in the early neonatal period. In* Pediatric nephrology, *vol 22, New York, 2007, Springer Science+Business Media, p 1336.)*

In* Pediatric nephrology, *volume 22, New York, 2007, Springer Science+Business Media, p 1337.)*

adults, radial artery systolic BP measurements can be 20% to 30% higher than central values, although mean and diastolic measurements are comparable (Pauca et al, 1992). However, radial pressures may more closely mimic aortic pressures in newborns (Gevers et al, 1993). Complications associated with intraarterial catheters include thrombosis and infection; therefore they should be used to monitor BP only when the catheter is needed for another indication, such as frequent arterial blood sampling.

Noninvasive (Indirect) Measurement

Noninvasive BP measurement commonly involves three methods: auscultation, Doppler ultrasound, and automatic oscillometry. Blood pressure measurement by auscultation is usually insensitive in the setting of low stroke volume, although it is recommended to recheck a high BP reading by auscultation (National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents, 2004). Doppler ultrasound does not accurately detect diastolic BP but measures systolic BP reliably. Oscillometry is the most commonly used noninvasive method. It gives an accurate and reproducible estimate of BP. It also measures mean arterial pressure instead of calculating it. For small infants, noninvasively measured BP readings tend to be too high, whereas larger infants tend to have falsely low BP readings (Dannevig et al, 2005). There may also be significant differences between oscillometer BP monitoring systems (Dannevig et al, 2005).

To get an accurate estimate of BP by noninvasive methods, it is important that an appropriate arm cuff is chosen and that the monitor is calibrated according to manufacturer's

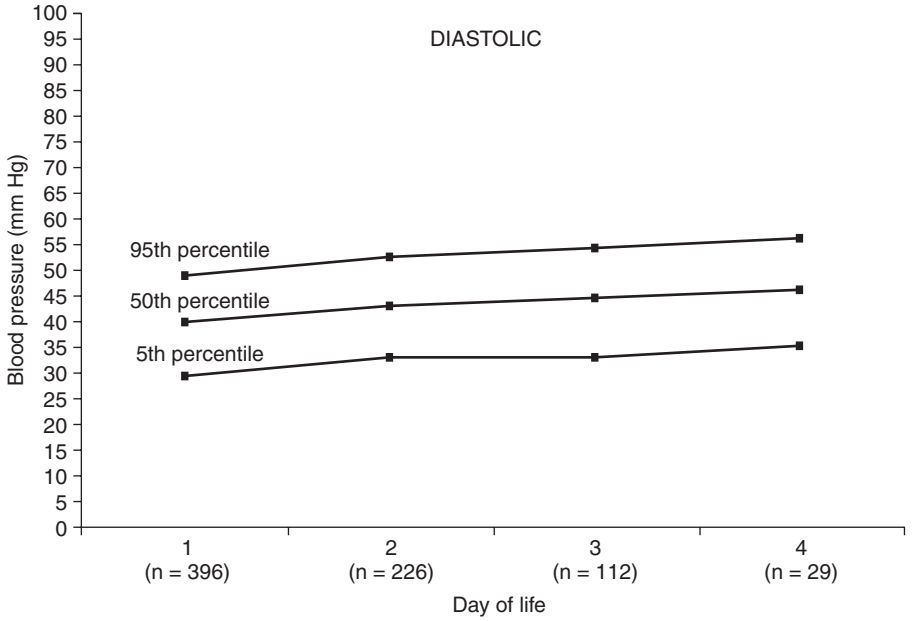

FIGURE 88-3 Diastolic blood pressure percentiles (5th, 50th, and 95th) at 1 to 4 days old. *(Reproduced with permission from Kent AL, Kecskes Z, Shadbolt B, et al: Normative blood pressure data in the early neonatal period. In* Pediatric nephrology, volume 22, *New York, 2007, Springer Science+Business Media, p 1337.)*

specifications. An appropriate cuff size has an inflatable bladder width that is at least 40% of the arm circumference at a point midway between the olecranon and acromion. For such a cuff to be optimal for an arm, the cuff bladder length should cover 80% to 100% of the arm circumference. This translates into bladder width-to-length ratio of at least 1:2. Blood pressure estimation is higher to a greater extent with a cuff that is too small and lower by a cuff that is too large. If a cuff is too small, the next largest size should be used, even if it appears large (Adelman, 1988).

In neonates the BP is significantly lower while prone than while supine. Blood pressure tends to decrease with repeated measurements. First BP reading by oscillometry is significantly higher than the second or third reading (Nwankwo et al, 1997).

ETIOLOGY

Infants with hypertension and a history of umbilical arterial catheter do not always demonstrate thrombi in renal arteries (Flynn, 2000). Thromboembolic events related to umbilical arterial catheter are postulated to occur because of endothelial injury at the time of line placement. The suggested mechanism for hypertension is that thromboemboli decrease perfusion to the kidney, resulting in increased renin and aldosterone production with subsequent sodium and water retention (Kilian, 2003).

Neonatal hypertension usually occurs as a result of renal vein thrombosis, which is usually a result of perinatal hypoxia; this can result in persistent hypertension in up to 30% of cases (Mocan et al, 1991). Hypertension in the 1st month of life can also occur as a consequence of acute tubular necrosis and cortical necrosis, which may follow perinatal hypoxia or severe sepsis in extremely premature infants (Buchi and Siegler, 1986). Fluid overload in these circumstances is usually the cause of hypertension.

Antenatal steroids, administered to accelerate lung maturity, have been associated with an eightfold increase in the risk of developing neonatal systemic hypertension (Seliem et al, 2007), which supports the hypothesis of prenatal glucocorticoids and long-term programming (Seckl, 2004). Many animal experiments have also suggested that exposure to steroids in utero is associated with elevated BP (Koenen et al, 2002). Contrary to these studies, a 30-year follow-up of a randomized controlled trial after exposure to betamethasone showed no increased risk of hypertension (Dalziel et al, 2005).

Chronic lung disease in prematurity is a significant risk factor for developing systemic hypertension (Flynn, 2000). The underlying mechanism—whether related to altered neurohumoral regulation or increased catecholamines, angiotensin, or antidiuretic hormone concentrations—remains unknown (Abman, 2002).

Patent ductus arteriosus is a risk factor for neonatal hypertension (Seliem et al, 2007). It is difficult to discern whether the hypertension is a result of fluid retention or renal hypoperfusion, because many of these infants are treated with indomethacin (Box 88-5).

CLINICAL SIGNS

The magnitude of hypertension does not correlate with the presence of signs and symptoms or their severity. Some patients with severe hypertension manifest few or no symptoms. In many neonates, hypertension will be discovered on routine monitoring of vital signs, particularly in the most acutely ill neonates. In less acutely ill infants, hypertension can manifest with feeding difficulties, unexplained tachypnea, apnea, lethargy, irritability, or seizures. In older infants, unexplained irritability or failure to thrive may be the only manifestation of hypertension (Flynn, 2000) (Box 88-6).

EVALUATION

To diagnose the cause of hypertension, attention should be paid to a history that includes pertinent prenatal exposures, exposure to procedures such as umbilical catheter placement, and current medications. The physical examination

BOX 88-5 Causes of Neonatal Hypertension

VASCULAR
- Renal artery thrombosis
- Aortic thrombosis
- Coarctation of aorta
- Hypoplastic aorta
- Renal vein thrombosis
- Thrombosis of the ductus arteriosus
- Renal artery stenosis
- Intimal hyperplasia
- Idiopathic arterial calcification

RENAL PARENCHYMAL
- Acute renal failure
- Polycystic kidney disease
- Renal cortical and medullary necrosis
- Hypoplastic/dysplastic kidney
- Acute renal infection
- Pyelonephritis with scarring
- Obstructive uropathy
- Constrictive perirenal hematoma or urinoma
- Congenital mesoblastic nephroma
- Nephrolithiasis
- After pyleoplasty of a hydronephrotic kidney
- Multicystic kidney

ENDOCRINE
- Pheochromocytoma
- Neuroblastoma
- Adrenal disorders (hyperplasia, hyperaldosteronism, carcinoma, hematoma)
- Hyperthyroidism

IATROGENIC
- Corticosteroids
- Theophylline
- Pancuronium
- Intrauterine cocaine exposure
- Phenylephrine eye drops

OTHER
- Extracorporeal membrane oxygenation
- Bronchopulmonary dysplasia
- Increased intarcranial pressure/seizures
- Fluid and electrolyte overload
- After closure of abdominal wall defect

- Failure to thrive
- Adrenal mass

should include BP readings in all four extremities to rule out coarctation of the thoracic aorta. A thorough cardiac and abdominal examination should be performed. The presence of a flank mass may indicate ureteropelvic junction obstruction, and an epigastric bruit may indicate renal arterial stenosis. Pain or agitation should also be evaluated as a potential cause of hypertension. It is important to assess serum electrolytes, creatinine, and blood urea nitrogen and to perform a urinalysis (Flynn, 2000).

Ultrasound imaging, including Doppler ultrasound of the genitourinary tract, should be done in all hypertensive infants. Ultrasound can help to diagnose causes of hypertension such as renal venous thrombosis, aortic or renal arterial thrombosis, and anatomic or congenital renal abnormalities. An echocardiogram should be done to evaluate the effects of hypertension, such as concentric left ventricular hypertrophy, left ventricular systolic dysfunction, or left atrial dilation and aortomegaly (Peterson et al, 2006).

Radionuclide imaging should be performed in neonates with extremely severe BP elevation when ultrasonography is not diagnostic. An abnormal kidney typically shows decreased effective renal plasma flow, decreased urine flow rate, and increased isotope concentration. These findings may be present when the ultrasound appearance and serum creatinine concentration are normal. If radionuclide imaging is also inconclusive in neonates with severe hypertension, angiography should be considered. Angiography, though invasive, is the standard modality for diagnosis of renovascular hypertension. But angiography should be deferred in a small infant until the body weight is more than 3 kg. Magnetic resonance angiography has also been used as a less invasive way to detect a vascular lesion by some (Cachat et al, 2004).

TREATMENT

The threshold for starting antihypertensive therapy has not been well defined, therefore the optimal management of neonatal hypertension is uncertain. An asymptomatic

TABLE 88-1 Oral Antihypertensive Agents Used for Neonatal Hypertension

Drug	Class	Dose	Comments
Isradipine	Ca^{2+} channel blocker	0.05-0.15 mg/kg divided four times per day	Used in both acute and chronic HTN
Captopril	ACE inhibitor	0.05-0.5 mg/kg per day divided three times per day	Monitor serum potassium and creatinine
Chlorothiazide	Thiazide diuretic	10-40 mg/kg per day divided twice per day	Monitor serum electrolytes
Hydrochlorothiazide	Thiazide diuretic	2-4 mg/kg per day divided twice per day	Monitor serum electrolytes
Spironolactone	Aldosterone antagonist	1-3 mg/kg per day divided two to four times per day	Can cause hyperkalemia
Hydralazine	Vasodilator	0.75-7.5 mg/kg per day divided three or four times per day	Tachycardia, fluid retention, SLE-like syndrome in slow acetylators
Propranolol	β-Blocker	1.0-8.0 mg/kg per day divided three times per day	Can precipitate heart failure, bronchospasm, and hypoglycemia; avoid in infants with BPD
Labetalol	α- and β-blocker	4.0-40 mg/kg per day divided two or three times per day	Monitor heart rate. Avoid in infants with BPD
Minoxidil	Vasodilator	0.2-5 mg/kg per day divided two or three times per day	Most potent vasodilator. Used for refractory HTN
Amlodipine	Ca^{2+} channel blocker	0.05-0.17 mg/kg per dose divided once or twice per day	Longer duration of action than isradipine, useful for chronic HTN

ACE, Angiotensin-converting enzyme; *BPD*, bronchopulmonary dysplasia; *HTN*, hypertension; *SLE*, systemic lupus erythematosus.

neonate with a systolic pressure consistently between the 95th and 99th percentiles and with no end organ involvement should be observed but not treated. The hypertension resolves over time in most cases. If the systolic pressure is above the 99th percentile or if there is end organ involvement with a systolic pressure above the 95th percentile, the neonate should be treated. There is little if any evidence for a precise, single starting point of treatment. Treatment should be directed at the primary cause. If the neonate is receiving any treatment that could raise BP, attempts should be made to reduce or withdraw that treatment. Salt or fluid overload should be corrected as well (Watkinson, 2002).

If an antihypertensive agent is needed, the group of drugs chosen should depend on the cause of hypertension, routes available for administration, and possibility of impending hypertensive crisis. Treatment is difficult because of idiosyncratic responses to drugs in neonates with varying renal and hepatic function. All drugs should be started at their lowest doses. When an antihypertensive agent is started, the BP should be monitored closely. Neonatal hypertension can be treated with any of these five classes: diuretics, angiotensin-converting enzyme inhibitors, β-blockers, calcium channel blockers, and direct peripheral vasodilators. Diuretics increase salt and water excretion, which results in decreased extracellular and plasma volumes. Compensatory mechanisms then begin to maintain sodium homoeostasis, and plasma volume may return to normal. Despite these compensatory mechanisms, there is a sustained reduction in volume and BP (Sinaiko, 1993). Diuretics can contribute to a hypotensive crisis if used with other antihypertensive drugs in the absence of volume overload. Propranolol is the most extensively used β-blocker in neonates with hypertension; it has a low incidence of side effects. Labetalol blocks both β and α receptors, although it is much more potent than propranolol. Calcium channel blockers, such as isradipine and amlodipine, have vasodilator action that lowers peripheral vascular resistance. Direct vasodilators, such as hydralazine and minoxidil, reduce peripheral vascular resistance by directly acting on vascular smooth muscle. Minoxidil is more potent and has a number of side effects; therefore it is reserved only for refractory hypertension. Both hydralazine and minoxidil can initially cause an increase in heart rate and cardiac output with flushing. Angiotensin-converting enzyme inhibitors are more effective in neonates because renal vascular resistance is high in this population; however, if renal vascular disease is suspected, this latter class of drugs should be avoided until normal vasculature is confirmed. Captopril is a commonly used drug in this class (Watkinson, 2002) (Table 88-1).

In a hypertensive crisis, the drug of choice in this population is a calcium channel blocker—nicardipine. Other agents have also been used, such as esmolol, labetalol, hydralazine, sodium nitroprusside, and enalapril. Regardless of the drug used, BP should be monitored preferably continuously via an indwelling arterial catheter; if this is not an option, then monitoring by cuff readings should be done every 10 to 15 minutes. As a result, the drug can be titrated to achieve the desired degree of BP control. Intermittently administered intravenous agents, such as hydralazine and labetalol, can be used in infants. Intravenous sodium nitroprusside, a potent vasodilator, acts rapidly but has a short duration of action. Sodium nitroprusside can cause renal insufficiency or thiocyanate toxicity with greater than 72 hours of administration; therefore thiocyanate levels should be monitored with this drug if it is used for a prolonged period. Enalaprilat, the intravenous angiotensin-converting enzyme inhibitor, has also been reported to be useful in the treatment of neonatal renovascular hypertension. This drug should be used cautiously because its use, even in doses at the lower end of published ranges, can lead to significant and prolonged hypotension and oliguric acute renal failure (Flynn, 2000) (Table 88-2).

Neonatal hypertension caused by ureteral obstruction or aortic coarctation is best managed surgically. Balloon

TABLE 88-2 Intravenous Antihypertensive Agents Used for Hypertensive Emergency

Drug	Class	Dose	Comments
Nicardipine	Ca^{2+} channel blocker	0.5-3.0 μg/kg per min by IV infusion	Monitor for tachycardia
Esmolol	β-Blocker	100-300 μg/kg per min by IV infusion	Very short acting
Labetalol	α- and β-Blocker	0.20-1.0 mg/kg by IV bolus; 0.25-3.0 mg/kg/h by IV infusion	Relatively contraindicated in BPD and heart failure
Hydralazine	Vasodilator	0.15-0.6 mg/kg	Monitor for tachycardia
Sodium nitroprusside	Vasodilator	0.5-10 μg/kg per min by IV infusion	Thiocyanate toxicity with >72 hr use or in renal failure
Enalaprilat	ACE inhibitor	5-10 μg/kg by IV bolus	Monitor for acute renal failure, prolonged hypotension

ACE, Angiotensin-converting enzyme; *BPD*, bronchopulmonary dysplasia; *IV*, intravenous.

angioplasty or surgical reconstruction can be used in infants with renal arterial stenosis. These infants are usually managed medically until they have grown sufficiently. Hypertension secondary to Wilms' tumor or neuroblastoma requires surgical tumor resection.

PROGNOSIS

In most cases of neonatal hypertension, BP can be controlled adequately with pharmacotherapy. Hypertension resulting from acute tubular necrosis resolves when renal function improves, as is the case with other reversible causes. In bronchopulmonary dysplasia, if hypertension is due to steroid intake (rarely used), it improves once the treatment is stopped. In hypertension secondary to renal artery or aortic thrombosis, the usual duration of drug therapy is a few weeks to several months. The infant can be weaned from medications once the BP is stable for 4 to 8 weeks, and ultrasonography is used to confirm resolution of thrombus (Adelman, 1987; Caplan et al, 1989). Because there is not enough information about the outcome of neonatal hypertension in early adulthood and beyond, close long-term follow-up with regular monitoring of BP and renal function is recommended.

Endocrine Disorders

CHAPTER 89

Embryology, Developmental Biology, and Anatomy of the Endocrine System

Lewis P. Rubin

ENDOCRINE AND NEUROENDOCRINE DEVELOPMENT IN THE FETUS AND PERINATAL TRANSITION

The endocrine system consists of interacting effector-target organ feedback pathways. This chapter reviews several developmental themes, many of which are explored further in the following chapters in Endocrine Disorders and other parts of this text. In addition, lessons learned from development of critical endocrine interactions and intracellular regulatory events, such as the endocrine pancreas (Puri and Hebrok, 2010), are being applied to regenerative medicine and modulating cell fate determination in the adult.

The placental-fetal unit sustains "the unique endocrine milieu of the fetus" (Fisher, 1986) and promotes adaptation for postnatal life. During fetal development into the perinatal transition, the organism shifts from dependence on placenta to independent homeostatic regulation. The functional development of fetal endocrine glands and hormonal responsiveness of target tissues are influenced by fetal genotype, maternal genotype, maternal pre-pregnancy and pregnancy health and nutrition, and pregnancy-associated and preexisting maternal conditions. This complex interplay of genotype and environment is emerging as a central thesis in translational research. By modifying placental and fetal growth and metabolism, hormones play a central role in programming development in utero and adjusting phenotype, especially in response to adverse intrauterine conditions (Fowden and Forhead, 2009).

Of note, much understanding about endocrine developmental biology has been derived from large animal fetal physiology models and gene manipulation in mice. When comparing ontogenic studies performed in different species, one must consider similarities and differences from human fetuses and newborns. A critical point for interspecies comparisons is the maturational state at birth. Different species (and different organ systems in the same species) may be classified either as immature (altricial) or more developed (precocial). In particular, the human term newborn has a relatively mature (precocial) brain and respiratory, neuroendocrine and parathyroid-renal pathways but is relatively clumsy, that is, is motorically immature (altricial).

A second principle is that the human fetal endocrine system begins development more or less independent from maternal endocrine influence. This separation is possible because the placenta is an efficient barrier to fetal access to most maternal hormones, including steroids, sterols, peptides, glycoproteins, and catechols. Nevertheless, transplacental passage of even minute amounts of several maternal hormones can be essential for normal fetal development. For example, in human fetuses with congenital hypothyroidism (Chapter 93), maternal-fetal transfer of thyroid hormone (T_4) may result in neonatal plasma levels 25% to 50% of those in normal newborns (Vulsma et al, 1989). Therefore, neurodevelopmental outcome in congenital hypothyroidism is generally good when T_4 replacement is initiated within the first 2 weeks after birth. In contrast, maternal hypothyroidism during pregnancy adversely affects neurodevelopmental outcome in the offspring (Haddow et al, 1999), and the combination of severe maternal and fetal hypothyroxinemia results in profound neurodevelopmental disability (Yasuda et al, 1999).

A third principle is that disturbances in transplacental substrate transfer—for example, calcium (Chapter 90) or glucose (Chapter 94)—can modify development of fetal and neonatal hormonal pathways. Maternal immunoglobins and certain therapeutic agents also are transported to the fetus. In the example of Graves' disease (autoimmune hyperthyroidism), transplacental transfer of maternal thyroid-stimulating antibodies may cause fetal hyperthyroidism, and maternal antithyroid medications (e.g., propylthiouracil, methimazole) in sufficient doses suppress fetal thyroid function (Chapter 93).

MOLECULAR DETERMINANTS OF ENDOCRINE DEVELOPMENT

Genotyping studies show that functional mutations in a single gene, usually one encoding a transcription factor (TF), can produce endocrine organ hypoplasia or aplasia. Important clinical instances include isolated growth hormone (GH) deficiency or combined pituitary hormone deficiencies associated with mutations in TFs encoding genes that control organogenesis or cell differentiation. Hesx1, a "master switch" essential for normal optic nerve and pituitary development, orchestraties expression or activation of other factors involved in pituitary organogenesis (Corneli et al, 2008). Mutations in HESX1 are reported in patients with hypopituitarism either with

typical septo-optic dysplasia (SOD) or with neuromorphologic abnormalities not included in classic SOD. At least nine mutated pituitary transcription factors have been identified that alter hypothalamic-pituitary development and structure (Table 89-1). More recently, mutations in OTX2, a pituitary HESX1-regulated TF, has been shown to produce a variety of pituitary phenotypes (Dateki et al, 2010). Genetic causes of other endocrine glandular development occur with IPF1 (insulin promoter factor 1) in pancreatic agenesis (Schwitzgebel et al, 2003; Stoffers et al, 1997) and neonatal diabetes mellitus, PAX8 in congenital hypothyroidism associated with thyroid hypoplasia (Tonacchera et al, 2007), or DAX1 in X-linked adrenal hypoplasia congenita and hypogonadotropic hypogonadism (McCabe, 2007).

Congenital (nonneoplastic) endocrine hyperfunction also often is caused by single gene mutations that lead to gene inactivation (CaSR, SUR1, Kir6.2) or activation (TSHR, LHR, GK, GLUD1) (Table 89-2). Proteins currently known to cause fetal and neonatal nonneoplastic endocrine hyperfunction disrupt hormone exocytosis or cell sensing of an extracellular regulator of hormone exocytosis (Marx, 1999).

A second important genetic mechanism for developmental endocrinopathies involves genomic imprinting. In mammals, some (imprinted) genes are expressed solely from either the paternally or maternally inherited allele. Maternal and paternal imprints are established, respectively, in dividing diplotene oocytes and prospermatogonia. Lack of imprinting of specific chromosomes or chromosome segments occurs as a result of uniparental disomy or deletions of imprinted centers. Imprinting defects can cause distinct developmental abnormalities according to the chromosome involved (Tilghman, 1999). The chief mechanism involves differential methylation of specific sites in or near imprinted genes. These methylation marks are maintained

TABLE 89-1 Human Mutations Causing Abnormal Hypothalamopituitary Development

Gene	Syndrome	Phenotype	Inheritance
POU1F1	Combined pituitary hormone deficiency (CPHD)	GH, TSH, PRL deficiencies; usually severe; small to normal AP	Recessive, dominant
PROP1	CPHD	GH, TSH, LH, PRL deficiency; evolving ACTH deficiency; small, normal or enlarged AP	Recessive
HESX1	Specific syndrome	IGHD, CPHD, septo-optic dysplasia; APH, EPP, absent infundibulum, ACC	Recessive, dominant
LHX3	Specific syndrome	CPHD (GH, TSH, LH, FSH, PRL deficiencies), short neck, limited rotation; small, normal or enlarged AP, short cervical spine	Dominant
LHX4	Specific syndrome	CPHD (GH < TSH < ACTH defs.); small AP, EPP, cerebellar abnormalities	Dominant
SOX3	Specific syndrome	IGHD, mental retardation, panhypopituitarism; APH, infundibular hypoplasia, EPP	X-linked
SOX2	Specific syndrome	Hypogonadotrophic hypogonadism; APH, bilateral anophthalmia/microphthalmia, abnormal corpus callosum, learning difficulties, esophageal atresia, sensorineural hearing loss	De novo
TBX19	Specific syndrome	Neonatal ACTH deficiency	Recessive

Adapted from Kelberman D, Dattani MT: Hypothalamic and pituitary development: novel insights into the aetiology, *Eur J Endocrinol* 157:S3-S14, 2007.
ACC, Agenesis of the corpus callosum; *ACTH*, adrenocorticotropic hormone; *AP(H)*, anterior pituitary (hypoplasia); *EPP*, ectopic posterior pituitary; *GH*, growth hormone; *IGHD*, isolated GH deficiency; *LH*, luteinizing hormone; *PRL*, prolactin; *TSH*, thyroid-stimulating hormone.

TABLE 89-2 Features of Nonneoplastic Endocrine Hyperfunction Disorders

Tissue Expressing Hyperfunction	Syndrome	Gene Mutated	Typical Onset Age (years)	Treatment
Parathyroid cells	FHH	***CaSR***	0	None
	NSHPT	*CaSR*	0	Total excision
Pancreatic islet β-cells	PHHI-1	*SUR1*	0	Near total excision
	PHHI-2	*Kir6.2*	0	Near total excision
	PHHI-3	*GK*	15	Diazoxide
	PHHI-4	*GLUD1*	0	Diazoxide
Thyrocytes	Congenital thyrotoxicosis	*TSHR*	0-10	Medical or ablate
Leydig cells	Testotoxicosis	*LHR*	3	Medical

CaSR, Gene for calcium sensing receptor; *FHH*, familial hypocalciuric hypercalcemia; *GK*, gene for glucokinase; *GLUD1*, gene for glutamate dehydrogenase type 1; *Kir6.2*, gene for β-cell ATP-binding subunit of inward rectifying potassium channel; *LHR*, gene for luteinizing hormone receptor; *NSPHT*, neonatal severe hyperparathyroidism; *PHHI*, persistent hyperinsulinemic hypoglycemia of infancy; *SUR1*, gene for β-cell specific sulfonylurea receptor (component of potassium channel); *TSHR*, gene for thyroid stimulating hormone receptor.

throughout development and are only erased and reestablished in the germ line. Human endocrinopathies caused by imprinting defects include transient neonatal diabetes mellitus (Chapter 94) and Albright's hereditary osteodystrophy (*GNAS1* imprinting defect) (Chapter 90).

STEROIDOGENESIS AND THE MATERNAL-PLACENTAL-FETAL UNIT

During pregnancy, the mother, fetus, and placenta function in concert as a steroidogenic unit for estrogen and progesterone production. Maternal cholesterol is the principal substrate for placental synthesis of progesterone precursors in fetal androgen production. Although the placenta lacks 17-hydroxylase and 17,20-desmolase (CYP17) activities for estrogen synthesis, the human fetal adrenal compensates with a considerable output of Δ5-steroids (17-hydroxylated precursors), particularly dihydroepiandrosterone sulfate (DHEAS) (Figure 89-1). In primates, estrogen plays an integrative role in modulating placental-fetal communication and in intrauterine development (Albrecht and Pepe, 1999). Estrogen promotes placental trophoblast differentiation into syncytiotrophoblast and upregulates key enzymes in progesterone biosynthesis and cortisol-cortisone conversion.

Throughout most of gestation, protection from hypercortisolism is critical for normal neuroendocrine development. Late in gestation, with activation of the fetal hypothalamic-pituitary-adrenal (HPA) axis, fetal cortisol triggers parturition; lung, gastrointestinal, brain and adrenal medullary maturation; induction of numerous metabolic pathways; and increased β-adrenergic receptor density in heart, lung, and brown fat. Studies on the role of glucocorticoids in preterm labor and fetal maturation have led to the successful, widespread use of antenatal glucocorticoids to accelerate fetal, especially lung, maturation (Liggins and Howie, 1972) (Chapter 42). On the other hand, chronic or repetitive fetal exposure to antenatal glucocorticoid has a profound, sometimes deleterious, influence on postnatal adaptation and activity of the endocrine pancreas, pituitary-adrenal axis, and cardiovascular activity (see Developmental Origins of Health and Disease Hypothesis, later) (Challis et al, 2001).

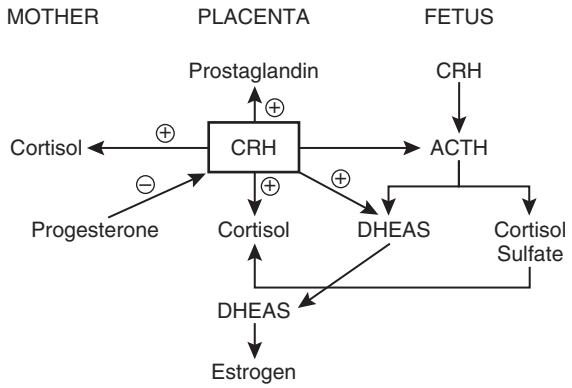

FIGURE 89-1 Schematic representation of the interrelationships among the mother, placenta, and fetus in the upregulation of placental CRH production in response to stress. Maternal and/or fetal cortisol stimulates placental CRH expression. Placental CRH, in turn, stimulates the fetal HPA axis and secretion of DHEAS from the fetal zone of adrenal cortex. *CRH*, Corticotropin-releasing hormone; *DHEAS*, dihydroepiandrosterone sulfate. *(Adapted from Challis JRG, Sloboda D, Matthews SG, et al: The fetal placental hypothalamic-pituitary-adrenal [HPA] axis, parturition and post natal health*, Mol Cell Endocrinol *185:135-144, 2001.)*

It is not surprising that in all placental species studied, including humans (Beitins et al, 1973), fetal access to maternal glucocorticoid is restricted and fetal glucocorticoid levels (cortisol or corticosterone) are low. This maternal-fetal gradient is maintained by the enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD). The type 1 isoform is bidirectional. The type 2 isoform (11β-HSD2) unidirectionally converts cortisol and corticosterone to inactive cortisone and 11-dehydrocorticosterone, respectively. The low cortisol:cortisone ratio in fetal circulation (approximately 0.3) reflects low fetal cortisol production and high placental 11β-HSD2 activity. After birth, the cortisol-cortisone ratio rises.

As pregnancy progresses into the third trimester, the maternal-placental-fetal steroidogenic unit activates the fetal HPA axis. This is a central mechanism for the fetus to exert an influence on pregnancy duration. Placental production of corticotropin-releasing hormone (CRH) is correlated with the length of gestation so that maternal plasma levels of CRH rise exponentially as pregnancy progresses toward term and peak during labor (Grammatopoulos, 2008). A CRH/ACTH (adrenocorticotropic hormone)/cortisol surge near term induces involution of the fetal adrenal cortex, increased adrenal 3β-hydroxysteroid dehydrogenase (3β-HSD) activity, and a relative reduction in the placental 11β-HSD2-11βHSD1 ratio. In humans, the fall in placental 11β-HSD2 mRNA expression and the rise in fetoplacental cortisol levels lead to a rise in placental prostaglandin (PGE_2 and $PGF_{2\alpha}$) synthesis that, in turn, stimulates uterine contractility and further CRH expression (see Figure 89-1). The increased fetal adrenal cortisol production and decreased placental cortisol clearance synchronize maturation of critical organs (lung, liver, intestine, adrenal, brain). In effect, term birth may be viewed as an escape mechanism from this intrauterine environment of increasing hypercortisolemia. The postnatal transition is promoted by the newborn's disconnection from this robust placental steroid production.

A critical aspect of intrauterine endocrinology is the opposite effect of the increase in late fetal cortisol levels on hypothalamic and placental CRH expression. Cortisol inhibits hypothalamic CRH production via the HPA negative feedback loop but stimulates placental CRH production, an effect mediated via the cAMP response element in the CRH promoter (Cheng et al, 2000). Positive feedback loops are intrinsically unstable and, in this instance, terminate in birth.

Human placental CRH production may have evolved to stimulate fetal ACTH release and adrenal steroidogenesis, thus satisfying the high demand for synthesis of dehydroepiandrosterone (DHEA), the predominant source of placental estradiol (E_2). Placental CRH stimulates the fetal adrenal zone, an adrenal structure unique to primates (see later discussion), to produce DHEA sulfate (DHEAS), which is converted to E_2 by the placenta (Power and Schulkin, 2006). Placental CRH-induced cortisol output from the fetal and maternal adrenal glands induces further placental CRH expression, forming a positive feedback

system that results in increasing placental production of E_2. Concomitant CRH stimulation by placental CRH of fetal cortisol and DHEA would couple the glucocorticoid effects on fetal organ maturation with the timing of parturition, as Majzoub et al (1999) have pointed out, an obvious benefit in postnatal survival. Umbilical plasma E_2 and progesterone levels are quite high and fall by approximately 100-fold during the 1st day after birth.

From this perspective, preterm birth may have adverse endocrine consequences for the newborn. Current evidence suggests that relative adrenal insufficiency in extremely low-birthweight (ELBW) infants may be inadequate for systemic response to stress. Low cortisol concentrations in these infants have been correlated with increased severity of illness, hypotension, mortality, and development of bronchopulmonary dysplasia (Aucott et al, 2008; Watterberg et al, 2007). Selective hydrocortisone supplementation may be a promising strategy for care of these infants.

Similarly, the consequences of E_2 and progesterone withdrawal so early in development remain largely unknown. Pilot studies of E_2 and progesterone supplementation in ELBW infants have shown trends toward increased bone mineralization and a decrease in chronic lung disease (Trotter et al, 2001, 2007). Further clinical trials of "physiologic replacement" in extremely preterm newborns may answer some of these important clinical questions.

HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

The hypothalamus forms an interface between the endocrine and autonomic systems and regulates thermoregulation, blood pressure, energy balance, and behavioral responses. Advancing pregnancy is associated with HPA axis maturation. In utero and at birth, this neuroendocrine network facilitates adaptation to environmental stresses and regulates somatic growth, reproduction, and lactation.

Early specification signals for forebrain induction are required before or during gastrulation. Later in embryogenesis, ventralizing and rostralizing signals from the axial mesoderm (e.g., Sonic hedgehog) are required to induce the cell types of the presumptive hypothalamus (Michaud, 2001). The fetal hypothalamus begins to form soon after the appearance of the hypothalamic sulcus in the 32-day embryo. Classic dating studies have established that the hypothalamus follows an "outside-in" pattern of neurogenesis, with neurons of the lateral hypothalamus being born before the medial ones. The developmental program for neurons of the anterior hypothalamus requires function of the TF Sim1 (Caqueret et al, 2006). Between 6 and 12 weeks, the basal hypothalamus differentiates into distinct nuclei and fiber tracts and produces hormones detectable by immunohistochemistry or immunoassay. Portal vascular connections to the anterior pituitary are established by about 12 weeks (Thliveris and Currie, 1980), although the definitive hypothalamo-hypophyseal portal system develops primarily in the third trimester. Failure of ventral forebrain induction causes holoprosencephaly (see Chapter 60). Endocrine deficiencies caused by hypothalamic and/or pituitary dysfunction may be the only clinical sign in milder forms of (lobar) holoprosencephaly.

Neuropeptide secretion from hypothalamic neurons and negative and positive feedback loops from target organs regulate the synthesis and secretion of distinct pituitary hormones. The anterior pituitary gland (adenohypophysis) derives from ectodermal thickening of the diencephalon and roof of the oral pit. The pituitary diverticulum (Rathke's pouch) bulges into the floor of the prosencephalon by week 4. In week 6, sphenoidal mesenchyme pinches off the pituitary diverticulum from the oral pit. The precursor cells of the anterior pituitary begin to differentiate by week 8. These distinct pituitary cell types arise in a temporally and spatially specific pattern and in tandem with their inputs from hypothalamic nuclei. Development of the hypothalamo-hypophyseal portal veins permits the local circulation of releasing hormones, including thyrotropin-releasing hormone (TRH), growth hormone–releasing hormone (GHRH), CRH, and somatostatin (SS).

During the second trimester, the anterior pituitary differentiates into the five endocrine cell types that secrete six hormones: (1) proopiomelanocortin (POMC) (which is proteolytically cleaved to adrenocorticotropic hormone [ACTH] in corticotropes and melanocyte-stimulating hormone [MSHα] in melanotropes), (2) thyroid-stimulating hormone (TSH) in thyrotropes, (3) growth hormone (GH) in somatotropes, (4) prolactin (PRL) in lactotropes, and (5) follicle-stimulating hormone (FSH) and (6) luteinizing hormone (LH) in gonadotropes (Figure 89-2). Serum GH concentrations peak at 20 to 24 weeks (Suganuma et al, 1989) and decline steadily thereafter, perhaps as a result of hypothalamic-pituitary maturation and increased interaction between GHRH and somatotropin release-inhibiting hormone (SRIH).

Anterior pituitary organogenesis illustrates how mutation of a single regulatory gene can cause multiple hormone deficiencies (MPHDs or panhypopituitarism) (Romero et al, 2009), even though the genes encoding those hormones are dispersed throughout the genome. Transient embryonic morphogenetic signaling gradients induce overlapping expression patterns of transcription factors (repressors, activators) and co-regulators and direct positional cell fates. These pituitary and hypothalamic transcription factors coordinate gland formation, differentiation, expansion, and definitive function of the distinct pituitary cell types. Pituitary development and hormone expression require Pit-1, a pituitary-specific transcription factor. Pit-1 gene expression directs differentiation and proliferation of somatotrophs, lactotrophs, and thyrotrophs and transactivation of the GH, PRL, and TSHα genes. Several Pit-1 mutations have been shown to be responsible for a phenotype of multiple congenital pituitary hormone deficiency involving GH, PRL, and TSH (Kelberman and Dattani, 2007). The repressor Hesx1 (homeobox gene expressed in embryonic stem cells) is expressed early in the anterior region of the embryo and is involved in the initial determination of optic nerves and anterior pituitary (see Figure 89-2). Hesx1 mutations can cause recessive and autosomal forms of hypopituitarism and septo-optic dysplasia.

The neural component of the pituitary, the posterior pituitary gland or neurohypophysis, grows from an

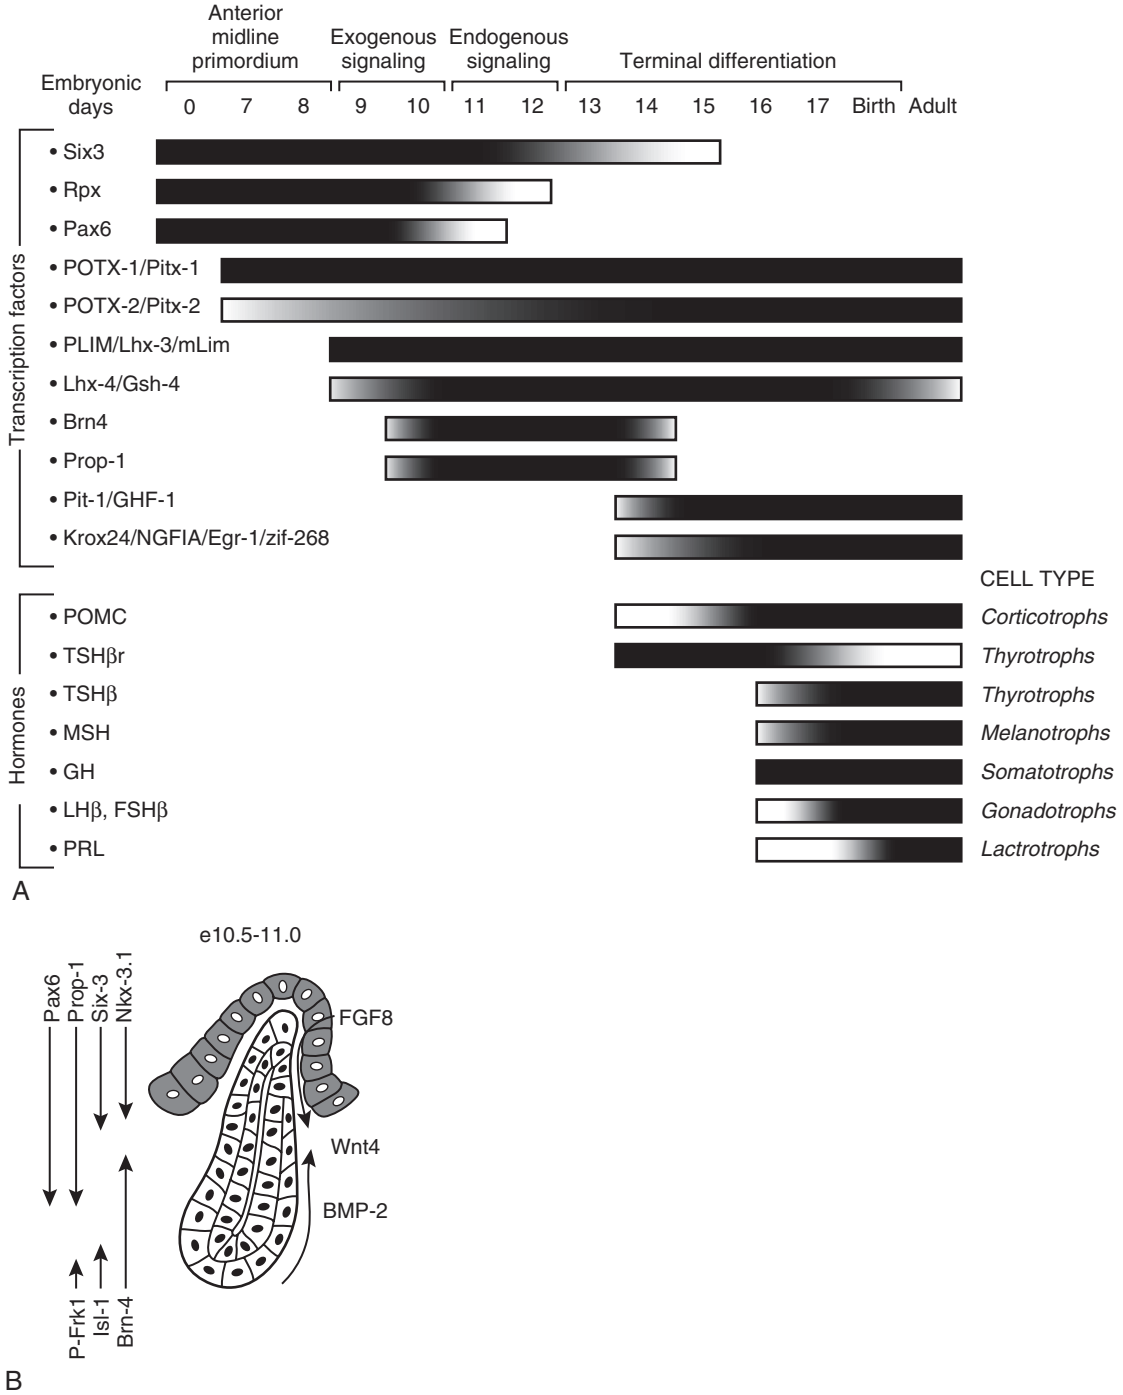

FIGURE 89-2 Modified overview of pituitary development adapted from embryologic studies performed in murine species. The development of the mature pituitary gland is dependent on contact of the oral ectoderm with the ventral diencephalon (neural ectoderm) followed by a cascade of events consisting of both signaling molecules and transcription factors expressed in a specific temporal and spatial manner. At approximately embryologic day 9.5 (e9.5), BMP-4 and Nkx2.1 along with Sonic hedgehog (Shh) participate with the initial evagination of ventral diencephalon and invagination of oral ectoderm to form the primordial Rathke's pouch (RP). In addition, expression of Gli 1,2, Lhx3, and Pitx 1,2 plays an important role in the development of progenitor pituitary cell types. This is closely followed by the expression of Hesx1, Isl1, Pax6, and Six3, 6, which are also implicated in cellular development, proliferation, and migration. Interactions between factors is illustrated by the attenuation of Hesx1 (*hashed arrows*) at approximately e12.5 that is required for the expression of Prop1. By e12.5, RP has formed, and by e17.5, differentiation of specific pituitary cell types has been completed. The expression of Pit1 is also marked with the attenuation of Prop1 expression (*hashed arrows*). The mature pituitary gland is marked by the differentiated cell types: somatotrophs (S), lactotrophs (L), thyrotrophs (T), gonadotrophs (G), and corticotrophs (C). Also shown are the posterior and intermediate lobe of the pituitary and the location of melanotropes (M). *(From Kioussi C, Carriere C, Rosenfeld MG: A model for the development of the hypothalamic-pituitary axis: transcribing the hypophysis,* Mech Dev *81:23-35, 1999.)*

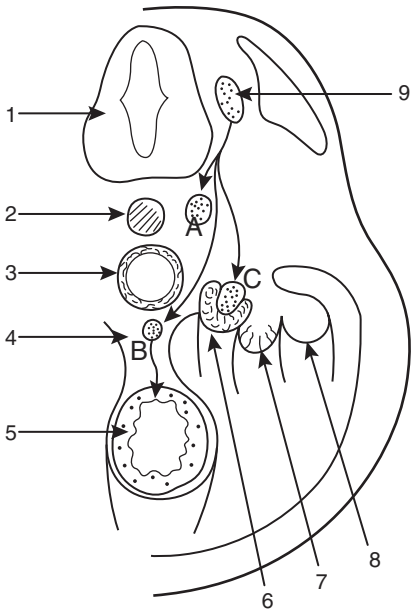

FIGURE 89-3 Transverse cross-section of human adrenal development: neural tube *(1)*, chorda *(2)*, aorta *(3)*, base of the mesentery *(4)*, digestive tube *(5)*, adrenal cortex *(6)*, undifferentiated gonad *(7)*, mesonephros *(8)*. Migration of neuronal cells (*arrows*) from the neural crest *(9)* forms the sympathetic trunk ganglia *(A)*, sympathetic plexuses *(B)*, and the medulla and paraganglia *(C)*. *(From Avisse C, Marcus C, Patey M, et al: Surgical anatomy and embryology of the adrenal glands*, Surg Clin North Am *80:403-415, 2000.)*

infundibular sac projecting from the floor of the diencephalon (5 to 8 weeks). Magnocellular neurons from the hypothalamus synapse with posterior lobe neurosecretory cells. Two hormones, oxytocin and vasopressin, are secreted directly into the general circulation.

The adrenal (or suprarenal) glands develop as a fusion of two distinct embryologic tissues, the cortex and the medulla (Figure 89-3). The adrenal cortex arises bilaterally from coelomic mesothelium between the base of the mesentery (mesogastrium) medially and the mesonephros and undifferentiated gonad (urogenital ridge) laterally. The close proximity of these embryonic structures explains why ectopic cortical tissue may be located inferior to kidneys and sometimes associated with ovaries or testes. In week 6, coelomic cells become embedded in the underlying mesoderm, where they meet and envelop neural crest cells migrating from the sympathetic chain.

This migration of neuroblasts (neuroectoderm) forms the ganglia of the sympathetic trunk and sympathetic plexuses as well as the catecholamine-secreting paraganglia. In the human embryo, the sympathetic trunk arises by about week 7. After weeks 10 to 12, chromaffin tissue (stains brown with chromium salts) develops along the aorta and subsequently differentiates into paraganglia and the adrenal medulla. Most of the paraganglia reach maximal size by about 28 weeks. However, ventral to the aortic bifurcation, the organ of Zuckerkandl continues to enlarge until term (Lagerkrantz, 2003). Usually, paraganglionic chromaffin tissues involute with age, but they may develop into extraadrenal pheochromocytomas.

The adrenal medulla functions as a classic endocrine (ductless) gland, that is, it secretes hormones directly into the bloodstream. It also participates in sympathetic control via preganglionic sympathetic nerve fibers. Pheochromocytoblasts give rise to the medullary pheochromocytes, which are epinephrine- and norepinephrine-secreting homologues of sympathetic postganglionic cells. Histologically, medullary cells are chromaffin and argyrophilic (stain with silver salts). By 3 months in utero, adrenal pheochromocytes secrete epinephrine and norepinephrine into the medullary sinusoids and then into the systemic circulation. In humans, the hypothalamic-pituitary-*medullary* adrenal axis becomes sufficiently functional by mid-gestation so that fetal stress responses can be independent of those of the mother (Gitau et al, 2001). This fetal catecholamine stress response contrasts with the fetal cortisol output capacity. The fetal adrenal *cortex* minimally secretes cortisol before mid-gestation, and fetal cortisol surges are determined by placental transfer from the mother.

From the 3rd month, the superficial shell of adrenal cortical cells forms the precursor of the postnatal zona glomerulosa and zona fasciculata, that is, the definitive or adult cortex. The more superficial zona glomerulosa has a pseudoglomerular histology and secretes the mineralocorticoid aldosterone. The zona fasciculata contains large cells packed in columns alternating with sinusoids and arterioles and secretes cortisol. The third definitive cortical layer, a network of cell cords called the zona reticularis, is absent at birth and develops from 3 years onward. It is an extragonadal source of sex steroids.

Deep to the presumptive definitive layer, cells proliferate inward, forming a "fetal cortex" that is unique to primate gestation. The outer (transitional) zone of the fetal cortex contains smaller (10- to 20-μm) basophilic cells. This transitional zone, between the inner (fetal) and outer (definitive) zones, expresses CYP17 and 3βHSD relatively late in gestation, contributing to increased fetal adrenal cortisol production which also increases only relatively late in normal gestation. Most of the inner fetal zone consists of large (20- to 50-μm) eosinophilic cells that are the primary site for steroidogenesis, including abundant secretion of Δ5 steroid substrates for placental estrogen production (see Steroidogenesis and the Maternal-Placental-Fetal Unit, earlier). The fetal zone accounts for about 80% of fetal adrenal mass, or about 8 g at birth. During the 1st year, the fetal cortex regresses and adrenal mass diminishes to 2 to 3 g.

Evaluation of the HPA axis in infants is used to test for primary adrenal suppression as well as for secondary adrenal insufficiency, either in preterm neonates who are thought to be cortisol deficient (Watterberg et al, 2005) or following dexamethasone treatment. Short CRH tests may more reliably assess HPA insufficiency than ACTH(1-24) testing for various neonatal indications (Bolt et al, 2002; Karlsson et al, 2000; van Tijn et al, 2008). It remains controversial whether the low circulating cortisol levels in ELBW infants reflect clinically relevant glucocorticoid deficiency.

HYPOTHALAMIC-PITUITARY-THYROID AXIS

Throughout gestation, maternal transfer of thyroid hormone (T_4), detectable in embryonic fluids by 4 weeks, protects fetal brain development (Obregon et al, 2007). Maturation of the fetal thyroid axis occurs in three

phases: hypothalamic, pituitary, and thyroidal (Raymond and LaFranchi, 2010). At 10 to 20 weeks' gestation, secretory granules can be identified in differentiating pituitary thyrotropes, and TSH is detectable by bio- and immunoassay.

The thyroid is the first endocrine gland to develop in the embryo. It forms at about 24 days from a pharyngeal outpouching, the thyroid diverticulum, and, as the anterior embryo grows, it migrates ventrally to the developing hyoid bone and laryngeal cartilages. By 7 weeks, the thyroid gland assumes its definitive lobar shape and final location in the neck. By 10 to 11 weeks, clusters of endodermal epithelial cells form single layers around lumens, the thyroid follicles, in which colloid begins to appear. Umbilical blood sampling has demonstrated that fetal TSH and T_4 are already detectable by 12 weeks and increase gradually through pregnancy to about 7 mU/L TSH and 19.9 pmol/L T_4 by term (Thorpe-Beeston et al, 1991). The fetal pituitary-thyroid feedback mechanism appears to be fully responsive by 18 to 20 weeks. By that time, in pregnant women with Graves' disease, transplacental passage of maternal thyroid-stimulating autoantibodies can induce fetal hyperthyroidism (Rakover et al, 1999). Biochemical hypothyroidism often occurs in extremely preterm newborns. It remains uncertain whether this phenomenon is largely a biomarker for immaturity or has clinical consequences. Currently, trials of thyroid supplementation in prematurity are in progress or being planned (La Gamma et al, 2009).

Because pituitary and thyroid differentiation is contemporaneous, it has been suggested that the controlling events are independent. During the second half of gestation, fetal thyroid gland function is believed to mature under the influence of increased hypothalamic TRH secretion, pituitary TSH secretion, thyroid cell sensitivity to TSH, and pituitary sensitivity to negative feedback by T_4 (Chapter 93). However, as described earlier (Endocrine and Neuroendocrine Development in the Fetus and Perinatal Transition), small amounts of maternal thyroid hormones cross the placenta, and adequate functioning of both maternal and fetal thyroid glands is important for normal fetal development. In congenital hypothyroidism due to defects in glandular ontogenesis (athyreosis), maternal thyroid hormones lessen the impact on fetal neurologic development. Early neonatal diagnosis and T_4 treatment permit normalized growth and development. In contrast, when the mother is hypothyroid throughout gestation, the consequences for the conceptus are more severe (Glinoer and Delange, 2000).

ENDOCRINE PANCREAS

During the first 4 weeks of gestation, the ventral and dorsal pancreatic anlage arises from evaginations of the embryonic foregut. After rotation of the stomach and duodenum, the ventral pancreatic bud migrates and fuses with the dorsal bud. Branching morphogenesis of the ductal pluripotential epithelial cells gives rise to endocrine and acinar cells under the influence of locally acting signals and activation of lineage-specific transcription factors (Peters, 2000; Puri and Hebrok, 2010). Figure 89-4 indicates early pancreatic cell specification in mouse studies. Beginning by week 7 of human gestation, scattered endocrine cells produce somatostatin, pancreatic polypeptide (PP) and glucagon and, by week 9, insulin. Pax and Ndx family transcription factors control the further fate determination of α, β, γ, and PP endocrine cells. Ongoing β-cell proliferation and differentiation are dependent on IGF-II gene expression in islets.

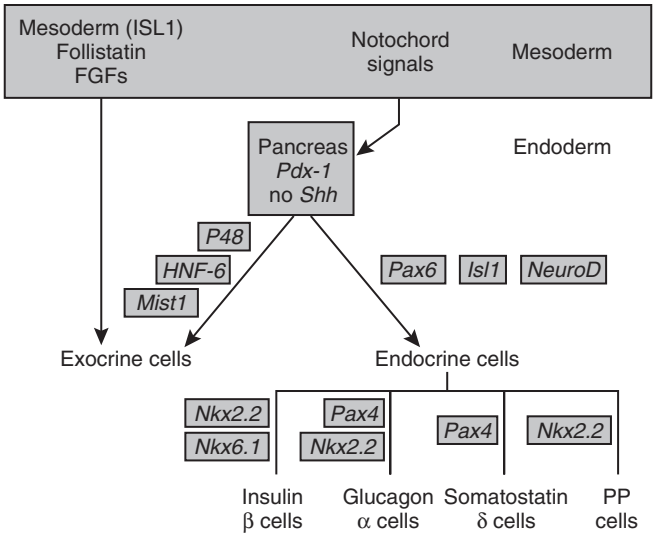

FIGURE 89-4 Molecular control of cell fate choices in the pancreas. *Pax6 and Isl1* are expressed early, and their disruption leads to the reduction or absence of endocrine differentiation which suggests that they could be expressed in endocrine progenitors able to give rise to all cell types. In *Isl1* mutant mice, *Pax6* is not expressed, which suggests *Pax6* is downstream of *Isl1*. Although *Pax4*, *NeuroD*, *Ndx2.2*, and *Ndx6.1* are expressed as early as *Pax6* and *Isl1*, they affect the differentiation of only a subset of lineages. *Pax4* is required for glucagon- and somatostatin-producing cell differentiation. *Ndx2.2* is expressed in all islet cells, except somatostatin-producing cells, and its inactivation leads to the absence of the cell types where it is expressed. *Ndx6.1* is itself required for insulin cell differentiation. Although *Mist1* and *HNF-6* are expressed in endocrine cell lineages, their function has not yet been assessed by inactivation experiments. *FGFs*, Fibroblast growth factors; *PP*, pancreatic peptide. *(From Grapin-Botton A, Melton DA: Endoderm development: from patterning to organogenesis,* Trends Genet *16:124-130, 2000.)*

In the human, islet formation begins by week 12. Polyclonal clusters of endocrine cells aggregate in response to developmental expression of cell adhesion molecules. In 24-week fetuses, islets generally remain in direct contact with the ducts, whereas by term, the islets have separated from the ducts. In adults, the islets are dispersed throughout the lobule (Watanabe et al, 1999). Islet volume also increases from about 4% to 13% of total pancreatic tissue by term (Peters, 2000). Endodermal differentiation into pancreatic endocrine cells, like other epithelial differentiation, depends on inductive signals derived from surrounding mesenchyme. Targeted gene deletion studies in mice have demonstrated critical roles for several transcription factors in pancreatic endocrine development.

Neonatal insulin kinetics and end-organ sensitivity to insulin appear to be established during the third trimester in preparation for extrauterine fuel metabolism. The maternal environment and fetal genome appear to influence the number and/or function of pancreatic β-cells in early life, with lifelong implications for postnatal diabetes. In contrast, insulin gene–knockout mice and human newborns with pancreatic agenesis suffer severe intrauterine growth restriction (IUGR), consistent with insulin's role in mitogenesis and growth.

PARATHYROID-RENAL AXIS

The parathyroid-renal (PTH–vitamin D) axis is the principal regulatory pathway in mammalian mineral and bone homeostasis (Chapter 90). The parathyroid glands arise from the dorsal parts of pharyngeal or branchial ("gill") pouches 3 and 4. These paired endodermal cell masses migrate ventrally and come to rest and differentiate in the back of the thyroid lobes as the superior (fourth pouch) and inferior (third pouch) parathyroid glands. The presence of immunoreactive PTH-containing cells can be detected in the human fetal parathyroids at 10 weeks. Defects in neural crest cell migration, such as DiGeorge syndrome (Chapter 90), result in embryonic field defects including parathyroid aplasia or hypoplasia. The caudal pharyngeal complex (pouches 4 and 5) develops into the calcitonin-secreting C cells embedded in the thyroid gland. Calcitonin is detectable in fetal thyroidal C cells as early as 14 weeks. The fetal renal tubules can synthesize the active hormonal form of vitamin D, $1,25(OH)_2$-vitamin D, at least as early as the second half of gestation. Fetal plasma $1,25(OH)_2$-vitamin D levels remain low, however, as a result of high placental clearance.

GONADAL AXES

Human reproductive system development is regulated by complex genetic, endocrine, and environmental signals. The gonadal primordium is the only tissue in mammals that has two divergent developmental fates, leading ultimately to the formation of either a testis or an ovary (Cederroth et al, 2007). Sex-specific organogenesis begins in the early embryo, and sexual dimorphism results in the development of either ovaries or testes by birth. Further sexual maturation occurs in the perinatal period and at puberty (Chapter 92).

In mammals, genetic sex is determined by inheritance of either an X or Y chromosome from the male gamete. The initial stages of gonadal and genital development in male and female embryos are morphologically indistinguishable. The gonads arise from thickening of the ventrolateral surface of the embryonic mesonephros (the genital ridge). Several genes are required for testicular induction of the bipotential gonads, including the orphan nuclear receptor Steroidogenic Factor-1 (SF-1), the Wilms' tumor-associated gene (WT1), and the homeobox genes Lhx1 (Lim1) and Lhx9. The two pituitary gonadotropins, LH and FSH, play a key role in cell fate determination and maturation of the sexual organs. Mutations in gonadotropin-subunit or gonadotropin-receptor genes have been associated with various types of hypogonadism in males and females.

In females, the müllerian ducts give rise to the uterus, fallopian tubes, and proximal vagina. The fetal ovarian germ cells are maintained in early meiotic arrest. The fetal ovary has late expression of the LH receptor (compared to the testis), late onset of aromatase activity, and low estradiol (E_2) content. Postnatally, ovarian follicles are prominent, and serum E_2 levels in female neonates remain low.

In males, wolffian ducts develop into the epididymis, vas deferens, seminal vesicles, and prostate. Divergence from the female developmental pathway toward male sexual differentiation requires secretion of several testicular hormones. After gonad formation, expression of the SRY (sex-determining region of the Y chromosome) gene initiates the male developmental cascade. SRY contains a high-mobility group (HMG) box, a conserved transcription factor motif that, in this instance, targets testicular Sertoli cell differentiation. Mutations in the HMG box are associated with 46,XY pure gonadal dysgenesis and sex reversal. Early events in testis development are differentiation of Sertoli cells and androgen-producing Leydig cells, LH receptor and steroid enzyme expression, autonomous steroid secretion, and high testosterone content. In contrast, germ-cell maturation occurs later in gestation. Postnatally, testicular Leydig and Sertoli cells are prominent and serum testosterone levels are high.

Müllerian inhibiting substance (MIS) produced by Sertoli cells induces müllerian duct regression. LH and placental human chorionic gonadotropin induce Leydig cell androgen synthesis. In turn, testosterone and dihydrotestosterone promote development of the wolffian duct derivatives (male internal reproductive tract) and the virilization of external genitalia. Therefore, inadequate fetal and neonatal testosterone secretion (e.g., due to hypogonadotropic hypogonadism or panhypopituitarism) impairs normal phallus and scrotum development. Leydig cell insulin-like hormone 3 (INSL3) with androgen mediate transabdominal testicular descent into the scrotum (Nation et al, 2009). Female embryonic differentiation continues when the absence of MIS permits persistence of müllerian structures, a lack of androgens permits wolffian duct degeneration, and the absence of INSL3 maintains gonads in the abdomen.

FETAL AND NEONATAL CIRCADIAN RHYTHMS

Neuroendocrine rhythmicity is an essential aspect of normal physiology and behavior. Certain rhythms occur in response to light:dark cycles. Ultradian rhythms have a periodicity shorter than 1 day but longer than 1 hour. Others, termed circadian rhythms, occur with a periodicity roughly matching the earth's rotation (24 hours) and persist even in the absence of environmental stimuli. As yet, there are few data on the maturational onset of ultradian or circadian hormonal secretion in the face of perturbing factors such as prematurity or intrauterine and neonatal hormone treatment.

The master clock or pacemaker that controls circadian rhythms is located in oscillating neurons of the hypothalamic suprachiasmatic nuclei (SCN). The molecular mechanisms of SCN rhythmogenicity involve pulsed expression of specific transcription factors that induce the oscillatory secretion of neuropeptides including somatostatin, vasoactive intestinal peptide (VIP), vasopressin (AVP), and neurotensin. Efferent pathways project from the SCN to other nuclei, such as the paraventricular nucleus (PVN). SCN efferents to the PVN stimulate secretion of CRH, which results in circadian adrenal cortisol secretion (see Hypothalamic-Pituitary-Adrenal Axis, earlier), and pineal gland expression of melatonin.

Regulation and entrainment of the circadian clock(s) occur by transcriptional negative feedback loops and posttranscriptional controls. In the human fetus, heart

rate, fetal movements, and some other outputs may be entrained to maternal rhythms. However, by late pregnancy the fetus establishes a circadian rhythm of cortisol secretion, presumably controlled by the fetal hypothalamic pacemaker. The adult pattern of circadian cortisol secretion is established by 2 to 4 months after birth (Rivkees, 2003). Importantly, adult-type salivary cortisol circadian rhythm is rarely evident in hospitalized preterm infants born before 30 weeks' gestation (Kidd et al, 2005). The onset of salivary cortisol circadian rhythm appears at the same postnatal age in mono- and dizygotic twin infants, suggesting less genetic than environmental impact on this phenomenon; additionally, each twin pair in this study showed synchrony, implying the importance of shared prenatal and postnatal environmental synchronizers (Custodio et al, 2007). The onset of circadian melatonin secretion is related to postconceptional, not postnatal, age. Understandably, exploration of environmental influences on biologic rhythms of preterm infants is an emerging area of emphasis in neonatal care.

DEVELOPMENTAL ORIGINS OF HEALTH AND DISEASE HYPOTHESIS

Research from a wide range of disciplines has shown that endocrine function in adult life is influenced, sometimes profoundly, by environmental influences acting at different stages of development spanning conception into infancy. Initially called the "fetal origins of adult disease" hypothesis, this emerging theme in development is more appropriately referred to as the developmental origins of health and disease (Godfrey, 2010; Wadhwa et al, 2009). Programming is a process by which environmental stimuli during critical periods of growth and development have lasting effects on the structure or function of tissues and physiologic systems. For example, intrauterine stresses can affect HPA axis development and program distinct autonomic, neuroendocrine, and behavioral responses into adulthood.

The developmental origins hypothesis proposes that the fetus adapts to a limited supply of nutrients, yielding a fetal/neonatal "thrifty phenotype" adapted for survival, but in a manner that permanently alters its physiology and metabolism and increases risk of disease in later life (Hales and Barker, 1992). The Dutch famine of 1944–1945 provided a unique opportunity to examine the long-term effects of intrauterine malnutrition in humans. The famine was imposed for a defined period on a previously well-nourished population. Extensive and reliable records have permitted unprecedented analysis of a birth cohort exposed to this discrete intrauterine insult (Heijmans et al, 2008). Additionally, David Barker and colleagues in Southampton, UK, have exploited detailed obstetric records in British hospitals to establish that IUGR is a strong predictor of adult metabolic and cardiovascular disease (e.g., Barker, 1998). For example, the relative risk for insulin resistance, obesity, and the metabolic syndrome (including type 2 diabetes, hypertension, and hyperlipidemia) is significantly higher in individuals who were thin at birth with a low ponderal index. Clinical studies also uphold the association of maternal psychosocial state or stress in pregnancy with qualitative and quantitative changes in birth outcome and fetal and neonatal neuroendocrine activity (Wadhwa et al, 2005).

Increased fetal access to glucocorticoids during critical developmental periods may be a common mechanism explaining how diverse maternal and uteroplacental stresses, including maternal undernutrition, psychosocial stress, and uteroplacental hypoxemia, induce fetal programming. Increased fetal glucocorticoids and stress both program specific effects in the brain, notably the HPA axis and dopaminergic-motor systems (Challis and Connor, 2009; Welberg et al, 2005) and can induce IUGR. The principal stress-mediated catecholamines (norepinephrine, epinephrine) transcriptionally repress placental trophoblast 11β-HSD2 expression via α-adrenergic pathways (Sarkar et al, 2001), thereby increasing transplacental transfer of maternal cortisol to the developing fetus.

IUGR and metabolic programming in girls interact with the genotype to influence the onset of endocrine, metabolic, and cardiovascular disease in later life (Ibáñez et al, 2001, 2007). Intrauterine stress producing low birthweight is associated with altered basal and stimulated cortisol levels as an early marker of HPA responsiveness, followed by glucose intolerance (insulin resistance) and hypertension (Levitt et al, 2000). Similarly, some nutritional practices in the neonatal intensive care unit may promote excessive adiposity in ELBW infants as they recover over time (Rubin, 2009).

IUGR also results in a reduced β-cell population at birth (van Assche et al, 1977). Fetal β-cell growth and development may be more sensitive to ambient amino acid than to glucose concentrations, suggesting a role for intrauterine protein availability in normal insulin homeostasis. In IUGR due to fetal malnutrition, altered expression of IGF-II (an islet cell survival factor) or IGF binding proteins may severely alter β-cell ontogeny and result in a β-cell population poorly suited for responding to subsequent metabolic stress (Hill and Duvillie, 2000).

ENVIRONMENTAL ENDOCRINE HYPOTHESIS

Recent environmental changes may have potentially important effects on the development of the endocrine system. Specifically, industrial and agricultural chemicals, through their actions on endocrine function, may be responsible for a number of reproductive and developmental abnormalities in a wide range of species, including humans (Cooper and Kavlock, 1997; Krimsky, 2000). These exogenous agents, or "endocrine disruptors," can interfere with the synthesis, storage/release, transport, metabolism, binding, action, or elimination of natural hormones. This importance of environmental endocrine-disrupting chemicals for public health and ecology, first stressed by Theo Colborn in the late 1980s, prompted passage in the United States of the Food Quality Protection Act and the Safe Drinking Water Estrogenic Substances Screening Act of 1996.

Three independent lines of research have provided the initial evidence for the importance of environmental agents on human endocrine development: recognition of the adverse effects of the potent synthetic estrogens and endocrine disrupters, that is, diethylstilbestrol (DES),

bisphenol A, and related compounds, on female and male reproductive tract development; field and laboratory studies associating wildlife reproductive malformations to chemical pollutants; and research linking xenoestrogens to declines in human sperm counts (Krimsky, 2000). Some structural abnormalities of the reproductive tract, including hypospadias and cryptorchidism, which have potential hormone-mediated origin and a critical developmental component, may show upward secular trending.

During development, reproductive tract tissues are especially sensitive to low concentrations of sex steroids. Androgens secreted by a maternal adrenal tumor can virilize a female fetus (Kirk et al, 1992). Increased placental estradiol production has been associated with cryptorchidism in male newborns (Hadziselimovic et al, 2000). A mechanism is estrogenic downregulation of Insl3 expression by embryonic Leydig cells. Similarly, endocrine disruptors with antiandrogenic or estrogenic activity can have feminizing effects in the developing male fetus. Estrogens may induce adverse reproductive changes in female fetuses, but antiandrogens have little effect (Toppari and Skakkebaek, 1998). Changes induced by intrauterine exposure to endocrine disruptors may be irreversible, in contrast with the reversible changes induced by transient hormone exposure in the adult.

Endocrine disruptors such as organochlorines—for example, the pesticide DDT—can alter normal gonadal ontogeny. Prenatal exposure to the estrogenic agent DES increases risk of reproductive teratogenicity in female and male offspring. Exposure of the conceptus to antiandrogenic pharmaceuticals such as the androgen receptor antagonist flutamide and the 5α-reductase inhibitor finasteride generally affects males, causing hypospadias, cryptorchidism, reduced testicular mass, or decreased sperm production. Exposure to polychlorinated biphenyl (PCB) congeners, either in utero or via breastfeeding, has structural, functional, and behavioral effects, particularly on thyroidal axis development and differentiation of the male reproductive tract (Brouwer et al, 1998). It is evident that the endocrine system presents a number of target sites for adverse effects of environmental agents. Much more information is needed about these specific ecologic and public health risks.

CHAPTER 90

Disorders of Calcium and Phosphorus Metabolism

Lewis P. Rubin

HOMEOSTATIC CONTROL OF CALCIUM AND MAGNESIUM

Calcium plays two important physiologic roles. Calcium salts in bone provide structural integrity. Calcium ions present in the cytosol and extracellular fluid (ECF) are essential for maintenance and control of many biologic processes, including cell-cell communication, cell aggregation and division, coagulation, neuromuscular excitability, membrane integrity and permeability, enzyme activity, and secretion. This functional diversity is made possible by the maintenance of a large electrochemical gradient between the ECF Ca^{2+} concentration, which is in the 1 mmol/L range, and resting intracellular (cytosolic) Ca^{2+} concentration, which is about 0.1 μmol/L.

Significant alterations in serum calcium concentration occur frequently in the neonatal period. It is important to evaluate these potential derangements in light of normal dynamic changes that take place during the perinatal transition. After the first 2 to 3 extrauterine days, normal serum calcium concentrations vary only slightly with age, range between 8.8 and 10.6 mg/dL, and average about 10 mg/dL. In the United States, serum or plasma calcium levels usually are reported as mg/dL, which may be converted to molar units by dividing by 4 (e.g., 10 mg/dL is equivalent to 2.5 mmol/L).

Approximately 55% to 60% of the total plasma calcium is diffusible (or ultrafilterable), the remainder being protein bound. Most diffusible calcium is ionized, but about 5% of total circulating calcium is complexed to plasma anions, such as phosphates, citrate, and bicarbonate. Ionized calcium (Ca^{2+}) is the only biologically available fraction of ECF calcium. It is subject to precise metabolic control based on the integrated regulation of calcium fluxes with respect to the intestine, kidneys, and bone. The precise regulation of circulating Ca^{2+} is controlled by calcium itself, through a calcium receptor and several hormones, the most important of which are parathyroid hormone and $1,25(OH)_2$-vitamin D (Allgrove and Shaw, 2009; Carmeliet et al, 2003; Ramasamy, 2008).

Hypoalbuminemia leads to a decline in total serum calcium, but proportionate increases in the ionized fraction usually maintain serum Ca^{2+} within the normal range. Acute alkalosis (e.g., hyperventilation or bicarbonate infusion) or rapid administration of citrate-buffered blood (e.g., during exchange transfusion, initiation of extracorporeal membrane oxygenation [ECMO], cardioplegia, or organ transplantation) may acutely lower serum Ca^{2+} by increasing albumin binding or citrate chelation. These conditions can produce transient clinical manifestations of hypocalcemia but do not lower the total serum calcium concentration. Electrocardiogram Q-Tc intervals and algorithms for correcting serum total calcium for alterations in serum albumin concentration and/or pH or for calculating "free" calcium concentration have not proved to be reliable compared with actual measurement of Ca^{2+} using ion-selective electrodes (Clase et al, 2000). Generally, for routine clinical purposes, measuring total serum calcium often suffices.

Bulk calcium exchange takes place in kidney, bone, and intestine. Although the intestine has considerable calcium absorptive capacity, renal tubular calcium reabsorption usually exceeds intestinal absorption by at least 40-fold. Most of the tubular Ca^{2+} load is reabsorbed in the proximal tubule and thick ascending limb of the loop of Henle via paracellular, passive flux (coupled with sodium reabsorption) driven by the existing electrochemical gradient. A transcellular pathway in the distal nephron tightly regulates the rest of urinary Ca^{2+} reabsorption. Calcitropic hormones regulate the distal Ca^{2+}-selective, Na^+-independent channels. More than 98% of total body calcium is deposited in the skeleton as hydroxyapatite $[Ca_5(OH)(PO_4)_3]$; the ECF and soft tissues contain the remainder. A small fraction of skeletal calcium freely exchanges with the ECF and serves as an important buffer of circulating calcium. Consequently, decreased skeletal calcium is a hallmark of most metabolic bone diseases.

Magnesium homeostasis also is largely renally mediated. Approximately 80% of total plasma magnesium is filtered through the glomerulus and is reabsorbed mainly in cortical segments of the thick ascending limb of the loop of Henle. Once the maximal tubular reabsorption is exceeded, filtered magnesium is excreted into the urine. Hormones regulate magnesium reabsorption by changing the transepithelial voltage and paracellular permeability of tubular cells.

HOMEOSTATIC CONTROL OF PHOSPHORUS

Blood inorganic phosphate (P_i) concentration varies with age. It is highest during infancy and gradually declines to adulthood. Approximately 10% of plasma P_i is noncovalently bound to protein, whereas 90% circulates as ions or as complexes with sodium, calcium, or magnesium. About 80% to 85% of total body phosphorus contributes to mechanical support as part of the hydroxyapatite lattice of bone. The remainder is distributed in the ECF, largely as inorganic ions or complexes, and in soft tissues as phosphate esters. Intracellular phosphate esters and phosphorylated intermediates regulate cell metabolism and gene expression (via phosphorylase, kinase, and phosphatase activities) and generate and transfer cellular energy

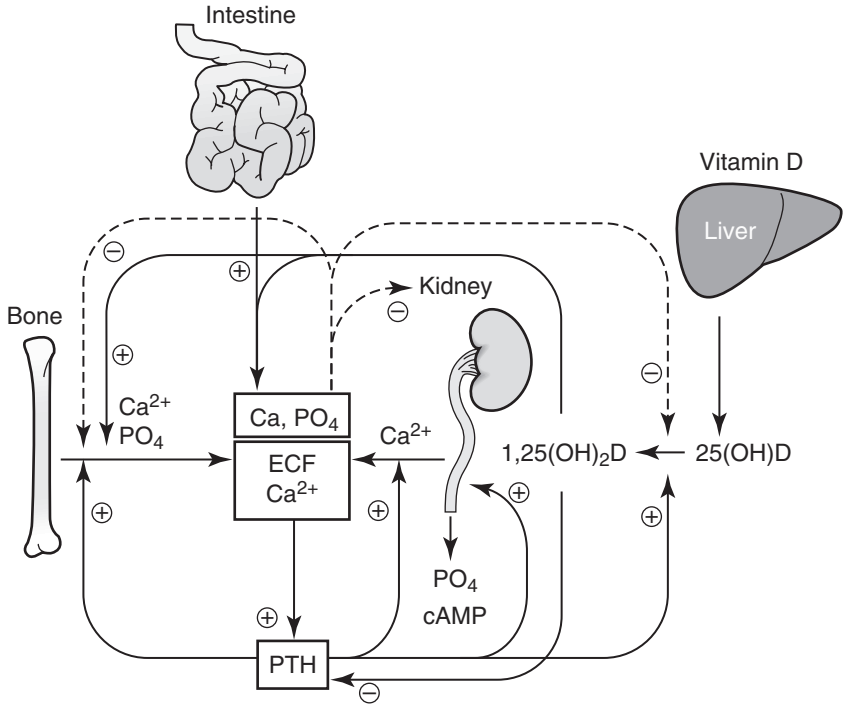

FIGURE 90-1 Hormonal regulation of calcium and phosphate by PTH and $1,25(OH)_2D$. Decreased Ca^{2+} stimulates PTH and $1,25(OH)_2D$ secretion. Renal, gastrointestinal, and skeletal mechanisms increase Ca^{2+}, inhibiting PTH secretion and closing the negative feedback loop. *Ca^{2+}*, Ionized calcium; *cAMP*, cyclic adenosine monophosphate; *ECF*, extracellular fluid; *25(OH)D*, 25-hydroxyvitamin D; *$1,25(OH)_2D$*, 1,25-dihydroxyvitamin D; *PO_4*, inorganic phosphate; *PTH*, parathyroid hormone. *(From Brown EM, MacLeod RJ: Extracellular calcium sensing and extracellular calcium signaling,* Physiol Rev *81:239-297, 2001.)*

(i.e., via adenosine triphosphate [ATP]). Cytosolic and ECF phosphorus levels (approximately 0.1 mmol/L and 0.2 mmol/L, respectively) are less stringently regulated than are levels of Ca^{2+} and Mg^{2+}.

Dietary phosphate generally is absorbed in proportion to its content in food. Although phosphorus and calcium can be absorbed along the entire length of the small intestine, most phosphate transport takes place in the jejunum and ileum, whereas most calcium absorption occurs in the duodenum. The renal proximal tubule is the principal regulatory site for phosphorus homeostasis (Silver and Naveh-Maney, 2009). Renal regulation is accomplished primarily by varying the threshold for phosphate reabsorption (the tubular maximum for P_i/glomerular filtration rate, or TmP/GFR). Hormones (parathyroid hormone [PTH], parathyroid hormone–related protein [PTHrP], growth hormone) and dietary phosphate reset this theoretical threshold by regulating apical tubular Na^+-P_i cotransporters (Murer and Biber, 1995). Essentially, the TmP/GFR is the "set point" that defines the fasting serum phosphorus concentration. At lower serum phosphorus levels, most filtered phosphorus is reabsorbed; at higher levels, most filtered phosphorus is excreted. To assess the TmP/GFR, a fasting urine specimen is obtained for measurement of phosphorus and creatinine along with simultaneous determination of serum phosphorus and creatinine. A nomogram has been constructed so that TmP/GFR can easily be derived from these values (Walton and Bijvoet, 1975).

The higher serum phosphate levels in infants (e.g., 4.5 to 9.3 mg/dL) compared with those in adults (3.0 to 4.5 mg/dL) reflect infants' greater tubular phosphate resorption. This adaptation permits avid tubular phosphate conservation despite high ambient serum phosphate levels. For this reason, neonatal disorders of chronic hypophosphatemia and/or phosphorus depletion usually result from inadequate dietary supply (as in preterm infants) or intrinsic (e.g., familial hypophosphatemic rickets) or extrinsic (e.g., hyperparathyroidism) alterations in TmP/GFR. Similarly, chronic hyperphosphatemia usually implies either intrinsic (e.g., renal insufficiency) or extrinsic (e.g., hypoparathyroidism) abnormalities in TmP/GFR.

PARATHYROID-RENAL HORMONAL AXIS

In mammals, calcium and phosphate homeostasis is controlled by a parathyroid-renal hormonal axis involving PTH and 1,25-dihydroxyvitamin D [$1,25(OH)_2D$]. The influence of these two hormones on bone deposition, mobilization of mineral, and regulation of intestinal and renal absorption is depicted in Figure 90-1. Deficiency or excess of either hormone causes hypocalcemia or hypercalcemia, respectively.

PARATHYROID HORMONES

PTH is a 9500-Da, single-chain polypeptide. PTH is synthesized by the four parathyroid glands, which are derived from the embryonic third and fourth pharyngeal pouches. The messenger RNA (mRNA) for PTH (preproPTH) encodes the 84 amino acids of the mature peptide, an amino-terminal (N-terminal) "pre" sequence of 25 amino acids, and a basic "pro" hexapeptide, which is clipped intracellularly. After secretion, the intact PTH molecule

[PTH(1-84)] is further metabolized and rapidly cleared from the circulation, with a half-life of less than 4 minutes. The N-terminal region of the PTH molecule [PTH(1-34)] binds the PTH receptor and shows full biologic activity, whereas the C terminus has specific, albeit poorly understood, activities in osteoclasts and osteoclastic precursors.

Secretion of PTH fragments by the parathyroid glands and prolonged clearance of carboxyl-terminal (C-terminal) PTH metabolites add considerable immunoheterogeneity to circulating PTH. The numerous inconsistencies found in reports on PTH pathophysiology until the late 1980s are due to use of earlier-generation "C-terminal" and "mid-molecule" PTH assays. In contrast, current two-site "intact PTH" assays are sufficiently sensitive and specific to detect physiologic levels of biologically active PTH(1-84) and to distinguish hypoparathyroid from euparathyroid states. The normal circulating levels of intact PTH range from approximately 10 to 60 pg/mL; the maximally stimulated (hypocalcemic) and maximally suppressed (hypercalcemic) levels for normal parathyroid function are about 100 to 150 pg/mL and 2 to 5 pg/mL, respectively.

Parathyroid cells are exquisitely responsive to changes in ambient Ca^{2+}. PTH secretion may be described as an inverse sigmoid hysteretic relationship between serum PTH and Ca^{2+} with a parathyroid cell set point (the Ca^{2+} at which PTH secretion is half-maximal) of 1.2 to 1.25 mmol/L. The parathyroid "calcistat" detects perturbations of blood Ca^{2+} as small as 0.025 to 0.05 mmol/L and promptly adjusts PTH secretion. The molecular mechanism that enables specific cells (e.g., parathyroid cells, thyroidal C cells, renal tubular cells, osteoblasts) to sense these minute changes in ECF Ca^{2+} involves a member of the family C of G protein–coupled receptors (GPCRs), the Ca^{2+}-sensing receptor (CaSR). ECF Ca^{2+} (and, at lower affinity, Mg^{2+}) binds the CaSR, activates several intracellular effector pathways, and ultimately leads to oppositely directed changes in PTH secretion and altered renal cation handling (Gamba and Friedman, 2009). CaSR activation inhibits renal cellular Ca^{2+} absorption induced by PTH, as well as passive paracellular Ca^{2+} transport. As described later, loss-of-function (or inactivating) mutations in the *CaSR* gene are responsible for neonatal hyperparathyroidism and familial hypocalciuric hypercalcemia, whereas gain-of-function *CaSR* mutations result in autosomal dominant neonatal hypocalcemia (Brown, 2007).

PTH mobilizes calcium and phosphorus from bone, stimulates calcium reabsorption, inhibits phosphorus reabsorption by reducing TmP/GFR, and stimulates the renal synthesis of $1,25(OH)_2D$, which participates with PTH in reabsorbing bone mineral and also increases efficiency of intestinal absorption of calcium and phosphorus. Therefore, PTH secretion causes the serum calcium concentration to rise and the serum phosphorus concentration to be maintained or decline.

PTH-related protein (PTHrP) is a second member of the PTH family, first identified as the cause of humoral hypercalcemia of malignancy. The amino acid sequences of PTHrP and PTH are homologous at the N terminus, and 8 of the first 13 amino acids are identical. Beyond this region, the sequences have little in common. PTHrP is a multifunctional molecule, like neuropeptides such as pro-opiomelanocortin (the precursor of corticotropin, endorphins, and melanocyte-simulating hormones). The three PTHrP isoforms (139, 141, and 173 amino acids) give rise to several secreted peptide fragments. PTHrP is widely expressed, especially in fetal tissues, and has important local functions in morphogenesis and differentiation. The normal circulating levels of PTHrP are considerably lower than the levels of PTH, and it is doubtful that PTHrP has a major role in calcium homeostasis. Two important exceptions are in the fetus and lactating woman, for whom PTHrP appears to be an important calcitropic hormone (Mitchell and Jüppner, 2010).

The actions of PTH on its two major target organs, kidney and bone, are mediated through the type 1 PTH/PTHrP receptor (PTHR1) (Kronenberg, 2003), a GPCR belonging to a receptor subfamily that includes receptors for calcitonin, secretin, and corticotropin-releasing hormone. This versatile receptor mediates actions of its two physiologic ligands in multiple tissues and signals through several second messenger pathways. The best-characterized effector of PTH action is cyclic adenosine monophosphate (cAMP).

VITAMIN D

Vitamin D is a secosteroid synthesized in the skin or absorbed from the diet (Holick et al, 2007; Kimball et al, 2008). Exposure to sunlight (290–320 nm) cleaves the B ring of 7-dehydrocholesterol (7-DHC), or provitamin D, the immediate precursor of cholesterol, to form a sterol, previtamin D. Previtamin D in the skin undergoes isomerization to the biologically inert vitamin D. Vitamin D enters the circulation bound to vitamin D–binding protein and is transported to the liver, where a mitochondrial cytochrome P450 vitamin D-25-hydroxylase produces 25-hydroxyvitamin D [25(OH)D]. 25(OH)D (provitamin D) is the major circulating vitamin D metabolite. Because activity of hepatic 25-hydroxylase is not tightly regulated, measurement of serum 25(OH)D is a useful assessment of vitamin D stores. In renal proximal tubule cells, mitochondrial cytochrome P450 25(OH)D–1α-hydroxylase metabolizes 25(OH)D to the biologically active hormone, $1,25(OH)_2D$. The normal circulating level of 25(OH)D is approximately 10 to 50 ng/mL. The normal circulating concentration of $1,25(OH)_2D$ ranges from 30 to 75 pg/mL, or about 1/1000 that of 25(OH)D.

Serum 25(OH)D levels are increased by sunlight exposure and by vitamin D ingestion and are decreased in vitamin D deficiency and in hepatobiliary disorders. Circulating $1,25(OH)_2D$ levels are increased by hyperparathyroidism and phosphate depletion and are reduced in hypoparathyroidism. $1,25(OH)_2D$ is biologically inactivated through a series of reactions beginning with 24-hydroxylation. $1,25(OH)_2D$ induces the 24-hydroxylase in vitamin D target cells. Hypocalcemia, by increasing PTH levels, suppresses this enzyme. 24-Hydroxylase metabolizes 25(OH)D as well as $1,25(OH)_2D$. In vitamin D–sufficient states, the kidney preferentially 24-hydroxylates the prohormone, 25(OH)D, to $24,25(OH)_2D$. In contrast, when vitamin D action is required, 25(OH)D–1α-hydroxylase is preferentially activated for $1,25(OH)_2D$ synthesis.

A chief biologic function of $1,25(OH)_2D$ is to increase intestinal absorption of calcium and phosphorus. During

low calcium intake, increased PTH levels stimulate the renal conversion of 25(OH)D to $1,25(OH)_2D$, which in turn stimulates osteoclast differentiation and bone resorption. Most of the identified biologic actions of $1,25(OH)_2D$ are mediated via binding to the vitamin D receptor (VDR), a member of the intracellular receptor superfamily. VDR interacts with specific response elements (VDREs) in promoters of vitamin D–responsive genes.

The parathyroid-renal [PTH-$1,25(OH)_2D$] axis, reminiscent of the hypothalamic-pituitary-adrenal axis, is the principal means for systemic response to a sustained or major hypocalcemic challenge. In this long-loop feedback system, $1,25(OH)_2D$-mediated calcium absorption provides the ultimate feedback on PTH secretion. PTH secreted in response to hypocalcemia is the principal regulator of renal production of $1,25(OH)_2D$ that, in turn, feeds back to suppress PTH gene expression (see Figure 90-1). PTH regulates minute-to-minute perturbations of ECF [Ca^{2+}]. Maximal adjustments of intestinal calcium absorption via the PTH-$1,25(OH)_2D$ axis require 1 to 2 days to become fully operative, so $1,25(OH)_2D$ effects come into play only when a hypocalcemic stress persists.

CALCITONIN

Calcitonin, a peptide hormone synthesized by thyroid parafollicular C cells, has an antihypercalcemic effect, that is, opposite that of PTH. Human calcitonin is a 32-amino-acid chain with a 1,7-disulfide bridge and a C-terminal prolinamide. Alternative splicing of several transcripts from the calcitonin gene produces several polypeptide products, some of which have uncertain calcitropic importance. The primary stimulus for calcitonin secretion is a rise in circulating calcium concentration. Calcitonin lowers serum calcium and phosphorus chiefly by inhibiting bone resorption.

Currently, there is no compelling evidence that the calcitonin-like calcium-lowering hormones are critical regulators of calcium homeostasis in nonpregnant adult humans, perhaps because the low prevailing rate of bone turnover blunts the impact of the antiresorptive actions. However, calcitonin may have important calcitropic functions in pregnant and lactating women and in the fetus and neonate, and in other mammals, particularly rodents, whose bones are constantly growing. In human newborns, the C cell population and serum calcitonin concentrations are much greater than in adults.

PERINATAL MINERAL METABOLISM

During human pregnancy, approximately 30 g of calcium and more than 16 g of phosphorus are transferred transplacentally from the maternal circulation to the growing fetus, the bulk during the third trimester when fetal calcium accretion is approximately 140 to 150 mg/kg per day. In humans, a doubling of maternal intestinal calcium absorption and a net increase of calcium accretion into bone compensate for the formidable demand on maternal calcium (Prentice, 2000). A mid-molecule PTHrP hormone (Kovacs et al, 1996) expressed principally by placenta regulates this transplacental calcium pump. TRPV6, a member of the transient receptor potential channel superfamily, may be the primary calcium channel at the trophoblast apical membrane. Calcium flux across the placenta in TRPV6-null mice is reduced by approximately 40% (Suzuki et al, 2008).

PREGNANCY

Pregnancy constitutes a unique hormonal milieu that promotes a state of "physiologic absorptive hypercalciuria" (Gertner et al, 1986). Maternal total serum calcium declines slightly during pregnancy, reaches a nadir in the mid-third trimester, and then increases slightly toward term. The maternal serum phosphorus and magnesium profiles are similar to that of calcium. Maternal serum 25(OH)D varies seasonally and with vitamin D intake, but the vitamin D transport protein (DBP) increases during pregnancy. Serum $1,25(OH)_2D$ concentrations increase early in pregnancy and continue to rise through gestation (Seely et al, 1997). The calculated concentration of free $1,25(OH)_2D$ also rises. For many years, it was believed that PTH levels also increased steadily through pregnancy. However, use of newer immunometric "sandwich" assays indicates that PTH actually declines during the course of pregnancy (Davis et al, 1988; Saggese et al, 1991; Seely et al, 1997). PTHrP levels, in contrast, may be higher in pregnant than in nonpregnant women (Bertelloni et al, 1994). The role of circulating calcitonin in pregnancy is uncertain.

$1,25(OH)_2D$ drives enhanced maternal intestinal mineral absorption (reviewed in Kovacs, 2008). After parturition, $1,25(OH)_2D$ concentrations and calcium absorption rates (Kent et al, 1991) fall to prepregnancy levels. The interplay of calcitropic and progestational hormones in pregnancy protects the maternal skeleton from demineralization. In contrast, during the relatively low estrogen state of lactation, calcium is mobilized from bone stores, possibly under the influence of PTHrP (Dobnig et al, 1995).

In the third trimester, fetal plasma total and ionized calcium and phosphorus levels are higher than maternal levels, producing a state of "physiologic fetal hypercalcemia" (Rubin et al, 1991). Fetal plasma PTH is low, and calcitonin and PTHrP levels are relatively high. Even these low circulating PTH levels may be functionally important in fetal calcium and magnesium metabolism. There also is a close correlation between maternal and fetal serum 25(OH)D levels, consistent with transplacental transfer of this metabolite. Low levels may be found in infants born to women with low circulating 25(OH)D resulting from poor dietary intake of vitamin D and lack of sunlight exposure. Fetal plasma $1,25(OH)_2D$ also is relatively low, despite robust renal 25(OH)D–1α-hydroxylase activity, whereas concentrations of $24,25(OH)_2D$ are high. In fact, the major function of the fetal kidneys in calcium homeostasis may be production of $1,25(OH)_2D$, rather than renal tubular regulation of calcium excretion. The high circulating concentrations of calcitonin may support this stimulated fetal 25(OH)D–1α-hydroxylase activity. In contrast, the relatively low circulating fetal $1,25(OH)_2D$ concentrations are a consequence of enhanced placental clearance (Ross et al, 1989). Constitutively activated placental 24-hydroxylase activity (Rubin et al, 1993) also preferentially hydroxylates maternally derived 25(OH)D

to 24,25$(OH)_2$D. This placental capacity to metabolize 25(OH)D and 1,25$(OH)_2$D accounts for the enhanced clearance of fetal 1,25$(OH)_2$D, limits access of placentally synthesized 1,25$(OH)_2$D to the fetal and maternal circulations, and, in effect, partitions the maternal and fetal vitamin D pools.

THE NEONATE

Placental transfer of calcium ceases abruptly at birth. In healthy term newborns, total calcium concentration and Ca^{2+} decline from nearly 11 mg/dL and 6 mg/dL, respectively, in umbilical cord blood to serum levels of 8 to 9 mg/dL and 5 mg/dL by 24 to 48 hours. The nadir of Ca^{2+} may range from 4.4 to 5.4 mg/dL. Concomitant rises in PTH and 1,25$(OH)_2$D stabilize serum calcium as the newborn adapts to extrauterine mineral homeostasis and dietary calcium intake. In preterm infants, calcium absorption from the intestine is nonsaturable and may be vitamin D–independent (Bronner et al, 1992). Serum calcitonin levels increase sharply during the 1st day and remain elevated compared with those in adults. In the mother, prolactin helps stimulate PTHrP expression in lactating breast tissue. PTHrP is secreted into milk at concentrations 10,000-fold higher than in serum. It is likely that the abundant milk PTHrP content ingested by the neonate also is important for mineral regulation. By 2 weeks of life, serum calcium rises to the mean values observed in older children and adults.

During the 1st week of life, urinary phosphate excretion is significantly higher in preterm than in term infants but then approximates that of term infants, possibly owing to accelerated postnatal renal maturation. Calcium excretion is low during the 1st week, when the newborn must compensate for the postpartum fall in serum calcium. After the first several days, calcium excretion increases with a magnitude inversely proportional to gestation. The high urinary calcium-to-creatinine ratio (UCa/Cr) of young infants then steadily declines with age (Sargent et al, 1993). However, in preterm breastfed infants who are more than 2 weeks old, the UCa/Cr can exceed 2.0 (Karlen et al, 1985). These changes may reflect the relative phosphate deficiency in many preterm infants, which results in an adaptively low urinary phosphate excretion, decreased bone mineralization, and, consequently, relatively high urinary calcium excretion.

CALCIUM METABOLISM IN THE NEWBORN

NEONATAL HYPOCALCEMIA

Neonatal hypocalcemia has been variously defined as a serum calcium level of less than 8 mg/dL, less than 7.5 mg/dL, or less than 7.0 mg/dL and as a Ca^{2+} level of less than 4.0 mg/dL. Under conditions of normal acid-base status and normal serum albumin, serum total calcium and Ca^{2+} levels are linearly correlated, so total serum calcium measurements remain useful as a screening test. However, because Ca^{2+} is the physiologically relevant fraction, in sick infants it may be preferable to assay [Ca^{2+}] directly in freshly obtained blood samples. A precise definition of hypocalcemia, like hypoglycemia, in preterm infants is particularly difficult to formulate. Preterm hypocalcemia is probably best defined with reference to Ca^{2+}.

A useful approach to the classification of neonatal hypocalcemia is by time of onset. "Early" and "late" occurring hypocalcemia (Box 90-1) have different causes, usually

BOX 90-1 Causes of Neonatal Hypocalcemia

- Early-onset hypocalcemia (<48 hours of age)
  - Prematurity
  - Perinatal distress/asphyxia
  - Infants of diabetic mothers
  - Intrauterine growth restriction
- Late-onset hypocalcemia (1st week of life)
  - High phosphate load ± hypoparathyroidism or vitamin D deficiency
- Neonatal hypoparathyroid syndromes
  - Parathyroid agenesis
  - DiGeorge syndrome (22q11.2 deletions)
  - Familial isolated hypoparathyroidism
    - PTH gene mutations
  - Autosomal dominant hypocalcemic hypocalciuria (ADHH)
    - Activating mutations of the Ca^{2+}-sensing receptor
  - Neonatal hypoparathyroidism secondary to maternal hyperparathyroidism
  - Autoimmune-candidiasis-ectodermal dystrophy (APECED or APS1)
  - Hypoparathyroidism associated with skeletal dysplasias
    - Kenny-Caffey syndrome
    - Sanjad-Sakati (hypoparathyroidism-retardation-dysmorphism [HRD]) syndrome
    - Osteogenesis imperfecta type II
  - PTH resistance (transient neonatal pseudohypoparathyroidism)
  - Hypomagnesemia ± distal renal tubular acidosis
    - Primary hypomagnesemia
    - Renal tubular acidosis type 1
- Abnormal vitamin D [1,25$(OH)_2$D] production or action ("hypocalcemic rickets")
  - Vitamin D deficiency (secondary to maternal vitamin D deficiency)
  - Acquired or inherited disorders of vitamin D metabolism
  - Resistance to the actions of vitamin D
- Hyperphosphatemia
  - Excessive dietary phosphate
  - Phosphate-containing enemas
  - Rhabdomyolysis-induced acute renal failure
  - Hyperphosphatemic renal insufficiency
- "Hungry bones syndrome" (mineralization outpacing osteoclastic bone resorption)
- Other causes
  - Metabolic or respiratory alkalosis
  - Phototherapy
  - Long chain 3-hydroxyacyl-CoA dehydrogenase deficiency (LCHAD)
  - Pancreatitis
  - Sepsis, septic shock
  - Rotavirus gastroenteritis
  - Osteopetrosis and other skeletal dysplasias
  - Pseudohypocalcemia (hypoalbuminemia)
  - Medications
    - Bicarbonate
    - Rapid transfusion or plasmapheresis with citrated blood
    - Furosemide-induced
    - Lipid infusions

CoA, Coenzyme A; *1,25$(OH)_2$D*, 1,25-dihydroxyvitamin D.

occur in different clinical settings, and should prompt different approaches to evaluation and management.

Clinical Findings

Because Ca^{2+} couples excitation and contraction in skeletal and cardiac muscle, increased neuromuscular excitability (tetany) is a cardinal feature of hypocalcemia. However, hypocalcemic signs in neonates are variable and may not correlate with the magnitude of the decline in Ca^{2+}. Although some infants are severely affected, others having equally depressed serum calcium levels may be asymptomatic.

Tetanic infants are jittery and hyperactive, frequently exhibit muscle jerks and twitches, and may have generalized or focal clonic seizures. Exaggerated responses to environmental noises (e.g., "spontaneous" Moro reflex) can indicate hyperacusis. Occasionally, respiratory or gastrointestinal rather than neurologic signs predominate. Laryngospasm with inspiratory stridor, sometimes severe enough to cause cyanosis or anoxia, or wheezing due to bronchospasm may be a presenting manifestation. Vomiting, possibly related to pylorospasm, sometimes causes hematemesis or melena. At times, the gastrointestinal signs are severe enough to mimic those of intestinal obstruction. Other signs of neonatal tetany include extensor hypertonia, apnea, tachycardia, tachypnea, and edema. Carpopedal spasm and Chvostek's sign are not as reliably elicited in hypocalcemic newborns as in older children or adults.

Early Neonatal Hypocalcemia

Hypocalcemia occurring during the first 3 days of life, usually between 24 and 48 hours postpartum, is termed *early neonatal hypocalcemia*. It is a pathologic exaggeration of the normal decline in circulating calcium. Early neonatal hypocalcemia typically is seen in any of four circumstances: prematurity, severe stress or asphyxia, maternal diabetes, or significant intrauterine growth restriction (IUGR). In preterm infants, there is a steeper and more rapid postnatal decline in serum calcium; the magnitude of depression is inversely proportional to gestational age. Untreated, many low-birthweight (LBW) infants and essentially all extremely low-birthweight (ELBW) infants exhibit total calcium levels of less than 7.0 mg/dL by day 2. However, the fall in Ca^{2+} is not proportional to the fall in total calcium concentration, and the ratio of ionized to total calcium in these newborns is higher than at term. This "sparing" of Ca^{2+} may be related to the lower serum protein concentration and pH in prematurity. The sparing effect on Ca^{2+} also, in part, explains the frequent absence of hypocalcemic signs in preterm infants.

The neonatal parathyroid glands, regardless of degree of prematurity, can mount an appropriate PTH response to hypocalcemia. In fact, hypocalcemia in extremely preterm newborns (Rubin et al, 1991) or infants undergoing cardiac bypass (Robertie et al, 1992) stimulates increases in serum PTH at least as great as those seen in adults during citrate-induced hypocalcemia (Grant et al, 1990). PTH resistance plays an uncertain role in early neonatal hypocalcemia. A several-day delay in the phosphaturic and renal cAMP responses to PTH has inconsistently been reported, suggesting that there might be a maturational delay in renal responses to PTH. High renal sodium excretion in preterm infants also probably aggravates calciuric losses. In addition, the preterm infant's exaggerated rise in calcitonin may promote hypocalcemia. Currently, there is no convincing evidence that abnormalities in vitamin D metabolism are involved in the etiopathogenesis of hypocalcemia in preterm infants. Like fetuses, even ELBW newborns efficiently synthesize $1,25(OH)_2D$ when vitamin D stores are adequate.

Early neonatal hypocalcemia with hyperphosphatemia is frequently observed in severely stressed or asphyxiated infants. The causes are probably multifactorial and include, to varying degrees, renal insufficiency, tissue catabolism, and acidosis. There is an exaggerated serum calcitonin response and elevated PTH levels. Low serum Ca^{2+} and elevated serum magnesium levels have been correlated with severity of hypoxic-ischemic encephalopathy and poor outcome (Ilves et al, 2000).

Infants of diabetic mothers (IDMs) show an exaggerated postnatal drop in circulating calcium levels compared to gestational-age controls. The course usually is similar to that of early neonatal hypocalcemia in preterm infants, although hypocalcemia sometimes persists for several additional days. Maternal and neonatal hypomagnesemia (Banerjee et al, 2003) and low fetal PTH/PTHrP biologic activity (Rubin et al, 1991) may be causative factors. The greater bone mass and relative undermineralization typical of macrosomic IDMs also may increase the neonatal demand for calcium, producing a deeper and prolonged decline in postnatal serum calcium levels. Similar mechanisms may come into play in the transient hypocalcemia often observed in small-for-gestational-age (SGA) infants. Hypercalcitonemia, hypoparathyroidism, abnormalities in vitamin D metabolism, and hyperphosphatemia all have been implicated, but none has been consistently found.

Historically, symptomatic neonatal hypocalcemia in IDMs has been associated with the severity of maternal diabetes (e.g., White classification) and inadequate glycemic control. Not surprisingly, preterm IDMs who have sustained IUGR and asphyxia as a result of uteroplacental insufficiency invariably become quite hypocalcemic. In recent years, improved metabolic control for pregnant diabetic women has markedly diminished the occurrence and severity of early neonatal hypocalcemia in IDMs (Demarini et al, 1994). Healthy IDMs who are able to begin milk feedings on the 1st day do not require serum calcium monitoring unless suspicious signs (e.g., jitteriness, stridor) are noted.

Late Neonatal Hypocalcemia

Late neonatal hypocalcemia, or hypocalcemia developing after 3 to 5 days of life, occurs more frequently in term than in preterm newborns and is not usually associated with maternal diabetes, birth trauma, or asphyxia. Historically associated with cow's-milk or cow's-milk formula feedings, it also occasionally occurs in breastfed infants. The entity of "late infantile tetany" seen in infants fed whole cow's milk has become a rarity with adjustment of phosphorus content in humanized cow's-milk and soy infant formulas.

The hyperphosphatemia that is a prominent feature of late neonatal hypocalcemia may result from varying combinations of dietary phosphate load, immature renal tubular phosphate excretion, transiently low levels of circulating PTH, hypomagnesemia, and marginal maternal vitamin D intake. A relatively high dietary phosphate load coupled with a low GFR leads to an increase in serum phosphate levels and a reciprocal decline in serum calcium levels. The physiologic response to hypocalcemia is an increase in PTH secretion, leading to increased urinary phosphate excretion and tubular calcium resorption. It is relevant, therefore, that low circulating PTH levels are sometimes observed in infants with late neonatal hypocalcemia. Serum calcium levels frequently increase when these infants are placed on a low-phosphate formula and supplemental calcium. After several days to weeks, serum PTH usually increases, and the infants then can tolerate more dietary phosphate. The pathogenesis of this "transient hypoparathyroidism" in late neonatal hypocalcemia is not readily apparent. Some of these infants show a persistent or recurrent inability to mount an adequate PTH response to a hypocalcemic challenge, indicating partial hypoparathyroidism.

In other infants, maternal vitamin D deficiency can cause late (or occasionally "early") neonatal hypocalcemia. This possibility is checked by measuring maternal and neonatal serum 25(OH)D levels. Maternal vitamin D deficiency also is implicated by the increased incidence of late neonatal hypocalcemia in winter. The high prevalence of enamel hypoplasia of incisor teeth reported in affected infants indicates that the mineralization defect begins during the third trimester of pregnancy.

Hypocalcemia and hyperphosphatemia after the first 2 to 3 days always should prompt a thorough investigation for underlying cause(s) (see Box 90-1). Hypocalcemia in this setting usually implies primary or secondary dysregulation of (1) the parathyroid-renal [PTH-1,25$(OH)_2$D] axis, (2) hypomagnesemia, or (3) renal insufficiency. The primary hormonal and end-organ disturbances that cause neonatal hypocalcemic syndromes are described in a later section. As a cautionary note, earlier observations of generally favorable neurologic outcomes in newborns with hypocalcemic or hypomagnesemic seizures (which may have been related to a nutritional metabolic disturbance) may be less relevant to the current neonatal population, in which hypocalcemia or hypomagnesemia due to dietary phosphate overload seldom is observed. In this group, neurologic prognosis may be more closely related to the causative disorder (Lynch and Rust, 1994).

Hypocalcemia Caused by Hypoparathyroid Syndromes

The biochemical hallmarks of hypoparathyroidism are hypocalcemia and hyperphosphatemia in the presence of normal renal function. Serum PTH concentrations are inappropriately low or undetectable. Cytogenetic and molecular genetic diagnosis also permits characterization of several types of congenital hypoparathyroidism. Isolated hypoparathyroidism is usually sporadic but may show X-linked, autosomal recessive, or autosomal dominant inheritance.

Congenital hypoparathyroidism is a common feature of the DiGeorge syndrome (DGS). Fully expressed DGS comprises hypoparathyroid hypocalcemia, thymic hypoplasia with defects in T-cell immunity, conotruncal cardiac defects, palatal insufficiency, characteristic facies, and neurobehavioral and psychiatric features. The phenotypes result from defects in cervical neural crest cell migration into the derivatives of the third and fourth pharyngeal (branchial) pouches. DiGeorge, velocardiofacial (Shprintzen), and conotruncal face anomaly (Takao) syndromes commonly result from contiguous gene deletions in the same chromosomal region. That also is true for some isolated cardiac outflow tract defects and transient congenital hypoparathyroidism in the absence of a DGS phenotype. These infants should be evaluated and monitored for recurrence of hypocalcemia.

Most persons having a clinical diagnosis of DGS share a common 1.5- to 3-Mb deletion (monosomy or partial monosomy) of chromosome region 22q11.2, but there is molecular heterogeneity and rearrangement within this region (Emanuel, 2008). Haploinsufficiency of the TBX1 transcription factor gene may be responsible for most features. Fluorescence in situ hybridization (FISH) using 22q11 probes had a higher detection rate than that for high-resolution G band karyotyping. However, the most sensitive (and preferred) laboratory assay is array-comparative genomic hybridization (aCGH). Additionally, rarer identification of other cytogenetic abnormalities suggests that several distinct molecular defects (Rope et al, 2009) can lead to disturbed cranial neural crest cell migration and DGS phenotypes.

The incidence of DGS may be at least 1 case per 5000 live births (Ryan et al, 1997). Sporadic loss in the DGS region is more common than parental transmission. In members of the same family, DGS may be associated with different phenotypic features, depending on whether endocrinologic, cardiac, craniofacial, or palatal abnormalities are the initial focus of attention.

DGS often manifests in the 1st week of life with hypocalcemic tetany or seizures. Craniofacial features include microretrognathia, submucous cleft palate, low-set and abnormal pinnae, telecanthus with short palpebral fissures, short philtrum, and a relatively small mouth. The presence of cardiac outflow tract or aortic arch abnormalities (especially pulmonary atresia/tetralogy of Fallot, type B interrupted aortic arch, truncus arteriosus, anomalies of aortic arch laterality, or abnormal branching of the brachiocephalic vessels), even in the absence of other DGS features, should prompt genetic investigation. Parents of an infant with DGS should be screened for carrier status. These neonates require close anticipatory monitoring for the onset of hypocalcemia. Absence of a thymic shadow on chest radiograph is not a reliable indicator. Because of the potential for inducing graft-versus-host disease, until Tcell competence has been demonstrated, irradiated red blood cell transfusions may be preferred.

A normal serum PTH obtained when an infant is relatively normocalcemic also does not exclude the diagnosis of DGS. Infants with DGS may show resolution of hypoparathyroidism by early childhood, although PTH reserves may remain inadequate for defense against hypocalcemic stresses.

Hypoparathyroidism is a prominent feature of several rare skeletal dysplasias. Kenny-Caffey syndrome is a rare osteosclerotic bony dysplasia associated with hypocalcemia and ocular abnormalities. Autosomal recessive and autosomal dominant inheritance patterns have been described. Features include IUGR, transient neonatal hypoparathyroidism, short stature, macrocephaly, delayed fontanel closure, dysmorphic facies, and cortical thickening of tubular bones. In hypoparathyroidism-retardation-dysmorphism (HRD) syndrome (Sanjad-Sakati syndrome), hypoparathyroidism also is associated with IUGR, poor postnatal growth, characteristic facies (deep-set eyes, depressed nasal bridge, beaked nose, long philtrum, thin upper lip, micrognathia, large and floppy earlobes), small hands and feet, skeletal defects, and developmental delay (Sanjad et al, 1991). This autosomal recessive disorder has been described in persons of Gulf Arab and Bedouin ancestry. The loci for HRD syndrome and recessive Kenny-Caffey syndrome and HRD syndrome are allelic on chromosome 1q42-q43. Parvari et al (2002) have identified mutations in the gene encoding tubulin-specific chaperone E (*TBCE*) in both disorders.

Although osteogenesis imperfecta (OI) type II usually is perinatally lethal, some infants have prolonged survival. Knisely et al (1988) showed that acute parathyroid hemorrhage ("parathyroid apoplexy") is a common event in OI II and may contribute to early death.

The parathyroid glands are an infrequent target for autoimmunity, the exception being autoimmune polyglandular syndrome type 1 (APS 1), also known as autoimmune-candidiasis-ectodermal dystrophy (APECED), in which autoimmune hypoparathyroidism is the rule (Brown, 2009). APS 1 is a rare autosomal recessive disorder characterized by hypoparathyroidism, adrenal insufficiency, and chronic mucocutaneous candidiasis. Afflicted persons often eventually develop chronic hepatitis, malabsorption, juvenile-onset pernicious anemia, alopecia, and primary hypogonadism. APS 1 results from inheritance of mutations in an autoimmune regulator gene (*AIRE*). When this disorder is diagnosed in early infancy, which is rare, hypocalcemia (with or without candidiasis) typically is the presenting sign.

The association of several forms of autosomal dominant and autosomal recessive congenital hypoparathyroidism with allelic variants of the *preproPTH* and calcium-sensing receptor (*CaSR*) genes has advanced diagnosis and therapy for these disorders. Affected infants have subnormal or undetectable serum PTH levels but do not have congenital anomalies or developmental field defects, DGS locus deletions, candidiasis or autoimmune polyglandular failure, or anti-endocrine antibodies. Autosomal dominant and autosomal recessive forms of familial isolated hypoparathyroidism have been related to mutations in the *preproPTH* gene (Sunthornthevarakul et al, 1999). Activating *CaSR* gene mutations cause autosomal dominant hypocalcemic hypocalciuria (ADHH) or "CaSR hyperfunction." The parathyroid and renal calcistat is reset downward, so that hypocalcemia does not elicit normal compensatory PTH secretion or renal calcium reabsorption. Because de novo *CaSR* mutations producing CaSR hyperfunction may account for many cases of so-called sporadic idiopathic hypoparathyroidism (Egbuna and Brown, 2008), mutational analysis of the *CaSR* gene should be considered in the work-up of isolated hypoparathyroidism in infants, especially when hypocalcemia manifests with inappropriately normal urinary calcium excretion (relative hypercalciuria). In fact, hypercalciuria and nephrocalcinosis can develop even when serum calcium remains below the normal range. Therefore, these patients require close monitoring of urinary calcium excretion for adjusting therapy with $1,25(OH)_2D$ analogues.

There are three principal forms of hormone resistance to PTH. Deletion of the PTH/PTHrP receptor is embryologically or perinatally lethal. Loss of one allele for *GNAS1*, which encodes $G_s\alpha$, the G protein α subunit required for receptor-stimulated cAMP generation, produces pseudohypoparathyroidism type 1A (PHP1A). PHP1A is characterized by PTH-resistant (pseudo)hypoparathyroidism and characteristic somatic features (short stature, brachydactyly, and subcutaneous ossification), which collectively are known as Albright hereditary osteodystrophy. Isolated PTH resistance in the absence of this somatic phenotype is called pseudohypoparathyroidism type 1B (PHP1B). This disorder is an imprinting defect in which both *GNAS1* alleles have an unmethylated (paternal) pattern (Liu et al, 2000). Although most persons eventually diagnosed with a PTH resistance syndrome usually are not hypocalcemic during the 1st month of life, transient neonatal pseudohypoparathyroidism occasionally has been reported (Minagawa et al, 1995). Neonatal PTH resistance, which has an unknown frequency, can manifest as hypocalcemic seizures with hyperphosphatemia and an elevated PTH.

Neonatal Hypocalcemia Associated With Maternal Hyperparathyroidism

Hypocalcemia is commonly observed in newborns of hyperparathyroid mothers. These infants may show increased neuromuscular irritability during the first 3 weeks of life but, occasionally, do so much later as limited PTH reserve and latent hypoparathyroidism emerge under stress or with time. The serum calcium levels usually range from 5.0 to 7.5 mg/dL, and the serum phosphate levels are often greater than 8.0 mg/dL. Hypocalcemic signs may be exacerbated by high-phosphate diets or maternal vitamin D deficiency. In some instances, signs of hypocalcemia can be quite severe and resistant to therapy. Calcium supplementation, which in some instances must be continued for several weeks, produces eventual improvement.

In maternal hyperparathyroidism, the increased maternal serum calcium facilitates transplacental calcium transport, producing fetal hypercalcemia greater than the moderate elevations of serum calcium normally observed in the third trimester. As a result, fetal PTH secretion is suppressed more than it is in normal pregnancy. The suppressed parathyroids are unable to maintain normal serum calcium levels postpartum. The reason for the hypomagnesemia observed in some infants born to hyperparathyroid mothers is uncertain, but this derangement may be due to (1) maternal magnesium depletion as a complication of hyperparathyroidism; (2) transient neonatal hypoparathyroidism; or (3) hyperphosphatemia, which may result from transient hypoparathyroidism or high dietary phosphate intake, or both.

Maternal serum calcium and phosphorus should be assayed whenever this diagnosis is suspected. Hypocalcemic tetany occurring in the infant may lead to diagnosis of hyperparathyroidism in an asymptomatic mother. Maternal serum calcium values in the upper normal range may be falsely reassuring if the samples were obtained during pregnancy, a time when serum calcium levels normally decline.

Neonatal Hypocalcemia Associated With Hypomagnesemia or Renal Tubular Acidosis

Hypomagnesemia causes hypocalcemia by interfering with the parathyroid cell CaSR-mediated release of PTH and by blunting end-organ PTH response. Depression of serum magnesium levels in newborns may be chronic, sometimes as primary hypomagnesemia with secondary hypocalcemia, or transient.

Hypomagnesemia with secondary hypocalcemia (HOMG1), also known as hypomagnesemia with secondary hypocalcemia (HSH), can present in the first weeks of life as persistent hypocalcemia, tetany, and seizures uncontrolled by anticonvulsants or calcium therapy. Delay in establishing the diagnosis may lead to permanent neurologic impairment. This rare autosomal recessive disorder results from defective intestinal magnesium absorption and renal magnesium leak. HOMG1 is caused by mutations in the TRPM6 gene, a member of the transient receptor potential channel family expressed in intestinal epithelia and renal tubules (Schlingmann et al, 2005).

Several forms of primary renal hypomagnesemia have been described, including autosomal recessive familial hypomagnesemia with hypercalciuria and nephrocalcinosis caused by mutations in the claudin-16 (paracellin-1) gene (Simon et al, 1999) and a genetically heterogeneous autosomal dominant "isolated renal magnesium wasting" (Kantorovich et al, 2002). The clinical spectrum includes polyuria, hyposthenuria, moderate metabolic acidosis with an inappropriately high urine pH and a positive urine anion gap, low citrate excretion, renal magnesium and calcium wasting, secondary renal potassium wasting, nephrocalcinosis, muscle weakness, persistent tetany, seizures, and sometimes abnormal facies and sensorineural hearing loss. The partial distal acidification defect, which is probably secondary to a medullary interstitial nephropathy, can be functionally distinguished from primary distal renal tubular acidosis (RTA1) (Rodriguez-Soriano and Vallo, 1994). In primary hypomagnesemia, the serum magnesium is frequently less than 0.8 mg/dL (normal 1.6 to 2.8 mg/dL), and the magnesium deficiency leads to parathyroid failure and peripheral PTH resistance, despite hypocalcemia. High-dose enteral magnesium leads to spontaneous parallel increases in serum PTH and calcium levels and renal phosphate clearance. Renal transplantation normalizes serum magnesium and urinary calcium.

A transient hypomagnesemia in newborns often occurs in association with hypocalcemia. Less commonly, the serum calcium level may be normal. In transient hypomagnesemia, the decrease in serum magnesium level typically is less severe (0.8 to 1.4 mg/dL) than in magnesium transport defects. In many infants with transient hypomagnesemia, the serum magnesium level increases spontaneously as the serum calcium level normalizes following the administration of calcium supplements. However, in other cases, hypocalcemia responds poorly to calcium therapy, but when magnesium salts are given, both serum calcium and magnesium levels rise.

Secondary hypomagnesemia from renal magnesium wasting can result from drug administration (loop diuretics, aminoglycosides, amphotericin B) or by urinary tract obstruction. It also may occur during the diuretic phase of acute renal failure. The disorder may be mistaken for neonatal hypoparathyroidism because of tetany and hypocalcemia, or for Bartter's syndrome (hypokalemic alkalosis with hypercalciuria) because of secondary potassium wasting. An index of suspicion should be raised whenever hypomagnesemia occurs in one of these situations. Finding low serum magnesium levels with inappropriately high urinary magnesium excretion confirms a diagnosis of renal magnesium wasting. Regardless of cause, hypokalemia is a common laboratory feature of magnesium depletion. Attempts to replace the potassium deficit with potassium alone usually are unsuccessful unless magnesium is given concurrently.

Distal renal tubular acidosis (i.e., RTA1) is characterized by hypocalcemia, hypercalciuria, varying degrees of hypomagnesemia, hyperchloremia, low serum bicarbonate, and a fixed urinary specific gravity and urinary pH (about 5.0). The mineral excretion defect leads to nephrocalcinosis and metabolic bone disease. RTA1 sometimes manifests during early infancy, when hypocalcemia may precede the RTA. Lewis (1992) proposed that Tiny Tim in Dickens' *A Christmas Carol* had RTA1, which would account for Tim's growth failure, osteomalacia, fractures, and neuromuscular weakness.

Hypocalcemia Resulting from Vitamin D Disorders

In older children and adults, disorders of vitamin D intake or metabolism rarely present as isolated hypocalcemia. Instead, most persons having abnormalities in either production or action of $1,25(OH)_2D$ manifest with rickets or osteomalacia. In sharp contrast, young infants may exhibit hypocalcemic tetany before rachitic features become conspicuous. Abnormalities in vitamin D metabolism can be divided into three broad categories: vitamin D deficiency, acquired or inherited disorders of vitamin D metabolism, and resistance to vitamin D actions.

Maternal vitamin D deficiency is the major risk factor for neonatal vitamin D deficiency manifesting as hypocalcemia. Maternal vitamin D deficiency is becoming less common in countries where dairy products and other foods are supplemented with vitamin D. It is still a common and serious health problem of women of reproductive age and their infants in developing countries. Female immigrants from the Middle East or South Asia who wear traditional concealing dress, have inadequate dietary vitamin D intake, or are dark-skinned are at particularly high risk (Dijkstra et al, 2007; Hobbs et al, 2009), especially during pregnancy. Breastfed infants of lactovegetarian mothers also are susceptible to early-onset hypocalcemic rickets. Nutritional rickets in newborns can be prevented

by daily supplementation of 400 IU for infants and 400 IU daily for mothers during pregnancy and lactation or 1000 IU daily if begun in the third trimester.

Intestinal absorption of fat-soluble vitamin D requires a functioning exocrine pancreas, biliary tract, and bowel mucosa. Consequently, pregnant women with malabsorption syndromes may be vitamin D deficient. Anticonvulsant therapy (e.g., with phenobarbital or diphenylhydantoin) during pregnancy, which increases hepatic catabolism of 25(OH)D, also can induce maternal and fetal vitamin D deficiency. Pregnant women who take anticonvulsants should receive vitamin D supplementation (800 to 1000 IU/day).

Phosphate-Induced Hypocalcemia

Hypocalcemia is the systemic response to hyperphosphatemia. Conditions conducive to phosphate-induced neonatal hypocalcemia are excessive phosphate intake, rhabdomyolysis-induced acute renal failure, and hyperphosphatemic renal insufficiency. In the instance of excess intake, phosphate-containing enemas can produce significant phosphate absorption. Their use is hazardous and contraindicated for infants. Chronic renal failure is the primary cause of secondary hyperparathyroidism. Patients with mineral metabolism disorders commonly present with low serum calcium levels, hyperphosphatemia, and calcitriol deficiency. In uremic conditions, however, parathyroid glands become hyperplastic and leave quiescence. In recent years, there has been identification of important molecular mediators including the CaR, parathyroid expression of the vitamin D receptor (VDR), and a central role of the fibroblast growth factor 23 (FGF-23) (Cozzolino et al, 2009).

Other Causes of Neonatal Hypocalcemia

It is important to recognize that hypocalcemia may occur whenever skeletal mineralization significantly outpaces the rate of osteoclastic bone resorption. Examples of this type of hypocalcemia occur with overzealous vitamin D replacement in infants with rickets or hypoparathyroidism. Pancreatitis can cause hypocalcemia and tetany through the action of pancreatic lipase on retroperitoneal and omental fat to release free fatty acids (FFAs). FFAs avidly chelate calcium and remove it from the ECF. Pancreatitis also may release pancreatic calcium-lowering factors (Tomomura et al, 1995). Sepsis and septic shock cause hypocalcemia by unknown mechanisms. Neonatal or infantile hypocalcemia and hypocalcemic seizures may accompany long-chain 3-hydroxyacyl-coenzyme A (CoA) dehydrogenase deficiency (LCHAD) (Ibdah et al, 1999) and severe cases of rotavirus gastroenteritis (Foldenauer et al, 1998). Hypocalcemic jitteriness or seizures can be the presenting sign of infantile osteopetrosis (Srinivasan et al, 2000). Prompt recognition permits early referral for bone marrow or hematopoietic stem cell transplantation. Certain other skeletal dysplasia syndromes are associated with neonatal hypocalcemia, which may be severe.

Several common therapeutic interventions can induce hypocalcemia. Bicarbonate therapy, as well as any form of metabolic or respiratory alkalinization, decrease both Ca^{2+} levels and bone turnover. Rapid blood transfusion or plasmapheresis can promote calcium complexes with the infused citrate, decreasing Ca^{2+}. Hypocalcemia after initiation of ECMO is related to composition of the circuit-priming solution and to acute citrate loading and may lead to hemodynamic instability (Meliones et al, 1995). Furosemide therapy promotes calciuresis and nephrolithiasis. Phototherapy for hyperbilirubinemia may be associated with mild hypocalcemia. This effect has been attributed to decreased melatonin secretion, which potentiates glucocorticoid actions on bone metabolism. Lipid infusions may elevate serum FFAs, which form insoluble complexes with calcium. Most of these effects are transient, and cessation of therapy is followed by a return to normal serum calcium levels. The major exception is aggressive furosemide therapy, which, when prolonged, may lead to bone demineralization and renal dysfunction (Downing et al, 1992).

Treatment

The decision to treat hypocalcemia in an infant depends on the severity of the hypocalcemia and the presence of clinical signs and symptoms. The morbidity associated with calcium treatment must be weighed against the potential benefits. Hypocalcemic preterm infants who have no symptoms and are not ill from any other cause probably do not need specific treatment. Early neonatal hypocalcemia should resolve by day 3. Some clinicians begin treatment in preterm newborns once serum calcium levels have dropped to 6.0 to 6.5 mg/dL or after Ca^{2+} has decreased to 2.5 to 3.0 mg/dL. Another reasonable approach is to initiate prophylactic calcium infusions (or calcium-containing parenteral nutrition) for all ELBW infants within the first 24 hours. There is no role for prophylaxis or treatment with pharmacologic doses of vitamin D. For newborns who exhibit cardiovascular compromise (e.g., severe respiratory distress, pulmonary hypertension, asphyxia, sepsis) or who require cardiotonic drugs or blood pressure support, monitoring blood [Ca^{2+}] is particularly helpful, with the aim of preventing the onset of significant hypocalcemia.

The mainstay of treatment for neonatal hypocalcemia is intravenous administration of calcium salts. Calcium gluconate is preferred over calcium chloride (which, in sufficient doses, produces hyperchloremic acidosis) or calcium lactate. A 10% solution of calcium gluconate contains 9.4 mg Ca/mL. A constant infusion of approximately 45 to 75 mg/kg/day usually produces a sustained increase in serum calcium level (7 to 8 mg/dL). Bolus infusions are hazardous and only transiently effective.

Risks associated with calcium infusions are minimized by attention to detail. Rapid intravenous infusion of calcium can cause sudden elevation in serum calcium, leading to bradyarrhythmias. Bolus infusion of calcium should be reserved for treating hypocalcemic tetany and seizures. Extravasation of calcium solutions into subcutaneous tissues may cause necrosis and subcutaneous calcification. Therefore, meticulous care of peripheral intravenous catheter sites is particularly important when calcium-containing solutions are infused. Inadvertent intrahepatic infusion of calcium through an umbilical vein catheter (due to failure to reach the inferior vena cava) can cause

hepatic necrosis. Rapid intraaortic infusion via an umbilical artery can cause arterial spasm and, at least experimentally, intestinal necrosis.

Hypocalcemic Crisis

For emergency treatment of hypocalcemic crisis with seizures, tetany, or apnea, 1 to 2 mL/kg of a 10% solution of calcium gluconate should be given over 5 to 10 minutes. The initial serum calcium level may be less than 5.0 mg/dL. Careful observation of the infant and infusion site is essential, and the infusion should be discontinued if there is bradycardia or when the desired clinical result is obtained. The intravenous dose of calcium gluconate necessary to stop convulsions is usually 1 to 3 mL/kg. Toxic reactions are avoided if the maximum intravenous dose of calcium gluconate given at any one time does not exceed 2 mL/kg; doses above 3 mL/kg should be administered with caution. If necessary, intravenous calcium therapy may be repeated 3 or 4 times in 24 hours to help control acute symptoms.

Nonemergency Treatment

After acute symptoms have been controlled, calcium therapy should be continued as needed to maintain serum calcium above 7.0 mg/dL. In part, the level of serum calcium to be achieved depends on serum total protein, particularly albumin. In hypoalbuminemic infants, lower levels of total serum calcium are normally present. In preterm and sick infants for whom oral intake is limited, 5 to 8 mL/kg of 10% calcium gluconate (45 to 75 mg Ca/kg) may be infused with intravenous fluids over a 24-hour period. The lower dose range is preferred whenever there is hyperphosphatemia. If oral feedings are tolerated, 10% calcium gluconate may be given in the same daily dose divided into 4 to 6 feedings. Alternatively, calcium glubionate (Neo-Calglucon), which contains 23.6 mg Ca/mL, may be given in a dose of 2 mL/kg/day divided into feedings. Oral calcium gluconate is better tolerated by young infants because the high sugar content and osmolality of calcium glubionate may cause gastrointestinal irritation or diarrhea. Intravenous or oral calcium supplements should be continued until the serum calcium level stabilizes.

Dietary factors and hypoparathyroidism are important in the pathogenesis of late neonatal hypocalcemia. Therefore, therapy is often directed at reducing the phosphate load and increasing the calcium-to-phosphorus ratio of feedings to 4:1. This can be accomplished by the use of low-phosphorus feedings such as human milk or Similac PM 60/40 in conjunction with calcium supplements. These interventions inhibit intestinal absorption of phosphorus. Phosphate binders are not generally necessary. Serum calcium and phosphorus levels should be monitored at least once to twice weekly and the calcium supplements discontinued in a stepwise fashion after several weeks.

Magnesium Administration

When hypomagnesemia contributes to (or causes) hypocalcemia, administration of magnesium salts is indicated. Magnesium may be given intramuscularly as a 50% solution of magnesium sulfate (50% $MgSO_4 \cdot 7H_2O$ contains 4 mEq/mL of magnesium). The suggested intramuscular or intravenous dose of 50% magnesium sulfate is 0.1 to 0.2 mL/kg. Intravenous infusions should be administered slowly using electrocardiographic monitoring to detect rhythm disturbances, which may include prolonged atrioventricular conduction time and sinoatrial or atrioventricular block. The magnesium dose may be repeated every 12 to 24 hours, depending on the clinical and serum magnesium response. Many infants with transient hypomagnesemia will respond sufficiently to one or two magnesium injections. Infants with primary hypomagnesemia have permanent magnesium wasting. The low serum magnesium levels may require lifelong treatment with magnesium supplements.

Vitamin D Treatment

Infants with normal intestinal absorption who develop late hypocalcemia with vitamin D deficiency rickets usually respond within 4 weeks to 1000 to 2000 IU/day of oral vitamin D. These infants should receive at least 40 mg/kg/day of elemental calcium in order to prevent hypocalcemia because the unmineralized osteoid may avidly incorporate calcium once vitamin D is provided ("hungry bones" syndrome). PTH-dependent renal production of $1,25(OH)_2D$ is deficient in all hypoparathyroid states. Therefore, in persistent congenital hypoparathyroidism, long-term treatment with vitamin D or a shorter-acting vitamin D analogue is indicated.

NEONATAL HYPERCALCEMIA

Hypercalcemia usually is defined as total serum calcium concentration greater than 11.0 mg/dL and $[Ca^{2+}]$ greater than 5.0 mg/dL. Neonatal hypercalcemia is associated with several clinical entities (Box 90-2). It may be asymptomatic and discovered incidentally or may manifest dramatically (especially if serum calcium is 14.0 mg/dL or greater) and be life-threatening, requiring immediate intervention. The clinical findings may include poor feeding, vomiting, constipation, polyuria, hypertension, tachypnea, dyspnea, hypotonia, lethargy, and seizures. Polyuria is due to an impaired renal response to vasopressin (nephrogenic diabetes insipidus) and may lead to dehydration. The hypertension is probably due to a direct vasoconstrictive effect of the elevated ECF calcium as well as to increased activity of the renin-angiotensin system resulting from renal arteriolar constriction. The central nervous manifestations result from direct neuronal effects of calcium, hypertensive encephalopathy, and cerebral ischemia. Persistent hypercalcemia may produce extraskeletal calcification in the kidney, skin, subcutaneous tissue, falx cerebri, arteries, myocardium, lung, or gastric mucosa. Nephrocalcinosis, nephrolithiasis, diffuse bone undermineralization (and occasionally osteitis fibrosa) are well-recognized hypercalcemic complications. In infants, the predominant manifestation of chronic, moderate elevations of serum calcium may be failure to thrive. The physical examination usually is otherwise normal, except in those infants who have subcutaneous fat necrosis, Williams syndrome, or skeletal dysplasias.

Normally, the parathyroid-renal axis prevents hypercalcemia via inhibition of PTH secretion and $1,25(OH)_2D$ synthesis, which reduces calcium absorption from the intestine, mobilization from bone, and reabsorption from the kidney. (The physiologic role of calcitonin is uncertain.) An elevated serum calcium, therefore, indicates an

BOX 90-2 Causes of Neonatal Hypercalcemia

- Iatrogenic (calcium salts)
- Parathyroid hyperfunction
  - Neonatal severe primary hyperparathyroidism (NSPHP)
  - Ca^{2+}-sensing receptor mutation homozygosity
  - Familial (benign) hypercalcemic hypocalciuria (FBHH)
  - Ca^{2+}-sensing receptor mutation heterozygosity
  - Neonatal hyperparathyroidism associated with multiple endocrine adenomatosis
  - Renal tubular acidosis with secondary hyperparathyroidism
  - Neonatal hyperparathyroidism secondary to maternal hypoparathyroidism
- Williams syndrome (elastin gene locus deletions)
- Idiopathic infantile hypercalcemia ("Lightwood-type")
- Phosphate depletion
- Hypervitaminosis D
  - Vitamin D intoxication
  - Subcutaneous fat necrosis
- Blue diaper syndrome
- Hypercalcemia associated with skeletal dysplasias
  - Infantile hypophosphatasia
  - Jansen metaphyseal chondrodysplasia (activating mutations of the PTH/PTHrP receptor)
- Other causes
  - Tumor-associated hypercalcemia
  - Congenital disaccharidase deficiencies
  - Acute adrenal insufficiency
  - Hypervitaminosis A
  - Thyrotoxicosis
  - Mucolipidosis type 1
  - ECMO

ECMO, Extracorporeal membrane oxygenation; *PTH*, parathyroid hormone; *PTHrP*, parathyroid hormone-related protein.

inappropriate calcium influx to the ECF from one or more of these pools. Because the kidney is the principal organ for stoichiometric calcium balance, hypercalcemia usually means that the renal capacity to excrete calcium has been exceeded. In fact, abnormalities in distal tubular resorption are involved in the pathogenesis of many hypercalcemic conditions (e.g., hyperparathyroidism), and renal impairment frequently accompanies many hypercalcemic syndromes.

Neonatal Hyperparathyroid Syndromes and Familial Hypocalciuric Hypercalcemia

Neonatal severe primary hyperparathyroidism (NSPHP) is a rare, life-threatening disorder (Egbuna and Brown, 2008). The enlarged (hyperplastic) parathyroid glands are resistant to regulation by Ca^{2+}, resulting in marked hypercalcemia, although milder clinical expression also occurs. These infants may appear normal at birth or have a narrow thorax, depressed sternum, or thoracolumbar kyphosis. Signs of hypercalcemia usually develop during the first days of life. Serum calcium levels may range between 15 and 30 mg/dL, serum phosphorus concentration is frequently less than 3.5 mg/dL with significant hyperphosphaturia, and PTH levels are very elevated. Anemia, hepatomegaly, and splenomegaly have been reported. Skeletal radiographs may show generalized undermineralization, irregular metaphyses (subperiosteal erosions), and multiple pathologic fractures of the long bones and ribs (Nyweide et al, 2006). Nephrocalcinosis is common. The bone findings initially may be mistaken for osteogenesis imperfecta or abuse.

Inheritance studies have long suggested a connection between NSPHP and a milder disease, familial (benign) hypocalciuric hypercalcemia (FBHH), as well as a relationship of both to PTH-independent "resetting" of parathyroid Ca^{2+} sensing and renal calcium handling. Sequencing of the parathyroid and renal CaSR has clarified these relationships. Partial or total inactivating Ca*SR* mutations cause increased renal tubular calcium reabsorption (hypercalciuria) and persistent PTH secretion despite hypercalcemia. Homozygosity for inactivating Ca*SR* mutations causes NSPHP, whereas heterozygosity results in the autosomal dominant FBHH. FBHH is genetically heterogeneous and includes at least three types, FBHH1, FBHH2, and FBHH3, whose chromosomal locations are 3q21.1, 19p, and 19q13, respectively. FBHH1, related to NSPHP, is caused by mutations of CaSR, but the abnormalities underlying FBHH2 and FBHH3 are unknown. Additionally, certain de novo or inherited heterozygous *CaSR* mutations account for some cases of NSPHP (Gunn and Gaffney, 2004).

Newborns (and older children and adults) with FBHH have mild (often asymptomatic) intermittent hypercalcemia without hypercalciuria. In distinction to neonatal hyperparathyroidism, circulating levels of PTH, phosphorus, and $1,25(OH)_2D$ tend to be normal. Persons who have FBHH are at risk for having a child with NSPHP. Conversely, parents of an infant with hyperparathyroidism should be screened with serum calcium and phosphorus levels and a urinary UCa/Cr. A UCa/Cr below 0.01 supports the diagnosis. Early diagnosis and parathyroidectomy have been necessary for survival in fulminant NSHPT. Recently, bisphosphonate (pamidronate) therapy has been used in term (Waller et al, 2004) and preterm (Fox et al, 2007) infants having NSHPT in order to reverse the severe hypercalcemia and postpone parathyroidectomy until the infants were clinically stable. In less severe cases, which can be self-limiting and are often due to heterozygous *CaSR* mutations, conservative management may be warranted.

Neonatal hyperparathyroidism occasionally occurs as part of the syndrome of multiple endocrine adenomatosis. There also have been reports of sporadic and familial forms of renal tubular acidosis with secondary hyperparathyroidism manifesting as hyperchloremia, hypercalcemia, elevated serum PTH, and severe metabolic acidosis (Igarashi et al, 1992; Savani et al, 1993). Serum calcium and PTH may promptly revert to normal values after initiation of alkali therapy. Often, the acidification defect is transient (Igarashi et al, 1992). As the hyperparathyroidism and ECF volume contraction are corrected, serum calcium normalizes.

Neonatal Hyperparathyroidism Associated With Maternal Hypoparathyroidism

Fetal and neonatal hyperparathyroidism may occur in infants born to mothers with poorly controlled (hypocalcemic) hypoparathyroidism. Maternal hypocalcemia leads

to impaired transplacental calcium transfer and causes chronic stimulation of the fetal parathyroid glands. In contrast to infants with NSPHP, these newborns are frequently of low birthweight and have depressed or normal (rather than elevated) serum calcium levels and normal to mildly elevated (rather than depressed) serum phosphorus levels. The reasons for these differences between the two groups are unknown.

Mortality rates are high in infants born to poorly or untreated hyperparathyroid mothers, especially if there is significant IUGR. In survivors, the skeletal abnormalities usually regress and bone radiographs normalize by 4 to 7 months. In hypoparathyroid pregnant women, correction of hypocalcemia with calcium and vitamin D supplements can prevent fetal hyperparathyroidism.

Williams Syndrome and Idiopathic Infantile Hypercalcemia

Williams syndrome (WS) (or Williams-Beuren syndrome) is an autosomal dominant, multisystemic neurodevelopmental disorder caused by a hemizygous deletion of 1.55 Mb on chromosome 7q11.23 spanning 28 genes (Ferrero et al, 2010). It is one of the better described human microdeletion syndromes. Fully expressed WS includes transient hypercalcemia in infancy and cardiac defects, especially supravalvular aortic stenosis and multiple peripheral pulmonary arterial stenoses (Collins et al, 2010). Haploinsufficiency of the elastin (*ELN*) gene is responsible for these defects. Other common features are elfin facies, mental and height deficiency, and dental malformations. The specific facial features include supraorbital fullness with a broad forehead, short palpebral fissures with a medial flare to the eyebrows, a flat nasal bridge with a full tip and anteverted nostrils, ocular hypertelorism, strabismus, stellate iris, malar hypoplasia with a wide mouth and a full lower lip, and hypoplastic teeth with malocclusion. Hallux valgus with a small curved fifth digit is common. Pectus excavatum and umbilical or inguinal hernia are less commonly noted.

Two thirds of newborns with WS are small for gestational age, and many are born post-dates. The frequency of WS is estimated to be about 1 in 10,000 to 1 in 20,000. Expression of the full WS phenotype may be related to the size of the deletion. FISH for the detection of deleted WS gene markers is an appropriate initial diagnostic assay.

Although the hypercalcemia is often diagnosed after the 1st month, the child with WS sometimes comes to clinical attention in the neonatal period (Shimizu et al, 1994). The hypercalcemia rarely persists beyond several months and generally resolves spontaneously, but hypercalciuria may persist. The pathogenesis of hypercalcemia in WS is not well established. Elevated serum calcium associated with normal or increased serum phosphorus levels and characteristic radiographic findings differentiate WS from primary hyperparathyroidism. In some older infants, the serum calcium level is normal, but the presence of nephrocalcinosis and other soft tissue calcifications suggests that hypercalcemia occurred earlier. Increased calcium absorption has been demonstrated, but enhanced vitamin D sensitivity or other disorders of specific calcitropic hormones have not been consistently found. A cautionary note is that many of these children were studied after their hypercalcemia had resolved. A low-calcium diet usually controls the hypercalcemia.

In the early 1950s in England, Lightwood (1952) reported a series of infants with severe hypercalcemia. Hypervitaminosis D was suggested by the findings of osteoporosis and dense bands of mineralization at the metaphyseal ends of long bones. Epidemiologic investigations revealed that a majority of these infants were born to mothers who ingested foods heavily fortified with vitamin D. Some infants also had received 3000 to 4000 IU of vitamin D daily in an effort to prevent nutritional deficiencies. With reduction of vitamin D supplementation, the incidence of infantile hypercalcemia has declined dramatically. However, in other instances, no known previous exposure to excessive maternal vitamin D intake has occurred. The incidence of this milder (Lightwood-type) "idiopathic" infantile hypercalcemia (IIH) without WS phenotypic features has remained relatively fixed over time. Further distinction between these conditions probably awaits more extensive genetic analysis and definition of the mineral metabolic derangement(s). In contrast to WS, serum calcium levels remain elevated for a prolonged period in severely affected infants having IIH. There may be an exaggerated increase in serum $1,25(OH)_2D$ in response to exogenous PTH administration. Therefore, in addition to dietary calcium restriction and avoidance of vitamin D, glucocorticoid therapy to reduce gastrointestinal calcium absorption sometimes is helpful.

Neonatal Hypercalcemia Associated With Subcutaneous Fat Necrosis

Hypercalcemia is an occasional, severe complication of subcutaneous fat necrosis of the newborn (SFN) (Mahé et al, 2007). SFN is a rare, self-limited disorder that may appear up to several weeks after delivery in term or postterm neonates. Frequently, there is a history of difficult delivery, trauma, hypothermia, or asphyxia. Erythematous to violaceous, indurated subcutaneous nodules and plaques often overlie bony prominences on the buttocks, thighs, trunk, cheeks, or arms. Lesions may resemble those of sclerema neonatorum.

Hypercalcemic infants may present with poor weight gain despite adequate energy intake or with nephrocalcinosis. Hypercalcemia should be sought for in all infants with subcutaneous fat necrosis. Laboratory evaluation shows high blood $1,25(OH)_2D$ levels and usually normal phosphorus and alkaline phosphatase. Radiographs of the long bones also are usually normal, although periosteal elevation, features similar to those of WS, or ectopic calcification may be present. Lesion punch biopsy or aspirate specimens show lobular panniculitis with necrotic adipocytes, abundant histiocytes, and giant cells with radial crystals. Magnetic resonance imaging (MRI) may point to the correct diagnosis without biopsy.

Hypercalcemia in SFN, like in other granulomatous disorders, is caused by unregulated production of $1,25(OH)_2D$ by activated macrophages. Lesion prostaglandin E release also may contribute to hypercalcemia and osteoclastic bone resorption. Hypercalcemia associated with SFN may persist for days to weeks. Treatment consists of intravascular

volume expansion, furosemide, prednisone, a low-calcium, low-vitamin D diet, and, increasingly, bisphosphonates (pamidronate).

Blue Diaper Syndrome

Blue diaper syndrome is a rare familial disease in which hypercalcemia and nephrocalcinosis are associated with a defect in the intestinal transport of tryptophan (Drummond et al, 1964). Current speculations focus on causal defects in L-type (e.g., LAT2) and T-type (e.g., TAT1) amino acid transporters. Bacterial degradation of tryptophan in the intestine leads to excessive indole production, which is converted to indican in the liver. Oxidative conjugation of indican in the urine forms the water-insoluble dye indigo blue (indigotin), with a consequent peculiar bluish discoloration of the diaper. The clinical course is characterized by failure to thrive, recurrent unexplained fever, infections, marked irritability, and constipation. The mechanism of hypercalcemia is uncertain, although oral tryptophan loading in human subjects and experimental animals also elevates serum calcium. Treatment consists of glucocorticoids and a low-calcium, low–vitamin D diet.

Hypercalcemia Associated With Skeletal Dysplasias

Several skeletal dysplasia syndromes are associated with hypercalcemia. The distinctive phenotypes point to the appropriate diagnosis.

Hypophosphatasia (Mornet, 2007) is a rare autosomal recessive condition caused by mutations in the liver/bone/kidney alkaline phosphatase gene (ALPL) leading to deficiency of the tissue-nonspecific alkaline phosphatase. The perinatal and early infantile onsets are characterized by defective bone (and tooth) mineralization. Depending on the age at diagnosis, six clinical forms are currently recognized: perinatal (lethal), perinatal benign, infantile, childhood, adult, and odontohypophosphatasia. Prominent features of the early-onset, severe forms are respiratory complications, premature craniosynostosis, widespread undermineralization, rickets, and hypercalcemia. Attempts to control the hypercalcemia, hypercalciuria, and chronic bone demineralization using chlorothiazide, calcitonin, and bisphosphonates have been disappointing.

Jansen metaphyseal chrondrodysplasia in newborns is characterized by hypercalcemia and skeletal radiographs that mimic rachitic changes. This severe autosomal recessive disorder results from gain-of-function mutations in the PTHR1 receptor that result in ligand-independent receptor activation (Schipani and Provot, 2003). PTH and PTHrP levels are low or undetectable. The functional consequences are premature chondrocyte maturation, accelerated endochondral bone formation, and hypercalcemia.

Hypercalcemia Associated With Phosphate Depletion

Neonatal hypercalcemia due to phosphate depletion is most often seen in very-low-birthweight (VLBW) infants who are fed unsupplemented human milk. The low phosphate content of human milk leads to hypophosphatemia, which stimulates renal $1,25(OH)_2D$ synthesis and intestinal calcium absorption. When phosphate is limited, little calcium can be deposited in bone, leading to osteopenia, hypercalcemia, and hypercalciuria. Extremely high serum calcium levels (greater than 15 mg/dL), serum phosphorus less than 2 mg/dL, and suppressed PTH may be observed in VLBW infants in this setting. These infants respond to cautious phosphate replenishment. The condition is preventable by anticipatory monitoring of serum calcium and phosphorus levels in high-risk infants. Hypophosphatemic bone disease in VLBW infants is discussed later (see section Osteopathy of Prematurity).

Vitamin D Toxicity

Excessive supplementation with vitamin D will cause hypercalcemia in newborns and infants. In preterm infants, prolonged feeding with preterm formula or mineral- and vitamin D–supplemented human milk fortifiers also has led to mild to significant hypercalcemia. Infants respond to discontinuation of vitamin D supplements. These occurrences have prompted vitamin reformulation of preterm nutritional products. Laboratory studies in hypervitaminosis D typically show elevated 25(OH)D but not $1,25(OH)_2D$. Serum PTH usually is suppressed by the hypercalcemia. Biochemical resolution may be protracted because vitamin D accumulates in body fat.

Other Causes of Neonatal Hypercalcemia

Hypervitaminosis A and thyrotoxicosis also accelerate bone turnover and can induce hypercalcemia. Tumor-associated hypercalcemia in neonates is extremely rare. Most cases have been associated with congenital mesoblastic nephroma, the most common renal tumor of early infancy. Hypercalcemia in the presence of chronic diarrhea should suggest hereditary disaccharide intolerance type I (congenital sucrase-isomaltase deficiency) or type II (congenital lactase deficiency) (Belmont et al, 2002). Modest hypercalcemia also may occur in acute adrenal insufficiency. The pathogenesis is uncertain. ECMO initiation and prolonged support have been associated with hypercalcemia (greater than 11 mg/dL) (Fridriksson et al, 2001; Hak et al, 2005). The causes appear to be multifactorial.

Treatment

The first principle of the medical management of hypercalcemia is to increase urinary calcium excretion by maximizing glomerular filtration rate (GFR) and urinary sodium excretion. In the normal kidney, sodium and calcium clearances are very closely linked during water or osmotic diuresis. Two-thirds normal to isotonic saline containing 20 to 30 mEq of potassium chloride per liter may be infused intravenously at a rate to correct dehydration and maximize GFR. After rehydration, furosemide (1 mg/kg) may be given intravenously at 6- to 8-hour intervals to inhibit tubular reabsorption of calcium.

When severe hypercalcemia is associated with hypophosphatemia, 30 to 50 mg/kg/day of oral or intravenous phosphorus as a phosphate salt may be given. Unlike sodium, phosphate does not remove calcium from the

body but causes a redistribution of calcium. The goal of phosphate therapy is to maintain serum phosphorus levels in a range of 3 to 5 mg/dL. The oral route is preferable because of the potential for serious complications with intravenous phosphate treatment. Therapy usually results in a significant reduction in serum calcium concentration over 1 to 2 days. In more severe and resistant cases, glucocorticoids (e.g., prednisone, 2 mg/kg per day) may be added. Glucocorticoids suppress intestinal calcium absorption and increase renal excretion. Although glucocorticoids are effective in several types of hypercalcemia, they are relatively ineffective for the treatment of hypercalcemia associated with primary hyperparathyroidism. Clinical experience with use of other antihypercalcemic agents has been limited, although bisphosphonates are assuming an increasing role in management of neonatal hypercalcemia and calcium wasting from bone (e.g., Zeitlin et al, 2003).

The mainstays of the *nonacute* treatment of milder neonatal hypercalcemia are restriction of dietary calcium, elimination of vitamin D supplements, and limiting sunlight exposure.

NEONATAL DISORDERS OF SERUM MAGNESIUM

Neonatal hypomagnesemia is discussed in a preceding section (Neonatal Hypocalcemia Associated with Hypomagnesemia or Renal Tubular Necrosis).

Neonatal hypermagnesemia usually is due to maternal magnesium sulfate administration or magnesium in neonatal parenteral nutrition solutions that exceeds magnesium clearance. Later-onset neonatal hypermagnesemia can result from use of magnesium hydroxide–containing antacids (e.g., "milk of magnesia"). The hypermagnesemic newborn may exhibit varying degrees of flaccidity, unresponsiveness, respiratory insufficiency and apnea, ileus, or delayed passage of meconium. These signs may be mistaken for those of perinatal asphyxia. Occasionally, short-term endotracheal intubation and mechanical ventilation are required. Feedings should be deferred until normalization of bowel function occurs. Prolonged fetal hypermagnesemia also increases the risk of meconium obstruction. Aside from this latter possibility, the neonatal effects of hypermagnesemia are usually transient. Generally, newborns effectively excrete a magnesium load, and serial monitoring of serum levels may not be necessary. However, in preterm newborns, who have limited renal magnesium excretory capacity, hypermagnesemia may persist for more than 48 hours. No magnesium should be added to parenteral nutrition solutions until serum magnesium falls. Early hypermagnesemia in preterm infants also may suppress PTH secretion (Rantonen et al, 2001). Finally, infusion of calcium salts may antagonize some of the adverse effects of excess magnesium.

METABOLIC BONE DISEASE IN NEWBORNS AND INFANTS

Forms of metabolic bone disease manifesting in infants and children are listed in Box 90-3. The following are commonly used definitions:

BOX 90-3 Forms of Metabolic Bone Disease Manifesting in Newborns and Infants

- Vitamin D deficiency
  - Maternal vitamin D deficiency (congenital rickets)
  - Inadequate intake of dietary vitamin D
  - Lack of adequate sunlight exposure + dietary inadequacy
- Vitamin D malabsorption
  - Hepatic disease (steatorrhea)
  - Short bowel syndrome
  - Pancreatic insufficiency
- Vitamin D metabolic defects
  - Hepatic rickets (inadequate vitamin D 25-hydroxylation)
  - Vitamin D-dependent rickets (VDDR1) defects in 1α-hydroxylation
  - Renal insufficiency (renal osteodystrophy)
  - Anticonvulsants [increased 25(OH)D metabolism]
- Vitamin D receptor defects
  - Vitamin D–resistant rickets (VDRR2)
- Phosphate deficiency rickets
  - Osteopathy of prematurity
  - X-linked hypophosphatemic rickets
  - Fanconi's syndrome
  - Antacid-induced osteopathy (aluminum hydroxide)
  - Tumor (including hemangioma)-associated rickets
- Calcium deficiency rickets
  - Osteopathy of prematurity
  - Inadequate intake of dietary calcium after weaning
  - Inadequate calcium in TPN solution

TPN, Total parenteral nutrition; *25(OH)D,* 25-hydroxyvitamin D.

Osteopenia is defined as radiographic evidence of diminished bone density. Osteopenia is present in rickets, osteomalacia, and osteoporosis.

Rickets is a disorder of the bone matrix, or osteoid, in growing bone resulting from undermineralization of cartilage; it involves both the growth plate (physis) and newly formed trabecular and cortical bone. In infancy, the most rapidly growing bones are the skull, upper limbs, and ribs. Early development of rickets, therefore, leads to craniotabes ("ping-pong ball" sign), widened cranial sutures, frontal bossing, swollen epiphyses of wrists, costochondral beading ("rachitic rosary"), and Harrison's sulcus (caused by diaphragmatic depression of the lower thorax on inspiration). The thoracic osteochondrodystrophy increases risk of pneumonia. Manifestations of muscle weakness (myopathy) may include dilated cardiomyopathy and ventricular dysfunction, which respond to vitamin D therapy (Brown et al, 2009). Radiographic features in rickets result from expansion of the cartilaginous growth plate and delayed mineralization. They include lucency and widening of the gap between metaphysis and epiphysis (the zone of provisional calcification), that is, irregularity, cupping, or fraying of the metaphyseal margin and osteopenia. Serum phosphorus or calcium or both characteristically are depressed and serum alkaline phosphatase is elevated. An exception is the hyperphosphatemia of renal osteodystrophy.

Osteomalacia is rickets that occurs in the absence of linear growth. This is the typical pattern in adults, but it also may occur in poorly nourished preterm infants. In osteomalacia, the radiographic features of rickets at the cartilage-shaft junction are generally absent.

Osteoporosis in adults is defined as a state of reduced bone mass per unit volume with a normal ratio of mineral to matrix. Unlike in rickets and osteomalacia, where mineralization defects predominate, the primary abnormality in osteoporosis is either a decrease in matrix formation or an increase in matrix and mineral resorption. There is no generally accepted pediatric definition for osteoporosis.

OSTEOPATHY OF PREMATURITY

In preterm infants, osteopenia with or without rachitic changes at the cartilage-shaft junction usually appears between 3 and 12 weeks of age. This metabolic bone disorder, which remains very common, has also been called "rickets of prematurity" or "osteopenia of prematurity." "Osteopathy" is probably the most accurate term. The incidence and severity increase with decreasing gestational age and birthweight and are more common in preterm infants having a complicated medical course and delayed nutrition. On the other hand, osteopathy usually is not a problem for healthier, larger preterm infants. In VLBW babies, postnatal bone mineralization significantly lags behind the expected intrauterine bone mineralization rate. The pathogenesis involves increased endosteal resorption more than decreased bone formation—that is, it is a high-turnover osteopathy (Beyers et al, 1994).

The clinical findings in VLBW infants having severe osteopathy, as in older, term infants with rickets, include a widened anterior fontanel, craniotabes, bony expansion of wrists, costochondral beading, and rib or long-bone fractures. Rib undermineralization, softening, and fractures can lead to respiratory distress (especially tachypnea), atelectasis, or pneumonia. However, long-term effects of osteopathy of prematurity may include delayed dental maturation (Seow, 1996) and reduced height and bone mineral density in adulthood (Hovi et al, 2009). Bone mineral density later in childhood and adulthood is also probably influenced by polymorphisms in multiple bone regulatory genes.

Although the clinical features of nutritional rickets in term infants and osteopathy of prematurity are similar, the latter has a distinctive pathogenesis. Preterm osteopathy is caused chiefly by deficiencies in dietary phosphate and calcium, rather than by vitamin D deficiency. Eighty percent of bone mineralization in the fetus occurs during the third trimester, when fetal calcium and phosphorus requirements are at least 100 to 120 mg/kg/day and 60 to 75 mg/kg/day, respectively. Low mineral (especially phosphorus)-content diets predispose preterm infants to osteopathy. The greatest risks for phosphate deficiency result from (1) feeding unsupplemented human milk, (2) milk formulas not designed for use in preterm infants, or (3) prolonged parenteral nutrition. Even close attention to nutrition support does not prevent a high prevalence of bone disease in ELBW infants (Mitchell et al, 2009).

Most often, neither hyperparathyroidism nor vitamin D deficiency is present in phosphate-deficient osteopathy of prematurity. In contrast, the pathogenesis of calcium-deficiency rickets and that of vitamin D deficiency are similar in that hypocalcemia causes hyperparathyroidism. The elevated PTH increases bone resorption and enhances renal $1,25(OH)_2D$ synthesis, which, in turn, increases intestinal calcium and phosphorus absorption. Individual preterm babies may have predominant phosphate depletion, but mixed phosphate and calcium deficiency is more common; isolated calcium deficiency is rare. In dual mineral deficiency, laboratory values may show low, normal, or slightly elevated serum calcium and low to low-normal phosphorus. In cases of severe or complicated bone disease, serum 25(OH)D is a useful screen for evaluating sufficiency of vitamin D stores; levels less than 6 ng/mL indicate *severe* vitamin D deficiency. For evaluating bone mineral status in preterm neonates, measurement of bone cortical thickness and visual inspection of the proximal humerus on a chest radiograph are a simple and effective screen (Figure 90-2).

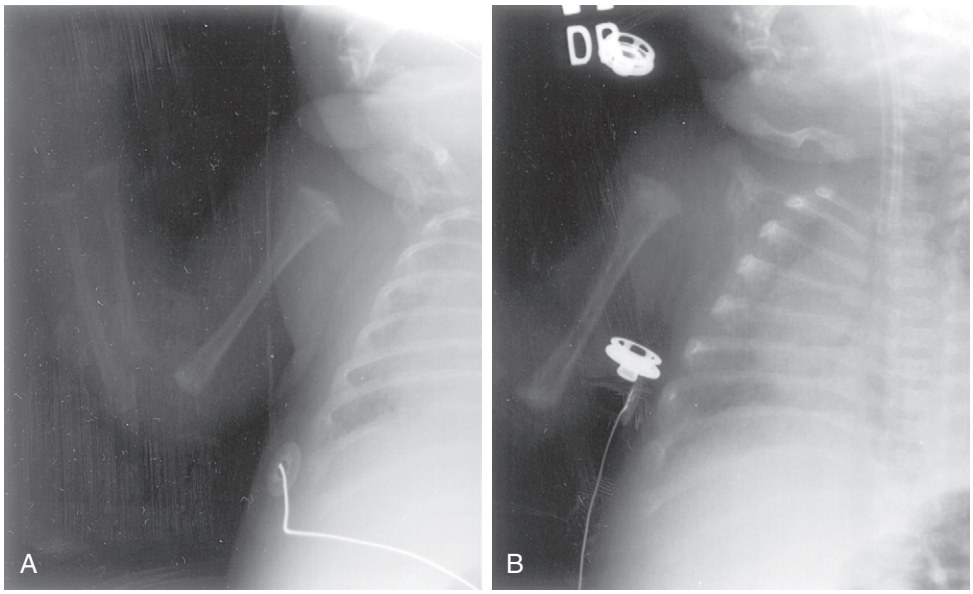

FIGURE 90-2 Chest radiographs from a 700-g-birthweight, 25-week-gestation infant with bronchopulmonary dysplasia and osteopathy of prematurity. **A,** At 34 weeks of postconceptional age, mild osteopenia and metaphyseal changes (especially in right arm and wrist) are evident. **B,** Two weeks later, signs of rachitic healing can be seen in ribs and long bones.

Serum alkaline phosphatase, a marker of osteoblastic bone formation, is frequently used to monitor skeletal metabolism in preterm infants. However, the magnitude of elevations in alkaline phosphatase (or osteocalcin) concentrations is not a good predictor of the extent of bone mineral deficits. Serial urinary biomarkers of bone metabolism (e.g., pyridinoline, deoxypyridinoline) have not yet been shown useful in predicting severe osteopathy, because levels are related to bone volume and normative data for growing preterm infants are lacking. Longitudinal quantitative ultrasound measurement of the speed of sound in long bones, combined with serum bone markers, is a promising assessment tool (Ashmeade et al, 2007). Longitudinal assessment of bone mineral content by dual x-ray absorptiometry is not widely available.

Phosphate depletion and osteopathy occur in rapidly growing preterm infants fed unsupplemented human milk, which has low phosphate content. Characteristically, these infants develop hypophosphatemia, hypophosphaturia, hypercalcemia, and hypercalciuria. Serum PTH may be low or normal, 25(OH)D is normal, and $1,25(OH)_2D$ is elevated. The hypophosphatemia stimulates production of $1,25(OH)_2D$, which in turn increases intestinal calcium absorption. However, in the presence of hypophosphatemia, only limited amounts of calcium can be deposited in bone, leading to hypercalcemia and hypercalciuria. The hypercalcemia inhibits PTH secretion.

This form of osteopathy does not respond to vitamin D therapy unless vitamin D deficiency also is present. In fact, vitamin D supplementation without prior correction of the underlying dietary phosphate deficiency may aggravate hypercalcemia and hypercalciuria by enhancing intestinal calcium absorption. The bone disease in these infants does respond to increased dietary phosphate, accomplished by adding a human milk supplement designed for preterm infants or switching to a preterm milk formula; both diets provide additional calcium as well as phosphorus. Addition of 20 to 25 mg/kg/day of potassium phosphate also will increase serum phosphorus levels. However, because phosphate repletion promotes bone mineralization, serum calcium may fall to subnormal levels ("hungry bones" syndrome) unless supplemental calcium (e.g., 30 mg/kg/day) also is provided. Recommended intakes of calcium and phosphorus (Demarini, 2005) have benefits of improved bone growth, less severe dolichocephaly, and avoidance of fractures. For infants having a history of osteopathy of prematurity, it is important that after hospital discharge a mineral-enriched diet and serial laboratory monitoring be maintained for several weeks to months.

Human milk has a total antirachitic sterol activity of only 25 to 50 IU/L (Reeve et al, 1982), which may be insufficient for maintaining normal 25(OH)D levels in preterm infants. Therefore, preterm infants fed unsupplemented human milk also should receive 400 to 600 IU daily of vitamin D. Current recommendations are that preterm infants who are feeding fortified human milk or standard high-calcium, high-phosphorus preterm formulas also receive vitamin D supplementation of 400 to 600 IU daily.

Additional, nonnutritional risk factors for osteopathy in ill preterm infants are the early withdrawal of placental estradiol and progesterone, lack of mobility, and therapy with dexamethasone, methylxanthines, or aminoglycosides, any of which can increase urinary calcium excretion and contribute to serum mineral imbalance, nephrocalcinosis, and osteopenia. Mechanical stimulation in preterm and term newborns with musculoskeletal problems is becoming an important therapeutic option (Moyer-Mileur et al, 2008). Glucocorticoids decrease bone formation by inhibiting osteoblast growth and increasing cell death of osteoblasts and osteocytes and, at least over several months, increasing osteoclastogenesis and bone resorption. Copper deficiency is a rare contributor to osteopenia in preterm infants (Olivares and Uauy, 1996).

NUTRITIONAL (VITAMIN D DEFICIENCY) RICKETS

Rickets most often occurs in exclusively breastfed infants who also have little exposure to sunlight and are dark-skinned. Historically, a marked rise in prevalence in nutritional rickets has accompanied industrialization and urban crowding. Clinical rickets often manifests at 3 months of age or later, but onset in early infancy is not uncommon. In developed countries, nutritional rickets has never been eradicated, and there is a resurgence of vitamin D deficiency in North America and Europe (Rovner and O'Brien, 2008). As reviewed (see Hypocalcemia Resulting from Vitamin D Deficiency, earlier), maternal vitamin D deficiency during pregnancy and lactation puts the newborn at high risk. There are long-term deleterious effects on musculoskeletal health (Nabulsi et al, 2008). The 2008 American Academy of Pediatrics (AAP) statement for Prevention of Rickets and Vitamin D Deficiency (Wagner et al, 2008) doubles the previous AAP vitamin D intake recommendation. These new guidelines state that breastfed and partially breastfed infants should be supplemented with 400 IU/day of vitamin D beginning in the first few days of life. All infant formulas available in the United States must contain at least 400 IU/L of vitamin D. Consequently, the guidelines also state all nonbreastfed infants who are ingesting less than 1 L/day of formula should receive a vitamin D supplement of 400 IU/day. Higher doses of vitamin D may be necessary for infants having fat malabsorption or those taking anticonvulsant medications. Vitamin D status should be assessed using 25(OH)D and PTH concentrations and measures of bone mineral status. Stoss therapy, which occasionally is used to treat rickets, consists of a single intramuscular large dose (150,000 to 500,000 IU) of vitamin D.

Nutritional rickets worldwide can be due to degrees of vitamin D deficiency or calcium deficiency. Calcium deficiency is the major cause of rickets in Africa and some parts of tropical Asia, but is being recognized increasingly in other parts of the world (Thacher et al, 2006). As a consequence, in tropical populations, rickets may occur later than at higher latitudes, between 1 and 2 years of age, after weaning and with introduction of a low-calcium diet. A recent study showed, for example, that in Turkey most rachitic children had vitamin D deficiency, whereas in Egypt they had mostly calcium insufficiency combined

with vitamin D deficiency (Baroncelli et al, 2008). It is likely that relative deficiencies of calcium and vitamin D interact with genetic (e.g., vitamin D receptor genotypes) and/or environmental factors to stimulate the development of rickets. Therefore, the current North American and European recommendations for vitamin D supplementation may need adjustments for other pediatric populations with limited calcium intake.

Congenital rickets should always prompt an investigation for maternal vitamin D deficiency. Rickets, hypercalciuria, and hypophosphatemia also occur in Fanconi renotubular syndrome. Prolonged treatment with aluminum-containing antacids can induce hypophosphatemia and rickets (Pattaragarn and Alon, 2001). These antacids should be avoided or used with caution during infancy.

RENAL OSTEODYSTROPHY

Because normal renal function is essential for physiologic mineral and bone metabolism, renal insufficiency induces hyperphosphatemia and bone disease. Renal osteodystrophy can be predominantly high or low bone turnover, or the two types may alternate during the clinical course in an individual infant. High bone turnover or osteitis fibrosa is a manifestation of secondary hyperparathyroidism. Parathyroid hyperfunction often occurs early in the course of renal failure. Contributing factors include phosphate retention, impaired renal $1,25(OH)_2D$ synthesis, hypocalcemia, parathyroid gland hyperplasia, and skeletal resistance to PTH actions. Low-turnover osteodystrophy (adynamic bone or osteomalacia) results from suppressed bone formation; it is a major concern in management of dialyzed infants. The relative incidences of renal osteodystrophy in newborns have not been explored.

A principal goal of therapy is to lower serum phosphate in order to prevent hypocalcemia and severe hyperparathyroidism. Phosphate restriction is accomplished with feeding breast milk or Similac PM 60/40. Hypocalcemia and metabolic acidosis should be treated with appropriate supplements. If serum $1,25(OH)_2D$ is low, $1,25(OH)_2D$ therapy will increase intestinal calcium absorption, transcriptionally suppress PTH gene expression, and decrease parathyroid hyperplasia. Serum calcium, phosphorus, and PTH levels, as well as linear growth and bone radiographs, should be serially monitored. Management of severe renal osteodystrophy in neonates is particularly complicated by increased phosphate requirements for growth. Calcium supplementation and use of potent vitamin D metabolites also may produce an "oversuppression" of PTH. As with any complex disorder, effective clinical management requires close monitoring and an integrated team approach.

INHERITED METABOLIC BONE DISEASE IN INFANCY

Several forms of metabolic bone disease or rickets have been described that can present in newborns and infants (DiMeglio and Econs, 2001). Vitamin D–dependent rickets type 1A (VDDR1A) is caused by mutations in the gene encoding 25(OH)D–1α-hydroxylase (CYP27B1). This autosomal recessive disorder is most common in French Canadian kindreds. Muscle weakness and rickets appear shortly after birth. Treatment with 1α-hydroxylated vitamin D analogues induces remission.

Vitamin D–dependent rickets type 2A (VDDR2A) is caused by mutations in the vitamin D receptor (VDR) gene. Affected infants show early-onset rickets, hypocalcemia, elevated serum $1,25(OH)_2D$ levels, secondary hyperparathyroidism, and alopecia. Depending on the genotype, there is a variable response to supraphysiologic doses of $1,25(OH)_2D$ analogues and calcium.

X-linked dominant hypophosphatemia (XLH), also known as familial hypophosphatemic rickets or vitamin D–resistant rickets, is a disorder of phosphate homeostasis. Its prevalence is 1 in 20,000. XLH is characterized by poor linear growth, rickets, and hypophosphatemia associated with a low TmP and renal tubular phosphate leak. Defective regulation of vitamin D metabolism results in inappropriately normal $1,25(OH)_2D$ concentrations in the face of hypophosphatemia. XLH is caused by mutations in the phosphate-regulating endopeptidase homologue, X-linked gene *(PHEX)*. The phenotypes and responses to therapy are highly variable. Autosomal recessive hypophosphatemic rickets (ARHR1 and ARHR2) are caused, respectively, by mutations in the dentin matrix acidic phosphoprotein (DMP1) and ectonucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1) genes that interfere with bone mineralization and renal phosphate handling.

Neonatal rickets with increased bone density rather than osteopenia can occur in infantile osteopetrosis, a rare autosomal recessive disorder of osteoclast formation. Diagnosis may be obscured by concurrent maternal vitamin D deficiency (Popp et al, 2000).

CHAPTER 91

Disorders of the Adrenal Gland

Saroj Nimkarn and Maria I. New

THE ADRENAL GLAND

EMBRYOLOGY

The dual embryologic origin of the human adrenal gland results in two distinct parts of the gland, an outer adrenal cortex and an inner adrenal medulla. Each part secretes different vital hormones; therefore normal adrenal function is critically important for maintenance of intrauterine homeostasis, promotion of organ maturation, and adaptation to extrauterine life. Embryologically, the adrenal cortex develops from the coelomic mesoderm of the urogenital ridge, whereas the medulla arises from neural crest tissue in the adjacent sympathetic ganglion at celiac plexus level. During the 5th week of fetal development, mesothelial cells from the posterior abdominal wall, between the root of the bowel mesentery and developing mesonephros, proliferate and form the primitive adrenal cortex. In the 6th week, a second wave of mesothelial cells surrounds the primitive cortex and later forms the adult or definitive cortex. By 8 weeks' gestation, the cortical mass separates from the rest of mesothelial tissue and becomes surrounded by connective tissue (Sadler, 2000). This separation divides adrenocortical and gonadal primodium (Mesiano and Jaffe, 1997). Chromaffin cells, which originate from neural crest, migrate toward the adrenal cortex around this time and gradually invade the medial aspect of the cortical tissue along its central vein to gain central position, forming the adrenal medulla. However, encapsulation of the adrenal medulla does not occur until late fetal development. Postnatally, the fetal or primitive zone of the adrenal gland rapidly involutes to disappear by approximately 6 months of age (Kempna and Fluck, 2008). Zonation of the cortex, zona glomerulosa, and fasciculata is present at birth, but full differentiation into three separate zones occurs much later, at approximately 3 years of age, when zona reticularis development takes place (Barwick et al, 2005). This chapter focuses on the development, function, and pathophysiology of the steroidogenic adrenal cortex.

MORPHOLOGY

The adrenal glands are bilateral structures, located above the kidneys in the retroperitoneum area. At birth, the adrenals are 10- to 20-fold larger than the adult glands relative to body weight, thereby approximating one third the size of neonatal kidneys (Moore and Persaud, 1998). In late fetal and neonatal phases, the glands predominantly consist of cortex, where active production of glucocorticoids, steroid precursors, estrogens, and progesterone occurs during the third trimester and the first 3 months after birth. Ultrasonographically, the neonatal adrenal gland characteristically has a thin reflective core surrounded by a thick transonic zone. The gland subsequently decreases in size as the active fetal cortex regresses to reach approximately 8% of the kidney size in adulthood (Barwick et al, 2005).

Histologically, the fetal adrenal cortex consists of a small outer definitive zone, which appears to produce few adrenal steroid hormones until late gestation, and a larger inner fetal zone that produces adrenal steroid hormones throughout gestation. In addition, there is a transitional zone where cortisol production takes place toward the end of fetal development (Mesiano and Jaffe, 1997). At birth, the large fetal zone of the fetal adrenal involutes and disappears by 6 months of age. Concurrently, the definitive zone together with the transitional zone develops into the fully differentiated zona glomerulosa and fasciculata by the age of 3 years. The zona reticularis begins to develop only after 4 years of age and may not be fully differentiated before the age of 15 years. In an adult adrenal gland, these three distinctive zones lie adjacent to one another. The zona glomerulosa is located immediately below the capsule, the zona fasciculata being in the middle, and the innermost zone next to the medulla is the zona reticularis.

FETAL AND ADULT ADRENAL FUNCTIONS

A cascade of adrenal steroidogenesis in adult is shown in Figure 91-1. Three major pathways of mineralocorticoid, glucocorticoid, and androgen synthesis take place mainly in the glomerulosa, fasciculata, and reticularis zones of the cortex, respectively. Aldosterone is the main mineralocorticoid regulating sodium and fluid volume homeostasis; it is under the control of the renin-angiotensin system and blood potassium concentrations (Kuhnle et al, 1981). The prinicipal glucocorticoid in humans is cortisol, with a wide range of roles in regulating body functions, from carbohydrate metabolism, immune system, and acute and chronic stress response to musculoskeletal metabolism. Cortisol production is regulated through a negative feedback loop involving hypothalamic corticotropin-releasing hormone (CRH) and pituitary adrenocorticotropic hormone (ACTH) (New and Wilson, 1999). Adrenal androgens have an age-specific secretion profile from adrenarche around the time of puberty and a gradual decrease with aging until andropause (Orentreich et al, 1984). The regulatory mechanism behind normal adrenal androgen production is largely unknown, but involves ACTH to some extent (Hanley and Arlt, 2006).

In the fetal adrenal gland, steroidogenic enzymes are found as early as 7 weeks' gestation (Goto et al, 2006; Hanley and Arlt, 2006). At 8 weeks' gestation, the fetal adrenal gland produces cortisol under ACTH control. A transient expression of 3β-hydroxysteroid dehydrogenase type 2 (3β-HSD2) during this critical time from 7 to 12 weeks' gestation allows the fetal adrenal gland to produce cortisol. Activation of 3β-HSD2 serves principally to prevent

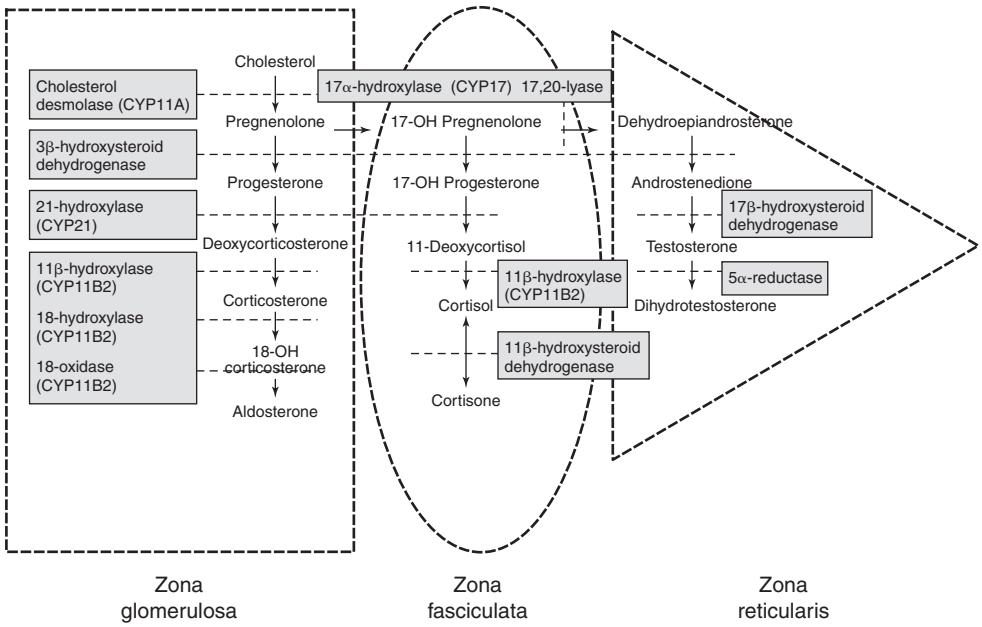

FIGURE 91-1 Steroidogenesis of the adult adrenal gland. Each of the three biosynthetic pathways take place in different zones: aldosterone biosynthesis in zona glomerulosa, cortisol biosynthesis in zona fasciculata, and androgen production in zona reticularis. The enzymes that catalyze the reactions are indicated in *boxes*.

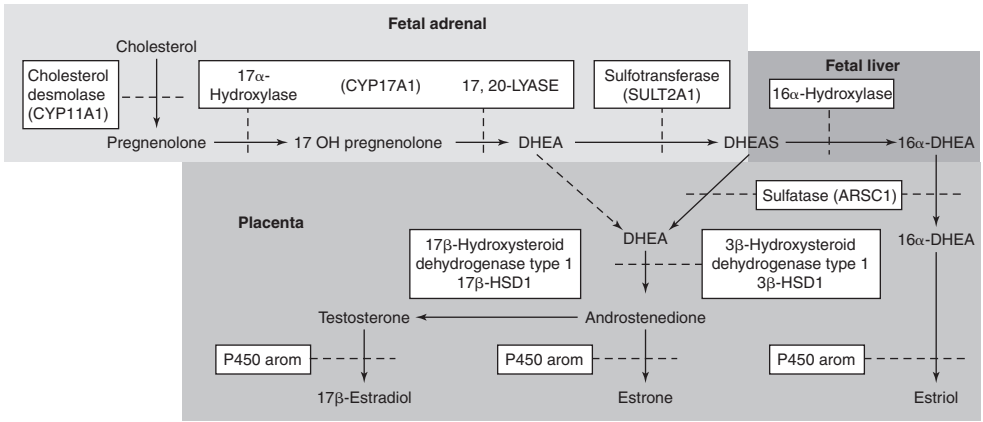

FIGURE 91-2 Steroidogenesis of the fetal adrenal gland and fetoplacental unit. Predominant DHEA and DHEAS production occurs after 12 weeks' gestation.

virilization of the female genital enlage because of overwhelming amounts of DHEAS and its downstream androgen metabolites. It is believed that a transient peak of cortisol during this time suppresses the fetal hypothalamic-pituitary-adrenal (HPA) axis, keeping DHEAS production at a low level (Goto et al, 2006; White, 2006). By the end of the first trimester, cortisol secretion from the fetal adrenal gland begins to wane as a result of decrease in 3β-HSD2 expression, thus decreasing HPA axis suppression with resultant increased DHEAS secretion. During the second and third trimesters, the fetal adrenal gland secretes abundant amounts of DHEA and its sulfated derivative DHEAS, earning the term *androgen factory* (Kempna and Fluck, 2008). The rate of steroid secretion by the fetal adrenal glands may be fivefold that of the adult adrenal glands at rest (Carr and Simpson, 1981). Placenta can also convert DHEAS back to DHEA by a sulfatase enzyme (i.e., arylsulfatase). These adrenal steroids serve as precursors for P450C17 and 17,20 lyase enzymes for androgen production and subsequent estrogen production (Figure 91-2). In addition, DHEAS is oxidized in the fetal liver to a 16α-hydroxylated derivative, which is converted by the placenta to estriol by the same set of enzymes as in estradiol synthesis.

The physiology of human pregnancy involves a continuous supply of relatively increased amount of estrogens. In near term human pregnancy, the rate of estrogen production increases strikingly, reaching concentrations 1000-fold greater than that of nonpregnant women (Carr and Simpson, 1981). During early gestation, the estradiol required to maintain pregnancy is provided by the corpus luteum of the maternal ovary. But after 8 weeks' gestation, most of the estradiol is synthesized by the fetoplacental unit (Simpson and MacDonald, 1981).

As mentioned earlier, DHEAS is the main steroid secreted by the fetal adrenal cortex from mid-gestation onward. The activity of 3β-HSD2 controls the fetal cortisol

synthesis. By the end of pregancy, fetal cortisol is required in preparation for parturition (i.e., lung maturation or surfactant production) and could have a role in triggering parturition, as shown in other species (Gross et al, 2000). Maternal cortisol cannot normally reach the fetus because it is oxidized to cortisone, an inactive steroid, by placental 11β-hydroxysteroid dehydrogenase type 2 (Wilson et al, 2001). When pregnancy approaches term, *HSD3B2* expression increases again and remains high, allowing increased cortisol secretion. In a child, 3β-HSD2 secretion is high in the adrenal gland until adrenarche, when 3β-HSD2 activity decreases again to allow an increase in DHEA (Gell et al, 1998) and its downstream androgen metabolite secretion, which gives rise to the development of pubic and axillary hair.

CONTROL OF GLUCOCORTICOID AND MINERALOCORTICOID PRODUCTION

Two distinct regulatory circuits control adrenal glucocorticoid and mineralocorticoid secretion. The HPA axis determines the set point for circulating glucocorticoid (cortisol) concentration. The neuropeptide CRH and arginine vasopressin are synthesized in the hypothalamic paraventricular nucleus and released into the hypophysial portal circulation at the median eminence in response to stress (Aguilera, 1994) and, beginning at approximately 6 months of age, to circadian cues (Onishi et al, 1983). These neuropeptides stimulate the release of ACTH from the anterior pituitary corticotrophs. ACTH released into the systemic circulation augments adrenocortical secretion of DHEA and cortisol by acting on the ACTH receptor (Clark and Cammas, 1996), a member of the melanocortin receptor family. The ACTH receptor is present on steroidogenic cells of the fetal zone and transitional zone of the fetal adrenal as well as the adult adrenal cortex. The resulting increase in plasma cortisol concentration limits further release of hypothalamic neuropeptides and ACTH by negative feedback through glucocorticoid receptors at the central nervous system and pituitary sites. As a corollary, if glucocorticoid production is impaired by intrinsic adrenal dysfunction, then neuropeptide and ACTH release are augmented.

The components of the HPA axis are present early in human development (Mesiano and Jaffe, 1997). As detailed earlier, the fetal adrenal gland begins to develop at 4 weeks' gestation, when initial evagination of the pituitary primordium occurs (Conklin, 1968). ACTH-producing pituitary cells can be detected at 7 weeks' gestation, and an intact hypophysial portal vascular system is present by 12 weeks' gestation (Baker and Jaffe, 1975; Thliveris and Currie, 1980). Nerve terminals containing CRH can be detected in the hypothalamus by approximately 16 weeks' gestation. Virilization caused by increased production of adrenal androgens in females with congenital adrenal hyperplasia occurs before 12 weeks' gestation; therefore ACTH-producing corticotrophs must undergo cortisol-mediated feedback modulation at the initial stages of hypothalamic-pituitary development (White, 2006).

Mineralocorticoid (aldosterone) release by the zona glomerulosa of the adrenal cortex is determined by the renin-angiotensin system, with acute modulation to a lower extent by ACTH as well (Dzau, 1988). Decreases in vascular volume result in increased secretion of renin by the renal juxtaglomerular apparatus. Renin, a proteolytic enzyme, cleaves angiotensinogen to angiotensin I. Angiotensin I is then cleaved and activated by angiotensin-converting enzyme in the lung and other peripheral sites to angiotensin II. Angiotensin II and its metabolite angiotensin III possess vasopressor and potent aldosterone secretory activity. Although angiotensin II receptors are present on cells of the definitive zone at 16 weeks' gestation, significant aldosterone production by the fetal adrenal gland does not occur until the third trimester of pregnancy (Mesiano and Jaffe, 1997).

MOLECULAR BASIS OF ADRENAL DEVELOPMENT

Several transcription factors are critically important for normal adrenal development. Two related transcription factors have emerged as key regulators of adrenal development: the nuclear receptors DAX1 (dosage-sensitive sex reversal, adrenal hypoplasia congenita [AHC], critical region on the X chromosome, gene-1, NR0B1/*AHC*) and steroidogenic factor-1 (SF1, *NR5A1*, also known as Ad4BP). SF1 knockout mice lack adrenal glands and gonads, and subsequent identification of SF1 mutations in humans with adrenal insufficiency confirms the essential role of SF1 in development (Parker, 1998). SF1 expression is found in the early urogenital ridge of the mouse in cells that give rise to both the bipotential gonad and adrenal cortex. Expression of SF1 remains high throughout embryogenesis, the postnatal period, and adult life (Parker, 1998).

DAX1 (dosage-sensitive sex reversal–adrenal hypoplasia congenita critical region on the X chromosome) is an orphan nuclear receptor that colocalizes with SF1 in the cells of adrenal glands, gonads, gonadotropes, and ventral-medial lateral nucleus of the hypothalamus. Deletion of DAX1 results in adrenal hypoplasia congenita. Although the exact role of DAX1 in adrenal development is not known, it has been shown to interact with SF1 (Ikeda et al, 2001). Normally, DAX1 recruits the nuclear corepressor N-CoR to SF1 and represses SF1 (Crawford et al, 1998)

Similarly, the WT1 (Wilms' tumor gene) protein has been shown to interact with SF1. *WT1* encodes 24 different protein isoforms that act as transcription factors. WT1 is detected in the urogenital ridge of the mouse embryo, but is not detected in adult or fetal adrenals. Mutations in *WT1* have resulted in abnormal development of the adrenal in the mouse, but have not been clearly correlated with abnormal human adrenal development (Vidal and Schedl, 2000).

ASSESSING ADRENAL FUNCTION IN THE NEWBORN

Significant evolution of adrenal steroid production occurs over the first days and months of life as the adrenal cortex plays a major role in the newborn infant's postnatal adaptation. During interpretation of the newborn adrenal steroidogenic function, special attention must be paid to age-related changes in adrenal steroid intermediates,

circulating cortisol, and aldosterone concentrations that reflect ongoing adrenal maturation (Lashansky et al, 1991; Sippell et al, 1978, 1980). For example, until at least 1 month postnatally, a large proportion of cortisol and its metabolites are excreted as sulfate esters. This sulfation may serve to inactivate a number of circulating cortisol metabolites during fetal and neonatal life (Ducharme et al, 1970).

As mentioned previously, immediately after birth the third-trimester fetal zone that once was the predominant component of the adrenal cortex in the fetus and preferentially produced DHEA and DHEAS, starts to reduce in size. This rapid loss of the fetal zone during this period results in a dramatic fall of the circulating DHEA concentration over the 1st week to 1 month postnatally. The variable pattern of decline in the ensuing weeks probably reflects variation in remodeling of the fetal zone and emergence of the zona fasciculata of the definitive zone, the latter being feature of an adult cortex. In addition to diminished 3β-HSD2 activity, preterm infants have sustained elevations in 17-hydroxyprogesterone and the 17-hydroxyprogesterone-to-cortisol ratio, suggesting a reduction in 21-hydroxylase activity (al Saedi et al, 1995; Lee et al, 1989). Because blood-spot 17-hydroxyprogesterone concentration is used for newborn screening of congenital adrenal hyperplasia (CAH) in many states (White, 2009), many preterm infants initially have an abnormal test result. Subsequent follow-up testing is then required to determine whether CAH is present. Plasma aldosterone concentrations tend to be higher in preterm infants than in term infants, both of which in turn are higher than in older children and adults (Doerr et al, 1988; Kotchen et al, 1972).

Cortisol has a critical role in maintaining homeostasis in response to stress. Relative adrenal insufficiency occurs when the hypothalamic-pituitary-adrenal axis produces less than adequate cortisol for the degree of illness or stress. Immaturity of the adrenal gland and the HPA axis of the premature newborn infant suggests a rationale for why preterm infants are at increased risk of cortisol insufficiency (Fernandez and Watterberg, 2009). Clinicians are commonly faced with critically ill infants who have cardiovascular insufficiency with hypotension, a condition that has also been associated with adverse consequences. The question often arises as to whether these manifestations reflect underlying glucocorticoid insufficiency. There is increasing evidence that relative adrenal insufficiency may be a cause of hemodynamic instability and hypotension in the crticially ill newborn, but there is definitely a paucity of data in this population.

Random plasma cortisol measurement is often inadequate to answer this question, because the majority of critically ill newborns have low cortisol and ACTH values, without the expected increase in response to critical illness. However, response to exogenous ACTH (cosyntropin) is usually normal, suggesting that the inadquate response to critical illness in these newborns does not result from adrenal dysfunction, but arises from some other components of the HPA axis (Fernandez et al, 2008). Interestingly, in extremely low-birthweight infants (500 to 999 g) low cortisol concentrations were not predictive of adverse short-term mortality and morbidity. In contrast, high basal cortisols were associated with severe intraventricular hemorrhage, and extremely elevated values were associated with morbidity and death (Aucott et al, 2008).

Data associating treatment of adrenal insufficiency with outcomes in the term newborn are limited, and there have been no studies on outcomes beyond the immediate neonatal period. Nonetheless, no adverse events have been attributed to glucocorticoid treatment based on a relatively small number of study subjects. A multicenter, randomized trial of hydrocortisone treatment for prophylaxis of relative adrenal insufficiency is currently underway (Aucott et al, 2008). Currently there is insufficient evidence to support the routine use of glucocorticoids in critically ill newborns. On encountering an infant with vasopressor-resistant hypotension, accompanied by signs of cardiac hypofunction, the clinician must consider the risk-to-benefit ratio before arriving at the appropiate management. Therapeutic trials with hydrocortisone at the dose of 1 mg per kilogram of body weight have been suggested (Fernandez and Watterberg, 2009) and can be discontinued if there is no clinical improvement or if the pretreatment cortisol level is later observed to be greater than 15 μg/dL. Special attention should be paid to the premature newborn who concurrently is receiving indomethacin, because this combination is associated with spontaneous gastrointestinal perforation (Peltoniemi et al, 2005).

PRIMARY ADRENAL DISORDERS

STEROIDOGENIC DEFECTS CAUSED BY ADRENAL ENZYME DEFICIENCY

Congenital adrenal hyperplasia refers to a family of inherited disorders in which defects occur in one of the enzymatic steps required to synthesize cortisol from cholesterol in the adrenal gland; therefore impaired cortisol synthesis is the cornerstone shared by all forms of CAH. The pathway of steroidogenesis in the adrenal cortex is illustrated in Figure 91-1. Five forms of CAH with autosomal recessive mode of inheritance are summarized in this section.

Disorders That Lead to Virilization in Females

21-Hydroxylase Deficiency

Pathophysiology

In 21-hydroxylase deficiency (21-OHD), responsible for 90% to 95% of all CAH cases, the conversion of 17α-hydroxyprogesterone (17-OHP), the main substrate of the 21-hydroxylase enzyme, to 11-deoxycortisol in the pathway of cortisol synthesis is impaired and precursors are shunted through the androgen pathway. The enzyme defect also impairs the conversion of progesterone to aldosterone, causing abnormal salt loss (New and Seaman, 1970; New et al, 1966). There are two forms of classic 21-OHD: simple virilizing and salt wasting, distinguished by the adrenal gland's ability to produce adequate aldosterone. In both forms, severe 21-OHD results in elevated levels of adrenal androgens that cause ambiguous genitalia in the genetic female fetus. Diagnosis is made by the detection of extremely high concentrations of basal and stimulated 17-OHP after performing

an ACTH stimulation test. The diagnosis is confirmed by molecular genetic analysis of the *CYP21* gene.

Clinical Signs and Symptoms

Females with simple virilizing CAH can be diagnosed at birth immediately because of the apparent genital ambiguity (Prader, 1958). For newborn males, however, differentiation of the external genitalia is not affected, because the main source of testosterone is the testes and not the adrenal gland. Postnatally, genitalia may continue to virilize because of an excess of adrenal androgens, and pseudoprecocious puberty can occur. In affected adolescent females, signs of hyperandrogenism include facial, axillary, and pubic hair, adult body odor, temporal balding, severe acne, irregular menses, and reduced fertility. Poor control of adrenal androgens in males has been associated with small testes, infertility, and short stature. Infertility occurs because the excess androgens are aromatized peripherally to estrogens, which suppress pituitary gonadotropins and function of the gonads. The high estrogens also advance bone age. The high levels of androgens can also accelerate growth in early childhood, producing an unusually tall and muscular child. Thus, the patients are tall children but short adults. The salt-wasting phenotype, which occurs in approximately 75% of CAH cases (New and White, 1995), is biochemically distinct from the simple virilizing form because of a deficiency of aldosterone, the salt-retaining hormone (New et al, 1966; Nimkarn et al, 2007). Resulting hyponatremia, hyperkalemia, high plasma renin activity, and fluid volume depletion are potentially fatal.

Epidemiology

Newborn screening worldwide of almost 6.5 million babies has demonstrated an overall incidence of 1:15,000 live births for the classic form of 21 OHD (Pang and Clark, 1990, 1993; Pang et al, 1988). The incidence of classic CAH in either homogeneous or heterogeneous general populations is as high as 1 case per 7500 live births (Speiser et al, 1985).

Molecular Genetics

Hormonally and clinically defined forms of 21 OHD CAH are associated with distinct genotypes characterized by varying enzyme activity demonstrated by in vitro expression studies. The gene encoding 21 hydroxylase is a microsomal cytochrome P450, family 21, subfamily A, polypeptide 21 *(CYP21A2)* located on the short arm of chromosome 6, within the human leukocyte antigen complex (Dupont et al, 1977; Nebert et al, 1991). *CYP21A2* and its homolog the pseudogene *CYP21A1P* alternate with two genes, *C4B* and *C4A*, that encode two isoforms of the fourth component of the serum complement system (White et al, 1986). More than 100 mutations have been described to date. These mutations include point mutations, small deletions, small insertions, and complex rearrangements of the gene (Stenson et al, 2003). The most common mutations appear to be the result of two types of meiotic recombination between *CYP21A2* and *CYP21A1P:* (1) misalignment and unequal crossing over, resulting in large-scale DNA deletions, and (2) apparent gene conversion events that result in the transfer to *CYP21A2* of smaller-scale deleterious mutations present in the *CYP21A1P* pseudogene. It is not always possible to accurately predict the phenotype on the basis of the genotype; such predictions have been shown to be 79% to 88% accurate (Speiser et al, 1992; Wedell et al, 1992; Wilson et al, 1995) with some nonconcordance. Studies have demonstrated that there is often a divergence in phenotypes within mutation-identical groups, the reason for which requires further investigation (Chemaitilly et al, 2005; Krone et al, 2000).

Management Issues

Hormonal replacement therapy with corticosteroids is used to correct the deficiency in cortisol secretion, which will in turn suppress ACTH overproduction and subsequent stimulation of the androgen pathway (New and Wilson, 1999). Thus, further virilization is prevented, allowing normal growth and onset of puberty. The dose of cortisol required is usually 15 to 20 mg/m^2/day divided into two to three doses per day (Clayton et al, 2002; New et al, 2006). It is important that the appropriate balance must be maintained to avoid hypercortisolism, which can result in Cushing's syndrome and suppression of linear growth. Attempts to suppress 17OHP levels to normal will inevitably result in iatrogenic Cushing's syndrome. Hormonal control can be difficult to achieve in many cases, and adrenalectomy may be offered as an alternative therapeutic option in select patients (Gmyrek et al, 2002; New, 1996; Van Wyk et al, 1996). Patients with salt-losing CAH have elevated plasma renin activity and require mineralocorticoid replacement with 0.05 to 0.2 mg per day of fludrocortisone. In infancy, patients also require oral salt supplement as in other forms of primary adrenal insufficiency. Because females with classic 21 OHD CAH are born with ambiguous genitalia caused by the production of excess androgens in utero, corrective surgery is contemplated. However, before surgical correction is considered as a form of treatment in patients with ambiguous genitalia, consultation with the patient's parents, psychoendocrinologists, pediatric endocrinologists, and pediatric urologists is essential. Prevention of antenatal virilization in affected females is possible with proper prenatal diagnosis and treatment program. The disease can be diagnosed prenatally through molecular genetic analysis of fetal DNA. Appropiate prenatal treatment by dexamethasone administration before the 9 weeks' gestation to the pregnant mother carrying an at-risk fetus is effective in reducing virilization in the genetic female, making postnatal genitoplasty unnecessary and thereby avoiding potential impairment of sexual function. After diagnosis is made by fetal DNA analysis obtained from chorionic villus sampling at 8 to 12 weeks' gestation, therapy in unaffected or male fetuses is discontinued (Nimkarn and New, 2006). There are accurate, compelling data from the largest human studies (Forest et al, 1989; Mercado et al, 1995; New et al, 2001) indicating the benefit of prenatal treatment and that it is safe in the short term for both the fetus and the mother. Preliminary data from long-term studies also support these results (Nimkarn and New, 2009), although long-term follow-up studies are still underway.

11β-Hydroxylase Deficiency

Pathophysiology

The 11β-hydroxylase deficiency (11β-OHD) form of congenital adrenal hyperplasia represents 5% to 8% of all cases in the general population (White et al, 1994).

Deficiency of this enzyme results in an accumulation of 11-deoxysteroid precursors, which are shunted into the androgen pathway. Excess adrenal androgen secretion results in ambiguous genitalia in the affected female fetus. Hypertension in patients with this disorder is commonly attributed to deoxycorticosterone (DOC)-induced sodium retention (Nimkarn and New, 2008b). The hallmark serum abnormality in patients with 11β-OHD is suppressed renin, because hypokalemia is not uniformly present in all cases. Diagnosis is made by extremely high basal and stimulated levels of DOC and compound S after performing an ACTH stimulation test. The diagnosis can be confirmed by molecular genetic analysis of the *CYP11B1* gene.

Clinical Signs and Symptoms

Hypertension occurs in approximately two thirds of patients with 11β-OHD and distinguishes 11β-OHD from the more common 21 OHD in cases of virilizing CAH (Nimkarn and New, 2008b; Rosler et al, 1982). However, hypertension correlates variably with the presence of hypokalemia or with the extent of virilization (Rosler et al, 1982). Patients can present with or without hypokalemic alkalosis. It is usually not identified until later in childhood or in adolescence, although its appearance in early childhood has been documented. A patient was positively identified by the newborn screening program aiming for 21 OHD CAH (Peter et al, 2008).

Epidemiology

Classic 11β-OHD CAH occurs in approximately 1 in 100,000 births in the general white population (Zachmann et al, 1983). A large number of cases have been reported in Israel, where the incidence was estimated to be 1 in 5000 to 1 in 7000 births, with a gene frequency of 1 in 71 to 1 in 83. Subsequent study showed that 11β-OHD CAH occurred in a lower frequency (Paperna et al, 2005), yet remains more common in this population than in others. This unexpected clustering of cases was traced to Jewish families of North African origin, particularly from Morocco and Tunisia (Rosler et al, 1992).

Molecular Genetics

Two 11β-hydroxylase genes have been identified within the human adrenal cortex, each encoding for a different enzyme with distinct enzymatic ability. The two genes *CYP11B1* and *CYP11B2* are located 30 to 40 kilobases apart on chromosome 8q (Chua et al, 1987; Taymans et al, 1998). Although gene conversions occur between *CYP11B1* and *CYP11B2* (Merke et al, 1998; Mulatero et al, 1998), the majority of the mutations found in *CYP11B1* are random point mutations (Curnow et al, 1993; Rosler et al, 1982; White et al, 1991; Zachmann et al, 1983), unlike what was found in 21 OHD CAH. To date, approximately 41 mutations in *CYP11B1* from individuals of diverse ethnic backgrounds have been identified (Krawczak and Cooper, 2003).

Management Issues

Similar to 21-OHD CAH, glucocorticoid therapy is the most effective means of regaining hormonal control in patients with 11β-OHD. Corticosteroids at the same dose range as for 21-OHD CAH provide feedback inhibition of ACTH, reduce stimulation of the androgen pathway, and allow normal growth and the onset of puberty. Treatment with corticosteroids also contributes to the reduction of DOC and thus controls hypertension. Through careful clinical monitoring, doses can be continuously adjusted to match patients' needs while avoiding suppression of linear growth caused by overdosing. In addition to hormonal therapy, reduced salt intake is often used to reduce fluid volume and hypertension. Maintaining fluid balance in children, however, is often difficult and poses an ongoing challenge to treatment. Affected females suffer from genital ambiguity and may require genital reconstructive surgery after multidisciplinary consultations. To prevent antenatal virilization, a similar protocol to 21 OHD CAH for prenatal diagnosis and treatment can be performed (Cerame et al, 1999).

Disorders That Lead to Undervirilized Males

17-Hydroxylase (CYP 17) Deficiency

Pathophysiology

This form of CAH involves an enzyme that catalyzes more than one reaction—namely both the 17α-hydroxylation and 17,20-lyase reactions—and both reactions are commonly impaired in the disorder. Affected individuals cannot produce cortisol but synthesize large amounts of corticosterone (a weak glucocorticoid that mitigates the adrenal insufficiency) and deoxycorticosteroid, which causes hypertension and hypokalemia. Deficiency of 17,20-lyase impairs the ability to synthesize androgens and estrogens and cause male pseudohermaphroditism, the new term being 46,XY disorder of sex development (DSD) (Hughes et al, 2006), at birth and results in failure to virilize at puberty. Affected females have primary amenorrhea and clinical hypogonadism (Auchus, 2001; Yanase et al, 1991).

Clinical Features

The typical features of complete deficiency include hypertension and hypokalemia with associated sexual infantilism in genetic females and pseudohermaphroditism and sexual infantilism in genetic males. Nevertheless, there is considerable variability in the clinical and biochemical features, including a few mutations that cause isolated 17,20-lyase deficiency (Auchus, 2001). The age of onset of hypertension and the severity of hypokalemia are highly variable, even among individuals with the same mutations (Costa-Santos et al, 2004). Sexual infantilism is more consistent.

Epidemiology

This disorder has an estimated frequency in most countries of approximately 1 case per 50,000 newborns and accounts worldwide for approximately 1% of all cases of congenital adrenal hyperplasia (Yanase et al, 1991). However, CYP17 deficiency is the second most common cause of CAH in Brazil (Costa-Santos et al, 2004; Santos et al, 1998), and this remarkable frequency is the result of two founder effects in areas with high coefficients of inbreeding so that two mutations account for more than 80% of cases in that country (Costa-Santos et al, 2004).

Molecular Genetics

Since the cloning of the gene (Picado-Leonard and Miller, 1987) nearly 50 different mutations have been described in *CYP17* (Krawczak and Cooper, 1997). Founder effects probably explain the high incidence of the disease in other patient populations in the Netherlands and Japan (Costa-Santos et al, 2004). Severity of disease tends to be milder with mutations that retain partial catalytic activity, but the nature of the variability in hypertension and hypokalemia is unclear.

Management Issues

Adequate glucocorticoid administration suppresses ACTH and the excessive mineralocorticoid secretion and generally normalizes the blood pressure. Adult females and males reared as females require estrogen therapy. Abdominal testes should be removed because of the risk of malignancy. Adult genetic males reared as males need surgical correction of the external genitalia and androgen replacement.

3β-Hydroxysteroid Dehydrogenase Type II Deficiency

Pathophysiology

3β-Hydroxysteroid dehydrogenase converts 3β-hydroxy $^{5}\Delta$steroids to 3-keto $^{4}\Delta$ steroids and is essential for the biosynthesis of mineralocorticoids, glucocorticoids, and sex steroids (Mebarki et al, 1995). Two forms of the enzyme have been described in humans: type 1 enzyme expressed in placenta and skin, and type 2 expressed in adrenal glands and gonads. The type 1 and 2 genes are known to be closely linked on chromosomal region 1p13.1. The two forms are closely related in structure and substrate specificity, although the type 1 enzyme has higher substrate affinity and a fivefold greater enzymatic activity than for type 2 (Simard et al, 2005).

Clinical Signs and Symptoms

3β-HSD2 enzyme is essential for the formation of progesterone, the precursor for aldosterone, 17-OHP, the precursor for cortisol in the adrenal cortex, androstenedione, testosterone, and estrogen. Simultaneous 3β-HSD2 deficiency in both gonads and adrenal glands result in incomplete virilization of the external genitalia in males. Male patients with 3β-HSD2 deficiency present with ambiguous external genitalia, characterized by micropenis, perineal hypospadias, bifid scrotum, and blind vaginal pouch (Simard et al, 1994) with or without salt loss (Mebarki et al, 1995). Gynecomastia is common at pubertal stage in affected males. In females, virilization of external genitalia occurs as a result of the androgen effect from the peripheral conversion of circulating $^{5}\Delta$ precursors to active $^{4}\Delta$ steroids; therefore genital ambiguity can result in both sexes. Clinical presentations also include salt wasting crisis, premature pubic hair development, hirsutism, and menstrual disorders (Lutfallah et al, 2002).

Epidemiology

The exact frequency of this rare disorder remains unknown.

Molecular Genetics

The disorder has an autosomal recessive inheritance. *HSD3B2* is the gene responsible for 3β-HSD2 deficiency CAH. There are approximately 40 mutations in the *HSD3B2* gene already described (Krawczak and Cooper, 2003). Mutations that lead to the abolition of 3β-HSD2 activity lead to the salt-wasting form (Alos et al, 2000; Chang et al, 1993; Lutfallah et al, 2002; Rheaume et al, 1992). Mutations that reduce but do not abolish type II activity lead to CAH with mild or no salt loss, which in males is associated with pseudohermaphroditism (46,XY DSD) as a result of the reduction in androgen synthesis (Lutfallah et al, 2002). Mild mutations were also associated with hyperandrogenic symptoms of premature pubic hair development and hirsutism (Mermejo et al, 2005; Pang et al, 2002).

Management Issues

Similar to other forms of CAH, corticosteroid is the mainstay therapy. Salt-wasting phenotypes in some patients can be managed the same way as the salt-wasting form of 21 OHD CAH. Male patients with 3β-HSD2 deficiency have ambiguous external genitalia. Although most males are raised as males and retain the male social sex at puberty (Mendonca et al, 2008), gender identity is an important management issue. In one Brazilian family, two cousins with 46,XY DSD caused by 3β-HSD2 deficiency were reared as females; one of them was castrated in childhood and retained the female social sex; the other was not castrated in childhood and changed to male social sex at puberty (Mendonca et al, 1987).

Male patients may require testosterone replacement therapy during puberty and adulthood. The aim of the surgical treatment in this condition is to allow development of adequate external genitalia and remove internal structures that are inappropriate for the social sex. Patients must undergo surgical sex reversal procedure preferably before 2 years of age, which is the time when the child becomes aware of his or her genitals and social sex. Only skilled surgeons with specific training in the surgery of DSD should perform these procedures (Hughes et al, 2006).

Lipoid Congenital Adrenal Hyperplasia

Lipoid CAH is a severe form of congenital adrenal insufficiency. Affected patients exhibit glucocorticoid and mineralocorticoid deficiencies early in life, and males exhibit undervirilization. The reduced synthesis of steroids in patients with lipoid CAH results from an inability to transfer cholesterol to the inner mitochondrial membrane where the cholesterol side-chain cleavage complex is located (Lin et al, 1995). It is characterized by lipid droplet accumulation in the cytoplasm of the adrenocortical cells. Most cases of lipoid CAH are caused by recessive mutations in the gene encoding steroidogenic acute regulatory protein (StAR). StAR locus is in the 8p11.2 region and is a protein with an essential role in cholesterol transfer from the outer to the inner mitochondrial membrane, thus providing the substrate for steroid hormone biosynthesis (Bose et al, 1996). Once in the mitochondria, cholesterol is converted to pregnenolone by the cytochrome P450 side-chain cleavage (CYP11A1) enzyme, and then steroid biosynthesis is initiated. Karyotypic 46,XY persons are phenotypically female because of Leydig cell destruction and impaired testosterone production. The ovary in XX subjects is initially spared damage because steroidogenesis is delayed until the time of puberty, after which stimulation of steroidogenesis by the

tropic hormones (i.e., luteinizing and follicle-stimulating hormones) causes progressive damage to the ovary (Fujieda et al, 1997). StAR mutations have been described most frequently in Japanese and Palestinian populations, in part because certain mutations occur repeatedly, probably reflecting a founder effect (Bose et al, 1996; Nakae et al, 1997). Although less common than mutations in StAR, mutations in CYP11A1 can also cause lipoid CAH (Hiort et al, 2005; Katsumata et al, 2002).

Rare Form of Congenital Adrenal Hyperplasia With Variable Phenotypes

Cytochrome P450 oxidoreductase deficiency is a disorder of steroidogenesis with a phenotypic spectrum ranging from cortisol deficiency at the milder end to classic Antley-Bixler syndrome (ABS) at the severe end, and the phenotype of cortisol deficiency can range from clinically insignificant to life threatening. Manifestations can include ambiguous genitalia in both males and females, primary amenorrhea and enlarged cystic ovaries in females, poor masculinization during puberty in males, and maternal virilization during pregnancy if the fetus is affected. Manifestations of Antley-Bixler syndrome include craniosynostosis; hydrocephalus; distinctive facies; choanal stenosis or atresia; low-set, dysplastic ears with stenotic external auditory canals; skeletal anomalies (radiohumeral synostosis, neonatal fractures, congenital bowing of the long bones, joint contractures, arachnodactyly, clubfeet); renal anomalies (ectopic kidneys, duplication of kidneys, renal hypoplasia, horseshoe kidney, hydronephrosis); and reduction of cognitive function and developmental delay. In moderate cytochrome P450 oxidoreductase deficiency, craniofacial and skeletal anomalies are less severe than in Antley-Bixler syndrome (Scott and Miller, 2008).

Familial Glucocorticoid Deficiency

Familial glucocorticoid deficiency (FGD) is an autosomal recessive disorder resulting from defects in the action of adrenocorticotropic hormone (ACTH) to stimulate glucocorticoid synthesis in the adrenal. It is also known as isolated glucocorticoid deficiency or hereditary unresponsiveness to ACTH. The majority of patients with FGD have episodes of hypoglycemia in the neonatal period. These episodes will often respond quickly to more frequent feeding regimens. In a few cases, excessive skin pigmentation is recognized at this early stage. Biochemically, patients with FGD have low or undetectable cortisol levels and—because of the failure of the negative feedback loop to the pituitary and hypothalamus—grossly elevated ACTH levels are seen. Mineralocorticoid deficiency usually is not a presentation; therefore aldosterone levels, plasma renin measurements, and serum electrolytes are normal. A clinical feature sometimes observed in patients with FGD is tall stature that is identified later in life (Elias et al, 2000). Approximately half of all cases result from mutations in the ACTH receptor (melanocortin 2 receptor) FGD type 1 or from mutations in the melanocortin 2 receptor accessory protein (MRAP), FGD type 2, but other genetic causes of this potentially lethal disorder remain to be discovered. (Clark et al, 2009).

Allgrove Syndrome

Allgrove, or triple A, syndrome is a similar disorder to FGD, with additional features of alacrima and achalasia. Presenting in the first decade of life, it is frequently associated with progressive neurologic dysfunction, polyneuropathy, deafness, mental retardation, and hyperkeratosis of palms and soles (Houlden et al, 2002). Some of these families have a defect in the alacrima–achalasia–adrenal insufficiency syndrome gene encoding a protein named ALADIN, which is postulated to be involved in either cytoplasmic trafficking or peroxisomal activities (Tullio-Pelet et al, 2000). ALADIN belongs to a WD-repeat family of regulatory proteins that shares a common made up of highly conserved repeating units usually ending with Trp-Asp (WD) (Neer et al, 1994).

Neonatal Adrenoleukodystrophy

Neonatal adrenoleukodystrophy (NALD) is a fatal autosomal recessive disease of impaired peroxisome biogenesis. NALD belongs to a class of disorders involving peroxisomal biogenesis that includes Zellweger syndrome and infantile Refsum's disease. NALD is the only one of the three diseases that often involves adrenal insufficiency. Mutations in seven different peroxisome biogenesis factors have been shown to cause NALD (Moser, 1999). Mutations in PEX1 (peroxisome biogenesis factor 1), are the most common cause of NALD (Tamura et al, 2001). As in X-linked adrenoleukodystrophy (X-ALD), patients with NALD accumulate very long-chain fatty acids and develop degenerative changes of the white matter of the nervous system and adrenal atrophy. Infants with NALD characteristically demonstrate dolichocephaly, prominent and high forehead, esotropia, epicanthic folds, broad nasal bridge, high-arched palate, low-set ears, and anteverted nostrils. Affected patients usually die in early childhood (Walter et al, 2001). X-ALD is a recessively inherited X-linked defect of the adrenoleukodystrophy protein. It is also a peroxisomal defect that usually results in adrenal insufficiency and CNS deterioration. However, X-ALD does not usually appear before early childhood but manifest later in adulthood (Moser et al, 1984).

Defective Cholesterol Metabolism: Smith-Lemli-Opitz Syndrome

The clinical picture of adrenal insufficiency and 46,XY gonadal dysgenesis may be caused by a deficiency of 7-dehydrocholesterol C-7 reductase enzyme that catalyzes the final step in cholesterol biosynthesis leading to primary adrenal insufficiency. The syndrome results from mutations in the sterol Δ-7-reductase gene (*DHCR*7) located at 11q12-q13. Smith-Lemli-Opitz (SLO) syndrome can manifest with typical facial appearance, mental retardation, microcephaly, proximally placed thumbs, congenital cardiac abnormalities, syndactyly of the second and third toes, incomplete development of the male genitalia, and photosensitivity. The biochemical abnormalities of SLO syndrome include low cholesterol and high 7-dehydrocholesterol (Tint et al, 1994) In utero, the primary defect in fetal adrenal glands results in a combination of low maternal estriol levels, sex reversal, and large adrenal glands in the fetus with SLO syndrome. Preliminary studies suggest

that cholesterol supplementation may be of benefit to patients with the SLO syndrome (Andersson et al, 1999). The birth prevalence of SLO syndrome is estimated to be approximately 1:20,000 to 1:40,000 live births (Tint et al, 1994). Among persons of northern or central European ancestry, it has been estimated to range from 1:10,000 to 1:60,000 (Porter, 2000). SLO syndrome is less common in those of Asian or African ancestry.

Adrenal Insufficiency Associated With Other Syndromic Disorders

Lysosomal Storage Disorders

Complete deficiency of lysosomal esterase can also result in adrenal insufficiency in Wolman disease, a rare autosomal recessive disease. Wolman disease is rare, with only 50 reports of the disease published in the worldwide medical literature. Wolman disease usually is fatal in the 1st year of life. Affected infants exhibit mild mental retardation, hepatosplenomegaly, vomiting, diarrhea, growth failure, and adrenal calcifications. Calcifications that delineate the outline of both adrenals are pathognomonic of this condition (Wolman, 1995).

Mitochondrial Disorders

Adrenal insufficiency can result from mitochondrial disorders, characterized by chronic lactic acidosis, myopathy, cataracts, and nerve deafness (Bruno et al, 1998; Nicolino et al, 1997). Cases with the Kearns-Sayre syndrome form of mitochondrial myopathy, deafness, with large-scale deletions in mitochondrial DNA are often associated with endocrine dysfunction, particularly short stature, hypogonadism, diabetes, hypoparathyroidism, hypothyroidism, and adrenal insufficiency (Artuch et al, 1998; Boles et al, 1998).

Intrauterine Growth Retardation, Metaphyseal Dysplasia, AHC and Genital Anomalies

Three patients with adrenal hypoplasia congenita and additional findings that represent a new syndrome known as *IMAGe* (i.e., intrauterine growth retardation, metaphyseal dysplasia, AHC and genital anomalies) were reported. Genital abnormality was described as bilateral cryptorchidism, small penis, and hypogonadotropic hypogonadism. The patients also had hypercalciuria with or without hypercalcemia resulting in abnormal calcium deposits in vital organs. They all had no evidence of glycerol kinase deficiency and no alteration of either the *SF1* or *DAX1* gene (Vilain, 1999).

Adrenal Hypoplasia Congenita

AHC, a rare familial condition in which the adrenal cortex has arrested development, occurs in approximately 1 in 12,500 births (Jones et al, 1995; Laverty et al, 1973). The disorder can manifest as four clinical forms of primary adrenal insufficiency: (1) a sporadic form associated with pituitary hypoplasia; (2) an autosomal recessive form with a distinct miniature adult adrenal morphology, characterized by small glands with a permanent cortical zone but a diminished fetal zone (the genetic basis of the recessive form of AHC is unknown); (3) an X-linked cytomegalic form associated with hypogonadotropic hypogonadism; and (4) an X-linked form associated with glycerol kinase deficiency and Duchenne muscular dystrophy (Bartley et al, 1982). Mutations in *DAX1* are responsible for both X-linked forms.

The X-linked or cytomegalic form of AHC is characterized by the absence or near absence of the permanent or adult zone of the adrenal cortex and by structural disorganization of the fetal cortex with abnormally large cells. It differs from the autosomal recessive miniature adult form of AHC, in which the adrenal cortex has the normal adult structure but is small. X-linked AHC results in severe primary adrenal insufficiency involving glucocorticoids and mineralocorticoids and failure to respond to elevated levels of ACTH with usual age at onset in the neonatal period or during infancy. However, in some patients, age of onset is later, up to several years of age and presumably caused by residual functional cortex (Achermann et al, 2001; McCabe, 2000). The secretion of other pituitary hormones is not impaired. Hypogonadotropic hypogonadism can manifest with cryptorchidism or delayed puberty (Golden et al, 1977). Whereas presentation of adrenal insufficiency can occur from birth, there is great variability of presentations. Isolated adrenal insufficiency in infancy, isolated adrenal insufficiency later in life, isolated hypogonadotropic hypogonadism, adrenal insufficiency and hypogonadotropic hypogonadism, delayed-onset adrenal insufficiency from 2 to 9 years of age with incomplete hypogonadotropic hypogonadism, and delayed puberty in females all may result (Ten et al, 2001). The phenotypical variation does not correlate well with genotype.

Adrenal Hypoplasia as Part of Contiguous Gene Deletion Syndrome

An X-linked form of adrenal insufficiency, associated with glycerol kinase deficiency is characterized by psychomotor retardation, muscular dystrophy, characteristic facies with hypertelorism, alternating strabismus, and drooping mouth. Additional phenotypic features can include testicular abnormalities (anorchia or cryptorchidism), short stature, and osteoporosis. Time of presentation can vary from birth through childhood. Nearly all patients reported were male. The genetic locus was mapped to Xp21.3-21.2 and variants of contiguous gene deletion syndrome (glycerol kinase deficiency, Duchenne muscular dystrophy, ornithine transcarbamylase deficiency, and mental retardation) can be seen.

ABNORMALITIES OF DEVELOPMENT: DAX1 AND SF1 DEFICIENCY

The nuclear receptors DAX1 (dosage-sensitive sex reversal, AHC, critical region on the X chromosome, gene-1, NR0B1/*AHC*) and SF1 (*NR5A1*, also known as Ad4BP) (Phelan and McCabe, 2001) have an important role in adrenal development and function, and mutations in these transcription factors have been found in patients with adrenal hypoplasia (see Molecular Basis of Adrenal Development, earlier). Both SF1 and DAX1 belong to the family of nuclear hormone receptors. DAX1 protein is expressed in the developing urogenital ridge, ovary, testis, all zones of the fetal adrenal cortex, hypothalamus, and anterior pituitary gland—sites in which it colocalizes with

SF1 (Guo et al, 1995; Parker et al, 2002). SF1 is essential for the development of the adrenal cortex, gonads, and ventromedial nucleus of the hypothalamus because it interacts with the genes for the α-subunits of the pituitary glycoprotein hormones, müllerian-inhibiting hormone, and the promoter of the *DAX1* gene (Kawabe et al, 1999). Furthermore, SF1 is a transcription factor that regulates gene expression of the CYP steroid hydroxylases (21-hydroxylase, the aldosterone synthase isoenzyme of steroid 11β-hydroxylase, CYP11A), 3-β-hydrosteroid dehydrogenase, aromatase, and StAR in the adrenal gland; therefore it is essential for development of the adrenal cortex.

In one large study of this relatively rare disease, *DAX1* mutations were found in 58% of 46,XY phenotypic boys referred with adrenal hypoplasia and in all boys with hypogonadotropic hypogonadism and a family history suggestive of adrenal failure in males. *SF1* mutations causing adrenal failure were found in only two patients with 46,XY gonadal dysgenesis. No *DAX1* or *SF1* mutations were identified in the adult-onset group (Lin et al, 2006).

Human mutations in SF1 are even rarer and have been described in a few patients with primary adrenal failure. Two individuals with a 46,XY genotype, female phenotype, and müllerian structures harbor missense mutations that affect DNA binding (Achermann et al, 1999, 2002), whereas a 46,XX girl with an SF1 mutation had primary adrenal failure and apparently normal ovarian development (Biason-Lauber and Schoenle, 2000). In addition, it is now emerging that heterozygous nonsense or frameshift mutations associated with haploinsufficiency of SF1 can cause 46,XY gonadal dysgenesis in patients with normal adrenal function (Correa et al, 2004; Hasegawa et al, 2004; Mallet et al, 2004). Therefore it is possible that a range of different endocrine phenotypes are associated with mutations in different domains of SF1.

Adrenal Hemorrhage

Adrenal hemorrhage is not uncommon at birth. At birth, adrenal hemorrhage from anoxia or sepsis is most common, and adrenal insufficiency from CAH usually manifests in neonates (Ten et al, 2001). The incidence in the neonate is reported to be 1.7 cases per 1000 autopsied infants and as many as 3% of infants screened by abdominal ultrasound examination. The etiology of neonatal adrenal hemorrhage is largely unknown, but it has been associated with birth trauma related to difficult deliveries, sepsis, coagulopathies, traumatic shock, and ischemic disorders. Infants with minimal hemorrhage may be asymptomatic and be discovered incidentally to have adrenal calcifications, indicating an earlier hemorrhage. Major adrenal hemorrhage can manifest as an abdominal mass, anemia from blood loss, or jaundice from reabsorption of the hematoma. Hemorrhage can also lead to adrenal insufficiency, which can manifest as neonatal hypoglycemia, hypotension, hypothermia, apnea, or shock. Because of the location of the right adrenal gland between the liver and spine, it is the one most often affected by hemorrhage (Velaphi and Perlman, 2001).

In meningococcal septicemias, hemorrhage into the adrenal glands can complicate the clinical picture, leading to circulatory collapse (Waterhouse-Friderichsen syndrome or adrenal hemorrhage in association with fulminant septicemia; Enriquez et al, 1990). Other infections in the neonate that have been associated with adrenal hemorrhage and insufficiency include those caused by herpesvirus, *Pseudomonas aeruginosa*, *Bacteroides* spp., herpes simplex virus type 6, echovirus types 11 and 6 (Bekdash and Slim, 1981; Jain et al, 1996; Margaretten et al, 1963; Ohta et al, 1978; Schmitt et al, 1996). Septic shock in newborns, especially in those who are small for age, can result in adrenal hemorrhage with rhabdomyolysis and renal insufficiency (Ten et al, 2001).

Secondary and Tertiary Adrenal Insufficiency

Iatrogenic Adrenal Insufficiency

Secondary and tertiary forms of adrenal insufficiency result from defects in pituitary corticotroph and hypothalamic function, respectively. Supraphysiologic doses of glucocorticoids often are used for the treatment of bronchopulmonary dysplasia. With prolonged use of supraphysiologic doses of glucocorticoids, these neonates are at risk for iatrogenic suppression of corticotroph ACTH release, with secondary adrenocortical atrophy and adrenal insufficiency (Axelrod, 1992). Evidently, even a single course of antenatal betamethasone treatment induces a suppression of stress reactivity in healthy newborns (Schaffer et al, 2009). The duration of recovery of corticotroph function from adrenal suppression, once administration of glucocorticoids is discontinued, is highly variable with evidence of suppression of the HPA axis evident in some patients for more than 1 year (Livanou et al, 1967). Even in preterm infants, the HPA axis behaves in a similar manner as in adult subjects, and the pituitary function recovers earlier than that of hypothalamus and adrenals (Ng et al, 2008).

Developmental Adrenal Insufficiency

Secondary or tertiary adrenal insufficiency in the neonate often is a consequence of abnormalities in development of the hypothalamus and pituitary associated with adrenal insufficiency, including de Morsier syndrome (septooptic dysplasia; De Morsier, 1956), hydrancephaly or anencephaly, and pituitary hypoplasia or aplasia. If these infants have concomitant diabetes insipidus, they have an increased risk of sudden death during childhood (Dattani et al, 1998; Kelberman et al, 2006). Patients with developmental abnormalities of the pituitary or hypothalamus often have deficiencies of other hormones. ACTH deficiency can be part of mutiple pituitary hormone deficiency syndrome caused by abnormal expression of transcription factors such as HESX1, LHX4, SOX3, or PROP1 (Mullis, 2001). Isolated ACTH insufficiency is a rare condition that can be caused by mutations in TPIT, a T-box factor that controls transcription of the proopiomelanocortin gene in corticotrophes only, thereby resulting in an adrenal-only phenotype (Vallette-Kasic et al, 2005). However, approximately 50% of patients do not carry mutations in TPIT, suggesting that other unknown factors exist (Metherell et al, 2004; Vallette-Kasic et al, 2004). Septooptic dysplasia

can be caused by mutations in HESX1 and SOX2 (Dattani et al, 1998; Kelberman et al, 2006). Signs of hypopituitarism in a neonate include hypoglycemia, prolonged jaundice, shock, and microphallus in males. Trauma to the hypothalamus, pituitary, or hypophysial portal circulation from significant head injury, cerebrovascular accident, Sheehan syndrome, or hydrocephalus may be a cause of central adrenal insufficiency. Historical factors associated with increased risk for central adrenal insufficiency include maternal drug use and traumatic delivery.

There have been rare case reports of families with inherited abnormalities of neuropeptides involved in HPA axis regulation. Adrenal insufficiency, pigmentary abnormalities, and obesity have been described in families with a defect in POMC (Krude et al, 1998). One kindred has been reported with Arnold-Chiari type I malformation and suspected *CRH* deficiency. The mutation in this kindred is linked to the *CRH* locus; however, a specific mutation in the *CRH* gene has not yet been defined (Kyllo et al, 1996).

MANAGEMENT

Adrenal crisis is a potentially life-threatening disorder that can manifest with a salt-losing crisis or profound hypoglycemia in infancy or childhood and requires immediate resuscitation and appropriate steroid replacement. Determining the exact cause of this condition can be challenging once the child has started treatment, but defining a precise etiology has important implications for long-term management, for identifying associated features, and for appropriate counseling regarding inheritance and the risks of other family members being affected (Lin et al, 2006). Detailed questioning about family history that could reveal any insight into possible adrenal disease is important.

Initial Management

In the event of a suspected adrenal crisis, blood for determination of electrolytes, aldosterone, plasma renin activity, cortisol, and ACTH should be drawn and treatment started before the results are obtained. Fluid resuscitation with normal saline containing 5% dextrose should be given as a bolus to restore cardiovascular stability. Plasma sodium should be monitored closely, as rapid correction of hyponatremia with sodium repletion of more than 0.5 to 1 mEq/L/h increases the risk of central pontine myelinolysis. The sodium deficit may be calculated by subtracting the infant's sodium from a customarily normal sodium of 140 mEq/L and then multiplying this value by 0.6 × weight (in kg). The rate of replacement should occur over an initial rate such that the sodium increase does not exceed 0.5 mEq/L/h. Intravenous hydrocortisone should be given initially at 100 mg/m^2 and then continued at 100 mg/m^2/day, divided every 6 to 8 hours, until the infant's condition is stable.

Maintenance Therapy

Corticosteroid and mineralocorticoid replacement therapies should suppress the excessive secretion of CRH, ACTH, and resting renin levels. The normal daily cortisol production rate has been shown to be 6 to 7 mg/m^2/day in children and adolescents (Kerrigan et al, 1993; Linder et al, 1990). This rate translates to approximately 10 to 12 mg/m^2/day of oral hydrocortisone, to allow for step-down losses from absorption, hepatic processing, and metabolic bioavailability. Because the bioavailability of oral steroids varies from person to person (Bright and Darmaun, 1995), infants should be monitored closely for signs of either inadequate cortisol replacement or cortisol excess (Heazelwood et al, 1984). Although adults and older children may be able to take hydrocortisone twice daily, most infants should be dosed three times daily to avoid hypoglycemia associated with low cortisol on a twice-daily regimen (DeVile and Stanhope, 1997; Groves et al, 1988). It is conceivable to say that other steroids can be used; hydrocortisone is preferred in infants because it has fewer growth-suppressive effects than those associated with use of synthetic steroids (Allen, 1996; Allen et al, 1998; Punthakee et al, 2003). The U.S. Food and Drug Administration withdrew oral hydrocortisone suspension from the market because of poor absorption and undertreatment of children (Ten et al, 2001).

In primary adrenal insufficiency, aldosterone production is usually decreased. Physiologic doses of hydrocortisone do not provide enough mineralocorticoid activity to prevent salt wasting (New et al, 1966); therefore these infants often require 0.05 to 0.2 mg/day of fludrocortisone acetate (Florinef) (Ten et al, 2001) and added salt. Because after the 1st month of life aldosterone production does not vary, the dose of fludrocortisone does not change with growth and aging (Sippell et al, 1978; Weldon et al, 1967). Infants with mineralocorticoid deficiency require 1 to 2 g of NaCl (1 g contains 17 mEq of sodium) added to their diet, because formula and breast milk are low in sodium content (approximately 8 mEq/L) (Mullis et al, 1990).

Stress Replacement

The normal response to surgery, trauma, or critical illness is to increase plasma ACTH and cortisol levels (Lamberts et al, 1997). The secretion rate of cortisol has been found to be proportional to the degree of stress and ranges from 60 to 167 mg/day in adults after surgery (Chernow et al, 1987; Hume et al, 1962). Based on data from adults, it is recommended that infants with adrenal insufficiency receive 30 to 100 mg/m^2/day divided every 6 to 8 hours of hydrocortisone when stressed. Stress doses of hydrocortisone should be given with the onset of fever and gastrointestinal or other significant illness, and continued for 24 hours after the symptoms resolve (Nimkarn and New, 2008). Usually this treatment translates to the routine steroid dose being tripled and administered over three divided daily doses. If oral steroids are not tolerated, an intramuscular or intravenous dose should be given. For surgery, infants should be given 30 to 100 mg/m^2 of intravenous hydrocortisone on call to the operating room before the administration of anesthesia. Stress dosing of hydrocortisone (30 to 100 mg/m^2/day divided every 6 to 8 hours) should be continued postoperatively for the next 24 to 48 hours. It is unnecessary to give mineralocorticoids over such periods if the patient begins the operative period in adequate salt balance.

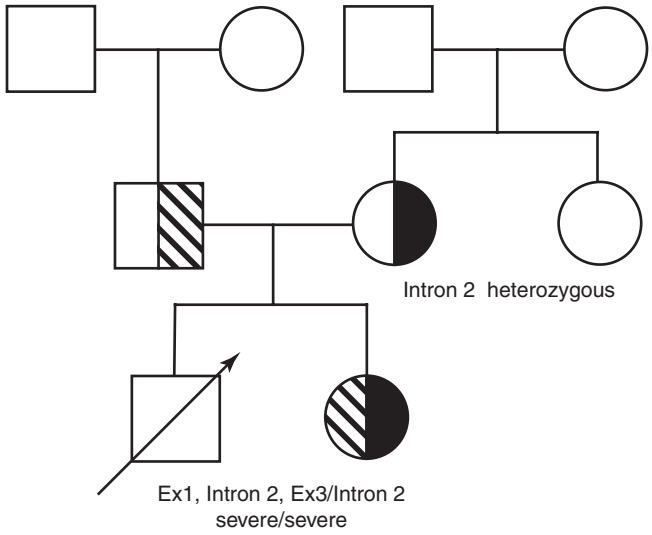
The patients and their families should have instructions for such instances. Every patient should wear a medical identification (e.g., MedicAlert) bracelet or necklace and carry the emergency medical information card that is supplied with it. Both should indicate the diagnosis, the daily medications and doses, and the physician to call in the event of an emergency.

Secondary or Tertiary Adrenal Insufficiency

Cortisol replacement for patients with secondary or tertiary adrenal insufficiency is the same as described for patients with primary adrenal insufficiency. To minimize growth suppression, these children can be treated with doses of hydrocortisone that are slightly less than physiologic replacement doses. Furthermore, because mineralocorticoid production is under the control of the renin-angiotensin system, patients with secondary or tertiary adrenal insufficiency do not require mineralocorticoid replacement. However, these infants require evaluation for deficiencies of other pituitary hormones.

Case Study 1

A 3-week-old phenotypic male infant presented with lethargy, poor oral intake, and progressive vomiting for 1 week. He refused to eat over the previous 7 hours. There was no history of fever. Prenatal history was unremarkable. Birth history: normal vaginal delivery, Apgar scores of 8 and 9 with a birthweight of 8 pounds, 14 ounces (4.03 kg). The newborn examination performed in the nursery identified perineal hypospadias, but the infant was discharged home on day 2 of life. Over the first 2 weeks of life, weight gain was poor, and appetite was markedly decreased over the 1 to 2 days before evaluation in the emergency department. Family history revealed that he was the second child of the family, from a nonconsanguineous marriage of Chinese background. (The first boy died at 1 month of age in China because of gastroenteritis.) On examination, vital signs were body temperature, 36.5° C; blood pressure, 52/32 mm Hg; pulse, 160 beats/min. He was severely dehydrated. There was no hyperpigmentation. The physical examination was notable for a weight of 3.1 kg and a phallus with a length of 2.5 cm, a midshaft diameter of 1.5 cm with hypospadias near the perineum, a hyperpigmented and rugated shawl scrotum, and no palpable testes. Initial blood glucose level was 40 mg/dL. The infant's mental status was improved after administration of 25% dextrose via an intraosseous line. Resuscitation was continued with dextrose containing normal saline. Initial laboratory values showed sodium of 107 mmol/L, potassium of 7.1 mmol/L, chloride of 87 mmol/L, total CO_2 of 5.0 mmol/L. Blood urea nitrogen was 40.5 mg/dL, creatinine was 0.6 mg/dL. After the critical blood sample was obtained, the infant was given 100 mg/m^2 of intravenous hydrocortisone. Additional evaluation revealed 46,XX chromosomes and enlarged adrenals, as well as a small uterus on ultrasound examination. The clinical course was complicated by necrotizing enterocolitis that led to a stay in the hospital for 3 weeks with conservative management including administration of antibiotics. Initial laboratory results noted 17 OHP of 111,000 ng/dL, ACTH of 4755 pg/mL, and cortisol 3.9 of μg/dL before hydrocortisone (no ACTH stimulation performed). Aldosterone and renin analyses were not performed because of difficulty obtaining adequate blood. CYP21A2 analysis revealed a genotype as follows: exon1, intron2, and exon3/intron2 mutations (<1% of enzyme activity in vitro for both mutations). This case is a classic presentation of the salt-wasting form of 21 OHD CAH. Family pedigree is shown below:



Comment

The lesson learned from this case is that in a phenotypic male without palpable testes, the genitourinary anomalies should be considered ambiguous genitalia. Further work-up is merited in the immediate perinatal period. Family history suggests a severe recessive disorder. Genetic analysis is available and can be used to confirm the diagnosis before lifetime therapy and is of value in genetic counselling. In addition, the institution of newborn screening for elevated 17-OHP allows earlier detection of salt-wasting 21 OHD, before the occurrence of a life-threatening event.

CHAPTER 92

Ambiguous Genitalia in the Newborn

Karen Lin-Su and Maria I. New

"Is it a boy or a girl?" is often one of the first questions asked when a baby is born. For parents of a newborn infant with genitalia that are not clearly male or female, the ambiguity can be a distressing matter that needs to be addressed with sensitivity and with some urgency. There are four general classifications that can cause disorders of sexual differentiation: (1) masculinization of the 46,XX female, (2) incomplete masculinization of the 46,XY male, (3) gonadal differentiation and chromosomal disorders, including ovotesticular disorder of sexual differentiation, or (4) syndromes associated with incomplete genital development (Box 92-1). The first two categories comprise a majority of definable cases of ambiguous genitalia.

This chapter presents an overview of the pathophysiology of disorders of sexual differentiation (DSDs), including a discussion of the practical aspects of diagnosis and management. An overview of the traditional surgical methods used in the management of infants with DSDs, including the risks and benefits of these procedures, is included at the end of the chapter.

GENERAL CONSIDERATIONS IN THE APPROACH TO THE NEWBORN WITH AMBIGUOUS GENITALIA

The medical evaluation of a newborn with ambiguous genitalia is necessarily time-consuming. Open and honest discussions with the parents are invaluable in allaying anxiety and establishing a trusting relationship. Full disclosure of available information is essential in this regard.

Care must be taken to avoid premature gender assignment for the infant. Proper evaluation of the infant with ambiguous genitalia requires a multidisciplinary team that should include the primary care physician, neonatologist, pediatric endocrinologist, psychologist, pediatric urologist, and pediatric geneticist. Psychological assessment and support of the family are essential in the newborn period, along with long-term psychological follow-up evaluation (Guerra-Junior, 2007; Hines, 2004; Slijper et al, 1998). Decisions regarding the gender of rearing should be made collaboratively between the multidisciplinary team and the parents, with the recognition that cultural and psychosocial factors are likely to be influential (Grumbach and Conte, 1998, Kuhnle and Krahl, 2002).

In the past, gender assignment was based largely on phallus size, relative ease of surgical reconstruction, or the potential for fertility. This approach has come under criticism as dissatisfaction with gender assignment based on these criteria has been reported in several case studies (Diamond and Sigmundson, 1997b; Hughes et al, 2007; Phornphutkul et al, 2000; Reiner, 1997). The importance of prenatal androgen imprinting has been implicated as an important variable in some of these cases (Reiner, 1997). Studies in undervirilized 46,XY males indicate that a small phallus can be associated with a satisfying adult sex life (Reilly and Woodhouse, 1989). Other studies have found that gender role tends to increasingly correspond with assigned sex as individuals with DSD proceed into adulthood (Pappas et al, 2008); therefore female gender assignment might not be necessarily warranted for intermediately undervirilized 46,XY males.

The degree of genital virilization is still an important determinant of gender assignment in the infant with ambiguous genitalia; however, other, incompletely understood factors appear to be involved. The formation of a healthy gender identity seems to involve a complex interplay between psychobiologic and environmental factors (Meyer-Bahlburg et al, 1996, 2006; Money and Ehrhardt, 1972; Singh et al, 2009; Slijper et al, 1998).

EMBRYOLOGY OF SEXUAL DIFFERENTIATION

Normal and abnormal sexual differentiation constitute superb examples of how an understanding of embryology is critical to the approach and management of a group of complex and intriguing clinical disorders.

Sexual differentiation is a sequential process that can be divided into three stages. Jost (1970) established the sequence as follows: chromosomal sex is determined at fertilization and dictates the differentiation of the gonad, which in turn dictates the phenotypic sex, or the differentiation of the internal ductal system and external genitalia (Grumbach and Conte, 1998).

Chromosomal sex is determined at the moment of conception by the sex chromosome complement of the fertilizing sperm. If this sperm carries an X chromosome, a 46,XX (normal female) complement results. If the sex chromosome is Y, a 46,XY (normal male) genotype results. The *SRY* (i.e., sex-determining region of the Y chromosome) gene is necessary but not sufficient for testicular differentiation. *SRY* causes the medullary region of the gonad to develop into Sertoli cells and later into testis cords and seminiferous tubules.

In addition to X chromosome genes, autosomal genes also may influence sexual differentiation, insofar as mutations to these genes result in disorders of sexual differentiation. Some of these genes include *WT1* (Wilms' tumor gene 1), associated with Denys-Drash syndrome and WAGR (*W*ilms' tumor, *a*niridia, *g*enitourinary abnormalities, mental *r*etardation) syndrome; the steroidogenic factor 1 gene; and *SOX9*, which has been associated with camptomelic dysplasia (Grumbach and Conte, 1998). The *DMRT1* and *DMRT3* genes, when deleted, are associated with male-to-female sex reversal. The *BPESC1* gene exhibits testis-specific expression and is located within the

BOX 92-1 Differential Diagnosis for Ambiguous Genitalia

46,XX VIRILIZED FEMALE

- Congenital adrenal hyperplasia
  - 21-Hydroxylase deficiency
  - 11-Hydroxylase deficiency
  - 3β-Hydroxysteroid dehydrogenase deficiency
  - Aromatase deficiency (fetal and maternal virilization)
- Virilizing maternal conditions
  - Congenital adrenal hyperplasia
  - Adrenal/ovarian tumors/luteoma of pregnancy
  - Maternal ingestion of progestins, androgens

46,XY UNDERVIRILIZED MALE

- Androgen insensitivity
  - Partial
  - Complete
- 5α-Reductase-2 deficiency
- Testosterone biosynthetic defects
  - 17β-Hydroxysteroid hydrogenase 3 deficiency
  - 3β-Hydroxysteroid dehydrogenase deficiency
  - 17α-Hydroxylase/17,20-lyase deficiency
  - Congenital lipoid adrenal hyperplasia
- Leydig cell hypoplasia
- Idiopathic, undetermined
- Drug ingestion: progestins, spironolactone, cimetidine, phenytoin
- Persistent müllerian duct syndrome

GONADAL DIFFERENTIATION AND CHROMOSOMAL DISORDERS

- 46,XY gonadal dysgenesis
  - Complete (Swyer syndrome)
  - Partial
  - Mixed (45,X/46,XY)
- True hermaphroditism
  - 46,XX, 46,XY, 46,XX/46,XY

SYNDROMES ASSOCIATED WITH AMBIGUOUS GENITALIA

- Gonadal dysgenesis
  - 46,XY partial gonadal dysgenesis (Turner syndrome features)
  - Camptomelic dysplasia
- Renal degenerative diseases and gonadal dysgenesis
  - Denys-Drash syndrome
  - Frasier syndrome
  - WAGR (*W*ilms' tumor, *a*niridia, *g*enitourinary abnormalities, mental *r*etardation) syndrome
- Smith-Lemli-Opitz syndrome (7-dehydrocholesterol reductase deficiency)
- Robinow syndrome

homologous region in the human at 3q23 (Crisponi et al, 2001). The *DAX1* gene is located on Xp22 and appears to be necessary for correct testis determination and, in the mouse at least, necessary for the upregulation of *Sox9* expression (Bouma et al, 2005). The gene *WNT4* is critical for normal ovarian and female sexual development. A mutation in *WNT4* leads to müllerian duct regression and virilization in a 46,XX female (MacLaughlin and Donahoe, 2004), whereas duplication of the locus containing WNT4 leads to 46,XY sex reversal (Jordan et al, 2001). The Desert hedgehog gene (*Dhh*) is a member of a family of signaling genes with an important role in regulating morphogenesis. The *follistatin (Fst)* and the *bone morphogenetic protein 2 (Bmp2)* genes appear to be important for ovary organogenesis (Menke et al, 2003; Yao et al, 2004). Mutations in *Gata4* or *Fog2* can cause sex reversal in mice (Ketola et al, 2000; Tevosian et al, 2002; Viger et al, 1998).

The gonad develops from both somatic and germ cells. The somatic cells are located at the ventral region of the mesonephros and arise from the mesonephric cells and the coelomic epithelium. Somatic cells become the Sertoli cells of the testis and the granulosa cells of the ovary. The germ cells migrate from a more inferior position on the yolk sac to the genital ridge, just medial to the mesonephros on each side (Figure 92-1, *upper left*). This migration occurs between 4 and 6 weeks' gestation. Once the germ cells reach the gonadal ridge, they become surrounded by the somatic cells, which appear to regulate germ cell differentiation.

Gonadal sex is established by 7 weeks' gestation. At this stage the fetus contains two internal ductal systems—wolffian and müllerian—and undifferentiated external genital primordia. The wolffian or mesonephric duct is a tubular structure that connects the capillary network of the mesonephros to the urogenital sinus. Evagination of the coelomic epithelium leads to formation of a second tubular structure adjacent to the mesonephric duct—the paramesonephric, or müllerian, duct. The distal ends of these two ducts are joined. That portion of the urogenital sinus distal to the termination of these ducts contributes to external genital development, whereas the proximal portion develops into the bladder, trigone, and posterior urethra.

Phenotypic sexual differentiation is predicated on establishing gonadal sex. If an ovary develops, the wolffian ducts involute because of a lack of testosterone, and only its terminal portion persists as Gartner's duct. The müllerian ducts develop into the proximal vagina, uterus, and fallopian tubes (see Figure 92-1). The unfused cephalic portions of the müllerian ducts form the fallopian tubes, whereas the caudal ends fuse to form the ureterovaginal canal (see Figure 92-1). The union of the fused caudal ends of the müllerian ducts and urogenital sinus forms the vagina. The proximal two thirds of the vagina is of müllerian duct origin, and the distal third is of urogenital sinus origin.

Male phenotypic differentiation is the result of the elaboration of two distinct testicular hormones: testosterone and müllerian-inhibiting factor (MIF). These factors are produced and secreted by the 8-week stage of development, and they are essential for normal male differentiation. Involution of the müllerian ducts is caused by MIF, which is a glycoprotein secreted by the fetal Sertoli cells. The remnants of the müllerian ducts persist caudally as the prostatic utricle and cephalically as the appendix testis. MIF exerts its action unilaterally and locally (exocrine secretion) rather than bilaterally via the systemic circulation.

Immediately after müllerian duct regression, the wolffian ducts develop under the influence of testosterone secreted by the fetal Leydig cells. The Leydig cells, like the Sertoli cells, differentiate from the mesenchymal cells within the gonadal ridges; this occurs at 9 to 10 weeks' of gestation. Under the influence of testosterone, the wolffian ducts evolve into the epididymis, vas deferens, and seminal vesicles (see Figure 92-1). The mesonephric tubules develop into the ductuli efferentes, which will provide continuity between the seminiferous tubules and rete

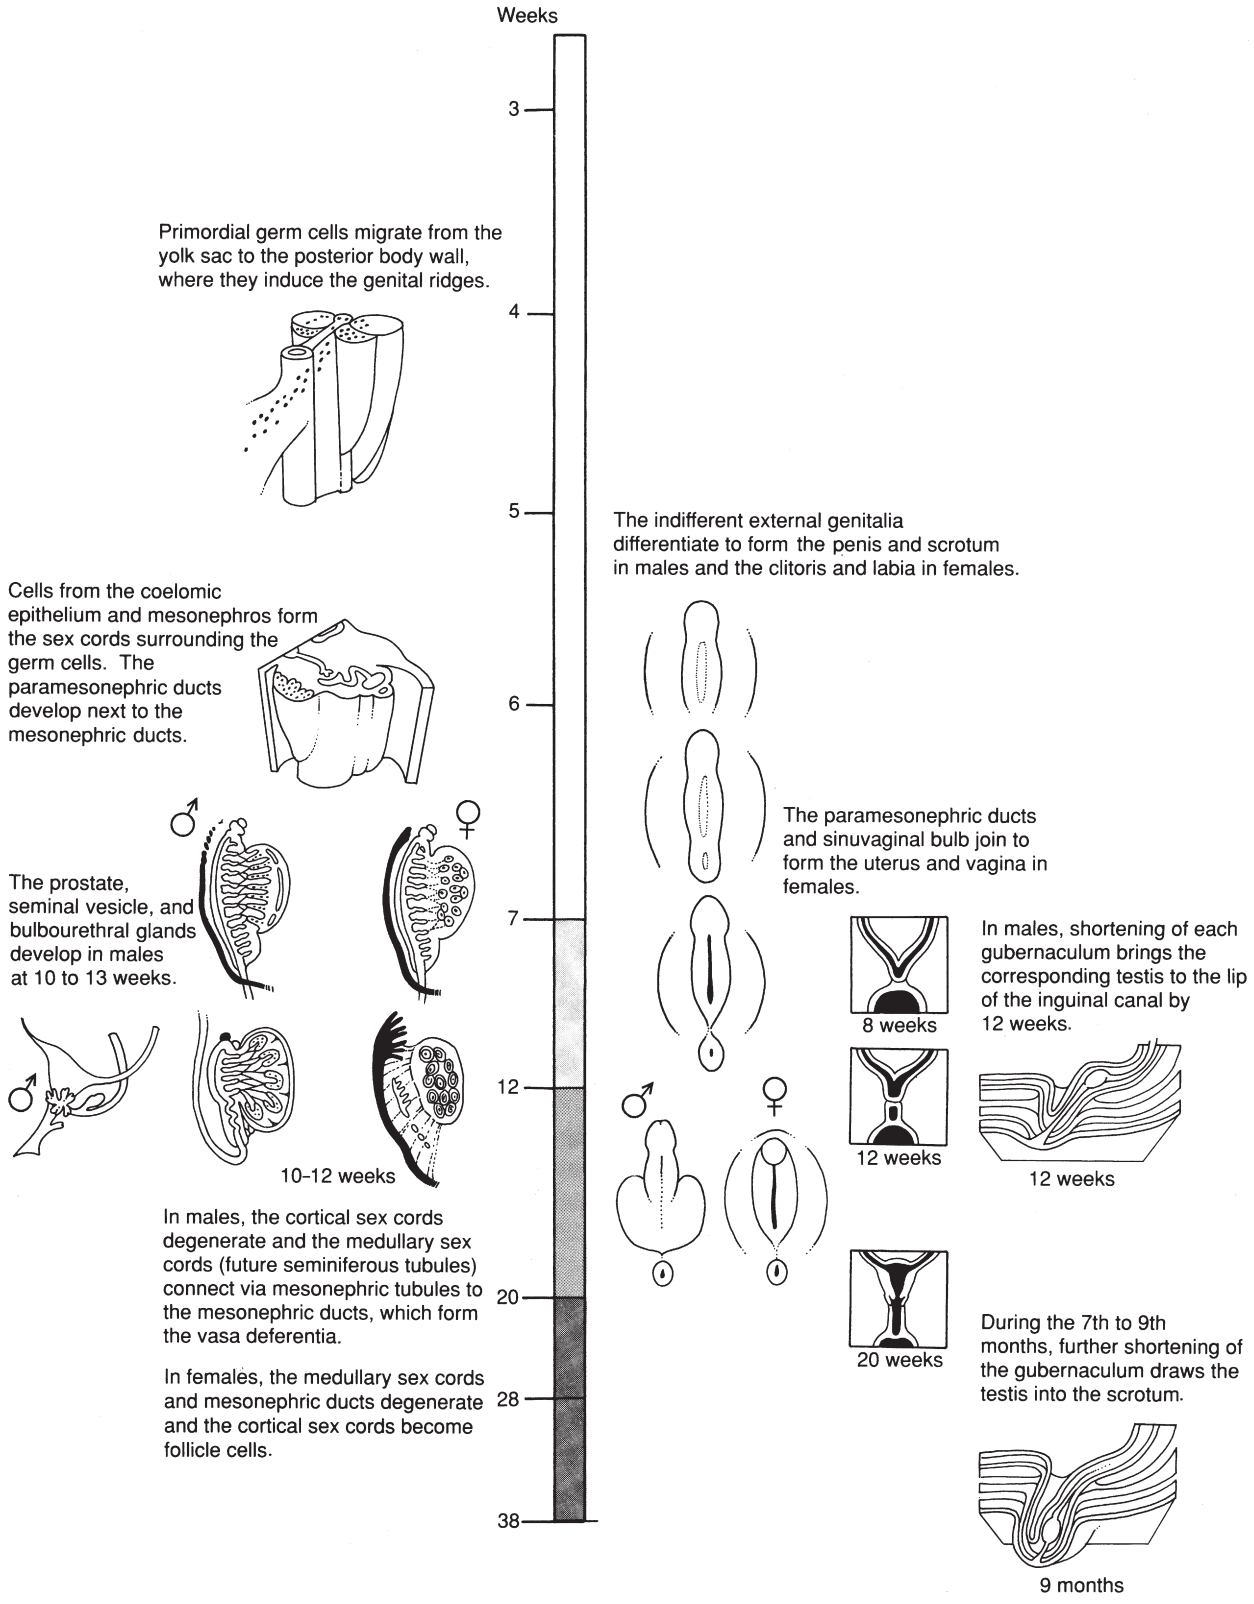

FIGURE 92-1 Embryologic time line for gonadal and internal and external genitalia development. *(From Larsen WJ: Human embryology, New York, 1993, Churchill Livingstone, p 237.)*

testis to the vas deferens. This process occurs as a direct action of testosterone on the ductal structures.

Virilization of the male external genitalia, starting at approximately 8 weeks' gestation (see Figure 92-1), relies on the ability of the tissues involved to convert testosterone into a more potent androgen—dihydrotestosterone. The target cells possess the enzyme 5α-reductase, which is necessary for this conversion. By 12 to 14 weeks' gestation, formation of the male external genitalia is nearly complete. Androgen exposure after this time results in further phallic enlargement.

CLINICAL ASSESSMENT OF DISORDERS OF SEX DIFFERENTIATION

HISTORY

A detailed family history is important in the evaluation of ambiguous genitalia. Information on early neonatal deaths, consanguinity, or urogenital anomalies should be obtained. A family history of female infertility or amenorrhea can be suggestive of a DSD. In one study of androgen insensitivity disorders, a positive family history of a sex differentiation disorder was often overlooked (Viner et al, 1977).

The presence of maternal virilization is suggestive of a variety of disorders that can affect fetal masculinization. Features of maternal virilization include hirsutism, severe acne, deepening of the voice, and clitoromegaly on examination.

The ingestion of any recreational drugs, alcohol, or medications by the mother during pregnancy should be noted. Particular attention to medications with androgenic or progestational activity is indicated. Medications that affect fetal genital development include cimetidine, spironolactone, hydantoin, and progestational agents (Grumbach and Conte, 1998).

PHYSICAL EXAMINATION

There is significant overlap of the genital anatomy among the various sex differentiation disorders. The physical examination, however, can provide the first clues to the underlying pathology. In addition, the physical examination will provide important information about the degree of virilization of the external genitalia and the presence or absence of palpable gonads.

Clitoris

Significant clitoral enlargement deserves a careful evaluation. A point to keep in mind is that premature infants have relatively underdeveloped labia majora, so that the clitoris may appear enlarged. A truly enlarged clitoris can be distinguished from a generous clitoral hood by the presence of palpable corporal or erectile tissue.

Penis (Phallus)

Measurements of the phallic stretch length and middle shaft diameter are important in determining the degree of virilization. The phallus should be stretched and measured from the pubic ramus to the tip of the glans. Gestational age–corrected phallic stretch lengths are shown in Figure 92-2. The presence of a chordee structure on the ventral surface of the phallus can impair measurement of the true phallic length (Feldman, and Smith 1975) (Figure 92-3). A chordee is residual urethral tissue that tethers the phallus to the perineum. Measurement of the middle shaft diameter is particularly useful in this circumstance. For term male infants, a normal middle shaft diameter is approximately 1 cm (Feldman and Smith, 1975).

A microphallus warrants careful evaluation for the presence of hypopituitarism or growth hormone deficiency, particularly in the presence of hypoglycemia or unexplained jaundice. Microphallus and undescended testes may occasionally be the presenting phenotype for a DSD.

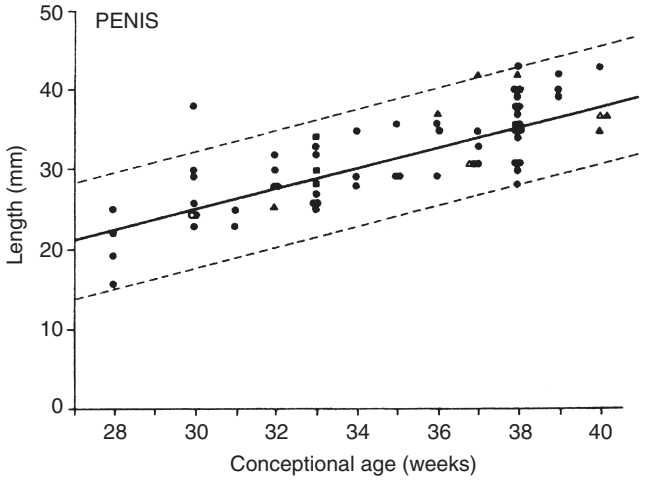

FIGURE 92-2 Penis stretch length in 63 normal premature and full-term male infants (•), showing lines of mean ±2 SD. Superimposed are data for two small-for-gestational age infants (Δ), seven large-for-gestational age infants (▲), and twins (■). *(Reproduced with permission from Feldman KW, Smith DW: Fetal phallic growth and penile standards for newborn male infants,* J Pediatr *86:395-398, 1975.)*

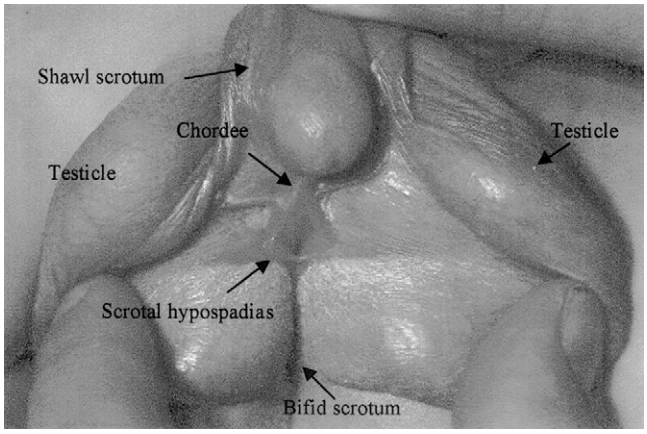

FIGURE 92-3 Undervirilized male demonstrating bifid scrotum, scrotal hypospadias, chordee, and bilateral descended testes.

Labioscrotal Folds

Assessment of the degree of fusion of the labioscrotal folds should be performed. When the infant is exposed to androgens during embryogenesis, fusion of the labioscrotal folds progresses from a posterior to an anterior direction. The spectrum of labial fusion can vary from mild posterior fusion to complete labial fusion (Figure 92-4). The examiner should note whether the folds are rugate or hyperpigmented. Is the phallus positioned in the normal superior position relative to the scrotum, or is there a shawl scrotum? Is the scrotum fused normally in the midline or is the scrotum bifid? (See Figure 92-3.)

Gonads

Careful examination for the presence of gonads should be performed in all infants with ambiguous genitalia. The presence of bilateral gonads in the labial folds is highly

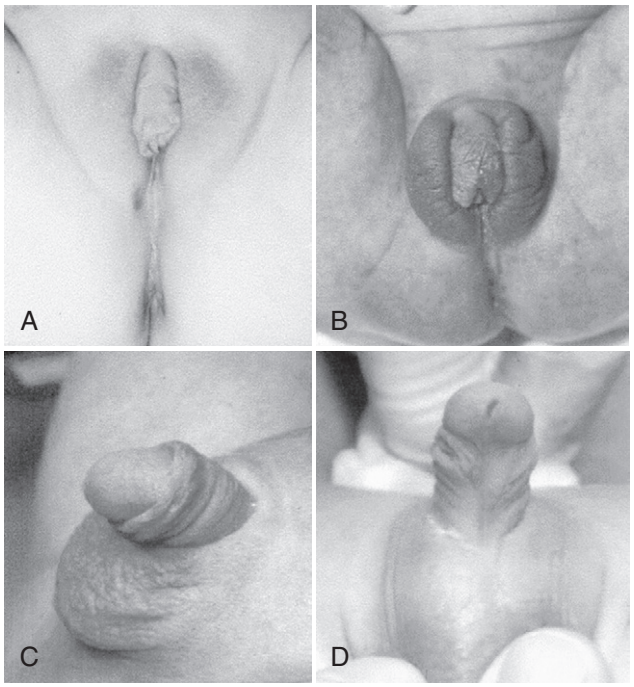

FIGURE 92-4 Virilization of external genitalia in 46,XX congenital adrenal hyplasia (21-hydroxylase deficiency). A, There is a mild to moderate degree of virilization, with primarily clitoral hypertrophy and significant fusion of the labia. **B,** Virilization is moderate, with clitoromegaly, labial fusion, and rugation of labial folds. **C** and **D,** Complete masculinization is evident.

suggestive of an undermasculinized genetic male (see Figure 92-3). A unilaterally palpable gonad is often seen in infants with mixed gonad dysgenesis or hermaphroditism (Figure 92-5), although other disorders such as androgen insensitivity can manifest similarly. When cryptorchidism and hypospadias occur simultaneously, there is a greater than 25% chance of a DSD (Albers et al, 1997; Rajfer and Walsh, 1976).

Hypospadias, Perineum

The severity of hypospadias can vary, with the condition ranging from mild glandular to penoscrotal, although most disorders of sexual differentiation manifest with severe penoscrotal or scrotal hypospadias (see Figures 92-3 and 92-3). Examination for the presence of separate urethral and vaginal openings versus a single perineal opening (urogenital sinus) conveys important anatomic information. The vagina may be blind-ending or completely formed. A urogenital sinus results from failure of the urologic and genital tracts to differentiate completely. In virilized females, the level at which the vagina enters the sinus (low- versus high-level vaginal entry) has important implications for determining the ease of subsequent surgical exteriorization of the vagina (Figure 92-6). In addition, when the urethra enters a urogenital sinus, there is potential for urinary stasis and therefore urinary tract infections. Excessive pigmentation of the genitals or signs of dehydration should alert the examiner to the possibility of congenital adrenal hyperplasia (CAH).

Dysmorphic features suggestive of Turner syndrome indicate the possibility of gonadal dysgenesis or mixed

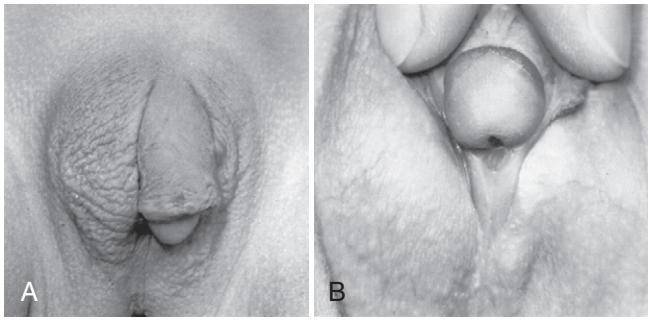

FIGURE 92-5 Asymmetric external genitals with left unilateral descended testis **(A),** penoscrotal hypospadias, and chordee **(B)**. Asymmetrical external genital development or gonadal descent would be characteristic of mixed gonadal dysgenesis or hermaphroditism.

gonadal dysgenesis. Such abnormalities or multiple congenital anomalies could indicate any of a variety of syndromes associated with ambiguous genitalia (see Box 92-1).

RADIOLOGIC INVESTIGATIONS

Pelvic Ultrasonography

Pelvic ultrasonography reveals vital information in the evaluation of DSDs. The presence or absence of a uterus is a critically important determinant in the initial evaluation (Figures 92-7 to 92-9). The newborn period is a time when the uterus, ovaries, and adrenal glands are optimally visualized (Wright et al, 1995). The presence of a well-developed uterus will direct the differential diagnosis toward virilization of a genetic female, true hermaphroditism, or persistent müllerian duct syndrome (PMDS); however, a rudimentary uterus may be seen in gonadal dysgenesis or hermaphroditism. Ultrasonography can locate undescended testes and determine gonadal size or irregularity, such as an oblong ovotestis. Gonads in the newborn are not always well visualized by ultrasound examination, but that does not necessarily mean they are absent or abnormal. In ovotesticular DSD, loss of the uniform testicular echotexture suggests the presence of an ovotestis. Ultrasound examination can determine whether the adrenal glands appear enlarged, as in CAH; however, normal adrenal size does not rule out CAH.

Genitourethrogram

A genitourethrogram is a fluoroscopically guided genital dye study that can provide important information on the urethra and internal genital ducts (Wright et al, 1995). An experienced radiologist should perform this study. It is important to ensure that all perineal orifices are examined. The main features to be noted are the presence or absence of a vagina (or prostatic utricle) and the relationship between the vagina and the urethra (see Figure 92-6). Demonstration of the level at which the vagina opens into the urogenital sinus and its relationship to the external sphincter has important surgical implications. Recognition of male or female urethral configurations also may be possible during genitourethrography.

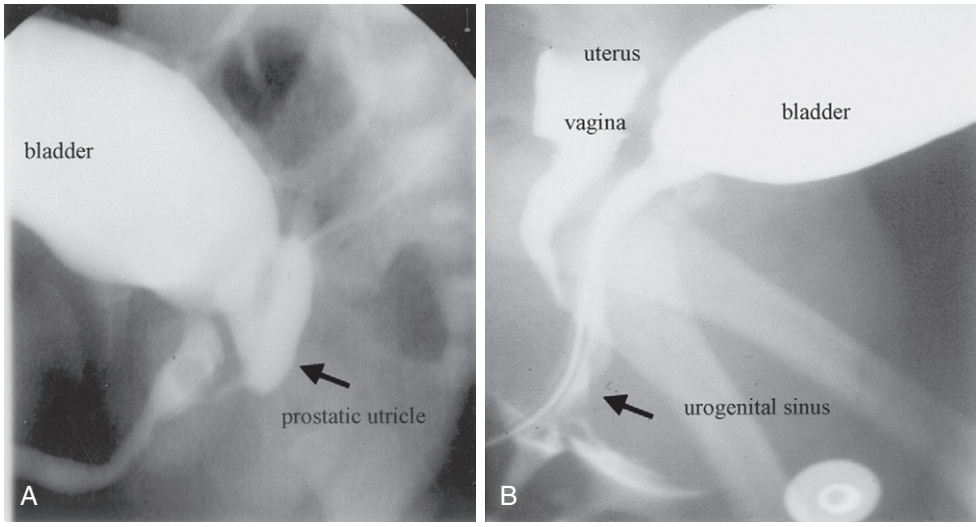

FIGURE 92-6 Genitourethrograms. A, Genitogram from a 46,XY infant with microphallus and undescended testes with a clearly delineated prostatic utricle (see Case Study 2). **B,** Genitogram from a 46,XX infant with congenital adrenal hyperplasia and severe masculinization of external genitals. The confluence of the vagina with the urogenital sinus is of intermediate severity.

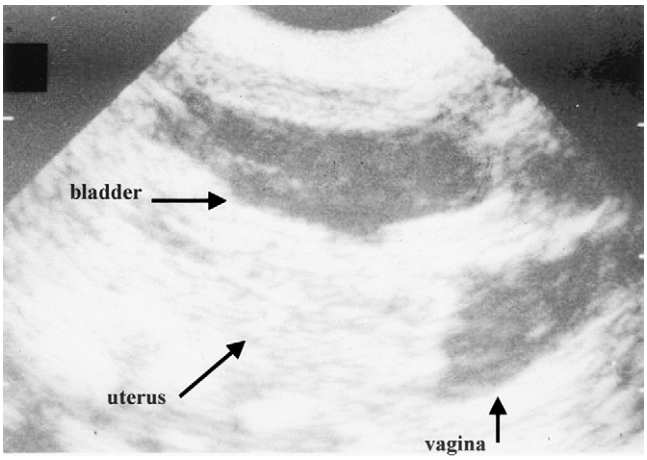

FIGURE 92-7 Ultrasound image from a 46,XX infant with ambiguous genitalia. Note the presence of a well-developed uterus with an endometrial stripe.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has been used to assess the internal genitalia of a limited number of infants and children with genital differentiation disorders. The strength of MRI lies in its ability to image large areas in multiple planes and characterize soft tissues. Detailed information about müllerian and wolffian structures and the position of the gonads can be obtained; however, thin sections (3 to 5 mm) are required for an adequate study. Streak gonads remain difficult to visualize. MRI has the capability to differentiate between an enlarged clitoris and a penis, because the bulbospongiosus muscle and transverse perineal muscle are absent or poorly visualized in the virilized female (Wright et al, 1995). MRI is a promising modality for the evaluation of ambiguous genitalia; however, further study is needed to demonstrate efficacy over other imaging modalities.

Laboratory Investigations

Endocrine and genetic laboratory studies are germane in the evaluation of ambiguous genitalia in the newborn. Day 1 of life is an ideal time to obtain serum testosterone and dihydrotestosterone (DHT) levels, as testosterone levels fall rapidly in the first several days of life (Forest et al, 1980). Material for chromosomal studies should optimally be obtained on day 1, as at least 48 to 72 hours are required to complete the study. On days 2 or 3 of life, determinations of serum 17-hydroxyprogesterone, 17-hydroxypregnenolone, 11-deoxycortisol, dehydroepiandrosterone (DHEA), androstenedione, and plasma renin activity are performed if CAH is suggested. Some clinicians perform an adrenocorticotropic hormone (ACTH) stimulation test at this time to

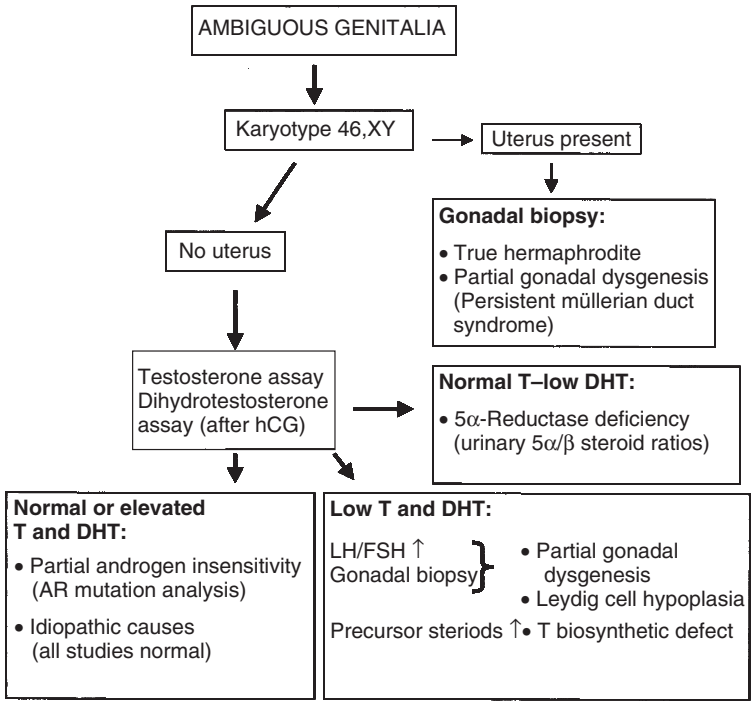

FIGURE 92-9 Algorithm for evaluation of the infant with ambiguous genitalia and 46,XY karyotype. The presence or absence of a uterus would be determined by radiographic imaging including ultrasound examination, genitourethrogram, or magnetic resonance imaging, as appropriate. Testosterone *(T)* and dihydrotestosterone *(DHT)* levels ideally should be obtained after human chorionic gonadotrophin (hCG) stimulation. *AR*, Androgen receptor; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone.

more clearly demonstrate a block in steroid biosynthesis. Results of these studies should be sent immediately to the appropriate reference laboratory for analysis. Alerting the reference laboratory to the urgent nature of the studies performed will facilitate rapid processing. 17-Hydroxyprogesterone levels are physiologically elevated in the 1st day of life, and screening for congenital adrenal hyperplasia should preferably not be done at this time. Serum gonadotropins are often suppressed in the immediate newborn period, so they should be measured after 1 week of life. Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels are helpful in assessing for androgen insensitivity, gonadal dysgenesis, and LH receptor abnormalities. Repeated LH, FSH, testosterone, and DHT testing should be done between 2 and 8 weeks of life in the evaluation of undervirilized males. This time period coincides with the physiologic testosterone surge seen in healthy male infants (Forest et al, 1980). When congenital adrenal hyperplasia is suggested, it is important to check sodium and potassium levels on a daily basis to prevent a salt-wasting crisis.

A human chorionic gonadotrophin (hCG) test will be useful in the evaluation of suspected incomplete masculinization of the genetic male. HCG binds the LH receptor and stimulates the testes to synthesize sex steroids. An adequate testosterone response rules out a testosterone biosynthetic defect, and a normal testosterone-to-DHT ratio argues against 5α-reductase-2 deficiency. In addition, the test can result in phallic enlargement. Almaguer et al (1993) reported an increase in phallic length of 0.25 to 0.75 cm in six 46,XY males with idiopathic microphallus within 5 days of beginning injections. A bolus of 1500 IU of hCG was given intramuscularly on 3 consecutive days, with steroids and phallic length measured on the 5th day. Growth of the phallus in response to hCG suggests that the phallus will further virilize at puberty, although no longitudinal study has documented this assumption.

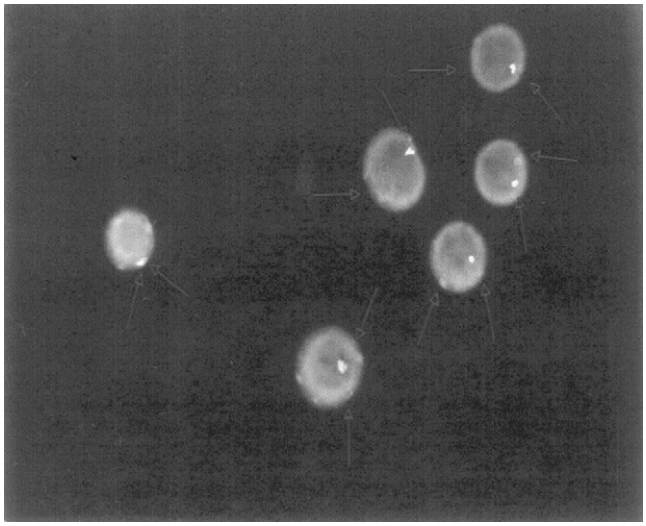

FIGURE 92-10 Fluorescence in situ hybridization (FISH) technique demonstrating the sex chromosome constitution of peripheral blood leukocytes.

A testosterone level greater than 200 ng/dL with a testosterone-to-DHT ratio of less than 8:1 is considered a normal response to hCG.

Fluorescence in situ hybridization (FISH) can rapidly determine the sex chromosome complement of the newborn by using X chromosome– and Y chromosome–specific centromeric probes (Schwartz et al, 1997) (Figure 92-10). In addition, this methodology allows for the detection of low levels of chromosomal mosaicism, because hundreds of cells can be analyzed rapidly. FISH is also useful in identifying a translocated SRY to an X chromosome (Wang et al, 2009). FISH analysis for determination of sex chromosome constitution has been shown to be

highly reliable, although this methodology has not been used extensively in the evaluation of ambiguous genitalia of the newborn. As a result, results should be interpreted with some degree of caution until confirmation by karyotypic analysis is available.

In a small percentage of ambiguous genitalia cases, laparoscopy with gonadal biopsy is necessary to confirm the diagnosis of true hermaphroditism, gonadal dysgenesis, or Leydig cell aplasia. Obtaining a karyotype from gonadal tissue may be helpful when sex chromosome mosaicism is suggested.

DISORDERS RESULTING IN AMBIGUOUS GENITALIA

VIRILIZATION OF THE FEMALE

Virilization of an XX infant is most commonly caused by CAH, although other virilizing conditions can be involved (see Figure 92-8). CAH encompasses a group of disorders of adrenal steroid hormone biosynthesis, of which more than 95% are due to 21-hydroxylase deficiency (New, 1992) (Figure 92-11).

Occasionally, the presence of excess androgens of maternal origin can result in virilization of the female fetus (Grumbach and Conte, 1998). A unique cause of both maternal and fetal masculinization is placental aromatase deficiency (Conte et al, 1994). 46,XX male sex reversal syndrome can occur when the SRY gene is translocated from the Y to an X chromosome. Most patients with SRY-positive 46,XX male sex reversal syndrome have normal male external genitalia, but occasionally the genitalia are ambiguous (Ergun-Longmire et al, 2005; Wang et al, 2009).

CONGENITAL ADRENAL HYPERPLASIA

21-Hydroxylase deficiency is the most common cause of ambiguous genitalia in the newborn female (New, 1992). 21-Hydroxylase deficiency has a population frequency of approximately 1 in 15,000, and the disorder is inherited in an autosomal recessive fashion. Males and females are equally affected; however, in classic cases, females usually are virilized at birth, resulting in the clinical presentation of ambiguous genitalia.

Deficiency of the 21-hydroxylase enzyme results in excess accumulation of the substrate 17-hydroxyprogesterone, which is shunted into the androgen synthesizing pathway and results in excess levels of androstenedione (see Figure 92-11). Androstenedione is then converted peripherally to testosterone. The excess production of androgens results in masculinization of the external genitalia of the female fetus, whereas a male infant with 21-hydroxylase deficiency is phenotypically normal. The degree of masculinization in the female is variable and can range from mild enlargement of the clitoris to complete closure of the urethra at the tip of the phallus (see Figure 92-4). The degree of virilization can be classified by Prader stages, ranging from I to V (Figure 92-12). Stage I represents mild enlargement of the clitoris only. Stage V

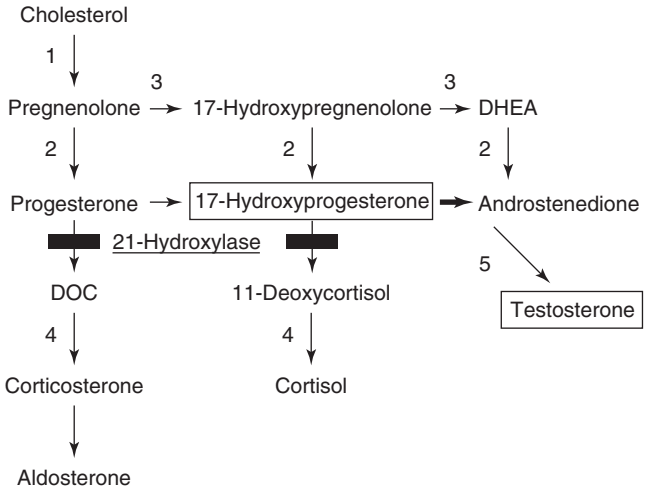

FIGURE 92-11 Steroid biosynthetic pathway demonstrating the defect in 21-hydroxylase deficiency *(solid bars)* and accumulated precursor 17-hydroxyprogesterone. Note the increased shunting into androgen-producing pathways. Steroidogenic enzymes are indicated as follows: (1) steroidogenic acute regulatory protein and side chain cleavage, (2) 3β-hydroxysteroid dehydrogenase, (3) 17α-hydroxylase/17,20-lyase, (4) 11β-hydroxylase, and (5) 17β-hydroxysteroid dehydrogenase. *DHEA*, Dehydroxyepiandrosterone; *DOC*, deoxycorticosterone.

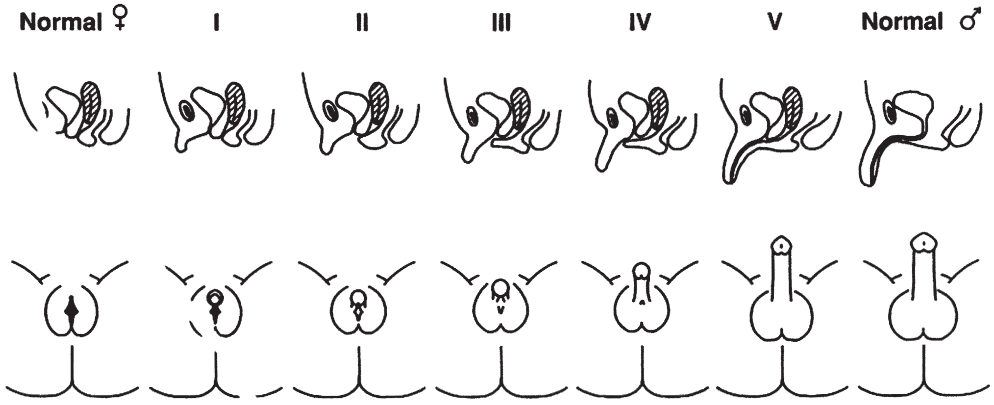

FIGURE 92-12 The stages of virilization of the female with congenital adrenal hyperplasia as developed by Prader. Stage I indicates mild clitoromegaly only; stage V indicates complete masculinization. *(Reproduced with permission from Migeon CJ, Berkovitz G, Brown T: Sexual differentiation and ambiguity. In Kappy MS, Blizzard RM, Migeon CJ, editors:* Wilkens' diagnosis and treatment of endocrine disorders in childhood and adolescence, *ed 4, Springfield, Ill, 1994, Charles C. Thomas, p 573.)*

represents complete masculinization of the external genitalia, with intermediate stages designating lesser degrees of involvement. The internal genitalia (ovaries, uterus, and fallopian tubes) of virilized females are normal, however, and wolffian duct–derived structures are absent.

The degree of masculinization of the external genitalia of 46,XX fetuses is dependent on the timing and magnitude of androgen exposure of the fetus. Exposure of the female fetus to high androgen levels earlier then 12 weeks' gestation results in fusion of the labial folds with formation of a urogenital sinus. In severely masculinized cases, the external genitalia may appear completely male (see Figure 92-4, *C* and *D*). High-level androgen exposure after 12 weeks' gestation will result in mainly clitoral hypertrophy (see Figure 92-4, *A*).

CAH with 21-hydroxylase deficiency will result in mineralocorticoid deficiency and salt loss in up to 75% of cases (New, 1992; Therrell et al, 1998). However, clinical manifestations of salt loss typically will not become apparent until several days or weeks after birth; therefore all infants with suspected salt-losing CAH need to be followed carefully during this time. Of note a male infant with salt-losing CAH will be phenotypically normal, and he is at great risk for salt-losing crisis after discharge from the newborn nursery. Fortunately, all 50 states within the United States now screen for CAH to prevent males from developing salt-losing crisis, and to prevent incorrect gender assignment of profoundly virilized female infants.

NEWBORN SCREENING

Diagnosis of 21-hydroxylase deficiency can be made by microfilter paper radioimmunoassay for 17-hydroxyprogesterone; this has been useful as a rapid screening test for congenital adrenal hyperplasia in newborns (Pang et al, 1977). This convenient test requires only 20 μL of blood, obtained by heel stick and blotted on microfilter paper, to provide a reliable diagnostic measurement of l7-hydroxyprogesterone, a cortisol precursor that accumulates in elevated concentrations in 21-hydroxylase deficiency. The simplicity of the test and the ease of transporting the microfilter paper specimens through the mail have facilitated the implementation of many congenital adrenal hyperplasia newborn screening programs in the United States and worldwide (Therrell et al, 1998).

There are, however, certain limitations to the screen (Gruneiro-Papendieck et al, 2001; Olgemoller et al, 2003; Therrell et al, 1998; van der Kamp et al, 2005). First, it is not always possible to determine the subtype of CAH solely through the screening of 17-hydroxyprogesterone; therefore, once a diagnosis of CAH has been made, genotyping is recommended to aid in classifying the subtype. Second, to maintain good specificity, many cases of the mild nonclassic form will be missed. Third, the cutoff values for a positive screen vary among different countries and among the different states within the United States. Fourth, preterm infants have higher 17-hydroxyprogesterone levels because of immaturity of the adrenal cortex (Hingre et al, 1994), which may present a challenge in determining what is normal. Cutoff values in the United States, Canada, and New Zealand are typically based on birthweight, although reports from screening programs in other countries indicate that gestational age, despite being less reliable than birthweight, may be a better predictor (Gruneiro-Papendieck et al, 2001; van der Kamp et al, 2005).

Finally, 17-hydroxyprogesterone levels rapidly decline after birth, and interpretation of the screening value depends on when the sample was drawn. It has been suggested that using a multitiered method using both birthweight and postnatal age can improve the positive predictive value of the screen (Olgemoller et al, 2003). Despite some issues that still need to be resolved, overall the newborn screening program for CAH has been widely successful in achieving the goals of an ideal screen: a relatively easy and efficient test, high morbidity and mortality if the screened disorder is untreated, relatively high disease incidence, and established effective treatment to minimize life-threatening complications after diagnosis.

The diagnosis of 21-hydroxylase deficiency should be suspected in all newborns with ambiguous genitalia (or clitoral hypertrophy) and absent gonads in the labial or scrotal folds. A serum 17-hydroxyprogesterone level obtained after the 1st day of life will often be diagnostic. 17-Hydroxyprogesterone levels are usually 50- to 100-fold above the normal range in classic cases, with typical random levels of 10,000 ng/dL or higher (New, 1992). In

Case Study 1

History

- A 3.5-kg term infant born after uncomplicated pregnancy
- Cryptorchidism and hypospadias noted, so infant discharged home as a male with plan for outpatient surgical evaluation
- Infant fed poorly at home, with intake of approximately 4 oz/day, no vomiting
- On day 5 of life, notification of abnormal newborn screen for congenital adrenal hyperplasia by health department; referred to emergency department

Evaluation

- On presentation to emergency department: infant was well-appearing, weight 2.9 kg (representing a loss of 0.6 kg)
- Genital examination: 2.3 × 1.1 cm phallus, severe hypospadias, marked labial fusion, no palpable gonads, marked hyperpigmentation of genitalia
- Electrolytes: sodium 140 mEq/L, potassium 5.8 mEq/L, chloride 107 mEq/L, CO_2 19 mEq/L, BUN 15 mg/dL, Cr 1.0 mg/dL
- Glucose 94 mg/dL
- Ultrasound examination: uterus present, enlarged adrenals, no gonads seen
- Karyotype 46,XX
- 17-Hydroxyprogesterone 20,000 ng/dL (normal < less than 200—unstimulated)
- Plasma renin activity 201 ng/mL/h (normal < less than 26)

Management and Outcome

- Gender was reassigned female
- Hydrocortisone (Cortef) and fludrocortisone acetate (Florinef) started along with NaCl supplements
- On day 10 of life, weight 3.2 kg, feeding 4 oz/4 hours
- By 4 months of age, significant reduction in clitoral and labial enlargement as well as resolution of hyperpigmentation
- By 3 years of age, the clitoral size had not normalized and the mother became very concerned about the child showing signs of gender "confusion," and hence clitoral reduction surgery was performed

some cases of 21-hydroxylase deficiency, ACTH stimulation testing may be necessary to establish the diagnosis.

Levels of androstenedione, testosterone, electrolytes, and plasma renin activity should also be determined. Plasma renin activity is a sensitive indicator of the intravascular volume status of the infant. Impaired sodium-potassium and sodium-hydrogen exchange owing to aldosterone deficiency in the distal tubule of the kidney results in hyponatremic dehydration, hyperkalemia, and metabolic acidosis.

Assessment for the less common forms of CAH resulting in ambiguous genitalia—11β-hydroxylase deficiency and 3β-hydroxysteroid dehydrogenase deficiency (3β-HSD)—include measuring 11-deoxycortisol, deoxycorticosterone (DOC), and 17-hydroxypregnenolone. (Use of a comprehensive steroid panel from a reliable reference laboratory will limit the amount of required blood to 3 to 5 mL.)

11β-Hydroxylase deficiency accounts for approximately 5% of CAH cases worldwide, and this disorder will result in masculinization of the female fetus (see Figure 92-11). However, the presence of volume overload and hypertension distinguishes this disorder from 21-hydroxylase deficiency (New, 1992). Presumably the hypertension is caused by the excess mineralocorticoid activity of the DOC metabolite. Typically, 11-deoxycortisol (compound S) is elevated and plasma renin activity is suppressed in this disorder.

3β-HSD may result in ambiguous genitalia in the newborn period (see Figure 92-11). Unlike 21-hydroxylase deficiency, this enzyme is present in the gonads as well as the adrenal glands, and deficiency of 3β-HSD can result in undermasculinization of the male infant or mild masculinization of the female infant. The 3β-HSD enzyme is needed for testosterone biosynthesis; therefore the male fetus may be inadequately masculinized. This enzyme deficiency results in excess production of the steroid DHEA, which can be converted to more potent androgens peripherally. The female infant with this disorder can have clitoromegaly, although such children often are phenotypically normal. A marked increase in the ratios of 17-hydroxypregnenolone or 17-hydroxyprogesterone and of DHEA or androstenedione is diagnostic in mutation-positive forms of this disorder (Sakkal-Alkaddour et al, 1996).

Treatment of CAH in the newborn period consists of glucocorticoid and mineralocorticoid replacement. Hydrocortisone is the most physiologic form of synthetic glucocorticoids and is less likely to result in unwanted side effects. Hydrocortisone is administered orally at a dose of approximately 25 mg/m^2/day (divided into three doses) in the newborn period. No liquid preparation of hydrocortisone is currently available, so tablets must be crushed and administered carefully with formula or food. Mineralocorticoid replacement (fludrocortisone acetate [Florinef]) at a starting dose of 0.1 mg/day in the newborn is recommended. Sodium chloride supplements (approximately 1 to 2 g/day) may be a useful adjunctive therapy in salt-losing CAH, because formula and human milk have low salt contents. Once therapy is initiated, careful monitoring of the infant's growth and determination of serum 17-hydroxyprogesterone, androstenedione, testosterone, aldosterone and plasma renin activity are recommended.

Salt-losing crisis and acute adrenal insufficiency should be treated with stress doses of hydrocortisone (100 mg/m^2/day), which can be given either continuously as a drip or divided into equal doses every 6 hours. Intravenous fluids with ample sodium chloride (normal saline for boluses and one-half normal saline for maintenance fluids) are an essential component of treating salt-losing crisis. Care should be taken not to overhydrate or underhydrate the infant. Hyperkalemia often decreases after sodium chloride and hydrocortisone are provided intravenously, although severe cases of hyperkalemia may require additional therapies.

Gender assignment for 46,XX infants with 21-hydroxylase deficiency has traditionally been female (American Academy of Pediatrics Committee on Genetics, 2000; Donahoe, 1991; Forest, 2001; Migeon et al, 1994; New, 1992;). Gender identity of 46,XX adults with CAH typically is female, with various degrees of masculinized behavior (Money and Ehrhardt, 1972; Reiner, 1997). Prenatal androgenization affects gender-related behavior, but not gender identity, in girls with CAH aged 5 to 12 years (Meyer-Bahlburg et al, 2004a). Cases of gender identity disorder have been reported in treated females with CAH (Slijper et al, 1998), and cases of gender reassignment from female to male have been reported (Meyer-Bahlburg et al, 1996). Persons with undiagnosed 46,XX CAH who are profoundly virilized have functioned successfully as males (Blizzard, 1999; Meyer-Bahlburg, 2009). Diamond and Sigmundson (1997a) have suggested male gender assignment in profoundly virilized 46,XX individuals, although female gender assignment is likely to prevail in current practice until evidence is obtained to indicate otherwise (Crouch et al, 2008; Lee, 2001).

In addition to medical therapies for CAH, efforts to normalize the appearance of the external genitalia may be pursued. It should be kept in mind that hypertrophy of the clitoris will gradually lessen after medical therapy is instituted; however, complete normalization in the more virilized cases is not likely to occur. In severe cases of clitoral enlargement, clitoral reduction surgery is a treatment option, although suboptimal cosmetic results have been reported in long-term outcome studies. Atrophy or loss of the clitoris or excessive regrowth of clitoral tissue has been described in examinations of adolescent and adult patients who underwent genital surgery in early childhood (Alizai et al, 1999; Creighton et al, 2001). The risk of surgery needs to be balanced against the potential detrimental effects of masculinized genitalia on the development of a poor body image (Meyer-Bahlburg et al, 1996) and of social stigmatization by family or community members (Money et al, 1986). Recently, nerve-sparing ventral clitoroplasty in virilized females has been shown to preserve dorsal nerves for better sensitivity after surgery (Poppas et al, 2007).

Surgical correction of the vagina in CAH is performed to exteriorize the vagina and to enlarge the vaginal opening so that successful intercourse can occur later in life (see later section on surgery). There is considerable debate about when to perform vaginal exteriorization surgery. A number of studies have demonstrated the development of vaginal stenosis when vaginoplasties are performed in the prepubertal period (Alizai et al, 1999;

Creighton et al, 2001; Krege et al, 2000). The investigators advocate delaying vaginoplasty until puberty or later, when manual dilation can be undertaken by the patient and estrogenization of the vaginal mucosa can help to prevent stricture formation. Others recommend that vaginoplasties be undertaken early in life, because the procedure is technically easier in the first several years of life and the emotional trauma of a major surgery at adolescence is avoided (Donahoe, 1991; Schnitzer, 2001). Recent reports of long-term outcome of genitoplasty by patient advocate groups such as the Intersex Society of North America (ISNA) and others have called for a general moratorium on all nonessential genital surgery in infancy, until affected persons are old enough to express their wishes and give consent (Diamond and Sigmundson, 1997a). Problems with loss of sexual sensation and pleasure have been reported in adult patients as a consequence of genital surgery in early life. However, in cases of severe discordance between assigned sex and genital appearance, the psychosocial consequences of uncorrected genital anomalies can be damaging (Money and Ehrhardt, 1972; Money et al, 1986). Participation of the parents in the decision to pursue genital surgery after they have been fully informed of the benefits and risks is perhaps the most judicious approach at this time (Daaboul and Frader, 2001; Lee, 2001; Reiner, 1997).

Significant reductions in fertility have been reported in women with salt-losing CAH (Kuhnle et al, 1995; Mulaikal et al, 1987). Suggested explanations for reduced fertility included increased anovulatory cycles, low rates of heterosexual activity, inadequate vaginal introitus, and poor compliance with medical treatment (Mulaikal et al, 1987). Problems with a disturbed body image and feeling less feminine were associated with a lower rate of success among women with CAH in terms of the ability to establish a partnership or marry (Kuhnle et al, 1995). Overall quality of life for female patients with CAH was comparable with that for controls, suggesting that affected women may develop coping strategies and cognitive appraisals that enable them to accept their life and view it as satisfying (Kuhnle et al, 1995).

PRENATAL DIAGNOSIS AND TREATMENT

DIAGNOSIS

Since the report by Jeffcoate et al (1965) of the successful identification of an affected fetus by elevated concentrations of 17-ketosteroids and pregnanetriol in the amniotic fluid, investigators in the past have performed prenatal diagnosis for congenital adrenal hyperplasia by measurements of hormone levels in pregnancy (Jeffcoate et al, 1965; Levine et al, 1986; New and Levine, 1973). The most specific hormonal diagnostic test for 21-hydroxylase deficiency is elevated 17-OHP in the amniotic fluid (Frasier et al, 1974; Hughes and Laurence, 1979, 1982; Nagamani et al, 1978; Pang et al, 1980); Δ4-androstenedione can be used as an adjunctive diagnostic assay (Pang et al, 1980). Amniotic fluid testosterone levels might not be outside the normal range in an affected male (Wilson et al, 1995). Measuring hormone levels in amniotic fluid detects only severe cases, and for the most part it has been replaced by molecular diagnosis.

HLA genotyping of amniotic fluid cells is another possible means of diagnosis, but it has been superseded by direct molecular analysis of the 21-hydroxylase locus. With the advent of chorionic villus sampling, evaluation of the at-risk fetus is currently possible in the first trimester at 9 to 11 weeks' gestation. The fetal DNA is used for specific amplification of the *CYP21A2* gene using polymerase chain reaction and Southern blotting, which has the advantage of requiring small amounts of DNA (Speiser et al, 1990). Because of improved accuracy and earlier diagnosis, molecular analysis of fetal DNA is now the method of choice for prenatal diagnosis. See Chapter 91 for more details.

TREATMENT

Treatment with dexamethasone can be used in pregnancies at risk for 21-hydroxylase deficiency (Dorr et al, 1986; Evans et al, 1985; Forest and David, 1991; Mercado et al, 1995; Speiser et al, 1990). When properly administered, dexamethasone is effective in preventing ambiguous genitalia in the affected female. The current recommendation is to treat the mother with a pregnancy at risk for 21-hydroxylase deficiency with dexamethasone in a dose of 20 μg/kg divided into two or three doses daily (Mercado et al, 1995).

Adrenocortical steroidogenesis begins at approximately 6 weeks' gestation, and differentiation of the external genitalia and urogenital sinus begins at approximately 9 weeks' gestation (New et al, 1989). The institution of dexamethasone therapy is recommended as soon as pregnancy is confirmed and no later than 9 weeks after the last menstrual period; this will effectively suppress adrenal androgen production, allow normal separation of the vaginal and urethral orifices, and prevent clitoromegaly. The need to initiate at such an early date means that treatment is blind to the sex of the fetus. If the fetus is determined to be a male upon karyotyping or an unaffected female upon DNA analysis, treatment is discontinued. Otherwise, treatment is continued to term.

Between 1978 and 2002, prenatal diagnosis and treatment of CAH caused by 21-OHD was performed in 595 pregnancies at The NewYork–Presbyterian Hospital–Weill Medical College of Cornell University, of which 108 infants were affected with classic 21-OHD. Of these, 64 were females, 51 of whom were treated prenatally with dexamethasone. Dexamethasone administered at or before 9 weeks' gestation was effective in reducing virilization, thus avoiding postnatal genitoplasty (Carlson et al, 1999; New et al, 2003). No significant or enduring side effects were noted in the mothers (other than greater weight gain and a higher incidence of striae and edema than untreated mothers) or the fetuses. There was no statistically significant difference in hypertension or gestational diabetes between treated and untreated mothers. All mothers who took partial or full treatment stated they would take dexamethasone again in the event of a future pregnancy. In our report and in others, no cases have been reported of cleft palate, placental degeneration, or fetal death, which have been observed in a rodent model of in utero exposure

to high-dose glucocorticoids (Goldman, 1978; Nimkarn, 2005). In contrast, another study noted some significant maternal side effects, including excessive weight gain, cushingoid facial features, severe striae resulting in permanent scarring, and hyperglycemic response to oral glucose administration (Pang et al, 1992).

A long-term follow-up study of 44 children treated prenatally in Scandinavia demonstrated normal prenatal and postnatal growth compared with matched controls (Lajic et al, 1998). Prenatally treated newborns also did not differ in weight, length, or head circumference from untreated, unaffected newborns (Carlson et al, 1999; New et al, 2003). Moreover, a survey of 174 children aged 1 month to 12 years and exposed prenatally to dexamethasone (including 48 with CAH) compared with 313 unexposed children (including 195 with CAH) found no differences in cognitive or motor development between the two groups (Meyer-Bahlburg et al, 2004b). Therefore we believe that proper prenatal treatment of fetuses at risk for CAH can be considered effective and safe. Long-term studies on the psychological development of patients treated prenatally are currently under way. This therapy may be controversial in other centers.

The efficacy of prenatal treatment in 11β-OHD CAH has been shown as well. In 1999 Cerame et al (1999) reported the first prenatal diagnosis and treatment of an affected female with 11β-OHD CAH. As an indication of the treatment's success, the prenatally treated newborn had normal female external genitalia.

INCREASED MATERNAL ANDROGENS AND PROGESTINS

Masculinization of the female fetus has been reported in pregnant mothers taking various progestational agents to prevent miscarriage. These agents include norethindrone, ethisterone, and medroxyprogesterone. Danazol, which has been used in the treatment of endometriosis, has been associated with fetal masculinization (Grumbach and Conte, 1998). Masculinization of the female fetus due to maternal virilizing ovarian or adrenal tumors or luteomas of pregnancy has been reported. In such cases, virilization beyond the time of birth does not occur, and the prognosis is good (Grumbach and Conte, 1998).

PLACENTAL AROMATASE DEFICIENCY

Placental aromatase deficiency has been associated with masculinization of the female fetus. Aromatase is a cytochrome P450 enzyme that is responsible for the conversion of testosterone to estradiol and of androstenedione to estrone. Autosomal recessive inheritance of aromatase deficiency causes virilization of the female because of a failure to metabolize the large amounts of androstenedione and testosterone produced by the placenta. This disorder also will cause significant virilization of the mother. The affected infant will be virilized with normal müllerian structures. Gonadotropins are elevated in infancy, and ovarian cysts may develop. At puberty, females have hypergonadotropic hypogonadism with failure to feminize and progressive virilization. Plasma androstenedione and testosterone levels are elevated, whereas estrone and estradiol levels are low. Postpubertal patients have delayed bone maturation, tall stature, and osteopenia (Conte et al, 1994).

INCOMPLETELY MASCULINIZED MALES

Incomplete masculinization refers to absence of or incomplete masculinization of the external and internal genitalia in a person with a 46,XY karyotype and normal testes. Disorders leading to incomplete masculinization of the male include androgen receptor defects, testosterone biosynthetic defects, 5α-reductase deficiency, Leydig cell hypoplasia, and effects of maternal medications (see Figure 92-9).

It should be noted that in 25% to 50% of undermasculinized males, a specific cause cannot be found (Al-Agha et al, 2001; Eil et al, 1984). Other factors such as medications and placental insufficiency may potentially interfere with genital masculinization. Placental insufficiency may be related to genital underdevelopment through the presumed mechanism of inadequate hCG production. Placental hCG is required for early fetal testosterone production and therefore early fetal genital development.

Medications such as cimetidine, spironolactone, phenytoin (Dilantin), phenobarbital, medroxyprogesterone, and cyproterone acetate have been associated with altered androgen action or metabolism. Their use during pregnancy may be detrimental to male genital development (Donahoe, 1991; Grumbach and Conte, 1998). Furthermore, various xenobiotics can bind the androgen receptor; therefore there has been speculation regarding the role of environmental factors in abnormal sex differentiation (Danzol, 1998).

ANDROGEN RECEPTOR DEFECTS (ANDROGEN INSENSITIVITY)

Disorders of the androgen receptor are the most common definable cause of incomplete masculinization of the genetic male (Quigley et al, 1995). Disorders of the androgen receptor can be divided into complete androgen insensitivity and partial androgen insensitivity (PAIS) syndromes. The gene for the androgen receptor (*AR*) is located on the X chromosome, and more than 300 mutations have been found (Griffin et al, 2001). Mutations have been found throughout the *AR* gene, with most mutations occurring in the DNA or steroid-binding domains. Despite extensive characterization of the molecular genetics of *AR* mutations, no genotype–phenotype correlation has been found (Quigley et al, 1995).

The sex-differentiating actions of testosterone and DHT are mediated by the androgen receptor. DHT is important in the differentiation of the male external genitalia and prostate, whereas testosterone is important in the differentiation of internal wolffian ducts to epididymis, vas deferens, and seminal vesicles.

Complete Androgen Insensitivity

Complete androgen insensitivity syndrome in a 46,XY individual is characterized by phenotypically normal female external genitalia (Figure 92-13). Affected

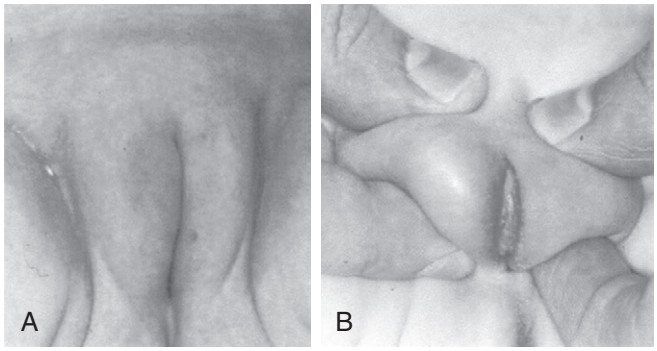

FIGURE 92-13 **A,** Appearance of external genitalia of a 46,XY infant with complete androgen insensitivity syndrome. **B,** Note presence of bilateral palpable gonads.

children will have an inguinal hernia before puberty or primary amenorrhea after puberty onset. Robust breast development occurs at puberty that is due to peripheral aromatization of testosterone to estrogen. There is usually scant or absent pubic and axillary hair with some vulvar hair. The vagina is short and blind-ending, and müllerian structures (cervix, uterus, fallopian tubes) are absent. There are only vestigial or no wolffian duct–derived internal structures. The testes are located in the abdomen or inguinal canal or in the labia majora. Gender identity and role behaviors are typically female. Removal of the testes is recommended because of risk for development of gonadoblastoma, although there is no consensus on the timing of orchidectomy (Forest, 2001; Migeon et al, 1994).

Partial Androgen Insensitivity

PAIS is characterized by varying degrees of ambiguity of the external genitalia. The term *Reifenstein syndrome* formerly was used to describe partial androgen insensitivity with intermediate degrees of masculinization. Affected infants have a small phallus and a ventral chordee that tethers the phallus to the perineum. There is often a penoscrotal hypospadias and a bifid scrotum, which may or may not contain gonads (see Figure 92-3). Cryptorchidism is a common finding. Müllerian structures are absent, and the wolffian duct–derived structures are absent or poorly developed. A genitourethrogram may demonstrate a urogenital sinus.

The diagnosis of partial androgen insensitivity is complex. A family history of ambiguous genitalia in male relatives would be suggestive of this diagnosis. However, Viner et al (1977) reported a positive family history in only 25% of patients with PAIS. 5α-Reductase deficiency and testosterone biosynthetic defects should be ruled out by appropriate steroid analysis. This can be accomplished by measuring intermediates in testosterone biosynthesis and by measuring the ratio of testosterone to DHT. It should be noted that abnormal testosterone-to-DHT ratios can be seen in PAIS (Ahmed et al, 1999); this could be caused by poor development of tissues, which express 5α-reductase-2 in PAIS (Griffin et al, 2001).

Androgen levels in normal newborns are highest at birth and then decline rapidly during the 1st week. A second testosterone surge occurs between 15 and 60 days of life (Forest et al, 1980). Androgen and LH levels should be obtained at these peak production times. Alternatively, an hCG stimulation test may be performed as follows: a dose of 1500 IU of hCG is given intramuscularly daily for 3 days; androgen and gonadotropin levels are measured at baseline and then 24 hours after the third dose. Abnormally elevated levels of LH, testosterone, or both in the first several months of life are suggestive of androgen insensitivity. However, a recent report of five neonatal cases of PAIS showed testosterone values in the high-normal range on days 2 to 7 of life (mean, 107 ± 27 ng/dL) and on day 30 (mean, 411 ± 154 ng/dL; Bouvattier et al, 2002). LH levels were elevated in comparison with historic controls (mean LH levels on days 7 to 15 of life were 5.2 IU/L ± 4.0 ng/dL; on day 30 of life mean levels were 8.7 IU/L ± 2.5 ng/dL). Testosterone response to hCG and LH response to gonadotropin-releasing hormone were exaggerated (Bouvattier et al, 2002).

The androgen receptor binding assay was considered standard for defining this disorder in the past. However, normal ligand binding does not rule out androgen insensitivity, because there may be mutations in domains of the androgen receptor not involved in ligand binding. Direct sequencing of the androgen receptor for mutation analysis is commercially available (GeneTest) and can detect up to 95% of mutations associated with complete androgen insensitivity. Androgen receptor mutations, however, are not always found in cases of possible partial androgen insensitivity, and it is speculated that defects in androgen receptor–interacting proteins may be involved.

Determining the gender of rearing in partial androgen insensitivity is a difficult task, and multiple factors must be considered. If there is a significant degree of virilization (Prader stages 4 and 5; see Figure 92-12), then male sex assignment is made (Diamond and Sigmundson, 1997b; Reiner, 1997). If masculinization is severely limited (Prader stages 1 and 2), then female sex assignment is recommended. In intermediate forms (Prader stage 3), responsiveness to exogenously administered hCG or testosterone may be of help in the decision-making process (Daaboul and Frader, 2001; Grumbach and Conte, 1998). However, adult males with a small phallus have reported satisfactory sex lives (Reilly and Woodhouse, 1989). These cases perhaps deemphasize the importance of phallic size in male sex assignment. Slijper et al (1998) reported the absence of serious gender identity disorder in five undervirilized 46,XY males, although these boys were "more fearful and bothered about the smallness of their penises." Money and Ehrhardt (1972) cautioned about the devastating psychosocial effects of male sex assignment when the phallus is only slightly larger than a clitoris and does not respond to testosterone.

In a study of 32 undervirilized males who were assigned female gender for rearing, significant gender transposition (i.e., gender change and homosexual orientation) correlated with the presence of childhood stigmatization and a relatively late age at feminizing surgery (Money et al, 1986). Stigmatization in the home was reflected by treating the child differently from other children, including elaborate efforts at maintaining the privacy of the genital anomaly, keeping the child at home and

forbidding play with neighborhood children, and refusal of open communication within the family about the medical condition. Stigmatization in the community was reflected by teasing, such as about the genital anomaly, body habitus, and mannerisms. Stigmatization by parents or the community also was found to be associated with gender transposition in undervirilized males who were assigned male gender for rearing; cosmetic inadequacy of the external genitalia was less important (Money and Norman, 1987).

These studies indicate the importance of a nurturing, supportive environment to a successful long-term outcome for these children. More comprehensive long-term outcome studies of partial androgen insensitivity are greatly needed.

5α-REDUCTASE-2 DEFICIENCY

5α-Reductase-2 deficiency is an autosomal recessive disorder that results in an inability to convert testosterone to DHT. DHT is required for the development of the male external genitalia.

At birth, these 46,XY infants typically have a very small phallus that appears to be a normal or slightly enlarged clitoris. However, more significant virilization of the phallus may occur, and the affected child will then be identified as a male with hypospadias. There is usually severe penoscrotal hypospadias. The scrotum is bifid, with slight posterior fusion. The testes are usually in the inguinal canals or labial folds. Approximately half of these patients have a penoscrotal urethra with a separate blind-ending vagina; a smaller percentage have a single urogenital sinus opening on the perineum (Griffin et al, 2001). Müllerian structures are absent, and wolffian duct–derived structures (vas deferens, epididymis, seminal vesicles) are well developed. The prostate is poorly developed.

At the time of puberty, individuals with this disorder will characteristically virilize. The phallus will typically increase to a length of 4 to 8 cm (Migeon et al, 1994). In affected persons who were raised as females, a change to the male gender role after puberty is commonly seen (Griffin et al, 2001; Imperato-McGinley, 1997). Unlike in partial androgen insensitivity, gynecomastia does not occur in the pubertal period.

5α-Reductase-2 deficiency has been diagnosed in the postpubertal period in most cases, although diagnosis in the newborn period has been reported (Imperato-McGinley et al, 1986; Odame et al, 1992). The disorder is diagnosed by assessing the ratio of testosterone to DHT in blood (Peterson et al, 1977). The normal testosterone-to-DHT ratio in the newborn period is 4:1, whereas the ratio in infants and children with this disorder is often greater than 14:1. An hCG stimulation test usually is needed to obtain a more definitive diagnosis in the prepubertal period. A positive response to hCG rules out Leydig cell aplasia or a testosterone biosynthetic defect. Measurement of normal androstenedione levels will rule out the testosterone biosynthetic defect—17β-HSD dehydrogenase deficiency. This enzyme is responsible for the conversion of androstenedione to testosterone, and the clinical presentation in infancy can be similar to that of 5α-reductase deficiency.

In addition, abnormal ratios of 5β- to 5α-urinary steroids can establish a definitive diagnosis of 5α-reductase deficiency-2 (Imperato-McGinley et al, 1986). Distinguishing 5α-reductase deficiency from partial androgen insensitivity is important, because androgen insensitivity can cause a secondary DHT deficiency owing to the incomplete development of tissues that express 5α-reductase activity (Griffin et al, 2001). Measurement of urinary 5β- and 5α-glucocorticoids will help to make this distinction, because only 5α-reductase deficiency will also affect glucocorticoid metabolism. Analysis of 5α-reductase-2 activity in genital fibroblasts also can be determined. Finally, analysis for mutations in the *SRD5A2* gene is diagnostic; however, this test is not commercially available.

Sex assignment in cases of 5α-reductase deficiency is a complicated issue, but there is long-term outcome information available. As in androgen insensitivity disorders, sex assignment is often significantly influenced by the degree of masculinization at birth, and because infants with this disorder usually are markedly undervirilized, female sex assignment has been advocated (Grumbach and Conte, 1998; Migeon et al, 1994). However, if the disorder is diagnosed early, topical DHT treatment has been shown to enlarge the phallus (Odame et al, 1992). In addition, the natural history of the disorder is for masculinization of the phallus to occur at puberty. Testicular histopathologic analysis in of males with this disorder has shown that, unlike in isolated bilateral cryptorchidism, their testes display type Ad (i.e., dark) spermatogonia and a normal germ cell count. These patients are largely infertile because of defective transformation of spermatogonia into spermatocytes (Hadziselimovic and Dessouky, 2008).

There are frequent reports of reversal from female to male gender behavior after puberty (Wilson, 2001; Wilson et al, 1993). The accumulated evidence would support male sex assignment in this disorder (Imperato-McGinley, 1997), although female sex assignment is likely in the newborn period if the diagnosis is overlooked.

TESTOSTERONE BIOSYNTHETIC DEFECTS

Five enzymes are necessary for the synthesis of testosterone. A defect at any step will result in inadequate testosterone synthesis (see Figure 92-11). Defects in the first three enzymes of the testosterone synthesis pathway will also affect adrenal steroid production, resulting in both an undervirilized male and CAH. Because testosterone production is impaired in these disorders, wolffian duct structures are likely to be underdeveloped, whereas müllerian structures are absent because of normal testicular MIF production. These enzyme deficiencies are rare; therefore these disorders are discussed only briefly.

17β-Hydroxysteroid Dehydrogenase-3 Deficiency (17-Ketosteroid Reductase Deficiency)

The final step in testosterone biosynthesis involves the conversion of androstenedione to testosterone by the enzyme 17β-HSD in the testicle. Mutations that impair the function of 17β-HSD are the cause of this relatively rare autosomal recessive disorder (Wilson, 2001).

The clinical presentation externally is that of a female at birth with perhaps a mild degree of clitoral enlargement. The phenotype is female; therefore these infants typically are raised as females. At puberty, there is progressive masculinization, with enlargement of the phallus to 4 to 6 cm with labial enlargement and rugation. By late puberty, the testes are found at the lower ring of the inguinal canal, and they are of normal size and consistency. Internal wolffian duct–derived structures are found. In addition, a male body habitus develops, with deepening of the voice and appearance of male body hair, including mustache and beard (Migeon et al, 1994).

Most patients receive a diagnosis at puberty or as adults. Endocrine studies reveal markedly elevated androstenedione levels, whereas testosterone levels are in the low-normal range (Mendonca et al, 2000). Plasma LH levels are consistently high. In infancy or childhood, the presence of inguinal hernias may bring the child to medical attention. Androstenedione levels in the prepubertal patient may be normal, and the hCG stimulation test is required to elucidate the defect.

Gender of rearing often is influenced by the cultural context. In societies in which a high priority is given to the male gender, gender reassignment at puberty has been successful (Forest, 2001). Mendonca et al (2000) have observed changes in gender role (female to male) in 3 of 10 affected individuals. Despite virilization in some affected persons, the female gender role was maintained.

Congenital Lipoid Adrenal Hyperplasia

Lipid accumulation in both the adrenal glands and gonads is characteristic of this disorder pathologically—hence the name *congenital lipoid adrenal hyperplasia*. Because all adrenal and gonadal steroid synthesis is affected by this disorder, infants are likely to exhibit complete adrenal insufficiency, characterized by vomiting, weight loss, and hypotension. The phenotype is likely to be female, although there is clinical variability. In the 35 cases reported in the medical literature, only 11 patients have survived beyond infancy (Forest, 2001).

Endocrinologic findings include elevation of ACTH and plasma renin activity, but low or immeasurable levels of all steroid hormones. The main consideration in the differential diagnosis is CAH. The presence of markedly enlarged lipid-laden adrenals on ultrasound, computed tomography, or MRI studies is highly suggestive of the disorder. Successful treatment has occurred and requires replacement of both glucocorticoids and mineralocorticoids. All persons with this diagnosis have been raised as females (Grumbach and Conte, 1998).

In vitro studies performed on either adrenal or testicular tissue demonstrated an inability to convert cholesterol to pregnenolone in these patients. A defect in the first step of adrenal and gonadal steroid biosynthesis mediated by the cytochrome P450 side chain cleavage (P450scc) enzyme was suspected. However, subsequent molecular studies demonstrated mutations in the steroidogenic acute regulatory protein (StAR) (Grumbach and Conte, 1998). StAR acts to promote sterol translocation to the P450scc enzyme in mitochondria (see Figure 92-11 and Case Study 2).

Case Study 2

History

- The infant was born at 41 weeks' gestation, weighing 3.2 kg.
- Pregnancy was complicated by preterm contractions from 29 to 34 weeks requiring bed rest.
- Triple screen was abnormal and amniocentesis was performed, revealing a 46,XY karyotype with no mosaicism. The parents did not want to know the karyotype because they did not wish to know the sex of the baby.
- At birth the infant was thought to have normal female genitalia and was assigned to the female sex.
- On careful physical examination the infant was found to have mildly virilized genitalia.

Physical Examination and Laboratory Studies

- Genital examination: mild clitoromegaly, mild posterior labial fusion, a single urogenital sinus, and bilateral inguinal hernias with gonads present
- Ultrasound examination: testicle like structures in the upper portion of the inguinal canal without evidence of a uterus or ovaries
- Karyotype and FISH: confirmed 46,XY, no mosaicism
- Endocrine studies

6 Weeks of age

- Testosterone, 20 ng/dL; DHT, 11 ng/dL
- FSH, 4.3 mIU/mL; LH, 9.0 mIU/mL
- No mutations identified in the androgen receptor

3 Months of age

- Patient underwent a bilateral orchiectomy, inguinal hernia repair, and vaginoplasty.
- Testicular pathology was consistent with prepubertal seminiferous tubules, spermatic cord with vas deferens, epididymis, and hernia sac.

Further clinical course: 6 months of age

- The patient had 2-week history of irritability and, several days of intermittent vomiting, and was admitted to the hospital with dehydration and in adrenal crisis.
- Serum sodium (Na^+) was 124 meq/mL.
- Serum potassium (K^+) was 7.7 meq/mL.
- There were low levels of all adrenal hormones, including testosterone, with no response to ACTH stimulation; baseline cortisol was 10 μg/dL, stimulating to only 12 μg/dL 60 minutes after ACTH was administered.
- Plasma renin activity was 14,345 ng/dL/h.
- Baseline ACTH level was 4781 pg/mL.
- Genetic analysis revealed c.178+1G>C intron 2 homozygous splicing mutation of the *StAR* gene.

Diagnosis

- Congenital lipoid adrenal hyperplasia owing to StAR protein gene mutation

Management and Outcome

- Glucocorticoid supplementation with hydrocortisone and mineralocorticoid supplementation with fludrocortisone initiated
- Female gender assignment maintained

3β-Hydroxysteroid Dehydrogenase Deficiency II

3β-HSD deficiency was first reported by Bongiovanni (1962). 3β-HSD is an important enzyme required for the conversion of Δ-5 to Δ-4 steroids in the adrenal glands and gonads (see Figure 92-11). There is marked heterogeneity in clinical presentation, and both genders are affected (Forest, 2001). With severe deficiency of 3β-HSD, salt-losing crisis can occur. Male infants may have ambiguous

or completely feminine external genitalia, whereas female infants may be mildly virilized. Severely undervirilized males may have normal mineralocorticoid activity; fully masculinized males may display salt loss.

Diagnosis of this disorder in the newborn period can be difficult because of relatively high levels of Δ-5 steroids physiologically. The diagnosis is based on the ratio of 17-hydroxyprogesterone to 17-hydroxypregnenolone and of DHEA to androstenedione in the basal and stimulated states (Sakkal-Alkaddour et al, 1996).

17α-Hydroxylase/17,20-Lyase Deficiency

A single enzyme encoded on the P450c17 (*CYP17A1*) gene mediates the 17-hydroxylation of pregnenolone and progesterone and the conversion of 17-hydroxypregnenolone and 17-hydroxyprogesterone to DHEA and androstenedione. Specific mutations can cause partial loss of 17α-hydroxylase/17,20-lyase activites or dissociation between the 17α-hydroxylase and 17,20-lyase function (Dhir et al, 2009). Clinical disorders of this enzyme affect primarily either the hydroxylation or the lyase reaction, although there have been reports of combined 17α-hydroxylase and 17,20-lyase deficiency (Sahakitrungruang et al, 2009). Cases of primarily 17-hydroxylase deficiency should be considered in undervirilized males or females with low renin hypertension and hypokalemic alkalosis. The hypertension is presumably due to elevated levels of DOC and corticosterone (see Figure 92-11). Most cases are diagnosed in the pubertal period because the 46,XY phenotype is largely female. Of interest, although cortisol synthesis is blocked, the overproduction of DOC and corticosterone is protective against adrenal insufficiency. This disorder is treated with glucocorticoid, which suppresses ACTH overproduction and subsequently suppresses DOC and corticosterone overproduction (Grumbach and Conte, 1998). Sex steroid replacement is needed at puberty.

17,20-Lyase deficiency results in various degrees of undermasculinization of the 46,XY infant. The phenotype ranges from complete female external genitalia to ambiguous genitalia to a mildly undervirilized male. 46,XX females will fail to enter puberty. Gonadotropins will be elevated, along with impaired formation of DHEA and androstenedione (see Figure 92-11). DOC and corticosterone are normal in this form of the disorder. HCG and ACTH stimulation tests may be helpful to more fully reveal the steroid biosynthetic block.

LEYDIG CELL HYPOPLASIA

Failure of the testicles to produce testosterone in response to hCG is characteristic of this disorder. Histologic examination of the testes reveals absent or low numbers of Leydig cells, normal-appearing Sertoli cells, and seminiferous tubules with spermatogenic arrest (Grumbach and Conte, 1998). LH receptor mutations have been described in this disorder. Phenotypically, the external genitalia range from those of a normal female to those of a male with microphallus. Müllerian-derived structures are absent in all patients, whereas wolffian structures may be present. LH and FSH levels are elevated in postpubertal patients, and LH levels decrease after testosterone administration. In less severe forms of the disorder, testosterone therapy augments phallic growth. In severe forms of testicular unresponsiveness to hCG/LH, gender assignment has been female. The gonads are removed, and estrogen replacement therapy is instituted at the time of expected puberty (Grumbach and Conte, 1998).

PERSISTENT MULLERIAN DUCT SYNDROME

The diagnosis of PMDS often is made in otherwise phenotypically normal 46,XY males at the time of surgery for an inguinal hernia or orchidopexy. In the case of hernia repair, a fallopian tube and uterus are often found along with a partially descended testis. In other cases, testes, uterus, and fallopian tubes are found in the pelvis. Inheritance of PMDS is autosomal recessive, although the female phenotype is completely normal. The disorder has been found to be due to a mutation in the antimüllerian hormone or receptor (Grumbach and Conte, 1998). Therapy involves orchidopexy and partial hysterectomy, with care taken to avoid injuring the vas deferens that is embedded in the uterine wall.

GONADAL DIFFERENTIATION AND CHROMOSOMAL DISORDERS

46,XY Complete Gonadal Dysgenesis

46,XY complete gonadal dysgenesis was first described by Swyer in 1955 (Grumbach and Conte, 1998). The phenotype of the external genitalia was female with normal development of müllerian-derived internal structures. Streak gonads are found that are completely nonfunctional; therefore müllerian structures do not regress, and wolffian structures are poorly developed or absent (Figure 92-14). Most affected persons are seen in the teenage years with lack of pubertal development. Serum gonadotropin levels are elevated. Mutations in the *SRY* gene account for only a small proportion of these cases (Forest, 2001). Familial cases have been reported. There has been report of a 46,XY mother who developed as a normal woman and gave birth to a 46,XY daughter with complete gonadal dysgenesis in a family with multiple disorders of sexual development, suggesting an unidentified sex-determining gene (Dumic et al, 2008). In up to 30% of affected persons, gonadoblastomas will develop in the streak gonad; therefore removal of the streak gonad is recommended (Migeon et al, 1994) (see Figure 92-14). Estrogen replacement therapy will provide appropriate feminization.

46,XY Partial Gonadal Dysgenesis

Patients with 46,XY partial gonadal dysgenesis will typically be seen in the newborn period for evaluation of ambiguous genitalia (Berkovitz et al, 1991). The extent of masculinization of the external genitalia depends on the extent of testicular differentiation. Gonadal tissue is usually intraabdominal, but testes can be found in the scrotum. One quarter of these patients will have phenotypic features of Turner's syndrome (Migeon et al, 1994). Testosterone response to hCG is variable but usually low. In most cases, there is a mix of müllerian and wolffian structures. The presence of müllerian structures on genitourethrogram or ultrasound

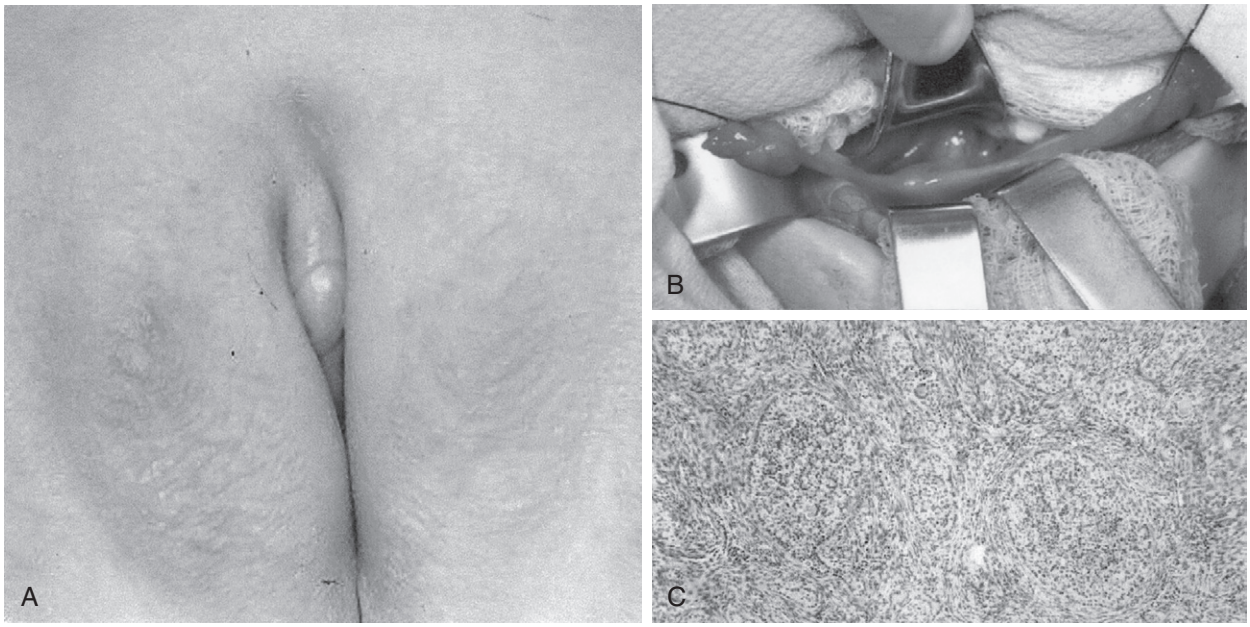

FIGURE 92-14 **A,** Appearance of external genitalia in complete gonadal dysgenesis in a 46,XY infant with features of Turner's syndrome. **B,** Uterus and fallopian tubes were found at surgery, along with a gonadoblastoma, at 1 year of age. **C,** Micrograph of tumor cells.

examination increases the index of suspicion for this disorder. The diagnosis is confirmed by gonadal biopsy. Some affected children are found to have one dysgenetic gonad on one side and a streak gonad on the other; others have bilateral dysgenetic gonads. Dysgenetic gonads are histologically defined by poorly formed and disorganized seminiferous tubules surrounded by wavy ovarian stroma. In many cases, the dysgenetic gonads resemble ovotestes, except that primordial ovarian follicles are lacking (Berkovitz et al, 1991).

MIXED GONADAL DYSGENESIS

Mixed gonadal dysgenesis (MGD) refers to asymmetric gonadal dysgenesis with ambiguous genitalia (see Figure 92-5) and a mosaic karyotype with an XY cell line. The most common karyotype is 45,XO/46,XY. There is a wide spectrum of phenotypes, ranging from a female with clitoral enlargement to a male with hypospadias. Asymmetric external and internal genital development has been classically described in this syndrome (Forest, 2001). Considerable phallic development was reported in a majority of patients in one study, and there was often penoscrotal hypospadias (Davidoff and Federman, 1973). The phenotypic features of Turner's syndrome are described in a significant percentage of patients, although these features may not be readily apparent in the newborn period. An incompletely formed uterus is found in almost all patients. Fallopian tubes are always found on the side of the streak gonad and often on the side with the dysgenetic gonad. Wolffian structures may be developed on the side with the dysgenetic gonad.

A genitourethrogram is likely to demonstrate internal müllerian structures that can be confirmed at laparoscopy. Demonstration of abnormal gonadal histopathologic features will confirm the diagnosis. It should be noted that mixed gonadal dysgenesis shares many features with partial gonadal dysgenesis, and some authors view these disorders as representing a continuum of gonadal dysgenesis (Berkovitz et al, 1991). Histologic analysis will also differentiate this disorder from true hermaphroditism. Although the characteristic karyotype is 45,XO/46,XY, it should be noted that this genotype has been associated with normal male differentiation in a majority of cases diagnosed by prenatal amniocentesis (Wheeler et al, 1988).

Some authors advocate female sex assignment in mixed gonadal dysgenesis, because surgical repair of the vagina is usually easy and a uterus or hemiuterus is present. In addition, the dysgenetic gonad is at risk for development of a tumor and should be removed, particularly if the gonad cannot be brought down into the scrotum (Forest, 2001). However, sex assignment is likely to be guided by the degree of virilization, with the more virilized cases being assigned as males. The capacity for near-normal androgen production in this disorder has been described (Davidoff and Federman, 1973). In all cases, the streak gonads should be removed because of the risk for malignancy.

TESTICULAR REGRESSION SYNDROME

Testicular regression syndrome refers to the spectrum of disorders affecting persons with 46,XY karyotype who demonstrate evidence of prior testicular function, followed by usually symmetric gonadal regression. Loss of testicular function between weeks 8 and 10 of gestation would result in ambiguous genitalia and variable internal genitalia. Loss of testicular function after 12 to 14 weeks' gestation would result in normal male genital differentiation with a small phallus. When the male external and internal ducts are completely normal, the term *vanishing testis syndrome* is used by some authors. Presumably the testes were lost during the second half of pregnancy. Testicular torsion has been invoked as a possible explanation in this syndrome.

FSH levels are elevated in infancy, and an exaggerated response to gonadotropin-releasing hormone in the prepubertal period typically is seen (Grumbach and Conte, 1998). Antimüllerian hormone levels in infancy and childhood are very low in anorchia and intermediately low with abnormal testes (Lee, 2001).

OVOTESTICULAR DISORDER OF SEX DIFFERENTIATION

Ovotesticular DSD is defined as the presence of both testicular tissue with distinct seminiferous tubules and ovarian tissue containing mature graafian follicles in a single individual. Both testicular and ovarian elements may be found in the same gonad, or one testicle and one ovary may be found in the same individual. In a majority of cases the karyotype is 46,XX; 46,XX/46,XY chimerism and 46,XY karyotypes also can be found. Clinically the external genitalia are often ambiguous, but predominantly male or female phenotypes have been described (Grumbach and Conte, 1998; Hadjiathanasiou et al, 1994). In ambiguous cases, a relatively marked degree of virilization can be found. Almost all have some degree of hypospadias and incomplete labioscrotal fold fusion. The labioscrotal folds are asymmetric, with an appearance of a hemiscrotum on one side and labium majus on the other being seen in 10 of 22 cases (Hadjiathanasiou et al, 1994). At least one gonad is usually palpable. A vagina and uterus are present in most patients, and a genitourethrogram may be required for elucidation. Internal duct development is consistent with the associated gonad, although müllerian ducts predominate with an ovotestis. Breast development is common during puberty, and menses can occur in up to 50%.

The diagnosis should be suggested in 46,XX/46,XY individuals with ambiguous genitalia. Palpation of a polarized gonad should also lead the clinician to suggest the diagnosis. In one study, 11 of 12 46,XX true hermaphrodites examined before 6 months of age had baseline testosterone levels greater than 40 ng/dL; normal levels for females of this age would be less than 15 ng/dL (Hadjiathanasiou et al, 1994).

Gender assignment depends on the degree of masculinization, capacity of testicular tissue to secrete testosterone, and the presence or absence of a uterus and tubes. In general, a female gender assignment is favored because of the presence of ovarian tissue and external genitalia that can more easily be reconstructed as female. Male gender assignment is more likely if there is significant virilization. Removal of ductal or gonadal structures not consonant with the gender of rearing is recommended. Testes are usually dysgenetic, which carries an increased risk of gonadoblastoma formation; therefore careful follow-up evaluation is indicated. As in all cases of DSD, gender identity and behavior issues, along with general psychological well-being, should be evaluated longitudinally.

SYNDROMES ASSOCIATED WITH AMBIGUOUS GENITALIA

Denys-Drash syndrome is a rare syndrome consisting of the classic triad of congenital nephrotic syndrome leading to end-stage renal failure, XY ambiguous genitalia, and Wilms' tumor. The external genitalia of 46,XY individuals are either ambiguous or female. Gonadal development encompasses a spectrum from streak gonads to dysgenetic testes. Nephropathy and proteinuria are noted at an early age, and renal biopsy will demonstrate mesangial sclerosis. Greater than 90% of cases will have a mutation in the *WT1* gene, which is a critical gene for the development of the normal genital tract. *WT1* also is associated with the WAGR syndrome. Large deletions of chromosome 11p13 that encompass the *WT1* gene are responsible for this disorder. Frasier syndrome also involves the *WT1* gene. This syndrome manifests in 46,XY females with gonadal dysgenesis and progressive glomerulopathy.

Camptomelic dysplasia is a rare autosomal dominant disorder associated with often lethal skeletal dysplasia, in which 75% of affected 46,XY males have dysgenetic testes associated with undervirilization (Grumbach and Conte, 1998). Manifestations of this disorder include bowing of the femora and tibiae, hypoplastic scapulae, 11 rib pairs, pelvic malformations, bilateral clubfoot, cleft palate, macrocephaly, micrognathia, hypertelorism, and a variety of cardiac and renal defects. The disorder is caused by heterozygous mutations in the *SOX9* gene (Grumbach and Conte, 1998). Most patients die in the neonatal period from respiratory distress.

Smith-Lemli-Opitz syndrome is an autosomal recessive disorder with an estimated frequency of 1 in 20,000 to 1 in 40,000. The disorder is caused by 7-dehydrocholesterol reductase deficiency (Forest, 2001). This enzyme catalyzes the final step in cholesterol biosynthesis; therefore the combination of low serum cholesterol and a high serum 7-dehydrocholesterol is suggestive of the diagnosis. Growth and developmental delay and multiple congenital anomalies characterize this disorder. Genital anomalies may include hypospadias, cryptorchidism, micropenis, and hypoplastic scrotum. Craniofacial abnormalities may include microcephaly, narrow bifrontal diameter, broad maxillary ridges, ptosis of the eyelids, micrognathia, and anteverted nostrils (Jones, 1997). Syndactyly of the second or third toes is a common feature. Adrenal insufficiency has been reported in this condition. Treatment with cholesterol improves growth and neurodevelopmental status.

Robinow syndrome is an autosomal dominant disorder characterized by a flat facial profile, short forearms, and hypoplastic genitals (Jones, 1997). Sporadic cases have been reported. Microphallus may be severe in males, although normal virilization at the time of puberty has been reported (Jones, 1997). Undescended testes have been reported in 65% of affected boys. Females have characteristic hypoplastic labia and clitoris. Other features include small size at birth, macrocephaly, frontal bossing, hypertelorism, prominent eyes, small upturned nose, micrognathia, and posteriorly rotated ears. Short forearms are seen in 100% of described cases. Other skeletal abnormalities include thoracic hemivertebrae, fusion or absence of ribs, and scoliosis. The abnormal facial features become less pronounced as the child grows, and cognitive performance has been normal in most affected persons.

OTHER DISORDERS OF GENITAL DIFFERENTIATION

Hypospadias is one of the most common anomalies of male genital development, with an estimated incidence of 4 to 8 cases per 1000 male births (Grumbach and

Conte, 1998). Hypospadias can be classified as glandular, penile, penoscrotal, scrotal, and perineal. Typically the more severe forms of hypospadias have been associated with DSDs, although the phenotypic spectrum of DSDs is wide. In a study of 33 patients with severe (scrotal or penoscrotal) hypospadias, 12 were found to have a DSD, which included Denys-Drash syndrome (in 3 of the 12), partial androgen insensitivity (in 2), true hermaphroditism (in 2), chromosomal abnormality (in 1), MIF abnormality (in 1), gonadal dysgenesis (in 1), 5α-reductase deficiency (in 1), and 46,XX male karyotype (in 1, *SRY*positive) (Albers et al, 1997). It should be noted that the testes were undescended in 11 of the 12 patients. Aarskog (1970) found an approximately 15% prevalence of DSDs in association with hypospadias, in addition to a significant role for maternal progestins.

Thus, severe cases of hypospadias require a thorough evaluation including karyotype and hCG stimulation testing, along with examination of the genitourinary tract, particularly if accompanied by undescended testes.

OVERVIEW OF THE SURGICAL MANAGEMENT OF DISORDERS OF SEXUAL DIFFERENTIATION

Surgery for DSD conditions has been criticized recently. The criticism has focused not only on the timing of surgery but on whether reconstructive surgery should be done at all. Some authorities have advised that surgery be postponed until the affected person is of an age to make his or her own decision regarding the advisability of surgical correction (Diamond and Sigmundson, 1997a). Others have found that delay in surgery may be associated with problematic outcomes (Meyer-Bahlburg et al, 1996; Money et al, 1986; Reiner, 1997). It is imperative that these divergent viewpoints be discussed with the parents of an infant with a DSD condition.

These issues must be kept in mind in any decision regarding surgery for management of DSDs. Current surgical techniques that are available for correction of ambiguous genitalia and DSDs are presented next.

FEMINIZING GENITOPLASTY

Feminizing genitoplasty is one of the more common procedures done for correction of ambiguous genitalia. Feminizing genitoplasty is indicated in the genetic female who is externally virilized, most commonly as the result of CAH. The degree of virilization can be highly variable (see Figure 92-4). The degree of virilization will have a significant influence on the type of procedure done, especially the vaginoplasty portion of the operation. Reconstruction in this group of patients has three components: clitoral reduction, vaginoplasty, and labial reconstruction. The timing of surgical correction also has undergone some changes over the years. The current thinking is that once a decision is made to proceed with genital reconstruction, performing this type of surgery at a younger age will have distinct advantages, including easier mobilization of the urogenital sinus and a more benign postoperative course.

Clitoral Reduction

Attempts at managing the enlarged clitoris in genetic females with clitoral hypertrophy started with total clitorectomy. Young (1937) originally advocated this procedure. Later, Lattimer (1961) suggested a recession rather than a resection of the clitoris, and he hoped to be able to preserve the arousal function of the clitoris. This led to cases in which painful clitoral erections occurred later in life; therefore further modification was needed. Spence and Allen (1973) advocated the preservation of the glands with reduction in the size of the clitoris. Since then, several reports have examined preservation of the neurovascular bundle using a clitoral reduction and recession type of approach. Kogan (1987) and Snyder (1983) and their colleagues separately described a similar approach in which the erectile tissue of the clitoris is removed, but preservation of the neurovascular bundle and the glands is afforded to preserve the neurologic and arousal functions of the clitoris. If the gland is unusually large in size, then a reduction of the gland size may be indicated as well.

Vaginoplasty

Reconstruction of the vagina in cases of virilization in females requires an understanding of the anatomy. One may consider the anatomic abnormality an embryologic arrest of maturation with a persistence of an early embryologic stage. The anatomic issue that is important to the surgical management of the common urogenital sinus is the site of confluence of the genital tract and urethra. This site varies considerably but is somewhat predictable from the appearance of the degree of external virilization. Children with severe degrees of external virilization are more likely to have a higher confluence of the urethral and vaginal channels, leading to a longer urogenital sinus or a more masculinized urogenital sinus. In the classic article on urogenital sinus abnormalities, Hendren and Crawford (1969) described the variable anatomy that can be seen in these children and noted that the operative procedures needed to be tailored toward the location of the confluence of the urinary and genital tracts. One may describe the confluence anatomically as it relates to the external sphincter, with confluences distal to the external sphincter being considered *low* and those proximal to the external sphincter being referred to as *high*. One also may describe the variable anatomy according to the length of the urethra from the bladder neck to the point of confluence. If that length of urethra were long, then one would consider this a low confluence. Conversely, if the length of the urethra were short and therefore close to the bladder neck, then a high confluence would be present (see Figure 92-6, *B*).

The low confluence cases can generally be repaired either by a cutback procedure on the fused labioscrotal folds or by a flap vaginoplasty. A cutback procedure would be indicated in cases with a minor degree of fusion of the labioscrotal folds. The middle to high vaginal confluence, however, generally requires either a pull-through vaginoplasty or a total urogenital mobilization to bring the vagina down to the perineum.

Flap Vaginoplasty

The flap vaginoplasty should be used for a low confluence of the urogenital sinus. The procedure entails mobilization of a perineum-based flap with its apex at the meatus of the urogenital sinus. Dissection then proceeds along the posterior wall of the urogenital sinus until the vaginal opening is identified. The perineum-based flap is then inserted into the posterior wall of the vagina, thereby exteriorizing the vagina to the perineum.

Total Urethral Mobilization

Total urogenital mobilization can be used for the high urogenital sinus, which has been advocated by Pena (1997) and subsequently substantiated by reports from Rink et al (1997). This approach has been shown to have a superior cosmetic result, compared with that obtained with a flap vaginoplasty, for a middle to high confluence. In addition, there has been a reduced incidence of urethral vaginal fistula and vaginal stenosis. The mobilization occurs in a plane both anterior to the urogenital sinus and up to the bladder neck under the pubic symphysis and posteriorly along the urogenital sinus, and then along the posterior wall of the vagina.

Pull-Through Vaginoplasty

The pull-through vaginoplasty is reserved for use in severely masculinized genetic females, whose surgical management continues to present a major challenge. Initially, the approach was a combined perineal and abdominal approach with complete mobilization of the vagina and uterus and separation of the vagina from the urethra at the confluence. The abdominal mobilization will then allow the vagina to be brought down to the perineum. A modification of this approach was described by Passerini-Glazel (1989) in which the more distal urogenital sinus tissue was used to provide an anterior vaginal wall flap, which will then connect to the true vagina and allow for a complete perineal approach to the procedure.

VAGINAL AGENESIS

Vaginal replacement has a role in certain DSDs or structural abnormalities of the genital urinary tract. The DSDs in which vaginal replacement may be indicated are 46,XX vaginal agenesis, 46,XY male karyotype with severely inadequate virilization or complete androgen insensitivity syndrome, structural urogenital defects such as cloacal exstrophy or persistent cloaca, or after a pelvic exenteration for malignancy. There are a variety of tissues and techniques used for vaginal reconstruction: skin grafting, progressive perineal indentation, and split-thickness or fold thickness tissue grafts with expanders, myocutaneous flaps, and bowel. The critical point in creating a vagina is to maintain an adequate perineal opening, an adequate-length tunnel, and good fixation to pelvic structures. This area is highly controversial in terms of the best management. Overall, the most popular tissue for vaginal plate replacement has been the split-thickness skin graft as described by McIndoe (1950). The major disadvantage of this technique has proved to be the need for long-term dilatation to maintain patency and to avoid vaginal stenosis. The use of bowel segments for vaginal replacement was first described by Baldwin (1904). Because of an extraordinarily high mortality rate associated with this approach, earlier attempts using this technique were abandoned. Since then, this approach has been adopted by many groups and has been shown to be highly successful, with minimal complication rates. A major advantage of a bowel-segment vagina over a skin graft is the minimal risk of "poor take" because of the vascularized pedicle to the segment of bowel that is used. Length and patency of the bowel are not issues for similar reasons, because it maintains its blood supply. No dilatation is needed. Early on, intestinal mucus production can be a problem, but this lessens over time, and mucus may act as a natural lubricant. Minimal perineal scarring is associated with this approach as well, and it can be done at a very young age (Hensle and Dean, 1992).

UNDERVIRILIZED MALES

Inadequate virilization results in hypospadias with or without cryptorchidism. In more severe cases, such as a complete form of androgen insensitivity, these children may appear as phenotypically normal females and present at the time of puberty with primary amenorrhea. Vaginoplasty is frequently needed after puberty in that population. Children with varying degrees of hypospadias, with or without cryptorchidism, will usually require a repair following the usual principles of hypospadias and cryptorchidism repair. These repairs are generally done at 6 months of age and are tolerated well as outpatient procedures.

GONADECTOMY

Gonadectomy is required under two circumstances in DSDs. Gonadectomy would be recommended when the gonads are inconsistent with the sex of rearing. This is most commonly seen in androgen insensitivity syndrome (46,XY karyotype) in which normal testes are present, but a female gender assignment has been made. The timing of the gonadectomy is controversial; however, it is currently thought to be best managed once the diagnosis has been made, because the role of postnatal testosterone imprinting in a child's psychosocial development is uncertain.

The other circumstance in which gonadectomy is recommended is in DSDs in which gonadal malignancy is a significant risk. This is most likely to occur in cases in which dysgenetic gonads and a Y chromosome are present. An example is shown in Figure 92-14, in which a 1-year-old infant with pure XY gonadal dysgenesis was found to have a gonadoblastoma on gonadectomy. Other syndromes in which gonadal malignancy is a concern include mixed gonadal dysgenesis and the presence of a dysplastic testis in a dysgenetic XY male.

CONCLUSIONS

Significant advances have been made in our understanding of the pathophysiology and molecular genetics of DSD. A systematic diagnostic approach to the infant with ambiguous genitalia should be undertaken to identify the

underlying disorder. Establishing the diagnosis will often provide a better understanding of the natural history of the disorder.

The need for surgical intervention in DSDs should be assessed on a case-by-case basis. The parents need to be informed about the risks and benefits of surgery. Surgery on the external genitalia should perhaps be reserved for individuals with significant discord between the sex of rearing and the appearance of the external genitalia.

The infant with a DSD and the family will have to cope with difficult psychosocial challenges throughout life. Physicians caring for these patients should try to ensure the integration of well-trained mental health professionals into the longitudinal care of these complex infants and children.

ACKNOWLEDGMENT

This chapter was originally written by Gregory Goodwin and Anthony Caldamone. It has been modified and updated to its current form by Karen Lin-Su and Maria I. New.

CHAPTER 93

Disorders of the Thyroid Gland

Sureka Bollepalli and Susan R. Rose

Thyroid hormone is an integral requirement for normal fetal brain development and for growth and regulation of energy metabolism throughout infancy and childhood. An understanding of thyroid physiology and embryogenesis of the thyroid gland in the perinatal period is important for proper interpretation of abnormal laboratory results and initiation of appropriate treatment. Currently, in the United States and in most other countries, newborn screening is available for early recognition of abnormal thyroid function and to aid in early intervention. However, certain conditions such as hyperthyroidism and central hypothyroidism may be missed by newborn screening. Thyroid hormone abbreviations are defined in Table 93-1.

EMBRYOGENESIS OF HYPOTHALAMIC-PITUITARY-THYROID AXIS

The human thyroid gland is a derivative of the primitive buccopharyngeal cavity. It develops from contributions of two anlagen: a midline thickening of the pharyngeal floor (median anlage) and paired caudal extensions of the fourth pharyngobranchial pouch (lateral anlagen). All of these structures are visible by days 16 to 17 of gestation. The median anlage is initially in close contact with the endothelial tubes of the embryonic heart. A pair of ultimobranchial bodies arise from the lateral anlagen. The parafollicular or C cells arise from the ultimobranchial bodies in mammals and are the source of calcitonin. By 40–50 days' gestation, the median and lateral anlagen have fused and the buccal stalk has ruptured. During this period, the thyroid gland migrates caudally to its definitive location in front of the second to sixth tracheal ring, helped in part by its relationship with developing cardiac structures. The pharyngeal region contracts to become a narrow stalk called the thyroglossal duct, which subsequently atrophies. An ectopic thyroid gland or persistent thyroglossal duct or cyst results from abnormalities of thyroid descent (Brown et al, 2005; Santisteban, 2005).

By the latter part of the 10th week of gestation, the histogenesis of the thyroid is virtually complete, although the follicles do not contain colloid until 13 weeks' gestation (Santisteban, 2005). A single layer of endothelial cells surrounds the follicular lumen. Thyroxine (T_4) has been detected in the serum of a 78-day-old fetus. At this age, the fetal thyroid is capable of trapping and oxidizing iodide (Foley, 1994). Then fetal thyroid begins to secrete thyroid hormone and contributes to the fetal circulation of thyroid hormone by the beginning of the second trimester.

At the same time as the development of the thyroid gland, the fetal pituitary and hypothalamus are also forming and beginning to function. The anterior pituitary gland is derived from Rathke's pouch, which originates at the roof of the pharynx. Histologic differentiation of pituitary cells can be observed by 7 to 10 weeks' gestation, and thyroid-stimulating hormone (TSH) can be detected in fetal blood by 10 to 12 weeks (Kratzsch and Pulzer, 2008). The hypothalamus develops from the ventral portion of the diencephalon (Santisteban, 2005). Thyroid hormone–releasing hormone (TRH) has been found in fetal whole-brain extracts by 62 days and in the hypothalamus by 9 weeks of gestation (Polk et al, 1991).

FETAL-PLACENTAL-MATERNAL THYROID INTERACTION

In considering the fetal-maternal relationship, the placenta is of major importance (Figure 93-1). The fetus requires thyroid hormone throughout pregnancy for optimal neurodevelopment. TSH does not cross the placental barrier, whereas TRH does. Maternal to fetal transport of T_4 during the first trimester is critical because the fetal thyroid axis is not independently functional until mid-gestation. The importance of sufficient maternal thyroid hormone supply, during the first half of pregnancy, is evidenced by poor neurodevelopmental outcomes in offspring of mothers with iodine deficiency or maternal hypothyroidism that was untreated (Kooistra et al, 2006; Morreale de Escobar et al, 2004).

Placental T_4 transfer in a fetus with a total inability to synthesize T_4 results in a fetal T_4 concentration that is 25% to 50% of that found in normal neonates. As a result, in a mother with normal thyroid function, the hypothyroid fetus is somewhat protected. The mother with hypothyroidism and a normal fetus may have a relative thyroid deficit in the first trimester of gestation, whereas the mother with hypothyroidism and a hypothyroid fetus may experience a more significant deficit (Glinoer, 2001).

Triiodothyronine (T_3) is not transferred across the placenta from the mother. Fetal serum T_3 results from metabolism of maternal T_4 that reaches fetal tissues (Calvo et al, 2002). Cerebral T_3 is necessary for normal development of the neocortex; however, T_3 in serum only minimally contributes to cerebral T_3. Therefore, fetal cerebral T_3 levels are dependent on maternal T_4, not serum T_3 (Morreale de Escobar et al, 1992). The astrocytes take up maternal T_4; the T_4 is then converted to T_3 by type II monodeiodinase (MDI) within astrocytes that deliver T_3 to neurons (Bernal, 1999).

Iodides cross the placenta readily. Iodides and iodine, when given in large quantities, produce a transient inhibition of T_4 synthesis by diminishing iodination, probably through effects on thyroidal autoregulation. Therefore, excess iodine given to the mother causes goiter in the offspring; however, pregnant women should be taking 250 μg of iodine daily (Abalovich et al, 2007).

Other clinically important compounds that can affect fetal thyroid function by crossing the placenta from the mother to the fetus are antithyroid drugs, environmental goitrogens, endocrine disruptors, and thyroid antibodies (Foley, 1994; Mastorakos et al, 2007). Antithyroid drugs include

TABLE 93-1 Abbreviation List

CH	Congenital hypothyroidism
FT_3	Free T_3
FT_4	Free T_4
hCG	Human chorionic gonadotropin
MTZ	Methimazole
PTU	Propylthiouracil
RI	Radioactive iodine
RIA	Radioimmunoassay
rT_3	Reverse T_3 (3,3′,5′-L-triiodothyronine)
TBG	Thyroid (thyroxine)-binding globulin
TBII	Thyrotropin binding inhibiting immunoglobulin
TBPA	Thyroxine-binding prealbumin
TG	Thyroglobulin
TPO	Thyroid peroxidase
TRBAb	TSH receptor–blocking antibodies
TRH	Thyroid–releasing hormone
TSA	TSH receptor stimulating antibodies
TSH	Thyroid-stimulating hormone (thyrotropin)
TSH-R	Thyroid-stimulating hormone Receptor
TSI	Thyroid-stimulating immunoglobulin
T_2	Diiodothyronine
T_3	Triiodothyronine (3,5,3′-L-triiodothyronine)
T_3U (T_3RU)	T_3 resin uptake to estimate thyroid binding
T_4	Thyroxine (tetraiodothyronine)
Type I MDI	Type I monodeiodinase
Type II MDI	Type II monodeiodinase
Type III MDI	Type III monodeiodinase

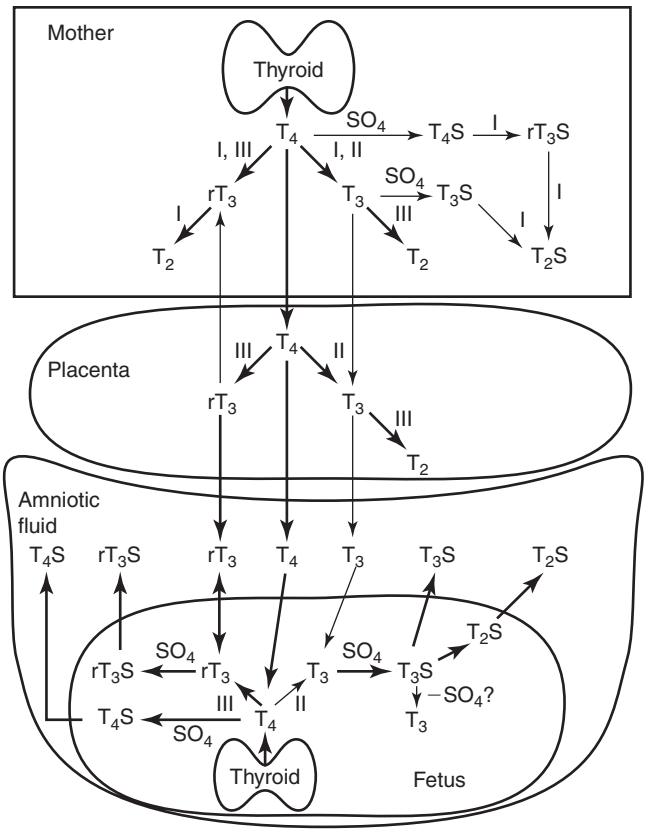

FIGURE 93-1 Interrelations of maternal, placental, and fetal thyroid metabolism. *(From Burrow GN, Fisher DA, Larsen PR: Maternal and fetal thyroid function*, N Engl J Med *331:1072-1078, 1994. Copyright 1994, Massachusetts Medical Society. All rights reserved.)*

perchlorates and thionamide compounds such as thiourea, thiouracil, propylthiouracil (PTU), methimazole, and carbimazole. Transplacental transfer of these drugs can result in fetal goiter with or without hypothyroidism (Laurberg et al, 2009). Transfer of thyroid-stimulating immunoglobulin (TSI) across the placenta to the fetus can lead to transient neonatal thyrotoxicosis (Polak, 1998) (see Hyperthyroidism, later); the placental transfer of TSH receptor blocking antibodies (TRBAb) can cause transient neonatal hypothyroidism (Brown et al, 1996).

In summary, placental permeability to maternal molecules may affect fetal thyroid function as a result of maternal pathophysiologic states (acute iodide administration, autoimmune thyroid disease, or pharmacotherapy of thyrotoxicosis). Maternal-to-fetal transplacental transfer of thyroid hormone continues throughout pregnancy and preserves normal fetal central nervous system maturation in fetuses with hypothyroidism. However, the fetal hypothalamic-pituitary-thyroid axis normally develops independent of the maternal thyroid axis influence.

THYROID SYSTEM MATURATION

The fetal thyroid gland is able to concentrate iodine for synthesis of iodothyronines by 12 weeks' gestation. Therefore, T_4 is detectable in fetal serum by the 12th week of gestation (Singh et al, 2003). Subsequently, both T_4 and free T_4 (FT_4) increase linearly in relation to gestational age. Mean cord concentration of T_4 between 20 and 30 weeks' gestation is 5.5 ± 1.6 μg/dL. Normal ranges have been published for thyroid hormone concentrations in third-trimester amniotic fluid (Singh et al, 2003). At term, T_4 reaches 10 μg/dL in umbilical cord serum, 10% to 20% lower than the corresponding value in maternal serum. FT_4 in cord blood is equal to or higher than that in maternal blood. Fetal T_4 metabolism differs markedly from that in postnatal life (LaFranchi, 1999).

In the fetus, T_4 is metabolized predominantly to reverse T_3 (rT_3) rather than T_3 by type III MDI in placenta. Type III placental MDI converts T_4 to rT_3 and T_3 to diiodothyronine (T_2) (Huang, 2005). Therefore, the concentration of rT_3 in the fetus exceeds 250 ng/dL early in the third trimester and progressively decreases to 150 to 200 ng/dL at term (Kratzsch and Pulzer, 2008). Fetal serum T_3 concentration remains low (less than 15 μg/dL) until 30 weeks' gestation, then rises slowly related to an increase in hepatic type I MDI activity. Type I MDI increases hepatic conversion of T_4 to T_3 and decreases placental degradation of T_3 by type III MDI (Kuiper et al, 2005). T_3 levels reach approximately 50 ng/dL in term cord blood (Kratzsch and Pulzer, 2008). TSH is also present in the 12-week-old fetus and rapidly rises thereafter, in parallel with the increasing FT_4 (LaFranchi, 1999). At term, the fetal value of TSH is more than twice that found in the mother, suggesting

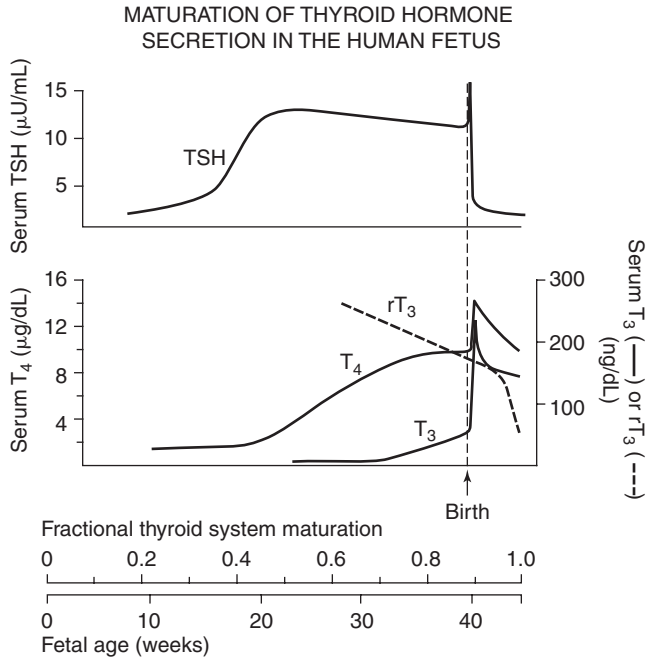

FIGURE 93-2 Patterns of circulating levels of TSH, rT_3, T_4, and T_3 in the fetus and newborn.

that fetal TSH regulates fetal thyroid function (LaFranchi, 1999; Thorpe-Beeston et al, 1992). Hypothalamic TRH levels coincide with this increase in TSH. Extrahypothalamic sources of TRH include the placenta and pancreas; however, their role in thyroid system maturation is unclear (Polk et al, 1991). The pattern of thyroid hormone secretion in the perinatal period is shown in Figure 93-2.

REGULATION OF THYROID FUNCTION

Control of thyroid function by the hypothalamic-pituitary axis matures in the latter half of gestation and continues during the early weeks of postnatal life (Fisher and Polk, 1989). Therefore, maternal hypothyroxinemia in the first half of gestation can contribute to a decreased IQ in offspring, because the fetus is dependent on maternal thyroid hormone concentrations in the first half of gestation as discussed earlier.

Basophilic cells of the anterior pituitary gland synthesize and store TSH (Kurosumi, 1991), a glycoprotein capable of rapidly increasing intrathyroidal cAMP. TSH release from the pituitary causes an increased uptake of iodine by the thyroid, accelerates virtually all steps of iodothyronine synthesis and release, and increases the size and vascularity of the thyroid. These changes are mediated by activation of adenylate cyclase and tyrosine kinase (Kohrle et al, 1990). Human chorionic gonadotropin (hCG) weakly competes with TSH for receptors on thyroid follicular cells. The mild TSH-like activity of hCG contributes to the elevation in maternal T_4 seen during pregnancy, along with the effects of increased concentrations of thyroid (thyroxine)-binding globulin (TBG) associated with higher amounts of estrogen during pregnancy (Yoshimura and Hershman, 1995).

Secretion and plasma levels of TSH are inversely related to circulating levels of free T_3 (FT_3) and FT_4. Inhibitory feedback action of FT_3 and FT_4 involves a direct action of these hormones on the pituitary gland without involving the hypothalamus. Secretion of TSH is regulated directly by the ambient intrapituitary T_3 concentration and intrapituitary deiodination of T_4 to T_3 by type II MDI activity (Kuiper et al, 2005). A progressive decline in the T_4 secretion rate with increasing age partially reflects maturational changes in TRH and TSH secretion (Elmlinger et al, 2001; Fisher et al, 2000).

A circadian variation of circulating TSH has been found in normal children and adults. A peak TSH concentration (about 3 to 4 μU/L) develops between 10:00 PM and 4:00 AM and is about twofold higher (50% to 300% higher) than the afternoon (2:00 PM to 6:00 PM) nadir values (Rose and Nisula, 1989). This nocturnal TSH surge is not directly related to sleep; it is blunted or absent in central (secondary or tertiary) hypothyroidism but maintained in primary hypothyroidism (Rose et al, 1990). The circadian pattern of TSH is not yet present in neonates but is established in infants as young as 4 months of age (Mantagos et al, 1992).

THYROID HORMONE SYNTHESIS

Circulating plasma iodide enters the thyroid follicular cells and is combined with tyrosine through a series of enzymatically mediated reactions to form the active thyroid hormones 3,5,3′-triiodothyronine (T_3) and thyroxine (T_4). The steps in synthesis and release of thyroid hormones include (1) active transport of inorganic iodide from plasma to thyroid cell; (2) synthesis of tyrosine-rich thyroglobulin, which acts as the intermediate iodine acceptor; (3) organification of trapped iodide as iodotyrosines; (4) coupling of monoiodotyrosines (MITs) and diiodotyrosines (DITs) to form the iodothyronines, T_3 and T_4, with storage of iodotyrosines and iodothyronines in follicular colloid; (5) endocytosis and proteolysis of colloid thyroglobulin to release MIT, DIT, T_3, and T_4; and, (6) deiodination of released iodotyrosines within the thyroid cell with reutilization of iodine. Defects in these biochemical processes can result in hypothyroidism.

SERUM PROTEIN BINDING OR TRANSPORT

Blood concentration of T_4 is 50 to 100 times greater than that of T_3. T_4 and T_3 secreted into the circulation are transported by loose attachment, through noncovalent bonds, to various plasma proteins including TBG, thyroxine-binding prealbumin (TBPA), and albumin. TBG serves as the primary transport protein for 75% of serum T_3 and T_4. The rest of the thyroid hormone is distributed almost equally between TBPA and albumin. The FT_4 concentration more accurately indicates the metabolic status of the individual than does either total T_4 or T_3, because only free hormones can enter cells to exert their effects. The binding affinities of these proteins are such that adult free T_4 and free T_3 concentrations are about 0.03% and 0.3%, respectively, of the total hormone concentration (Benvenga, 2005).

TBG, TBPA, and albumin are produced by the liver, and production of these proteins increases progressively

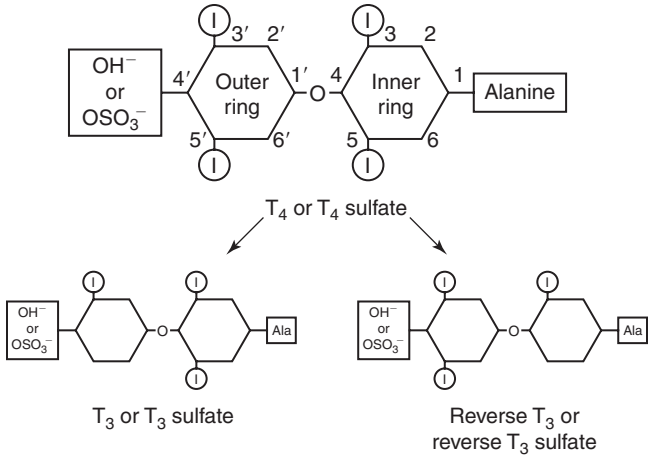

FIGURE 93-3 Structures of T_4, T_3, and reverse T_3. Sulfation at the 4′-hydroxyl position produces the sulfate conjugates of T_4, T_3, and reverse T_3. *(From Burrow GN, Fisher DA, Larsen PR: Maternal and fetal thyroid function*, N Engl J Med *331:1072-1078, 1994. Copyright 1994, Massachusetts Medical Society. All rights reserved.)*

during the second half of gestation. Hepatic TBG production is stimulated by estrogen, and the increasing levels of estrogens during pregnancy account, at least in part, for the progressive increase in total plasma T_4 concentration, from mid-gestation until 34 to 35 weeks' gestation (Ain et al, 1987). Although a rise in concentration of T_4 and T_3 follows an increase in TBG levels, the fetal concentration of FT_4 and FT_3 remains more stable.

FETAL THYROID HORMONE METABOLISM

Thyroid hormone metabolism results from enzymatic deiodination (Figure 93-3). Monodeiodination can occur at either the outer (phenolic) ring or at the inner (tyrosyl) ring of the iodothyronine molecule. Deiodination of T_4 at the outer ring produces T_3. T_3 is the active form of thyroid hormone with greatest affinity for the thyroid receptor. Deiodination at the inner ring of T_4 produces rT_3 and at the inner ring of T_3 produces T_2. Both rT_3 and T_2 are inactive metabolites (Kuiper et al, 2005).

There are three enzymes involved in deiodination: types I, II and III monodeiodinases (MDI). Type I MDI (an outer-ring and inner-ring deiodinase) is expressed predominantly in liver, kidney and thyroid. It is inhibited by PTU and stimulated by thyroid hormone. Outer-ring monodeiodination by type I MDI converts T_4 to T_3, and inner-ring monodeiodination converts T_4 sulfate to rT_3 sulfate and T_3 sulfate to T_2 sulfate. Type II MDI (an outer-ring deiodinase), located in brain, pituitary, placenta, skeletal muscle, heart, thyroid, and brown adipose tissue, is insensitive to PTU and inhibited by thyroid hormone. Outer-ring monodeiodination by type II MDI converts T_4 to T_3, contributing to both local and peripheral levels of T_3, including intraneuronal T_3 (Kuiper et al, 2005). Type III MDI (an inner-ring deiodinase) is located in most fetal tissues, including the brain, placenta, uterus, and fetal skin. This enzyme system catalyzes the conversion of T_4 to rT_3 and of T_3 to T_2 (Huang, 2005).

In the fetus, levels of three MDI enzymes vary throughout gestation and reflect changes in thyroid hormone values. Hepatic type I MDI activity is low throughout gestation until the final weeks of gestation (Fisher et al, 1994). Type II MDI activity in the fetal cerebral cortex increases between 13 and 20 weeks; levels increase in the cerebellum after mid-gestation (Kester et al, 2004). The predominance of type III MDI activity in the fetus accounts for increased levels of rT_3 in the fetus. Both type I and type II MDI enzymes are thyroid hormone–responsive. Therefore, a hypothyroid fetus has elevated levels of type II MDI in brain tissue and decreased levels of hepatic type I MDI. This allows for shunting of T_4 to the brain where it is preferentially deiodinated to T_3 by type II MDI, preserving normal central nervous system development (Fisher et al, 1994).

EXTRAUTERINE THYROID ADAPTATION

At the time of parturition, partly in response to cold and stress, an acute release of TSH occurs, resulting in a peak TSH level of 70–100 mU/L at 30 minutes of age (Figure 93-4). This hypersecretion of TSH persists during the next 6 to 24 hours (LaFranchi, 1999). Both T_3 and T_4 serum concentrations also increase four- to sixfold within the first few hours of life, peaking at 24 to 36 hours after birth. These levels then gradually decline to slightly higher than normal childhood values over the first 4 to 5 weeks of life. TSH has usually declined to less than 5 mU/L by 1 month of age (LaFranchi, 1979). By 2 months of age, most normal infants have a TSH of 0.5 to 4 mU/L, similar to adults (Baloch et al, 2003). It is important to recognize this gradual decline in interpreting TSH values during the first few months of life.

The increases in thyroid hormone that occur immediately after birth are not totally dependent on TSH and may represent other influences on the thyroid gland at the time of parturition. The high postnatal T_3 levels in days following birth are due both to TSH stimulation of thyroidal T_3 secretion and to rapid maturation of tissue outer-ring monodeiodinase activity (Santini et al, 1999).

Preterm infants qualitatively have a similar TSH surge, but it is blunted compared to that of the term infant as a result of immaturity of the hypothalamic pituitary thyroid axis (see Figure 93-4). TSH peaks to 40 mU/L at 30 minutes. The rise in T_4 and T_3 is also of a lesser magnitude (LaFranchi, 1999).

CONGENITAL HYPOTHYROIDISM

Congenital hypothyroidism (CH) is a common cause of mental retardation if not treated promptly. The overall incidence is 1 in 2500 to 1 in 3000 newborns (Harris and Pass, 2007; Waller et al, 2000). Higher rates of incidence have been reported in certain populations. A Dutch study reported an overall CH incidence of 1 in 1800 (Kempers et al, 2006). A retrospective study of an Italian population reported a higher incidence of CH, 1 in 1446, 32% with thyroid dysgenesis; of those with gland in situ, 78% had permanent thyroid dysfunction when evaluated 3 to 5 years later (Corbetta et al, 2009). The prevalence rates of

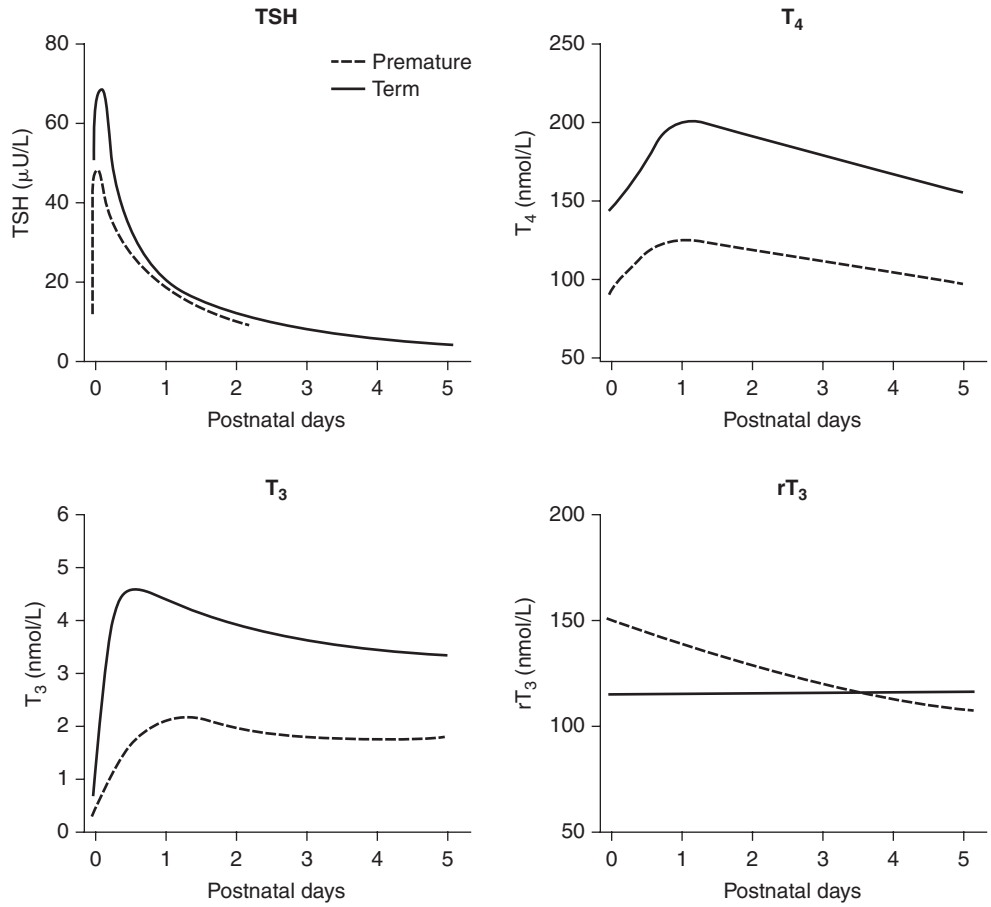

FIGURE 93-4 Postnatal TSH, T_4, T_3, and rT_3 secretion in the full-term and premature infant in the 1st week of life. *(Adapted from* www.thyroidmanager.org, *the free online thyroid textbook. In Brown R, Larsen PR, De Groot LJ, editors:* Thyroid gland development and disease in infants and children, *South Dartmouth, Mass., 2009, Endocrine Education, Inc, Chapter 15, Figure 15-4, p 9.)*

CH can vary with sex, ethnicity, and birthweight. Twice as many female as male infants are affected. Compared to whites, the prevalence of CH is higher in Asians and Hispanics and lower in blacks. A recent study noted an increased risk of CH in macrosomic (>4500 g) and low-birthweight (<2000 g) infants (Waller et al, 2000).

The underlying etiology of hypothyroidism may be transient or permanent. Potential causes are listed in Table 93-2. Regardless of duration of the thyroid dysfunction, immediate treatment with levothyroxine (T_4) in the newborn period is needed to prevent cognitive or neurodevelopmental decline. The developing fetal brain is protected in utero by an adequate source of T_3, supplied by local deiodination of maternal T_4 in the fetal brain.

CLINICAL MANIFESTATIONS

The diagnosis of hypothyroidism should be considered in any infant with prolonged jaundice, transient hypothermia, an enlarged (greater than 1 cm) posterior fontanel, failure to feed properly, or respiratory distress with feeding (Pezzuti et al, 2009). The classic signs evolve during the first weeks after birth. Fetal growth is normal; however, there is delay in bone maturation and a rapid reduction in growth rate after birth (Van Vliet, 2005), with progressively worsening myxedema in subcutaneous

TABLE 93-2 Thyroid Disorders and Their Approximate Incidence in the Neonatal Period

Disorder	Incidence
Thyroid dysgenesis	1/2500 to 1/4000
Agenesis	
Hypogenesis	
Ectopia	
Thyroid dyshormonogenesis	1/30,000
TSH receptor defect	
Iodide-trapping defect	
Organification defect	
Iodotyrosine deiodinase deficiency	
Defect in thyroglobulin	
Transient hypothyroidism	1/12,000 to 1/30,000
Drug-induced

Hypothalamic-pituitary anomaly	
Panhypopituitarism	
Isolated TSH deficiency	

tissues and tongue. The thickened tongue becomes protuberant, and increasing difficulty in nursing and handling salivary secretions is noted. The cry is hoarse because of myxedema of vocal cords. Additional signs and symptoms include marked muscular hypotonia; constipation; thick, dry, cold skin; long and abundant coarse hair; large tongue; abdominal distention; umbilical hernia; hyporeflexia; bradycardia; hypotension with narrow pulse pressure; anemia; and widely patent cranial sutures. The typical facies are characterized by a depressed nasal bridge, a relatively narrow forehead, and puffy eyelids (Foley, 1994). The cardiac silhouette may be enlarged, and the electrocardiogram shows low voltage and a prolonged conduction time. Some of the signs and symptoms are present by 6 to 12 weeks postnatally, especially lethargy, constipation, and the umbilical hernia. The cretinoid facies and growth retardation become increasingly obvious during the first several months of life.

Nonspecific symptoms and signs associated with hypothyroidism are listed in Table 93-3. Of note, clinical manifestations of hypothyroidism may not appear until weeks after birth, even in athyreotic infants. Newborn screening has enabled pediatricians to identify newborns with low thyroid hormone production and to initiate therapy within the first 2 weeks of life, before the development of signs and symptoms (Rose et al, 2006).

TABLE 93-3 Clinical Signs and Symptoms of Congenital Hypothyroidism in Infancy

Age/Manifestation	Frequency (%)
0 to 7 Days	
Prolonged jaundice >3 days	73
Birthweight >4 kg	40

Constipation	35
Hypoactivity	33
1 to 3 Months	
Failure to thrive	90
Umbilical hernia	49
Macroglossia	43
Myxedema	40
Hoarse cry	30

NEONATAL SCREENING FOR HYPOTHYROIDISM

Newborn screening programs for CH avoid delay in its diagnosis, because signs and symptoms of CH may not manifest for several weeks. The screening programs are designed to detect elevated serum TSH levels in blood samples collected on filter paper. Some programs measure TSH directly, and others measure TSH in those samples with low or low-normal T_4 concentrations. Screening programs have been established in the United States, western Europe, parts of eastern Europe, Japan, Australia, and parts of Asia, South America, and Central America. However, many countries still do not have a nationwide program for neonatal thyroid screening.

Both methods of screening (primary TSH and primary T_4 + TSH) appear to be capable of detecting almost all infants with primary CH. Primary CH is the only form of CH that carries a high risk of mental retardation if not detected early and treated adequately (Gruters and Krude, 2007; Rose et al, 2006). Primary CH is associated with a low serum T_4 and FT_4 and a high TSH concentration in cord blood or neonatal blood samples. It is estimated that 5% to 8% of affected infants can escape detection by newborn screening because of a delayed elevation in serum TSH or because of errors in sample collection or laboratory routine. Also, infants with TSH deficiency who have normal TSH levels are not detected, because most newborn screening programs report only those infants with elevated TSH levels. Infants who present with signs or symptoms suggestive of thyroid dysfunction (see Table 93-3) should be investigated regardless of previous screening results. A determination of serum FT_4, T_4, and TSH values is necessary in any infant with suspicious clinical or laboratory findings.

The practice of early hospital discharge (before 48 hours of age) has led to an increased frequency of false positive results because of the normal physiologic TSH surge that occurs after birth. Infants screened before 48 hours of age require recheck of the newborn screen by the primary care physician at 2 weeks of life.

THYROID FUNCTION TESTS

When the diagnosis of CH is suspected, thyroid function tests should be performed. It is advisable to assess FT_4, T_4, TSH, and thyroglobulin (TG) levels. Measurements of T_3, rT_3, FT_3, and T_3 resin uptake (T_3U) are not indicated (Rose et al, 2006). Elevated serum TSH value is the most sensitive and specific test to confirm the diagnosis of primary hypothyroidism. Typical laboratory findings for primary hypothyroidism include elevated TSH, with T_4 and FT_4 values in the low or low-normal range. A low or undetectable TG concentration (Sobrero et al, 2007) with TSH elevation confirms a dysgenetic or absent thyroid gland (Djemli et al, 2004), whereas a high TG with TSH elevation suggests an organification defect (Vulsma et al, 1991). In central hypothyroidism, TSH is usually normal, T_4 is low normal, and FT_4 is in the lowest third of normal (van Tijn et al, 2008).

INTERPRETING THYROID FUNCTION TESTS

In interpreting thyroid function tests, it is critically important to take into account the day of life the laboratory tests were drawn. Recommended time period for newborn screening of thyroid function is at 2 to 4 days of life. If screening is done at less than 24 hours of life, it must be rechecked, regardless of the results. After 24 hours of life, a TSH value >40 μU/L is highly suggestive of hypothyroidism but confirmatory testing is required. A TSH value above the normal limit for hours of life and gestational age

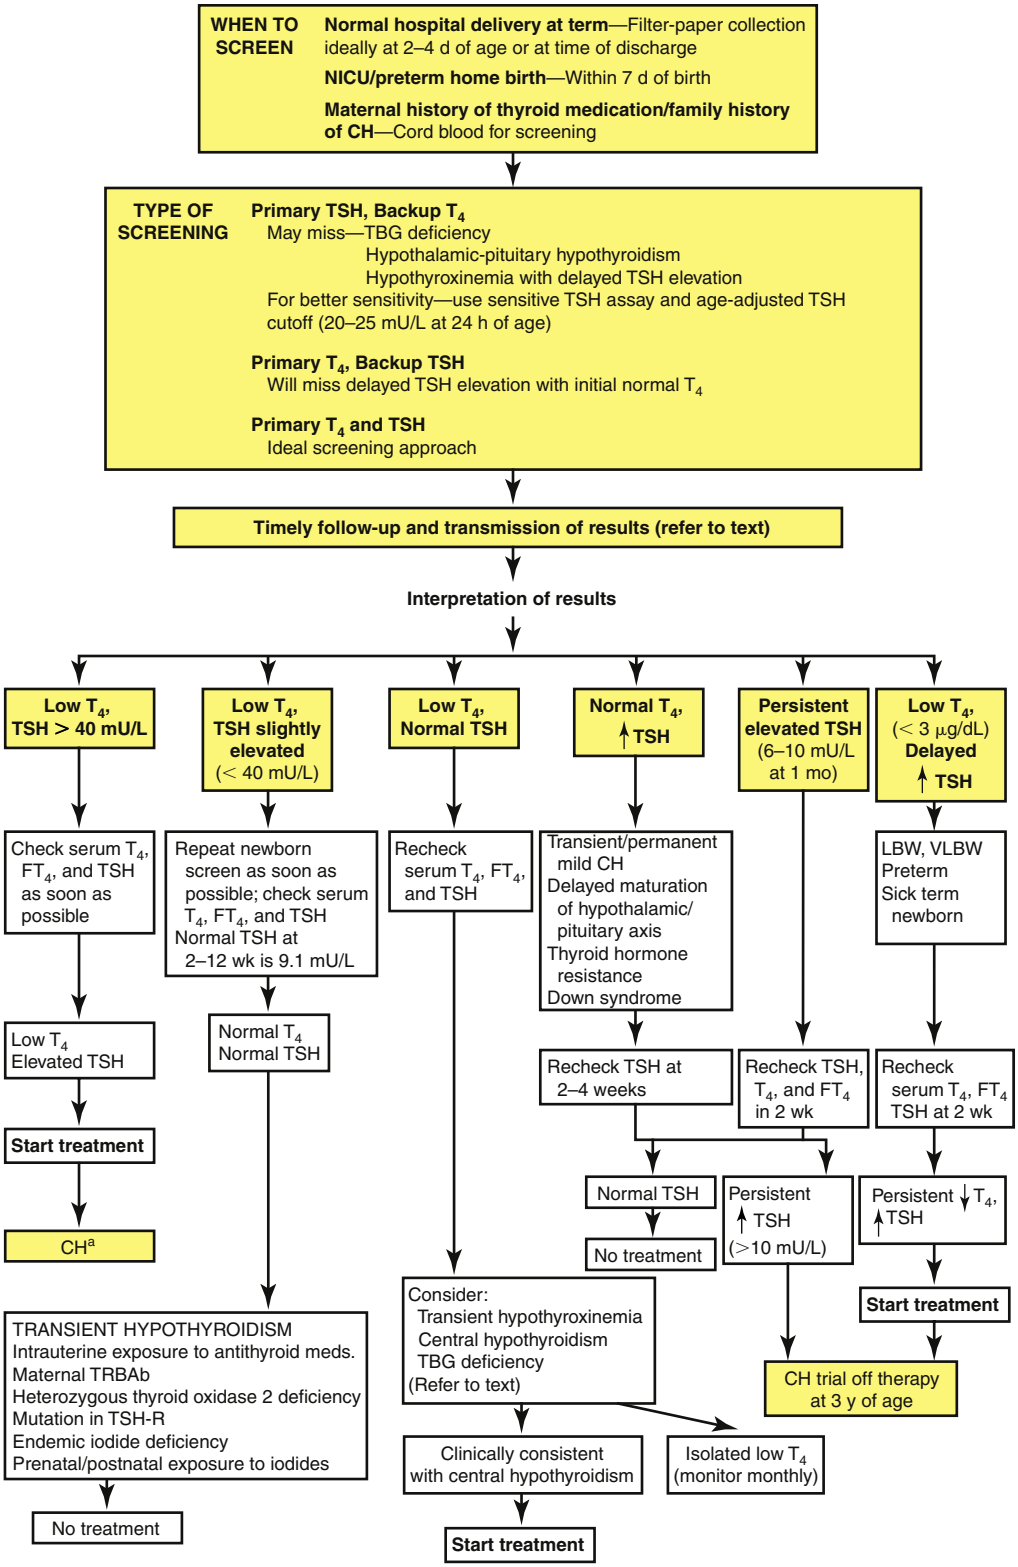

FIGURE 93-5 Algorithm for evaluating CH based on newborn screening results. *(Adapted from Rose SR, Brown RS, Foley T, et al: Update of newborn screening and therapy for congenital hypothyroidism*, Pediatrics *117:2290-2303, 2006. Copyright 2006 by the American Academy of Pediatrics.)*

but <40 mU/L is indeterminate. Therefore, repeat testing is necessary and the primary care physician is informed of the need to obtain a second screen (Figure 93-5). The practice of early hospital discharge (before 48 hours of age) has led to a higher rate of indeterminate results.

Eight percent to 10% of infants with CH have screening TSH values of less than 50 mU/L. One in 12 to 24 hypothyroid infants (1 in 50,000 to 1 in 100,000 newborns) will have a screening TSH level of less than 20 mU/L, with a delayed postnatal increase to hypothyroid levels (Hyman

et al, 2007). Therefore, any infant with suspicious screening or neonatal sampling results requires confirmatory testing with measurement of serum FT_4, T_4, and TSH concentrations (Rose et al, 2006).

The biochemical profile of hypothalamic-pituitary hypothyroidism comprises low serum T_4 concentration with a normal TSH value. A similar biochemical profile characterizes TBG deficiency. However, the two states can be differentiated by further assessment of TBG and FT_4 levels. Measurement of a low serum TBG concentration and a normal FT_4 level identifies patients with TBG deficiency. In contrast, a low or low-normal FT_4 and normal TBG levels identify a patient with hypothalamic-pituitary hypothyroidism. An infant with a low FT_4 concentration needs to be carefully examined for evidence of hypothyroidism, and other tests of pituitary function should be conducted. TRH stimulation testing can be used to differentiate between primary and central hypothyroidism. TRH, however, is not available in the United States. A subnormal TSH response to TRH or a normal but delayed and prolonged TSH response to TRH is indicative of central hypothyroidism (van Tijn et al, 2008). TSH deficiency may be isolated or associated with other pituitary hormone deficiencies. Frequently it is not possible to discriminate between secondary and tertiary hypothyroidism, so the most useful diagnostic term is central hypothyroidism.

THYROID DYSGENESIS

Among cases of permanent congenital hypothyroidism, 85% are associated with abnormal development of the thyroid gland, which includes agenesis (35%), ectopy (65%) or hypoplasia (<5%) of the gland (Topaloglu, 2006). There is female predominance associated with ectopic glands. Ectopic locations of the thyroid gland include lingual, neck, and substernal. Most cases are sporadic; however, more recent studies show evidence for genetic factors being involved in the pathogenesis. Studies in mice and fetal tissues show that congenital defects in thyroid gland development can be associated with mutations in transcription factors such as NKX2.1 (TTF-1), PAX-8, thyroid-stimulating hormone receptor (TSH-R), and FOXE-1 (TTF-2), which are involved in thyroid organogenesis (Deladoey et al, 2007; Trueba et al, 2005). Mutation in NKX2.5, a transcription factor involved in heart morphogenesis, has also been reported to be associated with thyroid dysgenesis (Dentice et al, 2006).

Extrathyroidal abnormalities occur at a higher frequency in children with congenital hypothyroidism. The most frequent malformations associated with thyroid dysgenesis are cardiac, largely septation defects (Devos et al, 1999). Other relatively common malformations include anomalies of the gastrointestinal tract, nervous system, and eyes (Gu et al, 2009; Kreisner et al, 2005; Olivieri et al, 2002).

The biochemical picture can vary depending on the amount of thyroid tissue remaining. The presence of residual thyroid tissue is evident by detectable thyroglobulin levels and normal or near-normal T_3 with low T_4 and elevated TSH values. The presence of residual thyroid tissue can be confirmed with a thyroid scan.

THYROID DYSHORMONOGENESIS

The remaining 10% to 20% of cases of congenital hypothyroidism involve defects in synthesis of thyroid hormone. These patients often present with a normally located and normal-sized gland. Thyroid enlargement can present at birth, but more commonly a goiter develops later in life. Inheritance pattern is autosomal recessive (Topaloglu, 2006). Elevated thyroglobulin is often observed in dyshormonogenesis.

Defects associated with trapping of iodide or in the oxidation or organification of iodide can result in dyshormonogenesis. These mutations include (1) point mutation in SLC5A5, the sodium-iodide symporter; (2) thyroid peroxidase (TPO) deficiency or a defective TPO, or defective cofactors that are required for activation of the TPO enzyme or for the hydrogen peroxide generating system (mutations THOX1 or THOX2) (de Vijlder, 2003; Moreno et al, 2002) usually associated with more severe hypothyroidism; (3) TG defect; and (4) biallelic mutations in the *SLC264A4* gene (Pendred's syndrome). Pendred's syndrome is an autosomal recessive disorder associated with a partial defect in iodine organification and sensorineural hearing loss. The anion transporter gene, *SLC264A4*, encodes pendrin. Pendrin functions to maintain the endocochlear potential and is involved in the apical efflux of iodide in the thyroid follicular cells (Kopp et al, 2008). A white forelock may be observed in patients with Pendred's syndrome.

CENTRAL HYPOTHYROIDISM

In the United States, combined incidence of secondary and tertiary hypothyroidism is about 1 in 80,000 to 1 in 100,000 births. Studies in the Netherlands suggest a higher incidence at 1 in 21,000 (Kempers et al, 2006; van Tijn et al, 2005). Congenital central hypothyroidism is often associated with mutations in transcription factors involved with pituitary development, including *Pit-1*, *LHX3*, *PROP1*, *HESX1*, and others and can also be associated with other hormone deficiencies.

Other midline facial, cranial, or intracranial defects should suggest the possibility of hypopituitarism, including altered functioning of the hypothalamic-pituitary-thyroid axis. Septo-optic dysplasia, often associated with pituitary hormone deficiencies, can be manifested as secondary or (more commonly) tertiary hypothyroidism. Clinical symptoms of hypopituitarism, such as neonatal hypoglycemia (from growth hormone and adrenocorticotropic hormone deficiencies), polyuria (from antidiuretic hormone deficiency), or a small phallus in boys (from gonadotropin deficiency), whether or not accompanied by the presence of blindness, congenital nystagmus, or midline defects of the brain, should alert the physician to suspect septo-optic dysplasia.

The consequences of central hypothyroidism are as neurologically devastating as those of primary hypothyroidism and therefore also require prompt treatment (van Tijn et al, 2005). However, many newborn screening programs that use elevated TSH values to recognize thyroid dysfunction are inadequate in identifying newborns with central hypothyroidism.

Central hypothyroidism may be acquired during difficult or breech delivery; however, the FT_4 may not become abnormal until 2 weeks of age. The biochemical picture comprises normal or low TSH with low or low-normal T_4 levels and low FT_4. Other laboratory evidence includes an abnormal TSH surge of less than 50% and a subnormal TSH response to a TRH stimulation test. Attention to other clinical features such as hypoglycemia, microphallus, and midline facial defects can lead to earlier identification of central hypothyroidism.

HYPERTHYROTROPINEMIA: DOWN SYNDROME

Incidence of CH (including dyshormonogenesis) is greatly increased in Down syndrome, as are acquired autoimmune diseases of the thyroid gland, pancreas, stomach, and adrenal gland (Hasanhodzic et al, 2006). Obvious CH occurs in 1 of about 140 subjects with Down syndrome. T_4 concentrations in 284 newborns with Down syndrome were significantly decreased compared with those in controls (van Trotsenburg et al, 2003). Many additional children with Down syndrome have mildly elevated TSH (5 to 15 mU/L) and low-normal FT_4 values. TSH bioactivity appears to be normal, suggesting that these children with Down syndrome and mild TSH elevation have mild tissue hypothyroidism. If TSH elevation persists up to 4 weeks of age, the child's mental development may be best protected by initiating thyroid hormone replacement, as in transient hypothyroidism (Rose et al, 2006).

CONSUMPTIVE HYPOTHYROIDISM

Consumptive hypothyroidism may occur in infants with hepatic hemangiomas (Huang et al, 2000). Hemangiomas occur at a high frequency in infancy, with rapid growth during the 1st year of life, followed by involution and gradual regression by adolescence. Because the period of growth of the hemangioma coincides with the critical period of growth and intellectual development, the infant is at risk for permanent neurological damage.

The mechanism involves increased expression of type III MDI mRNA in the tumor that accelerates the rate of degradation of thyroid hormone (Bessho et al, 2010; Huang et al, 2000). As previously discussed, type III MDI catalyzes the conversion of T_4 to rT_3 and T_3 to T_2, both of which are inactive metabolites. Because of the rapid rate of thyroid hormone breakdown, the degree of hypothyroidism is refractory to thyroid hormone replacement. Therefore, unusually high doses, up to 8 to 9 times more than usual doses of oral or intravenous liothyronine (T_3) and levothyroxine (T_4) are required to normalize TSH levels. T_4 must be given for neurologic benefit. The biochemical profile comprises low T_3 and T_4, elevated TSH and elevated serum rT_3 levels. The thyroid hormone levels normalize with regression of the hemangioma (Huang et al, 2000).

TRANSIENT PRIMARY HYPOTHYROIDISM

Hypothyroidism in the newborn period can be transient in 10% of cases (Rose et al, 2006). Studies in the Netherlands report an incidence of 1 in 12,000 (Kempers et al, 2006). The newborn screen is initially abnormal with a low T_4 and slightly elevated TSH. However, repeated laboratory evaluation may demonstrate normalization of thyroid function tests indicating a transient state of thyroid dysfunction. Because normalization may not occur for several months, thyroid hormone therapy should be initiated for protection of the infant's brain development if TSH remains elevated at 2 weeks of life. Therapy should be continued until age 3 years, when the child should be reevaluated. Transient hypothyroidism is more common in preterm infants. It may result from intrauterine exposure to maternal antithyroid medications, maternal TRBAb, heterozygous thyroid oxidase 2 deficiency, mutation in TSH-R, endemic iodide deficiency, or prenatal/postnatal exposure to iodides (Rose et al, 2006).

Transplacental passage of maternal TRBAb (also known as thyrotropin binding inhibiting immunoglobulin, or TBII) is estimated to cause transient thyroid dysfunction in 2% of newborns with congenital hypothyroidism (Brown et al, 1996). This transient thyroid dysfunction is often difficult to differentiate from permanent forms of hypothyroidism in the newborn period. These babies should be treated but will not require lifelong treatment.

Although many women with autoimmune disease are receiving thyroid replacement therapy, some may be clinically euthyroid and not on medications. Some of these women actually have hyperthyroidism or a history of Graves' disease but may not currently be on medication. Therefore, diagnosis of thyroid dysfunction may be delayed until the postpartum period (Brown et al, 1996).

TRBAb, like other IgGs, do not cross the placenta until after 16 weeks' gestation. Therefore, the TRBAb do not affect thyroid embryogenesis and infants do not develop permanent abnormalities in thyroid function (McKenzie and Zakarija, 1992). The severity and duration of the hypothyroid state in these newborns correlates with the initial titer of the blocking antibody and duration of its presence in the infant's blood (Brown et al, 1996).

If TSH remains elevated at 2 weeks of age, thyroid hormone therapy should be initiated for protection of the infant's brain development. Thyroid status should be reevaluated off therapy at age 3 years, or sooner if the diagnosis is known. Subsequent offspring remain at risk, because the antibodies can persist up to 7 years in maternal sera (Brown et al, 1996).

The biochemical profile is that of congenital hypothyroidism, comprising low T_4 with elevated TSH that subsequently normalize. A thyroid scan is not helpful because the TRBAb are sufficiently potent to block TSH-induced uptake of radioactive iodine, which can be misleading and suggestive of thyroid agenesis. The distinguishing feature is the presence of TRBAb in newborn and maternal sera. However, routine screening for TRBAb is not currently indicated. This diagnosis should be suspected in any infant with congenital hypothyroidism born to a woman who has history of autoimmune disease, or if previous offspring had thyroid disease (Brown et al, 1996).

EUTHYROID SICK SYNDROME

In acutely ill patients, serum T_3 is decreased. Current hypothesis is that alterations in thyroid hormone occur as an adaptive response to decreased basal metabolic rates in

severely ill patients. The syndrome has been recognized in sick infants and children (Carrascosa et al, 2008). These patients may have severe nonthyroidal illnesses that are either acute or chronic. The consistent finding is an abnormally low serum T_3 level, accompanied by an increase in the rT_3 level. T_4 may be low or normal and FT_4 may be normal, depending on metabolic clearance rate of T_4. Serum TBG may be low or normal, and TSH is normal. In preterm infants, T_4, FT_4, and T_3 levels are naturally lower than those in term infants, and rT_3 is high (Fisher, 2007). Therefore, thyroid tests in preterm infants may present a confusing situation when the infants are ill from nonthyroidal diseases.

In the neonatal period, preterm infants with respiratory distress syndrome are the most frequently encountered patients with euthyroid sick syndrome (Fisher, 2007; Tanaka et al, 2007). In children, a variety of nonthyroidal illnesses have been associated with this syndrome, including severe gastroenteritis, acute leukemia, anorexia nervosa, renal disease, burns, and surgical stress. An alteration in T_4 metabolism to favor production of rT_3 over T_3 occurs rapidly. Euthyroid sick syndrome is found in patients with acute metabolic stress (e.g., diabetic ketoacidosis) and occurs in all pediatric patients who underwent cardiac surgery. There is a sharp rise in rT_3 and a less dramatic fall in T_3 by 2 hours after cardiac surgery. Reverse T_3 returns to normal before T_3, and there is an inverse relationship between the severity of illness and the T_3 level. In euthyroid sick syndrome, abnormal thyroid function gradually reverts to normal function as the patient's primary illness improves (Foley, 1994). During recovery, TSH may be transiently elevated (up to 15 mU/L). Treatment with thyroid hormone is not indicated in these patients.

TRANSIENT HYPOTHYROXINEMIA OF PREMATURITY

Postnatal thyroid hormone concentrations in preterm infants differ from those of term infants, as reflected by changes in thyroid hormone production in utero, as discussed previously. The levels differ across the range of prematurity and are associated with multiple etiologies, including loss of maternal transfer of T_4 (Morreale de Escobar and Ares, 1998), immaturity of hypothalamic-pituitary-thyroid axis (Murphy et al, 2004) and peripheral metabolism of iodothyronines (Pavelka et al, 1997), iodine deficiency (Ares et al, 1997), nonthyroidal illness (Fisher, 2007), and decreased TBG concentrations secondary to compromised nutrition or hepatic dysfunction (Klein et al, 1997). Other factors that interfere with thyroid metabolism in the preterm infant include exogenous sources of iodine (antiseptic), dopamine infusions, blood transfusions, and glucocorticoid treatment.

In preterm infants, hypothalamic-pituitary-thyroid immaturity is evidenced by a limited neonatal TSH surge, decline in T_4 in the 1st week of life, limited TSH response to hypothyroxinemia, and a prolonged TSH response to TRH. Hypothalamic TRH production begins to increase markedly only in the third trimester (Fisher and Polk, 1989; LaFranchi, 1999).

The biochemical profile of transient hypothyroxinemia in premature infants (before 30 to 32 weeks' gestation) comprises low T_4 and FT_4 levels with normal or low TSH levels. Therapy has not been consistently effective in improving neurologic outcomes or reducing morbidity (Osborn, 2001; Valerio et al, 2004). Research efforts continue to evaluate this. At the current time, therapy is only recommended when low T_4 is accompanied by TSH elevation (Fisher, 2007; Osborn, 2001).

As mentioned previously, abnormalities in thyroid levels in preterm infants can be difficult to interpret when the infants are ill from nonthyroidal diseases. Therefore, preterm infants at risk should be monitored by serial determinations of FT_4 and TSH, and T_4 treatment should be initiated if there is a progressive increase in serum TSH and decrease in FT_4 (Fisher, 2007). Probably T_4 treatment should be initiated if the illness state is expected to be persistent and TSH remains elevated for a month or longer.

LOW TRIIODOTHYRONINE SYNDROME IN PREMATURE INFANTS

In the preterm infant, changes in thyroid function parameters during neonatal adaptation are qualitatively similar to those in term infants but at lower concentrations. The neonatal TSH surge and T_4 and T_3 peak responses diminish with decreasing gestational age (see Figure 93-4) (LaFranchi, 1999). Premature infants have an increased susceptibility to neonatal morbidity, including birth trauma, acidosis, hypoxia, hypoglycemia, hypocalcemia, and infection, all superimposed on feeding disorders and relative malnutrition. All of these factors tend to inhibit peripheral T_4-to-T_3 conversion, thereby aggravating the low-T_3 state characteristic of prematurity. Serum T_3 values may remain low in these infants for 1 to 2 months.

Features of the low-T_3 syndrome in premature infants include a low serum T_3 concentration secondary to a decreased rate of conversion of T_4 to T_3, variable but usually elevated serum rT_3 levels, and normal or low total serum T_4 concentrations. Free T_4 levels usually are in the range of values for healthy premature infants of matched gestational age and weight (LaFranchi, 1999). TSH values are low in these infants. Treatment is not warranted (Osborn, 2001; Valerio et al, 2004).

IODINE DEFICIENCY

Severe iodine deficiency is associated with cretinism. Iodine deficiency is a rare cause of transient hypothyroidism in North America but may occur in women who are dieting, and thus not eating bread or using salt. Many countries have initiated salt iodination.

Iodine is a critical component of thyroid hormone synthesis; therefore, even mild to moderate forms of iodine deficiency can result in adverse outcome for the fetus. Although the mother with iodine deficiency may be clinically euthyroid with normal T_3 levels, maternal T_4 is low in iodine deficiency. An increase in type II MDI is detected in the fetus in response to iodine deficiency. Because normal development of the fetal neocortex is dependent on maternal T_4, which is the primary source of cerebral T_3, low levels of maternal T_4 place the infants at risk for neurologic cretinism. The fetus can suffer several neurologic manifestations such as deafness, motor deficits (spasticity, trunk rigidity, flexion dystonia, and muscle

wasting), and mental retardation. Therefore, it is imperative for the pregnant mother to receive an adequate supply of iodine early in pregnancy to avoid brain damage in the fetus (Abalovich et al, 2007; Bernal, 1999). Prenatal vitamins should be used that contain at least 250 μg iodine daily (Abalovich et al, 2007).

Preterm infants are at increased risk of iodine deficiency. The premature separation from maternal supply of iodine and thyroid hormone prevents the preterm infant from accumulating adequate amounts of intrathyroidal hormone. Therefore, the infant is unable to keep up with postnatal thyroid hormone demands. The biochemical profile of iodine deficiency in the newborn comprises low T_4 and elevated TSH. Iodine deficiency is more common in preterm infants and can lead to a transient state of thyroid dysfunction.

DISORDERS OF THYROID HORMONE CARRIER PROTEINS

Thyroid hormones are linked to carrier proteins (TBG, transthyretin and TBPA) in serum as previously discussed. TBG, the main thyroid hormone transport protein, is a glycoprotein synthesized by the liver. Its gene is located on the Xq21-22 chromosomal region, and thus inherited defects in TBG are X-linked (Trent et al, 1987). TBG abnormalities manifest fully in homozygous males and partially in heterozygous females. Because 75% of T_4 and T_3 are bound to TBG, abnormalities in the affinity or capacity of TBG can alter the total thyroid hormone concentration. Because the bound form is in equilibrium with the free hormone, these patients are euthyroid and do not need treatment. The advent of newborn screening has allowed for earlier identification of abnormal thyroxine levels. The newborn screen can be misleading. TBG defects may be inappropriately diagnosed as hypo- or hyperthyroidism, and infants are unnecessarily started on treatment.

THYROXINE-BINDING GLOBULIN DEFICIENCY

The prevalence of TBG deficiency varies from 1 in 2500 to 1 in 5000 newborns (Bhatkar et al, 2004; Mandel et al, 1993). The frequency in males is much higher, 1 in 2400 to 1 in 2800 males, because it is transmitted as an X-linked trait (Mandel et al, 1993). TBG deficiency has no clinical importance but leads to abnormal laboratory tests. Serum TBG levels are very low in affected males and are approximately half of normal in carrier females. In about half of the families with this trait, the TBG level shown by radioimmunoassay (RIA) is very low. In the other half, the defect is partial; serum T_4 levels vary similarly. Affected persons are euthyroid, with normal serum TSH responses to exogenous TRH. Treatment is not indicated (Bhatkar et al, 2004).

As many as 26 different mutations have been reported in the *TBG* gene. Two novel mutations in the *TBG* gene identified most recently include a T insertion at the beginning of intron 1 between nucleotide 2 and 3, and a T deletion in exon 1 leading to a truncated protein. Both mutations fail to produce a functional TBG molecule (Mannavola et al, 2006).

The biochemical profile of TBG deficiency can vary between females, who tend to have partial TBG deficiency, compared to males, who generally have complete TBG deficiency. A partial deficiency comprises reduced TBG levels and normal TSH and FT_4, with T_4 values at the lower limit of normal. A complete deficiency comprises undetectable TBG levels with normal TSH, normal FT_4, and low levels of T_4. Another useful laboratory tool is T_3RU, which is elevated with TBG deficiency (Noguchi et al, 1993). However, this is an indirect measure of TBG levels.

THYROXINE-BINDING GLOBULIN EXCESS

The prevalence of TBG excess is estimated to be 1 in 15,000 to 1 in 25,000 individuals; TBG excess is also transmitted as an X-linked trait (Bhatkar et al, 2004). Persons with increased levels of TBG have increased total serum T_4 concentrations with normal TSH and FT_4 levels. Serum T_3 concentrations are modestly increased. In these persons, as in those with low TBG, TBG production rates and serum levels are correlated, suggesting that the mechanism for high TBG is increased production, presumably by the liver. TBG levels are increased four- to fivefold in affected persons. Studies are compatible with an X-linked mode of inheritance (Bhatkar et al, 2004).

FAMILIAL DYSALBUMINEMIC HYPERTHYROXINEMIA

Familial dysalbuminemic hyperthyroxinemia is characterized by almost a 60-fold increase in the affinity of albumin for T_4, but not for T_3. Mutations in the *ALB* (albumin) gene are transmitted as an X-linked trait (Cartwright et al, 2009). The biochemical profile comprises increased serum T_4 concentrations, but normal FT_4, total serum T_3, and TSH levels. Although binding of T_4 to albumin is increased, T_3 is less avidly bound, accounting for the preferential increase in serum T_4 concentration. Patients with the disorder are euthyroid, with normal thyroid hormone production rates (Cartwright et al, 2009).

Diagnosis is confirmed by protein electrophoresis of serum containing labeled T_4. The fraction of T_4 label associated with TBG, TBPA, or albumin is measured, and the albumin-bound T_4 can be calculated and related to normal values. Measurements of TBG and TBPA concentrations are also useful. Antithyroid therapy is not necessary in these patients, but it is important to make the diagnosis to avoid a misdiagnosis of hyperthyroidism (Stockigt et al, 1986).

THERAPY OF HYPOTHYROIDISM

Treatment of hypothyroidism relies on replacement with exogenous thyroid hormone. Levothyroxine (T_4) is the drug of choice because of its uniform potency and reliable absorption (Rose et al, 2006). Appropriate doses of synthetic T_4 produce normal serum levels of T_3 via peripheral conversion. The best guide to adequacy of therapy is periodic measurement of circulating levels of T_4, FT_4, and TSH. History and physical examination are important

in the follow-up evaluation, but mild hypothyroidism or hyperthyroidism cannot always be excluded on clinical grounds. The usual starting dose of thyroid hormone for hypothyroid infants is 10 to 15 μg/kg/day, which approximates 100 μg/m^2 per day. Recent studies have reported neurodevelopmental benefits of quick normalization of T_4 and FT_4 levels within 3 days of initiation of thyroid hormone with high-dose treatment. Thyroid hormone requirements, however, quickly drop after 2 weeks, and therefore close monitoring of growth and development along with thyroid function tests is necessary (Salerno et al, 2002; Selva et al, 2002). The treatment of each patient must be individualized. Adequate dosage of thyroid hormone in the 1st year usually ranges between 25 and 50 μg thyroid hormone daily. The tablet is crushed and given orally in a small amount of liquid. Using thyroid hormone for treatment, the goal of therapy is to maintain serum T_4 or FT_4 in the upper part of the normal range, which should result in a TSH of 0.5 to 4 mU/L (Baloch et al, 2003). The thyroid hormone-pituitary feedback set point is altered in rare infants with congenital hypothyroidism, and in such infants serum TSH concentration remains elevated in the face of a normal or even elevated serum T_4 level (Fisher et al, 2000).

Infants with presumably transient hypothyroidism resulting from maternal goitrogenic drugs need not be treated unless the low serum T_4 and elevated TSH levels persist beyond 2 weeks of age. Infants with TRBAb-induced hypothyroidism may require treatment for as long as 6 months.

In treatment of infants with severe myxedema associated with fluid retention, possible complications should be kept in mind. Cardiac insufficiency caused by overtaxing the myxedematous heart, through too rapid a mobilization of the myxedema fluid into the circulation, is well known in the adult. This complication in older children and adults is prevented by administering a small dose of thyroid hormone at first and gradually increasing the dosage. However, infants generally tolerate a rapid restoration to the euthyroid state better than adults, and a prompt restoration of T_4 to a normal value is important for the recovery of brain development and maturation. Nevertheless, excessive thyroid hormone therapy must be avoided, and the dose must be adjusted judiciously if there is evidence of severe myxedema, particularly of the heart.

After initiation of therapy with levothyroxine, growth rate should accelerate. Any growth deficit is commonly restored within a few months. Bone age is a sensitive index of thyroid deficiency; however, radiographs are not routinely obtained in the newborn period. Overtreatment can induce tachycardia, excessive nervousness, disturbed sleep patterns, and other problems suggesting thyrotoxicosis. Excessive thyroid hormone administered over a long period can produce premature synostosis of cranial sutures and undue advancement of bone age.

During the first years of life, patients should be monitored frequently: at least every 2 months during the first 6 months of life, every 3 months during the next 2 years, and then twice a year, to assess clinical progress, T_4, FT_4, and TSH (Box 93-1) (Rose et al, 2006). Because poor compliance and noncompliance have major sequelae, the initial and ongoing counseling of parents is of great importance.

Clinical observation should be supplemented with monitoring of the growth curve, T_4, FT_4, and TSH. Patients with permanent CH (e.g., dysgenesis, dyshormonogenesis) require lifetime substitution therapy. After age 3 years, if there is uncertainty about whether the disease is permanent or transient or if the dose of T_4 has not required an increase (TSH has remained in the target range of 0.5 to 4.0 mU/L), discontinuation of T_4 therapy for 4 to 6 weeks, with close monitoring of the TSH, should distinguish transient from permanent CH. Recent reports indicate that treatment for CH is discontinued within 3 years in more than one third of children being treated for CH. This is inconsistent with current guidelines; however, it remains unknown how many of the children who discontinued treatment prematurely experience adverse effects or require continued treatment.

BOX 93-1 Management of CH

- Initial work-up
  - Detailed history and physical examination
  - Referral to pediatric endocrinologist
  - Recheck serum TSH and FT_4
  - Thyroid ultrasonography and/or thyroid scan (see text for recommendations)
- Medications
  - L-T_4: 10–15 μg/kg by mouth once daily
- Monitoring
  - Recheck T_4, TSH
  - 2–4 wk after initial treatment is begun
  - Every 1–2 mo in the first 6 mo
  - Every 3–4 mo between 6 mo and 3 y of age
  - Every 6–12 mo from 3 y of age to end of growth
- Goal of therapy
  - Normalize TSH and maintain T_4 and FT_4 in upper half of reference range
- Assess permanence of CH
  - If initial thyroid scan shows ectopic/absent gland, CH is permanent
  - If initial TSH is <50 mU/L and there is no increase in TSH after newborn period, then trial off therapy at 3 y of age
  - If TSH increases off therapy, consider permanent CH

HYPERTHYROIDISM

The overall incidence of neonatal hyperthyroidism is low. It occurs more commonly in pregnancies complicated by Graves' disease. Of the offspring born to women with Graves' disease, 1% are affected with hyperthyroidism (Polak, 1998). The thyroid dysfunction in the fetus and newborn is associated with transplacental passage of TSH receptor-stimulating antibodies/thyroid-stimulating immunuglobulins (TSA/TSI), not transfer of maternal thyroid hormone. The antibodies stimulate the fetal and neonatal thyroid gland to produce a state of thyroid hormone. It is generally a transient state that clinically resolves by 4 months of age with the clearance of maternal antibodies from the infant's circulation (Polak, 1998). The underlying etiologies are more commonly maternal autoimmune thyroid dysfunction associated with active or inactive Graves' disease or, less commonly, Hashimoto thyroiditis. Other rare nonautoimmune causes of neonatal hyperthyroidism include activating mutations of the stimulatory G protein, as in McCune-Albright syndrome,

or an activating mutation of the TSH receptor (Chester et al, 2008; Guerin et al, 2004). A subset of patients can have persistent hyperthyroidism; however, these patients tend to either have a strong family history of Graves' disease or have activating mutations of the TSH receptor (Chester et al, 2008; Zimmerman, 1999).

In pregnancies complicated by maternal Graves' disease, the fetal levels of TSA approximate those of the mother at 30 weeks' gestation. Therefore, fetal thyrotoxicosis generally manifests in the third trimester with fetal tachycardia, fetal goiter, and intrauterine growth retardation. Fetuses of mothers with TSA levels greater than 250% of the upper limit are at increased risk for thyrotoxicosis. Therefore, these fetuses need to be monitored more closely (Zimmerman, 1999).

Graves' disease in the newborn is manifested by irritability, flushing, diarrhea, vomiting, tachycardia, hypertension, poor weight gain, thyroid enlargement, and exophthalmos. Thrombocytopenia, hepatosplenomegaly, jaundice, and hyperviscosity syndrome also have been observed. Arrhythmias, congestive heart failure, and death may occur if thyrotoxicity is severe and the treatment is inadequate. In some infants, the onset of symptoms and signs may be delayed as long as 8 to 14 days. Late onset of neonatal disease can occur for at least two reasons: (1) postnatal depletion of transplacentally acquired blocking doses of maternal antithyroid drugs and the abrupt increase in conversion of T_4 to active T_3 shortly after birth in the newborn, and (2) presence of maternal TRBAb, which can block the effect of TSA for several weeks (Zimmerman, 1999).

The diagnosis is confirmed by measuring high levels of T_4, free T_4, and T_3 in postnatal blood. Cord blood values may be normal or near normal, whereas levels at 2 to 5 days may be markedly increased; the serum TSH is suppressed below normal levels. Neonatal Graves' disease resolves spontaneously as maternal TSA in the newborn are degraded. The usual clinical course of neonatal Graves' disease is 3 to 12 weeks.

Fetal thyrotoxicosis is treated by administering antithyroid agents to the mother. PTU is recommended during pregnancy, because it is associated with a lower rate of fetal malformations than that with methimazole. PTU crosses the placenta to inhibit the fetal production of excess thyroid hormone (Aslam and Inayat, 2008). Hyperthyroid mothers on antithyroid drugs may breastfeed their infants, because the concentration of drug in breast milk is very low. Treatment of hyperthyroidism in the newborn period includes multiple medications depending on the severity of illness. Iodide or antithyroid agents are administered to decrease thyroid hormone secretion. These drugs have additive effects with regard to inhibition of hormone synthesis. In addition, iodide rapidly inhibits hormone release.

Lugol's solution (5% iodine and 10% potassium iodide, containing 126 mg/mL of iodine) is given in a dose of 1 drop (8 mg of iodine) three times daily. Antithyroid agents such as methimazole or carbimazole are administered in doses of 0.5 to 1 mg/kg/day, divided, at 8-hour intervals. PTU is no longer recommended for use in children because of increasing rates of PTU-induced liver failure (Rivkees and Mattison, 2009). Propranolol can be given in a dose of 2 mg/kg/day to decrease β-adrenergic symptoms and inhibit deiodination of T_4 to T_3. A therapeutic response should be observed within 24 to 36 hours. If a satisfactory response is not observed, the dose of antithyroid drug and iodide can be increased by 50%.

More severe cases may require corticosteroids in anti-inflammatory doses (1 to 2 mg/kg/day). Steroids suppress deiodination of T_4 to T_3. Digoxin treatment is useful if cardiac failure is present. If hyperthyroidism persists (as in cases with a strong family history of Graves' disease, an activating mutation of the stimulatory G protein, or an activating mutation of the TSH receptor), ablative therapy such as thyroidectomy must be performed (Chester et al, 2008).

Care must be taken to maintain euthyroidism (to avoid inducing hypothyroidism) in the infant. Frequent monitoring to adjust methimazole doses is indicated. Consideration can be given to suppressing thyroid production and adding back levothyroxine to achieve T_4 or FT_4 just above the mean to ensure euthyroidism.

CHAPTER 94

Disorders of Carbohydrate Metabolism

Vandana Jain, Ming Chen, and Ram K. Menon

One of the most difficult and complex challenges faced by the newborn at birth is the almost instantaneous transition from total dependence on maternal glucose supply via the umbilical artery to complete independence for glucose homeostasis after the severing of the umbilical cord. Thus the newborn is faced with a metabolic milieu characterized by intermittent supply of exogenous glucose with variable periods of fasting during which the newborn is dependent on endogenous glucose production for maintenance of glucose homeostasis. This challenge is compounded by the fact that, on a per body weight basis, the glucose needs of the newborn are three to four times higher than those of the adult. The increased glucose utilization rate in the newborn is primarily due to higher rates of cerebral glucose utilization as a result of the increased proportion of brain size compared with body weight in the newborn (Menon and Sperling, 1988). Glucose homeostasis in neonates is maintained by a complex balance between glucose utilization and production controlled by coordinated changes in the concentrations of insulin and the counterregulatory hormones, principally growth hormone, cortisol, glucagon, and catecholamines. After birth, there is an abrupt fall with subsequent rise in blood glucose concentrations within 1 to 2 hours as the pathways of glycogenolysis and gluconeogenesis are activated in response to increased circulating levels of cortisol, glucagon, and catecholamines. Over the first few days of life, with establishment of regular enteral feeding and continued maturation of hepatic gluconeogenesis, blood glucose levels further stabilize.

Transient disturbances in glucose homeostasis, especially hypoglycemia, are frequently observed in the neonate because of developmental immaturity of the glucose homeostatic pathways. Neonatal hypoglycemia is a more frequent occurrence when glycogen reserves are low, as in preterm babies and neonates with intrauterine growth restriction, or when energy demands are increased, as in sepsis, hypothermia, and birth asphyxia. Persistent hypoglycemia in the neonatal period is relatively less common and either is caused by congenital endocrine disorders, such as congenital hyperinsulinemia or hypopituitarism, or is secondary to inborn errors in the enzymatic pathways of glycogenolysis, gluconeogenesis, or ketogenesis. Hypoglycemia in neonates can manifest with seizures in the short term and can lead to significant neuromorbidity in the long term. Hence, hypoglycemia constitutes a neonatal emergency requiring urgent diagnostic evaluation and appropriate therapeutic intervention.

This chapter reviews the definition, pathophysiology, diagnostic work-up, and treatment of neonatal hypoglycemia. Also discussed are the less commonly seen conditions of transient and permanent neonatal diabetes.

DEFINITION OF HYPOGLYCEMIA

A consensus among experts regarding the precise definition of hypoglycemia remains elusive. Attempts have been made to identify a reliable evidence-based operational threshold at which intervention should be considered for neonatal hypoglycemia to prevent neurologic sequelae. In a population-based metaanalysis of plasma glucose levels among healthy full-term newborns, Alkalay et al (2006) estimated the lower threshold (<5th percentile) at 1 to 2, 3 to 23, 24 to 47, and 48 to 72 hours after birth to be 28, 40, 41, and 48 mg/dL, respectively. It should be noted that plasma glucose values are higher than those in whole blood by approximately 13.5% and should be factored in when comparing whole blood and plasma glucose thresholds.

The risk of hypoglycemic injury to the brain is modified by factors including the availability of alternative fuels such as ketones and lactate and the presence of comorbidities such as hypoxia and sepsis. Operational blood glucose concentration thresholds for therapeutic intervention that factor these variables into consideration have also been proposed: for example, <45 mg/dL for newborns with abnormal clinical signs and symptoms, <63 mg/dL for newborns with hyperinsulinemia (taking into account the low levels of alternative fuels in this cohort), and <36 mg/dL for at-risk neonates assessed as being healthy with absence of clinical signs and symptoms of hypoglycemia (Hussain, 2005). However, some experts contend that the sensitivity to hypoglycemia of a neonate's brain may not be less than that of older children, and therefore the threshold for hypoglycemia in the neonate should be 60 mg/dL (Stanley at al, 1999). In our opinion, in general a plasma glucose level of <50 mg/dL is a practical, reasonable, and safe threshold for assessing a newborn for hypoglycemia (Sperling and Menon, 2004).

SIGNS AND SYMPTOMS

Signs and symptoms of hypoglycemia in neonates are nonspecific and include jitteriness, lethargy, poor feeding, apnea, cyanotic spells, respiratory distress, myoclonic or multifocal clonic seizures, and, rarely, coma. Many neonates are asymptomatic or display minimal signs and symptoms, and therefore the detection of hypoglycemia requires a high index of suspicion, especially in at-risk neonates.

MEASUREMENT OF BLOOD GLUCOSE

The ideal method of blood glucose estimation should be accurate, rapid, and inexpensive; require small sample volume; and be available as a point-of-care test. However, none of the available methods fulfill all of these criteria.

Laboratory techniques based on the hexokinase method for estimation of glucose in serum or plasma are usually accepted as the reference method. Reagent strips and glucose reflectance meters are commonly used in newborn units but lack necessary reproducibility and accuracy. The use of skin-cleansing agents, variations in hematocrit, and operator technique (placing too little or too much blood on the strip) are common sources of error (Ho et al, 2004; Reynolds et al, 1993). Glucose biosensors that measure the molality of glucose in the water phase of blood or plasma are present in most blood glucose and electrolyte analyzer machines. Whereas the glucose biosensor method has not been extensively evaluated, a recent study reported good agreement between a potentiometric glucose oxidase sensor incorporated in a multianalyte analyzer and a laboratory-based reference method (Newman et al, 2002).

Another newer methodology of special relevance to preterm babies who require intensive glucose monitoring for prolonged periods is the continuous glucose monitor using a subcutaneously implanted catheter that continuously measures the concentration of small molecules (including glucose) in the interstitial fluid by microdialysis (Baumeister et al, 2001). Use of this method also reduces the discomfort and blood loss associated with the conventional methods; however, the accuracy of this method at low levels of blood glucose remains to be established.

NEWBORNS REQUIRING GLUCOSE MONITORING

It is essential that glucose monitoring at appropriate intervals be instituted in newborns at increased risk of hypoglycemia. Box 94-1 (modified from Deshpande and Ward Platt, 2005) summarizes the maternal and neonatal conditions that place the newborn at risk of hypoglycemia.

BOX 94-1 Maternal and Neonatal Conditions That Increase the Risk of Neonatal Hypoglycemia

MATERNAL CONDITIONS

Diabetes (gestational or pre-gestational)
Administration of drugs (β sympathomimetics, e.g., terbutaline, oral hypoglycemic agents)
Intrapartum dextrose infusion
Hypertension/ pre-eclampsia

NEONATAL CONDITIONS

Prematurity
Intrauterine growth restriction
Hypoxia-ischemia
Large/small for gestational age
Sepsis
Hypothermia
Polycythemia
Presence of syndromic features (microphallus, midline defects, Beckwith-Wiedemann syndrome)

Modified from Deshpande S, Ward Platt M: The investigation and management of neonatal hypoglycaemia, *Semin Fetal Neonatal Med* 10:351-361, 2005.

CLASSIFICATION OF NEONATAL HYPOGLYCEMIA

Neonatal hypoglycemia is classified (Box 94-2) as transient when it lasts days to weeks after birth and persistent when hypoglycemia continues in infancy.

TRANSIENT HYPOGLYCEMIA

The fetus receives a constant transplacental supply of maternal glucose via insulin-independent GLUT-1 and GLUT-3 glucose transporter mediated diffusion (Bier et al, 1977). This glucose is utilized for meeting the energy demands of the fetus and for assimilation of glycogen and fat stores. The doubling of fetal weight from an average of 1700 grams at 32 weeks to 3400 grams at term is chiefly contributed by the accrual of hepatic glycogen and adipose tissue fat depots.

Transient hypoglycemia is common in neonates if feeding is delayed because of the physiologic immaturity of pathways of glucose homeostasis. In healthy term, appropriate-for-gestational-age newborns, when feeding is delayed to 6 to 8 hours after birth, plasma glucose falls below 50 mg/dL in 30% and below 30 mg/dL in 10% (Lubchenco and Bard, 1971). This propensity for decrease in blood sugar concentrations is believed to be primarily due to developmental immaturity in the pathways of

BOX 94-2 Classification of Neonatal Hypoglycemia

TRANSIENT (DAYS)

Developmental immaturity in adaptation to fasting: prematurity, small for gestational age (SGA)
Stress in peripartum/postnatal period: trauma, asphyxia, hypothermia
Transient hyperinsulinemia: infants of diabetic mothers, intrapartum dextrose infusion to mother
Increased metabolic expenditure: sepsis, erythroblastosis fetalis, polycythemia
Other maternal conditions: toxemia, administration of tocolytics (β sympathomimetics)

TRANSIENT (WEEKS TO MONTHS)

Hyperinsulinism in SGA infants and infants with birth asphyxia

PERSISTENT

Hyperinsulinemic
- K_{ATP} channel defects
- Glutamate dehydrogenase (GLUD1)-activating mutation
- Glucokinase-activating mutation
- Short-chain 3-hydroxyacyl coA dehydrogenase (SCHAD) mutation
- Beckwith-Wiedemann syndrome (BWS)
- Hyperinsulinism in congenital disorders of glycosylation
- β-cell adenoma—MEN1
- Undefined

3. Normoinsulinemic
- Counterregulatory hormone deficiency
- Inborn errors of metabolism
- Glycogen storage disease (I, III, VI)
- Disorders of gluconeogenesis
- Defects in fatty acid catabolism and ketogenesis
- Organic acidurias
- Galactosemia
- Hereditary fructose intolerance

gluconeogenesis and ketogenesis wherein some of the key enzymes are not expressed at birth. The expression of these enzymes and the subsequent maturation of these pathways for adaptation to fasting occur rapidly in the postnatal period, usually within the first 24 hours of life.

Major causes of transient hypoglycemia in neonates are listed in Box 94-2, and some of the important causes are discussed in the following sections.

Hypoglycemia in Premature and Small for Gestational Age Infants

Preterm and small for gestational age infants are at increased risk of hypoglycemia because the developmental immaturity in fasting adaptation is coupled with inadequate reserves of glycogen and fat that serve as substrates for gluconeogenesis and ketogenesis. Management of hypoglycemia in these newborns consists of frequent blood glucose monitoring, frequent oral or nasogastric feeding, and intravenous dextrose infusion if enteral feeds are not tolerated. Glucose homeostasis is achieved usually within the first few days of life after establishment of regular feeding and activation of the relevant enzymatic pathways.

Hypoglycemia in Infants of Diabetic Mothers

These infants are characteristically macrosomic and have excess glycogen and fat reserves due to hyperglycemia in the fetal period. However, an elevated circulating level of insulin prevents these infants from appropriately mobilizing these reserves during the early postnatal period. This state of hyperinsulinism generally resolves within the 1st week of life with reestablishment of glucose homeostasis. Maintenance of maternal euglycemia, especially in the third trimester and the intrapartum period, decreases the incidence of hypoglycemia in the newborn (Andersen et al, 1985; Taylor et al, 2002). Management of the hypoglycemia consists of frequent feeding and supplementation with intravenous dextrose if required. The rate of dextrose infusion is titrated to maintain euglycemia. Decrements in dextrose infusion should be instituted in a stepwise manner to prevent rebound hypoglycemia precipitated by sustained insulin secretion after abrupt discontinuation of high rates of glucose infusion.

Transient Hyperinsulinism in Asphyxiated or Small for Gestational Age Infants

Hypoglycemia lasting from several days to a few weeks or months is occasionally observed in infants with birth asphyxia or intrauterine growth retardation. Hyperinsulinism, and possibly an associated deficiency of glucagon, is implicated in the pathogenesis of hypoglycemia. In these infants, exogenous dextrose requirement may exceed 20 mg/kg/ minute, and the hypoglycemia is unresponsive to glucocorticoid administration. Most infants show good response to drugs useful in hyperinsulinism, such as diazoxide, octreotide, and glucagon (Bhowmick and Levandowski, 1989; Clark and O'Donovan, 2001). Oral diazoxide is the usual regimen of choice and is administered until resolution of the hyperinsulinism.

PERSISTENT HYPOGLYCEMIA

Hyperinsulinemic Hypoglycemia

Hyperinsulinism characterized by inappropriate insulin secretion in the presence of low plasma glucose is the most common cause of persistent hypoglycemia in the neonate. This entity was first described in 1954 by McQuarrie as "idiopathic hypoglycemia of infancy" and subsequently referred to by various names such as nesidioblastosis, islet dysregulation syndrome, and persistent hyperinsulinemic hypoglycemia of infancy. Currently the preferred term is congenital hyperinsulinism of infancy (CHI). Worldwide the incidence of CHI is 1 in 30,000 to 1 in 50,000 live births. A particularly high incidence of 1 in 2500 has been reported from the Arabian Peninsula and is attributed to high rates of consanguinity (al-Rabeeah et al, 1995; Bin-Abbas et al, 2003).

The commonest and the most severe genetic defects responsible for CHI are mutations in genes coding the two subunits of the ATP-sensitive potassium (K_{ATP}) channel, the SUR1 and Kir6.2 proteins (Doyle et al, 1998; Thomas et al, 1995, 1996). Mutations in other genes that can also manifest as CHI are those coding for glucokinase, glutamate dehydrogenase (GDH), and the mitochondrial enzyme L-3-hydroxyacyl CoA dehydrogenase (HADH) proteins. A brief overview of these conditions is presented in Table 94-1. Hyperinsulinism is also observed in less common disorders such as Beckwith-Wiedemann syndrome (BWS) and congenital disorders of glycosylation. The salient causes of persistent hyperinsulinism in the newborn are discussed in greater detail in the following sections.

K_{ATP} Channel Defects

The commonest mechanism underlying CHI is dysfunction of the ATP-sensitive potassium channel located on the β-cell membrane. This channel has two subunits, the potassium inward rectifying (Kir6.2) pore and the sulfonylurea receptor regulatory subunit (SUR1). The Kir6.2 is encoded by the *KCNJ11* gene and the SUR1 subunit by the *ABCC8* gene, both located in the 11p15.1 region. In the unstimulated (resting) state, the ATP/ADP ratio is low and the channel remains open. This allows the β cell to maintain a polarized state with a resting membrane potential of approximately –65mV. When there is uptake and metabolism of glucose in the β cell, the concentration of ATP increases and that of ADP decreases. This causes the K_{ATP} channels to close, leading to depolarization of the cell membrane. Depolarization leads to opening of the voltage-gated Ca^{2+} channels with resultant influx of calcium and exocytosis of insulin (Figure 94-1) (Sperling and Menon, 2004). Inactivating (loss of function) mutations in the *KCNJ11/ABCC8* gene result in persistent closure of the channel, leading to depolarization of cell membrane, influx of calcium, and inappropriate release of insulin. More than 100 distinct mutations have been described in the SUR1 encoding *ABCC8* gene and are responsible for 50% to 60% of all cases of CHI. Mutations in the Kir6.2 encoding *KCNJ11* gene are responsible for 10% to 15% of all cases of CHI (Dunne et al, 2004).

TABLE 94-1 An Overview of the Genetic Causes of CHI

Inheritance	Molecular Defect	Chromosome	Histology	Clinical Features	Treatment	Outcome
Sporadic	Paternally inherited ABCC8/KCNJ11 mutation with loss of heterozygosity	11p15	Focal	Macrosomia, moderate to severe hypoglycemia in first few days to weeks of life	Poor response to diazoxide, local resection for focal and near-total pancreatectomy for diffuse form	Good in focal and guarded in diffuse
	De novo mutation in ABCC8/KCNJ11		Diffuse			
AR	ABCC8/KCNJ11 (inactivating)	11p15	Diffuse	Macrosomia, onset in first few days to weeks of life, family history or consanguinity may be present	Near-total pancreatectomy	Guarded
AD	ABCC8/KCNJ11 (inactivating)	11p15	Diffuse	Milder symptoms, may manifest in late infancy	Usually responsive to diazoxide	Good
AD	GLUD1 (activating)	10q	Diffuse	Modest hyperinsulinemia and hyperammonemia, onset usually >6 months	Diazoxide, restriction of leucine in diet	Good
AD	GCK (activating)	7p	Diffuse	Modest hyperinsulinemia, onset usually >6 months	Diazoxide	Good
AR	HADH	4q	Diffuse	Variable clinical presentation, abnormal acylcarnitine profile	Diazoxide	Fair

Modified from Sperling MA, Menon RK: Differential diagnosis and management of neonatal hypoglycemia, *Pediatr Clin North Am* 51:703-723, 2004.
ABCC8, ATP-binding cassette subfamily C, member 8; *AD*, autosomal dominant; *AR*, autosomal recessive; ; *GCK*, glucokinase; *GLUD1*, glutamate dehydrogenase 1; *HADH*, L-3-hydroxyacyl coenzyme A dehydrogenase hyperinsulinism; *KCNJ11*, potassium inward rectifying channel subfamily J, member 11.

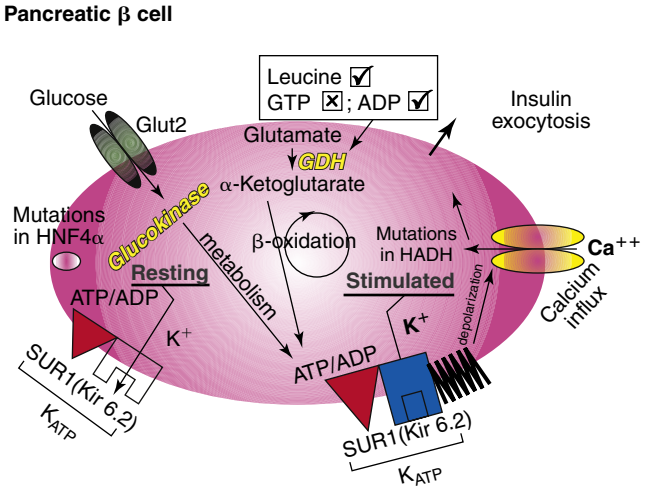

FIGURE 94-1 Mechanisms of insulin secretion by the β cell of pancreas. Glucose transported into the β cell by the insulin-dependent glucose transporter, GLUT 2, undergoes phosphorylation by glucokinase and subsequent metabolism, resulting in an increase in the intracellular ATP:ADP ratio. The increase in the ATP:ADP ratio closes the K_{ATP} channel and initiates the cascade of events characterized by increase in intracellular K concentration, membrane depolarization, calcium influx, and release of insulin from storage granules. Leucine stimulates insulin secretion by allosterically activating glutamate dehydrogenase (GDH) and by increasing the oxidation of glutamate, thereby increasing the ATP:ADP ratio and closure of the KATP channel. Mutations in the HADH gene, which codes for the mitochondrial enzyme L-3-hydroxyacyl-coenzyme A dehydrogenase that catalyzes the penultimate step in the fatty acid β-oxidation pathway, is also associated with CHI. Mutations in HNF4α cause multiple defects in glucose stimulated insulin secretion. ×, inhibition; √, stimulation. *(Modified from Sperling MA, Menon RK: Differential diagnosis and management of neonatal hypoglycemia*, Pediatr Clin North Am *51:703-723, 2004.)*

Histologically, CHI can be classified as either diffuse involvement of the pancreas or focal adenomatous hyperplasia (Kloppel et al, 1999). An estimated 40% to 65% of CHI is characterized as focal and the remainder as the diffuse form. In the diffuse form, the β cells have abundant cytoplasm and large nuclei throughout the pancreas, whereas in the focal form, the lesion is less than 10 mm in size with confluent proliferation of β cells that are normal in size and shape with intermingling of exocrine acinar cells (Figure 94-2, *A* and *B*). Both the forms manifest with similar clinical features, with no correlation between the severity of hypoglycemia and histologic classification. The molecular defect underlying the focal form is most commonly a paternally inherited mutation in SUR1 or Kir6.2 with loss of the 11p15 maternal allele in the pancreatic β cells (loss of heterozygosity). Since the loss of heterozygosity is a somatic defect, focal CHI always manifests as a sporadic event. The underlying defect in cases of diffuse CHI are more varied and include *de novo*, autosomal recessively or dominantly inherited mutations in *KCNJ11* or *ABCC8* genes and less commonly mutations involving β-cell enzymes as discussed later (De Lonlay et al, 2007).

Activating Mutation of the Glutamate Dehydrogenase (GLUD1) Gene

Glutamate dehydrogenase (*GLUD1*) activating mutation, also referred to as hyperinsulinemia hyperammonemia (HIHA) syndrome, is the second commonest cause of CHI. Glutamate dehydrogenase (GDH) is a mitochondrial enzyme that is normally activated by leucine and ADP and inhibited by GTP and ATP. GDH increases the oxidative deamination of glutamate to α-ketoglutarate

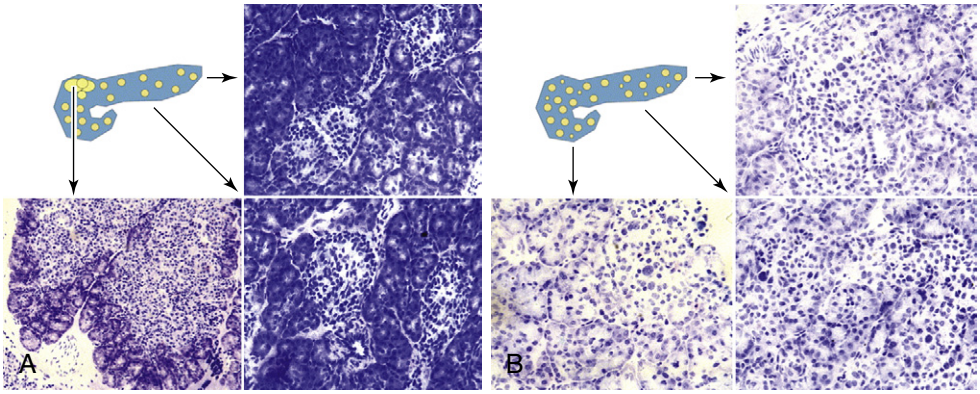

FIGURE 94-2 *(Supplemental color version of this figure is available online at www.expertconsult.com.)* **A,** Representation of frozen sections obtained from three pancreatic sites during surgery for a focal form of hyperinsulinism in the head. Specimens taken from tail and body show islets of Langerhans at rest with little cytoplasm, leading to crowded nuclei, whereas the focal form aspect from the head is that of multilobular involvement with local signs of β-cell hyperactivity: abundant cytoplasm and large, abnormal nuclei (toluidine blue stain; original magnifications ×200 and ×100). **B,** Representation of frozen sections obtained from three pancreatic sites during surgery for diffuse form of hyperinsulinism. On each biopsy, there is one islet showing hyperfunctional signs with abundant cytoplasm and irregular nuclei more than 4 times the size of the acinar nuclei nearby taken as internal control. The disease involves the whole pancreas and, in consequence, can be called diffuse, which does not mean that all islets are involved in the same manner (toluidine blue stain; original magnification ×200). *(Reproduced from Delonlay P, Simon A, Galmiche-Rolland L, et al: Neonatal hyperinsulinism: clinicopathologic correlation*, Hum Pathol *38:387-399, 2007.)*

and ammonia, thereby raising the ATP/ADP ratio, which results in closure of the K_{ATP} channel and release of insulin. This form of CHI usually presents beyond 6 months of age with recurrent hypoglycemia and persistent mild hyperammonemia (serum ammonia levels 2–5 times normal). The hypoglycemia is usually less severe than that in the K_{ATP} channel defects and is usually controllable by diazoxide therapy (Stanley et al, 1998).

Activating Mutation of the Glucokinase Gene

This rare form of CHI is caused by an activating mutation in the *GCK* gene resulting in increased affinity of glucokinase for glucose with resultant inappropriate insulin secretion (Glaser et al, 1998).

HADH (L-3-Hydroxyacyl-Coenzyme A Dehydrogenase) Gene Mutation

Mutations in the *HADH* gene, which codes for the mitochondrial enzyme L-3-hydroxyacyl-coenzyme A dehydrogenase (previously referred to as short-chain 3-hydroxyacyl dehydrogenase, SCHAD) that catalyzes the penultimate step in the fatty acid β-oxidation pathway, are also associated with CHI. The exact mechanism of increased insulin secretion in patients with this mutation is not clear. The clinical presentation can vary from severe neonatal-onset to mild late-onset hypoglycemia, but all forms show good response to treatment with diazoxide (Clayton et al, 2001; Eaton et al, 2003).

Beckwith-Wiedemann Syndrome

BWS is characterized by somatic overgrowth, macroglossia, visceromegaly, hemihypertrophy, transverse ear lobe creases, renal tract abnormalities, and predisposition to development of tumors. This condition is sporadic in approximately 85% of cases and inherited in an autosomal dominant manner in the remaining 15%. Several genetic and epigenetic alterations in the 11p15 region such as paternal isodisomy, methylation of H19/ IGF2, and mutations in *CDKN1C* gene have been described (Li et al, 1998). Hypoglycemia of varying severity is seen in 50% of infants and is transient in the vast majority of patients. In persistent cases, the response to treatment is variable. Good control of hypoglycemia with diazoxide is achieved in some patients, with other patients requiring partial pancreatectomy for control of hypoglycemia. The molecular mechanism(s) for hyperinsulinism in BWS has not been clearly defined (DeBaun et al, 2000).

Hyperinsulinism in Congenital Disorders of Glycosylation

Congenital disorders of glycosylation (CDG) are a family of disorders characterized by defects in glycosylation of various glycoproteins, with symptoms affecting multiple systems including brain, liver, gastrointestinal system, and skeleton. Hyperinsulinemic hypoglycemia has been described in CDG-Ia (phosphomannose mutase deficiency) in conjunction with neurologic symptoms (Bohles et al, 2001); CDG-Ib (phosphomannose isomerase deficiency) in association with protein-losing enteropathy and liver disease (Babovic-Vuksanovic et al, 1999); and rarely in CDG-Id (Sun et al, 2005). The pathophysiology of hyperinsulinism in these rare syndromes is not well understood. Hypoglycosylation of SUR1 or other proteins involved in insulin secretion has been postulated to be the responsible mechanism.

Dominant Heterozygous Mutations in the HNF4 α gene

Hepatocyte nuclear factor 4α (HNF4α) is a transcription factor belonging to the nuclear hormone receptor superfamily. This gene is expressed in liver, gut, kidney, and pancreatic islets. In the β cell, HNF4α regulates several key genes involved in glucose-stimulated insulin secretion. Heterozygote mutations in the human *HNF4A* gene generally present as maturity onset diabetes of the young subtype 1 (MODY1). However, recent reports have implicated mutations in the HNF4α gene as causing both transient and persistent CHI (Kapoor et al, 2008).

Diagnosis of Hyperinsulinism

The diagnosis of hyperinsulinism is based on clues from history, physical examination, and laboratory tests performed on a critical blood sample and complemented by molecular diagnosis by genetic testing when available. Infants with hyperinsulinism generally present with severe and persistent hypoglycemia within 4 to 5 hours of fasting, with seizures, lethargy, and apnea, and have high glucose requirements (usually greater than 10 mg/kg/minute). Macrosomia may be a feature in some newborns. Diagnosis is based on evidence of inadequate suppression of insulin secretion on a critical blood sample drawn during an episode of hypoglycemia. Presence of low levels of plasma free fatty acids and ketones (insulin suppresses lipolysis and ketogenesis) and a glycemic response (within 30 minutes of administration of glucagon at the time of the hypoglycemic event) of greater than 30 mg/dL indicating the presence of adequate hepatic glycogen stores are strong evidence of hyperinsulinism (Stanley and Baker, 1976). The diagnostic criteria for hyperinsulinism based on laboratory analysis of a critical blood sample are presented in Box 94-3. Other tests such as serum ammonia for HIHA caused by activating mutation of GDH and plasma acylcarnitine profile and urinary organic acids (increased plasma 3-hydroxybutyrylcarnitine and urine 3-hydroxyglutarate) for CHI caused by mutation in SCHAD enzyme may also be indicated in individual cases. Genetic testing for molecular diagnosis of several forms of CHI is also commercially available.

Differentiation between Focal Adenomatous and Diffuse Pancreatic Hyperplasia

Differentiation between infants with focal and diffuse forms of CHI preoperatively is very helpful in formulating the management strategy and prognosticating the outcome.

BOX 94-3 Diagnostic Criteria for Hyperinsulinism Based on Critical Sample at Time of Hypoglycemia

- Plasma insulin >2μU/ml
- Plasma free fatty acids <1.5 mmol/L
- Plasma β-hydroxybutyrate <2.0 μmol/L
- Glycemic response to 0.1 mg/kg intravenous glucagon >30 mg/dL

The focal form is curable with partial pancreatectomy and has an excellent prognosis, whereas diffuse disease requires near-total (95% to 98%) pancreatectomy with subsequent development of diabetes mellitus in approximately half and persistence of hypoglycemia in a third of the affected infants. Until recently, this differentiation was based on technically difficult and invasive methods with low reliability, such as intrahepatic portal venous sampling and selective pancreatic intraarterial calcium stimulation with venous sampling. Recently positron emission tomography (PET) scans with fluorine-18–L-3,4-dihydroxyphenylalanine (^{18}F-fluoro-L-DOPA) have been successfully used to accurately discriminate focal from diffuse CHI (Otonkoski et al, 2006). This test is based on the fact that β cells take up L-DOPA and convert it to dopamine via DOPA decarboxylase present in islet cells. In cases of focal CHI, there is localized accumulation of ^{18}F-fluoro-L-DOPA, and co-registration of PET and magnetic resonance (MR) images allows anatomic localization of the lesion (Mohnike et al, 2006).

Management

Table 94-2 provides a summary of drugs used in the management of hyperinsulinism. As described earlier, the syndromic, metabolic, and milder form of K_{ATP} channel defects (autosomal dominant with late onset) are usually responsive to diazoxide, which is the first line of treatment. The response should be evaluated after at least 5 days of therapy (based on diazoxide's half-life of 9.5 to 24 hours) and defined as maintenance of plasma glucose >70 mg/dL after 3 to 4 hours of fasting (deLeon and Stanley, 2007). In those infants who fail to respond, octreotide is tried as the second-line drug. Octreotide is a long-acting somatostatin analogue that inhibits insulin secretion. Most infants show an initial response to octreotide but develop tachyphylaxis after a few days. Thus, octreotide's major clinical role is in short-term management of infants awaiting surgery (deLeon and Stanley, 2007). Nifedipine, a calcium channel antagonist, has been reported to be effective in a limited number of cases (Muller et al, 2004), but long-term experience is lacking. Further, this drug can cause life-threatening hypotension in the newborn period and therefore avoided. Glucagon is useful in short-term management of infants awaiting surgery (Hussain et al, 2004).

TABLE 94-2 Drugs Used in the Management of Neonatal Hyperinsulinism

Drug	Dose/Route	Mechanism of Action	Adverse Effects
Diazoxide	5–20 mg/kg/d in three divided doses orally	Binds to SUR1 subunit, opens K_{ATP} channel	Fluid retention, hypertrichosis, rarely eosinophilia, leukopenia, hypotension
Chlorthiazide (in conjunction with diazoxide to decrease fluid retention)	7–10 mg/kg/d in two divided doses orally	Synergistic response to diazoxide	Hyponatremia, hypokalemia
Octreotide	5–25 μg/kg/d 6–8 hourly SC injection or IV infusion	Inhibits insulin secretion by binding to somatostatin receptors and inducing hyperpolarization of β-cells, direct inhibition of voltage-dependent calcium channels	Anorexia, nausea, abdominal pain, diarrhea, tachyphylaxis
Glucagon	1–20 μg/kg/h, SC or IV infusion	Increases glycogenolysis and gluconeogenesis	Nausea, vomiting, paradoxical insulin secretion at high dose
Nifedipine	0.25–2.5 mg/kg/d in three divided doses orally	Calcium channel blocker	Hypotension

IV, Intravenous; *SC*, subcutaneous.

Surgical therapy is required in those infants who fail to respond to medical management. In focal CHI, resection of the lesion will "cure" the infant. Infants with diffuse disease require a near-total (95% to 98%) pancreatectomy and may also require additional therapy with diazoxide, octreotide, and frequent feeding to maintain euglycemia.

Normoinsulinemic Hypoglycemia

Counterregulatory Hormone Deficiency

This is the second most frequent cause of persistent hypoglycemia presenting in the neonatal period. Hypopituitarism causing varying degrees of adrenocorticotrophic hormone (and hence cortisol) and growth hormone (GH) deficiencies may present with hypoglycemia in the neonatal period due to unopposed effects of insulin. Clues to hypopituitarism in the affected neonate are midline facial defects, cholestasis, nystagmus due to optic nerve hypoplasia, and microphallus in the male neonate (reflecting the role of pituitary gonadotropin action in the development of the external male genitalia). In the neonatal period, ketones are absent or low in affected babies, whereas in later infancy ketone levels are usually elevated. Diagnosis is established by demonstrating GH levels to be less than 10 ng/mL during an episode of hypoglycemia (Sperling and Menon, 2004). Provocative testing is not required because the average plasma concentration of GH in normal newborns ranges from 16 to 76 ng/mL in the first few weeks of life (Cornblath et al, 1965).

Primary adrenal insufficiency as in enzymatic deficiency of steroid biosynthesis (congenital adrenal hyperplasia), congenital X-linked adrenal hypoplasia, and adrenal hemorrhage can also present with hypoglycemia in the neonatal period. Presence of dyselectrolytemia (hyponatremia, hyperkalemia) or ambiguous genitalia (in congenital adrenal hyperplasia) may provide a clue to the diagnosis of adrenal insufficiency in the newborn. Familial glucocorticoid deficiency caused by adrenocorticotrophic hormone receptor defects manifests with hypoglycemia and hyperpigmentation without electrolyte disturbance because aldosterone secretion is unaffected. Diagnosis of adrenal insufficiency is established by demonstration of low serum cortisol concentration (<5μg/dL) during hypoglycemia.

Inborn Errors of Metabolism

Inborn errors in the enzymatic pathways of glycogen synthesis or breakdown, gluconeogenesis, and fatty acid oxidation can occur with hypoglycemia. However, these disorders rarely manifest in the neonatal period because several hours of fasting is needed for hypoglycemia to manifest, an unlikely situation in newborns, unless breastfed infants encounter latching-on difficulties. These disorders usually present in later infancy when feeding interval has increased and the infant has started sleeping through the night or during intercurrent illness with reduced oral intake. Some of the major inborn errors of metabolism presenting with hypoglycemia are discussed briefly in the following sections. The key metabolic pathways of intermediary metabolism are presented in Figure 94-3.

Glycogen Storage Diseases

Hypoglycemia is seen with several of the glycogen storage diseases (GSDs), most notably GSD1 caused by glucose-6-phosphatase deficiency. This is a key enzyme in the pathways of glycogenolysis as well as gluconeogenesis. Affected infants have hypertriglyceridemia, hyperuricemia, hypophosphatemia, and elevated levels of ketones and lactate with metabolic acidosis. Frequent feeding and high levels of alternate fuels for cerebral metabolism usually preclude the development of symptomatic hypoglycemia in the neonatal period. GSD3 is caused by the deficiency of amylo-1,6-glucosidase (debrancher enzyme) and has a phenotype similar to that of GSD1. Other forms of GSD such as liver phosphorylase and phosphorylase kinase deficiency (GSD types 6 and 9) and glycogen synthase deficiency (GSD type 0) are rare causes of hypoglycemia in infancy (Wolfsdorf et al, 1999; Wolfsdorf and Weinstein, 2003).

Disorders of Gluconeogenesis

Fructose 1,6-diphosphatase deficiency results in blockage of gluconeogenesis from all possible precursors below the level of fructose 1,6-diphosphate (see Figure 94-3). However, disorders of gluconeogenesis are likely to manifest with hypoglycemia only after prolonged caloric deprivation and are therefore unlikely to manifest in the neonatal period (Stanley et al, 2002).

Disorders of Fatty Acid Catabolism and Ketogenesis

Disorders of fatty acid oxidation represent errors in the uptake, activation, and mitochondrial oxidation of fatty acids. These disorders usually appear after prolonged caloric deprivation (6 to 8 hours in infants <1 year and 10 to 12 hours in older infants), as may occur during intercurrent illness. The phenotype may range from a severe Reye-like syndrome with coma and death to milder forms with varying degrees of involvement of liver, skeletal, and cardiac muscle. The clinical findings may include hepatomegaly, vomiting, hypotonia, muscle weakness, and cardiomyopathy. This group of disorders is characterized by low or absent plasma and urine ketones. The primary diagnostic tool in the evaluation of these disorders is determination of plasma acylcarnitine profile by tandem mass spectrometry. Specific abnormalities of the plasma acylcarnitines are seen in different disorders of fatty acid oxidation (Stanley, 1998).

Galactosemia

Galactosemia is caused by deficiency of the enzyme galactose-1-phosphate uridyl transferase. Deficiency of UDP-galactose-4-epimerase also has a similar clinical presentation. Affected infants present with vomiting, diarrhea, jaundice, and hepatomegaly in addition to hypoglycemia. *Escherichia coli* sepsis commonly occurs in affected infants. Cataracts, liver dysfunction, renal tubular defects, intellectual impairment, and ovarian failure are other clinical manifestations. Diagnosis is suspected in infants with non-glucose reducing substance in urine and confirmed by assay for galactose-1-phosphate uridyl transferase and epimerase enzymes. Management consists of dietary galactose restriction (Stanley et al, 2002).

Hereditary Fructose Intolerance

Hereditary fructose intolerance is caused by deficiency of the enzyme fructose-1-phosphate aldolase and manifests only after inclusion of fructose in the diet. In infants fed with fructose- or sucrose-containing formulas, there is acute postprandial hypoglycemia along with vomiting and abdominal distention. The hypoglycemia is caused by an acute inhibition of glycogenolysis and gluconeogenesis by the accumulation of fructose-1-phosphate (Stanley et al, 2002).

HYPERGLYCEMIA IN THE NEONATE

DEFINITION

Whereas the upper limit of blood sugar levels in healthy newborns has not been clearly defined, it is customary to consider the threshold for diagnosing hyperglycemia in the neonate to be similar (126 mg/dL) to that for children and adults. Blood sugar concentration >180 mg/dL or presence of glycosuria with osmotic diuresis is generally considered an indication for intervention.

ETIOLOGY

Transient hyperglycemia is generally an incidental finding during routine blood sugar monitoring in sick/preterm or SGA neonates. A common cause for this abnormality in glucose homeostasis is iatrogenic glucose overload. Other mechanisms for transient hyperglycemia in the newborn include impaired insulin secretion, insulin resistance, and immaturity of the hepatic enzymes involved in glucose homeostasis. Rarely the hyperglycemia may be due to neonatal diabetes (incidence 1 in 400,000) (Shield, 2007), which is discussed in the subsequent section.

BOX 94-4 Differential Diagnoses of Neonatal Hyperglycemia

COMMON CAUSES

Excessive intravenous glucose infusion
Impaired glucose homeostasis in preterm/sick/SGA infants
Sepsis
Stress
Corticosteroids

RARE CAUSES

Transient neonatal diabetes
Permanent neonatal diabetes

The differential diagnoses of neonatal hyperglycemia are presented in Box 94-4.

Neonatal Diabetes

Onset of diabetes before the age of 6 months is usually referred to as neonatal diabetes. In contrast to classic type 1 diabetes in children and adolescents, neonatal diabetes is not an autoimmune disease, and specific gene defects are the most common cause of neonatal diabetes. Neonatal diabetes is further classified as transient or permanent (Polak, 2007).

Transient Neonatal Diabetes Mellitus

In a recent report by Flanagan et al (2007), among a cohort of 97 patients with transient neonatal diabetes mellitus (TNDM), anomalies in the 6q24 chromosomal region were seen in 69, KCNJ11 mutations in 12, and ABCC8 mutations in 13 patients; only 3 patients had none of these genetic defects. A brief outline of the common causes of TNDM is presented next.

Chromosome 6q24 Anomalies

A majority of cases of TNDM result from anomalies in the imprinted region of 6q24 containing the *ZAC* (*z*inc, *a*poptosis and *c*ycle) and *HYMAI* (for *hy*datidiform *m*ole *a*ssociated and *i*mprinted) genes. In general, expression of a gene is similar whether the gene is inherited from the female parent (the maternal allele) or the male parent (the paternal allele). However, for a small subset of genes, differences in expression levels are observed when the maternal and paternal alleles are measured separately. This biased expression of one parental allele over the other is termed *genomic imprinting*. Paternal uniparental isodisomy of chromosome 6, unbalanced duplication of paternal 6q24, and loss of imprinting of maternal 6q24 are the three genetic defects that have been associated with TNDM and are believed to result in overexpression of *ZAC* and *HYMAI* genes and consequent inhibition of β-cell proliferation and impairment of glucose-stimulated insulin secretion (Cave et al, 2000).

Diabetes due to 6q24 anomalies usually manifests within the 1st week of life with severe hyperglycemia and dehydration with mild or no ketosis. The majority of affected infants have significant intrauterine growth retardation reflecting insulinopenia during the intrauterine period as well. The associated diabetes generally resolves within the first 3 months of life but reappears in more than half of patients at puberty or during the stress of intercurrent illness (Temple et al, 2000).

K_{ATP} Channel Defects

Recent reports have identified patients with TNDM bearing activating mutations in *KCNJ11* or *ABCC8* genes that code for the K_{ATP} channel subunits Kir6.2 and SUR1, respectively (Babenko et al, 2006; Gloyn et al, 2005). These activating mutations keep the K_{ATP} channel open even in the presence of increased ATP/ADP ratio, resulting in hyperpolarization of the cell membrane, reduced calcium influx, and reduced exocytosis of insulin vesicles. It is noteworthy that activating K_{ATP} channel mutations are more commonly associated with the permanent form of neonatal diabetes. It is speculated that the less severe mutations may manifest as TNDM where β-cell dysfunction is compensated over time by increase in islet mass. In most patients, however, the clinical course is biphasic, with recurrence of diabetes in adolescence or adulthood.

Infants with TNDM due to K_{ATP} channel defects usually have a less severe impairment of fetal growth as compared to those with 6q24 anomalies, present at a later age (at 4 weeks vs. 1st week), and achieve remission at a later age (35 weeks vs. 13 weeks) (Flanagan et al, 2007). However, the spectrum of presentation in both these etiologies significantly overlaps, and a distinction between these two entities cannot be made solely on the basis of clinical features.

Permanent Neonatal Diabetes Mellitus

In a recent report of 279 patients with permanent neonatal diabetes mellitus (PNDM), genetic mutations could be detected in 53% of patients, with *KCNJ11*, *ABCC8*, and *INS* gene mutations accounting for 31%, 10%, and 12%, respectively (Edghill et al, 2008). A synopsis of the common causes of PNDM is presented next.

K_{ATP} Channel Defects

Heterozygous activating mutations in *KCNJ11* gene, which encodes the Kir6.2 subunit of the K_{ATP} channel, are the commonest cause of PNDM. Because of the mutation, the K_{ATP} channel becomes insensitive to the inhibitory effect of increased ATP:ADP ratio and remains persistently open with ensuing efflux of potassium. Thus, the β-cell membrane remains hyperpolarized, the voltage gated-calcium channels remain closed, and insulin secretion is reduced (Hattersley et al, 2005).

The median age at presentation of patients with this genetic defect is 3 to 4 weeks and their mean birthweight is between the 10th and 25th percentiles. Ketoacidosis is present in approximately 30% of infants at presentation. About 20% of the affected infants have associated neurologic disease in the form of developmental delay with or without epilepsy or muscle weakness, reflecting the importance of the K_{ATP} channel in neuronal physiology. The severest form of neurologic involvement due to a K_{ATP} channel defect is seen in the DEND

(developmental delay, epilepsy, and neonatal diabetes) syndrome (Proks et al, 2005). Sulfonylureas close the K_{ATP} channel by binding to the SUR1 subunit, and a majority of patients with PNDM due to *KCNJ11* mutations respond to therapy with this group of drugs (Koster et al, 2005).

Heterozygous activating and compound homozygous activating/inactivating mutations in the *ABCC8* gene that encodes the SUR1 subunit of the K_{ATP} channel also cause PNDM. Similar to PNDM patients with *KCNJ11* mutations, the vast majority of patients with PNDM due to ABCC8 mutations can also be successfully transitioned to sulfonylurea therapy.

INS Gene Mutations

Heterozygous mutations in the insulin (*INS*) gene are the second commonest cause of PNDM. The identified mutations affect the region of preproinsulin critical for normal protein folding. The abnormally folded proinsulin molecule undergoes degeneration in the endoplasmic reticulum (ER), leading to ER stress and increased β-cell death, leading to progressive reduction in islet mass and diabetes (Stoy et al, 2007).

Other Rare Genetic/Syndromic Causes of PNDM

Homozygous IPF-1 Gene Mutation

Insulin promoter factor-1 (IPF-1) plays an important role in the development of pancreas as well as regulation of expression of insulin and somatostatin genes. Homozygous single nucleotide deletion within IPF-1 gene has been reported to present with pancreatic agenesis with neonatal diabetes and severe exocrine pancreatic insufficiency (Stoffers et al, 1997; Thomas et al, 2009). Heterozygous mutations result in MODY 4.

Homozygous Mutations in Glucokinase Gene

PNDM resulting from homozygous mutations in the glucokinase (*GCK*) gene with complete failure of glycolysis in the β cell is a rare entity (Njolstad et al, 2001). The more commonly occurring heterozygous mutations result in impaired fasting glucose (MODY 2).

IPEX Syndrome

IPEX or immune dysregulation, polyendocrinopathy, enteropathy, X-linked is a rare syndrome caused by mutation in the *FOXP3* gene, which plays a role in the normal regulation of T-cell production. The clinical features of this syndrome are failure to thrive, chronic diarrhea, neonatal diabetes, eczema, thyroiditis, hemolytic anemia, and thrombocytopenia (Wildin et al, 2002).

Wolcott-Rallison Syndrome

This is an autosomal recessive syndrome characterized by onset of diabetes in infancy and spondyloepiphyseal dysplasia. This syndrome is caused by a mutation in the *EIF2AK3* gene, which regulates protein synthesis in the endoplasmic reticulum. Mutations in this gene lead to unregulated protein synthesis with accumulation of malfolded proteins in the ER and increase in β-cell apoptosis (Senee et al, 2004).

TREATMENT

Transient Neonatal Hyperglycemia

Transient neonatal hyperglycemia usually resolves in a few days, and hence the treatment strategy should be conservative.

- Treat underlying cause such as sepsis.
- Minimize exogenous glucose infusion rate to 3–5 mg/kg/minute.
- In the presence of blood sugar >180 mg/dL or if osmotic diuresis manifests, treatment with insulin infusion (starting with 0.03 to 0.05 unit/kg/hour) with frequent blood sugar monitoring should be instituted as a last resort.

Neonatal Diabetes

Control of blood sugar is initially achieved by intravenous insulin infusion, starting at a rate of 0.03 to 0.05 unit/kg/hour and titrated according to blood sugar monitoring. Subsequently, these neonates should ideally be managed by pediatric diabetologists. The treatment options are either continuous subcutaneous insulin infusion (CSII) using an insulin pump or one to two subcutaneous injections per day of an intermediate-acting insulin such as NPH or an ultralong-acting insulin analogue such as glargine or determir.

Early genetic testing should be done in all neonates with diabetes. In those patients determined to harbor mutations in the *KCNJ11* or *ABCC8* genes, an attempt should be made to transition from insulin to oral sulfonylurea regimens.

PART XIX

Craniofacial and Orthopedic Conditions

CHAPTER 95

Craniofacial Malformations

Kelly Evans, Anne V. Hing, and Michael Cunningham

The neonatologist is often the first point of contact for a child born with a craniofacial malformation. Abnormalities of the face and head can be very distressing to a new parent, who is immediately wondering, "Is my child going to look, feel, and develop normally?" Having a basic understanding of the relationship between craniofacial abnormalities and feeding, hearing, vision, speech and overall development will help the neonatologist begin to counsel a family. Airway compromise is well described in multiple craniofacial syndromes, and early identification can be lifesaving. Prompt recognition of a constellation of anomalies pointing toward a syndrome or diagnosis will result in better targeted evaluations and therapies for that patient. (See Tables 95-1 and 95-2 for a concise presentation of potential ICU issues that may be encountered with certain craniofacial malformations and syndromes.) This chapter highlights the most relevant craniofacial malformations that a neonatologist will encounter. We describe here the epidemiology, genetics, diagnosis, phenotype and potential ICU issues as well as basic management recommendations to help guide the neonatologist in caring for an infant with craniofacial malformations.

MICROGNATHIA/ROBIN SEQUENCE

EPIDEMIOLOGY

The triad of micrognathia, glossoptosis and airway obstruction, originally described in 1923 by Pierre Robin, is known as Robin Sequence (or Pierre Robin Sequence [PRS]), Online Mendelian Inheritance in Man (OMIM) database classification number 261800. Whether cleft palate is an obligatory feature of PRS is debatable. Approximately one quarter of infants with cleft palate (CP) were found to have Robin sequence in a multi-site, population-based, case-control study (Genisca et al, 2009). The tremendous heterogeneity and lack of uniformly accepted diagnostic criteria for, or definitions of, PRS make it challenging to know the true prevalence. However, estimates of birth prevalence range from 1:8500 to 1:20,000 births (Breugem and Mink van der Molen, 2009).

PHENOTYPE

Robin sequence is an etiologically and phenotypically heterogeneous disorder. Over half of children with PRS have an associated syndrome with Stickler syndrome being the most common. While there is great variation in severity, PRS is characterized by the following phenotypic features: micrognathia (small and symmetrically receded mandible), glossoptosis (tongue of variable size falls backwards into the postpharyngeal space), and cleft palate (U-shaped more common than V-shaped) (Figure 95-1, *A* and *B*). Caouette-Laberge et al (1994) described cleft palate (U or V-shaped) in 90% of 125 individuals with PRS. Infants with PRS often have airway obstruction, feeding difficulties, and challenges gaining weight, and they may have associated anomalies, including hypotonia and limb reduction defects. Congenital heart defects are present in up to 25% of babies with PRS who die in early infancy (Gorlin et al, 2001b). Patent ductus arteriosus is the most common, followed by atrial septal defects, ventricular septal defects, and coarctation of the aorta. It has been reported that more than 20% of individuals will have developmental delay or cognitive impairment, and overall morbidity and mortality are higher in syndromic PRS or PRS with associated anomalies compared with isolated PRS (Caouette-Laberge et al, 1994).

ICU CONCERNS

In infants with PRS, the tongue is displaced toward the posterior pharyngeal wall, resulting in obstruction at the level of the epiglottis. The tongue can act as a ball valve, leading to inspiratory obstruction. In addition to micrognathia, other mechanisms may contribute to airway obstruction in individuals with PRS, such as pharyngeal hypotonia and airway inflammation from associated gastroesophageal reflux. The principal physiologic sequela of PRS is the inability to effectively feed and/or breathe due to airway obstruction. Patients with PRS may present in the immediate neonatal period with increased inspiratory work of breathing, cyanosis, and apnea. Obstruction is more common in the supine position and can be exacerbated during feeding and in sleep, or any state where there is loss of pharyngeal tone. Chronic obstruction can lead to failure to thrive, carbon dioxide retention, pulmonary hypertension, and eventually right-sided heart failure (cor pulmonale).

Airway obstruction is the main cause of feeding and growth issues in infants with PRS. Feeding problems can also be related to inadequate tongue control or pharyngeal hypotonia and complicated by presence of a cleft palate. Increased energy expenditures due to increased work of breathing may lead to failure to thrive if the infant is not

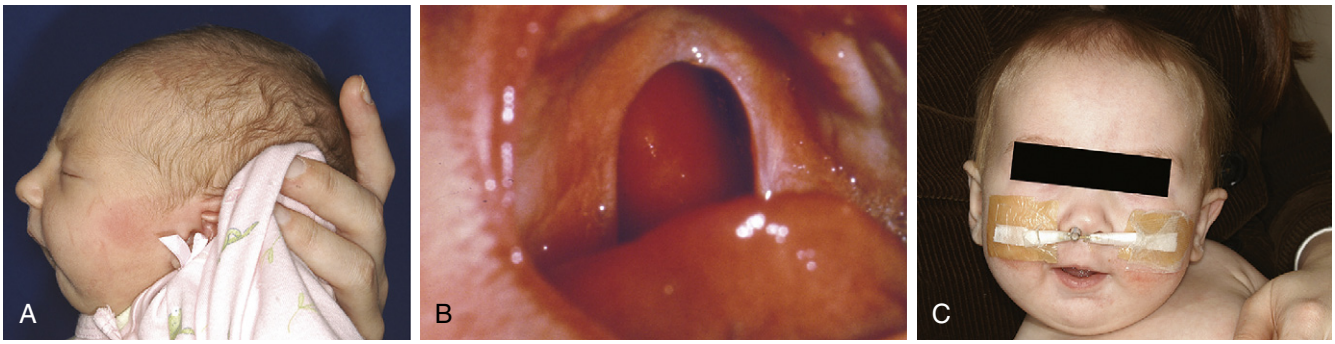

FIGURE 95-1 *(See also Color Plate 38.)* **A,** Infant with Pierre Robin syndrome (PRS) and significant micrognathia. **B,** U-shaped cleft palate. **C,** Infant with PRS and a nasopharyngeal tube in place.

receiving adequate caloric intake. Gastroesophageal reflux is common in PRS, as it is with other infants who have increased work of breathing.

MANAGEMENT

First and foremost, the airway must be addressed. Placement of a nasal trumpet or endotracheal tube may be required in an emergency, and it is important to realize that severe, life-threatening airway obstruction can present in the delivery room. Though uncommon, a prenatal diagnosis of micrognathia allows for involvement of neonatologists and otolaryngologists in the delivery room.

A number of therapeutic maneuvers can be used to stabilize the upper airway in PRS, ranging from positioning to surgery. Placing the baby in the prone or lateral decubitus position will often open up the airway and decrease the degree of obstruction. This may improve airway patency and air exchange, which decreases the work of breathing and may also improve tolerance of oral feeding. When prone positioning fails to provide adequate airway patency, alternative approaches include the use of a nasopharyngeal airway, treatment with tongue-lip adhesion (TLA), and mandibular distraction. Tracheostomy may be necessary to provide a safe and secure airway in some infants. Treatment protocols vary across institutions; however, most providers agree that the majority of neonates with PRS can be managed non-surgically (Schaefer et al, 2004).

A nasopharyngeal (NP) airway provides a temporary way to bypass the infant's airway obstruction (see Figure 95-1, *C*). An endotracheal tube can be modified so that it can be passed through the nares into the hypopharynx above the epiglottis, allowing oxygenation/ventilation by bypassing the obstruction at the base of the tongue (Parhizkan et al, 2010). The NP airway may prevent the need for more invasive procedures and allows the team to address oral skills and feeding (Wagener et al, 2003). In some institutions, the infant is discharged home with an NP airway in place. Children are monitored with oximetry and parents are taught NP airway maintenance (suctioning) and replacement. The NP tube is typically in place for 4 to 6 months or less if symptoms improve or other interventions become necessary.

When airway obstruction is localized to the tongue base and positioning has not improved breathing and feeding, a TLA (attachment of the anterior tongue to the lower lip) may be a temporizing measure to minimize obstruction while allowing for mandibular growth (Schaefer and Gosain, 2003). In some institutions, TLA has been shown to have a high initial success rate for correction of airway obstruction in a neonate. However, long-term follow-up indicates that many infants require secondary interventions to manage their feeding and airway and eventually their orthognathic issues (Denny et al, 2004).

The infant's clinical status, perceived need for long-term respiratory support, and failure of less invasive interventions will determine whether more invasive surgery is indicated (Evans et al, 2011). For some neonates, mandibular distraction osteogenesis may be an alternative to tracheostomy. Endoscopy may help delineate the level of obstruction, and computed tomographic (CT) imaging of the mandibular structures can assist in assessment of jaw anatomy before distraction. Recognition of other airway anomalies or issues, such as laryngotracheomalacia or subglottic stenosis, will also affect decision making regarding airway management. Children with PRS associated with syndromes, skeletal dysplasia, or neurologic conditions may have more than one factor contributing to their airway obstruction such that a tracheostomy may be indicated. Thus, infants with PRS who have airway obstruction unresponsive to positional techniques (side or prone) for whom surgical options are being considered (mandibular distraction versus tracheostomy) should have a comprehensive evaluation of their airway as well as an evaluation for diagnosis of an underlying syndrome and/or associated malformations that might impact respiratory status.

Nutrition can be maintained with a hypercaloric formula and/or fortified breast milk given by side-lying feeding using a cleft feeder, via nasogastric feeding tube, or via gastrostomy tube. Oral feeding can and should be introduced when the airway is stable. Oral stimulation is important to prevent oral aversion. As tone improves, the child gains better control of the tongue, and growth ensues, feeding will become less of a problem. Close observation for any symptoms of gastroesophageal reflux with proactive pharmacologic treatment can minimize airway inflammation.

Given the association with cognitive and motor delay, close monitoring of development and referral to early intervention services, such as a Birth to Three program, are recommended.

STICKLER SYNDROME

More than 50% of infants born with PRS will have an associated syndrome diagnosis, chromosomal abnormality, additional anomalies, or other medical concerns.

FIGURE 95-2 Infant with Stickler syndrome, showing a flat face, depressed nasal bridge, and epicanthal folds. This infant also has PRS and required tracheostomy.

Therefore, all infants with PRS should be evaluated for associated malformations, chromosomal abnormalities, and syndromic diagnoses and should be considered for genetic testing (Gorlin et al, 2001b). The most common associated syndromes are Stickler syndrome and 22q11.2 deletion syndrome. Thirty percent of individuals with PRS will have Stickler syndrome (Shprintzen, 1988). Stickler syndrome is an autosomal dominant (with variable expressivity) connective tissue disorder with predominantly ophthalmic, orofacial, auditory, and articular manifestations and has been divided into three types (type 1 and 2 have ocular findings, type 3 is nonocular). Type 1 Stickler (OMIM 108300) represents 75% of this syndrome.

Stickler syndrome is characterized by cleft palate, hearing loss, arthropathy, joint hypermobility, reduced height and eye abnormalities including myopia, cataracts, glaucoma and retinal detachment. The myopia of Stickler syndrome is usually congenital, nonprogressive, and of high degree. Facial features include flat midface with depressed nasal bridge, short nose, anteverted nares, and micrognathia, telecanthus, and epicanthal folds (profile appears scooped out; Figure 95-2). Sensorineural hearing loss is more common in type 2 Stickler syndrome.

The diagnosis of Stickler syndrome should be considered in any neonate with PRS or a U-shaped cleft, especially when associated with myopia or hearing loss. Spondyloepiphyseal dysplasia is not usually apparent in the newborn period. Mutations affecting one of four genes (COL2A1, COL9A1, COL11A1, and COL11A2) have been associated with Stickler syndrome, and clinical molecular testing by sequence analysis is available for all three types. The mutation detection rate for type 1 and 2 (COL2A1 and COL11A1 respectively) is approximately 90% (Robin et al, 2009). The diagnosis should also be considered in any newborn with a family history of PRS or Stickler syndrome.

In addition to appropriate management of feeding, breathing and growth (as described earlier in PRS), management of Stickler syndrome includes active detection of myopia because of the risk of retinal detachment and blindness, which are preventable. An initial ophthalmology evaluation is recommended for all children with PRS between 6 and 12 months of age or at the time of a definitive molecular diagnosis of Stickler syndrome, and then routine surveillance thereafter.

OROFACIAL CLEFTING

EPIDEMIOLOGY

Orofacial clefts of the primary and secondary palate are among the most common congenital anomalies. Classified as either cleft lip with or without cleft palate (CL±P) or cleft palate only (CPO), these two phenotypes are thought to be distinct in etiology. One case of orofacial cleft occurs in approximately every 500 to 550 births, and on an average day in the United States, 20 infants are born with an orofacial cleft (Tolarova and Cervenka, 1998). Cleft lip and palate (CLP) is the most common type of orofacial clefting, followed by cleft lip (CL), then CPO, and less prevalent are atypical clefts (macrostomia or lateral cleft, oblique and midline clefts). Unilateral CL±P is more common than bilateral involvement (Genisca et al, 2009). Clefting of the uvula can be a normal variant, found in 1 of 80 white births and, but can also be a sign of an associated submucous cleft palate, which can have the same functional impact as an overt CP (Gorlin et al, 2001b).

The causes of most orofacial clefts are unknown and are nonsyndromic (isolated) in 75% of infants with CL±P and approximately 50% of those with CPO (Tolarova and Cervenka, 1998). Neonates with orofacial clefting who are born prematurely or have low birthweight may have a higher incidence of associated congenital malformations (Milerad et al, 1997). Racial and ethnic variation in the prevalence of clefts has been described, with the highest prevalence of CL±P found in Native Americans, followed by whites and Hispanics, and the lowest overall prevalence of CL±P demonstrated in African Americans (Croen et al, 1998). The etiology of nonsyndromic clefts is complex and multifactorial, likely resulting from interaction between environmental and genetic factors. Recognition of contributing genetic factors such as the Van der Woude gene (IRF6) is increasing, and the impact of folate supplementation as an environmental modulator is under investigation. Although many candidate genes have been described, there is no routinely recommended genetic testing for a child with isolated CL±P in the absence of a family history. Recurrence risk information for the parents of a child with CL±P or for the affected individual is dependent either on the specific syndrome/genetic diagnosis or on empiric risks for those with nonsyndromic clefting. For a family with just one child affected with CL±P, the recurrence risk is 2% to 5% for a subsequent child, and increasing to 10% to 15% if there are other family members with clefts. The recurrence risk is slightly less if the child has CPO (Harper, 2004).

ANATOMY

The embryologic development of the primary palate begins very early in gestation, and the upper lip and primary palate have usually fused by the 7th week of gestation. A failure of fusion of the medial and lateral nasal processes with

FIGURE 95-3 **A,** Infant with a unilateral incomplete cleft lip. **B** and **C,** Infant with bilateral complete cleft lip and palate. **D,** Infant with midline cleft and hypertelorism. He also has a frontonasal encephalocele. **E,** Infant with premaxillary agenesis and holoprosencephaly. **F,** Infant with Van der Woude syndrome with unilateral complete cleft lip and a lip pit (*arrow*).

maxillary process produces cleft lip with or without cleft palate. Clefts can affect the primary palate (lip, alveolus, or anterior portion of the hard palate that extends to the incisive foramen) and secondary palate (posterior hard palate and soft palate). Clefts of the primary and secondary palate can be unilateral or bilateral and complete or incomplete. A complete cleft of the primary palate leaves no residual tissue between the alar base and the lip, whereas an incomplete cleft does not extend through the floor of the nose (Figure 95-3, *A* to *C*, *F*).

PHENOTYPE

The cleft of the primary and secondary palate will affect facial growth, causing reduced facial height, flat facial profile, midfacial retrusion, increased nasopharyngeal width, and shorter mandible (see Figure 95-3, *A–C*). Children with cleft palate are at increased risk for eustachian tube dysfunction, recurrent otitis media, and acquired hearing loss, as well as speech issues later in childhood. Associated dental findings include hypodontia and, less commonly, natal teeth. Feeding difficulties, nasal regurgitation of feeds, and difficulty gaining weight may occur in infants with a cleft palate (submucous and overt clefts of the palate).

Lateral facial clefting or macrostomia is associated with syndromes, including craniofacial microsomia and Treacher Collins syndrome. Amniotic rupture sequence can be associated with oblique facial clefts and may be associated with underlying central nervous system (CNS) malformations and transverse limb anomalies.

A true median cleft of the upper lip is the rarest type of facial clefting (see Figure 95-3, *D*). Midline clefting can be associated with other congenital defects as can be seen in orofaciodigital syndrome and frontonasal dysplasia. Some midline clefts are not true clefts, but actually represent hypoplasia or agenesis of the primary palate or premaxillary agenesis, which can be associated with holoprosencephaly (HPE) sequence (see Figure 95-3, *E*). Infants with a median cleft and HPE often have a depressed nasal tip and a short columella and appear hypoteloric (compared to frontonasal dysplasia or frontonasal encephalocele, where midline clefting may be present, but the infant has a broad nasal tip and/or columella and hypertelorism).

Orofacial clefting is rarely associated with clefting of the airway structures, such as cleft larynx or extension of clefting into the trachea. X-linked Opitz G/BBB syndrome (OMIM 145410) is a multiple congenital anomaly syndrome characterized by facial anomalies (100% will be hyperteloric and 50% will have CL±P), genitourinary abnormalities (90% will have hypospadias) and laryngotracheoesophageal (LTE) defects (present in 70%) (Meroni, 2007). Pallister-Hall syndrome (PHS; OMIM 146510) is characterized by a constellation of findings that include hypothalamic hamartoma (resulting in seizures and pituitary dysfunction), polydactyly, airway clefting, and other anomalies (genitourinary, renal, pulmonary, and imperforate anus). Bifid epiglottis is the most common airway manifestation in PHS, although LTE clefts have been reported. LTE defects may vary from LTE dysmotility in mild forms to laryngeal or tracheoesophageal clefts in more severe forms. Clefting of the larynx may result in stridor, a hoarse cry, respiratory distress, swallowing dysfunction, feeding difficulties, regurgitation, and aspiration.

ICU CONCERNS

The majority of infants with CL±P do not require ICU care. Thus, an infant with an apparently isolated cleft who develops significant respiratory or electrolyte abnormalities requiring ICU care should be considered syndromic until proven otherwise. In these infants, a genetics consultation should be considered.

The newborn with a midline cleft or premaxillary agenesis is at risk of serious underlying CNS anomalies,

including HPE. In the presence of HPE, detection of associated medical issues is important. Endocrine abnormalities can arise because the midline malformation affects the development of the hypothalamus and the pituitary gland. Clinical manifestations can include growth hormone deficiency, adrenal hypoplasia, hypogonadism, diabetes insipidus, and thyroid deficiency. Neurologic manifestations that warrant close attention include seizures, hypotonia, spasticity, autonomic dysfunction and developmental delays.

With an LTE cleft, there is longitudinal communication between the airway and the esophagus, allowing for tracheal aspiration of oral contents, including saliva and feeds. LTE defects may result in choking or coughing with feeds, aspiration, hypoxia, recurrent pneumonias, and eventually severe respiratory compromise if unrecognized. An infant boy with hypertelorism, hypospadias, orofacial clefting, and symptoms of airway obstruction or aspiration should be evaluated for Opitz syndrome. Infants with PHS may also have respiratory distress due to airway clefting, as well as other potentially life-threatening clinical manifestations such as seizures and severe panhypopituitarism. Genetic evaluation and consideration of molecular testing for Opitz syndrome and PHS can be coordinated through a geneticist.

MANAGEMENT

The specifics of management of orofacial clefting are center specific. Because of the potential impact of the orofacial cleft on breathing, eating, hearing, speech, facial growth, and dental health, it is recommended that infants and children with clefts be referred to a multidisciplinary care team for long-term management. In remote areas, the nearest cleft team may be found through the Cleft Palate Foundation website. Box 95-1 outlines one example of the multidisciplinary team of providers that might contribute to the care of a child born with a craniofacial malformation. Overview of recommended team care for cleft patients can be found at the American Cleft Palate-Craniofacial Association website (2009; Team CLPC, 2006).

On the initial assessment, the provider should assess the cleft and examine the infant for dysmorphic features and other anomalies. Hearing should be evaluated by evoked otoacoustic emissions, or by brainstem auditory evoked response if the newborn does not pass the initial hearing screen. A neonate with a complete cleft lip should be evaluated by a craniofacial or cleft team in the first 2 weeks of life, and some centers offer taping or presurgical molding (nasoalveolar molding) that can be initiated in this time period.

Many mothers will be able to breastfeed an infant born with an isolated cleft lip. Breastfeeding a baby with cleft palate (with or without cleft lip) will prove extremely challenging because the open palate will not generate the negative pressure needed for sucking. Thus, infants with cleft palate ± cleft lip should be offered expressed breast milk or infant formula using a specialized cleft feeder. There are a variety of cleft nipples/bottles that have been devised to allow for oral feeding including the cleft palate nurser (squeeze bottle), Haberman feeder, and Pigeon bottle (www.cleftline.org/parents/feeding_your_baby). Infants with cleft palate tend to swallow a lot of air during feedings. Make sure the child is feeding in an upright position, as gravity will help prevent nasal regurgitation. If the child is still having difficulty feeding, consult a feeding specialist. Adequate weight gain is important, because these children will undergo multiple surgeries in the 1st year of life. Newborns with clefts are considered nutritionally high risk, and a dietitian should be consulted to help determine caloric needs and to closely monitor growth.

In general, surgical closure of the lip and nasal deformity is done within the first 3 to 6 months of life. Palatoplasty typically occurs between 9 and 12 months of age to optimize speech and language development.

If there are concerns about airway clefting or anomalies of the larynx or trachea, a chest x-ray should be obtained and the airway evaluated, in addition to appropriate evaluation of associated anomalies. Microlaryngoscopy under general anesthesia remains the gold standard in the diagnosis of a laryngeal cleft (Rahbar et al, 2006). Given the risk for gastrointestinal manifestations such as gastroesophageal reflux, dysmotility, and risk for aspiration, antireflux precautions should be initiated in infants with suspected or confirmed LTE defects. Early diagnosis and proper repair of the laryngeal cleft are essential to prevent injury to the lungs. Significant LTE defects will need to be managed surgically, and tracheostomy may be necessary initially to ensure an adequate airway.

In the presence of a midline cleft, it is important to evaluate for underlying CNS malformations such as HPE. In any child with a midline cleft or facial features consistent with premaxillary agenesis/hypoplasia, CNS imaging with a CT scan is recommended. Consultation with a geneticist or genetic counselor may provide insight into the genetics, molecular testing options, and recurrence risk of HPE. Treatment of HPE is supportive and based on symptoms. The outcome depends on the severity of HPE and the associated medical and neurologic manifestations.

SYNDROMES ASSOCIATED WITH CLEFT LIP AND/OR PALATE

It is estimated that there are more than 400 syndromes associated with orofacial clefts (Gorlin et al, 2001b). The frequency with which associated malformations are encountered with CL±P is approximately 25% (Genisca et al, 2009). In approaching diagnosis of a syndrome, it is important to categorize the type of cleft (lip with or without palate, U-shaped or V-shaped cleft palate, or more atypical orofacial cleft) and to look for any other malformations. Table 95-1 describes the syndromes most commonly associated with clefting and the key features,

TABLE 95-1 Craniofacial Syndromes Commonly Associated With Cleft Lip or Palate

Syndrome	Phenotype	ICU issues	OMIM#
Robin sequence*	Micrognathia, glossoptosis, cleft palate, airway obstruction	Airway obstruction, feeding difficulties	261800
Stickler syndrome*	Cleft palate, micrognathia, glossoptosis, severe myopia, risk of retinal detachment and blindness, midfacial hypoplasia, hearing impairment, arthropathy, pectus, short fourth and fifth metacarpals	Airway obstruction, feeding difficulties	180300; 604841; 184840; 609508
Chromosome 22q11.2 deletion syndrome (velocardiofacial syndrome, VCFS, DiGeorge syndrome) *	Robin sequence, cleft palate, small mouth, myopathic facies, retrognathia, prominent nose with squared-off nasal tip, hypoplastic nasal alae, short stature, slender tapering digits	Cardiac anomalies, airway obstruction	192430
Opitz oculogenitallaryngeal syndrome (Opitz BBB/G syndrome) *	Hypertelorism, telecanthus, cleft lip and/or palate, dysphagia, esophageal dysmotility, laryngotracheoesophageal cleft (aspiration), hypospadias, bifid scrotum, cryptorchidism, agenesis of the corpus callosum, congenital heart disease, mental retardation	Laryngotracheoesophageal clefting (stridor, feeding difficulties, choking, aspiration)	145410
Pallister-Hall syndrome*	Cleft palate, flat nasal bridge, short nose, multiple buccal frenula, microglossia, micrognathia, malformed ears, hypothalamic hamartoblastoma, hypopituitarism, postaxial polydactyly with short arms, imperforate anus, GU anomalies, IUGR	Laryngotracheoesophageal clefting (stridor, feeding difficulties, choking, aspiration), panhypopituitarism	146510
IRF6-related disorders (including Van der Woude and Popliteal pterygium syndrome)	CL±P, CPO, lower lip pits or cysts, ankyloglossia; PPS will also have popliteal pterygia, bifid scrotum, cryptorchidism, finger and/or toe syndactyly, abnormalities of the skin around the nails, syngnathia and ankyloblepharon	Not anticipated	119300; 119500; 607199
CHARGE syndrome*	*C*oloboma of the eye, *H*eart malformations, choanal *A*tresia, growth *R*etardation, *G*enital anomalies, *E*ar abnormalities and/or deafness, facial palsy, cleft palate, dysphagia	Airway obstruction in bilateral choanal atresia, cardiac anomalies, feeding difficulties, aspiration	214800
Smith-Lemli-Opitz syndrome*	Cleft palate, micrognathia, short nose, ptosis, high square forehead, microcephaly, hypospadias, cryptorchidism, VSD, TOF, hypotonia, mental retardation, postaxial polydactyly, 2- to 3-toe syndactyly, defect in cholesterol biosynthesis	Cardiac anomalies, airway hypotonia/obstruction	270400
Ectrodactyly ectodermal dysplasia and clefting syndrome (EEC1, EEC2)	Cleft lip and/or palate, split-hand/split-foot, ectodermal dysplasia (sparse hair, dysplastic nails, hypohydrosis, hypodontia), genitourinary anomalies	Not anticipated	129900; 602077; 603273
Ankyloblepharon ectodermal dysplasia and clefting syndrome (AEC)	CL±P, CPO, intraoral alveolar bands, maxillary hypoplasia, ankyloblepharon (eyelid fusion), ectodermal dysplasia (sparse hair, dysplastic nails, hypohydrosis, anodontia)	Not anticipated	106260
Orofacialdigital syndrome	Median cleft of upper lip, cleft palate, accessory oral frenula, lobulated tongue with hamartomas, broad nasal root, small nostrils, syndactyly, brachydactyly, postaxial polydactyly, polycystic renal disease, agenesis of the corpus callosum	Not anticipated	311200
Kabuki syndrome*	Cleft palate, arched eyebrow, long palpebral fissures, eversion of lateral third of lower eyelid, brachydactyly, short fifth metacarpal, cardiac anomalies, postnatal growth deficiency/dwarfism, mental retardation	Cardiac anomalies	147920
Fryns syndrome*	Cleft lip ± palate, micrognathia, coarse facies, diaphragmatic hernia, distal limb hypoplasia, malformations of the cardiovascular, gastrointestinal, genitourinary and central nervous systems	Congenital diaphragmatic hernia, pulmonary hypoplasia; cardiac anomalies	229850
Miller syndrome*	Cleft palate (more than cleft lip), malar and mandibular hypoplasia, downslanting palpebral fissures, lower eyelid coloboma, microtia/atresia, conductive hearing loss, postaxial limb deficiency, absent fifth digit	Airway obstruction	263750

potential ICU issues, and OMIM database classification. The Online Mendelian Inheritance in Man (OMIM) database at the National Library of Medicine is a comprehensive collection of more than 12,000 human genes and genetic phenotypes. A referral to a clinical geneticist is recommended when an underlying diagnosis is suspected but not established.

Chromosome 22q11.2 Deletion Syndrome

Epidemiology and Genetics

22q11.2 deletion syndrome (22q11.2DS) is a genetic condition with an estimated prevalence of one in 4,000 births in which affected individuals are missing a region (typically 3 megabases) on one copy of chromosome 22 (Devriendt et al, 1998). Before the availability of genetic testing for this condition, individuals with clinical features of 22q11.2DS were classified under a range of other clinical syndromes, such as DiGeorge syndrome, velocardiofacial syndrome (VCFS), and Shprintzen syndrome, among others (McDonald-McGinn et al, 2005). Subsequently, a subset of children with overlapping features in these conditions (such as congenital heart disease and cleft palate) was also noted to share a deletion on chromosome 22q. Investigators later discovered that the majority of children clinically diagnosed with either DiGeorge or VCFS share the deletion on one copy of chromosome 22 (Carlson et al, 1997; Kerstjens-Frederikse et al, 1999; Shaikh et al, 2000; Robin and Shprintzen, 2005). It has been estimated that more than 90% of individuals with "classic" features of the 22q11.2DS have a detectable 22q deletion (McDonald-McGinn et al, 2005). Clinical testing can be performed via fluorescent in situ hybridization using DNA probes. In addition, many of the clinical comparative genome hybridization platforms are designed to detect deletions in this region. 22q11.2 deletion syndrome is associated with more than 180 clinical features, and phenotypic variation is a hallmark of this genetic condition (Robin and Shprintzen, 2005).

Phenotype

Neonates with 22q11.2DS present in various ways. Some infants with this condition are diagnosed prenatally. Testing may occur as part of the evaluation for fetuses with congenital heart disease, or due to parental history of 22q11.2DS. The clinical indications for genetic testing for this condition in neonates frequently include congenital heart malformations (particularly conotruncal anomalies), seizures secondary to hypocalcemia, dysphagia, cleft palate, and/or respiratory distress secondary to upper airway obstruction. In this section, we focus on the evaluation of infants with craniofacial characteristics suggestive of 22q11.2DS.

More than 25 craniofacial features have been observed in individuals with 22q11.2DS (Robin and Shprintzen, 2005); however, many of these are subtle and may not be apparent in the newborn period. Common features identified on the newborn physical exam include cleft palate, small, overfolded helices, and tapered fingers. Other clues to the diagnosis include dysphagia and/or nasal regurgitation (even in the absence of an overt cleft palate), congenital heart disease (most commonly conotruncal anomalies), and hypocalcemia (with or without seizures).

An estimated 8% of infants with cleft palate have 22q11.2DS (Gorlin et al, 2001c). For this reason, recommendations vary regarding routine testing of infants with isolated cleft palate. Most agree, however, that molecular testing is indicated for children with a cleft palate in combination with any of the other features that can be observed in 22q11.2DS. As high as 13% of children with PRS have been reported to have 22q11.2DS (Shprintzen, 1988). Thus, testing for 22q11.2 deletion should be considered for infants with PRS and other features of 22q11.2DS.

Evaluation and Management

Infants for whom there is a high clinical suspicion and those testing positive for this deletion should receive genetic counseling in addition to studies to identify associated health concerns. These screening evaluations

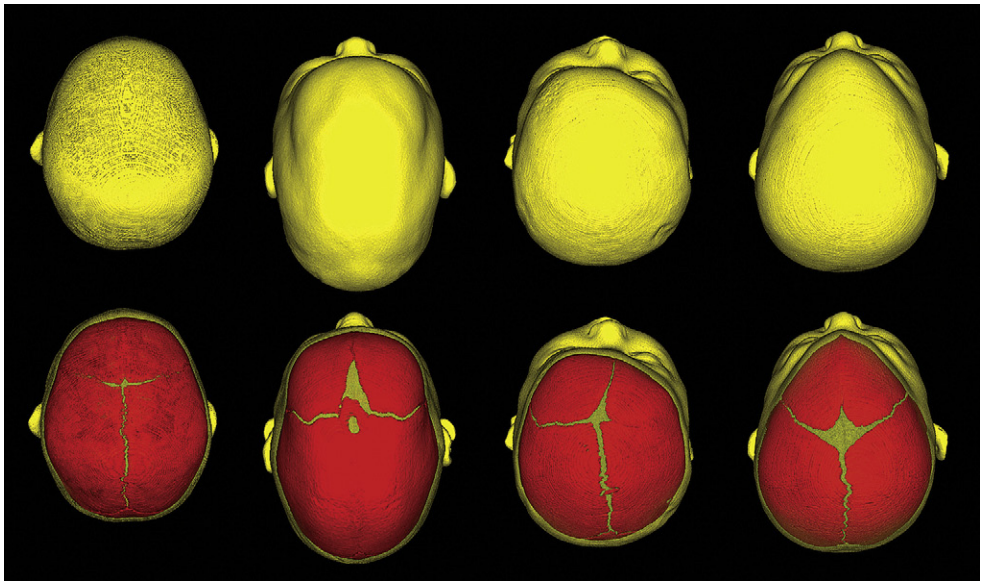

FIGURE 95-4 Representation of head shapes in single suture synostosis. *Left to right:* normal head shape, sagittal synostosis, coronal synostosis, and metopic synostosis.

include a total lymphocyte count, hematocrit, and platelet count and total and ionized calcium levels to screen for hypocalcemia. Additional studies include echocardiogram to evaluate for congenital heart malformations and renal ultrasound. Newborns should have a palatal exam to evaluate for overt or submucous clefting, as well as a diagnostic audiogram. Infants with evidence of dysphagia (even in the absence of a palatal cleft) would likely benefit from an evaluation by a feeding specialist to determine if a cleft bottle would be helpful. Additional recommendations for screening evaluations and management can be found at the GeneTests website (McDonald-McGinn et al, 2005).

CRANIOSYNOSTOSIS

DEFINITIONS/EPIDEMIOLOGY

Craniosynostosis refers to the premature fusion of one or more cranial sutures (metopic, sagittal, right or left coronal, or right or left lambdoid) that normally separate the bony plates of the cranium. Birth prevalence of all craniosynostoses is estimated to be 300 to 400 of every 1 million live births (Cohen, 2000a). In normal infants, open sutures allow the cranium to expand as the brain grows, producing the normal head shape. If one or more sutures fuse prematurely, there is restricted growth perpendicular to the fused sutures and compensatory growth in the patent sutures, producing abnormal head shape. Craniosynostosis is a heterogeneous disorder with significant health consequences that range from an abnormal head shape to secondary visual and intellectual impairments. Known causes of primary craniosynostosis include monogenic and chromosomal abnormalities as well as environmental factors. Nonsyndromic single suture craniosynostosis accounts for 85% of patients. Syndromic craniosynostosis may involve single or multiple fused sutures and additional anomalies (such as limb, cardiac, CNS, and tracheal malformations) or developmental delay. Multiple suture involvement is usually considered syndromic even when it does not fit a classic pattern of anomalies. Advances in molecular genetics are permitting the identification of defective genes and their pathways in describing these congenital anomalies. The genetic etiology of syndromic craniosynostosis in humans is only partially understood. However, for a subset, identification of the primary genetic cause and contributing factors is possible using clinically available molecular tests (targeted sequencing of FGFR1, FGFR2, FGFR3, TWIST1, MSX2, and EFNB1 genes noted later).

SINGLE SUTURE SYNOSTOSIS

Sagittal synostosis is the most common single suture synostosis (50% to 60%) with a prevalence of 1 in 4200 births (Cohen, 2000a). Known risk factors include male gender, intrauterine head constraint, twin gestation, and maternal smoking. Although uncommon, the most frequently encountered associated anomalies include congenital heart defects and genitourinary tract malformations. Syndromes with synostosis involving only the sagittal suture are rare. Premature union of the sagittal sutures hinders normal calvarial expansion, leading to scaphocephaly, an elongated, narrow calvaria, decreased bitemporal diameter, and frontal and occipital bossing (Figure 95-4). Premature fusion of the suture before birth leads to abnormal head shape in the newborn period. A breech-positioned neonate can have scaphocephaly or dolichocephaly that may be concerning for sagittal synostosis. However, in sagittal synostosis, frontal bossing progresses, whereas the head shape in a breech infant will normalize over time. There is a concern that children with isolated sagittal synostosis are at risk for elevations in intracranial pressure (ICP), local brain injury, and later developmental delays, although this is not completely understood (Kapp-Simon et al, 2007).

Coronal synostosis is the second most common single suture synostosis (20% to 30%) with a prevalence of one in 10,000 births (Cohen, 2000a). The skull is notable for a flat supraorbital rim and orbit that appears lower on the

FIGURE 95-5 **A,** Infant with Apert syndrome, a high and full forehead, proptosis and exotropia, midface hypoplasia, and a trapezoid-shaped mouth. **B** and **C,** Hands and feet in Apert syndrome. Note the syndactyly symmetrically affecting hands and feet. All five digits may be webbed, or a single toe, finger, or thumb may be free.

affected side with a frontal bulge on the contralateral side (see Figure 95-4). The face appears to twist away from the coronal fusion. Genetic syndromes are more frequently seen in individuals with coronal synostosis, including Saethre-Chotzen syndrome, Muenke syndrome, and craniofrontonasal dysplasia. All children with coronal synostosis should be offered genetic consultation and/or genetic testing to include FGFR2, FGFR3, TWIST, and EFNB1 based on clinical examination.

Metopic synostosis (15% to 20% of single suture craniosynostosis) has a prevalence of 1 in 15,000 births (Cohen, 2000a), although recent reports suggest that metopic synostosis may be as common as coronal synostosis (van der Meulen et al, 2009). Risk factors include male gender, twin gestation, and in utero exposure to valproate. Syndromes, associated anomalies, and chromosomal abnormalities occur in approximately one fourth of individuals with metopic synostosis (Azimi et al, 2003; Lajeunie et al, 1998). Premature fusion of the metopic suture results in a triangular head shape, or trigonocephaly, which features a midline forehead ridge, frontotemporal narrowing, hypotelorism, and an increased biparietal diameter (see Figure 95-4). Isolated metopic ridging is common in infancy and is not necessarily associated with metopic synostosis.

Lambdoid synostosis (3% of single suture craniosynostosis) is the least common. It is characterized by flattening of the ipsilateral occiput, posterior-inferior displacement of the ear, and bulge of the mastoid process on the fused side and an asymmetric and tilted skull base.

MULTIPLE SUTURE SYNOSTOSIS

Multiple suture (or multisuture) synostosis describes patients who have two or more fused sutures. Although children with multisuture synostosis are more likely to have a known syndromic form of craniosynostosis such as Apert's or Crouzon's syndrome, some have chromosome aberrations or patterns of craniosynostosis with birth defects and/or developmental delay not previously described. Here we briefly discuss select major syndromes with craniosynostosis that may have medical issues in the newborn period. Please refer to Table 95-2 for description of key phenotypic features and potential airway compromise.

Apert syndrome (OMIM 101200) was initially described as acrocephaly with four-limb syndactyly. It accounts for 4.5% of all craniosynostosis (Gorlin et al, 2001d) (Figure 95-5, *A* to *C*). Apert syndrome is an autosomal dominant condition associated with advanced paternal age. Neurocognitive outcomes vary, but a moderate to severe degree of cognitive impairment is most common. Four mutations in fibroblast growth factor receptor 2 (FGFR2) causing Apert syndrome have been identified.

Crouzon syndrome (OMIM 123500) is an autosomal dominant condition that demonstrates wide phenotypic variability. Shallow orbits (or proptosis) are an important diagnostic feature, although this feature may be more subtle in the newborn (Figure 95-6, *A* and *B*). Significant abnormalities involving the CNS include presence of a Chiari 1 malformation, progressive hydrocephalus, chronic cerebellar herniation, and intracranial hypertension. Compared with Apert syndrome, Crouzon syndrome is associated with more extensive suture involvement, smaller cranial volume, and more severe intracranial constraint. Like Apert's syndrome, Crouzon is caused by mutations in FGFR2. A less common form of Crouzon with acanthosis nigricans skin findings developing in the first 2 years of life is caused by a transmembrane mutation in FGFR3 (OMIM 612247).

Pfeiffer syndrome (OMIM 101600) is a hereditary craniosynostosis that shares significant overlap, both phenotypically and genetically, with Crouzon syndrome. Pfeiffer syndrome is an autosomal dominant inherited disorder that associates craniosynostosis, proptosis, broad and deviated thumbs and big toes, and partial syndactyly of the hands and feet (Figure 95-7, *A* to *C*). Mutations in FGFR1 and FGFR2 cause Pfeiffer syndrome. Type 1 (i.e., classic) Pfeiffer syndrome involves mild manifestations including brachycephaly, midface hypoplasia, and digital malformations. Type

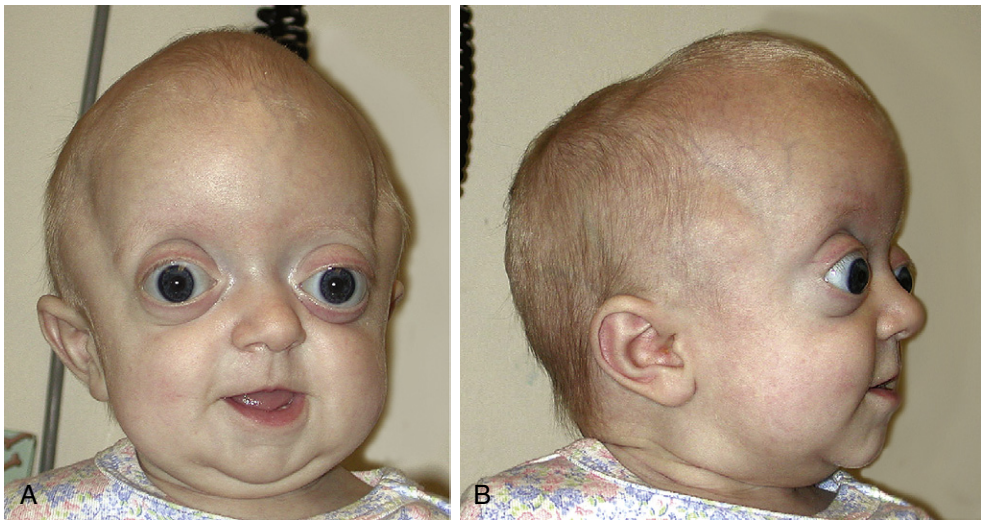

FIGURE 95-6 **A,** Infant with Crouzon syndrome with brachycephaly. **B,** Proptosis is seen in the lateral view.

FIGURE 95-7 **A** and **B,** Infant with Pfeiffer syndrome, brachycephaly, a high forehead, midface hypoplasia, proptosis and ocular hypertelorism. **C,** An older child with Pfeiffer syndrome and the typical broad thumbs with radial deviation.

FIGURE 95-8 **A** and **B,** Infant with Muenke syndrome, acrobrachycephaly due to bicoronal synostosis, absence of proptosis. **C,** Sibling of this infant also affected by Muenke syndrome; note the downslanting palpebral fissures.

2 consists of cloverleaf skull, extreme proptosis, digital malformations, elbow ankylosis, developmental delay, and neurological complications. Type 3 is similar to type 2 but without a cloverleaf skull. There is some debate regarding our classification of syndromes by phenotype when molecular pathogenesis is understood (Cunningham et al, 2007).

Muenke syndrome (OMIM 602849) is a relatively recently described autosomal dominant syndrome caused by a single P250R mutation in the FGFR3 gene. Like Apert syndrome, Muenke syndrome is associated with advanced paternal age. Individuals with Muenke syndrome have coronal (unilateral or bilateral) craniosynostosis or macrocephaly and variable degrees of proptosis, without significant midface hypoplasia (Figure 95-8, *A* to *C*).

Saethre-Chotzen syndrome (SCS, OMIM 101400) is caused by a mutation in the TWIST gene on chromosome 7. The inheritance is autosomal dominant, and many children diagnosed with SCS will have an affected parent. In addition to craniosynostosis, affected individuals commonly have a low frontal hairline, ptosis, 2,3 syndactyly of the fingers, and duplicated halluces. Although learning difficulties may be noted, mental retardation is not typical of SCS. Children with deletions rather than point mutations often demonstrate cognitive impairment.

TABLE 95-2 Craniosynostosis Syndromes and Potential Airway Compromise

Syndrome	Key Features	Tracheal Abnormalities	Midface Hypoplasia	OMIM#
Apert syndrome*	Craniosynostosis (coronal > lambdoid > sagittal), acrobrachycephaly (steep, wide forehead and flat occiput), proptosis, hypertelorism, exotropia, trapezoid-shaped mouth, prognathism, invariable symmetric syndactyly of hands and feet, radiohumeral fusion, cognitive impairment, narrow palate with lateral palatal swellings, widely patent sagittal suture connecting anterior and posterior fontanels	Tracheoesophageal fistula, tracheal cartilaginous sleeve less common	Significant maxillary hypoplasia, obstructive sleep apnea syndrome	101200
Crouzon syndrome*	Craniosynostosis (coronal > lambdoid > sagittal), brachycephaly, prognathism, exophthalmos, papilledema, hypermetropia, divergent strabismus, atresia of auditory canals, Chiari 1 malformation and hydrocephalus	Solid cartilaginous trachea or tracheal cartilaginous sleeve	Significant maxillary hypoplasia, obstructive sleep apnea syndrome	123500
Pfeiffer syndrome types I, II, III*	Craniosynostosis (coronal>sagittal>lambdoid), brachycephaly, hypertelorism, proptosis, broad 1st digits with radial deviation, variable syndactyly, cloverleaf skull	Solid cartilaginous trachea or tracheal cartilaginous sleeve	Significant maxillary hypoplasia, obstructive sleep apnea syndrome	101600
Muenke syndrome	Unilateral or bilateral coronal craniosynostosis, brachydactyly, downslanting palpebral fissures, thimble-like middle phalanges, coned epiphysis, carpal and tarsal fusions, sensorineural hearing loss, Klippel-Feil anomaly		Mild maxillary hypoplasia, no airway compromise anticipated	602849
Saethre-Chotzen syndrome*	Unilateral or bilateral coronal craniosynostosis, acrocephaly, brachycephaly, low frontal hairline, hypertelorism, facial asymmetry, ptosis, characteristic ear (small pinna with a prominent crus), 5th finger clinodactyly, partial 2-3 syndactyly of the fingers, duplicated halluces	.	Maxillary hypoplasia	101400
Carpenter syndrome	Craniosynostosis (coronal > lambdoid > sagittal), hypertelorism, proptosis, brachycephaly, brachydactyly, preaxial polysyndactyly, mental retardation	.	Maxillary hypoplasia	201000
Jackson-Weiss syndrome	Craniosynostosis (coronal), acrocephaly, hypertelorism, proptosis, midface hypoplasia, radiographic abnormalities of the foot including fusion of the tarsal and metatarsal bones, 2-3 syndactyly, broad short first metatarsals and broad proximal phalanges	.	Maxillary hypoplasia	123150

*Significant risk of airway morbidity.

Cloverleaf skull can result from multisuture craniosynostosis. The skull forms a trilobular appearance, as the cerebrum bulges through the sagittal and squamosal sutures, due to craniosynostosis affecting the coronal, metopic and lambdoid sutures. Cloverleaf skull can be isolated or more commonly associated with a syndrome, and it is estimated that up to 20% represent Pfeiffer syndrome.

ICU CONCERNS

The most significant concerns for the newborn with craniosynostosis are airway compromise (specifically, upper airway obstruction) and intracranial hypertension.

Midface hypoplasia and tracheal anomalies which may be present in syndromic craniosynostosis can lead to significant airway compromise (Table 95-2). With midface hypoplasia, there is decreased nasopharyngeal/oropharyngeal space due to posterior displacement of soft tissues and hypoplasia of maxilla, hypopharyngeal obstruction (at level of posterior choanae), leading to breathing problems, obstructive sleep apnea, asphyxia and even death if untreated (Figure 95-9). Obstructive sleep apnea is common in Apert, Pfeiffer, and Crouzon syndromes.

Cartilaginous tracheal abnormalities can be present in multisuture craniosynostosis syndromes. Vertically fused tracheal cartilage (also referred to as tracheal cartilaginous sleeve, solid cartilaginous trachea, and stovepipe trachea)

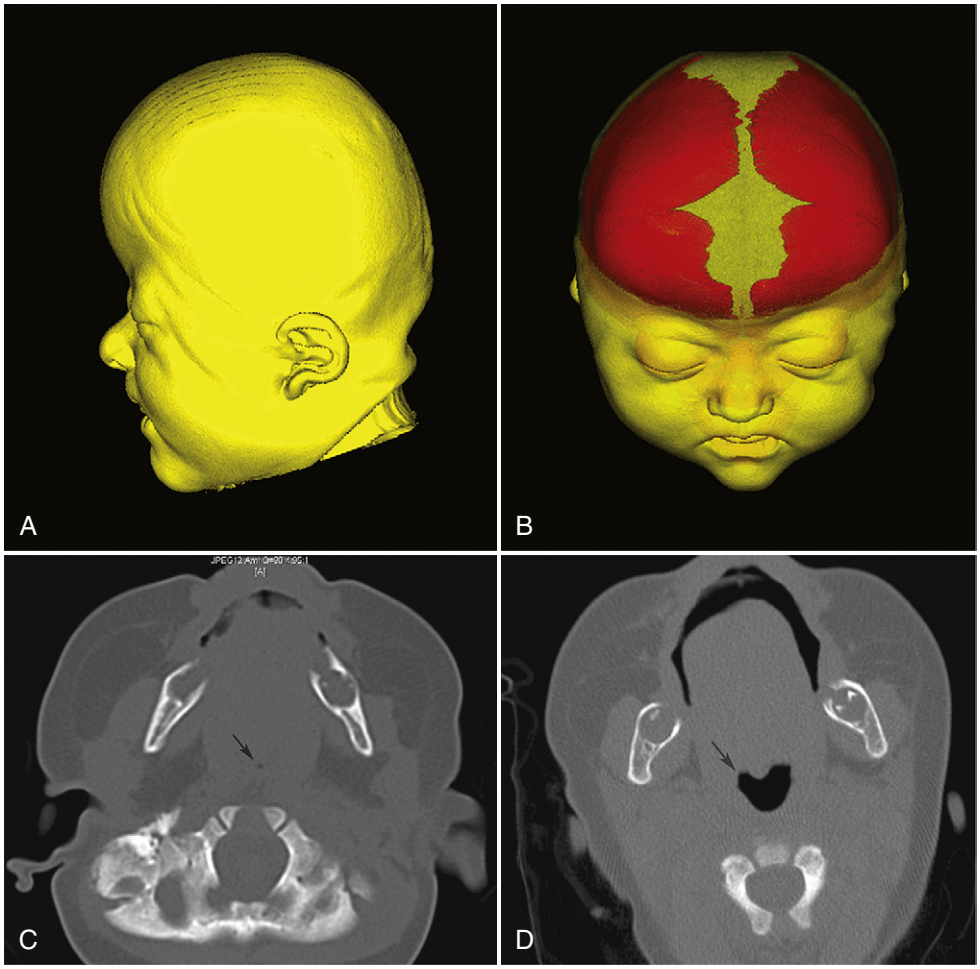

FIGURE 95-9 **A** and **B**, Three-dimensional reconstruction of a child with Apert syndrome with significant midface hypoplasia, leading to upper airway obstruction. Also notable is acrobrachycephaly due to bicoronal synostosis and the typical pattern of sagittal suture patency. **C,** CT scan axial slice at the level of the skull base in a newborn with Apert syndrome. *Arrow* pointing to airway illustrates significant airway obstruction. **D,** CT scan of a newborn illustrating a normal airway.

in Crouzon and Pfeiffer syndromes may produce a rigid trachea resulting in upper airway stenosis, inability to clear secretions, and increased risk of injury due to decreased distensibility. Characteristic tracheal cartilaginous rings are fused to form a continuous sleeve of cartilage, which may extend from below the subglottis to the carina or bronchus; rarely, the cartilaginous sleeve can begin more proximally, at the level of the cricoid cartilage. Infants with congenital tracheal anomalies may present with fixed stridor, apnea, cyanosis, or increased work of breathing due to the narrowing of the airway.

Neurologic abnormalities such as hydrocephalus and increased ICP may arise, especially in multisuture craniosynostosis. Increased ICP due to constraint of the growing brain within a restricted calvarium is usually low-grade and chronic, causing symptomatic intracranial hypertension when brain growth is accelerated in the first 2 years of life. ICP issues in the neonate are not usually life threatening, given the open fontanel and compensatory splaying of normal sutures or erosion of the calvarium, but brain injury and cognitive impairment may result if a cranioplasty is not performed.

Hydrocephalus, which is more common in Crouzon and Pfeiffer syndromes compared to other multisuture synostosis syndromes, can occur as a result of obstruction of cerebrospinal fluid at the basal cistern, aqueductal stenosis, impeded venous flow, or when there is an associated Chiari malformation. Hydrocephalus is extremely common in cloverleaf skull. Individuals with multisuture craniosynostosis (particularly Apert syndrome) more commonly have nonprogressive distortion ventriculomegaly or compensated hydrocephalus, which does not require shunting (Collmann et al, 2005). Abnormalities of the corpus callosum and septum pellucidum have been described in Apert syndrome, with no true relationship to neurocognitive outcomes (Reiner et al, 1996; Yacubian-Fernandes et al, 2005). Seizures presenting in multisuture craniosynostosis syndromes are usually due to encephalopathy, rather than increased ICP. Epilepsy is more common with increasing number of sutures involved, and seizures are found in approximately 10% of individuals with Crouzon syndrome (Cohen, 2000c).

Conductive and mixed hearing loss, most commonly due to middle ear disease, ossicular abnormalities, and abnormalities in the external auditory canal, can be present in syndromic craniosynostosis. Profound sensorineural hearing loss has been described in Seathre-Chotzen syndrome (Lee et al, 2002).

EVALUATION

The evaluation of the patient with craniosynostosis includes identification of the type of suture fusion, clinical syndrome diagnosis, evaluation for associated anomalies, and preparedness for surgical repair. A craniofacial team made up of the appropriate specialties allows for proper planning and cooperation so that the patient may receive the best possible care.

A careful family history, prenatal history, possible teratogen exposure, maternal hyperthyroidism, and any possible constraint factors (oligohydramnios, twins, fetal movement) and birth history should be ascertained specifically looking for risk factors.

A detailed physical exam should be performed as part of the initial evaluation, looking for any other anomalies with specific attention to cleft palate, limb defects, heart defects, and ear anomalies. The assessment of cranial and face shape, mobility of the calvaria, presence of sutural ridging, skull base, and ear position are important. Facial appearance with particular attention to degree of maxillary hypoplasia is important in determining the risk for airway compromise due to midface hypoplasia. If concerning sleep symptoms are present, such as snoring or apnea, consultation with a sleep specialist and polysomnography may help to quantify the presence and severity of obstructive sleep apnea. Close monitoring for any symptoms of airway obstruction, specifically tracheal malformations, such as vertically fused tracheal cartilage, is crucial in some craniosynostosis syndromes. With the increased awareness of this condition, the diagnosis of these tracheal malformations is increasingly made on direct laryngoscopy/bronchoscopy or with magnetic resonance imaging (MRI).

Neurologic assessment includes ascertaining a history, brain imaging, an audiologic evaluation (early screening for hearing loss in conjunction with frequent otologic examinations), ophthalmologic evaluation, and ongoing developmental assessments. In multisuture craniosynostosis, it is important to monitor for any signs or symptoms of increased ICP. Evaluation for hydrocephalus should be a part of the initial assessment of all children with multisuture craniosynostosis. A CT with three-dimensional reconstruction will ultimately help confirm the diagnosis and delineate the degree of suture involvement in preoperative planning. An MRI may be helpful in defining any associated CNS anomalies. Ophthalmology consultation is valuable in management of proptosis, strabismus, or nystagmus and in determining risk for optic atrophy.

In addition to the foregoing general recommendations, syndrome-specific recommendations are outlined as follows. In Apert syndrome, a cardiac and genitourinary evaluation is recommended. If proptosis is present, as can occur in Apert, Crouzon, and Pfeiffer syndromes, ocular lubricants may be helpful in prevention of exposure keratopathy. In Apert and Saethre-Chotzen syndromes, associated vertebral anomalies, particularly fusions, may be present and can be detected on spine radiographs (Cohen, 2000b). If any limb abnormalities are seen, as in Apert, Jackson-Weiss, Pfeiffer, and Saethre-Chotzen syndromes, radiographs with orthopedic consultation should be obtained.

All individuals with single suture synostosis and developmental delay or associated birth defects should be evaluated by a geneticist to determine association with a clinical syndrome and role for genetic testing. Children with multisuture synostosis due to known classic craniosynostosis syndrome should be offered appropriate genetic testing and genetic counseling. The remaining children with multisuture synostosis in the absence of a known syndromic form should be offered genetic consultation and comparative genomic hybridization (CGH) array testing.

MANAGEMENT

As with all children with functional craniofacial malformations, management with an established craniofacial team is recommended (see Box 95-1). Although specific timing of surgical craniotomy may vary between teams, it is generally accepted that individuals with synostosis should undergo cranioplasty in the 1st year of life. Cranioplasty involves release of fused sutures and repositioning and reconstruction of the calvaria, in order to prevent increased ICP and progressive abnormal craniofacial development.

Early recognition of tracheal malformations can be life saving. Awareness of potential airway compromise and proactive airway management are crucial in many craniofacial syndromes. Temporizing measures to bypass airway obstruction include placement of nasal stents, endotracheal intubation, and ultimately tracheostomy. Specific airway management in syndromic craniosynostosis will depend on the level of obstruction. Serious caution must be extended in the placement and care of tracheostomies in patients with tracheal cartilaginous sleeve malformation because of abnormal tissue healing and granulation tissue formation. Surgical cartilaginous sleeve reduction has been proposed as a cure for some forms of the tracheal anomaly (Noorily et al, 1999).

Midfacial surgery may be necessary in some children who have problems with swallowing, feeding, and dental malocclusion. This is usually performed later in childhood.

For individuals with craniosynostosis, we recommend involvement of a craniofacial team, including pediatrics, neurosurgery, ophthalmology, oral surgery, orthodontics, otolaryngology, nursing, nutrition, plastic surgery, and social work.

DISORDERS OF FIRST AND SECOND BRANCHIAL ARCHES

CRANIOFACIAL MICROSOMIA

Epidemiology and Genetics

Craniofacial microsomia (CFM, OMIM 164210), a congenital malformation in which there is asymmetric deficiency in skeletal and soft tissue on one or both sides of the face, is the most frequently encountered form of facial asymmetry. CFM affects approximately 1 in 5600 births (Grabb, 1965). Individuals with features of CFM have been classified under a variety of different diagnoses (hemifacial microsomia, oculo-aural-vertebral spectrum, facio-auricular-vertebral syndrome, first and second branchial arch syndrome, otomandibular dysostosis, Goldenhar

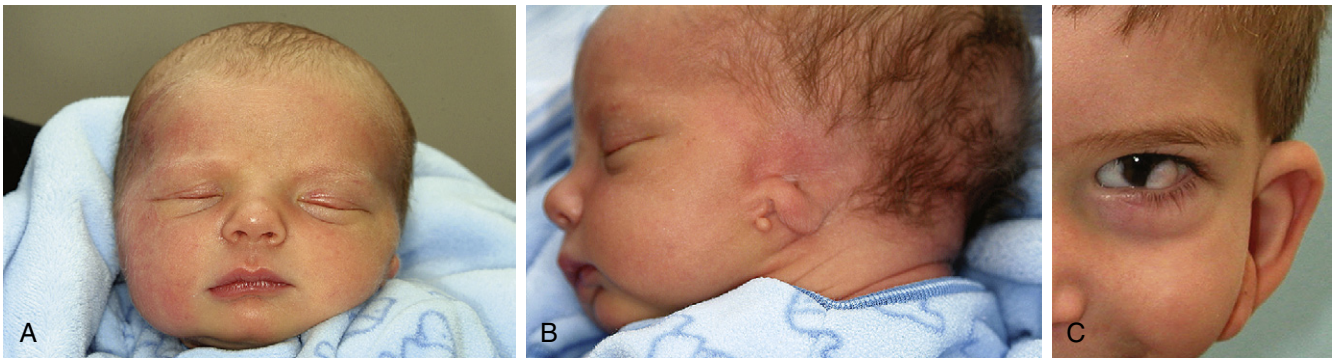

FIGURE 95-10 **A** and **B,** Infant with craniofacial microsomia, mandibular asymmetry, and left-sided microtia. **C,** *(See also Color Plate 39.)* Child with an epibulbar lipodermoid and craniofacial microsomia.

syndrome, lateral facial dysplasia) attesting to the phenotypic variability of disorders associated with mandibular hypoplasia. Most often CFM is a sporadic condition with recurrence risk of approximately 2% for future pregnancies, unless there is a known family history of microtia or CFM (Heike and Hing, 2009). Various causes, both environmental and heritable, have been studied, and for most, the etiology is thought to be multifactorial.

Phenotype

CFM is primarily is a syndrome of the first or second branchial arches, resulting in underdevelopment of the ear, temporomandibular joint, mandibular ramus, mandibular body, and mastication muscles. The affected ear may have an external soft-tissue malformation with or without preauricular tags and may be lower in position compared to the contralateral side. Hearing loss may result from maldevelopment of the ossicular chain and a stenotic or atretic external auditory canal. Second branchial arch defects can involve the facial nerve and muscles of facial expression, which can exacerbate the appearance of facial asymmetry. Even with bilateral facial involvement, there is usually asymmetry (Figure 95-10, *A*). The presence of microtia can be associated with significant risk for hearing loss on the affected side and increased risk of hearing loss in the opposite ear (Figure 95-10, *B*). Infants with CFM are often born small for gestational age, and the perinatal history may include polyhydramnios due to fetal swallowing dysfunction.

A common classification system for CFM is the OMENS Plus system, which characterizes the degree of involvement of facial structures: *O*rbital distortion, *M*andibular hypoplasia, *E*ar anomaly, *N*erve involvement, *S*oft tissue deficiency (Gougoutas et al, 2007). Extracraniofacial anomalies associated with CFM, including renal, cardiac, and vertebral anomalies, are common and will affect recommendations for screening and surveillance.

There can be extreme variability of phenotypic expression ranging from isolated microtia to significant mandibular hypoplasia, bilateral microtia, clefting and extracranial involvement. Isolated microtia may represent a forme fruste of CFM. Other craniofacial features include unilateral macrostomia (the most common form of orofacial clefting in CFM), cleft lip and/or palate, temporomandibular joint (TMJ) ankylosis, ankyloglossia, facial pits (most common in the distribution of the facial nerve), midface hypoplasia and malocclusion, epibulbar lipodermoids (Figure 95-10, *C*), microphthalmia, eyelid coloboma, facial palsy, and seventh nerve paresis. Goldenhar syndrome appears to be a subgroup variant of CFM characterized by vertebral anomalies and epibibulbar dermoids in addition to the ear and jaw findings. In CFM, deficient growth of the hypoplastic mandible and the compensatory growth of the contralateral maxilla and zygoma contributes to significant facial asymmetry that progresses with growth (Kearns et al, 2000).

OTHER BRANCHIAL ARCH MALFORMATIONS

Moebius Syndrome

Moebius syndrome (OMIM 157900) is a rare congenital condition affecting approximately 2000 people worldwide (Broussard and Borazjani, 2008). The sixth and seventh cranial nerves are universally affected. Sixth nerve palsy leads to inability to abduct eyes beyond midline. This is usually bilateral but may be unilateral or asymmetric. Paralysis of facial muscles results from the seventh nerve palsy. Newborns may have a masklike facies but can go unrecognized in the newborn period. Feeding difficulties may result from swallowing and sucking problems, aspiration, and palatal weakness presumed to be related to more widespread cranial nerve involvement. There have been associations with chest wall abnormalities including absence of the pectoralis muscle, suggesting a pathogenic relationship to the Poland anomaly (OMIM 173800). Exposure conjunctivitis and keratopathy can occur in facial paralysis and should be treated with appropriate ocular lubricants. Limb defects occur in half of children with Moebius syndrome, most commonly talipes deformity; however, transverse limb anomalies are also seen. Individuals with hypoglossia-hypodactylia or Hanhart's syndrome can have severe limb deformities, ankyloglossia, and TMJ ankylosis, in addition to Moebius-like features and micrognathia, and are at risk for significant swallowing dysfunction and airway compromise (Yasuda et al, 2003).

Treacher Collins Syndrome

Treacher Collins syndrome (TCS, OMIM 154500) is an autosomal dominant disorder of craniofacial development that affects approximately 1 in 50,000 live births (Rovin

FIGURE 95-11 **A,** Infant with Treacher Collins syndrome, microtia, severe mandibular and zygomatic hypoplasia, and airway obstruction requiring tracheostomy. **B,** An older child with TCS, downslanting palpebral fissures, eyelid colobomas, and bilateral microtia, wearing a hearing augmentation device. **C,** Three-dimensional reconstruction of TCS. Note the severe mandibular and zygomatic hypoplasia, which may lead to significant airway compromise. Also notable are the orbital defects seen in TCS.

et al, 1964). Like CFM, the tissues affected in TCS arise from the first and second branchial arches. The major clinical features of TCS include hypoplasia of facial bones (particularly the mandible and zygoma), external ear anomalies or microtia, external auditory canal atresia, bilateral conductive hearing loss, lateral downward sloping palpebral fissures, and lower eyelid colobomas (Figure 95-11 *A*, *B*). Hearing loss is present in up to 50% of individuals with TCS (Dixon et al, 2007). In severe cases, the zygomatic arch may be absent and cleft palate may occur. Extracraniofacial features are rare in TCS. TCOF1 gene mutations, the majority of which occur de novo, have high penetrance with marked phenotypic variability. Diagnosis of TCS is usually made clinically and can be confirmed with genetic testing for the TCOF1 gene (loss of function mutation).

In newborns with TCS, airway management may be required to address narrowing of the airway or extreme shortening of the mandible (Figure 95-11, *C*). When compared to CFM, the mandibular hypoplasia in TCS is usually bilateral and symmetric, leading to increased risk of upper airway obstruction, increased need for tracheostomy, and risk of death in the neonatal period. Choanal atresia and stenosis or severe micrognathia with glossoptosis can lead to airway obstruction in the infant with TCS (Katsanis et al, 2006).

ICU CONCERNS

Mandibular hypoplasia can lead to upper airway obstruction that may be obvious on physical exam, presenting with stridor or stertor concerning for and increased work of breathing, or may be more subtle, as with snoring obstructive sleep apnea. Airway compromise is a particular risk with bilateral severe mandibular and malar involvement as in Treacher Collins syndrome.

Infants with CFM may have feeding difficulties that may be related to palate dysfunction, or more commonly swallow coordination issues and dysphagia related to hypoglossal dysfunction and muscular and bony underdevelopment. Infants with Moebius syndrome may have cranial nerve palsies that affect swallow and oral coordination. These infants are at higher risk for aspiration and should be monitored clinically, especially if they are failing to thrive or developing any concerns for aspiration or lower respiratory disease.

MANAGEMENT

In newborns with suspected CFM, an evaluation should be undertaken for any associated anomalies. All children with external ear anomalies or any evidence of first or second branchial arch abnormalities should undergo a diagnostic

audiologic evaluation in the newborn period with follow-up audiometry in the 1st year of life. If there is any hearing loss, ongoing monitoring of hearing is routine. It is also important to monitor ear health and eustachian tube function in the patent/hearing ear. CT imaging to assess middle and inner ear anatomy is not recommended in the neonatal period. Consultation for ear reconstruction and atresia repair should occur by 4 years of age, although aural augmentation and habilitation in conductive hearing loss can be initiated earlier.

Renal ultrasound and cardiac examination (echocardiogram) should be undertaken in infancy to identify any serious structural malformations. Ophthalmology consultation should be sought for appropriate management of epibulbar lipodermoids (if present) and risk for exposure keratopathy. Malocclusion and dental issues will need to be addressed as the child gets older. Children should undergo cervical spine screening radiographs to identify vertebral defects in segmentation. If the newborn has no symptoms of C-spine abnormality, screening four-view cervical spine films can be deferred until the child is 2 to 3 years old, when cervical vertebrae are more easily imaged.

Mild airway obstruction in CFM may be improved or minimized with prone positioning. However, infants with severe mandibular hypoplasia may have significant airway compromise and require tracheostomy placement or early mandibular distraction/advancement. In cases with significant airway compromise, referral to a craniofacial center to evaluate for distraction should be considered.

Oral feeding should be introduced when the airway is stable. Oral stimulation is important to prevent oral aversion. Given the risk of feeding difficulty and aspiration in infants with malformations of the first and second branchial arches, early consultation with both a dietitian and a feeding therapist is recommended.

Mandibular distraction to reconstruct the hypoplastic mandible has been well described (McCarthy et al, 1998). The surgery consists of surgical osteotomy and placement of distraction device that slowly increases mandibular length and ramus height. The timing of surgery is dependent on the degree of mandibular hypoplasia, mandibular growth, and airway involvement. Infants with severe mandibular hypoplasia leading to airway compromise may be candidates for distraction during infancy; however, in those with severe hypoplasia of the mandible, bone grafting may be necessary for reconstruction before distraction.

CHARGE SYNDROME

EPIDEMIOLOGY AND GENETICS

The acronym CHARGE association (*C*oloboma, *H*eart defect, *A*tresia choanae, *R*etarded growth and development, *G*enital hypoplasia, *E*ar anomalies/deafness) was first coined by Pagon, given the observation that the associated malformations occurred more frequently together than one would expect on the basis of chance (Pagon et al, 1981). Over time, the facial features and associated malformations were better characterized as a syndrome, with mutations in at least one major gene described (OMIM 214800).

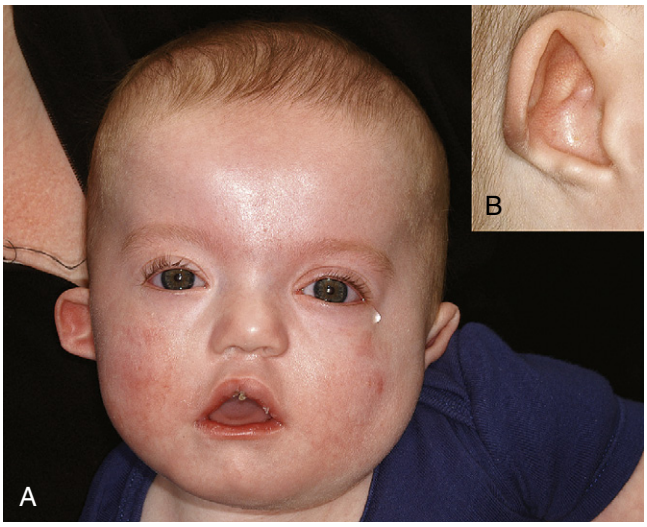

FIGURE 95-12 **A** and **B,** Child with CHARGE syndrome, with classic ear malformation—hypoplastic lobes, cupped and low-set.

This multiple malformation condition has a prevalence of approximately 1 in 10,000 births (Blake and Prasad, 2006). Although multiple chromosomal aberrations have been reported in children with the phenotype of CHARGE syndrome, mutations in the CHD7 gene account for 60% to 65% of cases. When the diagnosis of CHARGE syndrome is suspected, molecular testing for mutations in the CHD7 gene can be sent to confirm the diagnosis and provide more information to assist in counseling for the parents and the patient. For children in whom CHD7 gene testing is normal, evaluation for chromosomal abnormalities is possible using CGH array technology (Lalani et al, 2007).

PHENOTYPE

The diagnosis of CHARGE syndrome is based on a combination of major and minor clinical criteria, but the diagnosis should be suspected in any neonate with any of the major characteristics: ocular coloboma (80% to 90%), choanal atresia or stenosis (50% to 60%), cranial nerve dysfunction or facial palsy (40% to 90%, depending on which cranial nerve is involved), or classic CHARGE ears (90–100%) (Lalani et al, 2007). Polyhydramnios is commonly present prenatally when bilateral choanal atresia is present.

Distinctive ear anomalies (hypoplastic lobes, cupped or lop, position is often low-set and posteriorly rotated) or deafness occur in most individuals with CHARGE (Figure 95-12, *A*, *B*). Hearing loss can be a combination of conductive and sensorineural. Other craniofacial features include square face with malar flattening, broad forehead, facial asymmetry, pinched nostrils, full nasal tip, long philtrum, and cleft palate (40%). Ocular colobomas can range from a coloboma of the iris to anophthalmia. Cardiac defects can be a major source of morbidity in infants with CHARGE and are found approximately 80% of the time. Conotruncal and aortic arch anomalies are the most common congenital heart defects, but atrioseptal defects, ventriculoseptal defects, patent ductus arteriosus, hypoplastic left heart, and vascular rings have also been described (Lalani et al, 2007).

ICU CONCERNS

The most important postnatal emergency in CHARGE is bilateral posterior choanal atresia (Blake et al, 2009). Neonates with bilateral choanal atresia will have breathing difficulty and cyanosis within the 1st hour of life. As with all forms of nasal obstruction, crying relieves the cyanosis because it allows the obligate nose breather to take in air through the mouth; feeding exacerbates respiratory distress. Left untreated, the newborn with bilateral choanal atresia can asphyxiate and die. Symptoms of bilateral choanal stenosis or unilateral atresia may not present until after the newborn period with chronic rhinorrhea or breathing problems associated with respiratory infections. Respiratory distress in a newborn with CHARGE syndrome is usually due to choanal atresia, but other features, such as reflux and swallowing dysfunction, can contribute to aspiration and lower respiratory disease. These infants may also have micrognathia and glossoptosis, putting them at risk for airway obstruction at the level of the pharynx/hypopharynx. Infants with CHARGE may require multiple surgeries and procedures over the 1st year of life and are at increased risk for postoperative airway events (Blake et al, 2009).

Cyanotic heart disease may present in the immediate newborn period because of tetralogy of Fallot, outflow tract anomalies, and interrupted aortic arch. Awareness and recognition of the association of CHARGE and congenital heart defects is crucial.

A significant cause of morbidity is feeding difficulty. Feeding and secondary growth problems are common in early infancy and may be attributed to swallowing dysfunction, pharyngeal incoordination, gastroesophageal reflux, and aspiration. Cranial nerve palsies (specifically cranial nerves V, IX, and X) may contribute to swallowing dysfunction, and tracheoesophageal fistula (TEF) contributes to aspiration risk. Although it is well described that infants with CHARGE who survive the newborn period are more likely to survive childhood, the risk of death in infancy remains significant. Male gender, bilateral choanal atresia, TEF, cyanotic heart disease, atrioventricular septal defects, CNS malformations, and ventriculomegaly have all been associated with reduced life expectancy in infants with CHARGE syndrome (Blake et al, 2009; Issekutz et al, 2005; Tellier et al, 1998). A study of 77 individuals with CHARGE found mortality to be 13% (Issekutz et al, 2005).

MANAGEMENT

Children with CHARGE syndrome may require intensive medical management as well as surgical interventions. The primary management targets should be airway stabilization and circulatory support. With this in mind, neonates with CHARGE require immediate evaluation of their airway and cardiac structure and function. An oral airway should be placed if bilateral choanal atresia is suspected. This will allow stabilization of the airway by bypassing the choanal obstruction so that a confirmatory CT scan of the nasal passages can be obtained. A CT of the temporal bones can be included in conjunction with the facial CT and may reveal the characteristic inner ear findings (Mondini malformation of the cochlea and/or absent or hypoplastic semicircular canals) of CHARGE syndrome. If the oral airway does not allow for adequate air entry, endotracheal intubation may be required. In consultation with a pediatric otolaryngologist, transnasal stents may be placed to keep nasal passages patent in choanal stenosis (and postoperatively after choanal atresia repair). Given the significant risk for cyanotic heart defects, an echocardiogram and cardiology consultation should be obtained to assist in management (Blake and Prasad, 2006).

Infants with CHARGE should also have early audiologic and ophthalmologic evaluations in the neonatal period and should eventually be referred to Birth to Three/early intervention services.

Consultations with both a feeding specialist and dietitian are recommended in the newborn period. If an oral feeding evaluation or videofluoroscopic swallow study are concerning for swallowing dysfunction or aspiration, nasogastric feeding should be initiated. With prolonged feeding issues, gastrostomy tube feeding is often necessary. Infants with severe gastroesophageal reflux may be candidates for Nissen fundoplication at the time of gastrostomy tube placement.

MACROGLOSSIA/ BECKWITH-WIEDEMANN SYNDROME

EPIDEMIOLOGY AND GENETICS

The true prevalence is unknown, but it has been estimated that Beckwith-Wiedemann syndrome (BWS) (OMIM 130650) affects 1 in 13,700 births (Thorburn et al, 1970). This is probably an underestimate, given that there are mild cases of BWS that go undetected. The genetics of BWS is complex and variable. Most cases are sporadic and may result from chromosomal rearrangement, mutations, or epigenetic effects (DNA methylation changes) affecting imprinted genes on chromosome 11p15.5. Although there are no consensus criteria for diagnosis of BWS, the presence of macroglossia, overgrowth, and abdominal wall defects suggests the diagnosis of BWS. Data has suggested a possible link between imprinting disorders and assisted reproduction, and thus infants conceived by in vitro fertilization may be at higher risk for BWS (Maher et al, 2003). If there are features of BWS present or there is a family history of BWS, geneticists may suggest obtaining methylation or chromosome studies to detect abnormalities localized to 11p15. Although this may provide confirmation of diagnosis, sensitivity is not 100%, and thus management is based on the clinical diagnosis.

PHENOTYPE

BWS is a disorder of overgrowth with multiple features, including macrosomia, macroglossia, visceromegaly (involving the kidneys, pancreas, liver, spleen, or adrenal glands), abdominal wall defects (including rectus diastasis, umbilical hernia, and omphalocele), hemihyperplasia (asymmetric overgrowth of one or more regions of the body), renal anomalies (structural anomalies and nephrocalcinosis), and adrenocortical cytomegaly (Figure 95-13). Macroglossia is the most frequent and most

FIGURE 95-13 *(See also Color Plate 40.)* **A,** Premature newborn with Beckwith-Wiedemann syndrome, macroglossia, and rectus diastasis. **B,** Same child at 6 months of age. Macroglossia has increased and he now has a tracheostomy.

obvious manifestation of BWS (present more than 95% of the time) (Elliott et al, 1994). Other craniofacial features include capillary nevus flammeus, metopic ridge, large fontanel, mandibular prognathism, prominent eyes, anterior earlobe linear creases, and posterior helical pits. Less common findings in BWS include cleft palate, cryptorchidism, and cardiac defects (isolated cardiomegaly is more common than cardiomyopathy). Risk of embryonal tumors (Wilms' tumor, hepatoblastoma, neuroblastoma, or rhabdomyosarcoma) in childhood is estimated to be 7.5%, of which 95% present in the first 8 years of life, leading to recommendations for tumor surveillance (Firth and Hurst, 2005).

Some features suggestive of BWS may be present antenatally, including polyhydramnios (due to swallowing dysfunction), preeclampsia, fetal macrosomia, and a large placenta. Prematurity has been reported in 50% of births (Elliott et al, 1994), and in addition to complications of prematurity, the neonate with BWS may develop hypoglycemia and polycythemia.

ICU CONCERNS

Hypoglycemia due to hyperinsulinemia and islet cell hyperplasia occurs in up to 50% of neonates with BWS and usually develops in the first few days of life (Munns and Batch, 2001). It is critical to detect and treat hypoglycemia in any neonate with features of BWS in order to prevent seizures and CNS sequelae. Polycythemia can occur and may need to be treated in the early neonatal period.

Clinical symptoms related to macroglossia may present in the newborn period if macroglossia is severe. However, airway obstruction more commonly presents later in infancy, outside the newborn period. The enlarged tongue can occlude the airway at the level of the hypopharynx, leading to respiratory distress, apnea, and hypoxia. This may be averted by placing the baby on the side or prone. If the infant requires endotracheal intubation, it is important to exercise caution, because macroglossia can affect visibility of airway structures. A large tongue can also contribute to feeding issues, dysphagia and aspiration.

Infant mortality among infants with BWS has been reported as high as 21% and is related to complications of prematurity and macroglossia (Shurman et al, 2005).

MANAGEMENT

Hypoglycemia in newborns should be managed according to standard protocols for treating neonatal hypoglycemia. If hypoglycemia persists or is refractory to therapy, consider consultation with an endocrinologist. Neonates with an omphalocele may require surgery in the first few days of life.

There is no definitive approach to the management of macroglossia. If macroglossia results in significant airway obstruction or prolonged intubation, tracheostomy may be needed as a temporizing measure to bypass the obstruction. Tongue growth will slow over time, and as jaw growth accelerates, airway compromise should decrease. Some children may benefit from surgical reduction of the tongue, which is usually performed between 2 and 4 years of age, but may be offered as early as 3 to 6 months at some centers.

Referrals to an infant feeding specialist and dietitian are recommended in the infant with severe macroglossia or if the infant is not gaining weight. Although some infants are able to orally feed, others will benefit form nasogastric tube feeds and may go on to need gastrostomy tube feeds.

Although cardiac defects are rare, it is important to do a thorough cardiac evaluation, including electrocardiogram

and echocardiogram if any cardiac abnormalities are suspected.

Surveillance for tumors begins in the first months of life. An abdominal ultrasound to assess for organomegaly and a baseline CT or MRI of the abdomen should be performed. Abdominal ultrasounds every 3 months are recommended through 8 years of age. In conjunction, staggered serial serum alpha-fetoprotein measurements (every 6 to 12 weeks) are recommended through 4 years of age to assist in identifying hepatoblastomas before detection by screening ultrasound.

Referral to a craniofacial team may be helpful in the management of the airway obstruction in BWS, including evaluation for tongue reduction and facial hemihypertrophy. A geneticist and genetic counselor may recommend genetic testing for confirmation of diagnosis and/or recurrence risk counseling.

FRONTONASAL DYSPLASIA, HYPERTELORISM, ENCEPHALOCELE

EMBRYOLOGY

Frontonasal dysplasia (FND; also known as frontonasal malformation, median cleft face syndrome, and frontal nasal syndrome) is a malformation resulting from abnormal morphogenesis of the frontonasal process. The development of the facial midline is abnormal, leading to ocular hypertelorism and associated craniofacial features. Most cases of FND are sporadic (OMIM 136760).

PHENOTYPE

FND has been defined phenotypically as containing two or more of the following craniofacial features: ocular hypertelorism; broadening of the nasal root; midline facial cleft affecting the nose, lip, or palate; unilateral or bilateral clefting of the alae nasi; hypoplastic nasal tip; anterior cranium bifidum; and a V-shaped frontal hairline (Wu et al, 2007). Grading of hypertelorism is best achieved by measuring the interpupillary distance. In a term newborn, interpupillary distance greater than 4.5 cm is considered hyperteloric (Jones, 2006).

In addition to hypertelorism, eye anomalies, including epibulbar dermoids, colobomas, ptosis, nystagmus, or cataracts, may be present in FND and are associated with a more severe phenotype and an increased incidence of CNS abnormalities (Wu et al, 2007). Associated CNS manifestations include encephalocele, agenesis of the corpus callosum, and abnormal neuronal migration. Developmental delay is a significant risk, especially when there are CNS malformations. When FND is associated with extracephalic anomalies or when ocular hypertelorism is more severe, there is an increased association with cognitive impairment (Gorlin et al, 2001d). Encephaloceles may occur in isolation or may be associated with a syndrome. Frontonasal encephaloceles (and meningoceles) are the most common encephaloceles in FND (Gorlin et al, 2001a) (Figure 95-14).

A subpopulation of patients with frontonasal malformation also have coronal craniosynostosis and variable skeletal and ectodermal defects and have an X-linked condition termed craniofrontonasal syndrome (CFNS, OMIM 304110). Similar to FND, facial features include hypertelorism, frontal bossing, broad nasal bridge, and a bifid nasal tip. Children with CFNS often have significant facial asymmetry due to unicoronal synostosis. In this X-linked condition, females are affected more severely than males (and typically have hypertelorism and grooved nails), and mutations are detected in the EFNB1 gene. Affected individuals usually have normal intelligence.

FIGURE 95-14 MRI of an infant with frontonasal dysplasia and a midline cleft lip. The scan reveals a moderate-sized meningocele extending into the posterior nasopharynx. *White arrow* points to midbrain meningocele coming through the cribriform plate; *black arrow* points to the intraoral meningocele.

ICU CONCERNS

Intracranial abnormalities associated with FND may put the infant at risk for CNS manifestations such as hydrocephalus or seizures. If the pituitary gland is involved or deficient, as can be seen with HPE sequence, there can be serious endocrine abnormalities (as discussed in the section on orofacial clefting). Also, frontonasal encephalocele may contribute to upper airway compromise.

MANAGEMENT

In any infant with hypertelorism or features that raise suspicion for FND, awareness of potential underlying malformations is critical, and cranial imaging by CT scan or MRI should be considered. Placement of a nasogastric tube or suction catheter should be avoided or used with caution until the CNS anatomy has been delineated. Because infants with FND have a high incidence of frontonasal encephalocele or meningocele, routine placement of these catheters could lead to brain injury. If an infant with FND needs urgent or emergent endotracheal intubation, intraoral structures should be examined carefully to prevent injury to herniating CNS structures if present. Management of seizures or any electrolyte derangements

should be managed as per the NICU standard protocol. Consultation with a craniofacial team, including ophthalmology, can be helpful in understanding the work-up and management (including potential surgical interventions) for individuals with FND.

PRENATAL SCREENING FOR FETAL FACE ANOMALIES

The exact role of fetal face examination with ultrasound in a low-risk pregnancy is under evaluation. Routine obstetric surveillance includes a midtrimester anatomic ultrasound (US) at 18–22 weeks' gestation. Most studies looking at the recognition rate and incidence of ultrasonographic diagnosis of orofacial clefting focus on this anatomic examination. Adequate evaluation of the facial structures with ultrasonography can be achieved by 16 to 17 weeks' gestation. The following facial features can be visualized with two-dimensional (2D) routine US at 18 weeks' gestation with standard facial views (which include coronal images of the nose, lips' and orbits and sagittal profile views): orbital size and position, eye size including microphthalmia and anophthalmia, shape of nose, nasal hypoplasia, length of the philtrum, clefts of the upper lip, frontal bossing, retrognathia, micrognathia, macroglossia, and soft tissue abnormalities. Cleft lip with or without cleft palate can be detected by antenatal ultrasound, whereas isolated cleft palate, which is not typically associated with a cleft of the alveolus, may be obscured by the tongue, which has the same echogenicity as the secondary palate, thus making prenatal diagnosis of CPO more difficult. A retrospective study in a low-risk population demonstrated that routine prenatal ultrasound with standard facial views performed at 18 weeks estimated gestational age detected 93% of cases of CL+P, 67% of cases of isolated CL, and 22% of cases of CPO (Cash et al, 2001). Although the diagnosis is not definitive, prenatal diagnosis is particularly valuable in allowing for appropriate prenatal counseling. Families who have the opportunity to meet with members from a craniofacial team before delivery often appreciate having some understanding of what to expect in the newborn period.

CHAPTER 96

Common Neonatal Orthopedic Ailments

Klane K. White and Michael J. Goldberg

Although orthopedic afflictions of the newborn generally are not life threatening, they do have the potential to significantly impair functional performance, even when diagnosed and treated early. This chapter discusses the most commonly encountered of these orthopedic problems.

DEVELOPMENTAL DYSPLASIA OF THE HIP

The term *developmental dysplasia of the hip* (DDH) encompasses a spectrum of pathology from acetabular dysplasia, to "located" hips that are unstable (femoral head can be moved in and out of the confines of the acetabulum), to frankly dislocated hips in which there is a complete loss of contact between the femoral head and acetabulum. DDH occurs in 11.5 of 1000 infants, with frank dislocations occurring in 1 to 2 per 1000 (American Academy of Pediatrics, 2000; Guille et al, 2000). Risk factors for a positive newborn screening examination include female gender (19 per 1000 risk), positive family history (boys, 9.4 per 1000; girls, 44 per 1000), and breech presentation (boys, 26 per 1000; girls, 120 per 1000) (American Academy of Pediatrics, 2009). The left hip alone is affected in 60%, the right hip in 20%, and both hips in 20% of infants (Guille et al, 2000).

Dislocations can be divided into two groups: syndromic and typical. *Syndromic* dislocations are most frequently associated with neuromuscular conditions such as myelodysplasia and arthrogryposis or with dysmorphic syndromes such as Larsen's syndrome. These abnormalities probably occur in either week 12 or 18 of gestation (American Academy of Pediatrics, 2000). *Typical* dislocations occur in otherwise healthy infants in the prenatal or postnatal period.

Congruent reduction and stability of the femoral head are necessary for normal growth and development of the hip joint. The natural history of untreated DDH is controversial, because newborn instability may resolve or progress to subluxation or dislocation. In cases that progress, infants have significantly increased risk of developing precocious arthritis with moderate to severe hip pain as young adults (Cooperman et al, 1983; Wedge and Wasylenko, 1979). This pain can be debilitating. Early detection and treatment of DDH are therefore important in avoiding the devastating sequelae of a late diagnosis.

There are no pathognomonic signs of a dislocated hip. The physical examination requires patience on the part of the examiner and may be facilitated by having the baby feed from a bottle. Evaluation for asymmetry is perhaps the most important key to the evaluation for DDH, although asymmetry may not be evident in bilateral dislocations. Presence of asymmetric abduction is suggestive of a dislocation, as is a Galeazzi sign. The presence of asymmetric thigh folds may be indicative of DDH but is often present in unaffected infants. The Galeazzi sign is elicited with the baby placed supine on an examining table so that the pelvis is level, with the hips and knees flexed to 90 degrees. With the baby's hips in neutral abduction, the examiner determines if the knees are at the same height. If one femur appears shorter, the hip may be dislocated posteriorly (Figure 96-1). Limitations in hip abduction in babies older than 12 weeks is the most reliable examination finding suggestive of DDH. Adduction of 30 degrees and abduction of 75 degrees should be possible in most newborns. Side-to-side variations should be noted. Each of these signs, individually or in combination, may serve to increase the index of suspicion of the examiner and lower the threshold for further diagnostic studies or referral to a pediatric orthopedist.

There are two common ways of assessing hip stability in the newborn. The Ortolani test is performed on one leg at a time, with the calm newborn supine on the examining table. The index and middle fingers of the examiner are placed along the greater trochanter, while the thumb is placed on the medial aspect of the thigh. The pelvis is stabilized by placing the thumb and ring or long finger of the opposite hand on top of both anterior iliac crests simultaneously. Alternatively, the opposite thigh may be held in the same manner as the examined side while the hip is held in abduction. The hip is flexed to 90 degrees and gently abducted while the leg is lifted with the hip in neutral external/internal rotation. A palpable clunk is felt as the dislocated femoral head reduces into the acetabulum. This finding is reported as the Ortolani sign (positive result on the Ortolani test). The Barlow test is an attempt to dislocate or subluxate a located but unstable hip. The thigh is held and the pelvis stabilized in the same manner as for the Ortolani test. With the hip in neutral external/internal rotation and at 90 degrees of flexion, the leg is then gently adducted with a mild posteriorly directed pressure applied to the knee. A palpable clunk or sensation of posterior movement constitutes a positive result (i.e., the Barlow sign). Each hip should be examined separately. High-pitched clicks are frequently elicited with hip range of motion. These sounds are most frequently attributed to snapping of the iliotibial band over the greater trochanter and are not associated with dysplasia (Bond et al, 1997). With progressive soft tissue contractures, both the Ortolani and Barlow tests become unreliable after 3 months of age.

Imaging of the immature hip can be a valuable adjunct to the physical examination. An anteroposterior (AP) radiograph of the pelvis is difficult to interpret before age 4 to 5 months. The femoral head is composed entirely of cartilage until the secondary center of ossification appears. Before the appearance of the secondary center, ultrasound examination is the method of choice for visualizing the cartilaginous femoral head and acetabulum. Static ultrasound images allow visualization of acetabular and femoral head anatomy, while the complementary dynamic

FIGURE 96-1 Presence of Galeazzi sign.

FIGURE 96-2 The Pavlik harness.

images give information on the stability of the hip joint (Clarke et al, 1985; Graf, 1984). The primary limitation of hip ultrasonography is that results are dependent on the experience and skill of the operator, especially when performed within the first 3 weeks of life (Marks et al, 1994). For these reasons ultrasonography is recommended as an adjunct to clinical evaluation rather than as a screening tool (American Academy of Pediatrics, 2000). Studies conducted before 4 weeks of life maybe useful for confirming equivocal physical exam findings and for monitoring treatment of hips with known dislocations. Clinicians must be aware, however, that ultrasound images in this age group often reveal minor degrees of dysplasia that usually resolve spontaneously and may lead to overtreatment of physiological hip variations. Ultrasonography is the technique of choice for assessing infants at high risk for DDH after 4 to 6 weeks of age and, again, is useful in following the results of intervention. After 4 months of age, the gold standard remains the AP pelvic radiograph.

The American Academy of Pediatrics has published a revised clinical practice guideline to aid in the early diagnosis and initiation of appropriate intervention of DDH (American Academy of Pediatrics, 2009). All newborns should be screened for DDH by a properly trained health care provider by physical examination. Risk factors for DDH should be determined by the treating physician. These include the presence of a positive Ortolani or Barlow exam, breech presentation, and positive family history. If there are no risk factors, then serial examinations are recommended according to a standard periodicity schedule until the child is an established walker. If during these periodic visits physical findings raise suspicion of DDH, or if a parental concern suggests hip disease, confirmation is required by an expert physical examination, by referral to a pediatric orthopedist (or other practitioner with expertise in medical and surgical management of newborn hip disease), or by age-appropriate imaging. When a positive Ortolani or Barlow test is present at birth and persists beyond the usual age of spontaneous resolution (4 weeks), the infant should be referred to an orthopedist for management. However, if the positive Ortolani or Barlow test disappears by 4 weeks, then age-appropriate imaging (ultrasonography at 6 weeks or radiograph at 4 months) is warranted. If the baby has positive risk factors, such as female breech or positive family history, but a stable hip exam, then age appropriate imaging is recommended (ultrasonography at 6 weeks or radiograph at 4 months).

As previously recommended, triple diapering is not an accepted form of treatment in DDH, and communication between providers is encouraged if the practitioner examining the newborn in the hospital is different from the 2-week follow-up examiner. Despite newborn screening programs, 1 in 5000 will have a dislocated hip detected at 18 months of age or older (Dezateux and Godward, 1995). It is important to appreciate that not all dislocated hips are present at birth, and not all hips dislocated at birth are detectable in the newborn period.

Treatment of DDH is dependent on the age at presentation. For children 0 to 6 months of age, a reducible hip is treated in a Pavlik harness. The Pavlik is a dynamic splint that allows the infant to actively move the hips through a sphere of motion that encourages deepening and stabilization of the acetabulum (Figure 96-2). The harness is applied as soon as possible after the diagnosis of DDH is made. The length of treatment is dependent on age at presentation. Progress is judged by serial physical examinations and static and dynamic ultrasonography. In the case of a frankly dislocated hip, treatment is abandoned if no improvement is noted within 4 weeks of splint application. Closed reduction under general anesthesia, usually with arthrographic evaluation and subsequent spica casting, is then attempted at 4 to 5 months of age. For a persistently irreducible dislocation, which is unusual in the 0- to 6-month age group, open operative reduction of the hip with subsequent spica casting is undertaken. The success of Pavlik harness treatment is variable and correlates with

the severity of the hip dysplasia. Treatment is successful in nearly 100% of stable hips, greater than 90% in dislocatable (Barlow positive) hips, 61% to 93% in dislocated but reducible (Ortolani positive) hips, and as low as 40% in irreducible dislocations (Hangen et al, 1995; Lerman et al, 2001; Sucato et al, 1999; Swaroop and Mubarak, 2009; Viere et al, 1990).

TORTICOLLIS

Congenital muscular torticollis (CMT) manifests at birth or soon thereafter and is the most frequent cause of wryneck. However, other conditions, some more serious, may cause torticollis. These include congenital anomalies of the vertebra and skull (e.g., Klippel-Feil syndrome, hemivertebrae, basilar invagination, craniosynostosis) (Dubousset, 1986; Hensinger et al, 1974; Raco et al, 1999); abnormalities of the central nervous system (CNS; e.g., syringomyelia, tumors) (Kiwak et al, 1983); Chiari malformations (Dure et al, 1989); ocular abnormalities (Bixenman, 1981); pharyngeal abscess; and gastroesophageal reflux (e.g., Sandifer's syndrome) (Ramenofsky et al, 1978). Patients with CMT can be divided into those who demonstrate a sternocleidomastoid muscle (SCM) "pseudotumor," those with tightness or fibrosis of the SCM without pseudotumor (termed *muscular torticollis*), and those with all of the characteristic features of congenital torticollis without evidence of contracture or fibrosis of muscle (termed *postural torticollis*) (Cheng et al, 2001). CMT has been estimated to occur in 0.3% to 2.0% of live births (Cheng et al, 2001). It is usually discovered between 6 and 8 weeks of life. The infant presents with a cock robin appearance, with the head tilted toward and chin rotated away from the affected SCM. Twenty percent to 30% of patients will have a palpable pseudotumor present in the middle to inferior aspect of the affected SCM, which spontaneously regresses with time, leaving a fibrous band (Herring, 2002). More than half will have facial asymmetry. The left and right SCMs are affected in equal proportions. CMT probably results from ischemia within the SCM, leading to fibrosis (Davids et al, 1993). The cause of the ischemia is unknown, but intrauterine crowding may play a role, inasmuch as some authors have reported an association of torticollis with other deformations such as DDH and metatarsus adductus (Morrison and MacEwen, 1982; Tien et al, 2001).

Excellent results with a manual stretching program can be attained in children first seen before 1 year of age (Morrison and MacEwen, 1982). Initially, the parents are instructed in the technique of stretching the contracted SCM by rotating the infant's chin toward the affected SCM while simultaneously tilting the head away from it. This is completed 10 times each session and held for a count of 10 at least 10 times per day. Unfortunately, compliance may be an issue. If the child fails to improve substantially within 3 to 4 weeks, a physical therapist is enlisted to see the child two or three times weekly to supervise the program and reinforce the home therapy. Additionally, the parents are instructed to configure the infant's crib and toys in such a manner as to encourage active rotation toward the involved side. There is no justification to undertake surgery in any child less than 1 year of age or in any child who has not completed a minimum of 6 months of therapy (Cheng et al, 2001; Morrison and MacEwen, 1982). In a prospective study of 821 children with muscular torticollis, only 8% of patients with the history of a pseudotumor, and 3% of those without, required surgical intervention following a well-structured stretching program (Cheng et al, 2001). Because of the difficulty of monitoring exercise programs, because parental compliance is always in question, and because surgical intervention is infrequent, it is possible that many patients resolve spontaneously. No patients with postural torticollis require surgery. Risk factors for surgery include late initial presentation, presence of a pseudotumor, and rotation deficit of greater than 15 degrees.

The timing of surgical intervention remains controversial. In patients with significant plagiocephaly and facial asymmetry, surgery should be considered just before 2 years of age in order to maximize the chance for complete remodeling. For those with either no or mild facial asymmetry, good to excellent results can be expected with surgery up to 6 years of age (Ling, 1976). Acceptable results are reported as late as 12 years of age, but the ability to remodel facial asymmetry appears diminished (Lee et al, 1986). Surgery entails either release or lengthening of the SCM through cosmetically pleasing incisions (Ferkel et al, 1983). The use of a molded helmet to promote facial and skull remodeling is common in some centers. Prospective studies that establish the effectiveness of helmets are lacking.

A less frequent cause of congenital torticollis is osseous fusion between bones in the cervical spine. These fusions may be between the skull and C1 and/or C2 or in the lower cervical spine. They result from failure of the bones to properly segment during embryogenesis. These abnormalities, in combination with a low posterior hairline and a short webbed neck with limited range of motion and head tilt, constitute the triad referred to as *Klippel-Feil syndrome* (Copley and Dormans, 1998). These congenital bone fusions can range from involvement of two segments to involvement of the entire cervical spine. Colloquially, Klippel-Feil syndrome has come to refer to any congenital malformation in the cervical spine with or without other elements of the triad. In infants and young children, the neck may remain quite flexible despite the bone abnormalities. In a newborn with torticollis who does not improve with passive stretching exercises, radiologic evaluation is mandatory. Cervical spine films are not recommended in all patients initially presenting with neonatal torticollis, as these films are quite difficult to interpret in this age group because of the predominance of cartilage in the bones of the neck. Furthermore, many neonates would be subjected to unnecessary ionizing radiation.

The natural history of Klippel-Feil in most cases is quite favorable, requiring nothing more than periodic observation. In patients with severe involvement, however, the consequences of this disorder can include early spondylosis with the development of pain or stenosis, the development of progressive torticollis and scoliosis, and the occurrence of neurologic compromise and sudden death secondary to even minimal trauma (Herring, 2002). Despite these potentially devastating sequelae, the greatest advantage to early detection of Klippel-Feil syndrome is in being alerted to commonly associated disorders including

congenital heart disease (14% to 29%), renal anomalies (25% to 35%), scoliosis (60%), audiologic anomalies (80%), deafness (15% to 35%), synkinesis (15% to 20%), and, less commonly, posterior fossa desmoid tumors (Herring, 2002; Muzumdar and Goel, 2001). The recognition of a Klippel-Feil anomaly should prompt a thorough evaluation for these associations. Treatment for Klippel-Feil most often involves periodic observation with activity modification. In the face of progression of deformity or severe deformity, spinal fusion may be warranted.

Sandifer's syndrome (gastroesophageal reflux) also can cause a torticollis. With this syndrome, the torticollis is intermittent and may alternate directions, and there is no tightness of the SCM, with normal findings on radiographs (Ramenofsky et al, 1978).

Hemiatlas, or the failure of formation of a portion of the first cervical vertebra, is also a rare cause of torticollis (Dubousset, 1986). In the infant, the neck may be quite flexible and the torticollis passively correctable. An open-mouth (odontoid view) cervical spine radiograph reveals this deformity. If the torticollis is progressive or severe, gradual correction of the deformity with a halo vest followed by posterior occiput-to-cervical spine fusion is necessary. Other potential causes of torticollis in the neonate include CNS tumors and syringomyelia. If radiographs appear normal, a thorough neurologic examination and referral to a neurologist are recommended.

FOOT DEFORMITIES

Congenital deformities of the foot are relatively common but often overlooked in newborns. Consequently, the true incidence of the milder, self-limited deformities is unknown. For identification purposes, congenital foot abnormalities can be divided into those that result in the toes pointing upward (calcaneovalgus) and those that result in the toes pointing inward (metatarsus adductus, clubfoot).

Calcaneovalgus is thought to be a postural deformity secondary to intrauterine positioning in which the dorsum of the foot is, or can be, directly apposed to the anterior aspect of the leg. In the calcaneovalgus foot, the hindfoot is in the dorsiflexed position (calcaneus position) so that the plantar aspect of the forefoot is collinear with it. Plantar flexion of the foot is often limited from contracture of the anterior ankle soft tissues. The estimated incidence of calcaneovalgus is 0.4 per 1000 to 1 per 1000 live births (Nunes and Dutra, 1986; Wynne-Davies, 1964). It appears to be more common in girls and after breech deliveries (Nunes and Dutra, 1986). There may be an increased association with hip dysplasia, so a thorough hip examination is warranted, as outlined in the previous section on DDH. The prognosis for complete resolution with gentle stretching exercises conducted by the parents with each diaper change is excellent in the vast majority of cases. Complete resolution generally occurs by 3 to 6 months of age. Calcaneovalgus may be seen in conjunction with external rotation of the tibia, so that the toes appear to be rotated upward and outward. Additionally, a common association occurs with posteromedial bowing of the tibia, a unilateral deformity. Posterior medial bowing is likely to resolve slowly but may eventually lead to a leg length inequality necessitating limb equalization surgery. Occasionally, in the most severe cases of calcaneovalgus, the foot requires serial casting to facilitate correction. A deformity failing to resolve mandates referral to a pediatric orthopedist.

FIGURE 96-3 The appearance of the foot with metatarsus adductus.

Calcaneovalgus needs to be differentiated from congenital vertical talus, a rarer condition that frequently is associated with neuromuscular conditions and syndromes. Congenital vertical talus can be differentiated from calcaneovalgus by viewing the hindfoot. If the hindfoot is fixed in equinus (plantar flexion), the foot will demonstrate a "rocker bottom" appearance characteristic of congenital vertical talus, due to dorsal dislocation of the midfoot at Chopart's joint (talonavicular and calcaneocuboid joints). In instances where the midfoot can be reduced (as demonstrated radiographically), the condition is referred to as an *oblique talus*. Treatment during infancy consists of serial casting to stretch dorsal soft tissues and potentially reduce the midfoot. After reduction, through either casting or surgical release, the Achilles tendon is lengthened to treat the hindfoot equinus (Dobbs et al, 2006).

The two common neonatal foot deformities resulting in medial deviation of the toes are metatarsus adductus and talipes equinovarus (clubfoot). *Metatarsus adductus* is present at birth but frequently diagnosed later during the 1st year of life. It has been estimated to occur in 1 in 100 births (Widhe et al, 1988). The pathogenesis is unproved, but the condition is thought to result from intrauterine crowding. Characteristic features include a concave medial border of the foot with a curved lateral border, a "bean-shaped" sole of the foot, a higher-than-normal-appearing arch, fixed adductus of the forefoot when the hindfoot is held in neutral position, separation of the first and second toes, and spontaneous medial deviation of the foot with active movement by the infant (Figure 96-3) (Kite, 1967). Metatarsus adductus can be classified into cases that passively correct and those that do not. Feet in which passive correction is possible are best left alone and will improve spontaneously. Feet in which passive correction cannot be obtained

FIGURE 96-4 The appearance of an untreated newborn clubfoot.

should be treated with manipulation and serial casting. The corrections can then be maintained with straight-last shoes if necessary or with nighttime bivalved casts. Operative treatment should be considered only in children older than 3 years of age who have a rigid deformity and have failed to respond to a manipulation and serial casting program (Weinstein, 2000). Farsetti et al (1994) reported on 45 feet demonstrating metatarsus adductus, with an average follow-up period of 33 years. The 16 feet in which the deformities were passively correctible, and in which no intervention was undertaken, were all rated as good, demonstrating spontaneous resolution of the metatarsus adductus. The 29 feet with deformities initially deemed partially correctible or rigid were treated with manipulation and casting. At follow-up examination, 26 feet (90%) were reported as good. None required surgery. The difficulty in treating metatarsus adductus is in convincing the parents and grandparents of the affected infant that the condition will resolve without intervention. Frequently, reverse-last and straight-last shoes are prescribed for benefit of the parent rather than the child.

The term *clubfoot* describes a foot demonstrating hindfoot equinus (plantar flexion) with adduction and supination of the forefoot (Figure 96-4). Clubfoot represents a spectrum of congenital deformity that ranges from the mild "postural" clubfoot to the severe arthrogrypotic clubfoot. It occurs in 1 in 1000 to 2 in 1000 live births (Herring, 2002). Three prominent theories for the etiology of clubfoot have emerged. An arrest in embryonic development in the 6- to 8-week fetus (Bohm, 1929) secondary to connective tissue abnormalities, a primary germ plasm defect (Brockman, 1930), and a neuromuscular defect (Handelsman and Badalamente, 1982) have been proposed. A recently documented risk factor for clubfoot is early amniocentesis (11 to 13 weeks' gestation), which is hypothesized to cause decreased fetal movement during a critical phase of foot development (Tredwell et al, 2001). Although the etiology of clubfoot remains unproved, there appears to be dysplasia of all osseous, muscular, tendinous, cartilaginous, skin, and neurovascular tissues distal to the knee in the affected limb. On the mild end of the spectrum, postural clubfoot appears to represent a packaging problem due to intrauterine positioning. Postural clubfoot is passively correctible, lacks deep medial creasing, demonstrates minimal or no calf atrophy, and responds quickly to a stretching and casting regimen. At the opposite end of the spectrum is the arthrogrypotic or neuromuscular clubfoot that demonstrates severe rigidity; absence of skin creases, suggesting early in utero affliction; and failure to respond to nonoperative therapies. Between these two extremes lies the classic clubfoot deformity. The anatomic deformities in clubfoot are numerous, complex, and somewhat controversial. Although the specific anatomic abnormalities are well beyond the scope of this chapter, the most notable abnormalities include a small, contracted heel cord complex; medial subluxation of the navicular bone on the talar head so that it abuts or nearly abuts the medial malleolus; and parallelism between the calcaneus and talus bones when these are viewed radiographically from the lateral aspect and from an anterior-to-posterior perspective. Clinically, the foot demonstrates a medial crease, with the toes pointed toward the midline, the sole of the foot angulated medially, the hindfoot plantar flexed with a deep, single, posterior crease, and a smaller foot and calf than on the contralateral side (see Figure 96-4).

All clubfoot deformities should be referred to a pediatric orthopedist for treatment. Initial treatment for all cases of congenital clubfoot is nonoperative. Untreated clubfoot has a poor natural history, with development of early degenerative changes in the foot joints. Historically, good, early results were achieved with operative methods in 85% of cases (Weinstein, 2000). Early surgical correction, however, has yielded poor long-term results and a high recurrence rate. Despite adept surgical correction, approximately 15% of cases of clubfoot have demonstrated recurrence necessitating further surgical intervention. Consequently, this approach has been abandoned.

Some surgeons have advocated a completely nonoperative approach to clubfoot correction (Kite, 1964; Ponseti, 1996; Seringe and Atia, 1990) based on observations that in operated cases of clubfoot, the feet are often stiff and gradually develop scarring, which diminishes the result. These programs vary in the specifics of treatment but share a labor-intensive approach. Although many forms of nonoperative clubfoot treatment exist, the Ponseti method of cast correction has achieved preeminence in this regard (Ponseti, 1992). The Ponseti method uses a specific set of manipulations and serial corrective long-leg casts, followed by a prolonged period of bracing. The "French Functional Method" has also been successfully duplicated at at least one U.S. hospital with good results (Faulks and Richards, 2009; Herring, 2002). This method necessitates daily manipulations by a trained physical therapist for 8 weeks, with the addition of continuous passive motion during the first 4 weeks. This is followed by strapping and continued bracing. Both the Ponseti and the French "nonoperative" methods frequently employ Achilles tenotomy and, at times, tendon transfers to attain the ultimate desired result. Recurrences of deformity are common (16% to 37%), requiring further casting. A smaller percentage of patients (8% to 16%) require surgical release

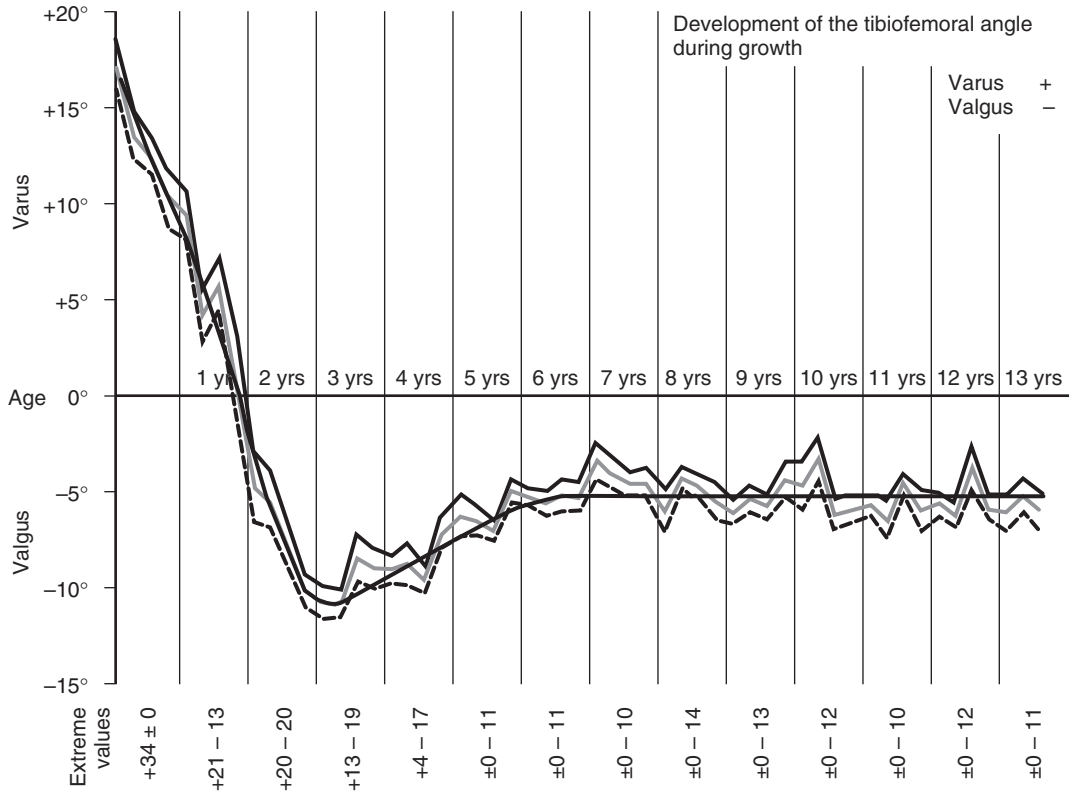

FIGURE 96-5 Development of the tibiofemoral angle during growth. *(Data from Salenius P, Vankka GK: The development of the tibiofemoral angle in children*, J Bone Joint Surg Am *57:259-261, 1975.)*

of the hindfoot to varying degrees (Faulks and Richards, 2009; Janicki et al, 2009).

With the Ponseti method, treatment is ideally commenced within the first few weeks of life, but successful treatment is commonly achieved when treatment is initiated up to 1 year of age (Dobbs, 2004). We prefer to initiate treatment after discharge from the hospital in most cases, allowing parental adjustment to the new child in their lives. Initial treatment usually consists of a manipulation and serial casting or taping program (Faulks and Richards, 2009; Janicki et al, 2009). In the Ponseti method, manipulation of the foot is carried out, and the correction is maintained with a long-leg cast. The casts are changed at 5- to 7-day intervals, with repeated manipulation and casting over 1 to 3 months, averaging four casts in the idiopathic clubfoot (Dobbs et al, 2006). This is followed by Achilles tenotomy in the majority of patients and 3 further weeks of casting. Children are then placed into a foot abduction orthosis full-time for a period of 3 months, and then part time, while sleeping, until approximately age 4 years.

ANGULAR DEFORMITIES OF THE LOWER EXTREMITIES

Torsional and angular deformities of the legs constitute the most frequent nontraumatic reason for referral to a children's orthopedist. Torsional deformities of the lower extremities rarely come to the attention of the physician before the child reaches walking age. Occasionally a neonate demonstrates bowing of the legs, or *genu varum*, of a sufficient degree to concern parents or grandparents. The true incidence of genu varum is unknown, but based on our experience, it is extremely common. The overwhelming majority of cases of genu varum resolve spontaneously, with a small minority of affected children manifesting a pathologic condition.

The legs of most neonates are bowed. This results from a combination of an external rotation contracture of the hips and internal tibial torsion. The apex anterior bowing of the femora in conjunction with the external rotation contractures of both hips allow the femoral bowing to be seen tangentially when the baby is viewed from the front. These contractures may not resolve until after walking age. Internal tibial torsion is nearly universal in neonates and spontaneously resolves between 2 and 3 years of age. Internal tibial torsion imparts an appearance of bowing to the tibia. When tibial bowing is viewed in combination with the apparent femoral bowing, a striking amount of leg bowing may be present. This is often concerning to both parent and physician.

Genu varum is physiologic up to the age of 2 years. Salenius and Vankka (1975) documented the tibiofemoral angles both clinically and roentgenographically in 979 children on the basis of 1408 examinations between birth and 16 years of age. They noted that newborns demonstrate a mean varus alignment of 15 degrees, which increases and becomes maximal at 6 months of age and then decreases to neutral at approximately 18 months. The maximum valgus of 12 degrees is then achieved by 3 to 4 years. By age 7, normal adult valgus alignment is achieved (Figure 96-5). Natural history studies have demonstrated

that physiologic genu varum is a self-limited process. Genu varum with angulation greater than 30 degrees has been shown to correct spontaneously with growth (Heath and Staheli, 1993).

Physical examination should include evaluation of the torsional profile (Staheli, 1977), which includes measurements of internal and external rotation of the hips and the thigh-foot angle. Measurement of the thigh-foot angle is performed with the child in the prone position and is an indicator of tibial torsion. The examiner should look for evidence of rhizomelic shortening, and genu varum, which may herald a diagnosis of achondroplasia or other skeletal dysplasia. Finally, note is made of whether onset of the varus of the lower extremities is gradual or abrupt. If it was abrupt, can the deformity be localized to the distal femur, the proximal tibia, or the midportion of the tibia? Considerations in the differential diagnosis of genu varum include focal fibrocartilage dysplasia, skeletal dysplasias such as achondroplasia, osteogenesis imperfecta, and metabolic bone disease such as vitamin D–resistant rickets, renal osteodystrophy, and tibia vara (infantile Blount disease). Blount disease does not occur before walking age, and most clinicians agree that this diagnosis cannot be made before 2 years of age.

Radiographs are indicated only with asymmetric deformities, with short stature, or in infants with progressive deformities. Photographs are the preferred method of follow-up evaluation for progression. Management of physiologic genu varum and tibial torsion consists of serial observation, reassurance, and parental education. Treatment with orthotics such as the Denis Browne splint is not indicated and in fact may be harmful to the ligaments of the knee.

Focal fibrocartilaginous dysplasia (FFD) involving the medial aspect of the proximal tibial metaphysis is a relatively rare cause of tibia vara in the newborn and infant. It was first reported in 1985 by Bell et al and continues to be recognized in scattered case reports. The pathophysiologic basis for the disease may be abnormal development of fibrocartilage at the insertion of the pes anserinus (sartorius, gracilis, and semitendinosus tendons). Children with FFD present before 1 year of age with unilateral bowing of the tibia that has prompted radiologic evaluation. The radiographs demonstrate a lytic defect in the proximal medial metaphysis of the tibia with surrounding sclerosis. The natural history of the deformity is that of progression until 2 years of age, with subsequent resolution by 4 years of age. During the progression, the deformity can become quite pronounced and unsettling. Up to 1 cm of tibial length discrepancy is likely. Use of orthotics is not indicated. Surgery is indicated only in patients older than 4 years without evidence of spontaneous resolution (Zayer, 1980).

Tibial bowing can be the cause of angular deformities in the shaft of the tibia. Two major types of bowing can be identified according to the direction of the apex of the bow. Posteromedial bowing has been previously described in conjunction with calcaneovalgus foot position in the neonate. Its etiology is unknown, but numerous hypotheses have been proffered, including intrauterine fracture with malunion and in utero malpositioning with subsequent growth retardation and soft tissue contractures (Thompson, 2001). The deformity is unilateral and evident at birth. There is an associated calcaneovalgus foot deformity. Other features include shortening of the tibia and a smaller calf circumference and smaller foot relative to the contralateral side. Frequently there is a dimple at the apex of the deformity. Radiographic examination of the entire extremity from hip to ankle should be performed. Radiographs demonstrate the degree of bowing well. Other radiographic findings include a normal proximal tibia with thickening and sclerosis of the diaphyseal cortices on the compression side of the deformity with obliteration of the intramedullary canal. There is no increased fracture risk associated with the deformity. Posteromedial bowing tends to resolve with growth, so that much of the deformity resolves by 2 years of age, with continued gradual correction beyond that. The shortening of the tibia and fibula persists, however, and progressively worsens during growth. Leg length inequality at skeletal maturity averages 4.1 cm (Hofmann and Wenger, 1981). Early referral to and serial follow-up assessments by a pediatric orthopedist are necessary to appropriately time epiphysiodesis surgery of the normal longer leg to allow for equal leg lengths at skeletal maturity. The foot deformity generally resolves by 9 to 12 months with stretching.

The second and most serious type of tibial bowing is anterolateral. It is usually identified at the newborn examination. It most frequently is associated with congenital pseudoarthrosis of the tibia but also can be associated with congenital longitudinal deficiency of the tibia or the fibula. Although its etiology is unknown, congenital pseudoarthrosis of the tibia is associated with neurofibromatosis (NF1) in 40% to 80% of cases (Masserman et al, 1974; Paterson, 1989; Thompson, 2001). It is arguably the most challenging congenital malformation to treat in orthopedics. It is estimated to occur in 1 in 140,000 live births (Crawford and Schorry, 1999). "Congenital pseudoarthrosis" implies that there is a nonunited fracture, which usually is not the case, so the term *congenital tibial dysplasia* (CTD) has been suggested (Crawford and Schorry, 1999). The newborn examination is notable for anterolateral bowing, which is unilateral. Other, cutaneous signs of NF1 may be evident. If they are not, NF1 should remain a consideration, because café au lait spots and other cutaneous manifestations may not be present in the newborn, and the child should be followed expectantly. If fracture has occurred, motion at the pseudoarthrosis site will be apparent. The foot may be normal or slightly small. The ankle may be in slight valgus to compensate for the bowing.

The natural history of congenital pseudoarthrosis of the tibia is that of fracture with nonunion and repeated surgical attempts at obtaining union. Most of these attempts fail; if one such procedure succeeds, however, repeat fracture is likely, and the cycle begins again. Frequently, amputation is the end result. Because of this possibility, efforts are best directed at prevention of initial fracture. Orthopedic consultation is imperative. In the preambulatory child, a total-contact (clamshell) ankle-foot orthosis should be fabricated and worn at all times except for bathing, to diminish the chance of fracture. When the child begins to walk, the orthosis may be extended above the knee with a drop-lock hinge to allow sitting. Bracing is continued until skeletal maturity is attained. Although definite proof that long-term bracing affects the natural

history of this condition is lacking, most orthopedists consider that bracing is warranted. Under no circumstances should an osteotomy to correct the bowing of an unfractured tibia be undertaken because development of a pseudoarthrosis is likely to result.

Many treatment options exist once a documented pseudoarthrosis occurs. Long-term immobilization, external fixation, internal fixation, bone transport, bone grafting, microvascular bone transfer, and electrical stimulation have been attempted, all with a high incidence of failure (Crawford and Schorry, 1999). When union is achieved, there is concern over its quality and longevity. Amputation has been advocated as a salvage procedure after failed attempts at union and as primary treatment for the initial pseudoarthrosis (Jacobsen et al, 1983). Herring et al (1986) reported that children who underwent Symes amputation (none of whom had CTD as the surgical indication, however) had better psychological and orthopedic functioning than that described in children who underwent numerous corrective surgical procedures. Similar results were reported by other authors (Davidson and Bohne, 1975).

CONGENITAL VERTEBRAL MALFORMATIONS

Congenital vertebral malformations occur in 0.5 to 1 in 1000 live births. Although a minority of cases may be due to genetic inheritance, there are no established gene defects that solely account for these disorders. Syndromes associated with them include Klippel-Feil, Goldenhar's, and VATER (VACTERL) sequence. Likewise, many congenital vertebral malformations occur in isolation and may be due to intrauterine exposures such as hyperglycemia, carbon monoxide, or antiepileptic drugs. The ultimate concern with congenital vertebral anomalies is their potential to result in significant spinal deformity, namely scoliosis, kyphosis, or a combination of the two. Many, however, remain asymptomatic throughout life.

Defects can be attributed to a failure of formation, a failure of segmentation, or both. Failures of formation result from asymmetric vertebral body formation and ensuing development of a hemivertebra. Hemivertebrae can be incomplete, with partial retention of the affected side, or complete. When partial retention of the pedicle occurs, a wedge vertebra develops. Complete hemivertebra can be further categorized. Radiographically, the presence of open disk spaces signifies the presence of growth plates and therefore growth potential. Unsegmented hemivertebrae, in which the segment is fused to one or both adjacent vertebrae, have less growth potential and therefore less deformity potential. Fully segmented hemivertebrae retain full growth potential from both the cranial and caudal ends and consequently much greater propensity to result in significant deformity. Failures of segmentation are characterized by bony fusions (bars) between adjacent vertebrae. Bilateral bars result in "block vertebrae" that, because of their symmetry, have minimal potential for deformity.

The propensity to result in a clinically significant deformity depends on the location of the defect, the type of defect, and the age of the patient (Hedequist and Emans, 2007). Curves at the lumbrosacral and cervicothoracic junctions may result in more clinically apparent deformities. Prediction of progression is largely driven by the presence of unbalanced defects. In order of severity, the risk of progression in congenital spinal deformities is associated with the following defects: unilateral bar with contralateral hemivertebra, unilateral bar, hemivertebra, wedge vertebra, and block vertebra. Additionally, the presence of multiple anomalies at multiple levels (e.g., multiple hemivertebra) can result in additional risk for progression when on the ipsilateral side or, conversely, may result in balanced growth when on contralateral sides of the spine.

All patients with known congenital spinal deformities should be evaluated for associated cardiac and renal anomalies. Cardiac anomalies are found in approximately 15% of these children and are usually clinically evident. Routine screening with an echocardiogram is not recommended unless clinical findings are suggestive (Prybis et al, 2007). Renal anomalies, on the other hand, are often clinically silent and have been reported in up to 37% of children with known congenital spinal anomalies (Riccio et al, 2007). Thus, routine sonography of the urinary tract system is recommended for all children with congenital spinal malformations.

Occult intraspinal anomalies are found in up to 30% of children with congenital spinal malformations. These include Chiari malformations, syringomyelia, tethered cord, reduced spinal cord diameter, or diastematomyelia. Associated physical examination findings are those consistent with occult dysraphism, such as dimpling of the skin, pigmentation changes, or the presence of hairy patches or skin tags in the lower back or intergluteal cleft. Changes to the lower extremities such as atrophy, foot deformities, and asymmetric or pathologic reflexes are also suggestive of intraspinal defects.

Infants with congenital spine anomalies should initially be evaluated with dedicated plain radiographs of the whole spine. Coned-down views of affected parts of the spine may offer additional information about the anatomy of interest. Rib anomalies should be noted, because they are commonly associated with thoracic spine malformations and may have significant long-term implications with regard to restrictive lung disease (Campbell and Hell-Vocke, 2003). The position of the scapula should also be evaluated, because Sprengel's deformity is found in up to 50% of children with congenital cervical spine anomalies (Hensinger et al, 1974). The use of magnetic resonance imaging is reserved for those children preparing to undergo surgical intervention or those with clinical evidence of neurologic abnormality (Hedequist and Emans, 2007). Cutaneous anomalies of the lumbar spine in the newborn may be evaluated by ultrasonography. This is a particularly effective method for determining the level of the conus medullaris and thus the presence of tethered cord. Computed tomography is typically not indicated in the newborn owing to concerns of unneeded radiation exposure, but if done for other reasons, it can give additional detail on spinal anatomy.

OBSTETRICAL TRAUMA

Birth trauma can be divided into two categories: fractures and neurologic injuries. *Birth fractures* most commonly involve the clavicle, with clavicular fractures occurring

in 2 per 1000 to 35 per 1000 vaginal births (Cohen and Otto, 1980; Farkas and Levine, 1950; Kaplan et al, 1998; Sanford, 1931). Birth fractures also occur in the proximal humerus (Broker and Burbach, 1990; Fisher et al, 1995), the femur (0.13 per 1000 births) (Morris et al, 2002), and even the thoracic spine. It is important to note that clavicular fracture can be seen in combination with a proximal humeral physeal separation or in combination with a brachial plexus injury. Reported risk factors for upper extremity birth fractures include large size of the baby, limited experience of the obstetrician, and a midforceps delivery (Cohen and Otto, 1980); risk factors for femoral fracture include twin gestation, breech presentation, prematurity, and osteoporosis (Morris et al, 2002). Nadas et al (1993) have reported an association of long-bone fractures with cesarean section, breech delivery with assistance, and low birthweight. The natural history of isolated birth fractures to the extremities is that of uneventful rapid healing without untoward sequelae. Clavicle fractures may be difficult to diagnose, because the neonate may be asymptomatic. In a study of 300 newborns, radiographs revealed 5 unsuspected clavicle fractures (Farkas and Levine, 1950). Newborns with either a clavicle fracture or a proximal humeral physeal separation often present with pseudoparalysis of the upper extremity. Considerations in the differential diagnosis include an obstetric brachial plexus palsy and hematogenous metaphyseal osteomyelitis of the humerus with septic glenohumeral arthritis. Pain with direct palpation of the clavicle may be present with obvious deformity. Pain with motion of the shoulder joint and with palpation of the proximal humerus may be caused by either fracture or infection. Eliciting neonatal reflexes such as the Moro reflex and asymmetric tonic neck reflex (ATNR) may be helpful in evaluating active upper extremity muscle function (Sanford, 1931). Radiographs should be obtained. Ultrasound evaluation of the proximal humerus may be helpful because the proximal humeral epiphysis is entirely cartilaginous at birth and therefore radiolucent. Ultrasound examination can detect proximal physeal separation, metaphyseal osteomyelitis, and septic shoulder arthritis (Broker and Burbach, 1990; Fisher et al, 1995).

Asymptomatic birth fractures of the clavicle and humerus in neonates can be observed. The fracture will unite in short order, with remodeling of bone with growth. Symptomatic fractures in which the child exhibits pseudoparalysis of the upper extremity should be treated with 7 to 10 days of immobilization in a soft dressing or until symptoms subside. Femoral birth fractures can be treated with a Pavlik harness with good results (Morris et al, 2002). This device provides a simple means of immobilization that is accepted well by new parents. Excellent outcomes with no residual deformities or limb length inequalities can be expected.

The presence of multiple long-bone and rib fractures at birth may herald the presence of osteogenesis imperfecta (OI). Prenatal diagnosis is commonly made at ultrasonographic screening, as early as 13 to 14 weeks' gestation on the basis of deformity (Cheung and Glorieux, 2008). OI is typically classified by the Sillence classification, with OI type II and type III being the most common types identified in the perinatal period (Sillence et al, 1979). Type II OI is lethal in the neonatal period, whereas most children with type III survive into adulthood with considerable short stature and fracture-related morbidity. Thus, prompt genetic consultation is critical to establish a diagnosis and prognosis for an affected child. Infants with type III OI often require substantial respiratory support and pain management because of rib fractures, with respiratory failure being identified as the most common cause of death in the neonatal period. Treatment of long fractures is primarily to support pain management and can be achieved by custom splints or merely soft supports, such as pillows or blankets. Patients with multiple fractures at birth who are expected to survive the neonatal period should be considered for bisphosphonate treatment (Shapiro and Sponsellor, 2009).

Brachial plexus injuries represent the second category of birth trauma afflicting newborns. The brachial plexus receives contributions from the anterior spinal nerve roots of C5 through T1. The various nerve roots combine to form trunks, which combine in turn to form divisions, which combine to form cords, which combine and divide to form the peripheral nerves that supply the motor innervation to the upper extremity. The mechanism of injury is a separation of the head from the shoulder by lateral bending of the neck with simultaneous shoulder depression during vaginal delivery resulting in a stretching of the brachial plexus. These injuries occur in 1 per 1000 to 4 per 1000 live births (Greenwald et al, 1984; Hardy, 1981). Obstetric brachial plexus palsies are most common in vertex deliveries with shoulder dystocia, in large-birthweight babies (in whom the increased size usually is secondary to maternal diabetes), and in multiparous pregnancies (Waters, 1997). It is rarely seen in cesarean section deliveries. Not all cases can be reliably predicted prepartum or prevented. Three major injuries are encountered. The most frequent injury is to the upper trunk that involves the C5 and C6 nerve roots primarily and results in an *Erb's palsy*. Affected infants lack external rotation and abduction of the shoulder. Hand function is preserved. The next most frequently occurring injury is a *global plexus palsy* involving the C5 through T1 nerve roots. This results in flaccid paralysis of the involved upper extremity, including the hand. An isolated lower plexus injury involving the C8 and T1 nerve roots, termed *Klumpke's palsy*, is the least common and may be a manifestation of a recovered global plexus injury (Waters, 1997).

The physical examination has proved to be the most reliable method of assessing the level and severity of the neural injury and thereby predicting the potential for spontaneous recovery (Noetzel et al, 2001; Waters, 1997). Myelography, computed tomographic myelography, magnetic resonance imaging, and electrodiagnostic studies have not proved useful in predicting recovery (Waters, 1997). Active shoulder, elbow, wrist, and finger motion need to be assessed. Frequently, such assessment can be facilitated by eliciting some primitive reflexes that are transiently present in normal newborns. The *hand grasp reflex* is normal in all newborns and disappears between 2 and 4 months. The examiner's little finger is placed on the ulnar aspect of the infant's palm, and the infant's fingers reflexively flex and grasp the examiner's finger. The *Moro reflex* begins to fade at 3 months of age. It is elicited by holding the newborn's hands while raising the baby off the table and then suddenly releasing them. In response, the

newborn extends the spine, abducts and extends all four limbs and digits, and then subsequently adducts and flexes the limbs and digits. Last, the ATNR, or *fencing reflex*, can be elicited in a normal newborn until the age of 4 months. With the infant lying supine on an examining table, the head is rotated to one side by the examiner. The infant should respond by extending the elbow on the side toward which the face is looking and by flexing the opposite elbow. In newborns with a brachial plexus injury, some of these reflexes will be abnormal because of lack of motor control. For instance, the newborn with an Erb's palsy will, most notably, not be able to actively flex at the elbow during the ATNR or the Moro. The presence or absence of Horner's syndrome also must be noted. The infant needs repeat serial examinations until 6 months of age.

Return of biceps function by 3 months is the most important indicator of brachial plexus recovery (Michelow et al, 1994). When biceps recovery is combined with the return of shoulder abduction, wrist extension, and finger extension, there is a 95% chance of normal function (Michelow et al, 1994). When biceps function recovers later than 3 months, it is rare for the child to have complete recovery of normal function (Waters, 1999). A total plexus palsy or the presence of Horner's syndrome also heralds a poor prognosis (Michelow et al, 1994; Waters, 1997). In one study of 142 patients with obstetric brachial plexus palsies, 50% demonstrated biceps recovery by 6 weeks, with the remainder demonstrating recovery at varying intervals beyond 6 weeks. At final follow-up evaluation, 67% had excellent shoulder function, 12% good, 5% fair, and 10% poor (Benson et al, 1996). In a similar prospective study, Waters (1999) found that 22 patients of 66 studied had return of biceps function by 3 months. Each of these went on to have normal function. Infants in whom recovery was delayed until the 4th to 6th month had significantly worse function.

The initial treatment for obstetric brachial plexus injury is aimed at avoiding contractures of the shoulder, elbow, forearm, and hand during the observation-for-recovery phase. Secondary treatment involves nerve repair and grafts to restore neurologic function that will not recover spontaneously. Finally, augmenting weak muscles, improving functional ranges of motion, and improving the appearance of residual deformities should be undertaken in children without full neurologic recovery.

Each neonate with an obstetric brachial plexus birth palsy must be referred to a pediatric orthopedist or upper extremity surgeon for early evaluation. Referral to a qualified therapist for passive range of motion exercises also is suggested. Monthly examinations by the orthopedist are undertaken. Brachial plexus exploration with subsequent reconstruction is indicated for infants with total plexus involvement, Horner syndrome, and no return of biceps function at 3 months, and for infants with a C5 to C6 (Erb's) plexopathy and no return of biceps function at 3 to 6 months (Waters, 1997). Surgery is undertaken between 3 and 6 months of age. Using this algorithm prospectively, Waters (1999) operated on 6 infants at 6 months and found that their results were better than those for the 15 patients with biceps recovery at 5 months but worse than those for the 11 patients with biceps recovery at 4 months. Despite treatment as outlined, some children will have residual deficits. Secondary reconstruction, for chronic brachial plexopathy resulting in a dysfunctional shoulder, can be achieved with a tendon transfer of the latissimus dorsi and teres major to the rotator cuff, or by derotational osteotomy of the humerus. These procedures and others designed to correct limitations in hand and forearm function are undertaken after the true scope of the disability has been assessed.

NEONATAL OSTEOMYELITIS AND SEPTIC ARTHRITIS

Osteomyelitis refers to a bacterial infection of bone, and *septic arthritis* is a pyogenic infection of a diarthrodial joint. Incidence rates of 0.12 per 1000 live births and 0.67 per 1000 neonatal intensive care unit (NICU) admissions (Ho et al, 1989) have been reported for septic arthritis. The mortality rate is reported to be 7.3% (Caksen et al, 2000). The hip, knee, and shoulder joints are involved most frequently. Neonates are particularly susceptible to osteomyelitis and septic arthritis, because of an immature immune response resulting in vulnerability to organisms that are not ordinarily virulent in infants and children, and a delay in expressing the classic physical findings associated with these conditions (Morrissy, 2001). Two subgroups of neonates are affected: premature neonates requiring prolonged hospitalization and otherwise healthy newborns who present within 2 to 4 weeks of discharge (Morrissy, 2001).

Most cases of neonatal osteomyelitis and septic arthritis result from hematogenous spread, but some occur from direct inoculation during percutaneous arterial blood sampling (especially from the femoral artery). Acute hematogenous osteomyelitis (AHO) and septic arthritis in hospitalized neonates usually occur in premature infants undergoing frequent blood drawing, invasive monitoring, intravenous feedings, and intravenous drug administration, especially in those with indwelling umbilical vessel catheters (Lim et al, 1977). These infections are frequently caused by *Staphylococcus aureus* or gram-negative organisms (10% to 15%). Up to 40% of these patients may demonstrate multiple areas of involvement characterized by swelling and tenderness and are systemically ill (Bergdahl et al, 1985; Fox and Sprunt, 1978). This contrasts with the typical out-of-hospital newborn with AHO and septic arthritis, who presents in weeks 2 to 4 of life with swelling, pseudoparalysis, and tenderness of the extremity and who feeds well and is not systemically ill (Morrissy, 2001). *S. aureus* and group B streptococci are the most common organisms encountered in this latter population.

Because of the immature immune response, neonates with AHO and septic arthritis frequently do not demonstrate fever, leukocytosis, or elevation in their erythrocyte sedimentation rates (Scott et al, 1990). However, C-reactive protein appears to be a reasonable indicator of AHO and septic arthritis (Pulliam et al, 2001; Unkila-Kallio et al, 1994). Blood cultures are positive in only 50% of patients; cultures of synovial aspirates identify an organism in only 30% (Lyon and Evanich, 1999). Plain radiographs demonstrate soft tissue swelling by 3 days, but bone changes are not present for a week after the onset of symptoms (Dormans and Drummond, 1994; Jackson and

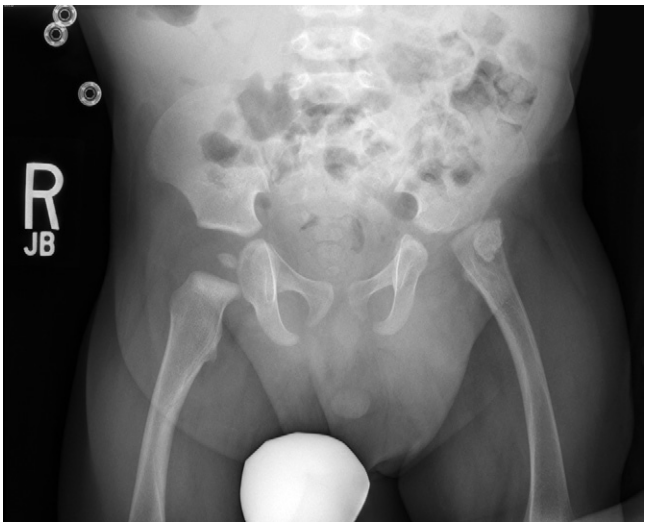

FIGURE 96-6 Unrecognized neonatal hip sepsis can result in complete dissolution of the femoral head as demonstrated in this child's left hip radiograph. This is a devastating complication, in which reconstructive options are limited.

Nelson, 1982). Bone scan is positive in only 32% of foci of osteomyelitis in neonates due to the usual location of infection near the growth plate (Ash and Gilday, 1980). Ultrasound examination has been advocated as a useful method for the diagnosis and assessment of osteomyelitis (Mah et al, 1994) and is our preferred radiologic method for evaluating the neonate with suspected AHO and/or septic arthritis.

AHO and septic arthritis coexist in up to 76% of neonates as a result of the unique blood supply of the chondroepiphysis (Bergdahl et al, 1985; Fox and Sprunt, 1978), which changes with growth. Infection begins in the metaphyseal veins. Vascular canals traverse the growth plate in the neonate, allowing for rapid spreading of the infection to the cartilaginous chondroepiphysis with subsequent abscess formation. These abscesses frequently rupture into the joint (Ogden, 1979). The growth plate becomes a barrier to the spread of infection in the older child. Additionally, the hip and shoulder, two of the more common sites of neonatal septic arthritis, have intraarticular metaphyses, allowing for a subperiosteal route of decompression for pus into the joint. Because of this unique ability to spread from the metaphysis through the growth plate into the joint, early detection and treatment are necessary to avoid permanent damage to each of these structures. The proteolytic enzymes released by the host response to infection can result in destruction of the growth cartilage and articular cartilage in short order, resulting in growth disturbances and precocious arthritis. When an area of involvement is suspected, aspiration should be undertaken (Morrissy, 2001). This may confirm the diagnosis and provide fluid for Gram stain and culture in order to better direct treatment. If pus is discovered in the neonate, surgical debridement in the operating room is required (Figure 96-6).

PART XX

DERMATOLOGIC CONDITIONS

CHAPTER 97

NEWBORN SKIN: DEVELOPMENT AND BASIC CONCEPTS

Bernard A. Cohen and Katherine B. Püttgen

SKIN DEVELOPMENT

Skin is the interface between an organism and its environment. It plays an important role in fluid balance and temperature regulation and provides a barrier against invading microbes and systemic absorption of topically applied agents. This chapter provides an overview of skin development. Emphasis is placed on factors that influence the clinical management of premature infants and the prenatal diagnosis of heritable skin diseases.

The study of skin ontogenesis has been organized primarily on the basis of the development of individual components: epidermis, basement membrane zone, dermis, immigrant cells, and appendageal structures. However, the initiation, differentiation, and growth of all of its components are intimately related. Prenatal skin biopsy for early diagnosis of severe genodermatoses is a useful procedure that depends on precise knowledge of the details of skin development. Disorders of keratinization, basement membrane integrity, melanocytes, and epidermal appendages have been detected as early as 16 weeks' gestation using this technique. In turn, fetal skin biopsy has helped to further clarify the details of epidermal development (Holbrook, 1991; Holbrook et al, 1993). Recent discoveries of genetic markers for many genodermatoses have also allowed for rapid and precise prenatal and neonatal diagnoses, and they have added to the understanding of molecular mechanisms of disease.

EPIDERMIS

The epidermis consists of ectodermally derived, stratified squamous cells with localized proliferations that form the appendages: hair follicles, sebaceous glands, eccrine sweat glands, apocrine glands, and the nail matrix. Melanocytes migrate into the epidermis from the neural crest, and Langerhans cells migrate from mesoderm. The epidermis forms initially as a single layer of indifferent ectoderm and then differentiates into two layers of epidermal cells by 6 weeks' gestation. The outermost layer, called *periderm*, covers the basal layer stem cells. During the next 2 weeks, the basal cells give rise to an intermediate layer beneath the periderm. By 8 weeks' gestation, epithelial cells are capable of expressing keratins, the major cytoskeletal proteins of the epidermis. K5 and K14 are the high-molecular-weight keratins expressed primarily by basal-layer cells, whereas intermediate-layer cells express K1 and K10 (Smack et al, 1994). Genetic abnormalities of these cytoskeletal components give rise to a spectrum of inherited scaling skin diseases that can be diagnosed by detection of specific genetic mutations and characteristic features on histologic examination and electron microscopy of skin specimens obtained by fetal skin biopsy, amniocentesis, and chorionic villus biopsy.

The 3rd month of gestation is an important period in skin development. Differentiation of the epidermis begins as two or three more layers of intermediate cells are added between the basal cells and periderm, while coordinated maturation progresses within other strata of the skin. By 22 to 24 weeks' gestation, granular cells have formed beneath the periderm. Granular cells are named for their prominent organelles, the keratohyalin granules. These granules contain a high-molecular-weight protein called *profilaggrin*, which has a crucial role in terminal differentiation of keratinocytes in the stratum corneum. Cornified cells first appear within the pilosebaceous follicle as early as 15 weeks' gestation. Interfollicular keratinization follows at 24 to 26 weeks' gestation. At 28 weeks' gestation the stratum corneum consists of two or three cell layers. By 32 weeks' gestation there are more than 15 layers of corneocytes, equivalent to that of adult skin (Holbrook, 1991).

BASEMENT MEMBRANE ZONE

Components of the basement membrane zone appear with the first epidermal cells at 35 days' gestation. Important components of the dermoepidermal junction, such as hemidesmosomes, anchoring filaments, and anchoring fibrils, are completely formed by 8 to 10 weeks' gestation. The epidermis and basement membrane generally are flat during fetal development. The undulating rete ridges that expand the surface area of the dermoepidermal junction do not appear until the third trimester and are not fully developed until 6 months after birth, which coincides with the accumulation of dermal matrix (Holbrook, 1991).

DERMIS

A network of stellate mesodermal cells is present beneath the epidermis of a 1- to 2-month embryo. The primary matrix secreted by these cells is composed of glycosaminoglycans. Hyaluronic acid is the predominant

glycosaminoglycan during the first trimester. Matrix proteins also are synthesized in the first trimester, including immature fibers resembling elastin and collagen types I, III, V, and VI. Type III and type V collagens are increased in quantity compared with adult dermis. In the 3rd month, the dermis is transformed from a cellular to a fibrous tissue, which coincides with epidermal differentiation. During months 3 to 5, the size and quantity of the matrix proteins increase, and the composition of the glycosaminoglycans changes. Immigrant cells, including Schwann cells, Merkel cells, melanoblasts, pericytes, and mast cells, are found in the dermis by the 5th month. The dermis continues to mature for approximately 6 months postnatally (Holbrook, 1991).

IMMIGRANT CELLS

Melanocytes from the neural crest and mesenchymally derived Langerhans cells migrate to the epidermis by week 8, but do not develop their characteristic organelles until after 65 days' gestation. Melanin production and transfer to adjacent keratinocytes occurs during the fourth to the fifth months, but melanin production is relatively low, even at birth. The antigen-presenting function of Langerhans cells has not been documented in utero (Holbrook, 1991).

EPIDERMAL APPENDAGES

Primordia of hair follicles, apocrine glands, eccrine sweat glands, and nails first appear at 10 to 12 weeks' gestation. The pilosebaceous unit is formed, hair is keratinized, and sebum is synthesized as early as 16 to 18 weeks' gestation. Sebum production and secretion are greatly increased in the third trimester under the influence of fetal and maternal androgens. The number of lipid-filled sebocytes in amniotic fluid has been used to assess fetal maturity. Sebaceous lipids, squalane, and wax esters constitute most of the vernix caseosa, especially in male infants. The vernix of female infants has a slightly higher proportion of cholesterol and cholesterol esters, which are lipids derived from keratinocytes (Holbrook, 1991; Nazzaro-Porro et al, 1979). Apocrine gland formation follows that of the sebaceous glands by 8 weeks' gestation. Apocrine secretion has been detected during the third trimester but not in the neonatal period. The palmoplantar eccrine sweat ducts are the first portion of the apparatus to develop. By 22 weeks' gestation, they open to the skin surface and join the differentiated secretory cells of the eccrine sweat gland. Maturation of the eccrine apparatus elsewhere on the body follows at 24 to 26 weeks' gestation. Neither the morphology of the glandular coil cells nor eccrine gland function is fully developed in the premature infant, but the full complement of the sweat glands and hair follicles is completely formed in utero, making them more densely distributed in infant than in adult skin. However, even in the full-term infant, thermal stress–induced sweating requires a greater stimulus than is needed to induce sweating in older children and adults. This functional response to heat improves with postnatal age (Green and Behrendt, 1973; Harpin and Rutter, 1982). Nail primordia begin to form at 8 to 10 weeks' gestation. Nail plate formation is initiated at 17 weeks' gestation and is complete by the 5th month (Holbrook, 1991).

TABLE 97-1 Comparison of Fetal and Adult Wound Repair

Feature	Fetus (<24 wk old)	Adult
Tissue environment	Amniotic fluid rich in growth factors and hyaluronic acid, relative hypoxemia, sterile	Air
Inflammatory infiltrate	Limited neutrophils and lymphocytes predominate	Macrophages predominate
Extracellular matrix	Nonexcessive deposition of types III and V collagen organized into a reticular pattern; increased amount of hyaluronic acid	Abundant type I collagen deposited into disorganized bundles

FETAL SKIN: WOUND HEALING

Human fetal skin wounds reportedly heal without scarring. This clinical observation, first made by surgeons who were pioneering antenatal diagnosis and treatment, has been followed by an explosion of experimental data elucidating the unique aspects of fetal wound healing (Buchanan et al, 2009; Coolen et al, 2010; Dostal and Gamelli, 1993; Longaker and Adzick, 1991; Mast et al, 1992). Wound healing in the fetus differs from that in the adult in several ways, including nature of tissue environment, inflammatory response, and components of the dermal extracellular matrix (Table 97-1). Wounds can cause scars in some human infants (Cartlidge et al, 1990; Den Ouden et al, 1986), but prospective examination of sternotomy scars (Lista and Thomson, 1988) and bacille Calmette-Guérin vaccination sites (Sivarajah et al, 1990) in children found a direct correlation between increasing age and more prominent scarring.

NEWBORN SKIN

The most clinically significant difference between the skin of premature and term infants is in the structure of the stratum corneum. Infants born before 32 weeks' gestation have a thin stratum corneum, which gives rise to a variety of problems (Rutter, 1988). The primary functions of the stratum corneum are conservation of body water and barrier protection. In premature infants the stratum corneum does not effectively prevent transepidermal water loss, percutaneous absorption of exogenously applied compounds, or invasion of microbes. In the dry postnatal environment, the premature infant experiences excessive losses of body fluid and heat (Baumgart, 1982; Rutter and Hull, 1979; Shwayder and Akland, 2005). A variety of seemingly benign clinical interventions can dramatically increase these losses. Desiccated skin is even more easily injured, providing a portal of entry for invading microbes and increasing the risk of disseminated infection (Baumgart, 1982; Gunnar et al, 1985; Harper and Rutter, 1983; Rosen et al, 1995; Rutter, 1988). A premature infant's increased ratio of body surface area to body weight, diminished metabolic capacity, and decreased immune responses compound these problems.

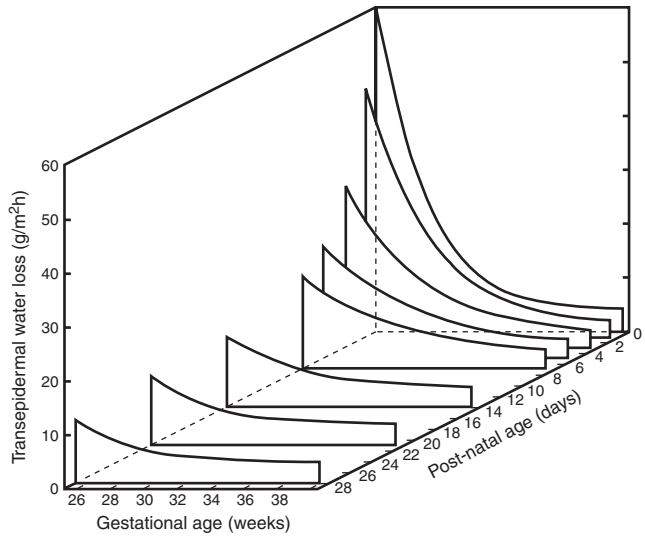

FIGURE 97-1 Transepidermal water loss in relation to gestational age at different postnatal ages in appropriate-for-gestational-age infants. *(From Hammarlund K, Sedin G, Stromberg B: Transepidermal water loss in newborn infants: VIII. Relation to gestational age and postnatal age in appropriate and small for gestational age infants*, Acta Paediatr Scand *72:721, 1983.)*

FIGURE 97-2 The cause of this full-thickness skin injury in a 26-week-old infant was innocuous enough to elude identification.

Rates of transepidermal water loss (TEWL) are objective measures of stratum corneum integrity. TEWL has been well studied in premature infants, using the evaporimeter, which provides direct measurements (Gunnar et al, 1985; Nonato and Lund, 2001). During the first 4 weeks after birth, there is an exponential relationship between TEWL and gestational age in appropriate-for-gestational-age (AGA) infants. TEWL is up to 15-fold higher in 1-day-old infants born at 25 weeks' gestation than in term neonates. In very low-birthweight infants, this TEWL can translate into a fluid loss of up to 30% of total body weight in 24 hours. As the stratum corneum develops, TEWL gradually decreases, but at 4 weeks after gestation, TEWL from an infant born at 26 weeks' gestation is still twice that of a term infant (Figure 97-1).

Loss of body water is accompanied by evaporative heat loss at a rate of 2.4 × 103 J/g (or 576 calories of body heat for every milliliter of water) (Hammarlund and Sedin, 1982; Smack et al, 1994). Evaporative losses are greatest in younger, more premature infants. Routine clinical interventions can exacerbate TEWL. Maintaining normal body temperature on an open radiant warmer bed in a nursery with low ambient humidity results in high evaporative loss of body water and heat (LeBlanc, 1991). Higher ambient temperatures are required to maintain normal body temperature under these conditions (Hammarlund and Sedin, 1982; Shwayder and Akland, 2005).

Traditional efforts to minimize these losses have centered on intravascular fluid replacement and modification of the infant's hospital bed. These approaches have inherent problems. Evaporative losses originate as free water from the extracellular compartment. Replacement has been conventionally determined by calculation based on standardized maintenance fluid requirements and measured changes of body weight and extracellular electrolytes, which have a typical lag time of several hours. Replacement fluids given in the form of isotonic intravenous solutions can result in sodium and glucose overload. Enclosed incubators with high ambient humidity carry a risk of colonization with pathogenic bacteria, although an increased incidence of infection has not been documented (LeBlanc, 1991). Shielding devices used on open radiant warmer beds limit access to infants. Furthermore, some materials used for shielding (e.g., glass, Plexiglas, Lucite, Perspex) absorb infrared energy and block overhead transmission of heat to the infant (Baumgart, 1990; LeBlanc, 1991) (see Chapter 30). Pure polyethylene plastic wraps (e.g., GLAD Wrap) are transparent to infrared heat, but plastic wrap made of more complex polymers can retain heat and have the potential to burn contacted skin (LeBlanc, 1991). More recent data have focused on limiting skin injury and developing methods to improve the cutaneous barrier.

Clinically occult skin injury accompanies routine care. Skin stripping by removal of adhesive-backed products causes acute injury as well as the potential for secondary infection and significant scarring (Baharestani, 2007; Cartlidge et al, 1990). Removal of a piece of tape or an adhesive-backed electrode will markedly compromise the stratum corneum (Cartlidge and Rutter, 1987; Harper and Rutter, 1983), an observation that has been used in a positive way to facilitate transcutaneous monitoring of serum glucose in newborns (De Boer et al, 1994). There have been several cases of full-thickness skin injuries from presumed innocuous local application of pressure or thermal heat (Figure 97-2). The precise causes of this type of wound are often difficult to identify and remain unreported. Ultraviolet light burns have occurred in association with white-light phototherapy for jaundice, from relatively limited inadvertent exposure to near-ultraviolet A (UVA) light, which is 1000 times less erythemogenic than ultraviolet B light (Siegfried et al, 1992). A Plexiglas safety shield, placed in front of daylight fluorescent bulbs, will filter out the ultraviolet A light. However, white-light phototherapy also is a source of infrared heat, and heat stress will exacerbate TEWL. In contrast, phototherapy delivered with blue light alone does not increase TEWL (see Chapter 79) (Kjartansson et al, 1992).

Increased percutaneous absorption of topically applied compounds through an immature stratum corneum has been both advantageous and hazardous to neonates,

although there has been little research on this topic in the past decade (Spray and Siegfried, 2001). A finding described in 1971 as "raccoon facies" is a visible periorbital ring of pallor from cutaneous vasoconstriction after the application of phenylephrine eye drops (Rutter, 1987). This effect can be quantified and is directly proportional to measurements of TEWL. Both methods have been established as useful markers of stratum corneum integrity in infants (Plantin et al, 1992; Rutter, 1987). Transdermal delivery may be the optimal route of administration for theophylline (Cartwright et al, 1990; Rutter, 1987) and diamorphine (Barrett et al, 1993) in premature infants. Lidocaine applied topically to premature skin probably is much more effective than after application to mature skin (Barrett and Rutter, 1994). Supplemental oxygen has been administered percutaneously to very small preterm infants with poor pulmonary function (Cartlidge and Rutter, 1988a, 1988b).

In contradistinction, numerous reports have described percutaneous toxicity in infants caused by absorption of topically applied agents (Lane, 1987; Rutter, 1987). Published accounts serve to document the most severe cases of toxicity, often manifested as nursery epidemics of obvious clinical signs or deaths (Table 97-2). The potential for subclinical toxicity must be considered by everyone caring for small newborns (Table 97-3). When several topical therapeutic options are available, the one with the least potential for toxicity should be used. *Poisindex* is an extensive, frequently updated, computer-based reference source for the identification of potentially toxic compounds (Micromedex, 2002). The information from this database and current published literature indicates a lower risk of percutaneous or systemic toxicity from chlorhexidine skin antisepsis than from povidone-iodine.

The important role of nutrition in skin maturation and wound healing can be overlooked in small, sick infants who receive maintenance nutrition with varying amounts of complex parenteral fluids. Acquired deficiencies and those resulting from inborn errors of metabolism (Table 97-4) are associated with classic cutaneous findings. Deficiencies of protein, essential fatty acids, zinc, biotin, vitamins A and C, and several B vitamins are possible. Daily requirements for most of these nutrients are higher in premature than in term infants (Table 97-5).

Attention to skin integrity will help to control translocation of water through the skin of premature neonates. Appropriate hydration of keratinocytes is essential for normal skin maturation (Rawlings et al, 1994), an optimized barrier against exogenous assault, and maintenance of thermal, fluid, and electrolyte balance. A successful basic skin care regimen should also allow easy access to and handling of infants. Therapeutic goals include minimizing postnatal trauma and providing an artificial barrier until the stratum corneum matures. Currently there is no uniformly defined or accepted standard of care for the skin of premature infants. Formal clinical investigation has been limited. A few studies have verified the safety and efficacy of semiocclusive, adhesive-backed polyurethane membrane barriers in preventing fluid losses (Barak et al, 1989; Knauth et al, 1989; Mancini et al, 1994; Vernon et al, 1990). However, these dressings are not widely used because they are difficult to apply and are thought to limit available area for surface monitors. Neonatal intensive care unit staff members often provide

TABLE 97-2 Reported Hazards of Percutaneous Absorption in the Newborn

Compound	Reference	Product	Toxicity
Aniline	Rutter, 1987	Dye used as a laundry marker	Methemoglobinemia,* death
Mercury	Dinehart et al, 1988	Diaper rinses, teething powders	Rash, hypotonia
Phenolic Compounds			
Pentachlorophenol	West et al, 1981	Laundry disinfectant	Tachycardia, sweating, hepatomegaly, metabolic acidosis, death
Hexachlorophene	—	Topical antiseptic (pHisoHex)	Vacuolar encephalopathy, death
Resorcinol	West et al, 1981	Topical antiseptic	Methemoglobinemia*
Boric acid	Goldbloom and Goldbloom, 1953	Baby powder	Vomiting, diarrhea, erythroderma, seizures, death
Lindane	Rutter, 1987; West et al, 1981	Scabicide	Neurotoxicity
Salicylic acid	Abidel-Magid and El Awad Ahmed, 1994; West et al, 1981	Keratolytic emollient	Metabolic acidosis, salicylism
Isopropyl alcohol (underocclusion)	Rutter, 1987	Topical antiseptic	Cutaneous hemorrhagic necrosis
Silver sulfadiazine	Payne et al, 1992	Topical antibiotic (Silvadene)	Kernicterus (sulfa component), argyria (silver component)
Povidine-iodine	Rutter, 1987; West et al, 1981	Topical antiseptic (Betadine)	Hypothyroidism, goiter
Neomycin	Rutter, 1987	Topical antibiotic	Neural deafness
Corticosteroids	Rutter, 1987; West et al, 1981	Topical antiinflammatory (Lotrisone)	Skin atrophy, adrenal suppression
Benzocaine	Gelman et al, 1996	Mucosal anesthetic (teething products)	Methemoglobinemia*
Prilocaine	Frayling et al, 1990; Reynolds, 1996	Epidermal anesthetic (EMLA)	Methemoglobinemia*

*Heritable glucose-6-phosphate deficiencies are associated with an increased susceptibility to methemoglobinemia, as is coadministration of several drugs such as sulfonamides, acetaminophen, nitroprusside, phenobarbital, and phenytoin.

topical emollient therapy to infants in a random way. The risks and benefits of the use of commercially available topical emollients have not been well defined. Concerns include the risk of systemic absorption and resulting toxicity, overgrowth of microbes, and secondary heat accumulation that could increase surface and core temperature.

There have been many studies of the mechanism of action and benefits of emollients on injured and diseased skin in adults. Petroleum wax–based ointment emollients (e.g., Vaseline petroleum jelly) act primarily by decreasing TEWL and accelerating barrier recovery (Ghadially and Elias, 1992). Some oils, such as safflower oil, contain essential fatty acids, which greatly influence cutaneous structure and function (Schurer et al, 1991; Ziboh and Chapkin, 1987). However, topical application of safflower oil does not prevent essential fatty acid deficiencies in preterm infants (Lee et al, 1993). Oils, oil- and water-based creams, and lotion emollients have greater tactile acceptance than has been identified for greasy ointments. However, these preparations provide a less effective moisture barrier than is conferred by ointment emollients (Lane and Drost, 1993). In addition, formulation of a cream or lotion emulsion requires the addition of several potentially irritating or toxic ingredients. Eucerin Creme is an emollient that has been studied for use in the nursery (Lane and Drost, 1993). It contains water, petrolatum, mineral oil, ceresin, lanolin alcohol, and methylchloroisothiazolinone/methylisothiazolinone (CMI/MI). Although susceptibility of premature infants to allergic contact sensitization is unknown, CMI/MI has been associated with allergic contact sensitization in up to 10% of exposed adults (Frosch et al, 1994). Aquaphor ointment contains essentially two ingredients: petrolatum in ointment—liquid (mineral oil) and solid (mineral wax) phases—and wool wax alcohol. One study documented that application of Aquaphor every 12 hours reduced TEWL, improved skin integrity, did not alter skin flora, and was associated with a significant reduction of the incidence of sepsis. No adverse effects were reported (Nopper et al, 1994). Skin surface temperature was stable, and there was no evidence of hyperthermia or burns after application of the petroleum-based emollient used under infrared warmers, even in infants receiving concomitant white-light phototherapy, confirming the results of a previous pilot study (Shwayder and Hetzel, 1989). These findings were also corroborated by Pabst et al (1999) in their study of 19 infants between 26 and 30 weeks' gestational age. Recent studies have confirmed the effectiveness and safety of topical emollients in the management of skin integrity of premature infants (Brandon et al, 2010). This study also showed that a novel noncytotoxic liquid film was as effective as the emollients, but with less manipulation of infant skin. Ahmed et al (2007) showed that inexpensive oils used on neonatal skin in the developing world may be as safe and useful as proprietary products marketed in North America and Europe. Increased understanding of the mechanisms contributing to skin development may one day provide therapy to accelerate barrier maturation in very premature infants. Until that time, therapy should be directed toward providing a safe, temporary barrier and minimizing additional skin injury. Proposed recommendations for newborn skin care are outlined in Box 97-1. A summary of dressing materials is outlined in Table 97-6.

DIFFERENTIAL DIAGNOSIS BY CUTANEOUS MORPHOLOGY

Diagnosis of skin disease is based on recognition of definitive morphology of the cutaneous examination. Dermatologists are trained to interpret the important features, including color, shape, texture, and distribution, while ignoring unimportant or misleading features. Skin disease is often categorized into morphologic groups based on the most prominent primary lesion. Use of this classification scheme helps in formulating a differential diagnosis and in directing further investigation. Important morphologic groups in neonatal dermatology are vesicles and pustules, erythroderma, collodion baby, nonblanching violaceous papules and plaques, vascular defects, pigmented lesions, and midline anomalies. Subsequent chapters in this section present more detailed information on specific disorders.

TABLE 97-3 Topically Applied Products That Should Be Used With Caution in the Newborn

Compound	Product	Concern
Triclosan	Lever 2000, liquid deodorant soaps	Risk of toxicities seen with other phenolic compounds
Propylene glycol	Emollients, cleansing agents (Cetaphil lotion)	Excessive enteral and parenteral administration has caused hyperosmolality and seizures in infants
Benzethonium chloride	Skin cleansers	Poisoning by ingestion, carcinogenesis
Glycerin	Emollients, cleansing agents (Aquanil lotion)	Hyperosmolality, seizures
Ammonium lactate	Keratolytic emollient (Lac-Hydrin)	Possible lactic acidosis
Coal tar	Shampoos, topical anti-inflammatory ointments	Excessive use of polycyclic aromatic hydrocarbons is associated with an increased risk of cancer

TABLE 97-4 Metabolic and Nutritional Disorders Manifesting With Dermatitis

Disorder	Reference
Acrodermatitis enteropathica	Goskowics and Eichenfield, 1993
Biotin-dependent multiple carboxylase deficiency	Wolf and Heard, 1991
Prolidase deficiency	Bissonnette et al, 1993
Methylmalonic acidemia	Bodemer et al, 1994; De Raeve et al, 1994
Maple syrup urine disease	Giacoia and Berry, 1993
Propionic acidemia	Bodemer et al, 1994; De Raeve et al, 1994
Citrullinemia	Goldblum et al, 1986
Cystic fibrosis	Darmstadt et al, 1992
Gaucher's disease	Sherer et al, 1993; Sidransky et al, 1992
Kwashiorkor	Goskowics and Eichenfield, 1993

TABLE 97-5 Nutritional Requirements and Cutaneous Signs of Deficiency in Infants

Nutrient	Infant's Daily Requirement		Cutaneous Signs
	Premature	Term	
Protein (g/kg/day)	2.7-3.0	2.5-2.7	"Flaky paint" scaling, hypopigmentation, peripheral edema
Linoleic acid (g/kg/day)	1.2	0.3-0.8	Alopecia, erythema with coarse scaling, erosive intertriginous dermatitis, poor wound healing
Zinc (g/kg/day)	400	100	Alopecia, acral and periorificial erosive, pustular dermatitis, poor wound healing
Biotin (g/kg/day)	6.0	5.0 (not >20)	Alopecia, intertriginous and periorificial dermatitis, generalized scaling
Vitamin C (mg/kg/day)	25	20 (not >80)	Perifollicular hemorrhages, poor wound healing, friable gums
Vitamin A (g/kg/day)	500	175 (not >700)	Generalized scaling
Riboflavin (mg/kg/day)	0.15	0.35* (not >1.4)	Intertriginous and periorificial dermatitis, mucositis
Pyridoxine (mg/kg/day)	0.18	0.25* (not >1.0)	Intertriginous and periorificial dermatitis, mucositis
Niacin (mg/kg/day)	6.8	4.25* (not >17)	Mucositis, symmetrical hyperpigmented plaques at sun-exposed sites

Adapted from Greene HL, Hambridge KM, Schanler R, Tsang RC: Guidelines for the use of vitamins, trace elements, calcium, magnesium, and phosphorus in infants and children receiving total parenteral nutrition: Report of the Subcommittee on Pediatric Parenteral Nutrient Requirements from the Committee on Clinical Practice Issues of the American Society for Clinical Nutrition 1-3, *Am J Clin Nutr* 48:1324, 1988; and Miler SJ: Nutritional deficiency and the skin, *J Am Acad Dermatol* 21:1, 1989. Used with permission.
*For full-term infants, the recommended doses of some water-soluble vitamins are probably high because toxicity has not been reported.

BOX 97-1 Proposed Guidelines for Basic Skin Care in the Newborn

Use adhesives sparingly.
- Place protective dressing (e.g., DuoDerm or Tegaderm) at sites of frequent taping (endotracheal tube and nasogastric tube placement).
- Use nonadhesive electrodes and change them only when they become nonfunctional (Cartlidge and Rutter, 1987).

Limit bathing
- Defer initial cleansing until body temperature has stabilized.
- Avoid cleansing agents for the first 2 weeks.
- Use warm water and moistened cotton pledgets in a humid environment.
- Surface cleansing is required no more than twice per week.
- If antimicrobial skin preparation is required, use short-contact chlorhexidine (except on the face).

Be aware of the composition and quantity of all topically applied agents.
- These agents include antimicrobial cleansers, diaper wipes, adhesive removers, and perineal products.
- Dispense from single-use containers, if possible.

Ensure adequate intake of protein, essential fatty acids, zinc, biotin, and vitamins A, D, and B.
- Erosive periorificial dermatitis is a sign of nutritional deficiency.

Apply a simple cream or ointment emollient every 8 hours (Nopper et al, 1994).

Guard against excessive thermal and ultraviolet exposure.
- Use thermally controlled water for bathing.
- Avoid surface monitors with metal contacts.
- Use Plexiglas shielding over daylight fluorescent phototherapy.

Protect sites of cutaneous injury with the appropriate occlusive dressing.
- Use a film dressing on nonexudative sites (Barak et al, 1989; Knauth et al, 1989; Vernon et al, 1990).
- Use a hydrogel dressing on exudative wounds.
- Maintain appropriate hydration at the skin-dressing interface.
- Remove necrotic debris with each dressing change.

TABLE 97-6 Occlusive Dressing Materials

Class	Examples	Indications
Films		
Polyurethane with out without adhesive backing	Tegaderm, Op-Site, Bioclusive, Omniderm	Superficial, non-exudative wounds, sites of friction
Microporous Teflon or silicone	Silon	
Hydrocolloids

VESICLES AND PUSTULES

Many conditions cause blisters and pustules in the newborn. Vesicles are small intraepidermal or subepidermal pockets of clear fluid. If the lesions are large (greater than 1 cm in diameter), they are referred to as *bullae*. Pustules are filled with purulent fluid. Diseases in this category range from totally innocuous and self-limited to severe and life-threatening.

A directed history, including family history of blistering diseases, and physical examination, including examination of the placenta, can focus the differential diagnosis. Small lesions in an otherwise healthy infant usually suggest a purely cutaneous process. Bullae and widespread involvement should prompt a more aggressive workup.

The initial diagnostic workup should include the following:

- Fluid aspirate taken from an intact vesicle, pustule, or scraping of the base of a ruptured vesicle or pustule for Gram stain, Wright stain, and fungal, viral, and bacterial cultures as well as for double fluorescent antibody or polymerase chain reaction when available

- Potassium hydroxide (KOH) preparation (or calcofluor white immunofluorescence) of the blister roof
- Scraping from the base of the blister for herpes viral culture or Tzanck smear
- Scraping from a carefully selected intact lesion, mounted in mineral oil, for scabies preparation
- Skin biopsy as indicated, depending on the morphology and extent of the lesions, and results of other evaluations

Differential Diagnosis

Infections Localized to Skin

- Candidiasis: KOH (or calcofluor white) preparation of the blister roof reveals pseudohyphae.
- Bullous impetigo: Wright stain reveals polymorphonuclear neutrophil leukocytes (PMNs); Gram stain shows gram-positive cocci.
- Gram-positive folliculitis: Wright stain reveals PMNs; Gram stain shows gram-positive cocci.
- Pityrosporum folliculitis: KOH preparation reveals short hyphae and spores.
- Neonatal herpes: Tzanck smear reveals viral cytopathic changes; polymerase chain reaction and immunohistochemical marker assays are highly sensitive studies and can be performed using a smear on glass slides submitted to the laboratory. Viral cultures are still the gold standard with high sensitivity and specificity. Only a small amount of blister fluid on a swab inoculated into transport media is necessary, and results may be available within 12 hours.
- Scabies: Mineral oil preparation reveals mites, ova, and feces.

Transient Noninfectious Causes

- Erythema toxicum neonatorum: Wright stain shows eosinophils.
- Neonatal pustular melanosis: Wright stain shows keratinous debris with PMNs; results of a Gram stain are negative.
- Neonatal acne: Close inspection reveals comedones.
- Milia: Wright stain shows keratinocytes only.
- Miliaria crystallina: These tiny, superficial noninflammatory vesicles represent obstruction of the sweat duct.
- Infantile acropustulosis: This pruritic condition mimics infantile scabies, but the vesicles are usually rounded, rather than elongated like burrows.
- Eosinophilic pustular folliculitis: Wright stain shows eosinophils.

Bullae and Extensive Blistering

- The bullous diseases may be life-threatening and may be impossible to distinguish from one another without skin biopsy. Appropriate therapy depends on correct diagnosis.
- Staphylococcal scalded skin syndrome: Skin biopsy reveals a split in the superficial epidermis. Culture of blister contents is negative; the locus of infection is nasopharyngeal, perianal, focus of impetigo, or abscess; mucous membranes may be red but not blistered or eroded, because the target of the staphylococcal exfoliative toxin is not present in mucous membranes.
- Congenital herpes simplex virus infection: Skin, eye, or mouth lesions are presenting signs in one third of infants. In newborns, the presenting part at delivery is most commonly affected.
- Toxic epidermal necrolysis: Skin biopsy reveals a split at the dermoepidermal junction; mucous membranes are diffusely eroded, unlike staphylococcal scalded skin syndrome.
- Bullous mastocytosis: Stroking will produce a wheal and flare (Darier's sign), and a Tzanck smear may show mast cells.
- Genetic disorders: These disorders vary in severity and probability of long-term sequelae. Early diagnosis and genetic counseling are important aspects of management.
- Epidermolysis bullosa: Blisters are most prominent at sites of friction. Familial forms are classified as epidermolytic or simplex, junctional, and dermolytic or dystrophic, based on the skin cleavage plane. Electron microscopic analysis or immunofluorescence mapping or both are required for precise diagnosis. Recently, genetic markers are being used to make a specific diagnosis in selected patients.
- Epidermolytic hyperkeratosis: Widespread erythema and blistering may be present at birth, causing confusion with epidermolysis bullosa and other blistering dermatoses. Thick, greasy, foul-smelling scales accentuated in skin creases may not become apparent until later in the 1st year of life.
- Incontinentia pigmenti: Vesicular skin lesions have a characteristic distribution along the lines of Blaschko. This striking pattern is seen with a variety of cutaneous abnormalities as a result of genetic mosaicism. Tzanck smear may show eosinophils but no multinucleate giant cells, and results of Gram staining are negative for organisms.

ERYTHRODERMA

Generalized redness and scaling in infancy have an alarming appearance and are often clinically and histologically nonspecific. An infant's general state of well-being is an important clue to the extent of the disease. Definitive diagnosis may be possible only after a period of observation. The newborn with erythroderma will have increased insensible heat and water loss requiring careful monitoring of weight, fluid and electrolytes, and body temperature. A neutrothermal and humidified environment may be necessary for the first few days of life. Topical emollients may help to control transepidermal water loss and lower the risk of infection.

Careful history, family history, physical examination, and directed laboratory evaluation may help to clarify the cause. The spectrum of disease includes common conditions limited to skin, infections, nutritional deficiencies, and immunologic disorders.

Infectious causes of erythroderma should always be considered first. The infant's skin should be carefully examined for more specific primary skin lesions. Laboratory evaluation should include complete blood cell count, KOH preparation (or calcofluor white immunofluorescence technique), Tzanck smear, and surveillance cultures of the nasopharynx,

rectum, umbilicus, conjunctivae, urine, and blood. Syphilis serologic studies and human immunodeficiency virus (HIV) assay should be considered in epidemiologically relevant locales, with initiation of empiric therapy as needed.

The diagnostic evaluation should be more aggressive in any infant who is not thriving, to search for metabolic or immunologic abnormalities. Components of the investigation should include dietary history, electrolytes, protein, albumin, alkaline phosphatase, microscopic examination of hair, and a sweat test. The results of these screening tests can suggest the need for further laboratory evaluation.

More directed laboratory evaluation includes blood smear to look for leukocyte vacuoles, HIV screening, plasma zinc determination, measurement of serum linoleic and arachidonic acids, amino acid profile, specific assays for biotinidase activity, antinuclear antibody (SS-A and SS-B) titers, quantitative immunoglobulins, tests of cell-mediated immunity, skeletal survey, hair examination, and skin biopsy.

Differential Diagnosis

Systemic infections associated with erythroderma are:

- Candidiasis
- Staphylococcal scalded skin syndrome
- Syphilis
- Acquired immunodeficiency syndrome (AIDS)

Primary Cutaneous Conditions

- Atopic dermatitis: Pruritus and involvement of the face and extensor extremities with marked sparing of the diaper area are helpful diagnostic clues.
- Seborrheic dermatitis: The diaper area and skinfolds are often prominently involved, and the eruption is asymptomatic or minimally pruritic.
- Psoriasis: Skin lesions are often sharply circumscribed, but scale may not be prominent. Psoriasis may clinically overlap seborrheic dermatitis.

Genodermatoses

Skin biopsy helps to distinguish among the ichthyosis-associated abnormalities disorders: lamellar ichthyosis, congenital nonbullous ichthyosiform erythroderma, epidermolytic hyperkeratosis, X-linked ichthyosis, multiple sulfatase deficiency, neutral lipid storage disease, Sjögren-Larsson syndrome, trichothiodystrophy, Netherton syndrome, and X-linked dominant chondrodysplasia punctata. The Foundation for Ichthyosis and Related Skin Types (www.scalyskin.org) is a useful source of information and will assist in the genetic evaluation of patients. Genetic markers for many of these disorders have been identified and may be useful for definitive diagnosis.

Ectodermal Dysplasias

Ectodermal dysplasias are a group of disorders involving abnormalities of the skin and its appendages. Excessive desquamation resembling that seen with postmaturity is a characteristic finding. The most well-recognized form is X-linked recessive hypohidrotic ectodermal dysplasia. Infants with this disorder have a decreased ability to sweat and a tendency toward hyperthermia. Clues include nail and hair anomalies as well as dysmorphic facies.

Immunologic Disorders Associated With Erythroderma

A clinical syndrome of erythroderma, diarrhea, and failure to thrive in infancy was first described in 1908 by Leiner, in association with nonsupplemented breast-feeding. Subsequently, similar signs have been reported in infants with increased susceptibility to infection. A defect in yeast opsonization was found in two infants with Leiner disease in 1972; however, this defect, present in 5% of the general population, does not define the disease. Other patients experienced dramatic clinical improvement after infusion of fresh plasma or a purified preparation containing the fifth component of complement, C5. Consequently, Leiner disease has been associated with C5 dysfunction. More recently, a variety of immunologic abnormalities with varied underlying defects have been reported in infants with similar clinical presentation; this condition has been called *syndrome of erythroderma*, *failure to thrive*, and *diarrhea in infancy* to avoid confusion (Glover et al, 1988). Other defined disorders in this category include the following:

- Primary immunodeficiencies (e.g., severe combined immunodeficiency [SCID], Wiskott-Aldrich syndrome, hyper-immunoglobulin E syndrome, Omenn syndrome)
- Secondary immunodeficiencies (AIDS, graft-versus-host disease)
- Langerhans cell histiocytosis
- Neonatal lupus
- Diffuse cutaneous mastocytosis

Metabolic and Nutritional Disorders Associated With Erythroderma

Patients with metabolic and nutritional disorders associated with erythroderma often exhibit erosive, periorificial dermatitis (see Table 97-5).

COLLODION BABY

Collodion baby represents a distinct subset of neonatal erythroderma that can be a clinical marker of a variety of underlying abnormalities. The phenotype includes parchmentlike hyperkeratosis, pseudocontractures, ectropion, eclabium, absence of eyebrows, and sparse hair. These infants have defective cutaneous barrier function, with resultant losses of free water and thermal energy. They are extremely susceptible to hypothermia, hypernatremic dehydration, and percutaneous infection. Although the collodion membrane desquamates in 15% of affected infants, leaving normal skin, the majority develop one of the ichthyosis variants (Oji and Traupe, 2009).

NONBLANCHING VIOLACEOUS PAPULES AND PLAQUES

Nonblanching violaceous papules and plaques may be localized or disseminated. Infants with widespread lesions have been described as *blueberry muffin babies*. The diseases in this category represent a variety of processes; most require aggressive evaluation and treatment.

Initial evaluation of a blueberry muffin infant should include complete blood cell count with white blood cell

differential; platelet count; reticulocyte count; liver function tests; maternal and neonatal TORCH (toxoplasmosis, other infections, rubella, cytomegalovirus infection, and herpes simplex) infectious agent titers; rapid plasma reagin (RPR) or similar syphilis assay; blood cultures for bacteria; urine, nasopharyngeal swab, and rectal swab samples for viral cultures; and ophthalmologic examination.

A skin biopsy specimen is necessary to distinguish simple hemorrhage into the dermis (purpura) from other infiltrative conditions (e.g., dermal hematopoiesis, tumor) manifesting in the neonatal period.

Differential Diagnosis

Purpura

Ecchymoses: These lesions constitute traumatic purpura, usually secondary to labor and delivery.

Bland thrombosis: Conditions in this category that can occur in the neonatal period include the following:

- Embolization of foreign material: this has been noted in infants receiving extracorporeal membrane oxygenation (ECMO).
- Purpura fulminans: neonatal purpura fulminans is most often associated with homozygous protein C or protein S deficiency (Knoebl, 2008; Marlar et al, 1989)
- Cryoglobulinemia: rarely occurs as a result of transplacental transfer of a monoclonal immunoglobulin G cryoglobulin (Laugel et al, 2004)

Infectious vasculitis: Purpuric lesions represent infectious, inflammatory microemboli, most commonly associated with the following:

- Gram-negative bacterial sepsis, including that due to *Escherichia coli* or meningococci, and ecthyma gangrenosum (*Pseudomonas* spp.)
- Listeriosis
- Aspergillosis

Thrombocytopenia, usually manifested by widely scattered petechiae

Isoimmune thrombocytopenic purpura

Maternal isoimmune thrombocytopenic purpura

Disseminated intravascular coagulopathy

Dermal Hematopoiesis

Dermal hematopoiesis is the histologic basis for the blueberry muffin skin lesions. Before 34 weeks' gestation, the skin serves as a hematopoietic center. It has yet to be shown whether blueberry muffin lesions are due to persistence or recurrence of this fetal potential.

- Rubella
- Cytomegalovirus infection
- Syphilis
- Other viral infections (e.g., coxsackievirus B2 infection)
- Twin-to-twin transfusion syndrome
- Rh hemolytic disease of the newborn

Malignancy

- Congenital leukemia
- Langerhans cell histiocytosis
- Neuroblastoma

VASCULAR DEFECTS

Although it can be difficult to distinguish among the various cutaneous vascular lesions in the neonatal period, attention to morphologic findings, location, distribution, patterns, and clinical course usually allows for a specific diagnosis. Lesions that lack distinctive findings can be diagnosed by gathering additional data from ultrasound imaging, magnetic resonance imaging, and skin biopsy.

Differential Diagnosis

Hemangioma

Hemangioma is the most common tumor of infancy. It usually becomes apparent during the first 2 to 4 weeks after birth and exhibits a characteristic rapid growth phase, peaking at 3 to 6 months in most infants followed by slow involution over the next 5 to 10 years. Although these lesions usually are not associated with extracutaneous findings, hemangiomas in special locations require further evaluation (Guggisberg et al, 2004):

- Lumbosacral and anogenital examination to exclude lumbosacral spine anomalies
- Large facial, scalp, neck, thoracic (PHACES syndrome) examination to exclude cardiac and posterior fossa anomalies
- Beard distribution to monitor and evaluate the airway
- Large segmental examination to evaluate for vascular and soft tissue anomalies of the involved area.

Vascular Malformations

Vascular malformations are a group of lesions, usually apparent at birth, that do not generally grow or involute. Salmon patches occur in 80% of infants in characteristic locations and usually fade or become camouflaged by normal pigment or hair. Port wine birthmarks, present in 0.3% of newborns, are capillary malformations that persist in childhood and become more prominent in later adolescence and adult life. Venous malformations are also present at birth and have a baglike or wormlike texture because of the larger vessels involved and their typical location in the deeper dermis and/or subcutaneous fat. Arteriovenous and lymphatic malformations are much less common and may pose difficult management problems.

Some vascular malformations are associated with characteristic extracutaneous abnormalities:

- Nevus flammeus (port wine stain)
- Klippel-Trénaunay syndrome
- Cobb syndrome
- Arterial, lymph, venous, or mixed malformations
- Cutis marmorata telangiectatica congenita

Lesions That Mimic Vascular Birthmarks

- Pilomatrixoma
- Giant juvenile xanthogranuloma
- Langerhans cell histiocytosis
- Congenital myofibromatosis

PIGMENTED LESIONS

Although a skin biopsy specimen may be necessary to distinguish these lesions, morphologic clues often aid in clinical diagnosis. Most of these lesions are benign, but some require careful monitoring. In general, skin biopsy of a congenital pigmented lesion can be postponed until after the neonatal period. The one exception is a nodular lesion suggestive of melanoma (see Chapter 101).

Differential Diagnosis

- Congenital nevocellular nevus: tend to have fuzzy borders, variable pigmentation and texture, and may have areas with coarse dark hair
- Café au lait macule: sharp edges, uniform pigmentation, no texture
- Nevus spilus (speckled lentiginous nevus): café au lait background component with variably pigmented and textured darker papules scattered throughout
- Mongolian spot: fuzzy borders, flat patches, blue-green-gray color
- Smooth muscle hamartoma: café au lait pigmentation with increased hair
- Plexiform neurofibroma: large soft compressible spongy mass often overlying large café au lait macule
- Nevus of Ota: Mongolian spot on the face particularly around the eye; unlike mongolian spots, these lesions often do not fade
- Epidermal nevus: warty linear plaques that follow the lines of Blaschko
- Urticaria pigmentosa, solitary mastocytoma: golden brown papules with fuzzy borders, leathery texture that urticate with rubbing (Darier's sign)
- Lentigines: large dark freckles that do not fade in the winter

MIDLINE FACIAL LESIONS

See Chapter 101 for a more detailed discussion of midline facial lesions. The main types are as follows:

- Dermoid: firm rubbery nodules typically in a baseball cap distribution on the forehead or scalp
- Nasal glioma: spongy mass arising from the base of the nose; mimics a hemangioma and communicates with the central nervous system
- Encephalocele: direct communication with the central nervous system; may be anywhere along the midline scalp or neck

CHAPTER 98

Congenital and Hereditary Disorders of the Skin*

Mark M. Tran and Bernard A. Cohen

The heritable disorders of skin—the genodermatoses—feature diverse aberrations of color, texture, and structural integrity of the epidermis, epidermal appendages, and connective tissue. Some of these diseases are cutaneous only; others are associated with anomalies of multiple organ systems. Many genodermatoses can be diagnosed prenatally by skin biopsy (Holbrook et al, 1993) (Box 98-1). This technique is being replaced, however, by molecular diagnostic methods as the genetic nature of most of these disorders is identified. Enormous progress has been made in the last few years in elucidating the molecular genetics responsible for many of the dermatoses in this chapter. The National Institutes of Health manages databases of genetic diseases through the National Center for Biotechnology Information that can be accessed online, including the Online Mendelian Inheritance in Man (www.ncbi.nlm.nih.gov/omim) and Entrez Gene (www.ncbi.nlm.nih.gov/gene). GeneDx is a private company that specializes in genetic testing for rare hereditary disorders (www.genedx.com). With these exciting new discoveries comes the hope for novel and more efficacious therapies.

GENODERMATOSES AND MOSAICISM

A genetic mosaic is an organism composed of two or more genetically different populations of cells that originate from one zygote. When the skin is involved, unique patterning is seen, reflecting the cellular heterogeneity. Variations of this striking pattern were clinically described and mapped in 1901 by Alfred Blaschko. The distribution is known as *Blaschko's lines*. Blaschko's lines are distinct from dermatomes, skin tension lines, and lines of lymphatic drainage. The pattern is linear and whorled and may be bilaterally symmetric, with a midline demarcation (Figure 98-1). An anatomic equivalent has been described in the eyes and teeth (Bolognia, 1994).

Several diseases are expressed in this fashion. The first to be recognized were X-linked disorders. Affected females are obligate heterozygotes because of the Lyon effect of X-inactivation. Examples include female carriers of the X-linked recessive disorder hypohidrotic ectodermal dysplasia and females with the X-linked dominant disorders, incontinentia pigmenti, chondrodysplasia punctata, CHILD syndrome (see later), and focal dermal hypoplasia. These conditions are seen almost exclusively in females, presumably because they are lethal in males. Autosomal mosaicism is not heritable unless the germ cells are affected (Happle, 1993).

*This chapter includes material from a chapter in the previous edition, to which Elaine C. Siegfried and Nancy B. Esterly contributed.

SPECIFIC GENODERMATOSES

ICHTHYOSES

The *ichthyoses* are a diverse group of heritable and acquired skin disorders that share the primary problem of widespread scaly, dry skin. Several distinct types of ichthyosis have been described on the basis of their clinical and histologic features and by their patterns of genetic transmission (Krug, 2009; Williams, 1983, 1986); however, nosology is constantly evolving. Several types of ichthyoses are primary disorders of cornification, with manifestations confined to the skin. Ichthyosiform syndromes have characteristic extracutaneous manifestations. More precise diagnostic criteria and better treatments are being recognized through collaborative research efforts, including genetic analysis. The National Registry for Ichthyosis and Related Disorders was created in 1995 to aid in this effort and can be contacted by telephone at (800) 595-1265. The Foundation for Ichthyosis and Related Skin Types is a privately funded national organization providing information and support for families with these disorders (for contact information, see Box 98-2).

Ichthyoses That Manifest in the Neonatal Period

Three ichthyosiform conditions have alarming presentations at birth. Two of these, the collodion baby and harlequin ichthyosis, have been historically described as distinct entities based on the associated striking and unique clinical appearance. Long-term survival of affected infants and more refined diagnostic studies have permitted identification of these conditions as phenotypically distinct but genotypically heterogeneous. A third condition, epidermolytic hyperkeratosis (autosomal dominant bullous congenital ichthyosiform erythroderma), has an equally striking neonatal appearance. Another severe category of infantile ichthyosis, congenital nonbullous ichthyosiform erythroderma–lamellar ichthyosis, presents a difficult diagnostic and management problem. Recognition of these conditions and appropriate management are vital to the survival of these infants.

Collodion Baby

Neonates affected with the uncommon condition termed *collodion baby* have a pathognomonic appearance. With time, they usually manifest more specific features of one of the ichthyoses.

Clinical Findings

Collodion babies are often premature and small for gestational age. Their skin is parchmentlike, shiny, and thickened at birth, distorting their facial features with ectropion and

eclabium, flattening the ears, and resulting in pseudocontractures of the digits (Figure 98-2). Histologic examination of the skin at this stage has been nonspecific, revealing a markedly thickened, compact stratum corneum. Nonetheless, these infants have an ineffective barrier against transepidermal water loss and invasion of pathogenic microbes, with accompanying temperature instability.

Causes

Several genetically distinct outcomes have been reported for the collodion baby phenotype (Table 98-1). Two thirds of these infants have nonbullous ichthyosiform erythroderma. Fifty-five percent of patients have mutations in the transglutaminase-1 gene (Farasat et al, 2009). Fifty percent of affected infants have no family history suggestive of ichthyosis (Pongprasit, 1993).

Diagnosis

Skin biopsy can be helpful, but is not likely to be specific until after the collodion appearance has resolved. Diagnostic studies should be carefully selected, based on the evolution of the cutaneous findings, associated abnormalities, and family history (see Table 98-1). Several outcomes have been reported,

BOX 98-1 Genodermatoses Diagnosed Prenatally Using Fetal Skin Samples

- Epidermolysis bullosa
  - Junctional
  - Recessive dystrophic
  - Dominant dystrophic
  - Epidermolysis bullosa simplex (general)
  - Epidermolysis bullosa simplex—Dowling-Meara
  - Unidentified forms
- Keratinization disorders
  - Bullous congenital ichthyosiform erythroderma
  - Nonbullous congenital ichthyosiform erythroderma/lamellar ichthyosis
  - Harlequin ichthyosis
  - Sjögren-Larsson syndrome
- Pigment disorders
  - Tyrosinase-negative oculocutaneous albinism
  - Congenital nevus
  - Incontinentia pigmenti
- Disorders of epidermal appendages
  - X-linked hypohidrotic ectodermal dysplasia
  - Autosomal-recessive anhidrotic ectodermal dysplasia
- Other disorders
  - Tay syndrome
  - Chédiak-Higashi syndrome
  - Griscelli syndrome
  - Restrictive dermopathy

including complete healing without sequelae (Frenk and de Techtermann, 1992; Shwayder and Ott, 1991). A prolonged period of observation may be required to determine the precise diagnosis and prognosis. Genetic counseling should be provided as soon as a definite diagnosis has been made.

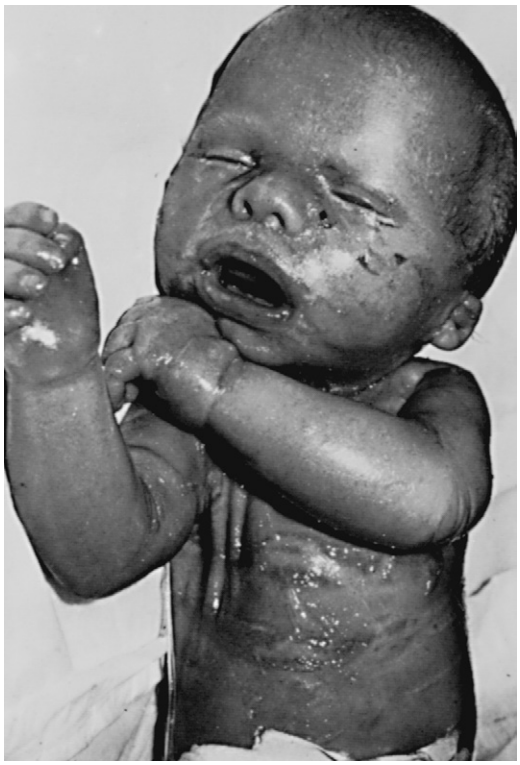

FIGURE 98-2 Collodion baby. Note the ectropion, eclabium, and areas of rupture in the membrane over the anterior thorax.

Treatment

Complications include marked temperature instability, defective barrier function, increased insensible water loss predisposing to hypernatremic dehydration (Buyse et al, 1993), pneumonia secondary to aspiration of squamous material in the amniotic fluid, and cutaneous infections from gram-positive organisms and *Candida albicans*.

Treatment consists of aggressive supportive care. Infants must be placed in a highly humidified incubator. Fluid and electrolyte balance must be monitored closely. A high index of suspicion must be maintained for signs of cutaneous or systemic infection; however, overzealous administration of antibiotics can lead to gram-negative infections and subsequent septicemia. Topical skin care should include application of a bland, occlusive ointment emollient every 6 to 8 hours until the hyperkeratosis has resolved. Potentially toxic topical agents should be avoided because of the increased risk of percutaneous absorption. Manual debridement is not indicated. The eyes should be protected with a bland lubricating ointment; aggressive surgical management of ectropion is almost never necessary. Systemic retinoids have not been useful (Waisman et al, 1989). With optimal supportive care, the thickened stratum corneum usually resolves in 2 to 4 weeks but can persist, especially in infants with lamellar ichthyosis.

Harlequin Ichthyosis

Harlequin ichthyosis is a rare congenital abnormality with more striking appearance and a graver prognosis than for collodion baby. Most infants are stillborn or die in infancy. Survival beyond infancy has been possible only recently. The harlequin phenotype is inherited as

TABLE 98-1 Collodion Baby: Differential Diagnosis and Laboratory Evaluation

Diagnosis	Inheritance	Associated Abnormalities	Diagnostic Tests*
Nonbullous ichthyosiform erythroderma (>60%)	AD, AR	—	Histologic findings are nonspecific; fetal skin biopsy is unreliable; the gene defect has not been identified
Lamellar ichthyosis	AD, AR	Persistent ectropion	Histologic findings are nonspecific; fetal skin biopsy is unreliable; the gene defect has been identified
X-linked ichthyosis	X-linked recessive	Maternal failure to initiate labor; hypogonadism, undescended testes; corneal opacities (carrier females and affected males)	Histologic findings are nonspecific; decreased serum cholesterol sulfate and steroid sulfatase activity; the gene defect has been mapped to Xp22.3
Netherton syndrome	Sporadic	Ichthyosis linearis circumflexa, atopic diathesis, impaired cellular immunity	Histologic findings are nonspecific; microscopic examination of hair shaft reveals pathognomonic trichorrhexis invagina
Gaucher disease	AR	Hepatosplenomegaly, thrombocytopenia, neurologic abnormalities	Liver biopsy; β-glucocerebroside activity; the gene defect has been mapped to 1q21 and sequenced
Trichothiodystrophy (Tay syndrome)	AR	Progeric facies, neurologic abnormalities, hypogonadism, cataracts, dental problems	Hair analyses: polarizing light microscopic examination reveals characteristic banding; there is decreased content of sulfur-rich matrix proteins
Sjögren-Larsson syndrome	AR	Spasticity, retardation, seizures	Pathognomonic retinal changes; fibroblast culture for fatty alcohol oxidoreductase activity
No detectable abnormality (lamellar exfoliation of the newborn)	AR, sporadic	—	Watchful waiting

Data on diagnostic tests from Paller AS: Laboratory tests for ichthyosis, *Derm Clinics* 12:99-107, 1994.
AD, Autosomal dominant; *AR*, autosomal recessive.
*In the immediate neonatal period, skin biopsy findings may be nonspecific. Histologic evaluation can be postponed until after age 3 to 6 months.

FIGURE 98-3 Harlequin fetus. *(Courtesy Marvin Cornblath.)*

an autosomal recessive trait; several biochemical defects probably underlie the clinical condition. *ABCA12* mutations have been identified in patients in recent investigations (Thomas et al, 2006).

Clinical Findings

The cutaneous scale is firm and platelike, distorting and flattening the nose and ears. Skin rigidity also causes deep fissures, marked ectropion, eclabium, and pseudocontractures of all joints. Chemosis of the conjunctivae obscures the globes. The nails and hair are hypoplastic or absent (Figure 98-3). Primary extracutaneous abnormalities are not prominent.

Diagnosis

The diagnosis is made by the pathognomonic appearance. The light microscopic examination always demonstrates compact hyperkeratosis. Additional light and electron microscopic abnormalities of the stratum corneum have not been identified consistently, supporting the theory that harlequin ichthyosis represents a common phenotype for several different genetic errors of cornification (Hashimoto et al, 1993).

Causes

The cause of harlequin ichthyosis is unknown. Although abnormalities of keratinization and epidermal lipid metabolism have been reported, few affected infants have been studied (Dale and Kam, 1993) with one recent report of a de novo deletion of 18q21 (Smith et al, 2001).

Prognosis and Treatment

Treatment consists of supportive care in a humid, temperature-controlled environment and frequent application of topical emollients to the skin and mucosal surfaces, as for collodion baby (Prasad et al, 1994). Nevertheless, infants given these therapies almost invariably succumb to their disease from sepsis, inability to feed, and inadequate ventilation. Survival beyond 6 weeks was extremely unusual before the use of oral retinoids. Recent reports have documented successful therapy of several affected infants using oral retinoids, with improved quality of life and survival well into childhood. Etretinate has been used most often in the past, at doses of 1 mg/kg/day. Although approval of this drug has been withdrawn by the U.S. Food and Drug Administration, isotretinoin has been used at a dose of 0.5 mg/kg. Infants receiving retinoids must be monitored for toxic effects (Harvey et al, 2010). All survivors have had severe ichthyosis as an outcome; some have intellectual impairment. Genetic counseling for the families of these infants is mandatory. Prenatal diagnosis may be made with a fetal skin biopsy specimen (Holbrook et al, 1993).

Epidermolytic Hyperkeratosis (Congenital Bullous Ichthyosiform Erythroderma)

Epidermolytic hyperkeratosis (EHK) is rare, with an estimated incidence of 1 in 250,000 births. Neonates with EHK are born with generalized erythroderma and blistering. The clinical appearance shares cutaneous features of other infantile bullous disorders, especially epidermolysis bullosa (EB). Molecular defects responsible for EHK have recently been identified with mutations found to be associated with the keratin *K1* and *K10* genes (Covaciu et al, 2010; Morais et al, 2009).

Clinical Findings

Infants may be born with generalized erythroderma and blistering. Hyperkeratosis may not be readily apparent. The neonatal course is complicated by temperature instability, susceptibility to hypernatremia, and sepsis, as in the other severe neonatal ichthyoses. With time, the skin changes evolve to include characteristic ridged scales, accentuated in the flexural areas. Palms and soles usually are involved. Excessive bacterial colonization often causes a distressingly foul odor. There are no extracutaneous manifestations.

Diagnosis

There is significant clinical similarity to other bullous disorders of infancy, including EB, toxic epidermal necrosis, and staphylococcal scalded skin syndrome (Cheng et al, 2009). Precise diagnosis can be lifesaving. Skin biopsy should be performed emergently, with examination of frozen sections. The histologic features of EHK are distinctive, showing intercellular edema and coarse, clumped material in the upper granular layers of the epidermis. Prenatal diagnosis is possible with a fetal skin biopsy specimen (Holbrook et al, 1993).

Causes

EHK is transmitted in an autosomal dominant fashion, with a high rate of spontaneous mutation. Ultrastructural analysis of skin from affected patients suggests an abnormality of keratin filaments in the suprabasal cells. Molecular analysis of affected families has identified genetic mutations in the genes encoding the synthesis of the keratin filaments that are preferentially expressed in the superficial epidermis, *K1* (located within the type I keratin gene cluster at chromosome 17q) and *K10* (located within the type II keratin gene cluster at chromosome 12q) (Francis, 1994; Nirunsuksiri et al, 1995; Smack et al, 1994; Steijlen et al, 1994a). A recent study has shown that these genetic mutations were due to a splice site and deletion mutations of the types I and 10 of keratin (Virtanen et al, 2003). The disorder also can be expressed in mosaic fashion as an epidermal nevus oriented along the lines of Blaschko (Paller, 1994). Prenatal studies for EHK may

FIGURE 98-4 Large dark scales characteristic of lamellar ichthyosis on the leg of an affected infant.

be indicated for the offspring of parents with extensive epidermal nevi.

Prognosis and Treatment

Infants with widespread blistering should be managed according to the same principles and techniques used for collodion babies. Attention to gentle handling will minimize further trauma. Application of a nonadhesive bioocclusive dressing (e.g., hydrogel, foam) will promote healing of denuded areas. Infants should be monitored closely for the development of secondary infection.

Nonbullous Congenital Ichthyosiform Erythroderma (Lamellar Ichthyosis)

The nonbullous form of infantile ichthyosiform skin disease, as distinct from the bullous variety (i.e., EHK), initially was characterized by its severity and autosomal recessive inheritance pattern. The term *nonbullous congenital ichthyosiform erythroderma* (NCIE) generally refers to a milder clinical variant. Recent studies suggest the mutation in NCIE lies in the *ALOX12B* gene encoding lipoxygenase (Akiyama et al, 2010). Ultrastructural differences have been described in skin biopsy specimens. The phenotypically more severe lamellar ichthyosis has proved to be genetically distinct, characterized by a defect in the transglutaminase-1 gene (Russell et al, 1995).

Clinical Findings

These conditions are characterized by congenital erythroderma and a varying degree of generalized scaling. The face, flexural sites, palms, and soles are also involved. A majority of collodion babies have these types of ichthyosis. In lamellar ichthyosis, the scales evolve to be thick, dark, and plate-like (Figure 98-4). Facial involvement causes chronic ectropion. Hair growth may be sparse, and nails may be dystrophic. Children with NCIE have generalized erythema with finer, white scales. There is no associated ectropion. Secondary cutaneous infections with bacteria, yeasts, and dermatophytes are common complications.

Diagnosis

Before genetic advances, the diagnosis of these forms of ichthyosis had been based on clinical features alone. Findings from a skin biopsy specimen are nonspecific; a normal granular layer is present. The differential diagnosis includes other causes of erythroderma and collodion baby (see Chapter 97). Prenatal diagnosis is possible for affected families (Holbrook et al, 1993). For patients without a previously defined family history, the appropriate laboratory assessment can be arranged through the National Registry for Ichthyosis and Related Disorders.

Causes

A majority of cases are inherited in an autosomal recessive fashion, but an autosomal dominant form of lamellar ichthyosis also has been described. Russell et al (1995) identified a common locus of genetic mutations identified in several families with recessive lamellar ichthyosis. The linked defects, located on chromosome 14, result in production of abnormal transglutaminase-1. This enzyme normally promotes cross-linking of intracellular proteins in the stratum corneum during terminal differentiation (Huber et al, 1995). New research has revealed genetic heterogeneity with two other loci on chromosomes 2 and 19. In addition, a locus on chromosome 3 was identified that was clinically consistent with NCIE (Fischer et al, 2000).

Prognosis and Treatment

The same management principles recommended for neonates presenting with the collodion baby phenotype can be applied to infants with erythroderma, although their neonatal course is marked by fewer complications. The mainstay of therapy for children with lamellar ichthyosis is the use of topical emollients and keratolytic agents. Successful treatment with topical calcipotriol has been described previously (Delfino et al, 1994; Russell and Young, 1994). Any topically applied agent will be transcutaneously absorbed to a much higher degree than through normal skin; dosing must be monitored carefully (Abdel-Magid and el-Awad, 1994; Lucker, 1994). Treatment with systemic retinoids

has had variable success (Steijlen et al, 1994b; Waisman et al, 1989).

Ichthyosiform Syndromes

Several syndromes manifesting in the neonatal period have ichthyosis as a major feature.

Recessive X-linked Ichthyosis

Recessive X-linked ichthyosis (RXLI) is an uncommon condition, affecting 1 in 6000 males. Signs of the disorder are present at birth in one fifth of affected infants; 85% develop skin changes by 3 months of age. The characteristic cutaneous finding is coarse, brownish scaling, most prominent on the neck and extensor extremities. The palms and soles are spared. Extracutaneous manifestations include hypogonadism and cryptorchidism, present in up to 25% of affected males. Severely affected males may have short stature and mental retardation, a variant that has been referred to as *Rud syndrome*. Characteristic corneal opacities are seen in affected males and heterozygote females, but usually not until late childhood or adolescence. Carrier females experience failure to initiate labor or prolonged labor. Light microscopic and ultrastructural findings in skin biopsy specimens are unremarkable. The pathogenesis of recessive X-linked ichthyosis is aberrant production of the enzyme steroid sulfatase (a form of arylsulfatase C), with accumulation of cholesterol sulfate (Cañueto et al, 2010; Williams, 1986). The genetic abnormality has been localized to the distal short arm of the X chromosome (Xp22.3), and prenatal diagnosis can be made with fluorescence in situ hybridization analysis (Watanabe et al, 2003).

Netherton Syndrome/Ichthyosis Linearis Circumflexa

Netherton syndrome is a rare, autosomal recessive condition. It often manifests at birth as ichthyosiform erythroderma with flexural accentuation. The characteristic migratory, polycyclic lesions with a peripheral double-edged scale, referred to as *ichthyosis linearis circumflexa*, do not appear until after 2 years of age. The syndrome is characterized by congenital ichthyosis, hair shaft defects (principally trichorrhexis invaginata), and atopic features (pruritus, hay fever, facial angioedema, and elevated immunoglobulin E), but until the advent of genetic testing, diagnosis in affected children often was not possible for the first several years of life (Judge et al, 1994b). Generalized aminoaciduria and impaired cellular immunity also have been reported. This distinctive pattern of ichthyosis linearis circumflexa can also manifest as an isolated cutaneous condition. Recently, pathogenic mutations in Netherton syndrome were localized to the *SPINK5* gene at chromosomal locus 5q32, which encodes the serine protease inhibitor LEKTI (Chavanas et al, 2000; Hewett et al, 2005). Subsequently, prenatal testing for the disorder was successfully attempted (Müller et al, 2002; Sprecher et al, 2001).

Sjögren-Larsson Syndrome

Sjögren-Larsson syndrome, inherited as an autosomal recessive disorder, usually manifests at birth with ichthyosiform erythroderma. The syndrome includes features that become evident only after the neonatal period: spastic diplegia, characteristic retinal lesions ("glistening dots"), and mental retardation. The diagnosis is supported by finding reduced or absent enzymatic activity of fatty aldehyde dehydrogenase from cultured skin fibroblasts, amniocytes, or chorionic cells (van den Brink, 2004). The genetic disorder that causes Sjögren-Larsson syndrome has been mapped to a locus on chromosome 17p11.2 that codes for a fatty aldehyde dehydrogenase (De Laurenzi, 1996).

Chondrodysplasia Punctata Syndromes (Conradi and Conradi-Hünermann Syndromes)

The chondroplasia punctata syndromes are a loosely defined group of syndromes sharing distinctive skin and bone abnormalities that are present at birth but may disappear with time. The skin lesions consist of patterned hyperkeratosis along the lines of Blaschko. Orthopedic abnormalities (including asymmetrical shortening of the long bones) prompt radiologic evaluation that reveals chondrodysplasia punctata, characterized by punctate calcifications of the epiphyses and cartilage. Abnormal facies and cataracts are associated features. Autosomal dominant, autosomal recessive, and X-linked dominant forms have been reported, and variable expressivity may reflect different patterns of X-inactivation (Ausavarat et al, 2008). The genetic abnormality associated with X-linked dominant Conradi syndrome has now been mapped to the *EBP* gene locus at Xp11.22-p11.23, which codes for a sterol isomerase (Braverman et al, 1999; Derry et al, 1999). Plasma sterol analysis has been found to be a highly specific and sensitive indicator of the presence of an EBP mutation in females with possible chondroplasia punctata syndrome (Herman et al, 2002).

CHILD Syndrome

CHILD syndrome is characterized by a striking phenotype consisting of *c*ongenital *h*emidysplasia, unilateral *i*chthyosiform erythroderma, and *L*imb *d*efects and also is known as *unilateral congenital ichthyosiform erythroderma*. CHILD syndrome is an X-linked disorder that shares some features with the X-linked dominant Conradi syndrome, with CHILD syndrome classically showing extreme lateralization and asymmetric skin lesions compared to the Conradi syndromes (Konig et al, 2002). Most cases of CHILD syndrome are caused by a mutation of the NADPH steroid dehydrogenase–like (NSDHL) protein gene, which has been mapped to Xq28 (Grange et al, 2000; Konig et al, 2000). This steroid dehydrogenase functions upstream of the sterol isomerase, which is defective in X-linked dominant Conradi syndrome in the cholesterol biosynthesis pathway. There have also been cases of mutations in the same *EBP* gene of X-linked Conradi syndrome that also included CHILD syndrome (Traupe and Has, 2000).

Keratitis-Ichthyosis-Deafness Syndrome

Keratitis-ichthyosis-deafness syndrome is a rare disorder of autosomal dominant inheritance (Wilson et al, 1991) that consists of congenital ichthyosiform erythroderma with characteristic pebbly palmoplantar thickening; abnormalities of the nails, hair, and teeth; vascularizing keratitis; and sensorineural deafness (Messmer et al, 2005). A few affected patients have died in infancy from overwhelming

sepsis (Caceres-Rios et al, 1996) or in adulthood from malignant proliferating pilar tumors (Nyquist et al, 2007). Recent evidence points to a mutation in connexin 26, encoded by the *GJB2* gene, as the pathogenesis of this disorder (Titeux et al, 2009; van Steensel et al, 2002).

Neutral Lipid Storage Disease

Neutral lipid storage disease, or Chanarin-Dorfman syndrome (CDS), consists of nonbullous congenital ichthyosiform erythroderma, myopathy, neurosensory deafness, and cataracts. Inheritance is autosomal recessive. Vacuolated leukocytes from lipid droplets, seen on peripheral smear, help to establish the diagnosis (Judge et al, 1994a). This disease is characterized by an intracellular accumulation of triacylglycerol droplets. Mutations in a newly discovered protein of the esterase-lipase-thioesterase subfamily, CGI-58, encoded by the *CDS* locus at 3p21, appear to be the cause of this disease (Lefèvre et al, 2001).

Trichothiodystrophy

Trichothiodystrophy (TTD) is a disorder of autosomal recessive inheritance that includes a spectrum of ectodermal abnormalities: congenital ichthyosis (sometimes manifesting initially as collodion baby), brittle hair, and short stature (Kousseff, 1991). More severely affected patients have a constellation of features that has been referred to as *Tay syndrome*. These features include abnormal dentition, cataracts, nail dystrophy, progeric facies, and photosensitivity, with an increased incidence of skin cancers and a wide variety of central nervous system (CNS) abnormalities (Faghri et al, 2008). Diagnosis is supported by detection of characteristic alternating light and dark bands within the hair shaft on examination under polarizing microscopy. Further analyses of hair and nails reveal a decrease in the sulfur-rich proteins (Itin and Pittelkow, 1990).

The genetic mutations that cause TTD are the subject of active research. Two genes implicated in TTD, *XPB* and *XPD*, have been found to encode DNA helicase subunits. Other mutations in these two genes can result in xeroderma pigmentosum, or Cockayne's syndrome. *XPB* has been localized to 2q21, and *XPD* has been localized to 19q13.2-q13.3. There is also evidence that a mutation in an unlocalized third gene, *TTDA*, also may cause TTD (van Brabant et al, 2000).

Primary Cutaneous Ichthyoses

Primary cutaneous ichthyoses are a group of familial disorders that have no prominent extracutaneous manifestations. Lamellar ichthyosis, congenital nonbullous ichthyosiform erythroderma, and EHK are also primary cutaneous ichthyoses.

Ichthyosis Vulgaris

Ichthyosis vulgaris is the most common form of ichthyosis, with an estimated incidence of 1 in 250 births. It is inherited as an autosomal dominant trait. Onset is usually after the first 3 months of life. Scaling is most prominent on the extensor surfaces of the limbs. The palms and soles also are affected. Affected persons often have coexisting keratosis pilaris and atopic dermatitis (Rabinowitz and Esterly, 1994). Skin biopsy distinguishes ichthyosis vulgaris from the other forms of ichthyosis by revealing small or absent keratohyalin granules. A major component of these granules, profilaggrin, is reduced or undetectable in the skin of affected persons (Nirunsuksiri et al, 1995). Recent molecular genetic investigations of the filaggrin gene have revealed the *R501X* mutation in European patients (Smith et al, 2006) versus the *S2554X* and *3321delA* mutations in Japanese patients (Nomura et al, 2007).

Erythrokeratodermia Variabilis

Erythrokeratodermia variabilis also is a rare type of ichthyosis that can manifest in infancy. It usually is inherited in an autosomal dominant fashion, although a probable case of autosomal recessive inheritance has been reported (Armstrong et al, 1997). Affected persons have transient migratory areas of discrete macular erythema and fixed hyperkeratotic plaques. A mutation in the connexin 31 gene, which codes for the gap junction protein β3, was reported as the cause of erythrokeratodermia variabilis, but a subsequent case did not have a mutated connexin 31 gene (Wilgoss et al, 1999). Studies have confirmed genetic heterogeneity in erythrokeratodermia variabilis affected by the intercellular communication mediated by both connexin 31 and connexin 30.3 genes in epidermal differentiation (Richard et al, 2003).

Prognosis and Treatment for the Ichthyoses

It is important to distinguish among the various forms of ichthyosis so that the physician can offer a prognosis and appropriate genetic counseling to the family. The prognosis is related to the severity of the condition and the type of ichthyosis. The clinical signs and pedigree data sometimes provide sufficient information to make a diagnosis. Skin biopsy for light microscopy is diagnostic only for EHK and ichthyosis vulgaris. Other general screening laboratory tests are equally nonspecific. Unfortunately, a period of observation beyond the first 4 weeks of life is frequently needed, and laboratory confirmation of the correct diagnosis requires specialized studies (Holbrook et al, 1993).

Standard therapy begins with topical care designed to hydrate the stratum corneum. Frequent, brief baths in tepid water should be followed immediately by liberal application of a bland ointment or cream emollient, such as petrolatum, Aquaphor, or Eucerin. Emollients containing keratolytics such as urea (10% to 25%), salicylic acid, propylene glycol, and α-hydroxy acids also are effective but are recommended only after infancy because of the risk of toxicity associated with increased percutaneous absorption. Irritating soaps and detergents should be avoided. Topical calcipotriol has been safe and effective as an agent for short-term therapy in adults with a variety of ichthyoses (Kragballe, 1995).

OCULOCUTANEOUS ALBINISM

The term *oculocutaneous albinism* (OCA) refers to a group of congenital disorders that are clinically manifested by an absence of pigment of the skin, hair, and eyes, with associated photophobia and nystagmus. All races are affected; estimates of gene frequency vary depending on the population under consideration. As with many genetic disorders, the incidence of affected persons is increased in certain racial isolates in which there is a high percentage of consanguineous marriages (Witkop et al, 1989).

Causes

All forms of OCA but one are inherited in an autosomal recessive fashion. The characteristic pigmentary changes are due to a spectrum of biochemical defects that interfere with melanin synthesis or transport. Three types of oculocutaneous albinism have been mapped to specific chromosomal regions that code for regulatory proteins in the transport and synthesis of tyrosine, a precursor in the melanin synthesis pathway (Oetting and King, 1994). OCA type 1 results from mutations in the gene that codes for tyrosinase (locus 11q14-q21). Tyrosinase is a copper-containing enzyme that catalyzes the two rate-limiting steps in the melanin biosynthetic pathway, and patients with homozygous mutations have a lifelong inability to produce melanin in the eyes, hair, and skin. More than 90 different mutations have been identified (Nakamura, 2002). OCA type 2, the most common form of OCA, results from mutations in the *P* gene. Recent findings suggest that the P protein has a major role in modulating the intracellular transport of tyrosinase (Toyofuku et al, 2002). OCA type 3 is caused by mutations in the tyrosinase-related protein 1 gene (*Tyrp1*). The encoded protein functions to maintain stability of tyrosinase (Sarangarajan and Boissy, 2001). Recent research suggests that other genetic mutations cause a fourth form of OCA (Newton et al, 2001).

Diagnosis

OCA type 1 can be distinguished from OCA types 2 and 3 on the basis of subtle clinical differences and the presence or absence of tyrosinase activity. OCA type 1 is the tyrosinase-negative variant and can be diagnosed prenatally with a fetal skin biopsy specimen (Holbrook et al, 1993). It results from any of several defects in the tyrosinase gene (Tomita, 1994). In type 2 and type 3 OCA, tyrosinase activity is positive. Genetic testing of tyrosinase and *P* genes may be necessary to distinguish OCA type 2 from type 3 (King et al, 2003). Oculocutaneous albinism should be distinguished from simple ocular albinism, which has sex-linked, autosomal dominant, and autosomal recessive forms.

Clinical Findings

Affected infants, regardless of their familial skin type, have a decrease in skin pigment. Hair and iris pigmentation can vary, depending on the genotype. Photophobia and nystagmus of varying degrees are also type-specific. Visual acuity is almost always impaired. Patients with tyrosine-negative OCA have the most severe form of visual impairment. Associated abnormalities may include hemorrhagic diathesis (Hermansky-Pudlak syndrome), small stature, and defective mentation. Deafness can occur in association with oculocutaneous albinism and with a number of other pigmentary disorders (Konigsmark, 1972).

Prognosis and Treatment

The most significant associated problems are visual impairment and the increased risk of sun-induced carcinogenesis. Treatment is supportive. Religious use of broad-spectrum sunblock with the highest available sun protection factor (SPF) is mandatory to protect against excessive exposure to sunlight. The safest approach for infants is zinc oxide ointment, sun-protective clothing, and sun avoidance. Persons with tyrosinase-positive albinism accumulate pigment with increasing age, decreasing the risk of sun-induced complications. The National Organization for Albinism and Hypopigmentation can provide additional information and support for affected families (see Box 98-2).

PIEBALDISM

Piebaldism is an autosomal dominant congenital leukoderma, characterized by a white forelock. Histologic studies show an absence of melanocytes in the depigmented areas of skin and normal melanocytes in the uninvolved skin (Jimbow et al, 1975). The molecular basis of the disease has been identified as a defect of the C-kit protooncogene. This gene encodes the cell surface receptor transmembrane tyrosine kinase for an embryonic growth factor. When c-*kit* function is reduced, the migration of melanocytes is curtailed during embryogenesis (Tomita, 1994). *c-kit* in a minority of affected patients is unaffected, but instead has mutations in the *SNAI2* gene (Sanchez-Martin et al, 2003).

Clinical Findings

A white forelock is present in 90% of cases. Other areas of the ventral skin may also be devoid of pigment, including the central forehead, chin, and trunk, with relative sparing of the dorsal surface. Eyebrows and midarm and midleg skin may also be depigmented. Within these areas, smaller, normally pigmented or hyperpigmented patches may be evident (Figure 98-5).

Diagnosis

Piebaldism is readily differentiated from albinism, in which the absence of pigment is uniform. Vitiligo may have a similar appearance, but it is not congenital and usually does not remain fixed. Occasional families may have associated defects such as sensorineural deafness and mental retardation (Telfer et al, 1971). Piebaldism is unrelated to Waardenburg's syndrome, an autosomal dominant condition that features a white forelock, widened nasal bridge, and cochlear deafness.

Prognosis and Treatment

The leukoderma and white forelock remain constant throughout life. Cosmetic camouflage is a treatment option suitable for infants and children. Surgical options are evolving.

APLASIA CUTIS CONGENITA

The congenital absence of skin is a cutaneous anomaly most often affecting the scalp, but occasionally involving the trunk and extremities.

Causes

Several distinct subtypes of aplasia cutis have been described based on the distribution, mode of inheritance, and associated abnormalities (Frieden, 1986). Most cases

FIGURE 98-5 **A,** Mother and child with piebaldism. Both have patches on the forehead, although of different sizes and shapes. The areas of nonpigmentation on the infant's trunk and extremities are unusually extensive. **B,** Siblings with different degrees of piebaldism. *(From Jahn HM, McIntire MS: Piebaldness, of familial white skin spotting; partial albinism*, Am J Dis Child *88:471-480, 1954. Copyright the American Medical Association.)*

of aplasia cutis congenita occur sporadically; autosomal dominant and autosomal recessive modes of transmission also have been well documented (Sybert, 1985). Associated abnormalities include cleft lip and palate, limb anomalies, cutaneous organoid nevi, and EB. Aplasia cutis may overlie embryologic malformations such as meningomyelocele and spinal dysraphia, omphalocele, and gastroschisis (Frieden, 1986; Sybert, 1985). In addition, scalp defects are associated with specific teratogens (methimazole, intrauterine varicella, herpes simplex) and malformation syndromes (trisomy 13, Johanson-Blizzard syndrome, amniotic band disruption complex, and the ectodermal dysplasias). Extensive aplasia cutis has been associated with elevated α-fetoprotein in maternal serum and amniotic fluid (Gerber et al, 1993).

The cause of aplasia cutis congenita is unknown. Basically, it is a phenotypic physical finding signifying disruption of the skin in utero and is attributable to any of a number of causes. Findings of a twin fetus papyraceus or a placental infarct have suggested vascular thrombosis as a cause in infants with lesions on the trunk and limbs (Levin et al, 1980).

Clinical Findings

The defect is usually along the midline of the scalp in the parietal or occipital area. Lesions are sharply marginated and may manifest as ulcers, bullae, or scars. Lesions may be solitary or multiple, measuring up to several centimeters in diameter (Figure 98-6). Up to 30% of affected infants have underlying defects of the calvaria. Multiple defects, particularly those on the trunk and extremities, may be strikingly symmetric in distribution (Levin et al, 1980). Larger defects are often deeper and can extend to the dura or meninges. These defects can be complicated by meningitis, hemorrhage (which can be fatal), or venous thrombosis.

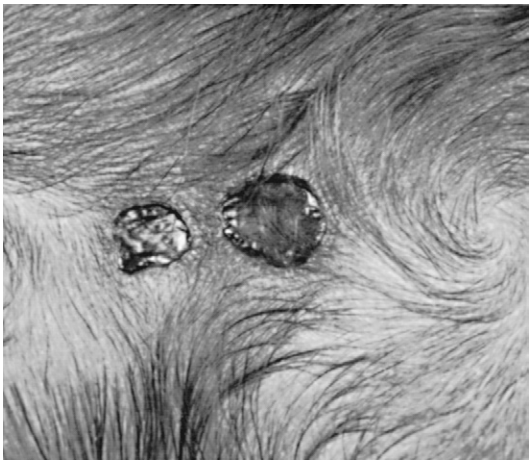

FIGURE 98-6 Skin is absent in two sharply marginated areas on the scalp of a normal newborn male infant whose mother's labor and delivery were normal. The defects extended to the subcutaneous tissue and healed in 3 weeks with the formation of thin, white atrophic scars.

Histologic examination of tissue from the defect demonstrates an absence of epidermis and a diminished number

of appendageal structures and dermal elastic fibers or, in deeper lesions, the absence of all layers of the integument. There is no evidence of inflammation or pathogenic organisms.

Prognosis and Treatment

Cutaneous and bony lesions can heal spontaneously over a period of weeks to months. A hypertrophic or atrophic patch of alopecia remains. Patients with larger and deeper lesions must be observed for the possibility of a complicating meningitis. Prophylactic excision with repair should be considered in these cases. Lesions that fail to heal or produce cosmetically unacceptable scars can be excised with primary closure (Kosnik and Sayers, 1975).

INCONTINENTIA PIGMENTI

Incontinentia pigmenti (IP), also known as the Bloch-Sulzberger syndrome, is a disorder of the developing neuroectoderm, characterized by three distinctive, transient stages of cutaneous lesions and variable persistent abnormalities of the CNS, eyes, teeth, hair, and nails.

Causes

IP is inherited in an X-linked dominant fashion. Surviving females are mosaics, whereas most hemizygous males do not survive embryogenesis. Molecular research indicates mutations at one genetic locus at Xq28 as the cause of all true cases of IP. Eighty percent of IP cases were found to result from a single mutation (Berlin et al, 2002). The mutation has been associated with the nuclear factor *k*B essential modulator gene (*NEMO*), which encodes for a transcription factor (Gautheron et al, 2010).

Clinical Findings

The diagnosis of IP is made by cutaneous examination. Most patients exhibit three stages of skin lesions that persist for varying periods (O'Brien and Feingold, 1985). The vesiculobullous phase manifests at birth and generally lasts for several months. It is characterized by widespread inflammatory vesicular lesions on the scalp, trunk, and extremities in a whorled and linear distribution along the lines of Blaschko (Figure 98-7, *A*). The infant is otherwise well, although markedly elevated leukocyte counts and peripheral eosinophilia with as much as 79% eosinophils may be associated (Berlin et al, 2002). Several pediatric cases of late recurrences of the first-stage of IP have been reported, often precipitated by infections, and have been presumed to be due to the persistence of mutant *NEMO* keratinocytes in the sites of previous lesions (Bodak et al, 2003). The vesicular phase evolves into a *verrucous* phase, in which warty lesions appear in roughly the same distribution as the blisters, but are most pronounced on the hands and feet. The third stage is characterized by macular gray or brown pigmentation distributed along the lines of Blaschko, independent of the sites of previous lesions (see Figure 98-7, *B*). The pigmentary lesions usually fade in later years and may disappear by adulthood. Rarely the stage-three pigmentary changes are present at birth,

FIGURE 98-7 Incontinentia pigmenti. A, Inflammatory vesicular and crusted lesions on the legs. **B,** Whorled pigmentation developing on the trunk of a 1-month-old infant who still has inflammatory lesions on the limbs.

and the first two stages are never evident (Lerer, 1973). Fourth-stage lesions, seen in some affected women, consist of hypopigmented, atrophic, anhidrotic streaks, usually localized to the legs (Moss and Ince, 1987).

Eighty percent of affected persons have extracutaneous involvement, including CNS aberrations (seizures, microcephaly, retardation, and spastic paralysis), patchy alopecia, defective dentition, ocular abnormalities, and less commonly, bone defects (Carney, 1976).

Diagnosis

Infants with IP usually have blisters. The linear distribution of blisters is often so characteristic that it permits instant recognition of the disorder, but other causes of blisters must be considered in the differential diagnosis (see Chapter 99). Skin biopsy during the bullous phase will show intraepidermal vesicles filled with eosinophils. These features are not pathognomonic but help to exclude more ominous causes of neonatal blistering. Clinicians should refer patients for genetic testing to the DNA Diagnostic Laboratory at Baylor College of Medicine (see Incontinentia Pigmenti in Box 98-2).

Prognosis and Treatment

Treatment of the skin lesions is not necessary. Occasionally vesicular lesions become extremely inflamed or secondarily infected. Patients should be monitored for the development of other anomalies, especially of the eyes, teeth, and CNS. Genetic counseling is indicated. Two IP support groups for patients and their families are the Incontinentia Pigmenti International Foundation and the Incontinentia Pigmenti Support Network (see Box 98-2).

CUTIS LAXA

Cutis laxa is a rare, heterogeneous group of genetic abnormalities of connective tissue with striking cutaneous features. Autosomal dominant, autosomal recessive, and X-linked forms have been described (Beighton, 1972; Byers et al, 1980). Cutis laxa–like skin changes can also be found in other disorders (e.g., combined immunodeficiency disease, the Prader-Willi and Langer-Giedion syndromes).

Clinical Features

Cutis laxa–like skin hangs in pendulous folds, producing a facies with a hooked nose, everted nostrils, a long upper lip, sagging cheeks, and a prematurely aged appearance (Figure 98-8). The infant may have a hoarse cry because of redundant laryngeal tissue. Persons with the autosomal dominant form of cutis laxa suffer few ill effects, apart from their altered appearance, and enjoy good health and a normal life span. Pulmonary and cardiovascular manifestations are absent or minimal. In contrast, patients with the recessive form of the disorder are often seriously compromised and may die in childhood of pulmonary or cardiovascular complications. Systemic manifestations include diverticula of the gastrointestinal and urogenital tracts, rectal prolapse, multiple hernias, pulmonary emphysema, and cardiac disease (Mehregan et al, 1978). A few infants have been reported who manifested additional defects, such as skeletal anomalies, dislocation of the hips, and intrauterine growth restriction (Sakati et al, 1983).

Diagnosis

The clinical manifestations of cutis laxa can be attributed to abnormalities of elastin, associated with a combined defect in *N*- and *O*-glycosylation because of the *ATP6V0A2* gene (Kornak et al, 2008). Elastic fibers are diminished in the papillary and upper dermis, whereas those in the lower dermis undergo fragmentation and granular degeneration (Mehregan et al, 1978). Similar changes occur in the elastic tissue of affected viscera. Autosomal recessive cutis laxa has been associated with a deficiency of lysyl oxidase, a copper-dependent enzyme mapped to chromosome 5 (Debret et al, 2010; Khakoo et al, 1997). The X-linked form has been associated with abnormal intracellular copper metabolism, with a decrease in the activity of lysyl oxidase. This form of cutis laxa, once classified as type IX Ehlers-Danlos syndrome, was redefined as occipital horn syndrome, an X-linked recessive condition allelic to Menkes syndrome (Beighton et al, 1988; Byers, 1994; Goldsmith, 1990) (see Figure 98-8).

Treatment

Plastic surgery can improve the physical appearance of patients with cutis laxa (Thomas et al, 1993). The internal manifestations are not amenable to therapy.

EHLERS-DANLOS SYNDROME

Ehlers-Danlos syndrome (EDS) is another heterogeneous group of inherited connective tissue disorders that share the common features of skin hyperextensibility, articular hypermobility, and tissue fragility (Beighton, 1993). In contrast to patients with cutis laxa, those with EDS have skin that is hyperextensible rather than loose; when stretched, the skin readily snaps back into place (Farmer et al, 2010). Skin fragility is another feature, leading to easy bruising and bleeding, gaping wounds, and numerous

FIGURE 98-8 Newborn infant with clinical features of Menkes syndrome and cutis laxa.

cigarette paper–like scars. Joint hypermobility is another major manifestation. The classification of EDS is evolving, and the latest classification scheme identifies six major types: classic, hypermobility, vascular, kyphoscoliosis, arthrochalasia, and dermatosparaxis. The kyphoscoliosis and dermatosparaxis types are inherited in an autosomal recessive fashion, whereas inheritance for the other four types is autosomal dominant. In addition, there are other known cases of EDS that do not fit into one of these types and await further characterization (Beighton et al, 1998). Persons with the vascular type of EDS (type IV by previous classification) can be easily distinguished from those with the other forms by their thin, translucent skin, marked bruising, and normal range of motion. It is especially important to identify this group because of its life-threatening complications (Byers, 1994).

Causes

All forms of EDS are believed to be due to defects in the biogenesis of collagen. The vascular type is characterized by a variety of defects in the synthesis of type III collagen, the kyphoscoliosis type by lysyl hydroxylase deficiency, the arthrochalasia type by defective processing of type I collagen, and the dermatosparaxis type by procollagen *N*-proteinase deficiency. These specific defects can be identified by culture of dermal fibroblasts from a skin biopsy.

Treatment

Recognition of the correct subtype is important for prognosis. The vascular type of EDS is particularly important to identify because of the life-threatening association with arterial, bowel, and uterine ruptures. There is no effective treatment for the various forms of EDS. Affected patients tolerate surgical procedures poorly because of difficulty in healing and frequent dehiscence of surgical wounds. Repair of cutaneous wounds may require the services of a plastic surgeon, and progressive joint disease will require ongoing orthopedic care. The Ehlers-Danlos National Foundation can provide additional information and support for affected families (see Box 98-2).

EPIDERMOLYSIS BULLOSA

EB is a diverse group of diseases that is characterized by skin blistering (Sawamura et al, 2010). Classification is based on clinical characteristics, inheritance pattern, and the level of cleavage within the skin, as determined by skin biopsy. This prominent histologic feature defines three main groups: simplex (cleavage within the basal cells of the epidermis), junctional (within the lamina lucida of the basement membrane zone), and dystrophic (beneath the lamina densa of the basement membrane). At each level, there are several protein components that contribute to skin integrity. These molecules all are expressed in utero during the first trimester, allowing prenatal diagnosis by skin biopsy (Holbrook et al, 1993). Further progress in the field has led to a simplified classification system that recognizes 10 major subtypes; three major EB types: epidermolysis bullosa simplex (EBS), junctional epidermolysis bullosa (JEB), and dystrophic epidermolysis bullosa; and 11 minor subtypes (Fine et al, 2000). Research efforts have been greatly enhanced by the Dystrophic Epidermolysis Bullosa Research Association of America (DEBRA) and the National Epidermolysis Bullosa Registry (see Box 98-2) (Fine, 1994). Identification of the molecular basis of a number of EB genotypes has facilitated prenatal and postnatal diagnoses and has also provided insight into the pathogenesis of blistering diseases, as well as the basic mechanisms of epithelial and basement membrane integrity (Uitto et al, 2010).

Epidermolysis Bullosa Simplex

EB simplex features blisters that arise within the basal layer of the epidermis. For this reason, the lesions of EB simplex do not scar. Four major subtypes and several minor subtypes have been recognized (Fine et al, 2000). The molecular defects of EB simplex have been localized to the genes encoding specific keratins, *K14* (located on chromosome 17) and *K5* (located on chromosome 12), except for EB with muscular dystrophy, which is due to a defect in plectin. Keratins K5 and K14 are expressed predominantly in the basal cells of the epidermis, and these disorders are closely related to epidermolytic hyperkeratosis (Francis, 1994) (see discussion under Ichthyoses That Manifest in the Neonatal Period). The four major subtypes are described next.

Epidermolysis Bullosa Simplex, Koebner Subtype

ES simplex, Koebner subtype, inherited as an autosomal dominant trait and is present at birth or early in infancy. Bullae arise most frequently over pressure points, such as the elbows and knees, as well as on the legs, feet, and hands. Mucous membrane involvement occurs primarily during infancy. The extensive erosions that sometimes result from the trauma of birth can be mistaken for aplasia cutis. Nails may be lost but almost always regrow. The prognosis is relatively good, and the propensity to blister may decrease with age.

Epidermolysis Bullosa Simplex, Dowling-Meara Subtype

EB simplex, Dowling-Meara subtype (EBS-DM), is inherited as an autosomal dominant trait and causes generalized, often extensive blistering in the neonatal period and early years of life. Herpetiform grouping of the blisters is characteristic. Additional findings include nail dystrophy, palmoplantar keratoderma as a late feature, and improvement with age. Molecular genetics studies reveal KRT5 and KRT14 mutations underlying patients with EBS-DM (Petek et al, 2010; Pfendner et al, 2005).

Epidermolysis Bullosa Simplex, Weber-Cockayne Subtype

EB simplex, Weber-Cockayne subtype, is inherited in autosomal dominant fashion and usually does not manifest during the neonatal period. The blisters in this disease usually are limited to the hands and feet, although they occasionally occur elsewhere on the body. The gene defects are associated with keratin 5 and keratin 10 (Müller et al, 1998).

Epidermolysis Bullosa Simplex With Muscular Dystrophy

EB simplex with muscular dystrophy (EBS-MD) is a rare variant that is inherited in an autosomal recessive fashion. Affected persons usually demonstrate blisters on the skin and mucous membranes at birth or shortly thereafter. EBS-MD is associated with tooth enamel hypoplasia and nail dystrophy. Progressive muscular dystrophy usually occurs later in life (Shimizu et al, 1999). Recent molecular studies identified plectin as the gene defect (Chiavérini, 2010).

Junctional Epidermolysis Bullosa

JEB is characterized by cleavage within the lamina lucida of the basement membrane zone. Three major subtypes are now recognized: JEB, Herlitz subtype; JEB, non-Herlitz subtype; and JEB with pyloric atresia. Molecular defects have been recognized within several proteins found in the basement membrane zone, including laminin-5, type XVII collagen, and the α_6,β_4-integrin complex. Several subtypes of JEB are relatively localized and benign (Fine et al, 2000). The major subtypes are described next.

Junctional Epidermolysis Bullosa, Herlitz Subtype

JEB, Herlitz subtype (JEB-H), was formerly known as *EB gravis* or *letalis* because many affected patients die in infancy. Generalized blistering is noted at birth. Persons with this form of JEB can, however, exhibit a spectrum of severity. Bullae and moist erosions occur on the scalp, in the perioral area, and over pressure points elsewhere on the body (Figure 98-9, *A*). Some of these erosions become the sites of vegetating granulomas, a pathognomonic finding. The hands and feet are relatively spared, and digital fusion, inevitable in the recessive dystrophic type of EB, does not occur. Nails are affected and may be lost permanently. Defective dentition is the rule, but mucous membrane erosions are inconspicuous and rarely cause problems. Laryngeal involvement can occur in childhood, manifested as hoarseness or stridor. These patients grow poorly, appear malnourished, and have chronic recalcitrant anemia. Mutations of any of the three α, β, and γ subunits of the *laminin 332* gene can produce the JEB Herlitz phenotype (Varki et al, 2006).

Junctional Epidermolysis Bullosa, Non-Herlitz Subtype

JEB, non-Herlitz subtype, is a disorder of autosomal recessive inheritance that carries the best prognosis of the major subtypes, with affected persons often surviving into adulthood. Onset is usually at birth, with generalized blistering; dystrophic nails or absence of nails is common (Fine et al, 2000).

Junctional Epidermolysis Bullosa with Pyloric Atresia

JEB with pyloric atresia is a rare, autosomal recessively inherited disease characterized by mucocutaneous fragility. JEB with pyloric atresia is usually fatal in the first few weeks of life, although mild cases have been reported. Polyhydramnios seen at ultrasound examination may be the first clue to gastric outlet obstruction. Generalized blistering and ulcerations of skin and mucous membranes usually are evident at birth. The urinary tract frequently is involved, stenosis being a common complication for survivors (Mellerio et al, 1998).

Dystrophic Epidermolysis Bullosa

Dystrophic EB is characterized by subepidermal blistering, below the level of the lamina densa of the basement membrane. The anchoring fibrils that link the lower part of the basement membrane to the papillary dermis are composed of type VII collagen. Mutations of the gene that codes for type VII collagen have been identified in most forms of dystrophic EB. This group of diseases is characterized clinically by milia and scarring at the sites of healed

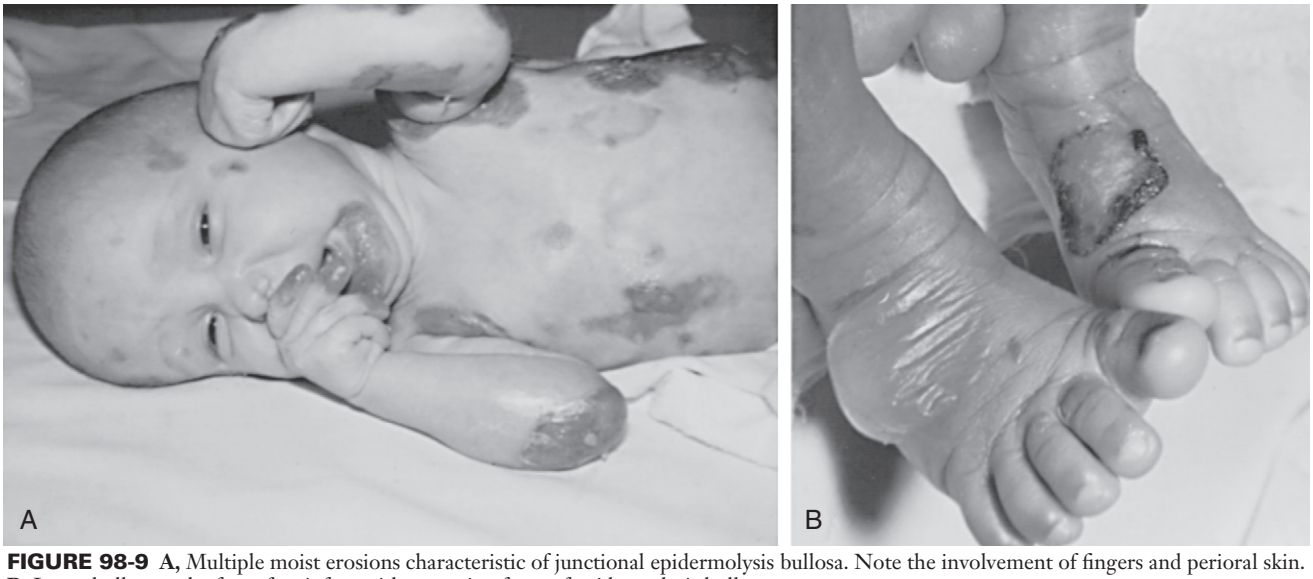

FIGURE 98-9 **A,** Multiple moist erosions characteristic of junctional epidermolysis bullosa. Note the involvement of fingers and perioral skin. **B,** Large bullae on the feet of an infant with a scarring form of epidermolysis bullosa.

blisters. There are three major subtypes and several minor subtypes. All are present at birth (Fine et al, 1991). Prenatal diagnosis as early as 8 to 10 weeks' gestation is possible by molecular techniques for some families. The three major subtypes are described next, as well as one of the more distinctive minor subtypes.

Dominant Dystrophic Epidermolysis Bullosa

Dominant dystrophic EB is a relatively mild form, inherited as an autosomal dominant trait. Generalized blistering usually is noted at birth. In some cases, blistering may appear only on the hands, feet, elbows, or knees; this pattern usually is due to mechanical trauma. Rarely does scarring cause immobility and deformity of the hands and feet. Small cysts or milia are seen at sites of scarring. There may be mild involvement of the mucous membranes; nails may be thick, dystrophic, or destroyed. Some persons affected by this form of EB may note the presence of small, firm, flesh-colored, or white skin elevations that appear spontaneously on the trunk and extremities, called *albopapuloid lesions*. Genetics studies of affected patients have indicated the collagen type VII alterations due to the *COL7A1* gene (Varki et al, 2007).

The Cockayne-Touraine and Pasini types of EB formerly were considered to represent two generalized forms of dominant dystrophic EB, but they are now included within dominant dystrophic EB in the new classification system. The bullae are subepidermal and heal with scarring, but the process may be relatively limited, involving mainly the hands, feet (see Figure 98-9, *B*), and skin over bony protuberances, or it may be generalized, particularly in the Pasini variant. Nails may be lost. Milia are common and may appear in profusion in the soft, wrinkled scars; pigmentary changes also are common. Mucous membrane lesions, if present, are mild and general health may be unimpaired. The appearance of albopapuloid lesions on the trunk during adolescence is a unique feature of the Pasini variant.

Transient Bullous Dermolysis of the Newborn

The rare variant transient bullous dermolysis of the newborn was first reported in 1985 (Hashimoto et al, 1985). Autosomal dominant and recessive forms have been described. The dominant form is now thought to be a form of dominant dystrophic EB. Affected neonates exhibit alarming acral or generalized blistering that heals with scars. Histologic analyses have localized the abnormality to the precursors of the anchoring fibrils, and genetic studies have shown mutations in a gene that codes for type VII collagen in some cases (Hammami-Hauasli et al, 1998). This condition is unique among the subsets of EB, because it spontaneously resolves within the first years of life.

Recessive Dystrophic Epidermolysis Bullosa, Hallopeau-Siemens Subtype

Recessive dystrophic EB, Hallopeau-Siemens subtype, is the more severe form of recessive dystrophic EB. Infants with Hallopeau-Siemens EB often have extensive denuded lesions at birth and during the neonatal period. Bullae may be hemorrhagic and occur on all surfaces, including the hands and feet; loss of the nails is common. Over subsequent years the mobility of the fingers and toes becomes severely impaired as fusion of digits, bone resorption, and the inevitable mitten-like deformity of the hands and feet ensue. Mucous membrane involvement can be severe, resulting in esophageal strictures and serious impairment of nutrition because of the restriction of oral intake. These bullae are subepidermal and always eventuate in scarring. Affected persons have a markedly increased risk of skin cancer, with a 39.6% cumulative risk of developing squamous cell carcinoma and a 2.5% cumulative risk of developing malignant melanoma by age 30 (Fine et al, 2000). Electron microscopy reveals diminished or absent anchoring fibrils associated with marked degeneration of type VII collagen in the papillary portion of the dermis. Also evident is excess abnormal collagenase in fibroblast cultures.

Recessive Dystrophic Epidermolysis Bullosa, Non–Hallopeau-Siemens Subtype

Recessive dystrophic EB, non–Hallopeau-Siemens subtype, is the less severe form of recessive dystrophic EB. It is characterized by onset at birth, generalized blisters that include the mucosal surfaces, atrophic scarring over bony prominences, and either nail loss or nail dystrophy. Milia, mild finger flexion contractures, albopapuloid lesions, dental disease, and external ear involvement also are often seen. According to one report, affected patients also have an increased risk of squamous cell carcinoma of approximately 14% by age 30 (Fine et al, 2000).

Diagnosis and Treatment of Epidermolysis Bullosa

Diagnosis

Arriving at the correct diagnosis can be difficult, especially in the neonatal period. The differential diagnosis includes the spectrum of blisters and bullae outlined in Chapter 97. The distribution of blisters can be a clue. In EB, the earliest lesions occur on points of friction, such as the heels, wrists, knees, and sacrum. The fluid within the bullae is likely to be clear or hemorrhagic, rather than purulent. A careful family history for blistering diseases should be obtained. The most precise diagnostic tool is a carefully performed skin biopsy to obtain specimens for immunofluorescence mapping and ultrastructural study. The sample for immunofluorescence should be obtained from normal or perilesional skin, excluding the palms or soles, and placed in Zeus or Michel transport medium. The ideal specimen for electron microscopy is a new spontaneous or induced blister preserved in glutaraldehyde (Fine et al, 1994). After the diagnosis of simplex, junctional, or dystrophic EB is made, further subclassification can be difficult during infancy for subsets without a defined genotype. In these patients without a relevant family history, distinguishing clinical features may take months or years to develop.

Treatment

To date, the mainstay of therapy for this group of disorders is supportive. The infant should be protected from frictional trauma; direct pressure is tolerated. Latex gloves

can stick to the skin and should be lubricated with petrolatum. Bedding should be of a soft material. Dressing changes should be performed daily. Adequate premedication for pain control should be given. Bathing may have to be restricted to avoid excessive handling. Compresses with normal saline or Burow's solution for eroded areas may be helpful in some instances. Tepid compresses should be used, because warm temperatures increase the tendency to blister. Intact blisters should be lanced with an adequate incision to drain the fluid, while the roof is maintained as a "biologic dressing." Wounds should be covered with petrolatum-impregnated gauze. Topical antibiotics may promote healing, but content and quantity should be carefully monitored in young infants. Topical mupirocin is the antibiotic of choice at several EB centers; bacterial resistance has been reported in chronic users with EB. Commercially available nonadhesive dressings are simpler to use and more effective than plain gauze wraps. Exudry pads, secured with SurgiNet or conforming gauze, are recommended for draining wounds on the body. Omiderm (Doak Pharmaceuticals) is a nonadhesive polyurethane dressing that provides an excellent barrier for moist wounds on the face and hands. Adhesive tape should never be applied, because large areas of epidermis may be torn off with its removal. Dressing should be applied to blistered areas only to maximize the infant's tactile stimulation. For the newborn, environmental temperature must be carefully monitored; overheating can result in extensive blistering. For patients with mucous membrane involvement, soft nipples, bulb syringes, and devices used for feeding infants with cleft palates should be used. Chronic serosanguineous drainage and gastrointestinal involvement often result in poor nutritional status. Iron deficiency anemia is another common complication in infants with severe disease. Routine use of aggressive nutritional supplementation is recommended. After discharge, cribs, high chairs, and infant seats should be well padded, and only soft toys should be offered for play (Gibbons, 1990).

Caregivers should be given anticipatory guidance about protective measures, wound care, and nutrition. The practitioner should encourage contact with DEBRA, a privately funded organization that is an excellent resource for affected families. DEBRA can provide practical information for day-to-day care and direct families to the appropriate regional center for specialized care (see Box 98-2). To register newly diagnosed patients, clinicians should contact the National Epidermolysis Bullosa Registry (see Box 98-2).

NEONATAL LUPUS ERYTHEMATOSUS

Neonatal lupus erythematosus (NLE) is an uncommon immune-mediated disease that results from transplacental transfer of maternal immunoglobulin G antinuclear antibodies. It manifests within the first 2 months of life. Infants exhibit a spectrum of signs, including transient cutaneous lesions, thrombocytopenia, hepatitis, and congenital heart blocks (Kim et al, 2009). All affected infants have serologic evidence of lupus erythematosus during the first few months of life (Lee, 1993; Lee and Weston, 1984; Provost et al, 1987).

Causes

NLE is always marked by the presence of anti-Ro (SS-A), anti-La (SS-B), or anti-U_1RNP autoantibodies in the mother and infant. With the exception of congenital heart block, most of the manifestations of neonatal lupus resolve with the disappearance of maternal antibodies, suggesting an important role for these antibodies in pathogenesis. An association with HLA-DR3 in the mother but not the infant also has been documented (Lee and Weston, 1984). Ro-positive HLA-DR2 mothers, in contrast, produce unaffected infants (Provost, 1987).

Clinical Findings

Half of the affected infants have skin lesions. These may be present with or without evidence of systemic disease (Hardy, 1979). Skin lesions are typically annular erythematous scaling plaques (Figure 98-10), with a predilection for sun-exposed areas. These lesions begin to resolve at approximately 6 months of age, concurrent with the disappearance of maternal antibodies. Persistent telangiectatic matting in a characteristic distribution, involving the scalp, lips, and vulva, also has been described (Figure 98-11) (Thornton et al, 1995).

Diagnosis

The skin lesions of NLE can be mistaken for several cutaneous disorders including syphilis, seborrheic dermatitis, dermatophytosis, atopic dermatitis, and psoriasis. A skin biopsy specimen may demonstrate the histopathologic features of lupus. More reliable, however, is the detection of Ro (SS-A) or La (SS-B) antibody, or both, in serum from the infant and the mother.

The North American Collaborative Study of NLE is an ongoing prospective study of all aspects of the disease. To arrange for enrollment and serologic testing of patients, clinicians should contact study investigators (see under Neonatal Lupus Erythematosus in Box 98-2).

Prognosis and Treatment

Affected infants should be protected from sources of ultraviolet light (e.g., sunlight, daylight fluorescent bulbs) by application of a broad-spectrum sunscreen such as titanium

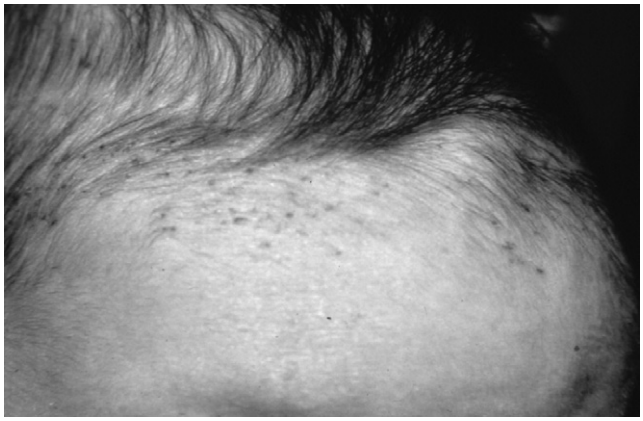

FIGURE 98-10 Newborn with cutaneous lesions of neonatal lupus erythematosus.

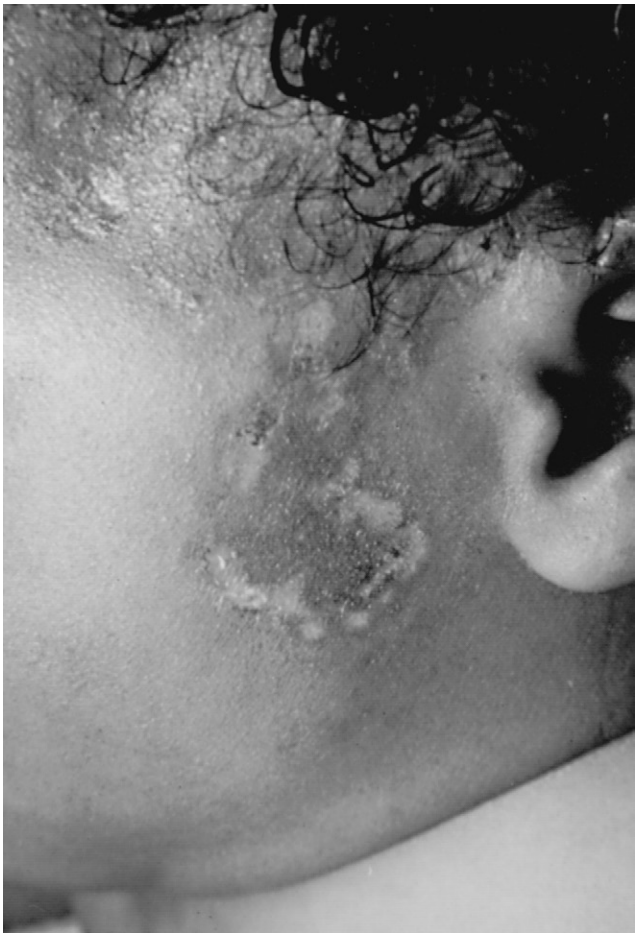

FIGURE 98-11 Telangiectatic matting of the scalp, lips, and groin is a recently recognized cutaneous marker of neonatal lupus.

dioxide, zinc oxide, and sun-protective clothing. Active skin lesions can be treated with a topical corticosteroid.

The prognosis is excellent, except in affected infants who develop congenital heart block. Most infants with congenital heart block will require a pacemaker, and death will occur in approximately 20% of patients (Tseng and Buyon, 1997).

It is important to recognize that asymptomatic mothers are at risk for development of disorders associated with their serologic abnormalities (e.g., Sjögren syndrome, subacute cutaneous lupus, systemic lupus erythematosus). There is a 25% risk of involvement for each subsequent pregnancy (Gawkrodger and Beveridge, 1984; McCune, 1987).

ECTODERMAL DYSPLASIAS

The ectodermal dysplasias (EDs) are a heterogeneous group of inherited disorders characterized by defects in the development of two or more structures of ectodermal origin. The major structures involved are hair follicles, nails, teeth, and sweat glands; sebaceous glands, conjunctivae, and the lens also may be affected. A formal classification system has been created for the EDs, based on the specific structures affected (Pinheiro and Freire-Maia, 1994). One hundred fifty-four syndromes have been included in this grouping. Several of these, such as incontinentia pigmenti and syndromes associated with ichthyosis, have not been traditionally regarded as ED. Many others have been reported rarely. The National Foundation for Ectodermal Dysplasias (NFED) is a privately funded organization committed to locating affected families and providing them with information and support (see Box 98-2). The NFED also coordinates and funds research efforts. Three of the more well-characterized types of ED are described next.

FIGURE 98-12 Girl with fully expressed anhidrotic ectodermal dysplasia. Note the sparse wispy hair, hyperpigmentation around the eyes, depressed nasal bridge, and protruding lips and ears.

Hypohidrotic Ectodermal Dysplasia

Hypohidrotic ED, inherited as an X-linked recessive disorder, was the first type of ED described as Christ-Siemens-Touraine syndrome. It was previously referred to as being *anhidrotic*, but affected persons may have a limited capacity to sweat, and the preferred descriptor is *hypohidrotic*. This type of ED occurs in 1 in 100,000 male births and manifests during the 1st year of life. The most serious problem is diminution of the sweating response because of rudimentary or absent eccrine sweat glands, which results in marked heat intolerance and episodes of hyperpyrexia, frequently misinterpreted as fever of unknown origin (Richards and Kaplan, 1969). If ED is not considered in the differential diagnosis, these infants may be subjected to numerous unnecessary hospitalizations and tests. Recent studies demonstrate genetic mutations in the EDA gene (Lexner et al, 2008).

Clinical Features

Patients with hypohidrotic ED have several characteristic features that may be subtle in the newborn. One common neonatal sign is severe peeling or scaling skin. This skin change, which can be misconstrued as an indication of postmaturity, may provide a valuable clue to the diagnosis (Executive and Scientific Advisory Boards of the National Foundation for Ectodermal Dysplasia, 1989). Thereafter the skin may appear relatively pale and dry, with a prominent venous pattern over most of the body, but hyperpigmented and wrinkled in the periorbital area (Figure 98-12).

The craniofacial characteristics of frontal bossing, depression of the midface, flattened nasal bridge, thick

protruding lips, and prominent chin may not be readily apparent in the newborn. The sparse, unruly, light-colored hair and scanty brows and lashes also are difficult to appreciate in the first few months. The changes in dentition cannot, of course, be detected until late infancy. Hypodontia with conical, poorly formed teeth is the rule; these changes can be identified on dental panoramic radiographs before eruption of the teeth. Atrophic rhinitis, diminished lacrimation, hoarseness, and hypoplasia or absence of mucous glands in nasotracheobronchial passages are also frequent findings in these patients (Reed et al, 1970). If the diagnosis is in doubt, palmar skin biopsy may demonstrate absent or hypoplastic eccrine sweat glands. Techniques used to elicit sweating, such as pilocarpine iontophoresis or examination of the sweat pores on the palm with *O*-phthalaldehyde, also can be used to demonstrate the defect (Esterly et al, 1973). Atopic dermatitis occurs frequently in these children (Reed et al, 1970), as well as a decrease in T cell function (Davis and Solomon, 1976).

Hypohidrotic ED is transmitted as an X-linked recessive trait. The gene has been localized to Xq11.21.1. First-trimester prenatal diagnosis is possible (Zonana et al, 1990). All affected males fully express the disease, whereas carrier females have variable expression of the clinical signs. This expression can be explained by the inactivation of a random percentage of abnormal X chromosomes. In these females, hypohidrosis can be demonstrated in areas of skin marking the lines of Blaschko (see the section on mosaicism) (Bolognia et al, 1994; Crump and Danks, 1971; Esterly et al, 1973; Gorlin et al, 1970).

Once the diagnosis is made, it is important to educate parents so that these children are protected from overheating. Defective lacrimation can be palliated by the use of artificial tears. The nasal mucosa should be treated with saline drops or irrigation followed by application of petrolatum. Regular dental evaluations should be started early in life, and dentures should be fitted to promote good nutrition, articulation, and normal appearance before the child starts school. Some of these children also choose a wig and reconstructive procedures later in life to improve facial configuration.

Hidrotic Ectodermal Dysplasia

Hidrotic ED, also known as *Clouston's syndrome*, is an autosomal dominant condition. Affected individuals have characteristic abnormalities of skin, hair, and nails, whereas eccrine and sebaceous functions and dentition are normal. The phenotype is easily recognizable in early childhood, with features including thickened, conical nails and widening of the distal periungual area with cerebriform furrowing. The skin over the joints often is hyperpigmented. The degree of alopecia is variable. The genetic abnormality in hidrotic ED has been mapped to the *GJB6* gene at 13q11-q12.1 encoding connexin 30 (Lamartine et al, 2000).

Ectodermal Dysplasia–Ectrodactyly–Cleft Lip/Palate Syndrome

The ectodermal dysplasia–ectrodactyly–cleft lip/palate (EEC) syndrome is an autosomal dominant condition featuring ectodermal dysplasia (including dental, ocular, nail, and hair defects), ectrodactyly (lobster-claw deformity of the hand), and cleft lip with or without cleft palate. The cutaneous and appendageal anomalies include diffuse hypopigmentation affecting both skin and hair, scanty scalp hair and eyebrows, dystrophic nails, and small teeth with enamel hypoplasia. Sweating appears to be intact, and sweat glands are present in a skin biopsy specimen. The clefting of the lip is usually complete and bilateral, and the palate has a median cleft. Dry granulomatous lesions in the corners of the mouth often are secondarily infected with *Candida albicans*. Other findings include lacrimal duct scarring, blepharitis and conjunctivitis, xerostomia, conductive hearing loss, and mental retardation. EEC syndrome is caused by a mutation in the *p63* gene located at 3q27 (Chiu et al, 2009). The *p63* gene, a homologue of the tumor suppressor *TP53* gene, is highly expressed in the basal layer of many epithelial tissues (Celli et al, 1999).

CHAPTER 99

Infections of the Skin

Dakara Rucker Wright and Bernard A. Cohen

As a group of potentially life-threatening and often easily treatable diseases, infections are often suspected first in a neonate with skin lesions. Recognition of characteristic morphologic features, aided by a few easily performed tests, will greatly enhance correct diagnosis and early initiation of appropriate therapy of the most common cutaneous infections. In this chapter, the focus is on disease caused by the most common pathogens responsible for neonatal infections that manifest with skin lesions: *Staphylococcus aureus*, *Streptococcus* spp. *Candida albicans*, and herpes simplex virus (HSV).

STAPHYLOCOCCUS AUREUS INFECTIONS

S. aureus is a ubiquitous organism, harbored as a commensal organism by greater than 30% of the general population (Ladhani, 2000). Colonization of the anterior nares and perineum is common, with frequent hand carriage (Dancer and Noble, 1991). This bacterial species is responsible for a variety of skin lesions. Infants become colonized with *S. aureus* during the first few weeks of life, following inoculation at the perineum or from handling. Cutaneous signs of *S. aureus* infection are mediated by local or circulating bacterial toxins that act directly on components of the epidermal keratinocytes, or as "superantigens" to stimulate exuberant immunologic responses (Tokura et al, 1994).

BULLOUS IMPETIGO

Impetigo is a group of superficial skin infections caused by group A streptococci or *S. aureus*, or both. However, neonatal bullous impetigo is primarily caused by coagulase-positive *S. aureus*. This form of impetigo can occur in nursery-based, epidemic patterns, often attributed to nasal carriage of *S. aureus*.

Clinical Findings

Impetigo is one of the most common neonatal skin infections. It occurs during the latter part of the first week or as late as the second week of life, manifested as vesicles or pustules on an erythematous base, most often seen in the periumbilical area, diaper area, or skin folds. Because the blisters are superficial, intact lesions are usually less than 1 cm in diameter. Larger lesions are flaccid and rupture so easily that they are usually seen as erosions, with a red moist base that develops a thin, varnish-like crust (Figure 99-1). These lesions heal rapidly without scarring. Lesions are usually not closely grouped, differentiating them from the vesicles of herpes simplex infection.

Etiology

S. aureus is the primary cause of both bullous and nonbullous impetigo. Group A streptococci usually are associated with the nonbullous form, especially affecting patients with atopic dermatitis. Bullous impetigo is caused by toxigenic strains of coagulase-positive hemolytic *S. aureus*. Most often, the organism can be classified as one of the group II phage types (71 and 55). The incubation period is 1 to 10 days. Skin lesions are the result of local production of an epidermolytic exotoxin that cleaves a desmosomal protein connecting cells in the granular layer of the epidermis, producing superficial blisters. This is the same toxin produced in staphylococcal scalded skin syndrome (Amagi et al, 2000; Yamaguchi et al, 2002).

Epidemiology

Persons with skin lesions are highly contagious, but the disease also can be transmitted by asymptomatic carriers. The anterior nares of 30% of the general population are colonized with *S. aureus*, providing a reservoir for hand carriage and nosocomial spread (Doebbeling, 1994; Kragballe et al, 1995). Colonization of health care workers by strains of methicillin-resistant *Staphylococcus aureus* (MRSA) poses a potentially serious problem, and outbreaks of MRSA have occurred in neonatal intensive care units (NICUs) caused by an MRSA strain previously found in the community (Regev-Yochay, 2005; Yamaguchi et al, 2002).

Sporadic cases of impetigo are common, but many nursery epidemics have been reported and should be treated aggressively (Dave et al, 1994). Infected infants may not develop skin lesions until after discharge, so infection control surveillance should include all exposed patients. Overcrowding, insufficient nursery personnel, and inadequate hand washing contribute to nosocomial spread. Treatment of the umbilical cord with an antimicrobial agent has been shown to control epidemic *S. aureus* infections in the NICU (Haley et al, 1995). In the setting of an outbreak, nursery personnel should be surveyed for colonization of the hands and nares. Application of mupirocin ointment to the anterior nares twice daily for 5 days will eliminate nasal carriage for up to 1 year (Doebbeling et al, 1994). Effective hand washing can prevent nosocomial spread; chlorhexidine is among the safest and most effective antimicrobial cleansers for hospital use (Doebbeling et al, 1992). The use of antiseptic hand rub has also been shown to be as or more effective than washing with soap. A study by Girou et al in 2002 showed that during routine patient care, hand rubbing with an alcohol-based solution was significantly more efficient in reducing bacterial counts than hand washing with antiseptic soap.

This chapter includes material from the previous editions, to which Nancy B. Esterly, Elisabeth G. Richard, and Elaine C. Siegfried, contributed.

FIGURE 99-1 Bullous impetigo. Multiple intact and ruptured bullae on the abdomen, hip, and thigh of a newborn infant. No underlying erythema is present.

Diagnosis

The diagnosis is supported by the presence of gram-positive cocci in clusters on Gram stain of the fluid from a pustule or vesicle or under crusted plaque of impetigo. Confirmation is made by bacterial culture taken from blood, skin, and soft tissues, especially in the case of suspected MRSA.

Treatment

Bullous impetigo is benign if treated early, but local proliferation with exotoxin production or dissemination can be life-threatening. Treatment should be instituted promptly and isolation maintained until the lesions have resolved. Infants should be closely monitored and a high index of suspicion maintained for evidence of systemic disease. Infants with periumbilical lesions are at risk for bacterial omphalitis. Extremely limited infections may be treated with topical mupirocin, but this form of therapy should be used with caution in neonates. More extensive lesions require a systemically (most recommend parenterally) administered penicillinase-resistant antibiotic for 7 to 10 days. Sensitivities of the organism cultured should ultimately determine the choice of antibiotics, especially with the rising incidence of MRSA. In this case vancomycin or linezolid would be considered.

STAPHYLOCOCCAL SCALDED SKIN SYNDROME

Staphylococcal scalded skin syndrome (SSSS) occurs as a generalized manifestation of a circulating toxin produced by *S. aureus* that specifically cleaves cell-to-cell adhesion proteins in the epidermis. Affected infants are erythrodermic, a striking cutaneous finding that suggests a long list of differential diagnostic possibilities. Early diagnosis and treatment of SSSS can be lifesaving.

Clinical Findings

Affected infants demonstrate abrupt onset of temperature instability and irritability with generalized skin tenderness and erythema that most often starts on the face and spreads rapidly. Erythema often is accentuated in skin folds. Facial edema, conjunctivitis, and crusting around the eyes, nose, and mouth give the infant a characteristic "sad mask" appearance. Flaccid bullae may develop, followed by widespread exfoliation (Figure 99-2) involving the entire skin surface within hours to days. Hypopigmentation may follow exfoliation in darker races that will repigment in time. Blistering is easily elicited by light stroking of intact skin, a diagnostic feature referred to as a Nikolsky sign. When blisters rupture, the skin peels off in sheets, leaving a painful moist, red base. Widespread skin involvement can exacerbate fluid and electrolyte problems (Frieden, 1989). Whereas in bullous impetigo *S. aureus* is identifiable in the blisters, in SSSS *S. aureus* is present at a primary distant site such as the nose, mouth, or conjunctiva.

FIGURE 99-2 Staphylococcal scalded skin syndrome (Ritter's disease). Intense erythema and peeling of large areas of epidermis are seen.

SSSS must be distinguished from toxic epidermal necrolysis (TEN), a life-threatening condition involving full-thickness epidermal necrosis, most commonly due to a drug reaction. In SSSS, mucosal erythema may be seen but there are no intraoral blisters, whereas in TEN, mucosal blistering is present.

Etiology

The signs and symptoms of SSSS are the result of circulating epidermolytic toxin, produced from an often subclinical focus of *S. aureus* infection. Fresh skin lesions do not contain bacteria, and the blisters are culture-negative. Two distinct epidermolytic toxins have been identified in SSSS, produced by toxigenic strains of *S. aureus*, phage group I, II, or III. Approximately 5% of *S. aureus* isolates produce the toxins (Farrell, 1999). The exotoxin cleaves desmosomal proteins within the epidermal granular layer, resulting in blisters (Amagi et al, 2002; Resnick, 1992). Superantigenic stimulation of cytokine production also has been demonstrated (Dave et al, 1994).

Diagnosis

If the diagnosis is in doubt, skin biopsy prepared for frozen section can be examined emergently. The presence of an intraepidermal rather than full-thickness blister will distinguish SSSS from TEN, allowing rapid initiation of appropriate therapy. Other conditions can be ruled out by examination of formalin-fixed sections. If the clinical impression is strong, surveillance samples will define the primary focus of infection. Gram staining may be performed emergently; cultures will confirm the diagnosis. Common sites of primary infection are the nasopharynx, umbilicus, and ocular conjunctivae; the urine also may demonstrate organisms. Bullous lesions do not contain organisms. Blood culture specimens should be obtained because sepsis, although uncommon, may occur. Phage typing may be of interest in epidemics.

Treatment

Systemic administration of a penicillinase-resistant penicillin is the therapy of choice. Fluid and electrolyte replacement and measures for maintenance of normal body temperature may be required. Approximately 2 to 3 days after initiation of therapy, the denuded areas become dry, and a flaky desquamation ensues. Crusted and denuded areas may be treated with compresses of Burow or normal saline solution. Application of a bland ointment emollient may accelerate the return of the skin to normal during the flaky desquamative phase. Resolution occurs in another 3 to 5 days. Because the intraepidermal cleavage plane is at the level of the granular layer, scarring occurs only in instances of secondary complications (Frieden, 1989).

STREPTOCOCCUS SPP INFECTIONS

Cutaneous streptococcal infections occur in the newborn but are less common than staphylococcal infections. Group A streptococci have been reported to cause disease of epidemic proportions (Dillon, 1966; Peter and Hazard, 1975) following the introduction of the organism into the nursery by maternal carriers or nursery personnel. The umbilicus (omphalitis) is a frequent site of infection. Conjunctivitis, paronychia, vaginitis, and an erysipelas-like eruption also have been described (Dillon, 1966; Geil et al, 1970; Isenberg et al, 1984). Because sepsis and meningitis may result, infected infants should be treated promptly, and strict isolation should be instituted. As with staphylococcal infection, serious efforts should be made to identify the source of the organism. Several nursery outbreaks have been difficult to terminate because colonized infants may show little evidence of disease (Lehtonen et al, 1984). Isolation and treatment of infected infants, disinfection of the umbilical stump as the most likely reservoir of the organism, and penicillin prophylaxis for carriers and exposed infants have been the most effective measures. The infections respond readily to penicillin, which should be administered over a 10-day course.

Group B streptococci are now one of the most frequently encountered pathogens in the newborn nursery. Early-onset disease (during the 1st week of life), probably acquired in utero or during delivery, most commonly becomes manifest as septicemia with respiratory distress and shock. Late-onset disease (7 days to 3 months) is acquired postpartum and more often takes on the form of meningitis. Patients with early-onset disease may harbor the organism on the skin; however, the presence of this agent on the skin is short-lived compared with other sites (Baker, 1977).

Skin infections caused by group B streptococci are uncommon but have been documented (Belgaumkar, 1975; Hebert and Esterly, 1986; Howard and McCrackin, 1974). The most common skin manifestation of GBS is cellulitis, usually of the face (Shet and Ferrieri, 2004). Vesiculopustular lesions and small abscesses and necrotizing fasciitis all have been noted. A 10-day course of procaine penicillin or clindamycin is considered the treatment of choice.

OMPHALITIS

CLINICAL FINDINGS

Omphalitis is infection of the umbilical stump that presents around day 3 of life. Clinically there is erythema, edema, and tenderness around the umbilicus with or without discharge. Infection can extend into the subcutis or along the abdominal wall causing necrotizing fasciitis.

ETIOLOGY

S. aureus, *Escherichia coli*, *Klebsiella* spp., and *S. pyogenes* are common organisms that cause omphalitis. Preterm infants, low-birthweight infants, and infants from home births and complicated deliveries are at increased risk (Sawardekar, 2004).

DIAGNOSIS

Gram stain and bacterial culture from moist umbilical stump fluid can be obtained, but because this area can be contaminated easily, clinical correlation is needed. True infection must be differentiated from embryonic duct remnants or umbilical papilloma.

TREATMENT

Ampicillin and gentamicin can be used initially until culture and sensitivities are obtained. Intravenous antibiotics can be switched to enteral once the skin improves clinically. In a Cochrane review, no difference was demonstrated in cord and other skin infections within 6 weeks of observation between cords treated with antiseptics as compared with dry cord care or placebo. However, there was a trend toward reduced colonization with antibiotics compared to antiseptics and no treatment (Zupan et al, 2004).

CANDIDA ALBICANS INFECTIONS

C. albicans is a frequent pathogen of the female genital tract, especially during pregnancy. Infantile infection may be acquired in utero, during delivery, or postnatally.

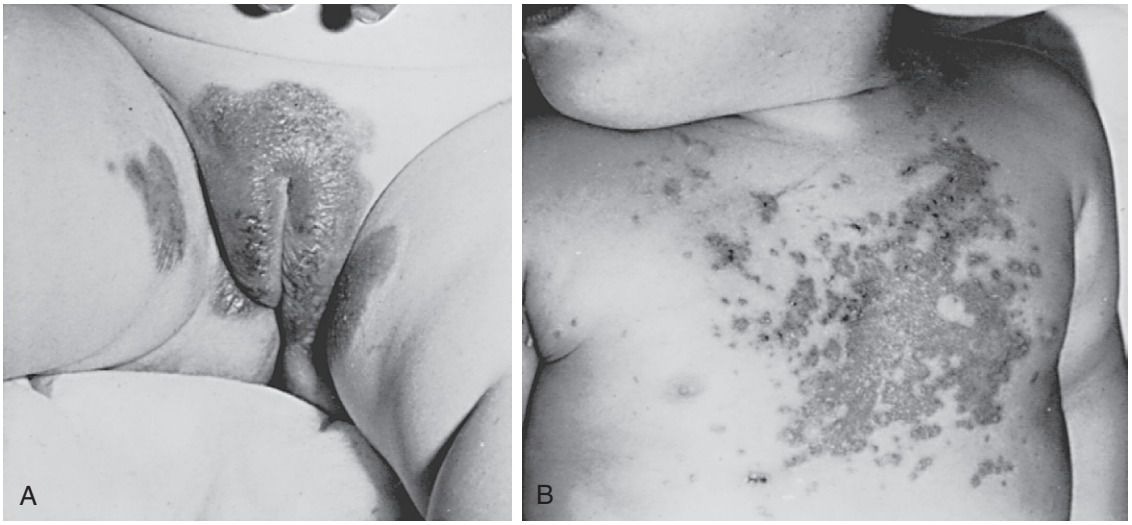

FIGURE 99-3 **A,** Sharply demarcated erythematous, scaly candidal rash in the groin. **B,** Candidal eruption on the central chest of an infant.

LOCALIZED *CANDIDA* INFECTION (PRIMARY CUTANEOUS)

Oral Candidiasis (Thrush)

C. albicans colonizes the oral cavity and gastrointestinal tract of most neonates, with peak incidence of thrush occurring at 4 weeks of age (Russell and Lay, 1973). The lesions are readily recognized as asymptomatic to moderately painful plaques of white, friable material on an erythematous base over the tongue, palate, buccal mucosa, and gingivae.

Diaper Dermatitis

Localized cutaneous candidal infections are common in infants, with peak incidence at 3 to 4 months of age. Characteristic primary lesions are tiny vesicopustules that erode and merge, forming bright, erythematous plaques often with a scalloped edge in the moist intertriginous areas of the perineum and perianal and inguinal creases (Figure 99-3). White scale and "satellite" pustules may be seen along the periphery. Thrush may also be present in conjunction with *Candida* diaper dermatitis. Other intertriginous areas such as the neck folds and axillae can also be infected with *Candida*, as well as the nails.

Diagnosis of Localized Cutaneous *Candida*

Presumptive diagnosis often is made by physical examination and history, but microscopic examination of scrapings suspended in 10% potassium hydroxide for yeast and pseudohyphal forms is useful. The diagnosis may be confirmed by identification of the organism on culture.

Treatment

Nystatin is an antibiotic derived from *Streptomyces noursei* with activity against *Candida* but not dermatophytes. Oral lesions usually respond promptly to a course of nystatin suspension, 100,000 to 200,000 units, administered by mouth four times daily for 14 to 21 days. In refractory cases, an increased dosage of nystatin or systemic therapy may have to be instituted (Hebert and Esterly, 1986). Localized cutaneous candidiasis in an otherwise healthy infant is most easily treated with a topical candidicidal agent, such as nystatin, one of the imidazoles (e.g., miconazole, clotrimazole, ketoconazole), or ciclopirox olamine (Gibney and Siegfried, 1996). Nystatin in an ointment vehicle may be the least irritating. If the breastfeeding mother is affected, treatment of the mother with nystatin cream or oral fluconazole may be indicated. Gentian (crystal) violet is a triphenylmethane antiseptic dye effective against *Candida* species. In a 0.5% or 1% aqueous solution it has been a time-honored, safe, and effective treatment for thrush. Gentian violet is infamous for deep purple staining of the skin, which is transient. Prolonged use of gentian violet has been associated with nausea, vomiting, diarrhea, and mucosal ulceration. Carcinogenicity in mice has been reported (Rosenkranz and Carr, 1971).

CONGENITAL (INTRAUTERINE) CANDIDIASIS

Congenital candidiasis is *Candida* infection acquired in utero from an ascending infection, crossing the fetal membrane and infecting surfaces that come in contact with amniotic fluid and manifests with symptoms in the first days of life. Even though the rate of vaginal colonization is 33%, congenital candidiasis is uncommon. Risk factors include the presence of a foreign body in the maternal uterus or cervix. Systemic dissemination of yeast is rare in the majority of term infants.

Clinical Findings

Lesions of congenital candidiasis can be seen on the placenta and fetal membranes, including characteristic granulomas of the umbilical cord (Hebert and Esterly, 1986; Schirar et al, 1974). The cord lesions are multiple yellow-white papules, usually measuring 1 to 3 mm in diameter. The cutaneous eruption of congenital cutaneous candidiasis may be sparse or widespread and consists of papules and

FIGURE 99-4 Congenital cutaneous candidiasis, pustular stage, in a 6-day-old infant. A maculopapular rash was present at birth. *(Courtesy P. J. Kozinn, N. Rudolf, A. A. Tariq, M. R. Reale, and P. K. Goldberg.)*

FIGURE 99-5 An 8-day-old infant with a generalized erythematous, scaly eruption sparing only the face and scalp. Oral mucosa was not involved. Hyphae and budding yeasts were seen on potassium hydroxide preparation, and *Candida albicans* was cultured from the lesions. The infant's mother had candidal vaginitis during the pregnancy.

vesicopustules on an intensely erythematous base. The face is relatively spared, as are the oral mucous membranes, and there is no predilection for the diaper area. Palmar and plantar pustules, paronychia, and nail dystrophy help distinguish this condition from more common, benign neonatal dermatoses (Figure 99-4). Bullae and desquamation usually are late features (Figure 99-5). Skin lesions usually resolve with desquamation within 1 to 2 weeks (Darmstadt et al, 2000). The prognosis is good in full-term infants. Topical treatment may be used.

Very low-birthweight infants may present with a less specific, scalded skin–like or erosive dermatitis owing to the organism's penetration of the immature, compromised epidermal barrier, leading to invasive disease. Generalized scaling is the dominant feature, but a careful search may reveal primary vesicopustules and periungual or nail involvement as helpful diagnostic clues (Gibney and Siegfried, 1996).

Diagnosis

The differential diagnosis includes conditions that cause blisters and pustules. Napkin psoriasis is also on differential. A potassium hydroxide preparation that reveals budding yeasts and pseudohyphal forms is the easiest and most cost-effective initial step in establishing the diagnosis. Calcofluor white stain and immunofluorescence microscopy is a more sensitive rapid technique. Positive results on cultures from an intact pustule, skin scrapings, or skin biopsy tissue also support the diagnosis. Cultures of blood, urine, and cerebrospinal fluid are usually negative; however, they are indicated when systemic disease is suspected and in all preterm infants.

SYSTEMIC/DISSEMINATED CANDIDIASIS

Systemic candidiasis infection (*Candida* infection in an otherwise sterile body fluid such as blood, urine, or cerebrospinal fluid) affects very low-birthweight infants more commonly than full-term infants. Most neonatal fungal infections are caused by *C. albicans* and *Candida parapsilosis*. Systemic or disseminated candidiasis can be due to congenital candidiasis (acquired in utero) in very low-birthweight infants, untreated localized *Candida* infection in preterm infants, or nosocomial spread. Risk factors for congenital systemic infection include birthweight of less than 1500 g, indwelling catheters, broad-spectrum antibiotic therapy, steroid administration, and hyperalimentation. Approximately 10% of NICU infants become colonized in the 1st week of life. *Candida* septicemia represents 10% to 16% of all cases of sepsis in the NICU, and early recognition and appropriate therapy are lifesaving (Gibney and Siegfried, 1996; Leibovitz, 2002). The estimated crude mortality rate for candidemia is 38% to 75% (Lupetti et al, 2002).

Clinical

Skin manifestations may occur in 60% of infants, which include burnlike dermatitis followed by desquamation, progressive diaper dermatitis with papules and pustules, and abscess. Systemic involvement occurs via hematogenous or lymphatic spread, most frequently involving the kidney, central nervous system (CNS), and skeletal system. Pneumonia may result from aspiration of infected amniotic fluid and manifests with respiratory distress. Other systemic signs include apnea, bradycardia, temperature instability, hypotension, guaiac-positive stools, and abdominal distention. Laboratory features include an elevated white blood cell count with a left shift reaching the level of a leukemoid reaction (e.g., 120,000/mm^3). In addition, persistent hyperglycemia and glycosuria may be present (Darmstadt et al, 2000).

Diagnosis

The differential diagnosis includes several other neonatal vesiculopustular eruptions that range from benign, self-limited cutaneous processes to rapidly progressive, life-threatening disease. Early and correct diagnosis is essential. Organisms from skin usually are demonstrable on potassium hydroxide or calcofluor white preparations and cultures of scrapings from involved skin. Disseminated

disease can be difficult to diagnose. Respiratory distress and infiltrates on chest radiograph will obscure evidence of *Candida* pneumonia because hyaline membrane disease often occurs in the same patient population. Ophthalmologic examination, chest radiograph, and blood, urine, and cerebrospinal fluid cultures may be helpful, but negative findings are not uncommon in disseminated candidiasis (Johnson et al, 1984). Histologic examination of specimens from the placenta and umbilical cord prepared with the appropriate stains may demonstrate fungal elements. Urinalysis positive for budding yeast or urine culture positive for *C. albicans* may be quickly dismissed as being due to contaminants, but such findings are strongly associated with systemic disease in infants at risk. The diagnosis of disseminated candidiasis can be expedited by a positive touch preparation of a punch biopsy specimen. Using this technique, the practitioner firmly imprints the dermal side of the specimen on a microscope slide and then looks for yeast after potassium hydroxide preparation or Gram staining (Held et al, 1988).

Prognosis and Treatment

Systemic infection with *C. albicans* in premature infants is a serious infection with high morbidity and mortality rates (Johnson et al, 1984). Congenital or acquired candidiasis warrants parenteral antifungal therapy (e.g., with amphotericin B) for infants with any of the following risk factors for disseminated disease: (1) evidence of respiratory distress or sepsis in the immediate neonatal period; (2) birthweight less than 1500 g; (3) treatment with broad-spectrum antibiotics or corticosteroids; (4) extensive instrumentation during delivery or invasive procedures in the neonatal period; (5) positive systemic cultures; (6) evidence of altered immune response; and (7) birth at less than 27 weeks of gestational age. A critical factor for survival in systemic candidiasis is not limited extent of infection but the early initiation of antifungal therapy (Botas et al, 1995; Johnson et al, 1984). A few single-center studies have demonstrated the efficacy of fluconazole in the prevention of both colonization and infection by *Candida* spp. (Kaufman et al, 2001; Manzoni et al, 2006), and a multicenter, prospective, randomized clinical trial has shown the safety and efficacy of fluconazole in preterm and very low-birthweight infants (Kicklighter et al, 2001).

HERPES SIMPLEX VIRUS INFECTION

Early recognition and prompt initiation of therapy for neonatal herpes are critical. The consequences of delaying antiviral therapy can be devastating.

CLINICAL FINDINGS

Onset of symptoms usually occurs at 1 to 2 weeks for most neonates, but congenital lesions have been reported (Salvador et al, 1994). Infection is categorized by extent of disease, as follows: skin-eye-mucosae (SEM) disease, CNS disease, and disseminated disease. Neonatal HSV infection often presents with a sepsis-like syndrome or with a new onset of seizures. Skin or mucosal lesions may appear only late in the disease course, or not at all. Only one third of infants present with cutaneous involvement (Frieden, 1989), although more than 80% develop typical skin lesions during the course of their disease (Overall, 1994).

Characteristic skin lesions begin as isolated or grouped, tense vesicles on an erythematous base and evolve into pustules, crusts, or small erosions over several days. Forty percent of infected infants have SEM disease. With early treatment, these infants have an excellent prognosis; if the infection is left untreated, it will progress in 75% of cases (Arvin and Prober, 1992). Thirty-five percent of infected infants have CNS disease, with a high incidence of developmental abnormalities. One fourth of the infants present with evidence of disseminated disease (e.g., sepsis, liver dysfunction, coagulopathy, respiratory distress). For this group, the prognosis is poor, with a 60% mortality rate and a 40% risk of long-term neurologic impairment in survivors (Arvin and Prober, 1992; Whitley, 1994).

Infants infected in utero have a distinctive clinical presentation. Skin lesions are almost always present at birth and include widespread erosions and bullae, scars, and scalp lesions that resemble those of aplasia cutis. Other frequent findings include chorioretinitis, microcephaly, hydranencephaly, and microphthalmia (Arvin and Prober, 1992).

ETIOLOGY

A majority of cases of neonatal herpes simplex are the result of vertical transmission. Two thirds of cases are caused by HSV-2 and one third by HSV-1. The usual route of infection is via intrapartum contact with genital mucosa, but ascending infection accounts for 5% of cases of neonatal herpes. Infants who become infected in utero are more often premature or small for gestational age, with more widespread and severe disease (Arvin and Prober, 1992).

EPIDEMIOLOGY

Prospective, single-center studies in the United States have shown rates of neonatal HSV infection as high as 31.2 cases per 100,000 (1 in 3200) live births (Corey and Wald, 2009). Most cases of maternal-fetal transmission involve women with undiagnosed genital herpes, many of whom have acquired primary HSV-1 or HSV-2 near delivery. One half of infected infants are born to mothers with primary infections. These women, who are usually without active lesions, have a 25% to 50% risk of transmitting disease to their newborns (Corey and Wald, 2009). One half of infants with neonatal herpes are born to mothers with recurrent genital herpes, generally from HSV-2. Most of these women also are asymptomatic at the time of delivery and may have no known history of genital herpes. In this group, the risk of transmitting infection is around 2.5%.

DIAGNOSIS

A high index of suspicion is required. The differential diagnosis includes the causes of vesicles and pustules in the newborn outlined in Chapter 97. Tzanck smears, viral cultures, and direct fluorescent antibody detection are the most widely used tests to detect herpes infection. The diagnostic yield for each is variable, largely influenced by

the age, quality, and handling of the specimen. Optimally, skin scrapings should be obtained from the base of a fresh vesicle. Other sites should be sampled as well, especially in infants suspected of having CNS or disseminated disease. Tzanck smear analysis is rapid and readily available but will reveal characteristic multinucleated giant cells in only 50% of HSV infections (Nahass et al, 1995). Immunofluorescence is 90% to 95% sensitive and specific but requires a specialized laboratory. IgM assays are not reliable. Viral culture is the diagnostic gold standard and yields positive results for 80% of specimens by 24 hours and for 90% by 48 hours, under optimal conditions of handling and transport. Molecular diagnosis by polymerase chain reaction assay can detect HSV from specimens that would be suboptimal for the other methods (e.g., Tzanck smears, crusts, paraffin-fixed biopsy specimens). Diagnostic polymerase chain reaction assay may be the easiest means of diagnosing HSV infection in the future; however, limitations include the lack of standardization of methodologies, adversely affecting the clinician's ability to interpret results (Kimberlin, 2001; Nahass et al, 1992, 1995).

TREATMENT

Early treatment with antiviral agents is critical to decrease the risk of serious complications and death. All cases of presumptive neonatal HSV infection should be treated with intravenous acyclovir. The standard dose of acyclovir has been 30 mg/kg/day divided every 8 hours. However, the higher dose of 60 mg/kg/day divided every 8 hours could significantly improve the outcome of infants with HSV CNS or disseminated disease (Corey and Wald, 2009; Kimberlin et al, 2001). In the Kimberlin et al study, 79 neonates with HSV disease were studied and treated with either 45 mg/kg/day or 60 mg/kg/day and compared with infants treated with 30 mg/kg/day for 10 days in the original National Institute of Allergy and Infectious Diseases (NIAID) Collaborative Antiviral Study Group trial. Those with disseminated disease who received the higher dose were three times as likely to survive and more than 6 times as likely to be developmentally normal. The only noted side effect was transient neutropenia, which occurred in 21% of those treated with the higher dose (Kimberlin et al, 2001). Vidarabine also is effective in preventing severe disease in infants with SEM disease but not for treatment of infants with more widespread herpes infection (Arvin and Prober, 1992). Morbidity in CNS disease and disseminated disease remains high, with corresponding mortality rates of 15% and 57%, respectively (Jacobs, 1998). Antiviral therapy with intravenous acyclovir reduces mortality from 85% to 31% among infants with disseminated disease and from 50% to 6% among infants with CNS disease (Corey and Wald, 2009). Concomitant administration of immunoglobulin products may improve disease outcome for these infants (Whitley, 1994).

Strategies to decrease risk of vertical transmission include cesarean delivery, serologic screening of pregnant women, prophylactic antiviral therapy, and maternal vaccination development. Delivery via cesarean section for women with active lesions or prodromal symptoms and prophylactic antiviral treatment for women with gestational HSV are some accepted approaches (Enright and Prober, 2002). Suppressive acyclovir reduces the frequency of genital lesions near term and the frequency of cesarean delivery, but there are no data to suggest that it reduces the risk of neonatal herpes. Because a direct correlation exists between the development of neurologic deficits and the frequency of recurrent cutaneous HSV, the use of suppressive oral acyclovir therapy after acute neonatal SEM disease may limit long-term morbidity (Kimberlin et al, 1996).

CHAPTER 100

Common Newborn Dermatoses*

Dakara Rucker Wright and Bernard A. Cohen

This chapter describes a group of cutaneous disorders that are unique to neonates. All of these disorders have well-recognized clinical and histologic features. Most are asymptomatic and self-limited, and rigorous searches have not been made for precise pathogenetic mechanisms or definitive therapies. It is important to recognize these common neonatal dermatoses so that they are not mistaken for more serious diseases, thus obviating the initiation of aggressive workup and treatment. However, distinguishing these common neonatal dermatoses from more serious neonatal dermatoses can be lifesaving. Important considerations in the differential diagnosis based on clinical morphology are outlined in Chapter 97.

ERYTHEMA TOXICUM NEONATORUM

CLINICAL FINDINGS

Erythema toxicum is an inflammatory cutaneous disease of unknown origin that affects approximately half of all full-term newborns (Berg and Solomon, 1987). It occurs less frequently among preterm infants (Carr et al, 1966; Taylor and Bondurant, 1957). In a majority of infants, the lesions develop between 1 and 3 days of age, but they may appear as late as 3 weeks. No predilection of the disorder for race, gender, season, or geographic location has been reported.

Affected infants appear healthy. The basic skin lesions are small (1 to 3 mm in diameter) erythematous macules that evolve into tiny white pustules, with a prominent halo of erythema, and can look similar to a flea bite. Individual lesions may persist for only a few hours, but the eruption lasts for several days or, rarely, for several weeks. The number of lesions present can vary from a few to dozens. The trunk is the most frequent site of predilection, but the face and extremities also may be involved. Palms and soles are almost always spared. Several lesions may coalesce into plaques measuring several centimeters in diameter (Figure 100-1).

DIAGNOSIS

A Wright-stained smear of pustule contents reveals large numbers of eosinophils, which supports the diagnosis. Skin biopsy may be necessary in clinically atypical cases. Histologic features consist of eosinophil-filled intraepidermal vesicles and a mixed intradermal inflammatory infiltrate that tends to localize around the superficial portion of the pilosebaceous follicle.

Considerations in the differential diagnosis include other benign, self-limited disorders such as transient neonatal pustular melanosis, miliaria, infantile acropustulosis, and eosinophilic pustular folliculitis. Acropustulosis of infancy is a pruritic eruption and is characterized by recurrent, itchy vesiculopustular lesions primarily on the palms, soles, and a few lesions on the dorsal distal extremities. Rarely lesions may be on the face and scalp. The etiology is unclear, but in some cases there may be an association with a preceding scabies infestation. Eosinophilic pustular folliculitis in infants typically occurs on the scalp and extremities, recurring in crops similar to acropustulosis of infancy. Infants may also have peripheral eosinophilia. The infantile type is, however, distinct from human immunodeficiency virus (HIV)-related eosinophilic pustular folliculitis (Adam, 2008; Humphrey et al, 2006).

Infections such as bacterial folliculitis, bullous impetigo, candidiasis, herpes, and scabies are also included in the differential and need to be ruled out. The early stage of incontinentia pigmenti can also be mistaken for erythema toxicum. The diagnostic workup outlined in Chapter 97 can differentiate among these conditions.

ETIOLOGY

The etiology of erythema toxicum is unknown. The eosinophilic infiltrate suggests that erythema toxicum is a hypersensitivity response, but studies attempting to incriminate chemical or microbiologic substances, acquired either transplacentally or vaginally from the mother (e.g., drugs, topical irritants, sebum, milk), have failed to provide support for this hypothesis (Bassukas, 1992). At a molecular level, there appears to be an accumulation and activation of immune cells in these lesions as seen by immunohistochemical staining of punch biopsy specimens from cutaneous lesions. Monoclonal antibodies placed in skin with lesions detected E-selectin in the vessel wall as well as dendritic cells, eosinophils, macrophages,

FIGURE 100-1 Florid lesions of erythema toxicum on the back of a newborn infant. The pustules are large and surrounded by an erythematous halo. Smears of the pustular contents showed only eosinophils.

*This chapter includes material from the previous edition, to which Nancy B. Esterly, Elaine C. Siegfried, and Rebecca A. Kazin contributed.

FIGURE 100-2 Numerous superficial pustules on the neck and back of a 1-day-old infant. A few pustules have ruptured, leaving a collarette of scales.

FIGURE 100-3 Transient neonatal pustular melanosis. Hyperpigmented macules on the lower back and buttocks, some of which are encircled by scales. *(From Ramamurthy RS, Reveri M, Esterly NB, et al: Transient neonatal pustular melanosis,* J Pediatr *88:831, 1976.)*

and E-selectin–expressing cells in these affected areas, whereas uninvolved skin demonstrated reduced or absent immunologic activity (Marchini et al, 2001).

TREATMENT AND PROGNOSIS

Erythema toxicum is asymptomatic, resolves spontaneously, and requires no treatment. A prolonged course and recurrence are rare. Once the diagnosis is confirmed, anticipatory guidance and reassurance should be provided to parents.

TRANSIENT NEONATAL PUSTULAR MELANOSIS

CLINICAL FINDINGS

This benign disorder was present at birth in 5% of African American and in 1% of white infants in one older study (Ramamurthy et al, 1976). Characteristic lesions are small, superficial pustules that rupture easily, leaving a collarette of fine scale and hyperpigmented macules that fade over several weeks to months (Figure 100-2). The lesions may be profuse or sparse and can involve all body surfaces, including the palms, soles, and scalp (Figure 100-3). The pustules last approximately 48 hours, but the macules can persist for several months.

DIAGNOSIS

Affected infants are otherwise healthy. A Wright-stained smear of pustule contents revealing keratinous debris and variable numbers of polymorphonuclear neutrophils with few or no eosinophils supports the diagnosis. Gram staining and bacterial cultures obtained from intact pustules uniformly fail to disclose the presence of organisms. The differential diagnosis includes the conditions listed for erythema toxicum.

ETIOLOGY

The cause of transient neonatal pustular melanosis is unknown. A prospective study reported that 17 infants with typical congenital lesions subsequently developed lesions of erythema toxicum, linking the two conditions (Ferrandiz et al, 1992).

TREATMENT

The disorder is asymptomatic and self-limited. Once the diagnosis is confirmed, further therapy is not required.

MILIA, EPSTEIN PEARLS, AND SEBACEOUS HYPERPLASIA

CLINICAL FINDINGS

Milia (a single lesion is a milium) are found in 40% of full-term infants (Gordon, 1949). They are single or sparsely scattered pearly (1 to 2 mm) lesions that occur on the face. The sites of predilection are the cheeks, forehead, and chin (Figure 100-4). Large milia (greater than 2 mm in diameter) are found in infants with type I oral-facial-digital syndrome (Solomon et al, 1970). Rarely, milia can occur in unusual sites, such as on the arms, legs, or foreskin.

Epstein pearls are milia that occur on the midline of the hard palate, and Bohn's nodules are on the gum margins. These tiny cystic lesions occur in approximately 85% of newborn infants. They usually are grouped, firm, and movable and appear opaque and white.

ETIOLOGY

Milia are due to retention of keratin within the dermis.

FIGURE 100-4 Numerous grouped milia on the chin of a newborn infant.

DIAGNOSIS

Histologically, a milium is an invagination of epidermal tissue, arising from the pilosebaceous apparatus of vellus hair, which forms a cyst filled with several layers of keratin-producing cells. The expressed contents of milial cysts resembles tiny white pearls and consists mostly of keratinocyte debris, a useful diagnostic feature.

Milia can be mistaken for sebaceous gland hyperplasia, which occurs in the same distribution. The papules of sebaceous gland hyperplasia are smaller (pinpoint) and more yellow and contain sebaceous lipids.

TREATMENT

Treatment is unnecessary because milia usually exfoliate spontaneously within 1 month. Epstein pearls are self-limited, but can take several months to resolve. Sebaceous hyperplasia also resolves spontaneously within the first few weeks of life.

MILIARIA

CLINICAL FINDINGS

Miliaria neonatorum is a vesicular or pustular dermatitis arising from the eccrine duct. Four clinical variants have been described, and their appearances are influenced by the site of obstruction within the duct. Miliaria crystallina (sudamina) consists of superficial, clear, thin-walled, noninflammatory vesicles that rupture easily. The vesicle is localized within the stratum corneum. Miliaria rubra (prickly heat) consists of small, erythematous, grouped papules often localized to skin folds and areas covered by clothing. These lesions arise within the deeper levels of the epidermis and are accompanied by inflammation. The papules can become pustular if there is a prominent inflammatory component or secondary bacterial infection, a condition sometimes referred to as *miliaria pustulosa*. Miliaria profunda is a mildly inflammatory papular eruption that arises within the deeper, dermal portion of the eccrine duct.

ETIOLOGY

Miliaria is believed to be caused by sweat accumulation within obstructed eccrine ducts. Obstruction of the eccrine duct in adults has been reported to result from a variety of triggers such as cutaneous injury, excessive hydration of the stratum corneum, or overgrowth of microbes (Fitzpatrick, 1990). Premature and even full-term neonates have a full complement of immature eccrine glands that are incompletely canalized which may predispose the newborn to miliaria (Straka et al, 1991). Overheating from excessive bundling and from phototherapy probably contributes to its pathogenesis. The widespread availability of environmental temperature control probably has decreased the incidence of this condition.

Recurrent episodes of pustular miliaria rubra could signal the rare condition type I pseudohypoaldosteronism. This potentially fatal condition, of autosomal recessive inheritance, is a disorder of mineralocorticoid resistance that leads to salt-wasting crises through the eccrine ducts. If this condition is suspected, an appropriate serologic workup should be initiated (Urbatsch and Paller, 2002).

DIAGNOSIS

The differential diagnosis for miliaria includes the conditions listed previously for erythema toxicum. Wright staining of vesicle contents from miliaria crystallina will show few cells; that of miliaria rubra will usually reveal a majority of lymphocytes. If screening studies are nondiagnostic, a skin biopsy analysis will be confirmatory (Fitzpatrick, 1990).

TREATMENT

Lesions rapidly resolve after the infant's environmental temperature is reduced. Application of occlusive emollients can exacerbate the eruption.

ACNE

CLINICAL FINDINGS

The appearance of acne in infancy is similar to that of typical acne vulgaris of adolescence. The spectrum of lesions includes comedones, inflammatory papules, pustules, and rarely cysts, generally limited to the face (Figure 100-5). Comedones are an easily recognized, pathognomonic feature of acne.

The condition occurs in up to 20% of infants and is more common in boys. Acne occurs in a bimodal distribution during infancy. Early-onset neonatal acne appears after 1 to 2 weeks of age and usually resolves spontaneously by 3 months. Infantile acne appears after 3 to 6 months and can persist for years.

ETIOLOGY

The pathophysiologic features of acne are similar at all ages. Important components are the increased size and activity of sebaceous glands, which are influenced by circulating levels of adrenal and gonadal androgens, of both endogenous and maternal origins. The role of *Propionibacterium acnes* in the pathogenesis of infantile acne has not been studied. This lipophilic, anaerobic, gram-positive rod has an important role in the pathogenesis of inflammatory lesions in adolescent acne. A family history of acne is

FIGURE 100-5 Papules, pustules, and comedones (diagnostic of acne) on the chin and cheeks of a male infant.

common, and affected infants have a higher risk of developing severe acne later in life (Hellier, 1954), suggesting a genetic predisposition (Forest et al, 1973).

In the past few years a potential etiologic factor of noncomedonal neonatal acne, or cephalic pustulosis, has been identified. *Malassezia* spp. is a lipophilic yeast that is part of the normal flora of adult skin. A variety of factors, including sebaceous gland activity, humidity, heredity, and corticosteroid treatment, may be influential in allowing it to become an opportunistic pathogen. Recently, several investigators have examined the connection between *Malassezia* spp. and neonatal acne. Findings include the rapid progressive skin colonization of neonates by *Malassezia* spp. as seen on smear and culture examination, specifically *Malassezia sympodialis* and *Malassezia globosa;* higher rates of skin colonization by *Malassezia* spp. in more severe cases of cephalic pustulosis; and isolation of *M. sympodialis* in the neonatal pustules (Bernier et al, 2002; Niamba et al, 1998). In a study conducted to explore this association, 8 of 13 patients (61%) with pustules testing positive for *Malassezia* spp. showed a favorable response to treatment with 2% ketoconazole (Rapelanoro et al, 1996.)

However, contrary evidence exists, including the lack of a complete correlation between *Malassezia* spp. and neonatal acne. Other studies have identified patients with neonatal acne in whom *Malassezia* spp. infection was not found, as well as patients without acne whose pustule cultures were positive for *Malassezia* spp. (Katsambas et al, 1999). As a result, further investigation is needed to clarify cephalic pustulosis and neonatal acne and to specifically address the possibility that these inconsistencies could be explained by methodologic or pathologic variation, or that *Malassezia* spp. may be one part of a multifactorial process, or that some cases of neonatal acne are not cephalic pustulosis but true comedonal disease (Bergman and Eichenfield, 2002.)

DIAGNOSIS

Considerations in the differential diagnosis include the papular and pustular disorders listed previously, but the diagnosis of acne can almost always be made by clinical inspection. No other disorder features comedones. Infants with severe or persistent acne should be evaluated for androgenic endocrinopathy.

TREATMENT

Aggressive treatment of neonatal acne is rarely required. For initial therapy, topical 2% erythromycin or 2.5% or 5% benzoyl peroxide can be applied daily. Tretinoin and more potent formulations of benzoyl peroxide may be too irritating. In more severe cases, a course of systemic erythromycin can be added, in divided doses of 30 to 50 mg/kg/day. Creams, ointments, and topical steroids may exacerbate the condition. If *Malassezia* spp. is isolated or suspected, an antifungal agent may be effective (Rapelanoro et al, 1996.)

Eczema

The term *eczema* is derived from a Greek term meaning "to boil over." It refers to a clinical and histologic cutaneous phenotype characterized by erythema, edema, and scaling, often accompanied by crusting and, in severe cases, blistering. The histologic hallmark of acute eczema is epidermal intercellular edema (i.e., spongiosis). Epidermal thickening is present in chronic eczema. A mixed perivascular inflammatory infiltrate usually is seen within the papillary dermis.

Different types of eczema can be defined by a spectrum of unifying clinical features. When an infant exhibits widespread eczema, a precise diagnosis sometimes requires a period of observation. Two eczematous conditions that manifest in otherwise healthy infants are seborrheic dermatitis and atopic dermatitis. These diseases differ in pathogenesis, distribution of skin involvement, prognosis, and therapeutic options. Infants with widespread eczema who are not otherwise healthy and those with prominent, erosive periorificial and diaper involvement should be evaluated for associated nutritional, metabolic, or immunologic abnormalities. A more extensive differential diagnosis is detailed under Erythroderma in Chapter 97.

SEBORRHEIC DERMATITIS

CLINICAL FINDINGS

Infantile seborrheic dermatitis is characterized by greasy yellow scales on an erythematous base and minimal pruritus. Onset usually is within the first 2 months of life. The most common sites of involvement are the face, scalp, and diaper area. The condition may be localized or disseminated. Flexural areas such as the posterior auricular sulcus, neck, axillae, and inguinal folds also can be affected. Hypopigmentation is often striking in dark-skinned infants (Figure 100-6). In severe cases, fissures may develop and become secondarily infected.

ETIOLOGY

Pityrosporum ovale is a lipophilic yeast that is commonly present on normal skin, increasing in density during and after puberty. The mycelial form has been identified as a causative agent in tinea versicolor. For a century, the yeast form has been linked to adult seborrheic dermatitis. Therapeutic trials with yeast-inhibiting agents have supported a causal role (Straka et al, 1991). There is a higher incidence of seborrheic

FIGURE 100-6 Infant with seborrheic eczema on the face and neck and in the axillae. Note the scaling and hypopigmentation. Temporary hypopigmentation is common in African American infants with this disorder.

dermatitis in immunocompromised patients, especially those with AIDS (Prose, 1991). The association between *P. ovale* and infantile seborrheic dermatitis also has been confirmed (Broberg and Faergemann, 1989; Ruiz-Maldonado et al, 1989). The pathogenesis of the disorder, and the reasons that carriers remain asymptomatic and immunocompromised persons can be more severely affected, remain unclear.

DIAGNOSIS

The diagnosis is usually made clinically, although skin biopsy can be obtained to differentiate between psoriasis and Langerhans cell histiocytosis, which is a more severe condition. Because seborrhea typically occurs in skin folds, *Candida* spp. infection should be ruled out with a fungal culture. Atopic dermatitis can sometimes overlap with seborrhea dermatitis, but atopic dermatitis causes much more itching.

TREATMENT

Infantile seborrheic dermatitis spontaneously resolves by the end of the 1st year of life. For infants with disfiguring or symptomatic disease, there are several therapeutic alternatives. Topical agents effective against *P. ovale* include topical ketoconazole in a cream or shampoo base (Cutsem et al, 1990), shampoos containing 1% zinc pyrithione or 1% to 2.5% selenium sulfide, and propylene glycol (Faergemann, 1988). Propylene glycol is a hygroscopic preservative, with antimycotic activity against *P. ovale*, that has been widely used for more than a century in foods and cosmetics, but can also rarely cause a contact dermatitis. The safety and efficacy of these products have not been established in infants. Nevertheless, widespread availability and popular use have not produced reports of toxicity. Brief application with daily bathing usually is effective and limits excessive percutaneous absorption. Daily application of 0.5% to 1% hydrocortisone cream is another short-term alternative.

ATOPIC DERMATITIS

CLINICAL FINDINGS

Atopic dermatitis (AD) is a chronic, relapsing, severely pruritic disorder defined by a spectrum of defined cutaneous and extracutaneous manifestations (Hanifin, 1991; Paller, 1991) that affects 15% to 20% of the population, particularly in industrialized areas. In 60% of cases, onset of signs and symptoms is in infancy; up to 10% of 1-year-old children are affected (Kay et al, 1994). The most easily recognized of the diagnostic criteria for AD may not be present until early childhood. These criteria include onset of rash before the age 2 years, flexural skin lesions, asthma or hay fever, and generalized dry skin (Williams et al, 1994). AD and seborrheic dermatitis share clinical features, often making correct diagnosis difficult during the neonatal period. A common feature that may distinguish one from the other form is involvement of the diaper area. This area is often dramatically spared in infants with AD and is primarily involved in infants with seborrheic dermatitis.

ETIOLOGY

Atopic disease has been clinically recognized since 1916; however, the pathogenesis remains elusive. Previous investigations of the mechanisms and treatment of AD have focused on immune alterations. There is an imbalance of T cell subsets, with inhibition of the cells that produce interferon-γ (T_H1 helper T cells) and a relative activation of the cells that produce IL-4 (T_H2 helper T cells). This can potentiate a vicious cycle of enhanced production of IgE, eosinophilia, mast cell proliferation, release of histamine by basophils and mast cells, and further expansion of T_H2 cells (Hanifin, 1991; Hanifin et al, 1993). Chronic AD shifts toward T_H1 inflammatory responses. Other in vitro immune abnormalities have been described, including alterations in monocyte cyclic AMP production, increased histamine release by basophils and mast cells, abnormal differentiation of antigen-presenting cells, increased serum levels of eosinophil cationic protein and interleukin-4 (IL-4), and diminished production of interferon-γ by circulating lymphocytes (Hanifin, 1991; Hanifin et al, 1993). Recently, filaggrin loss-of-function mutations have been linked to families with AD, particularly early-onset and persistent atopic dermatitis (Brown and Irvine, 2008; Palmer et al, 2006). Filaggrin is a protein in the top layers of the skin which play a role in epidermal differentiation and skin barrier maintenance. It is also present in the oral, esophageal, and nasal vestibulum but not in the bronchial mucosa (Brown and Irvine, 2008; Weidinger et al, 2008; Ying et al, 2006). This discovery helps to classify atopic dermatitis as a skin barrier abnormality for which the skin's function as an immunologic organ is compromised.

Staphylococcus aureus has an important role in the exacerbation of AD. Seventy-six percent to almost 100% of patients with AD carry this microbe on their skin. Staphylococcal exotoxins act as superantigens capable of stimulating a wide variety of T cell responses (Leung et al, 1995). The inflammatory cytokines suppress endogenous antimicrobial peptides, which are already decreased in AD (Huang et al, 2009).

Food and environmental allergens have a role in a minority of patients (Hanifin, 1991). Some authors report that prolonged breastfeeding and delayed exposure to diverse solid foods may protect against AD, especially

in infants with a strong family history of atopic disease (Zeiger, 1994).

TREATMENT

The goal of treatment is to control signs and symptoms. A definitive cure is not yet available, but spontaneous improvement occurs before puberty in 40% of patients (Hanifin, 1991). Maintenance therapy aims to hydrate and moisturize the skin, reduce inflammation, control pruritus, and eliminate inciting factors. Bathing daily with a mild cleanser followed by liberal application of a bland ointment emollient is part of skin care. Topical corticosteroids are to be used for flares, but long-term continuous use or inappropriate use can lead to skin atrophy, striae, folliculitis, systemic absorption, hypertrichosis, telangiectasias, bruising, and hypopigmentation.

Both tacrolimus 0.03% ointment and pimecrolimus 1% cream, nonsteroidal selective inhibitors of inflammatory cytokines, have been approved for the treatment of atopic dermatitis in children older than 24 months. However, although studies support the safe use of both agents in infants as young as 3 months, there is a black box warning label about the theoretical risk of lymphoma and skin malignancies. These agents are best used for maintenance. They are also useful for the face and skin folds, because they do not have the same local side effects that corticosteroids have.

Systemic antistaphylococcal antibiotics or topical mupirocin, or both, are sometimes necessary for superinfections or flares. Dilute sodium hypochlorite (bleach) baths have also been shown to decrease infection rates with *S. aureus* as well as disease severity (Huang et al, 2009).

Infants with AD have a relative cutaneous anergy and are at increased risk for the development of cutaneous bacterial, yeast, fungal, and viral infections. A high index of suspicion for secondary infection must be maintained.

DIAPER DERMATITIS

CLINICAL FINDINGS

This disorder is the most common neonatal skin condition, developing in approximately 25% of infants. Most affected infants are healthy, but occasionally diaper dermatitis may provide clues to underlying systemic disorders. Involvement of other skin sites may be helpful in establishing a specific diagnosis. The skin in the area most in contact with the diaper becomes inflamed by the presence of irritants exacerbated by friction and microorganisms. These irritants include moisture from urine and feces, fecal enzymes, and cleansing materials, as well as irritants within the diapers. The usual presentation is thus one of an irritant contact dermatitis with erythema and mild scaling of the gluteal crease, buttocks, convex surfaces of the pubic area (mons pubis, labia majora, scrotum), and perianal rim (Figure 100-7). Shiny plaques or erosions may also be present, particularly in more severe cases. The lower abdomen and upper thighs may also be involved; conversely, there may be relative sparing of the skin folds in the diaper region. The condition is self-limiting and episodic with a typical rash lasting 3 to 5 days (Nield and Kamat, 2007; Scheinfeld, 2005; Shin, 2005).

FIGURE 100-7 Erosive diaper dermatitis occurred in this four-month-old following a course of oral antibiotics. *(From www.dermatlas.org. Reproduced with permission.)*

ETIOLOGY

Although diaper dermatitis, described over a century ago, has been widely studied, the cause, true prevalence, and optimal treatment are still issues of debate. Most infants have episodes of diaper dermatitis, usually between 6 and 12 months of age (Jordan and Blaney, 1982). For decades, the condition was believed to be due primarily to the effects of ammonia. However, objective studies did not support this theory (Leyden et al, 1977). Many factors contribute to the pathogenesis of diaper dermatitis, but the nidus of the problem begins with occlusion, excessive hydration, friction, and maceration. Once skin barrier function has been compromised, irritants (urine, fecal lipases, proteases, bile salts) and microorganisms (urease-splitting bacteria, *S. aureus*, beta-hemolytic streptococci, *Pseudomonas* spp., *Candida albicans*) exacerbate the problem. Exogenous irritants, such as soaps, commercial diaper wipes, and a myriad of over-the-counter topical products, can perpetuate the process in susceptible infants.

DIAGNOSIS

Diaper dermatitis is a clinical diagnosis. There is limited histopathology of the condition and thus, no specific diagnostic test (Montes, 1978). Other skin eruptions in the diaper area which should be considered and excluded include both non-infectious and infectious skin conditions. Non-infectious causes of skin eruptions in the diaper area are infantile seborrheic dermatitis, allergic contact dermatitis, Langerhans cell histiocytosis, epidermolysis bullosa, acrodermatitis enteropathica (zinc deficiency), and certain metabolic disorders such as maple syrup urine disease or cystic fibrosis (Nield and Kamat, 2007; Scheinfeld, 2005; Shin, 2005). A distinguishing feature of these conditions is that there are often similar skin lesions in non-diapered areas. Infectious causes of skin eruptions in the diaper area are *Candida* or other fungal infections, *Staphylococcal* scalded skin syndrome, congenital syphilis, herpes simplex, and HIV infection (Scheinfeld, 2005). Similar to

the non-infectious causes, skin lesions associated with these infectious are typically also found elsewhere in non-diapered areas. The rash of *Candida* diaper dermatitis is clinically distinct from that of primary irritant diaper dermatitis. The rash associated with Candida is intensely erythematous and is often accompanied by satellite lesions (papules and pustules) which are typically seen in the groin region and perianal rim. Diaper rashes associated with *Staphylococcus aureus* and Group A *Streptococcus* infections are also clinically distinct, with the former typically presenting as bullous impetigo with scattered vesicles and bullae, and the latter as an erythematous perianal patch (Nield and Kamat, 2007). Once any of these infectious or non-infectious causes of diaper dermatitis are suspected, specific diagnostic tests can be done to rule them in or out. Because there is no specific diagnostic test for primary contact or irritant diaper dermatitis, the diagnosis is thus one of exclusion.

TREATMENT

Clearly the most important steps in preventing diaper dermatitis are maintaining skin barrier function and hygiene and preventing irritation. Traditionally, an effective but labor-intensive approach has been frequent diaper changes with gentle cleansing, thorough drying, and limited use of occlusive plastic or rubber diaper covers. This practice has been greatly simplified by the introduction of disposable diapers.

The first disposable diapers were marketed in 1963. Initially, the absorbent core was composed primarily of cellulose fluff. Subsequently, several conflicting studies were done to evaluate the incidence of diaper dermatitis in infants wearing cloth versus disposable diapers (Jordan and Blaney, 1982). In the mid 1980s, a superabsorbent core material was developed, containing a cross-linked sodium polyacrylate. Upon contact with fluid, this material undergoes a transformation to allow it to hold fluid within a gel and has the capacity to absorb many times its own weight. Several studies have concluded that superabsorbent diapers are superior to cloth diapers in preventing diaper dermatitis (Lane et al, 1990). In addition, superabsorbent diapers can prevent occult fecal contamination of clothing and fomites in daycare settings (Rory et al, 1991).

Routine use of topical preparations to prevent diaper dermatitis is not necessary in infants with healthy skin. For some of these products, additional risks have been recognized. Additives have the potential to cause contact sensitization or irritation. Powders applied vigorously enough to raise a cloud pose an aspiration hazard. This is especially true for talc, which can cause irritant pneumonitis. Talc (mainly hydrous magnesium silicate) also may cause granulomatous reactions when applied to wounds.

Appropriate treatment of diaper dermatitis begins with correct diagnosis of the underlying cause. Most infants develop acute diaper dermatitis as a result of the factors described previously. However, other primary pathologic processes must be considered for any infant with chronic, severe, or recurrent diaper rash. Primary cutaneous diseases that can manifest with diaper rash include allergic contact dermatitis, seborrheic dermatitis, psoriasis, and candidiasis. Uncommon causes of diaper dermatitis such as histiocytosis, congenital syphilis, cystic fibrosis, acrodermatitis enteropathica, bullous pemphigoid, and staphylococcal scalded skin syndrome have serious clinical implications (Kazaks and Lane, 2000).

Mild to moderate, common diaper dermatitis should be treated initially with traditional frequent diaper changes, leaving the area exposed, or both. All potential irritants or sensitizers should be discontinued. Commercial diaper wipes are an often overlooked and common source of these substances. Washcloths, dampened paper towels, and mineral oil–soaked cotton balls are safe alternatives. Zinc oxide ointment and zinc paste are inexpensive, bland, protective agents with antiseptic and astringent properties. Zinc also can have a role in wound healing (Maitra and Dorani, 1992; Okada et al, 1990; Rackett et al, 1993). Some caregivers may object to the difficulty in removing zinc oxide preparations. They should be reassured that it is not necessary to remove the salve. If a parent or clinician needs to remove zinc oxide to assess the skin, this can be easily accomplished with the help of mineral oil.

If there is no objective evidence of candidiasis, such as erythematous papules in skin folds, a short course of a topical low-potency corticosteroid may be beneficial. A topical anticandidal agent should be used when potassium hydroxide preparation or culture suggests yeast infection. Combination products containing potent topical corticosteroids and antifungal agents are less effective than an antifungal used alone (Reynolds et al, 1991). Widespread use of one such product combining a potent, fluorinated topical corticosteroid, 0.05% betamethasone dipropionate, with 1% clotrimazole (Lotrisone), applied under the occlusion of a diaper, has resulted in reports of skin atrophy, striae, and adrenal suppression (Barkley, 1987). Clotrimazole and a similar product combining 0.1% triamcinolone acetonide and nystatin (Mycolog II) are contraindicated for the treatment of diaper dermatitis.

HARLEQUIN COLOR CHANGE

Harlequin color change should not be confused with an entirely different disorder called *harlequin fetus*. Harlequin color change, first described in 1952, usually occurs during the first 4 days of life (Mortensen and Stougard-Andresen, 1959). It is characterized by reddening of one half of the body and simultaneous blanching of the other half. A sharp, midline demarcation runs from the center of the forehead down the face and trunk. Occasionally, the line of demarcation may be incomplete, sparing the face and genitalia. Turning the body from one side to the other accentuates blanching of the upper half and reddening of the lower half. There is no accompanying change in respiratory rate, pupillary reflexes, muscle tone, or response to external stimuli. The total duration of these episodes may range from a few minutes to several hours. Harlequin color change occurs most frequently in low-birthweight infants, but may be seen in up to 10% of term infants. The physiologic basis of the phenomenon has not been defined. It has no pathologic significance, requires no treatment, and can be expected to disappear no later than the 3rd week of life.

SUBCUTANEOUS FAT NECROSIS

CLINICAL FINDINGS

Subcutaneous fat necrosis affects full-term infants who have experienced perinatal distress. Lesions usually appear within the first 2 weeks of life; they may be single or multiple, are poorly circumscribed, and often are tender nodules or plaques that are initially firm with a dusky reddish-purple hue. The lesions are located most often in areas in which a fat pad is present: buttocks, back, arms, and thighs (Figure 100-8). With time, subcutaneous calcification may develop, with subsequent drainage and resultant scarring. The most serious association is hypercalcemia. Infants with hypercalcemia may be asymptomatic, so the incidence and time course have not been well documented (Cook and Stone, 1992). Clinical manifestations include irritability, vomiting, poor feeding, and failure to thrive.

FIGURE 100-8 Rear view of a newborn showing several large discolored areas of subcutaneous fat necrosis. They were irregular in size and shape, felt firm to palpation, and were not hot or tender.

ETIOLOGY

The development of subcutaneous fat necrosis has been related to ischemic injury from perinatal trauma, intrauterine asphyxia (Chen et al, 1981), and hypothermia.

DIAGNOSIS

The differential diagnosis includes sclerema neonatorum (see the following section). A skin biopsy from a well-developed lesion of subcutaneous fat necrosis of the newborn will reveal a subcutaneous granulomatous infiltrate with multinucleated giant cells. Damaged lipocytes contain characteristic needle-shaped clefts. Soft tissue necrosis and inflammation may stimulate local production of 1,25-dihydroxyvitamin D_3, resulting in hypercalcemia (Cook and Stone, 1992).

TREATMENT

In most infants, the process is self-limited; resolution occurs over a period of weeks to months. Infants should be followed closely for the development of hypercalcemia for several months. Hypercalcemic infants should be managed initially with hydration and furosemide-induced diuresis. Low calcium intake, vitamin D restriction, and sometimes systemic corticosteroids may be necessary (Cook and Stone, 1992; Norwood-Galloway et al, 1987). However, this approach may be only partially successful, and persistent hypercalcemia with its associated morbidity may ensue. Bisphosphonate agents, specifically etidronate, have recently been discussed for use as possible agents of last resort to control the persistent hypercalcemia that can be secondary to subcutaneous fat necrosis. In one case report, a newborn with subcutaneous fat necrosis refractory to conservative management had etidronate added to his regimen. After initiation of the drug, the patient's urinary calcium levels soon normalized. It was postulated that the mechanism of lowering the serum and urinary calcium by etidronate was primarily a decrease in bone resorption (Rice and Rivkees, 1999).

Other investigators have commented on the limited use of bisphosphonates in children and question whether the hypercalcemia of subcutaneous fat necrosis is secondary to enhanced bone resorption or intestinal absorption. Controlled trials have been recommended before the use of these agents for this indication can be recommended (Bachrach and Lum, 1999). In the one case study, etidronate had to be stopped because of a rash severe enough to be of clinical concern. Physicians must be aware of possible bisphosphonate-induced hypersensitivity reactions and stop the agent if suspected (Rice and Rivkees, 1999).

SCLEREMA NEONATORUM

CLINICAL FINDINGS

Sclerema neonatorum is a rare disorder that typically affects severely ill, preterm neonates in the first week of life. It is now classified under the Panniculitides which are inflammatory diseases involving subcutaneous adipose tissue (Zeb and Darmstadt, 2008). It manifests with widespread, stone-hard, non-pitting cutaneous induration, typically beginning in the buttocks, thighs, or trunk but spreading to involve any part of the body except the palms, soles, and genitalia. The skin appears pale and waxy, shaping the face into a masklike expression (Figure 100-9). The involved area may be discolored with a reddened or violaceous hue and the joints are stiff. The hardening hinders movement, feeding, and respiration. Associated metabolic acidosis, hypoglycemia, hyperkalemia, hyponatremia, and azotemia can occur. Sclerema neonatorum is a diffuse, systemic process with a grave prognosis (Fretzin and Arias, 1987; Zeb and Darmstadt, 2008).

ETIOLOGY

The mechanism responsible for sclerema neonatorum is unknown. In a recent review article on the disorder, Zeb and Darmstadt summarized the various theories on its pathogenesis into the following four categories: 1) unique

FIGURE 100-9 Sclerema neonatorum. Note the masklike facial expression, pseudotrismus of the partially immobilized mouth, and thickening of the skin over the face, arms, and hands. *(From the Collection of the American Academy of Pediatrics. Reproduced with permission of the officers of the Academy.)*

composition of neonatal fat; 2) defects in neonatal fat metabolism; 3) sign of severe toxicity of grave underlying disorder; 4) special form of edema affecting connective tissue septa (Zeb and Darmstadt, 2008). The disorder has been associated with prematurity, low birthweight, perinatal asphyxia, hypothermia, and sepsis (Ji et al, 1993; Zeb and Darmstadt, 2008).

DIAGNOSIS

The differential diagnosis of sclerema neonatorum includes subcutaneous fat necrosis (described earlier in this chapter), which occurs in healthy term or post-term infants, and scleredema, which occurs in preterm infants and usually involves pitting edema of the lower extremities. Zeb and Darmstadt (2008) summarized the history of the nomenclature of sclerema neonatorum as well as the clinical features, histopathology, and treatment of these three conditions, highlighting the diagnostic confusion which has existed over the years. The histologic changes of sclerema are not specific. Fat necrosis with crystallization may be seen, but thinning of the epidermis, dermal and subcutaneous fibrosis with edema, and thickening of the interlobular septa or trabeculae which support the subcutaneous adipose tissue are more conspicuous features (Dasgupta et al, 1993). There is usually sparse inflammatory infiltration of lymphocytes, histiocytes, and multinucleated giant cells and less inflammation surrounding the fat lobules than in subcutaneous fat necrosis.

TREATMENT

The treatment of sclerema neonatorum is primarily supportive care and treatment of any underlying disease, such as sepsis. Local therapy or warming the body have not proved to be beneficial. Steroid use has not improved survival but may limit the spread of lesions. The use of exchange transfusion for septic neonates with sclerema neonatorum has also been studied over the past several decades and results have been promising, particularly when done repeatedly and early in the course of the disease (Zeb and Darmstadt, 2008).

CHAPTER 101

Cutaneous Congenital Defects*

Katherine B. Püttgen and Bernard A. Cohen

The spectrum of congenital cutaneous defects can be organized by tissue of origin or location within the skin. This spectrum is summarized in Box 101-1. However, in many cases the clinical appearance is not diagnostic for the specific condition or even the tissue type. An overview of differential diagnosis by clinical appearance is included in Chapter 97.

This chapter presents information on the most common and clinically significant congenital cutaneous defects.

VASCULAR ANOMALIES

Precise diagnosis and appropriate management of cutaneous vascular anomalies have been confounded by tremendous confusion in nomenclature and poor understanding of the pathogenesis of the different conditions within this group. For example, the term *hemangioma* has been used indiscriminately to refer to lesions that differ considerably in morphology, behavior, and prognosis. A classification system originally proposed by Mulliken and Glowacki in 1982 and updated in 1996 by the International Society for the Study of Vascular Anomalies (ISSVA) to include infantile hemangioma (IH) variants, other benign vascular tumors, and combined lesions is accepted as the official classification scheme by the ISSVA (Enjolras and Mulliken, 1997; Hand and Frieden, 2002). This scheme separates vascular lesions of infants and children into two major categories: vascular tumors, the most common of which is IHs and vascular malformations. An *infantile hemangioma*, by definition, is a benign tumor of vascular endothelium, characterized by a proliferative phase and an involutional phase (Figure 101-1, *A*). In contrast, a *vascular malformation* is a developmental anomaly generated from a single vascular component or from a combination of vascular components: capillary, venous, arterial, or lymphatic. These two groups can be further differentiated according to clinical, cellular, hematologic, radiologic, and skeletal characteristics (Table 101-1).

INFANTILE HEMANGIOMAS

IHs are the most common tumors of infancy; mature lesions have been noted in 10% to 12% of 1-year-old infants, with more than double this incidence in preterm infants weighing less than 1000 g (Amir et al, 1986). They occur sporadically, most often as single lesions. Low birthweight is the single most important predictor of IH; the risk of IH increases by 40% for every 500-g decrease in birthweight (Drolet et al, 2008). Additional risk factors include prematurity, female sex, white ethnicity, multiple-gestation pregnancy, advanced maternal age, and placental abnormalities including placenta previa (Haggstrom et al, 2007). The male-to-female ratio in term infants is 1:3 (Esterly, 1995).

CLINICAL FINDINGS

Typically, hemangiomas are not clinically apparent at birth but manifest within the first 6 weeks of life as a faint blush or area of pallor, a change known as a *precursor lesion*. They follow a triphasic pattern of growth, marked by proliferation, plateau, and a long, slow period of involution. In the first 2 months of life, nearly all IHs double in size, and most IHs reach 80% of their maximum size between 3 and 5 months of age (Chang et al, 2008). The growth phase usually slows after 5 months and ends by 12 months of age, if not before. The end of involution does not necessarily indicate resolution, and up to 40% of lesions have residual textural changes and scarring characterized by fibrofatty residuum. The clinical appearance is dictated by the depth of the tumor. Superficial lesions are cherry red and sharply circumscribed. Though such terminology should be avoided because it is imprecise, these superficial IHs are often referred to as "strawberry" or "capillary" hemangiomas. Lesions that are confined to the deep dermis and subcutis appear bluish and dome-shaped. Most lesions are mixed and have both superficial and deep components. The head and neck regions are involved most commonly (60% of cases), followed by the trunk (25%), and extremities (15%) (Finn et al, 1983). Lesions can be designated as focal and seem to grow from a single point. Segmental hemangiomas comprise an apparent developmental unit and are thought to arise from embryonic developmental units or placodes, but their exact origin is not fully understood. Indeterminate lesions likely occupy part of a segment. Segmental and deep IHs are known to have a longer proliferative phase. Flattening occurs by age 5 in half of cases and by age 9 in an additional 40% (Esterly, 1995). Parents are frequently concerned about the risk of hemorrhage and should be reassured that significant bleeding rarely occurs. Several other complications are possible, however, and the more serious sequelae are described next.

Obstruction

A hemangioma that obstructs just one eye can pose a significant threat to visual development by limiting the visual field or compressing the globe. Permanent damage to vision can occur in a relatively short period of time. Obstruction of bilateral—but generally not unilateral—external ear canals will impair development of hearing. A lesion encompassing the chin, lower cheeks, and jaw, now referred to as segment 3 or the "beard" area, may indicate upper airway involvement, which can be life-threatening.

*This chapter includes material from previous editions, to which Nancy B. Esterly, MD, Elaine C. Siegfried, MD, and Allison Z. Young, MD, contributed.

BOX 101-1 Spectrum of Congenital Cutaneous Defects

VASCULAR DEFECTS

Hemangiomas
Malformations: lymphatic, venous, arterial, capillary, mixed

HYPOPIGMENTED LESIONS

Ash-leaf macules, confetti-like macules
Linear and whorled hypomelanosis
Nevus depigmentosis
Nevus anemicus
Hemangioma precursor

MELANIN-CONTAINING LESIONS

Nevocellular nevi
Melanoma
Lentigines
Café-au-lait macules
Nevus spilus
Mongolian spots
Nevus of Ota and nevus of Ito

TUMORS OF EPITHELIAL ORIGIN

Epidermal (keratinocytic) nevi/sebaceous nevi—nevus unius lateris, nevus verrucosis, ichthyosis hystrix
Nevus comedonicus
Pilomatrixoma
Porokeratosis of Mibelli

DERMAL TUMORS

Connective tissue nevi: collagen, elastic tissue
Digital fibroma

TUMORS OF EXTRACUTANEOUS ORIGIN

Cutaneous mastocytosis: urticaria pigmentosa, solitary mastocytoma, diffuse cutaneous mastocytosis
Juvenile xanthogranuloma
Lipoma
Osteoma cutis
Nasal glioma
Dermoid cyst
Meningioma

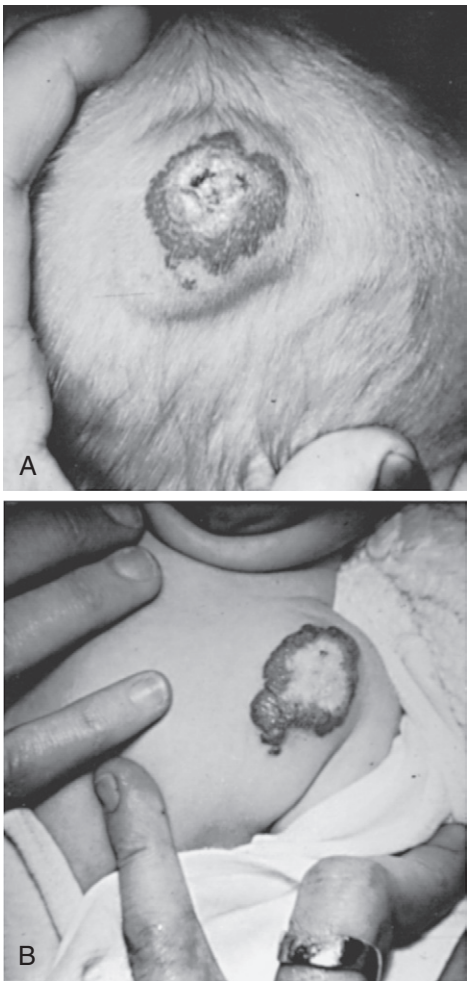

FIGURE 101-1 **A,** Hemangioma with small central ulceration on the scalp of an infant. **B,** Involuting hemangioma with central gray fibrotic area.

Ulceration

Ulceration occurs in up to 10% of hemangiomas and is more commonly seen in large lesions, those with segmental morphology, and with both superficial and deep components (Chamlin et al, 2007; Morelli et al, 1991, 1994; Mulliken et al, 1995). Areas of friction and chronic exposure to moisture such as the lip, neck, and diaper area are most likely to ulcerate. Ulcerated hemangiomas are painful and at risk for secondary infection. Those at highest risk for ulcer formation are large, of mixed clinical type, segmental in morphology type, and located on the lower lip, neck, or anogenital region. Ulceration most often occurs during the proliferative phase, in younger infants.

Disfigurement

During the 1st year of life, the presence of a prominent hemangioma can elicit a disturbing amount of unwanted attention. Many parents require emotional support through this time. In addition to the transient disfigurement, lesions of the central face and those with a significant superficial component predispose the affected child to permanent scarring. Disfigurement alone, regardless of threat to function, may be a reasonable indication for medical therapy in certain cases, if surgical reconstruction is likely to be problematic.

Kasabach-Merritt Syndrome

Though originally thought to be associated with IH, Kasabach-Merritt syndrome is now known to be associated with either kaposiform hemangioendothelioma or tufted angiomas, much rarer vascular tumors (Cooper et al, 2002). It is not seen in conjunction with IHs. The lesion consists of a rapidly expanding vascular tumor with compression and invasion of surrounding structures as well as primary platelet trapping and resultant consumptive coagulopathy. The mortality rate is 30% to 40%.

Central Nervous System Anomalies

Large facial hemangiomas may be associated with anomalies of the central nervous system (CNS) (Frieden et al, 1996). PHACE syndrome is a combination of *p*osterior fossa malformations, *h*emangiomas, *a*rterial anomalies, *c*oarctation of the aorta, and *e*ye abnormalities. Sternal cleft and supraumbilical raphe can also be seen, and the disorder is therefore sometimes referred to as PHACES. The

TABLE 101-1 Characteristics of Hemangiomas Versus Vascular Malformations

Hemangioma	Vascular Malformation
Clinical	
Usually nothing seen at birth, 30% manifest as red macule	All present at birth; may not be evident
Rapid postnatal proliferation and slow involution	Commensurate growth; may expand as a result of trauma, sepsis, hormonal modulation
Female to male 3:1	Female:male 1:1
Cellular	
Plump endothelium, increased turnover	Flat endothelium, slow turnover
Increased mast cells	Normal mast cell count
Multilaminated basement membrane	Normal thin basement membrane
Capillary tubule formation in vitro	Poor endothelial growth in vitro
Hematologic	
No specific abnormality	Primary stasis (venous); localized intravascular coagulation (LIC)
Radiologic	
High flow	Angiographic findings: diffuse, no parenchyma
Ultrasound: variable echogenicity, high vessel density, high flow, low resistance, little/no AV shunting	Low-flow (e.g., venous malformation): phleboliths, ectatic channels; MRI: T2 hyperintense, patchy/avid enhancement
MRI: T1 isointense, T2 hyperintense, homogeneously enhancing soft tissue mass. Flow voids in and around lesion	High-flow (e.g., arteriovenous malformation): enlarged, tortuous arteries with arteriovenous shunting; MRI: multiple enlarged flow voids, no soft tissue mass
Skeletal	
Infrequent "mass effect" on adjacent bone; hypertrophy rare	Low-flow: distortion, hypertrophy, or hypoplasia High-flow: destruction, distortion, or hypertrophy

Adapted from Mulliken JB, Young AE: *Vascular birthmarks, hemangiomas and malformations*, Philadelphia, 1988, WB Saunders, p 35.

diagnostic criteria for PHACE were recently formalized by a concensus panel, and clinical features grouped into major criteria. Definitive diagnosis of PHACE requires a facial segmental IH or an IH larger than 5 centimeters on face or scalp in addition to one major or two minor criteria. (Metry et al, 2009). For unknown reasons, the female to male ratio for PHACE is a striking 9:1. Because of associated anomalies, patients suspected of having PHACE syndrome are most likely to require imaging. Children with frontotemporal and frontonasal IH (known as segments 1 and 4) have a higher correlation with structural cerebral and cerebrovascular anomalies, whereas those with mandibular (segment 3) or "beard" distribution lesions are at higher risk for cardiac abnormalities and IH in the airway (Waner et al, 2003). The maxillary face (segment 2) appears to be a lower-risk segment for IH involvement. The most common and potentially devastating sequelae of PHACE syndrome are neurologic; these can be structural brain anomalies and abnormalities of cerebral vasculature. Progressive stenoses and occlusions of cerebral arteries can also be seen. Both moya-moya–like vasculopathy and arterial ischemic strokes have been reported (Drolet et al, 2006; Heyer et al, 2006).

Spinal Dysraphism and Genitourinary Abnormalities

Sacral and lumbar hemangiomas may reveal spinal dysraphism, including tethered spinal cord, lipomyelomeningocele, imperforate anus, renal anomalies, or abnormal external genitalia. (Albright et al, 1989; Goldberg et al, 1986; Laurent et al, 1998; Tavafoghi et al, 1978). Perineal lesions should also be imaged to rule out underlying abnormalities, especially those that are segmental in nature. In recent years, both SACRAL (*s*pinal dysraphism, *a*nogenital, *c*utaneous, *r*enal and urologic anomalies, associated with an *a*ngioma of *l*umbosacral localization) syndrome and PELVIS (*p*erineal hemangioma, *e*xternal genitalia malformations, *l*ipomyelomeningocele, *v*esicorenal abnormalities, *i*mperforate anus, and *s*kin tag) syndrome have been described to emphasize the potential for underlying spinal and genitourinary abnormalities in association with lumbosacral and perineal hemangiomas (Girard et al, 2006; Stockman et al, 2007).

Visceral Involvement

Diffuse neonatal hemangiomatosis manifests as widely scattered, small superficial hemangiomas. Infants with this pattern of cutaneous involvement may have lesions limited to the skin, known as benign neonatal hemangiomatosis. However, associated hemangiomatosis of the liver, gastrointestinal tract, lungs, and/or CNS can be complicated by visceral hemorrhage, hepatomegaly, high-output cardiac failure, or unexplained anemia or thrombocytopenia, with a significant mortality rate (Byard et al, 1991). Congestive heart failure can also occur with a large, isolated cutaneous hemangioma (Mulliken et al, 1995).

DIAGNOSIS

In most cases, a hemangioma can be diagnosed by its clinical appearance and pattern of evolution. A vascular lesion that is not obvious at birth, begins as a precursor noted

during the 1st month of life, and exhibits rapid growth is undoubtedly a hemangioma. A lesion that deviates from this typical picture presents a diagnostic dilemma. Considerations in the differential diagnosis include IH, vascular malformation, and a nonvascular mimic. Doppler ultrasound examination is an easily performed test that may help to distinguish between a hemangioma and a low-flow malformation. Other imaging modalities—magnetic resonance imaging (MRI) or angiography—may be indicated for large or obstructive lesions (e.g., ocular, upper airway) to help define the extent of involvement or associated abnormalities (Baker et al, 1993; Esterly, 1995). Skin biopsy is diagnostic for nonvascular tumors, which can mimic vascular birthmarks (e.g., pilomatricoma, juvenile xanthogranuloma, Langerhans cell histiocytosis, infantile myofibromatosis). Differentiating among various vascular tumors and malformations can be quite challenging even to experienced pathologists. GLUT1 is an immunohistochemical marker, highly selective and specific for IH, that is also expressed at the blood-brain barrier and in placental tissue. Its discovery has helped to make correct diagnosis of these challenging lesions more feasible, especially in cases with atypical presentations (North et al, 2000).

PATHOGENESIS

Hemangiomas in the proliferative phase are composed of syncytial aggregates of endothelial cells. These cells, like mature endothelial cells, express alkaline phosphatase, factor VIII antigen, and CD31 PECAM (platelet endothelial cell adhesion molecule), as well as Weibel-Palade bodies on electron microscopy, but ^{3}H labeling demonstrates active proliferation. Other histologic features that distinguish proliferating hemangiomas from malformations are the presence of multilaminate basement membranes bordering the endothelial syncytia, large numbers of mast cells (Esterly, 1995), and increased expression of other immunohistochemical markers, including proliferating cell nuclear antigen, vascular endothelial cell growth factor, type IV collagenase, urokinase, and basic fibroblast growth factor (bFGF) (Takahashi et al, 1994). Elevated bFGF can be detected in urine from infants with hemangiomas (Mulliken et al, 1995). Angiogenesis is a process that allows new blood vessel formation. It plays an important role in the growth of all vascular tumors, including hemangiomas. Identification of the basic processes that contribute to angiogenesis and effective angiogenesis inhibitors will provide insight into the pathogenesis and a more ideal therapy for hemangiomas (Morelli, 1993; Mulliken, 1991; O'Reilly et al, 1995).

It appears that hemangiomas constitute clonal expansions of endothelial cells, suggesting that these tumors are caused by somatic mutations in one or more genes regulating endothelial cell proliferation (Boye et al, 2001). It has been shown that Tie2 and its ligands angiopoietin-1 and angiopoietin-2 may be involved in the pathogenesis of hemangiomas (Yu et al, 2001).

TREATMENT

Eighty percent of hemangiomas are ultimately uncomplicated, and it is difficult to predict which ones will develop problems (Mulliken et al, 1995). For a majority of lesions, the initial treatment of choice is "active nonintervention." During the phase of rapid proliferation, patients with uncomplicated hemangiomas should be examined at 2- to 4-week intervals to evaluate degree of growth and development of problems. During this phase, parents often are anxious and require ongoing, directed anticipatory guidance. A common concern is the risk of significant hemorrhage. This is rare. Minor episodes of bleeding can result from trauma and respond to short-term compression, like any superficial wound. Demonstration of before-and-after photographs of growing and involuted lesions in other children helps diminish concern.

Decades of aggressive therapy followed by suboptimal outcome from the 1940s through the 1960s were followed by a passive approach to the treatment of minimally complicated hemangiomas. The dogma has been to avoid treatment because children whose hemangiomas were allowed to involute spontaneously had less severe scarring than those subjected to excision or ionizing radiation. However, up to 40% of hemangiomas leave permanent skin changes that can be disfiguring (Enjolras and Mulliken, 1993). Psychological and social problems may result from facial or other visible deformities. Early intervention should be considered for lesions with a higher potential for complications. Such lesions include hemangiomas of the periorbital area, central face, skin folds, and hands and those with a pattern suggestive of visceral involvement. Newer therapeutic approaches are aimed at minimizing growth or speeding resolution without the risk of additional scarring. At present, the benefits of newer approaches to therapy outweigh the risks in many cases. Early initiation of therapy, aimed at preventing growth, is more effective than therapy that is delayed until maximal growth has been reached. Treatment options include oral or intralesional corticosteroids and pulsed dye laser; most recently, use of the nonselective beta-blocker propranolol has been suggested as an addition to the therapeutic armamentarium. Because of the up to 20% risk of often irreversible spastic diplegia in infants treated with α-interferon, this therapy has fallen out of favor (Barlow et al, 1998; Deb et al, 1999; Wörle et al, 1999). Vincristine has been used in life-threatening IH but has multiple limitations, including placement of an indwelling catheter, slow time to response, and immune suppression.

Pulsed dye laser was postulated in the late 1980s and 1990s in a number of small case series and case reports to have the potential to halt the growth of superficial IHs and cause dramatic improvement in the appearance of these lesions at a young age (Ashinoff and Geronemus, 1991, 1993; Barlow et al, 1996; Garden et al, 1992; Glassberg et al, 1989; Haywood et al, 2000; Poetke et al, 2000; Scheepers and Quaba, 1995; Sherwood and Tan, 1990; Waner et al, 1994; Wheeland, 1995). However, a randomized prospective controlled trial of 121 infants found that pulsed-dye laser treatment in uncomplicated hemangiomas is no better than watchful waiting and that the primary difference noted after 1 year of treatment was that infants treated with laser were more likely to exhibit skin atrophy and hypopigmentation when compared to untreated infants (Batta et al, 2002). Pulsed-dye laser cannot prevent the preprogrammed growth pattern of hemangiomas and has a limited role during the proliferative phase. In contrast, it

is quite useful during involution, if there is residual redness or telangiectasias but relatively little fibrofatty residuum.

Corticosteroids may be administered by topical application, intralesional injection, or enteral/parenteral dosing. Each route utilizes corticosteroid preparations of different potency and duration of action. True comparative efficacy studies would be impossible. Experience is greatest with systemic administration, considered to be the optimal regimen by some experts; the recommended regimen is oral prednisone or prednisolone, 2 to 3 mg/kg/day as a single morning dose or in divided doses (Esterly, 1995; Mulliken et al, 1995). Within 1 to 2 weeks, 30% of hemangiomas will show dramatic response; 40% will respond equivocally. In patients with slower-responding lesions, slowly tapering therapy is required through the proliferative phase. If no response is detected, the medication should be rapidly tapered after 2 weeks.

Intralesional injections may be preferred for well-localized hemangiomas, including those involving the eyelid. Colloidal suspensions of triamcinolone and dexamethasone or betamethasone in 1:1 mixtures are used. Large doses are administered, in the range of 40 mg triamcinolone plus 6 mg of betamethasone in 2 mL of suspension (Kushner, 1979). Administration of this dose to a 5-kg infant is equivalent to 20 mg/kg of prednisone given as a single dose, which may ultimately allow for a lower total systemic dose. Complications include cutaneous atrophy, skin necrosis, ophthalmic artery occlusion, and blindness. Thus, periocular intralesional steroid injection should be performed only by experienced pediatric ophthalmologists. Simultaneous indirect ophthalmoscopy should be considered during the time of the injection to aid in prevention of complications (Egbert et al, 1996).

The paucity of information on the treatment of hemangiomas with topical steroids suggests that this route of administration is minimally effective in comparison with other treatment modalities and likely useful in only very superficial lesions (Ranchod et al, 2005). One retrospective study of ultrapotent topical corticosteroid use in proliferating hemangiomas found that 35% showed good response and 38% showed partial response, and growth ceased before the anticipated end of the proliferative phase based on the patients' age. Thin superficial lesions responded most markedly, with thicker lesions showing minimal improvement (Garzon et al, 2005).

Several small case series and case reports have been published suggesting the improved relative safety and efficacy of the nonselective beta-blocker propranolol as compared with other medical therapies, but at this time there are no data from randomized, controlled clinical trials to fully justify this therapy as the standard of care. Currently, clinical practice varies widely in the use of propranolol versus corticosteroids. Early results appear to be encouraging but more data is needed. The drug is administered as an oral suspension in divided doses every 8 hours; total daily dosing between 2 and 3 mg/kg/day is generally used. Monitoring for potential side effects of hypotension, bradycardia, hypoglycemia, and bronchospasm is necessary (Leaute-Labreze and Taieb, 2008; Leaute-Labreze et al, 2008; Sans et al, 2009).

Ulceration is a therapeutic challenge that may be treated initially with the appropriate occlusive dressing. The choice of dressing and frequency of changes are dictated by the amount of exudate produced. Coban dressing is ideally suited for secure dressings over hemangiomas on the extremities (Kaplan and Paller, 1995). For sites that are difficult to dress, frequent, liberal application of zinc oxide paste or petrolatum jelly is effective. To inspect the skin, zinc oxide is easily removed with mineral oil. There are few prospective trials examining treatment of ulcerated hemangiomas. Various dressing materials including petrolatum impregnated gauze and seaweed-derived alginate dressings are often recommended. Off label use of becaplermin gel, a recombinant human platelet-derived growth factor, has been reported to show dramatic healing in small case series. The product now carries a boxed warning from the FDA, which must now be taken into consideration before its use (Metz et al, 2004; Yan, 2008). Agents for pain control should be prescribed. Alternating doses of acetaminophen and ibuprofen usually are sufficient, but overuse of the latter may increase the risk of bleeding and cause pain from gastrointestinal upset that can be difficult to distinguish from the pain associated with ulceration. A high index of suspicion should be maintained for secondary infection, with a low threshold for use of either topical or systemic antibiotic therapy. If conservative therapy is unsuccessful, yellow-light laser may relieve pain and speed reepithelialization (Achauer and Vander Kam, 1991; Morelli et al, 1991, 1994). The ulcers will heal but will inevitably leave scars.

A hemangioma that interferes with the visual axis should be treated aggressively. Evaluation by an experienced pediatric ophthalmologist is recommended. A hemangioma that limits the visual field but does not distort the globe may be treated by patching the contralateral eye. More complicated lesions may be treated initially with propranolol or corticosteroids: topical, enterally administered, or intralesional. The intralesional route of administration carries the risk of embolic occlusion of the retinal arteries. This tragic adverse effect can occur ipsilaterally, contralaterally, or bilaterally (Brown et al, 1972; Fost and Esterly, 1968; Zuniga et al, 1987) (Figure 101-2). Surgical excision should be considered for vision-threatening hemangiomas that fail to respond to medical management (Mulliken et al, 1995; Walker et al, 1994).

There is no uniformly successful therapy for seriously complicated or life-threatening hemangiomas. Reported treatment options include high-dose corticosteroids, propranolol, aspirin, dipyridamole, interferon-α, cold steel excision, sclerotherapy, arterial embolization, cyclophosphamide, bleomycin, and vincristine (Enjolras et al, 1990; Esterly, 1995; Leaute-Labreze et al, 2008; Mulliken et al, 1995; Payarols et al, 1995; Sarihan et al, 1997;). All carry significant risks.

VASCULAR MALFORMATIONS

Vascular malformations may be indistinguishable from hemangiomas by clinical and light microscopic examination; however, they are biologically distinct lesions.

CLINICAL FINDINGS

Malformations are true structural anomalies, composed of one or more types of vessels—capillaries, veins, arteries, and/or lymphatics. Unlike hemangiomas, they are always

present at birth, although in certain cases they may not be noted until later in life. They affect males and females equally. Growth is commensurate with the child's growth, although the lesion may expand as a result of local thrombosis or inflammation. Primary platelet trapping with consumptive coagulopathy (e.g., Kasabach-Merritt syndrome) does not occur, but recurrent episodes of localized intravascular coagulopathy are a potential serious long-term problem (Dompmartin et al, 2008; Mazoyer et al, 2008).

Local skeletal or soft tissue destruction or hypertrophy is common. Spontaneous resolution is not expected except in one specific malformation, the salmon patch. Vascular malformations occur either as isolated cutaneous defects or in association with a variety of well-defined syndromes. The more common variations are described next.

Salmon Patch

The glabellar salmon patch (nevus simplex or nevus flammeus), also known in the vernacular as an "angel's kiss," is a bilaterally symmetric superficial capillary defect. It is

FIGURE 101-2 **A,** A flat hemangioma was noted at birth; by 3 weeks of age, the lesion had expanded, as shown. **B,** After 11 weeks of prednisone (20 mg/day), the lesion had regressed. **C,** Nearly complete regression is evident by age 4 years. The patient was a normally intelligent child whose only residual problem was strabismus.

the most common vascular malformation and the only one that almost always fades spontaneously. A similar lesion in the nuchal area, colloquially known as the "stork bite," usually is persistent. Large lesions may also involve the eyelids and alae nasi. Prominent glabellar salmon patches are associated with dysmorphic syndromes including Beckwith-Wiedemann syndrome and fetal alcohol syndrome (Burns et al, 1991).

Capillary Malformation (Port-Wine Stain)

Port-wine stain is an asymmetrical postcapillary venule malformation that occurs in 0.3% of neonates. A majority are isolated cutaneous lesions. At birth they are pink, macular, and blanchable. With time, most lesions darken; papulonodular surface change and ipsilateral soft tissue or even bone hypertrophy may occur in adulthood. Facial capillary malformation is a distribution that includes the forehead or upper eyelid and may be associated with buphthalmos or glaucoma. Complete ophthalmologic examination is indicated for affected infants.

Sturge-Weber syndrome (SWS) is a triad of facial capillary malformation, leptomeningeal vascular malformation, and glaucoma that occurs sporadically. The classic finding of double-contoured (tramline) calcifications on a skull film is not seen during infancy; this sign develops during childhood. CNS lesions are most reliably detected by MRI after 6 months of age. SWS occurs in less than 30% of infants with facial port-wine stains; the risk is increased in infants with more extensive lesions (Tallman et al, 1991). The degree of CNS involvement is variable in SWS, ranging from subclinical lesions to intractable seizures and intellectual impairment.

Two national organizations have been established to serve the needs of patients and their families:

The Vascular Birthmarks Foundation, PO Box 106, Latham, NY 12110; telephone 877-VBF-4646; *www.birthmark.org*

The Sturge-Weber Foundation, P.O. Box 418, Mt. Freedom, NJ 07970; telephone 973-895-4445 or 800-627-5482; *www.sturge-weber.org*

Arterial/Lymphatic/Venous Malformation

The arterial/lymphatic/venous malformation category includes a spectrum of isolated cutaneous vascular anomalies that have been given a variety of clinically descriptive names. Rather than relying extensively on eponymous names for a majority of malformations, it is recommended that each malformation be described by the vessel types that exist within it, as seen on radiologic imaging (Enjolras and Mulliken, 1997; Mulliken and Young, 1988).

These lesions do not resolve spontaneously. Corticosteroid therapy is not beneficial. Complications are related to the flow rate and extent of the lesion. Localized thrombosis and phlebitis occur in low-flow lesions; high-flow lesions can cause significant bleeding, destructive interosseous changes, and high-output cardiac failure. Many centers now have collaborative multidisciplinary groups to help manage the most complicated vascular malformations and vascular tumors, which typically require treatment by physicians in many specialties.

Cutis Marmorata Telangiectatica Congenita

Cutis marmorata telangiectatica congenita (CMTC) is a distinct, reticulated capillary-venous malformation that primarily affects the lower extremities (Figure 101-3). CMTC can occur as a single isolated patch or involve an extensive area. With time, associated atrophy and ulceration may occur. Larger lesions may be associated with ipsilateral hypertrophy or hypotrophy of the affected limb.

Klippel-Trénaunay and Parkes Weber Syndromes

Klippel-Trénaunay and Parkes Weber syndromes are clinically defined, sporadic conditions consisting of extensive capillary malformation, most often occurring unilaterally on the lower extremity, associated with underlying venous and lymphatic malformations, and marked by progressive ipsilateral limb hypertrophy. Parkes Weber syndrome is defined by an overlying capillary malformation and underlying arteriovenous malformation or fistula and its associated constellation of complications.

Cobb Syndrome

Cobb syndrome is a sporadic condition consisting of a posterior truncal nevus flammeus overlying a vascular abnormality that involves the spinal cord.

Bonnet-Dechaume-Blanc Syndrome

Bonnet-Dechaume-Blanc syndrome (also known as *Wyburn-Mason syndrome*) consists of a facial port-wine stain overlying a retinal and intracranial arteriovenous malformation. The retinal lesion appears as dilated, tortuous retinal vessels on routine ophthalmoscopy. Cranial bruit, mild proptosis, and conjunctival hyperemia may be present.

FIGURE 101-3 Cutis marmorata telangiectatica congenita. Note the striking network of dilated vessels, most distinct over the extremities. *(From Humphries JM:* J Pediatr *40:486, 1952.)*

Blue Rubber Bleb Nevus Syndrome [OMIM 112200]

Blue rubber bleb nevus syndrome condition, inherited as an autosomal dominant trait, is characterized by venous malformations of the skin and gastrointestinal tract associated with bleeding and iron deficiency anemia. Numerous lesions may be present at birth. They are blue macules or nodules that range in size from 1 mm to several centimeters, resembling the "blueberry muffin" lesions of congenital TORCH (*t*oxoplasmosis, *o*ther infections, *r*ubella, *c*ytomegalovirus, *h*erpes simplex) infection, but are easily compressible. They may be tender to palpation or surmounted by droplets of sweat. An underlying large venous malformation of the lower extremities or pelvis is often present, and patients should undergo magnetic resonance imaging.

Maffucci's Syndrome

Maffucci's syndrome is a sporadic condition that consists of mixed vascular malformations and characteristic enchondromas. Chrondosarcomas are the most common malignancy seen in this syndrome. In 25% of cases, manifestations are present at birth or in early infancy.

PTEN Hamartoma Tumor Syndrome

The hamartomatous tumor group comprises two clinically distinct genetic syndromes caused by mutations in the PTEN (phosphate and tensin homologue deleted on chromosome 10) tumor suppressor gene-Cowden and Bannayan-Riley-Ruvalcaba. There are reports of a Proteus-like syndrome with PTEN mutation (Smith et al, 2002; Thiffault, 2004; Zhou et al, 2000, 2001). Proteus syndrome is now thought to not be related to PTEN mutations. To date, only Cowden syndrome is associated with increased risk of malignancy, but all patients are recommended to undergo periodic cancer screening (Hobert and Eng, 2009).

Cowden syndrome [OMIM 15835], inherited in an autosomal dominant fashion, is characterized by trichilemommas, papillomatous papules, and acral and plantar keratoses. These benign growths are rarely seen before adulthood. Lhermitte-Duclos disease, macrocephaly, megencephaly and dolichocephaly manifest in childhood. Patients are at increased risk for breast, thyroid, and endometrial cancers.

Bannayan-Riley-Ruvalcaba syndrome [OMIM 15348] manifests with macrocephaly, lipomatosis, hemangiomas, intestinal polyps, penile lentigines, macrosomia, myopathy of proximal muscles, and bony abnormalities. Developmental delay and intellectual impairment is seen in half of patients.

Proteus-like syndrome is characterized by the extensive malformations and hamartomas with striking overgrowth, connective tissue and epidermal nevi, and hyperostosis.

Lymphedema

Lymphedema is a term used to describe diffuse soft tissue swelling characterized by firm, pitting edema. Lymphedema can occur in the setting of anomalous lymphatic drainage. Congenital variants have been reported. Females are affected more frequently than males. The lower limbs are the most commonly affected sites, but other sites also may be involved, and rarely, chylothorax or ascites may be present. *Milroy's disease* is an autosomal dominant condition that manifests with progressive lymphedema of the lower extremities. Lymphedema of the extremities occurs in *Turner (XO) syndrome*.

TREATMENT

Treatment for an uncomplicated capillary malformation is aimed at minimizing disfigurement. With time, these lesions thicken and develop irregular surface changes, often with friable nodules. In 1986, the yellow-light pulsed-dye laser was approved by the U.S. Food and Drug Administration (FDA) for the treatment of capillary malformations, as early as the neonatal period. The copper vapor laser and the argon-pumped tunable dye laser also are yellow-light lasers, but because of increased risk of scarring in comparison with pulsed-dye laser, these lasers are rarely used today. Most of the published data on laser treatment of port-wine stains in children is from studies utilizing the pulsed-dye laser. Children require an average of 5 to 10 pulsed-dye laser treatments for maximal lightening. The best results have been seen in children younger than 4 years of age. In this age group, 20% can expect 95% clearing (Goldman et al, 1993). Pulsed-dye laser therapy is less effective for facial port-wine stains that are close to midline or those on the extremities (Garden and Bakus, 1993; Renfro and Geronemus, 1993). A recent study comparing the effects of the pulsed-dye laser with those of the argon pumped-dye laser for the treatment of port-wine stains has shown that the pulsed-dye laser is clinically superior to the argon pumped-dye laser (Edstrom et al, 2002). Laser therapy can yield remarkable improvement for many port-wine stains, minimizing the emotional pain that accompanies facial disfigurement. Unfortunately, none of the currently available lasers is capable of permanently erasing port-wine stains in a majority of patients. There are also reports of redarkening of port-wine stains many years after effective lightening (Huikeshoven et al, 2007). Attempts to optimize laser treatment efficacy include using the pulsed-dye laser at higher fluences in conjunction with cryogen spray cooling (Kelly et al, 2002). A laser is also available that combines the 595-nanometer pulsed-dye laser with a 1064-nanometer neodymium-doped-yttrium aluminum-garnet (YAG) laser based on the theory that the longer wavelength of the second laser may be able to better target deeper vessels. The range of skin conditions that may benefit from yellow-light laser therapy is expanding rapidly to include a variety of skin lesions with vascular components.

HYPOPIGMENTED LESIONS

Localized areas of hypopigmentation on the skin of the newborn infant may be isolated phenomena, or they may be markers of extracutaneous abnormalities. The degree of hypopigmentation and the distribution of the defect help distinguish among the different conditions.

DEFINITION

A distinction must first be made between complete *depigmentation* and *hypopigmentation*. A depigmenting condition produces pure white lesions that are devoid of normal melanocytes. Even in fair-skinned infants, the lesions can

often be easily seen in ordinary daylight. This group of disorders includes tyrosinase-negative albinism and piebaldism, as well as vitiligo, which is rarely seen in infancy. A hypopigmented lesion often is subtly lighter in color than the surrounding skin. Histologic examination reveals a normal number of melanocytes. In fair-skinned children, these lesions may require Wood's lamp illumination to become obvious. This group includes anomalies with a deficient amount of either of the skin's pigments: melanin or hemoglobin. The ash-leaf macules and "confetti-like" lesions of tuberous sclerosis (Figure 101-4), the linear and whorled patterning associated with hypomelanosis of Ito (Figure 101-5, *A*), and simple nevus depigmentosus are hypomelanotic lesions (see Figure 101-5, *B*). Nevus anemicus and hemangioma precursors are areas of pallor that result from diminished superficial blood flow.

ASH-LEAF MACULES

Ash-leaf macules are small oval areas of hypopigmentation, named for their similarity in size and shape to a leaflet from a European mountain ash tree. They are one of the few congenital markers for infants with tuberous sclerosis. Tuberous sclerosis complex (TSC) is a disorder of autosomal dominant inheritance with variable clinical manifestations characterized by the development of benign and malignant tumors in a variety of tissues: skin, CNS, and kidney. Serious complications of tuberous sclerosis include hamartomas of the lung and kidney and congenital rhabdomyomas of the heart. The diagnosis is currently made by meeting a set of diagnostic criteria, but a majority of manifestations are not present in infancy (Gomez, 1991; Janniger and Schwartz, 1993; Schwartz et al, 2007; Zvulunov and Esterly, 1995). Abnormalities at two different genetic loci have been identified in kindreds with TSC (Wienecke et al, 1995). The two genetic loci are *TSC1* on 9q and *TSC2* on 16p, and the gene products are hamartin and tuberin, respectively. Both hamartin and tuberin are expressed in neurons and astrocytes, where they physically interact (Gutmann et al, 2000).

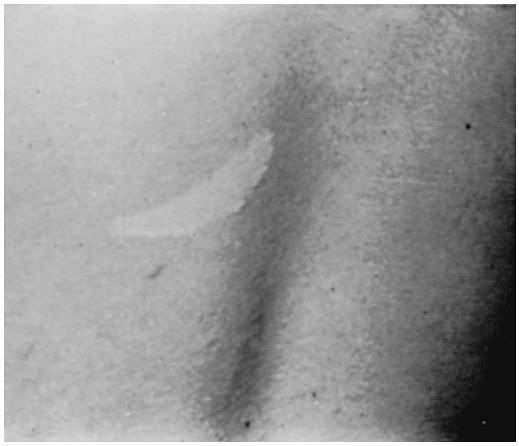

FIGURE 101-4 White ash-leaf macule on the back of a patient with tuberous sclerosis.

HYPOMELANOSIS OF ITO

The term *hypomelanosis of Ito* has been used as a diagnosis for a genetic disorder marked by a striking linear and whorled pattern of cutaneous pigment change oriented along the lines of Blaschko. Affected persons may have areas that are hyperpigmented or hypopigmented, or both. The pattern may be congenital or become apparent after birth.

This condition is a form of genetic mosaicism. In a subset of affected persons, karyotype abnormalities are demonstrable in tissue from affected sites. In a majority of reported cases, the patients have extracutaneous abnormalities (CNS, ocular, cardiac, and skeletal) (Alvarez et al, 1993; Dereser-Dennl et al, 2000; Devriendt et al, 1998; Tunca et al, 2000). Patterned pigment change confined to skin probably is a more common occurrence. For persons so affected, the term *linear and whorled nevoid melanosis* may be more appropriate. Chromosomal analysis from

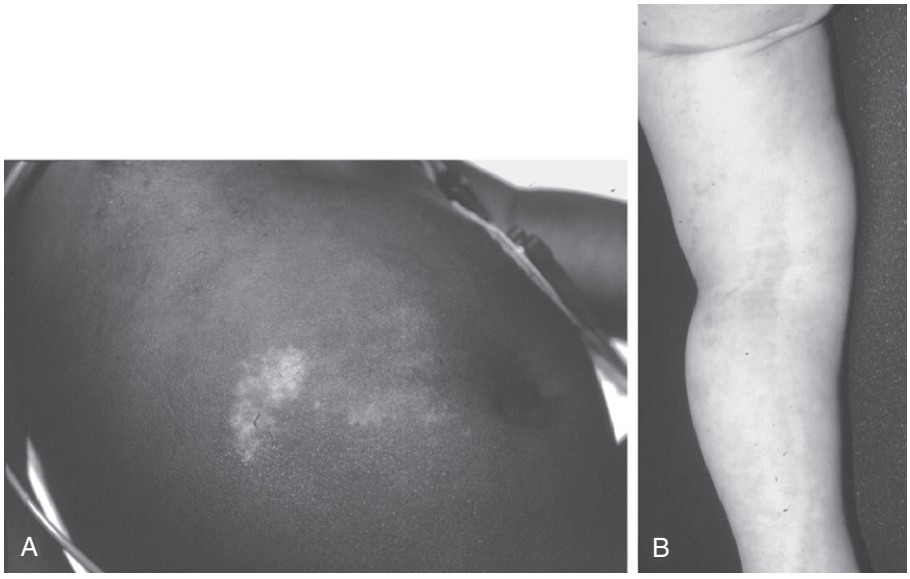

FIGURE 101-5 Nevus depigmentosus is an isolated congenital skin lesion that manifests as a hypomelanotic polygonal macule **(A)** or in a linear Blaschko distribution **(B)**.

separate tissues (e.g., blood, skin) is indicated for children with extensive skin lesions or evidence of extracutaneous involvement (Sybert, 1994).

MELANIN-CONTAINING LESIONS

Brown lesions usually reflect an increased number of melanocytic cells or an excess of melanin. Brown coloration also can be associated with a thickened epidermis. It may be difficult to distinguish among the lesions in this category without histopathologic examination. A majority of congenital brown lesions are isolated and benign, but it is important to recognize those that are syndrome-associated or potentially life-threatening (see Chapter 97 for a differential diagnosis).

In general, skin biopsy of a congenital pigmented lesion can be postponed until after the neonatal period. The one exception is a nodular lesion suggestive of melanoma.

NEVOCELLULAR NEVI

The category of nevocellular nevi includes congenital or acquired nevomelanocytic neoplasms. Nevomelanocytes are dendritic cells of neural crest origin. Nevocellular nevi traditionally have been categorized by the histologic position of the tumor nests within the skin. *Junctional nevi* are the most superficial, located at the junction between the epidermis and dermis. These lesions appear clinically as macules. *Intradermal nevi* are located deep to the dermoepidermal junction and are usually papular. "*Blue*" *nevi* are a variant located in the deep dermis, made up of cells that have elongated, neural features. *Compound nevi* have both junctional and dermal nests of nevomelanocytes.

Melanocytic nevi can be further divided into categories based on the size they are expected to attain by adulthood: small (less than 1.5 cm in greatest diameter), medium (1.5 to 19.9 cm), large (greater than 20 cm), and giant (greater than 50 cm); and time of onset: congenital, early-onset (before the age of 2 years), and acquired (Kovalyshyn et al, 2009). Diagnostic histologic features have been described for congenital and acquired lesions, but these features may be found in both types.

Large, multiple, or congenital melanocytic nevi have been reported in association with several syndromes (Marghoob et al, 1993) (Table 101-2).

CONGENITAL NEVOCELLULAR NEVI

Congenital nevocytic nevi are common and generally of little or no consequence. However, the infrequent but devastating association with malignant melanoma has made management a controversial issue.

Because size delineations are based on adult data, conversion factors have been developed to help predict ultimate size; for congenital melanocytic nevi (CMN) on the head, multiply size by factor of 1.7, lower extremities by 3.3, and trunk, upper extremities, and feet by 2.8 (Marghoob et al, 1996). Truly congenital lesions are present in 1% of white infants and in 2% to 3% of African American infants surveyed in the nursery (Osburn et al, 1987). Medium CMNs are seen in 1 in 1000 infants, large in 1 in 20,000, and giant in 1 in 500,000 (Castilla et al, 1981). There is a risk of malignancy associated with small nevi, but it may never be well defined. A distinct subset of melanocytic nevi in children, "early-onset nevi," has recently been recognized. These lesions are not necessarily congenital, appearing during the first 2 years of life. Early-onset nevi have been observed in 25% of children specifically examined for them. Twenty percent to 50% of melanomas arising in children and young adults may be associated with this type of nevus (Williams, 1993; Williams and Pennella, 1994). The frequency of CMN is paradoxically increased in African Americans, who have a much lower risk of melanoma (Shpall et al, 1994). The risk of melanoma associated with these very common pigmented skin lesions must be well below that in children with giant congenital nevi and

TABLE 101-2 Syndromes Associated With Melanocytic Nevi

Associated With:	Other Key Features
Congenital Nevi	
Carney syndrome (including LAMB and NAME syndromes)	Cardiac and cutaneous myxomas, endocrine abnormalities
Epidermal (linear sebaceous) nevus syndrome	Linear epidermal/sebaceous nevi, central nervous system and musculoskeletal defects
Neurocutaneous melanosis	Leptomeningeal melanocytosis and obstructive hydrocephalus
Neurofibromatosis type I	Cutaneous and plexiform neurofibromas, café-au-lait spots, Lisch nodules
Premature aging syndrome	Premature aging, short stature, birdlike facies, deafness
Occult spinal dysraphism/ tethered cord	Spinal cord abnormalities, lipomas, vascular malformations
Malformations associated with congenital melanocytic nevi	
Acquired Nevi	
Dysplastic nevus (atypical mole) syndrome	Increased incidence of cutaneous melanoma
Langer-Giedion syndrome	Distinctive facies, cone-shaped epiphyses, multiple exostoses
Congenital and/or Acquired Nevi	
EEC syndrome	*E*ctrodactyly, *e*ctodermal dysplasia, *c*left lip/palate, ocular abnormalities
Goeminne syndrome	Muscular torticollis, spontaneous keloids, genitourinary abnormalities
Kuskokwim syndrome	Skeletal abnormalities, joint contractures, muscle atrophy/ hypertrophy
Noonan syndrome	Webbed neck, heart defects, multiple other anomalies
Turner syndrome	Webbed neck, heart defects, multiple other anomalies, X-chromosome defect
Tricho-odonto-onychial dysplasia	Hypotrichosis, enamel defects, nail dystrophy

From Marghoob AA, Orlo SJ, Kopf AW: Syndromes associated with melanocytic nevi, *J Am Acad Dermatol* 29:373-388, 1993.

possibly no higher than the 1% lifetime risk of malignant melanoma in the general white population. Decisions about surgical removal of these lesions must be made on a case-by-case basis (Figure 101-6).

Large, giant (i.e., bathing trunk or garment) congenital nevi are rare and have a much greater potential for malignant degeneration (Figure 101-7). The cumulative risk of malignancy is estimated to be 2% to 15% over a lifetime, with 70% of melanomas diagnosed before the age of 10 years. Based on newer data, lifetime risk is probably closer to 6% (Kuflik and Janniger, 1994; Marghoob et al, 1996; Tannous et al, 2005; Williams and Pennella, 1994).

FIGURE 101-6 Dark brown irregular congenital nevus on the limb of an infant.

Conservative management of large congenital nevi by surveillance alone is complicated by the presence of features that strongly suggest melanoma. Most of these nevi have an irregular surface appearance from birth and are variably thickened, hairy, verrucous, or nodular. Smaller, widely scattered "satellite lesions" are almost always present. Extracutaneous lesions also have been detected in several sites, including the meninges, lymph nodes, and placental villi. Often, these nevi have atypical histologic features as well. For children who develop malignant melanoma within a giant nevus, the prognosis is very poor. However, many of the lesions with an alarming appearance from birth do not exhibit malignant behavior or produce widespread metastases, or cause death. In fact, congenital melanoma is very rare and is associated with congenital nevi in less than 50% of reported cases (Williams and Pennella, 1994).

The management of CMN remains controversial, with advocates for and against prophylactic excision. Newly published data question the rationale for routine excision. Nevertheless, case reports of melanoma arising in smaller CMNs, as early as 6 months of age, continue to dramatize the issue (Ceballos et al, 1995; De Raeve et al, 1993; Ozturkcan et al, 1994). To date, the incidence of melanoma arising in small CMNs remains unclear. A 3- to 21-fold increased relative risk for malignant transformation in both small and medium-sized lesions later in life has been reported, depending on the method of study (Richardson et al, 2002).

The least controversial recommendation has been for surgical excision of large or multiple CMNs during infancy (Casson and Colen, 1993). However, surgical removal

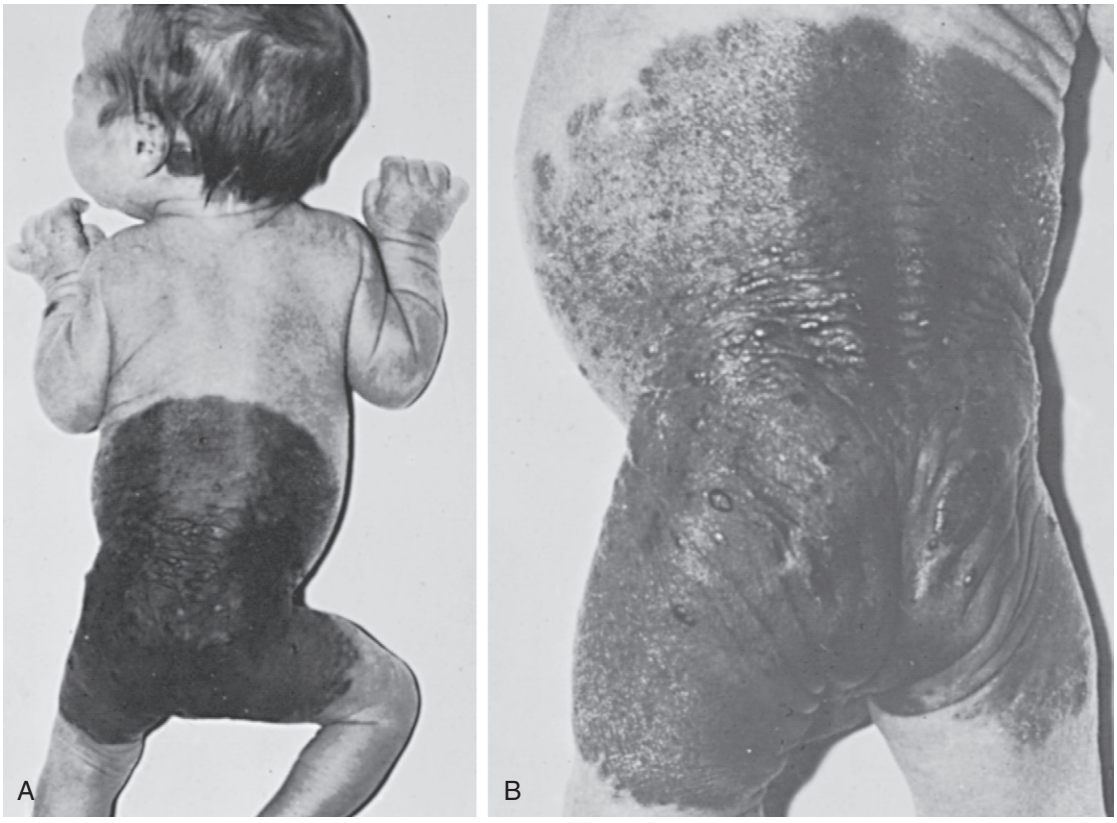

FIGURE 101-7 **A,** Newborn infant with large black nevus covering the "bathing trunk area." **B,** The closer view permits visualization of the nodular surface typical of giant nevi.

is never an easy option. Multiple procedures usually are required, with the attendant high risks of significant morbidity, sometimes yielding results that are more disfiguring than the birthmark. Newer techniques performed in early childhood, such as tissue expansion (Vergnes et al, 1993) and partial-thickness resection (Sandsmark et al, 1993), may improve the aesthetic outcome. The efficacy of such approaches in the prevention of malignancy has never been documented.

A Congenital Nevocytic Nevus Registry was established at the New York University Medical Center in 1978 to prospectively study the natural history of giant CMN (Gari et al, 1988; Kopf et al, 1979). To participate by mail, clinicians should contact the Skin and Cancer Unit, Department of Dermatology, New York University Medical Center, 550 First Ave., New York, NY 10016; telephone: (212) 340-5260.

Families with an affected child may benefit from information provided by the Nevus Network, a national support group founded by Dr. Bari Joan Bett, a physician with a giant congenital nevus. To receive information, contact The Nevus Network, The Congenital Nevus Support Group, PO Box 305 West Salem, OH 44287; telephone (419) 853-4525 (405) 377-3403. The website is *www.nevusnetwork.org*.

Neurocutaneous melanosis (NCM) is a congenital syndrome characterized by pigment cell tumors of the leptomeninges in patients with large or multiple (at least three) CMNs of the head, neck, or posterior midline (Kadonaga and Frieden, 1991). Symptomatic NCM manifests with signs or symptoms of increased intracranial pressure and carries a poor prognosis (Frieden et al, 1994; Sandsmark et al, 1994). MRI can aid in the diagnosis of NCM (Barkovich et al, 1994). Although initial reports emphasized thickening of the leptomeninges, the most common MRI sign of NCM is actually spin-lattice (T1) nuclear magnetic relaxation time in the parenchyma of the cerebellum or anterior temporal lobes (sometimes accompanied by spin-spin [T2] relaxation time). Radiologic identification of malignant degeneration is difficult. Roughly half of asymptomatic infants and children with giant CMN have evidence of NCM on MRI (Frieden et al, 1994), a finding suggesting that numerous and extensive operations to remove the cutaneous lesion may not be justified in these patients.

Other issues have been raised that challenge the interpretation of signs that have been accepted as ominous. The risk of melanoma in early infancy may have been overestimated by misinterpretation of the histologic findings and extent of the lesions. Neither cellular atypia nor widespread involvement, including lymph nodes and placenta, proves malignancy (Carroll et al, 1994; Hara, 1993). Attempts to further define the risk of malignant degeneration in these lesions have not been insightful (Barnhill et al, 1994; Heimann et al, 1993).

LENTIGINES

Lentigines are small tan-to-dark brown macules that most commonly appear sporadically in adulthood. They are distinguished from other pigmented lesions by histologic examination that reveals elongated rete ridges, an increased number of singly dispersed melanocytes along the basal layer, and increased melanization of the basal keratinocytes. Multiple or congenital lentigines are features of several syndromes.

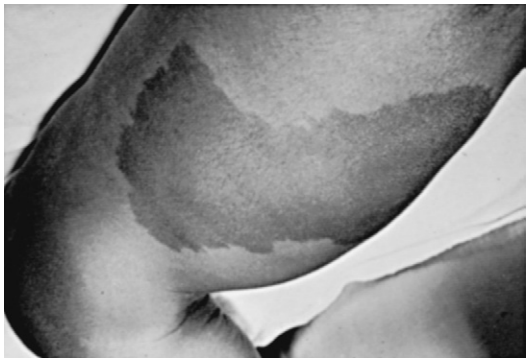

FIGURE 101-8 Large café-au-lait spot on the trunk of a newborn infant.

Carney Complex, Type 1 (Including NAME and LAMB) [OMIM 160980]

Carney complex is an autosomal dominant multiple neoplasia syndrome due to a mutation in the protein kinase A regulatory subunit-1-alpha gene (PRKAR1A) on 17q. Cardiac, endocrine, cutaneous, and myxomatous neural tumors occur. The related phenotypes designated NAME and LAMB share the features of *a*trial *m*yxoma and pigmented skin lesions. NAME includes *n*evi and *e*phelides, whereas LAMB includes *l*entigines and *b*lue nevi. Pigmented lesions are present at birth.

LEOPARD Syndrome [OMIM 151100]

Leopard syndrome is an autosomal dominant disorder due to mutations in the PTPN11 gene that includes multiple *l*entigines, *e*lectrocardiographic defects, *o*cular hypertelorism, *p*ulmonic stenosis, *a*bnormal genitalia, growth *r*etardation/restriction, and sensorineural *d*eafness. Skin lesions do not appear until after the 1st year of life.

Peutz-Jeghers Syndrome [OMIM 175200]

Peutz-Jeghers syndrome, a disorder of autosomal dominant inheritance, is due to mutations in the serine/threonine kinase STK11 gene and includes mucocutaneous pigmented macules and intestinal polyposis. The pigmented lesions may be congenital and usually appear on the lips, buccal and gingival mucosae, and dorsa of the fingers and toes.

CAFÉ-AU-LAIT MACULES

Café-au-lait macules (CALMs) are light brown macules that vary in size, ranging from several millimeters to several centimeters in diameter (Figure 101-8). They cannot always be distinguished from nevocellular nevi on clinical grounds, but histologic examination is diagnostic, showing increased melanin within the basal keratinocytes, without melanocyte proliferation. CALMs are present in 2% of white infants and in up to 12% of African-American infants. Large or multiple CALMs in the neonatal period

may be an isolated finding but should alert the physician to the possibility of an associated syndrome (Box 101-2).

NEUROFIBROMATOSIS

Neurofibromatosis (NF) consists of a group of variable multisystem disorders that includes cutaneous neurofibromas and multiple CALMs. Several subtypes exist, and NF1 and NF2 (discussed here) are the most well defined. Segmental NF1, familial CALMs, and schwannomatosis are considered within the rubric of neurofibromatosis. A cutaneous disorder of multiple CALMs and axillary freckling, due to mutations in the *SPRED1* gene, was described in 2007 (Brems et al, 2007).

The great majority of patients with NF have subtype 1 (NF-1) [OMIM 162200], or von Recklinghausen's disease. NF-1 is a relatively common autosomal dominant disorder, due to mutations in the *NF1* gene, which is a large gene with a high rate of new mutation. It occurs in 1 in 3500 people. Mutational analysis is available and can be used both for prenatal diagnosis and for individuals who do not meet complete diagnostic criteria. The diagnosis has traditionally been made by fulfilling a set of diagnostic criteria; the presence of six or more CALMs is the most common manifestation, occurring before age 6 years in 99% of affected persons (Boyd et al, 2009; Zvulunov and Esterly, 1995). CALMs may be present at birth but often arise and grow during childhood. Other diagnostic cutaneous findings are axillary or inguinal freckling (Crowe sign) and cutaneous neurofibromas, which may be present at birth. Bony dysplasias (sphenoid wing dysplasia, pretibial pseudarthrosis) also can be detected at birth in a minority of patients. Symptomatic CNS involvement (developmental delay, learning disabilities, seizures) occurs in about one third of patients with NF-1. The most ominous complication of NF-1 is the development of malignant tumors (neurosarcoma, pheochromocytoma, and juvenile chronic myelogenous leukemia) (Zvulunov and Esterly, 1995). A rare triple association of leukemia, NF-1, and cutaneous juvenile xanthogranuloma has been reported (see later discussion).

The genetic defects for NF-1 have been localized to chromosomal region 17q11;2. Most mutations occur on the paternally derived chromosome. "Sporadic" cases may be the result of paternal transmission from a mosaic mutation of a fraction of spermatozoa from a clinically normal father (Lazaro et al, 1994). A portion of the *NF1* gene has homology with mammalian genes that code for guanosine triphosphate–activating proteins. These proteins function to regulate cell proliferation. Therefore, a functional mutation of the *NF1* gene would result in unsuppressed cellular proliferation (i.e., tumorigenesis).

Type 2 neurofibromatosis (NF-2) [OMIM 101000] is an autosomal dominant disorder caused by mutations in the *NF2* gene which encodes neurofibromin-2, also called merlin. It has an incidence of about 1 in 25,000. It is characterized by bilateral acoustic neuromas, meningiomas, and schwannomas of the dorsal roots of the spinal cord. CALMs are not as prominent or numerous as in NF-1, occurring in less than 40% of affected persons (Zvulunov and Esterly, 1995).

McCUNE-ALBRIGHT SYNDROME [OMIM 174800]

McCune-Albright syndrome is a sporadic disease characterized by polyostotic fibrous dysplasia, sexual precocity and other hyperfunctional endocrinopathies, and large café-au-lait spots (Schwindinger et al, 1992; Shenker et al, 1993). It is due to early postzygotic somatic activating mutations in the *GNAS1* gene, which encodes the stimulatory G subunit of adenylate cyclase. In contrast with the CALMs seen in NF-1, those in this syndrome may be unilateral with irregular borders, in a distribution that suggests the lines of Blashchko and genetic mosaicism (Rieger et al, 1994).

NEVUS SPILUS

Nevus spilus (speckled lentiginous nevus) is a hyperpigmented lesion that consists of focal proliferation of melanocytes along the basal layer of the epidermis (the dark spots) within a café-au-lait spot. It may be disfiguring but has no other associated abnormalities.

BLUE-GRAY MACULE OF INFANCY

More than 90% of African American infants, 81% of Asians, and 10% of whites (Pratt, 1953) are born with blue-gray macule of infancy, formerly called *mongolian spot*. These are brown, gray, or blue macules, most commonly located on the lumbosacral area, but they can occur anywhere. The macules may be single or multiple and range in size from a few millimeters to several centimeters in diameter. They often fade within the first few years of life. Extensive lesions have been mistakenly attributed to abuse. Histologically, blue-gray macule of infancy is a collection of spindle-shaped melanocytes located deep in the dermis. Malignant change has never been reported.

NEVUS OF OTA/ITO

Nevus of Ota is a unilateral blue or gray discoloration involving the orbital and zygomatic areas, including the sclera and fundus. It is a sporadic condition, but it occurs

with the highest frequency in Asians, affecting up to 1% of persons in Japan (Kopf and Weidman, 1962). The discoloration is detected at birth in 60% of cases. Glaucoma is a frequent complication. A similar lesion, located in the deltotrapezius area, is called *nevus of Ito*. Histologically, these lesions cannot be distinguished from blue-gray macule of infancy. However, spontaneous resolution is not common, and rare association with malignant melanoma has been reported. Successful treatment has been achieved with Q-switched ruby and Q-switched YAG laser surgery.

TUMORS OF EPITHELIAL ORIGIN

EPIDERMAL NEVUS/NEVUS SEBACEUS

Epidermal nevus may manifest in the newborn period as a smooth hyperpigmented patch or rough, skin-colored plaque, most often on the trunk or extremities, frequently oriented along the lines of Blaschko. With time, epidermal nevi may enlarge; most become verrucous. Nevus sebaceus has a yellow hue, occurs most often on the head, and may be nodular at birth and again after puberty, flattening during childhood. A variety of neoplasms, both benign and malignant, including basal cell carcinoma, develop in up to 15% of patients with sebaceous nevi. Development of neoplasms rarely occurs before puberty.

Like other mosaic disorders, epidermal and sebaceous nevi are believed to be localized manifestations of somatic genetic mutations that would be lethal if fully expressed. A subset of patients with epidermal nevi are genetic mosaics for an autosomal dominant form of ichthyosis called *epidermolytic hyperkeratosis* (or bullous ichthyosiform erythroderma) (Paller et al, 1994). These persons may be at risk for having offspring with total body involvement. The striking appearance of epidermal nevi has inspired descriptive nomenclature. *Nevus verrucosus* is a solitary plaque. *Nevus unius lateris* (Figure 101-9) is an extensive linear lesion that is unilateral, following the lines of Blashchko. Both keratinocytic and sebaceous components may occur in the same patient, the former more commonly involving the trunk and extremities and the latter more often involving the head and neck.

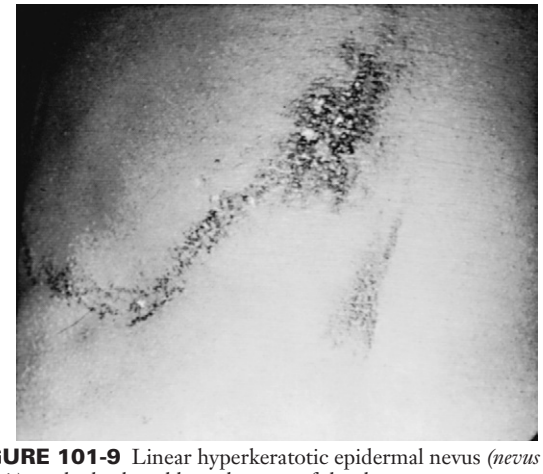

FIGURE 101-9 Linear hyperkeratotic epidermal nevus *(nevus unius lateris)* on the back and lateral aspect of the thorax.

The term *ichthyosis hystrix* refers to extensive, bilateral involvement with epidermal nevus.

Skin biopsy will rule out other conditions, distinguish between epidermal nevus and nevus sebaceus, and detect the diagnostic histologic features of epidermolytic hyperkeratosis. Small epidermal nevi do not require treatment. Nevus sebaceus carries a small risk of malignant degeneration. It may be excised in infancy, childhood, or adolescence, depending on the size of the lesion and the preference of the patient and family. Recent studies suggest that the risk of basal cell carcinoma, the most common malignancy to arise in nevus sebaceus, is closer to 1%, much lower than was reported in the past (Cribier et al, 2000).

There is no optimal therapy for larger lesions or those that are disfiguring. Full-thickness excision, including the subcutaneous tissue, is recommended to decrease the risk of recurrence. Laser therapy holds promise for the future. Topically applied keratolytic agents may be palliative. Genetic counseling about the risk for offspring of fully expressed disease should be considered for persons with epidermal nevi that reveal the histologic features of epidermolytic hyperkeratosis.

EPIDERMAL (LINEAR SEBACEOUS) NEVUS SYNDROME

In less than 10% of affected people, epidermal nevi and sebaceous nevi (especially those involving the head) are associated with a variety of extracutaneous abnormalities, mainly ocular (in 33% of cases), neurologic (in 50%), and skeletal (in 70%), a condition referred to as *epidermal nevus syndrome*. Bone abnormalities include vertebral anomalies, kyphoscoliosis, limb shortening, and hemihypertrophy. CNS disorders include seizures, mental retardation, and hemiparesis; ocular abnormalities include eyelid/conjunctival nevus, coloboma, corneal opacity, and nystagmus. Malignancies also occur in this syndrome with a greater-than-expected frequency, including Wilms' tumor, nephroblastoma, gastrointestinal carcinomas, and rhabdomyosarcoma (Marghoob et al, 1993).

DERMAL TUMORS

JUVENILE XANTHOGRANULOMA

Juvenile xanthogranuloma (JXG) is a benign, self-healing, non-Langerhans cell histiocytic tumor of infancy. JXG may be congenital; a majority of tumors manifest by 6 months of age (Nomland, 1959). Cutaneous lesions vary in color from red-brown to yellow. They occur most often on the upper half of the body (Figure 101-10), may be solitary or multiple, and range from several millimeters to several centimeters in diameter (see Figure 101-5). JXG also may be localized to the eye or mucous membranes (De Raeve et al, 1994).

Skin biopsy usually is diagnostic, revealing characteristic foamy histiocytes and Touton giant cells within the dermis.

The vast majority of infants with JXG are otherwise healthy. Giant JXG can have an alarming appearance and may be confused with other types of histiocytic tumors (Magana et al, 1994). JXG have two clinically significant associations; the first is with ocular JXG and its associated

complications. Fewer than 0.5% of children with skin lesions have ocular involvement, but one half of children with ocular JXG have cutaneous lesions (Chang et al, 1996). Ocular tumors may manifest as unilateral glaucoma, uveitis, heterochromia iridis, or proptosis; ocular JXG is the most common cause of hyphema in infancy (Gaynes and Cohen, 1967; Zimmerman, 1965). The iris is the most frequently affected ocular tissue (Hamdani et al, 2000). There are also reports of a rare triad of JXG, juvenile myelomonocytic leukemia (JMML), and NF-1. The appearance of JXG usually preceded the diagnosis of leukemia; the NF, marked by multiple CALMs, was often missed (Sherer et al, 1993). Routine screening for JMML is not recommended in NF-1 patients with or without JXG, but evidence of hepatosplenomegaly, lymphadenopathy, or pallor should prompt appropriate work-up (Burgdorf and Zelger, 2004). Fewer than 20 patients with intracranial JXG without cutaneous manifestations have been described (Bostrom et al, 2000; Schultz et al, 1997).

A majority of cases of JXG are asymptomatic and self-limited. Giant lesions have a similar prognosis (Magana et al, 1994). Ophthalmologic evaluation is indicated for children who present in the first 2 years of life with multiple lesions. Parents should be provided with anticipatory guidance about the ocular complications (Chang et al, 1996). JXG typically involutes within 3 to 6 years (Hansen, 1992). Recurrence has been documented after surgical excision; this form of therapy is indicated only for lesions that are frequently traumatized or are more disfiguring than the resultant scar would be.

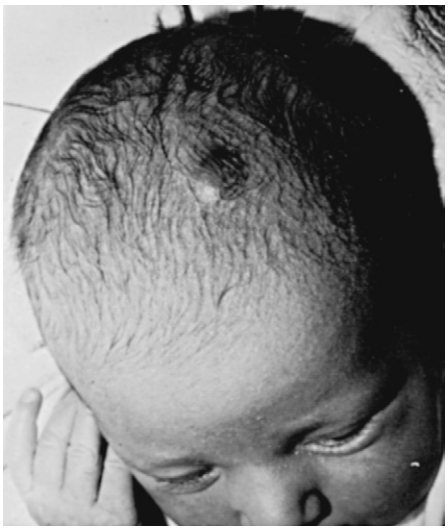

FIGURE 101-10 Solitary juvenile xanthogranuloma on the scalp, a typical site for these lesions.

MASTOCYTOSIS

Mastocytosis comprises a group of disorders characterized by increased numbers of tissue mast cells. The skin is the most common site of involvement, but the lymphoreticular system, gastrointestinal tract, and bone marrow also may be affected. Symptoms result from the local or generalized effects after the release of histamine and other mast cell mediators. Pruritus, edema, blistering, and flushing are common. Abdominal pain, diarrhea, and vomiting are unusual. Hypotension is rare (Kettelhut and Metcalfe, 1991). If rubbed or traumatized, skin affected by mastocytosis will develop a diagnostic wheal (Darier sign). The site may blister or become hemorrhagic in a neonate.

Urticaria pigmentosa is the name given to the most common form of mastocytosis in infants, featuring multiple, small (1 to 3 cm in diameter) papules usually located on the trunk (Figure 101-11). The disease may be congenital but usually manifests within the first 6 months of life (Kettelhut and Metcalfe, 1991). A single, localized lesion is known as a solitary mastocytoma. These tumors can vary in size from approximately 2 to 6 centimeters. Diffuse cutaneous mastocytosis is an unusual condition that may manifest at birth with widespread blistering or diffuse thickening of the skin

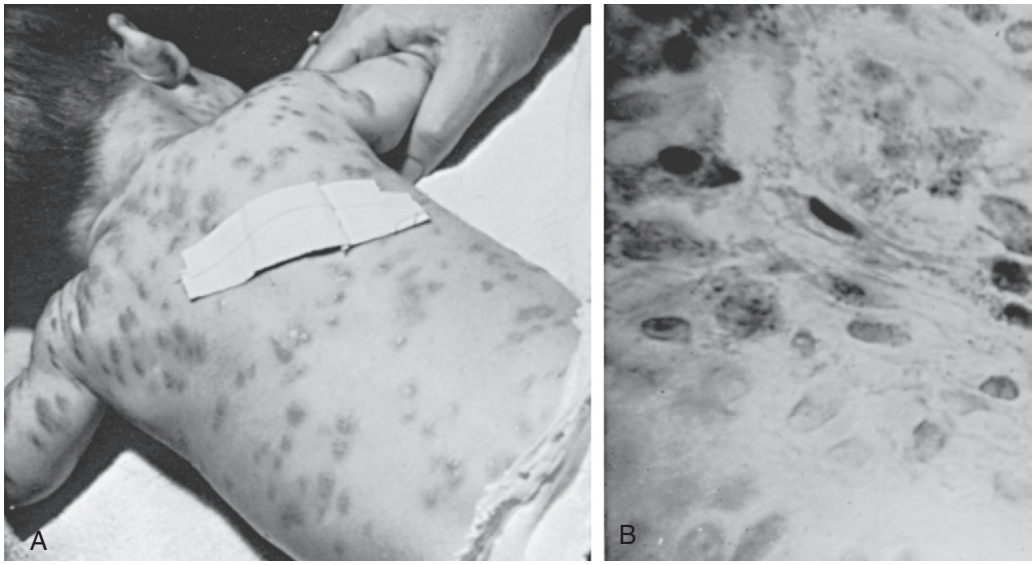

FIGURE 101-11 **A,** Deeply pigmented nodules and macules on the back of an infant with urticaria pigmentosa. A group of vesicles is visible just below the bandage that covers the biopsy site. **B,** Microscopic section from the biopsy specimen, stained with Giemsa stain. The mast cells can be identified as spindle-shaped cells containing granules that are located in the upper dermis.

(Sagher and Evan-Paz, 1967; Solomon and Esterly, 1973). Systemic mastocytosis is more commonly seen in adults and is defined by multifocal lesions in the bone marrow or other extracutaneous organs, together with signs of systemic disease. It is further divided into indolent systemic mastocytosis, systemic mastocytosis with an associated clonal hematologic non–mast cell lineage disease, aggressive systemic mastocytosis, and mast cell leukemia (Valent et al, 2001).

The diagnosis may be confirmed by a skin biopsy, which reveals mast cell hyperplasia within the dermis. Aminocaproate esterase is the most specific enzyme marker for identification of mast cells. Immunohistochemical stains for tryptase and *KIT* also are sensitive and specific markers for mast cells (Li, 2001). Mutations in c-*kit*, the gene encoding the receptor for stem cell factor, may play a significant role in the biology of mast cell malignancies (Gupta et al, 2002). Plasma histamine levels are elevated in a majority of children with mastocytosis, sometimes to remarkably high levels. Further work-up for evidence of systemic involvement should be limited to pediatric patients with extracutaneous signs and symptoms or those who require general anesthesia (Kettelhut and Metcalfe, 1991).

Caregivers should be educated to avoid exposing infants to factors that trigger mast cell degranulation, such as friction, pressure, temperature extremes, and substances that promote mast cell degranulation (aspirin, alcohol, narcotics, amphotericin B, or iodine-containing contrast media). If general anesthesia is required, perioperative administration of histamine receptor blockers is recommended (Lerno et al, 1990).

For patients with limited skin involvement, application of potent topical corticosteroids may hasten involution of lesions. Symptomatic patients may benefit from a classic histamine H_1 receptor blocker such as hydroxyzine or cyproheptadine. An H_2 blocker, such as ranitidine, or oral disodium cromoglycate may be added in the presence of gastrointestinal symptoms. Hypotension requires corticosteroids in addition to H_1 and H_2 antihistamines and intensive supportive care. Solitary mastocytomas usually involute by school age. Lesions of urticaria pigmentosa typically resolve by puberty.

MIDLINE ANOMALIES

Congenital midline defects are a distinct group of diagnostically and therapeutically challenging conditions. These anomalies are located deep to the dermis, occurring at the cranial or caudal midline. Some of these lesions mark an underlying CNS problem or an intracranial connection. Considerations in the differential diagnosis include lesions that occasionally occur in the midline by serendipity; hemangiomas are the most common. Vascular malformations, hair tufts, dimples, and lipomas also may occur at the cranial or caudal midline and can mark a CNS or spinal malformation (Hayashi et al, 1984; Martinez-Lage et al, 1992). A midline mass in the nasal area may represent a dermoid cyst, encephalocele, or glioma (Paller et al, 1991). Occipital lesions include aplasia cutis congenita, encephalocele, and heterotopic brain tissue. The "hair collar sign" may mark ectopic neural tissue and underlying CNS malformations (Commens et al, 1989; Drolet et al, 1995). Biopsy of a midline mass should not be performed unless an imaging study has been obtained to help clarify the nature of the lesion. If the possibility of an intracranial connection exists, referral to a neurosurgeon is indicated (Martinez-Lage et al, 1992).

PART XXI

The Eye

CHAPTER 102

Disorders of the Eye

Alejandra G. de Alba Campomanes, Gil Binenbaum, and Graham E. Quinn

The fast pace of development of the visual system in the neonatal period makes the recognition of ocular abnormalities extremely important. As early as 4 to 6 months after birth, some visual functions are permanently set and if impaired cannot be fully restored to normalcy. For example, a visually significant congenital cataract must be surgically addressed before the 3rd month of life to avoid potentially irreversible vision loss. This urgency makes the neonatal physician an invaluable player in the recognition and management of neonatal eye disease. Screening eye examinations are important in all infants, regardless of gestational age and whether in the neonatal intensive care unit (NICU), the nursery, or the office. Health care professionals taking care of newborns need to be familiar with indications for referral to a pediatric ophthalmologist, and in premature infants, the added risk of retinopathy of prematurity (ROP) mandates that neonatologists ensure timely diagnostic examinations by an ophthalmologist.

GENERAL EXAMINATION TECHNIQUES

THE NEWBORN EYE EXAMINATION: APPROACH AND EQUIPMENT

Effective physical examination of the newborn eye begins with familiarity with eye anatomy. Armed with a baseline understanding of "normal," the pediatrician can identify abnormalities or asymmetries in structure or function of the eyes by following a simple exam framework: I-ARM (Inspection, Acuity, Red Reflex, and Motility) (Simon and Calhoun, 1998). Detailed information on each of these components follows a discussion of general considerations when examining the eyes of a young infant.

A thorough eye examination, although necessary, can be stressful for a newborn or young infant. Swaddling, nesting, nonnutritive sucking, and oral sucrose before, during, and after an examination can be very helpful in this regard, particularly for premature babies undergoing an ROP exam for which an eyelid speculum is being used (Boyle et al, 2006; Grabskaet al, 2005; Marsh et al, 2005; Stevin et al, 1997). Gal et al (2005) undertook a randomized, double-blinded, placebo-controlled, cross-over study using the Premature Infant Pain Profile (PIPP), a previously validated scale, and found 2 mL of 24% oral sucrose to be more effective than placebo in reducing the immediate pain response during ROP exam using a lid speculum and topical anesthetic. Boyle et al investigated both nonnutrient sucking and 1 mL of 33% sucrose versus placebo in a two-by-two factorial design; they found use of a pacifier to be effective but there was no synergistic effect with sucrose (Boyle et al, 2006). The most distressing aspects of the eye examination are generally the bright light of the ophthalmoscope and the use of a speculum, the pain of which appears to result primarily from stretching of the eyelids. The use of a topical anesthetic, such as proparacaine HCl 0.5%, reduces the discomfort of the speculum but is not always sufficient and should be supplemented with other measures, such as sucrose, pacifiers, and nesting (Marsh et al, 2005). In addition, NICU and office staff should be aware that the chronic use of topical anesthetics can result in corneal ulceration and melting, so bottles should be properly disposed of and not confused with other medications, such as topical lubricants or antibiotics. Use of an indirect ophthalmoscope without a speculum produces significantly less pain response than that noted with examination with a speculum or with a contact fundus camera, such as the RetCam (Clarity Medical Systems, Pleasanton, Calif.) (Mehta et al, 2005). Nevertheless, a speculum is often necessary to adequately visualize ocular structures and should always be used if adequate visualization of the fundus is otherwise not possible. In the experience of the authors, it is extremely rare for a properly supported infant to be unable to tolerate a quick fundus examination, the discomfort of any observers notwithstanding. Finally, particular note should be made of the oculocardiac reflex, a dysrhythmia, typically bradycardia, resulting from direct manipulation of the eye; monitoring by an assistant during the examination is therefore important.

The infant is often best examined lying supine. If he or she is in an incubator, the top must be raised to allow the examiner to examine the eyes closely and from different directions. A parent or a nurse may cradle the baby for examination as well. In slightly older infants, visual tracking and motility are best assessed in an upright position. It usually takes more than one set of hands to examine an infant's eyes. As discussed earlier, assistance with comforting the baby and monitoring vital signs is important. In addition, the head and body of the infant may need to be securely held to allow both a detailed and safe anatomic examination. Such restraint should be applied carefully but firmly and is best left to the end of the examination, because once the child is upset, it will become difficult to assess certain parts of the ophthalmologic examination such as visual function, motility, or intraocular pressure. Under some circumstances, it may become necessary for

an ophthalmologist to perform an examination under sedation or general anesthesia.

Newborn eyelid skin is thin and delicate and must be handled gently. Proper technique can ensure that the eyelid fissures are open wide enough to adequately visualize the eyes, while minimizing eyelid trauma. Ideally, tips of the fingers are placed on the eyelid margins and gentle pressure is placed in upward and downward directions to separate the eyelids by their ends. Care must be taken not to abrade the surface of the eye, and the examiner's fingernails should be groomed short. Pulling the lids apart by pulling on the skin of the eyelids does not open the lids as well and may be more uncomfortable for the baby; however, this method is simpler and requires less skill than using the eyelid margins method. If the eyelids are slippery, placing gauze on the skin helps improve traction. Finally, use of an eyelid speculum is sometimes the quickest, most efficient, and even safest method of opening the lids for the skilled examiner. Care must be taken to ensure that the baby cannot grab the speculum while it is in place.

Examination of the eye requires adequate light and magnification. Even a simple flashlight or penlight and a magnifying glass are helpful and worth using if specialized instrumentation is not available. The ideal light source provides a variable, very bright and focused beam. The portable slit lamp microscope combines such a light source in combination with excellent binocular magnification. The light beam width is controllable, allowing three-dimensional cross sections of the anterior segment structures of the eye, including the conjunctiva, cornea, anterior chamber, iris, and lens. Although the slit lamp is an extremely useful instrument, it is expensive, and some degree of practice is needed to develop facility. Again, any simple magnifier and bright light source will prove invaluable for an eye examination in the NICU, emergency room, or pediatrician's office. The direct ophthalmoscope, typically available in all three settings, can serve this purpose and is discussed in the next paragraph. An additional method to identify pathology of the ocular surface is application of fluorescein ophthalmic solution, which will stain areas of denuded corneal and conjunctival epithelium. Once the solution is applied, a blue light source must be shone on the eye, and the examiner can identify corneal abrasions, which appear as patches of staining; corneal dryness, which appears as punctate staining; and multiple other conditions, such as dendritic herpetic lesions, more typical in older children. Most direct ophthalmoscopes have a blue light source, which may be used in conjunction with a magnifier. Alternatively, a Woods lamp may be used.

The direct ophthalmoscope is an important instrument for examining a newborn's or infant's eyes. It provides a light source to evaluate light perception and pupillary reactivity and to use together with a magnifier for examining the anterior structures of the eye. Red reflex testing with a direct ophthalmoscope (described in detail later) is a mandatory element of all newborn and well-baby physical examinations. Numerous vision-threatening and even life-threatening ocular diseases are primarily identified by a pediatrician checking red reflexes, and this technique is the pediatrician's principal method of detecting pathology in the posterior segment of the eye. The direct ophthalmoscope may of course be used to directly visualize the optic nerve head and retina, but particular considerations and limitations must be kept in mind. Pupil size must be maximal; typically this means pharmacologic dilatation (discussed later). If mydriatics are not used, dimming ambient light and, in older children, having the child fixate in the distance will maximize pupil dilation. The examiner must be very close to the infant (a few centimeters at most). Approaching from a slightly lateral angle and following the "arrows" of branching vessels back to the nerve head will help to identify the optic disk. Most important, the field of view or "spot size" of the direct ophthalmoscope is approximately the size of the optic nerve head, which represents but a tiny fraction of the ocular fundus. Therefore, it is not possible to adequately evaluate the retina for ROP or other pathology with a direct ophthalmoscope. The indirect ophthalmoscope requires both greater skill and a handheld lens to use but provides binocular viewing with depth perception and a much wider field of view, perhaps four disk diameters in size. Pharmacologically dilated funduscopic examination with an indirect ophthalmoscope is required for ROP and other retinal diagnostic examinations, such as for retinoblastoma or retinal hemorrhage in suspected abusive head trauma.

Pharmacologic dilatation with mydriatic eye drops is commonly performed by consulting ophthalmologists, typically on all new patient evaluations and at all ROP examinations. Occasionally, a pediatrician may find it helpful to dilate the pupils to better visualize the red reflex or optic nerve head. Drops are better deferred if an ophthalmology consultation will be requested, because dilating the pupils may make it difficult or impossible to accurately assess the pupils, ocular alignment, intraocular pressure, or iris. Dilating eye drops include sympathomimetics (e.g., phenylephrine) and anticholinergic drugs (e.g., tropicamide, cyclopentolate, atropine). Potential side effects of these drugs include elevated blood pressure, increased heart rate, cardiac arrhythmias, feeding intolerance, slowed gastric emptying, urticaria, contact dermatitis, and seizures (Bonthala et al, 2000; Chew et al, 2005; De mayo and Reidenberg, 2004; Fitzgerald et al, 1990; Isenberg et al, 1985; Wright, 1992). These authors typically use tropicamide 1% and phenylephrine 2.5% and avoid the use of cyclopentolate in children less than 6 months of age. Adverse effects are potentially of greater concern in preterm infants, who are of lower weight and typically require multiple doses to achieve adequate dilatation, as do many children with dark irides. Therefore, it may be prudent to use reduced concentrations of mydriatics in premature infants, particularly cyclopentolate. In a randomized masked trial, Chew et al concluded that cyclopentolate 0.2% + phenylephrine 2.5% is the mydriatic of choice in preterm infants with dark irides, because higher concentrations of cyclopentolate (0.5%, 1.0%) were more likely to result in increased mean blood pressure or feeding intolerance.[9] In all children, systemic absorption of eye drops can be minimized by compressing the lacrimal sac for a few minutes after instillation.

INSPECTION (THE I IN "I-ARM")

Inspection of anatomy is a key method of detecting eye disease. The eyes should be closely examined with proper lighting and magnification (as described earlier), and the periocular and ocular structures approached in a systematic

manner. One option is to begin with the external structures and work inward and posteriorly, looking at each eye carefully and comparing the two eyes with each other. As a guideline, any abnormality or asymmetry noted on examination should be referred to a pediatric ophthalmologist for further management. The urgency with which to seek consultation depends on the specific finding, and guidelines appear throughout this chapter. However, one should err on the side of urgency, because the neonatal period represents a critical period in visual development. To adequately inspect the eyes, familiarity with normal anatomy is required. A general overview of these structures follows (Figure 102-1).

The eyelids protect the eyes. The eyelids contain numerous glands, which continually produce tears to keep the ocular surface well lubricated, and blinking actively pumps the tears into the lacrimal drainage system. An inability to adequately close the eyes presents a major problem and can result in surface drying, corneal epithelial breakdown, and vision- or eye-threatening complications, such as ulceration, infection, or scarring. The lacrimal glands actually produce reflex tears. The nasolacrimal duct provides a means of egress for tears, which pass through the puncta, canalicula, and lacrimal sac to the duct. The duct can be blocked at birth in 5% to 10% of newborns, resulting in epiphora and discharge in an otherwise white and quiet eye; 90% of such blockages clear by 1 year of age, after which surgical probing is undertaken. Of note, congenital glaucoma can manifest with epiphora as well (see later discussion of corneal clouding).

The conjunctiva is a translucent membrane that overlies the surface of the eye and the inside of the eyelids. The sclera is the white fibrous wall of the eye. It is relatively flexible at birth and gradually toughens over the first few years of life. The cornea is continuous with the sclera, which it meets at the limbus, and is a clear dome-shaped structure in the center of the globe (eye). It is commonly overlooked by the casual observer, because it is normally transparent. The cornea provides two-thirds of the refractive power of the eye, is richly supplied with sensory nerves, and must be kept well lubricated to prevent surface breakdown. The cornea is a multilayered structure approximately 0.5 mm thick. It is kept clear by active pumping out of fluid by its endothelium. Any process that affects the clarity or integrity of the cornea can result in loss of vision.

The iris is a donut-shaped structure posterior to the cornea. The anterior chamber of the eye lies between the cornea and iris and is best visualized with slit lamp examination (see earlier discussion). The anterior chamber angle lies at the juncture of the cornea and iris peripherally and contains the aqueous fluid drainage structures of the eye; if these structures are occluded, a rapid rise in intraocular pressure and sight-threatening glaucoma can ensue. The iris contains muscle structures to constrict and dilate the pupil, which is a central aperture that is under nonvoluntary control and changes size with variations in incident light, focusing effort (accommodation), emotions, and medications. The iris is an immature structure at birth. The color tends to be gray or blue and may become darker as the pigmented layer of the iris stroma becomes more fully developed, which typically occurs by about 6 months of age. Heterochromia refers to differences in the color of the iris between or within eyes and can be seen in congenital Horner's syndrome (with mild ptosis and a poorly dilating miotic pupil), as well as syndromic conditions such as Waardenburg's syndrome or Hirschsprung's disease.

Behind the iris lies the crystalline lens, which provides one third of the eye's refractive power. The lens width and therefore refractive power can be varied by contraction of the ciliary muscle of the eye to provide accommodation or "focusing in" ability. An opacity in the lens is referred to as a cataract (see later section on leukocoria). The uvea is composed of the iris, the ciliary body, and the choroid. Inflammation of the uvea, uveitis, is diagnosable with slit-lamp and dilated-fundus examination by directly visualizing white blood cells and proteinaceous flare in the anterior chamber, as well as multiple other signs in the anterior and posterior segments of the eye. The ciliary body produces aqueous humor, which maintains eye pressure and nourishes the anterior segment structures. The choroid is a vascular structure that lies between the sclera and the retina; it supplies the retina and is in fact the most densely packed blood supply in the body.

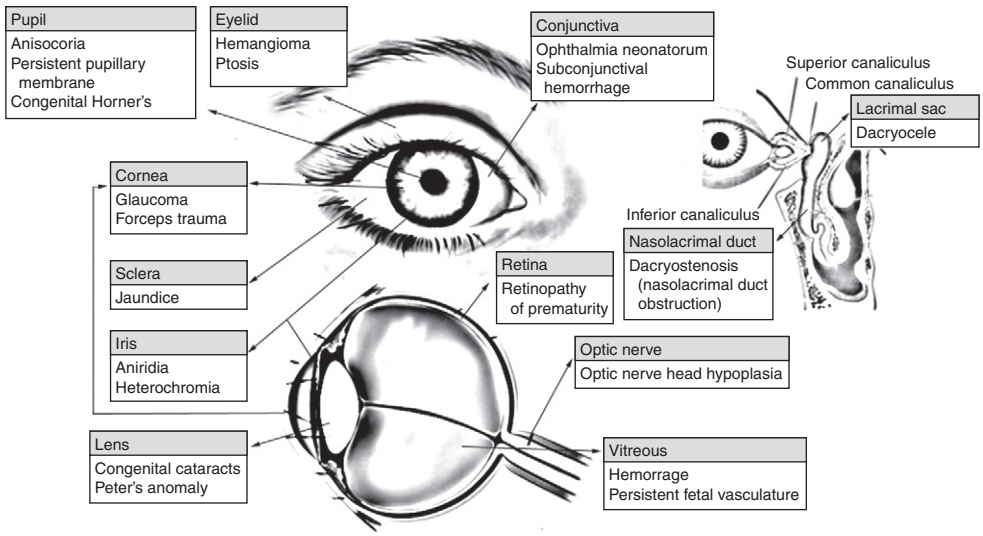

FIGURE 102-1 Anatomic structures and common neonatal pathology.

The retina is a multilayered, complex, highly metabolically active structure that lines the inside surface of the globe and contains photoreceptors that receive light and generate neuronal signals that are ultimately perceived as visual images. The macula is the central, posterior retina, between the superior and inferior temporal retinal vascular arcades, and the fovea is the very central retina containing the highest concentration of photoreceptors and producing central, high-resolution vision. Visual signals are transmitted through the optic nerve, whose cell bodies lie in the most anterior retina and which is actually composed of approximately 1 million individual nerve fibers. The proximal end of the optic nerve is visible as a normally golden disk approximately 15 degrees nasal and just superior to the fovea. The optic nerves lead to the optic chiasm and continuing visual and pupillary pathways in the brain. The anterior portion of the eye contains aqueous humor and the posterior segment contains vitreous humor, which is well formed at birth, but which undergoes gradual liquefaction (syneresis) with age. The vitreous is composed primarily of water, collagen, and hyaluronic acid. It is attached to the retina throughout the fundus (posterior inner surface of the eye), all the way to the retina's anterior extent or ora serrata, where the retina meets the ciliary body; however, it has particularly strong attachments at the ora serrata (vitreous base), optic nerve head, and along the retinal vessels in the most superficial layers of the retina.

ACUITY AND VISUAL DEVELOPMENT (THE A IN "I-ARM")

The visual system is very immature at birth. The fovea is not completely differentiated until 15 to 45 months (Hendrickson and Yuodelis, 1984), and myelination of the optic nerve is not completed until about 1 year of age (Magoon and Robb, 1981). The eye continues to develop synapses in the visual cortex during the first 10 years after birth, and although visual acuity reaches normal adult ranges by 2 years of age, this period continues to be important because any abnormality can lead to amblyopia (Isenberg, 1989).

Because of the immaturity of the system at birth, qualitatively estimating the vision of a newborn is seldom attempted. However, clinical and laboratory techniques can be used to grossly estimate vision in special situations. These include eliciting a nystagmus response with optokinetic targets (stripped patterns), preferential forced looking, visual evoked potentials, and electroretinograms. It is estimated that the visual acuity of a full-term infant is approximately 20/400. Other clues to the status of visual function are more commonly used. For example, visual fixation should be present at birth, although it is not well developed until after the 2nd month. A blink response to light is present at 26 weeks' postmenstrual age (Robinson and Fielder, 1990) and a blink in response to an approaching object (visual threat response) develops at approximately 16 weeks' postnatal age. Visually directed reaching should be seen around 8 weeks' postnatal age, and a failure to smile by 6 weeks' postnatal age may signify a serious visual defect (Levene and Chervenak, 2009). The absence of visual responsiveness by the age of 2 months should be taken seriously and prompt an ophthalmologic evaluation.

The knowledge of normal eye structures and certain growth parameters in the newborn is important because a deviation from these averages can be associated with significant pathology. For example, in congenital glaucoma, the corneal diameter is increased, and the axial length (sagittal length) of the eye is a parameter that is carefully followed to determine if the intraocular pressure is adequately controlled. At birth, the eyeball is 70% of the adult size (average axial length 17 mm) and reaches 95% of the adult size by age 3 years. The corneal horizontal diameter is usually 9.5 mm at birth, which is 80% of the adult diameter. These parameters can be assessed by simple bedside examination and with the aid of ultrasonography.

Poor vision or blindness should be suspected in any newborn with absent or poor pupillary responses, paradoxic pupillary response (the pupil dilates instead of constricting in response to a bright light), and nystagmus or searching eye movements, although these are not usually present until 2 to 3 months of age. Constant poking or rubbing the eyes can also be a sign of poor vision.

Causes of congenital blindness or poor vision include Leber's congenital amaurosis, other retinal dystrophies, congenital cataracts, glaucoma, optic nerve abnormalities, uveal colobomas, high refractive errors, and congenital infections. In most babies, the cause of poor vision is obvious after clinical examination. Occasionally, further investigation is necessary; this may include consultation with a pediatric neurologist, electrophysiologic testing, and neuroimaging. Babies affected with cerebral visual impairment (CVI), also known as cortical visual impairment, have a normal eye exam, including normal pupillary responses and no nystagmus. This term is used to describe children with visual impairment due to neurologic disease, which may be congenital or acquired. Perinatal causes include intrauterine infections, cerebral dysgenesis, asphyxia, hypoglycemia, intracranial hemorrhages, periventricular leukomalacia, hydrocephalus, trauma, meningitis, and encephalitis. In developed countries, CVI is the single greatest cause of visual impairment in children, and most of these children have an associated neurologic deficit (usually epilepsy or cerebral palsy), which places a major burden on children's special services in these countries (Taylor and Hoyt, 2005).

Amblyopia is defined as a reduction in vision that cannot be attributed directly to any structural abnormality of the eye or visual pathway. It is caused by abnormal visual experience early in life, and accordingly it is divided in three etiologic categories. Deprivational amblyopia results from obstruction at any point in the visual axis that causes the retina to perceive poor-quality, distorted, or no images. Causes of deprivational amblyopia include congenital or acquired cataracts, corneal opacities, ptosis, and vitreous hemorrhages. Strabismic amblyopia results from a child's preferring one eye over the other when the visual axes are misaligned. Refractive amblyopia is a consequence of a significant inequality of the refractive error in each eye. Any of these forms of amblyopia can be encountered in the first few months of postnatal life. Because amblyopia is responsible for more cases of unilaterally reduced vision in childhood than all other causes combined, and because it is preventable with early detection and treatment, all newborns and infants suspected to have any of these conditions should be referred promptly to an ophthalmologist.

PUPILLARY RESPONSE AND THE RED REFLEX (THE R IN "I-ARM")

The onset of the pupillary light reflex (constriction in response to light) occurs around 30 to 34 weeks' gestation (Robinson and Fielder, 1990) and is not fully developed until the 1st month after birth. The pupils should be examined for size, shape, symmetry, reactivity to light, and afferent defects.

As the light passes through the pupils and is reflected through the normal clear media of the anterior and posterior segments of the eye, a characteristic red reflex is produced. The red reflex test is vital for early detection of vision and potentially life-threatening abnormalities such as cataracts, glaucoma, retinoblastoma, retinal abnormalities, systemic diseases with ocular manifestations, and high refractive errors. Red reflex assessment is an essential component of the neonatal and infant physical examination. The American Academy of Pediatrics currently recommends that all neonates have an examination of the red reflex before discharge from the neonatal nursery. In addition, the test should be performed during all subsequent routine health supervision visits (American Academy of Pediatrics 2008).

The red reflex test should be performed in a darkened room, projecting the bright light of a direct ophthalmoscope onto both eyes of the child simultaneously, from approximately 18 inches away. It is not necessary to pharmacologically dilate the pupils. The symmetry of the color, clarity, and intensity of the red reflex between eyes is usually more useful than the qualitative assessment of each red reflex independently, as there may be significant variation in normalcy. A markedly diminished reflex, the presence of a white reflex (leukocoria) or dark spots, or an asymmetric reflex are all indications of immediate referral to an ophthalmologist who is experienced in the examination of children (American Academy of Pediatrics 2008). The exception to this rule is a transient opacity from mucus or a foreign body in the tear film that is mobile and completely disappears with blinking or manually opening and closing the eyelids. Unequal or high-refractive errors (need for glasses) and strabismus may also produce abnormal or asymmetric red reflexes. An expanded observation is the position of the light reflex on the corneal surface. Asymmetric positioning of this reflex can indicate misalignment of the eyes (strabismus).

In addition, the shape and regularity of each pupillary aperture should be assessed to look for colobomas and other congenital abnormalities (see Common Diagnostic Problems, later). Asymmetry of pupil size (anisocoria) can be a sign of Horner's syndrome, trauma, or a congenital 3rd nerve palsy. The tunica vasculosa lentis is a plexus of vessels that crosses the pupil, visible in preterm babies up to 34 weeks postmenstrual age. A failure of these vessels to regress can occasionally be seen as a persisting pupillary membrane.

MOTILITY AND ALIGNMENT (THE M IN "I-ARM")

Although the extraocular muscles are fully formed by 12 weeks' gestation and fetal eye movements can be detected as early as 16 weeks' gestation, the supranuclear eye movement system is not fully developed until after birth in full-term neonates.

The eyes of a healthy full-term neonate commonly appear misaligned. It is not unusual to see the eyes shift from orthotropia to esotropia to exotropia. Transient deviations (neonatal ocular misalignments) occur very commonly in the 1st month of life in visually normal infants. At this age, it is not possible to distinguish those infants who will progress to develop pathologic strabismus from those who will subsequently develop normal binocular vision (Horwood, 2003a). Exotropia is commonly observed in newborn nurseries and has been reported to occur in up to 33% of infants (Nixon et al, 1985); however, most exodeviations will usually resolve with development of the fixation reflex and are rarely observed beyond 6 months of age (Sondhi et al, 1988). In contrast, transient esodeviations in patients who do not go on to develop infantile esotropia do not usually persist beyond 10 weeks of age (Horwood, 2003b; Sondhi et al, 1988). Most full-term infants establish normal ocular alignment within the first 8 weeks of life. In some babies, the epicanthal folds of the upper eyelids hide the medial aspect of the sclera, creating the appearance of strabismus; however, in these cases the visual axes are not misaligned. This common condition is referred to as pseudostrabismus and can be confirmed by directing a bright light to both eyes simultaneously and observing that the reflection of the light on the corneas appears in the center of each pupil. When in doubt, any apparent misalignment after 2 to 3 months of age should be considered pathologic and referred (see later discussion).

It is recommended that all newborns have an ocular motility assessment (American Academy of Pediatrics, 2003). This is also important because vision assessment in young nonverbal children is accomplished by evaluating the child's ability to fix on and follow objects. This assessment should be performed binocularly and then monocularly in an awake and alert child. If poor fixation and following are noted after 3 months of age, a significant eye or brain abnormality is suspected, and referral is advisable (American Academy of Pediatrics, 2003).

COMMON DIAGNOSTIC PROBLEMS

LEUKOCORIA

The term *leukocoria* means "white pupil." It is often used more broadly to encompass a spectrum of opacities and abnormalities. On inspection, the pediatrician may grossly visualize a white lesion in the pupillary space or identify an abnormal red reflex. The differential diagnosis for leukocoria includes vision- and life-threatening conditions, and leukocoria in an infant or older child requires urgent ophthalmologic evaluation. These conditions include cataract, retinoblastoma, chorioretinal or optic nerve head coloboma, retinal detachment, retinopathy of prematurity, persistent fetal vasculature, Coats' disease, familial exudative vitreoretinopathy, toxocariasis, and uveitis. The distribution varies widely with the population studied. In one series, 60% of 71 children less than age 10 who presented to a tertiary referral center with leukocoria had cataracts and 28% had retinoblastoma (Haider et al, 2008).

CATARACT

A cataract is any opacification of the normally clear crystalline lens of the eye (Figure 102-2). Although some congenital cataracts are small and nonprogressive, dense

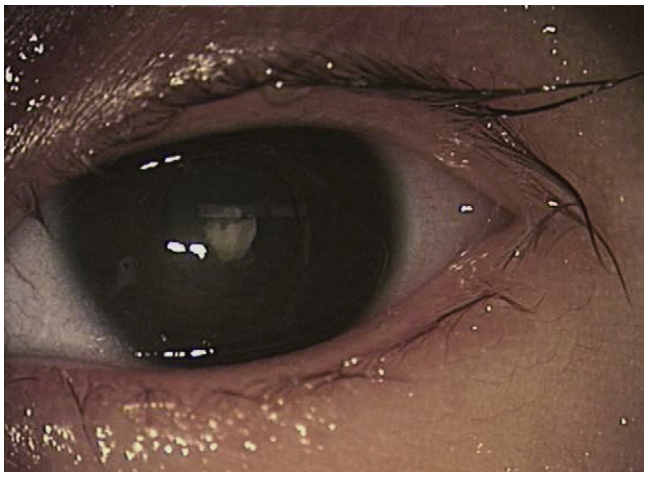

FIGURE 102-2 Congenital cataract. Note central dense opacity surrounded by clearer lens and poor pupillary dilation.

central opacities greater than 3 mm typically are visually significant. In contrast with adult-onset cataracts, which in most cases are removed at the preference of the patient, visually significant congenital cataracts must be surgically removed before 6 to 8 weeks of age to prevent irreversible vision loss from dense amblyopia (see the earlier discussion of visual development) (Birch et al, 2009; Lundvall and Kugelberg, 2002). Therefore, it is essential that all newborns and young infants have screening eye examinations by a pediatrician, because visual prognosis is directly tied to timely ophthalmologic referral. Cataracts can develop or progress with time, so examination for an abnormal red reflex should be repeated at each well-child visit even if prior exam findings appeared normal. Nystagmus may develop when there is a delay in presentation. Nystagmus is an ominous sign of poor visual prognosis and adds even greater urgency for surgical intervention.

Treatment does not end with surgery, because these infants are left aphakic (without a lens) and must receive optical correction with special contact lenses. Glasses, including bifocals, may be required in addition to aphakic contacts but may produce excessive optical aberrations when used as the sole means of refractive correction. Compliance with contacts, glasses, and, in the case of monocular cataracts, aggressive amblyopia treatment is essential for a successful visual outcome. Such children are also at risk for developing aphakic glaucoma, which may present after years, can be very difficult to treat, and is sight-threatening. There is evidence that very early cataract surgery increases the risk of glaucoma, and the optimal timing may lie between 3 and 6 weeks of age (Chak and Rahi, 2008; Khan and A1-Dahmesh, 2009; Michaelides et al, 2007; Swamy et al, 2007).

The etiologic distribution of congenital cataracts is approximately one third inherited; one third associated with systemic genetic, metabolic, or maternal infectious disorders; and one third idiopathic. Genetic inheritance is most commonly autosomal dominant and rarely autosomal or X-linked recessive (Francis et al, 2000; Hejtmancik and Smaoui, 2003). Multiple genes are involved in lens development, and numerous genetic loci have been identified (Hejtmancik and Smaoui, 2003). Marked variability can be present even within the same pedigree, and children with a family history should be examined early by a pediatric ophthalmologist. The same is true of children diagnosed with one of the numerous systemic conditions associated with cataracts. Examples include intrauterine infections (rubella, varicella); metabolic and endocrine disorders (galactosemia, neonatal hypoglycemia, diabetes mellitus, and hypoparathyroidism); fetal alcohol syndrome; chromosomal disorders (trisomy 21, Turner's syndrome, trisomies 13 and 15); craniofacial syndromes; dermatologic diseases (congenital ichthyosis, ectodermal dysplasia); skeletal and connective tissue disorders (Smith-Lemli-Opitz, Marfan, Conradi's, and Weill-Marchesani syndromes); renal disorders (Lowe, Alport's, and Hallermann-Streiff-Francois syndromes); neurofibromatosis; and myotonic dystrophy. A selective work-up may be pursued in infants diagnosed with cataract, particularly bilateral cataracts, and may include TORCH titers (including syphilis); urine tests for reducing substance (galactosemia), protein, amino acids, and pH (Lowe syndrome); blood glucose, calcium, and phosphate; quantitative amino acids and red blood cell enzyme levels (galactokinase, gal-1-uridyltransferase); genetic consultation; chromosome analysis; and ocular examination of parents and siblings.

RETINOBLASTOMA

Retinoblastoma is the most common ocular malignancy of childhood and accounts for 3% of all childhood cancers. The incidence is between 1 in 15,000 and 1 in 20,000 live births, with approximately 350 newly diagnosed cases in the United States per year (Moll et al, 1997; Seregard et al, 2004). Untreated retinoblastoma is almost uniformly fatal, and long-term survival for disease diagnosed after it has spread outside the eye is under 50% (Chantada et al, 1999; Leander et al, 2007). In contrast, 5-year survival rates are greater than 90% when timely recognition and referral to centers specializing in retinoblastoma treatment occur (Abramson, 1982; Abramson et al, 2003; MacCarthy et al, 2006; Moll et al, 1997; Sanders et al, 1988; Seregard et al, 2004). Abramson et al (2003) reviewed 1831 consecutive cases of retinoblastoma. The most common presenting sign was leukocoria (54%), followed by strabismus (19%), poor vision (4%), family history with request for early exam (5%), and red eye (5%). The mean age at diagnosis was 19.7 months overall, but 7.7 months among those with a known family history receiving screening examinations by an ocular oncologist. In most reports, a majority of cases are diagnosed between 1 and 2 years of age, but the earliest reported date has been in utero, and in a series of 400 cases reported by Shield et al, 8.7% of the patients were older than age 5 years (Maat-Kievit et al, 1993; Shields and Shields, 2004; Shields et al, 1991). In the series reported by Abramson et al (2003), the disease presenting sign was identified first by a family member or friend in 80% of cases, a pediatrician in 8%, and an ophthalmologist in 10%. Among patients presenting with leukocoria, the sign was first identified by the family in 90% of cases. These findings stress the importance of routine red reflex testing for all children seen by pediatricians, beginning with newborns. Any child found to have leukocoria should be referred to an ophthalmologist for urgent evaluation.

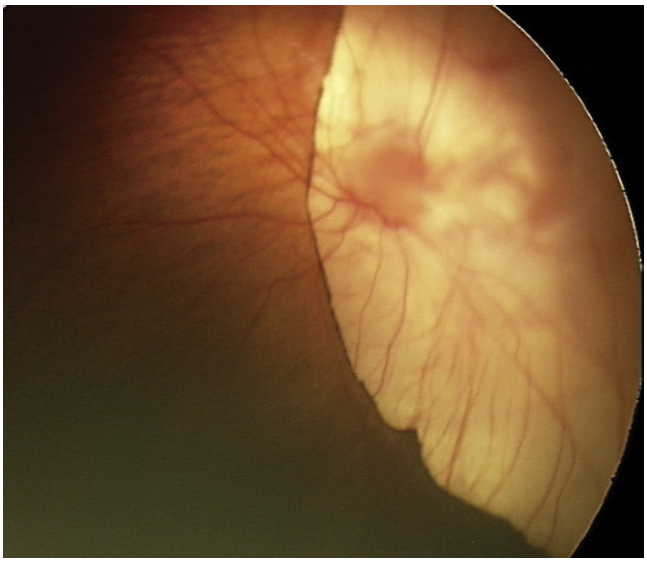

FIGURE 102-3 Chorioretinal and optic nerve head coloboma.

Once referral occurs, diagnosis of retinoblastoma can often be made by visualization using indirect ophthalmoscopy with scleral depression, frequently during examination under anesthesia. Imaging studies may provide useful information, including ocular ultrasonography to identify mass lesions and calcifications; magnetic resonance imagine (MRI) to image the globes and identify orbital and central nervous system (CNS) involvement; and computed tomography (CT) scans to identify calcification, although MRI is now favored over CT for its ability to image soft tissues and avoid ionizing radiation (Balmer et al, 2006; Maat-Kievit et al, 1993). Treatment modalities include enucleation, chemotherapy, focal destructive therapies such as retinal laser photocoagulation or cryotherapy, and radiation, including brachytherapy, stereotactic conformal radiotherapy, and accelerated proton beam irradiation (Balmer et al, 2006). External beam radiotherapy is now much less commonly used.

The retinoblastoma gene, *RB1*, located on chromosomal region 13q14, was the first tumor suppressor gene to be described. Forty percent of patients have an inherited, disease-causing germline mutation, which acts in an autosomal dominant fashion with 90% penetrance (Balmer et al, 2006). Such children, as well as those with spontaneous germline mutations, are also at increased risk of developing nonocular tumors at a rate of 1% per year, or 50% by 50 years of age (Abramson, 1999). A discussion of the risk of retinoblastoma in relatives of affected parents or children is beyond the scope of this chapter. However, children with a positive family history may require serial examinations under anesthesia by an ophthalmologist and referral for genetic counseling.

COLOBOMA

An ocular coloboma is a congenital anatomic defect or cleft that results from failure of part of the optic vesicle fissure to close during embryogenesis (Figure 102-3) (Gregory-Evans et al, 2004). The result is essentially an area of missing tissue in the eye, most commonly in the inferonasal quadrant. Involved structures can include the cornea, iris, ciliary body, lens, retina, choroid, and optic nerve (Gregory-Evans et al, 2004). An iris coloboma appears as an irregular "keyhole," or "cat's-eye" pupil. A chorioretinal or optic nerve head coloboma, depending on the size, will appear as an abnormal red reflex or leukocoria. The affected eye(s) may be microphthalmic. The visual prognosis depends on whether the central macula is involved, and children may have good central vision despite upper visual field defects if the macula is spared. Long term, there is a variable risk of complicating retinal detachment or choroidal neovascularization associated with retinal and optic nerve colobomas (Daufenbach et al, 1998; Gregory-Evans et al, 2004; Guirgis and Lueder, 2003). There are numerous genetic loci, chromosomal aberrations, ocular abnormalities, and systemic findings associated with coloboma. Examples are CHARGE association; 22q11 deletion; Treacher Collins, Walker-Wardburg, and Aicardi's syndromes; and many others. OMIM at www.ncbi.nlm.nih.gov/omim is a good first resource for more detailed information.

PERSISTENT HYPERPLASTIC PRIMARY VITREOUS

During embryogenesis and fetal development, the "primary vitreous" contains the hyaloid vasculature system, which fills the posterior segment of the eye and comes forward to surround the lens. This system normally disappears, and a spectrum of abnormalities can be seen when these structures fail to regress, ranging from persistent pupillary strands to a vascular stalk remnant to a retrolenticular membrane and retinal disorganization or detachment (Dass and Trese, 1999). Involved eyes are typically microphthalmic, and an abnormal red reflex or leukocoria may be identifiable. Depending on extent, surgical intervention may help to avoid recurrent hemorrhage, glaucoma, and phthisis bulbi (atrophy and degeneration of a blind eye, which can become painful), and in some cases useful vision can be achieved (Alexandrakis et al, 2000; Dass and Trese, 1999). In 500 consecutive patients examined by Shields et al at an ocular oncology practice, 288 had retinoblastoma and 212 had lesions that simulate retinoblastoma, the most frequent of which was persistent hyperplastic primary vitreous (PHPV) (38% of 212) (Shields et al, 1991). The next most common retinoblastoma-simulating lesions were Coats' disease (16%) and presumed ocular toxocariasis (16%), with cataract and ROP being less common.

CORNEAL CLOUDING

Opacification of the cornea in a newborn may be the result of congenital glaucoma; corneal dystrophies; developmental abnormalities of the cornea and or other anterior segment structures; infection; iatrogenic trauma; or metabolic disorders (Nischal, 2007). Close inspection with magnification will identify opacification in a focal, regional, or diffuse pattern, depending on the etiology. The cornea is normally clear all the way to its border with the sclera (the limbus), with iris details easily visible. An abnormality centrally may also result in an abnormal red reflex. When identified, congenital corneal opacification requires urgent ophthalmologic

evaluation to rule out congenital glaucoma, an infection that could worsen to become eye- or life-threatening, or an opacification that is amenable to surgical correction during the early critical period in visual development.

Glaucoma is an optic neuropathy usually associated with raised intraocular pressure. In contrast with adult- or juvenile-onset glaucoma, which may be successfully managed medically, congenital glaucoma is a surgical disease that requires prompt intervention, frequently in the neonatal period. Vision loss from glaucoma is typically irreversible. Key signs to identify include corneal clouding; corneal and eye enlargement (buphthalmos), even with a clear cornea; tearing; blepharospasm (blinking); Haab's striae (tears in Descemet's membrane, seen as linearities in the red reflex); and photophobia. It is worth highlighting that tearing is a sign of glaucoma, not just of a blocked tear duct, and that "large, beautiful eyes" require an evaluation to rule out glaucoma. Finally, congenital glaucoma has multiple systemic associations, such as Sturge-Weber, neurofibromatosis, Lowe syndrome, congenital rubella, and Rubenstein-Taybi disease.

Sclerocornea is characterized by cornea that is opacified and white like the sclera, with which it is developmentally continuous. Typically, these opaque areas are located at an indistinct corneoscleral limbus (border), can extend centrally, and contain superficial vascularization. Nischal differentiates between isolated sclerocornea and complex sclerocornea, which is associated with cataract, microphthalmos, and/or infantile glaucoma (Nischal, 2007). In contrast with sclerocornea, *Peters' anomaly* classically has a central corneal opacity with clear cornea peripherally, absence of posterior corneal stroma, and variable attachments between the posterior corneal surface and the iris and or lens (Yang et al, 2009). Glaucoma is a potential complication, and the long-term visual outcomes of surgical management with corneal transplantation are highly variable (Rao et al, 2008; Yang et al, 2009; Zaidman et al, 2007). Nischal recently claimed that the diagnosis of Peters' anomaly is imprecise and has proposed a more complex classification for congenital corneal opacities that requires anterior segment imaging with ocular coherence tomography or high-frequency ultrasound (Nischal, 2007). This classification is more specific with regard to pathogenesis, enables more accurate surgical prognostication, and explains the variability in surgical outcomes. Therefore, Peters' anomaly may soon no longer be considered a distinct clinical entity.

Infectious keratitis can be herpetic, resulting in a keratoconjunctivitis, characteristic epithelial dendritic keratitis, and stromal keratitis, all requiring topical and systemic antiviral medications in the newborn period. Of note, infection can occur despite cesarean delivery and intact membranes (Gallardo et al, 2005). *Bacterial keratitis* is less common in countries that practice routine administration of conjunctivitis prophylaxis at birth. However, a bacterial corneal ulcer can begin as a corneal abrasion (see later discussion) and then quickly enlarge, resulting in corneal thinning or perforation, endophthalmitis, and even bacterial sepsis. In the authors' experience, this chain of events can also occur in reverse, with bacteremia seeding the eyes and ultimately manifesting as a keratitis. Findings include a white corneal stromal infiltrate with an overlying corneal epithelial defect that stains with fluorescein. Aggressive topical and sometimes systemic antibiotics are required, and any infant with a red eye and suspicious corneal signs should be referred for immediate ophthalmologic evaluation.

Iatrogenic trauma may result in corneal injury and be the result of amniocentesis or forceps delivery. Injuries from the latter are characterized by linear breaks in Descemet's membrane, which are more likely vertical or diagonal than to be the horizontal breaks seen with glaucoma, and may be accompanied by other signs of trauma. Corneal dystrophies, such as congenital hereditary endothelial dystrophy and posterior polymorphous dystrophy, may also result in cloudy corneas. The former always manifests at birth, whereas the latter may or may not be present at birth (Nischal, 2007). Metabolic disorders, such as some mucopolysaccharidoses, may cause progressive clouding but often only later in life and rarely during the neonatal period.

RED EYE/EYE DISCHARGE

The most common and important causes of a red eye in neonates include infectious conjunctivitis, subconjunctival hemorrhages, foreign bodies, and vascular malformations.

The incidence of neonatal conjunctivitis (ophthalmia neonatorum) has decreased dramatically since the issuance of prophylaxis in 1881. Despite this, ophthalmia neonatorum still blinds approximately 10,000 babies annually worldwide (Isenberg et al, 1996). The etiologic cause of conjunctivitis in the newborn can be chemical, bacterial, or viral (Table 102-1). Although infections are usually transmitted to the infant by direct contact during passage through the birth canal, organisms can ascend to the uterus so that even infants delivered via cesarean section can be infected, particularly in the setting of prolonged rupture of membranes. Prophylactic agents include 1% silver nitrate, 0.5% erythromycin, 1% tetracycline ointment, and 2.5% povidone-iodine (Isenberg et al, 1995, 1996). No prophylactic agent completely eliminates the risk of developing an infection, and a high index of suspicion should be maintained, in particular in those patients with risk factors (maternal infection, lack of prenatal care, or premature rupture of membranes).

Despite common teaching, the onset of conjunctivitis is not a reliable diagnostic sign, because significant overlap exists among the different etiologic agents. For this reason, conjunctival cultures (in Thayer-Martin, blood agar, and chocolate agar media) and conjunctival scraping for Gram and Giemsa staining are mandatory and should be performed without delay. It is not necessary to wait for an ophthalmologic consultation to initiate laboratory investigation and treatment, because delays in treatment of gonococcal conjunctivitis can have devastating consequences. *Neisseria gonorrhoeae* can penetrate an intact corneal epithelium, rapidly leading to perforation of the globe within hours if treatment is not initiated; therefore, all forms of conjunctivitis must be considered bacterial until proven otherwise. Appropriate treatment should be instituted once the results of cultures are known but should never be delayed (Figure 102-4).

The infant with mucopurulent discharge must be distinguished from the infant who exhibits only excessive tearing and a relatively white eye. The latter is most likely to have nasolacrimal duct obstruction (NLDO), although the

TABLE 102-1 Diagnostic Features and Management of Neonatal Conjunctivitis

Etiologic Agent	Onset	Clinical Characteristics	Diagnosis	Treatment
Chemical	24 hours	Noninfectious Lid edema, watery discharge	History of exposure, self-limited in <48 hours	None
Gonococcal (see Figure 102-4)	3–4 days	Bilateral, hyperacute purulent conjunctivitis, marked lid edema, copious discharge Can perforate cornea	Cell culture and Gram stain Gram-negative intracellular diplococci	Ceftriaxone 25–50 mg/kg/day IV Topical irrigation Topical antibiotics only useful if corneal ulcer present
Chlamydia trachomatis (most common)	5–7 days	Mild mucopurulent nonfollicular conjunctivitis, lid edema, pseudomembrane formation Pneumonitis after 3–12 weeks	Cell culture, Giemsa stain, direct immunofluorescent assay, enzyme-linked immunoassay, PCR Basophilic intracytoplasmic inclusions in epithelial cells	Oral erythromycin 12.5 mg/kg every 6 hours for 2 weeks or Azithromycin suspension 20 mg/kg PO daily for 3 days
Staphylococcus, *Streptococcus*, and other bacteria	5–14 days	Nosocomial, mucoid discharge, conjunctival hyperemia and chemosis	Cell cultures, Gram stain	Broad-spectrum topical antibiotic (e.g., polymyxin B–trimethoprim 1 drop every 4 hours for 7 days)
Herpes simplex virus	6–14 days	Unilateral or bilateral conjunctivitis (nonfollicular), serous discharge, associated lid vesicles and occasionally, corneal epithelial dendritic defects that stain with fluorescein ± systemic involvement	Cell cultures, direct fluorescent antibody staining, enzyme immunoassay detection, PCR Multinucleated giant cells with intracytoplasmic inclusions	Acyclovir 60 mg/kg per day in 3 divided doses × 2 weeks (3 weeks if CNS or disseminated disease) + topical drops (1% trifluridine, 0.1% iododeoxyuridine, or 3% vidarabine)

CNS, Central nervous system; *IV*, intravenous; *PCR*, polymerase chain reaction; *PO*, by mouth.

FIGURE 102-4 A 6-day-old newborn with gonococcal conjunctivitis. Note the marked lid edema and copious purulent eye discharge.

possibility of congenital glaucoma must always be ruled out. Congenital obstruction of the nasolacrimal duct is present in 5% to 6% of infants (Paul and Shepherd, 1994) but usually resolves spontaneously by 12 months of age. Usually a thin mucosal membrane at the distal end of the nasolacrimal duct is the cause. Symptoms usually become manifest by 1 month of age in 80% of cases, with tearing or sticky mucoid discharge. As a consequence of chronic obstruction, secondary infection in the lacrimal sac may occur, a condition known as dacryocystitis. This manifests as a tender, erythematous swelling of the skin overlying the lacrimal sac and periocular skin. Pressure on the lacrimal sac causes a reflux of mucopurulent material from the punctum (see Figure 102-1). Acute and chronic conjunctivitis may also develop. NLDO usually resolved spontaneously within the 1st year of life; conservative management is indicated in uncomplicated cases and consists of digital massage downward from the lacrimal sac over the nasolacrimal duct on the side of the nose. The massage empties the sac, reducing the opportunity for bacterial growth, and at the same time it applies hydrostatic pressure to the obstruction, which occasionally opens the obstruction. Topical broad-spectrum antibiotic drops can be used if there is conjunctival injection and discharge. Referral to an ophthalmologist should be considered if the condition has not resolved toward the end of the 1st year, because probing and/or intubation of the lacrimal sac is sometimes necessary to relieve the obstruction (Katowitz and Welsh, 1987).

Orbital and preseptal cellulitis can also manifest with conjunctival injection, chemosis, and discharge. In addition, orbital cellulitis has altered ocular motility and pupillary reflexes and proptosis. Both are almost always unilateral and can rarely occur in the 1st month of life, sometimes secondary to acute dacryocystitis.

A subconjunctival hemorrhage is seen as a bright red discoloration under the conjunctiva obscuring the white scleral background and is common in the perinatal period. In a majority of cases it is caused by elevated venous pressure in the head and neck produced by compression during uterine contractions. Later in life, subconjunctival hemorrhages may be a feature of child abuse, although they can also occur spontaneously. Subconjunctival hemorrhages in isolation are completely innocuous and usually resolve in 10 to 14 days.

MOTILITY ABNORMALITIES AND NYSTAGMUS

Various eye motility and alignment abnormalities can be present in the 1st month of life. It is sometimes useful to determine whether it is a paralytic or restrictive problem, where the eye movements are evidently limited in one or several directions of gaze (incomitant strabismus) versus a comitant problem where the deviation is the same in every direction of gaze and there is no obvious restriction or motility deficit.

The most common form of strabismus in early infancy is infantile or essential esotropia. This form of convergent comitant strabismus is rarely congenital, so this term has been abandoned. It is usually present by age 3 to 4 months

and is characterized by a large angle deviation. These children tend to cross-fixate (use the left eye to view the right visual field and vice versa), simulating an abduction deficit, because it is hard to get the child to follow an object to the ipsilateral field. This can easily be mistaken for bilateral 6th nerve palsy. However, 6th nerve palsies in the neonatal period are extremely rare, and an abduction movement can sometimes be elicited by patching one of the child's eyes to force the other eye to abduct in search of an object or by using the doll's-eye (the eyes lag behind the turning of the head from side to side) or optokinetic nystagmus (OKN) maneuvers. Infantile esotropia is a condition that is not likely to spontaneously resolve without surgical correction. Because of a high associated risk of amblyopia, prompt referral of these patients to a pediatric ophthalmologist within the first few months of life is appropriate. Even if the child's age or systemic condition is not appropriate for surgical correction, patching and other treatments should be initiated as early as possible.

Congenital nystagmus (infantile nystagmus syndrome) is an involuntary, bilateral, conjugate oscillation of the eyes that develops within the first 6 months of life. Despite the name, the eye movement abnormalities are rarely noticed at birth. Disorders of the visual pathways resulting in blindness or severe visual deprivation before the age of 2 to 3 months can also result in nystagmus (sensory nystagmus) which can be manifest as large-amplitude "wandering" eye movements or with a smaller-amplitude, faster movement that resemble the congenital motor form. Any form of bilateral (and sometimes unilateral) visual deprivation, including cataracts, corneal abnormalities, glaucoma, optic nerve problems, and chorioretinal colobomas, can manifest with nystagmus, and a prompt ophthalmic evaluation is needed to rule out these conditions, which are treatable in some cases. Other conditions such as albinism, achromatopsia (congenital absence of the retinal cones), and aniridia can also result in nystagmus, but the ocular findings in these conditions are more subtle and easily missed. In these cases additional testing, including electroretinography, may be recommended.

Because of this overlap, motor nystagmus should always be considered a diagnosis of exclusion, as other ocular and neurologic disorders can manifest with the same clinical characteristics. Certain specific forms of nystagmus are commonly associated with neurologic dysfunction; these include upbeat nystagmus, see-saw nystagmus, and even monocular nystagmus. However, these forms have all been associated with sensory loss, and an ophthalmologic exam is necessary even when neuroimaging studies rule out intracranial pathology.

Other transient disorders of the ocular motor system include opsoclonus, or flutter-like, high-frequency, small-amplitude movements that in newborns may be self-limiting and resolve spontaneously within the first few weeks of life. Some infants can also present with transient downward deviation of the eyes. This disorder can be distinguished from the more serious sun-setting sign, associated with hydrocephalus, by demonstrating intact upgaze using vestibular-ocular responses. Neuroimaging fails to demonstrate any underlying neurologic disorder, and the deviation tends to improve gradually over the following months.

PTOSIS AND OTHER EYELID AND LACRIMAL ABNORMALITIES

External inspection of the eyes and eyelids should be performed in every newborn. The eyelids are fused usually until 25 weeks' gestation, but they may rarely remain fused until 30 weeks. Eyelid colobomas are rare congenital full-thickness defects, usually involving the upper eyelid border. Eyelid colobomas are commonly associated with Goldenhar's syndrome.

Most cases of congenital ptosis are cause by an isolated developmental anomaly of the levator palpebrae muscle. Other causes include congenital 3rd nerve palsy, Horner's syndrome, blepharophimosis syndrome, and Marcus-Gunn jaw-winking ptosis, which is a synkinesis between the levator palpebrae and the mastication muscles. This type of ptosis is characterized by elevation of the lid associated with sucking or chewing.

Because form deprivation amblyopia can occur as a result of complete obstruction of the visual axis, this condition must be managed aggressively by an ophthalmologist familiar with the treatment of lid disorders and amblyopia. Even though this type of amblyopia is the most severe and concerning to the neonatologist, it is important to remember that even without complete obstruction of the pupil, amblyopia can occur secondary to the blur induced by astigmatism produced by the ptotic eyelid on the cornea. If vision is not threatened, surgery may be deferred until 4 to 5 years of age, although some surgeons have argued the benefits of earlier surgery (Katowitz, 2002).

A number of eyelid tumors can be present at birth or shortly thereafter. Capillary hemangiomas can manifest as a localized area of dimpled, red skin that resembles a strawberry or as a deep diffuse purplish mass a few weeks after birth. Typically they progress over the first 5 to 8 months of life and then stabilize, regress, and involute over several years. They are amblyogenic because they can cause mechanical ptosis, obstruct the visual axis, or cause significant astigmatism. A variety of treatment options exist, including topical, intralesional, or systemic steroids; interferon-α; vincristine; and surgical resection. Favorable results have been reported recently with systemic nonselective beta-blockers (e.g., propranolol) (Leaute-Labreze et al, 2008).

Capillary hemangiomas should be distinguished from other capillary vascular malformations (such as port-wine stains) that are present at birth and do not exhibit regression. These are sharply circumscribed lesions that are usually unilateral. In these patients, Sturge-Weber syndrome should be suspected. When the skin lesion involves the eyelid, an ophthalmologic consultation should be requested to rule out glaucoma (occurring in about 50% of patients) and vascular abnormalities of the choroid.

A dacryocystocele is formed when a proximal and a distal obstruction coexist in the lacrimal sac and the lacrimal sac becomes distended. Clinically it is manifested as a bluish, nontender mass just inferior and nasal to the medial canthus (see Figure 102-1). The bulging of the mucosa at the lower end of the nasolacrimal duct into the nasal cavity can significantly compromise the airway and should be ruled out by inspection of the nasal passage (Paysse et al, 2000). A secondary infection of the distended sac is not uncommon and can have potentially serious consequences

in a neonate, including meningitis and septicemia. Intravenous antibiotics should be administered followed by decompression of the sac after 24 to 48 hours if the dacryocystitis shows no improvement. A dacryocystocele should be distinguished from a frontal encephalocele and can occasionally be confused with a hemangioma or a dermoid cyst.

OCULAR TRAUMA IN THE NEONATAL PERIOD

Newborns may suffer injuries to the eye as a result of birth, more commonly difficult births, such as those involving prolonged delivery, cephalopelvic disproportion, or forceps use. Intrauterine injuries may result from amniocentesis with discovery at birth. Some common injuries will heal without long-term visual or ocular sequelae (Holden et al, 1992). However, identification of birth-related eye trauma necessitates an ophthalmologic consultation to perform a complete dilated examination, identify all injuries, and assess the need for treatment.

Subconjunctival hemorrhage results from rupture of blood vessels on the surface of the eye. It is distinguished from conjunctival injection from an inflammatory or infectious cause by characteristically well-demarcated borders between spots of blood underneath the conjunctiva and completely white sclera directly adjacent to the blood. Subconjunctival hemorrhage will resolve spontaneously with time and does not require treatment. However, such hemorrhage can often be a sign of more significant trauma underneath the hemorrhage or within the eye, and a complete eye examination, including dilated funduscopic examination, is required. Recurrent subconjunctival hemorrhage could be a sign of a coagulopathy or platelet abnormality, and an appropriate work-up should be pursued in such cases.

Hyphema is the presence of red blood cells in the anterior chamber of the eye (the space between the cornea and the iris), most commonly the result of trauma, including birth trauma. It is often associated with ocular injuries. Clot or hemorrhage of varying magnitude may be seen on close inspection, ranging from a subtle crescent of blood at the corneoscleral limbus to an eye completely filled with blood, obscuring any view of the structures underneath. The red reflex is commonly abnormal. Hyphema is a potentially vision-threatening condition and requires close management by an ophthalmologist. The immediate concern is obstruction of the aqueous fluid drainage angle structures, resulting in an acute rise in intraocular pressure (IOP) or acute glaucoma. High IOP is painful enough to cause vomiting in children and adults and may manifest as crying, irritability, grimacing, poor feeding, or emesis in an infant. If the IOP is high enough for any prolonged period of time, irreversible optic nerve damage can ensue, with permanent vision loss. Corneal blood staining may also result and can take a year or more to clear, resulting in amblyopia. Often, IOP spikes occur with rebleeds, for which the greatest risk is during the first 5 days after an injury. Therefore, management includes full eye examination, daily monitoring, eye shield, avoidance of antiplatelet agents, bed rest in older children, sickle cell testing (portends higher risk of glaucoma), topical and systemic glaucoma medications, and possible surgical intervention to wash out the anterior chamber. Traumatic hyphema is associated with delayed glaucoma, which may only manifest years after the acute incident, so these children require long-term ophthalmic follow-up.

An open globe injury refers to a full-thickness break in the eyewall (e.g., sclera, cornea). These injuries can occur as a laceration or as a rupture, in which pressure is applied to the front of the eye and the eye wall breaks open at its weakest points, such as the corneoscleral limbus or extraocular muscle insertion sites. Key signs include an obvious break with the protrusion of intraocular contents (e.g., the iris), extensive subconjunctival hemorrhage, a flat anterior chamber (the iris and cornea have come together), hyphema, vitreous hemorrhage (seen as a poor red reflex), and abnormal eye contour or intraocular foreign body on orbital imaging. An open globe represents a surgical eye emergency. Management consists of shielding the eye, aborting any further examination, NPO status, intravenous antibiotics, antiemetics or sedation to minimize Valsalva straining, and exploration and repair in the operating room.

A corneal abrasion is an epithelial defect on the corneal surface. Staining with fluorescein will identify areas of missing epithelium, which appear green under a blue light source and magnification. Treatment includes an urgent, complete ophthalmologic examination to rule out other ocular injuries, topical antibiotics, and close follow-up to ensure complete healing and monitor for the development of bacterial keratitis (see the earlier discussion of corneal clouding). In a neonate, a corneal abrasion must be taken very seriously, because complications have included the sequential development of keratitis, endophthalmitis, septicemia, and meningitis (O'Keefe et al, 2005). Therefore, corneal abrasions should be managed by an ophthalmologist.

Other injuries include retinal hemorrhages (RH; see later discussion); corneal trauma from forceps, resulting in tears of the Descemet's membrane, visible as vertical or circumferential lines on red reflex examination, corneal thickening and opacification from edema, and corneal scarring; eyelid or adnexal injuries requiring surgical repair; choroidal rupture, which requires dilated fundus examination for diagnosis; and even traumatic optic neuropathy (Estafanous et al, 2000; Khalil et al, 2003; Lauer and Rimmer, 1998; Yang et al, 2005).

RETINAL HEMORRHAGES AND ABUSIVE HEAD INJURY

Retinal hemorrhage from birth is very common. The incidence is estimated to be between 10% and 40% of all newborns, depending on the examiner, time from birth, and specific population studied (Anteby et al, 2001; Critchley, 1968; Egge et al, 1980; Emerson et al, 2001; Hughes et al, 2006). The rate in children born through vacuum-assisted delivery is even higher, at 75% to 78% (Emerson et al, 2001; Hughes et al, 2006). The association between vacuum delivery and RH supports a role for mechanical trauma to the retinal vessels, for example from direct compression of the globe; however, there are likely additional factors involved, because head circumference and duration of labor are not significant factors, and RH occurs with cesarean section, albeit at decreased frequency (7%) (Emerson et al, 2001). Adequate description of retinal

findings requires dilated funduscopic examination with an indirect ophthalmoscope. However, some RH may be identified with a direct ophthalmoscope, and an abnormal red reflex may be noted in some cases.

Birth-related RH rarely has a long-term visual consequence. However, it is important to understand the characteristics that distinguish birth-related RH from those associated with abusive head trauma, as there may be considerable overlap. The great majority of birth-related RH is intraretinal; subretinal and preretinal hemorrhages are less frequent. Such hemorrhages include superficial flame and deeper blot hemorrhages, and larger hemorrhages may frequently contain white centers (Egge et al, 1980; Emerson et al, 2001; Hughes et al, 2006). Although commonly located in the posterior pole of the eye, they may also extend to the mid- and far- retinal peripheries and range in number from a few to too numerous to count (Emerson et al, 2001; Hughes et al, 2006). They may be bilateral, unilateral, or asymmetric.

The preceding characteristics are similar to the RH seen in abusive head trauma (see later discussion), although severity ranges higher in abuse. A key characteristic, therefore, is the time to resolution of birth-related RH. A majority of intraretinal hemorrhages clear within the first 2 or 3 weeks of life, some within the first few days (Anteby et al, 2001; Emerson et al, 2001; Hughes et al, 2006; Kaur and Taylor, 1992). In most series, all intraretinal hemorrhages have cleared by age 4 weeks, whereas preretinal or subretinal hemorrhages may take up to 6 weeks to clear (Emerson et al, 2001). Of note, Hughes et al (2006) reported two children who had isolated discrete, dense foveal and or peripheral RH that took up to 7 weeks to resolve and which they described as intraretinal. However, in their series, which included 18 infants with birth-related RH, all multiple, confluent intraretinal hemorrhages had cleared by 17 days; the persistent RH showed signs of resolving on photographs taken at 30 days, so that such RH has a different appearance from acute hemorrhage; and again, the persistent hemorrhages were single and isolated (Hughes et al, 2006). Therefore, multiple intraretinal hemorrhages present past 1 month of age should be considered not related to birth. Isolated, resolving intraretinal hemorrhage or persistent pre- or subretinal hemorrhage past 1 month of age may rarely be related to birth, but such RH would not at any age by itself be considered specific for any cause, including abuse.

Pediatric abusive head trauma (AHT) is a leading cause of death in infancy (Billmire and Myers, 1985; Brenner et al 1999; Centers for Disease Control, 1990; Duhaime et al, 1992; Overpeck et al, 1998). Previous names have included the shaken baby syndrome (SBS), inflicted or nonaccidental head trauma, and inflicted childhood neurotrauma (Duhaime et al, 1998; Forbes et al, 2004; Reece, 2003). AHT is characterized by intracranial hemorrhage with or without retinal hemorrhages and or additional injuries, including bony fractures (Duhaime et al, 1998). Affected children are under 3 years of age, with the great majority under a year (Binenbaum et al, 2009; Duhaime et al 1992, 1998). The mechanism of trauma is believed to be repetitive acceleration-deceleration of an infant with or without blunt impact. Based on numerous perpetrator confessions and a frequent lack of scalp and soft tissue injuries, a majority of child abuse experts believe that it is possible to produce this constellation of findings with shaking alone; however, most fatal and severe injuries include evidence of impact. Biomechanical models of infant head trauma are still in development and have known limitations (Duhaime et al, 1987, 1998; Gill et al, 2009; Prange et al, 2003; Raghupathi and Margulies, 2002; Raghupathi et al, 2004; Starling et al, 2004). Therefore, the term *abusive head trauma* has been adopted by the American Academy of Pediatrics as a term more inclusive of all mechanisms of injury and is preferable to "shaken baby syndrome" (Christian and Block, 2009).

RHs are present in 50% to 100% of victims of abusive head trauma (Altman et al, 1998; Binenbaum et al, 2009; Duhaime et al, 1992, 1998; Green et al, 1996; Kivlin, 2001; Morad et al, 2002).

Of note, however, this designation has been used indiscriminately by clinicians and investigators to describe a spectrum of findings. The presence of any RH in an infant is highly associated with abuse, and increasing RH severity correlates with increasing likelihood of abuse (Binenbaum et al, 2009; Bechtel et al, 2004; Christian et al, 1999; Forbes et al, 2004; Maguire et al, 2009; Morad et al, 2002). In AHT, RH may range from none to a few intraretinal hemorrhages confined to the posterior pole to bilateral, too numerous to count, intra-, sub-, and preretinal hemorrhages, extending to the far periphery or ora serrata (termination of the retina). The hemorrhages may be unilateral or markedly asymmetric. Macular retinal folds and hemorrhagic macular retinoschisis (splitting of the retinal layers) may be seen at the severe end of the spectrum. In comparison, RH associated with accidental head trauma typically are few in number, intraretinal, and limited to the posterior pole (Bechtel et al, 2004; Binenbaum, 2009; Buys et al, 1992; Christian et al, 1999; Duhaime et al, 1992; Forbes et al, 2004). However, more severe RH and even retinal folds may be seen with severe accidental trauma, such as fatal motor vehicle crashes (Kivlin et al, 2008). To date, hemorrhagic macular retinoschisis specifically has been reported only in abusive injury.

In addition to accidental head trauma, the differential diagnosis of RH in infancy includes birth-related RH (see earlier discussion), coagulopathy, septicemia, leukemia, anemia, and glutaric aciduria. These conditions are diagnosable through various diagnostic tests. Terson's syndrome refers simply to RH associated with subarachnoid hemorrhage; its etiology is not established, and it may in fact be a feature of AHT in some cases. Studies have demonstrated that prolonged chest compression with cardiopulmonary resuscitation very rarely results in RH, and when present, these RH are a few isolated posterior pole intraretinal hemorrhages (Odom et al, 1997). RH from convulsions are even rarer, and severe coughing has been reported not to result in RH (Goldman et al, 2006; Mei-Zahav et al, 2002; Sandramouli et al, 1997; Tyagi et al, 1998). RH associated with papilledema (swollen optic nerve head secondary to raised intracranial pressure) is limited to small splinter hemorrhages on the disk with moderate disk swelling or flame-shaped hemorrhages directly around the disk when papilledema is severe.

Children with AHT may present with a history of minor blunt head trauma, such as a short fall, or no trauma history at all and exhibit lethargy, seizures, increased or decreased

tone, vomiting, poor feeding, breathing difficulties, or apnea (Duhaime et al, 1998). Head CT identifies subdural or subarachnoid hemorrhage, sometimes with a combination of chronic and acute features, but very rarely may initially be normal; brain MRI provides a better look at the soft tissue and brain parenchyma to identify features such as hypoxic ischemic injury; plain film radiographs may reveal a skull fracture; and a skeletal survey is a critical modality for identifying other bony injuries (Duhaime et al, 1998; Ichord et al, 2007; Morad et al, 2004; Parizel et al, 2003). Because the provided history is often vague or unreliable, a high index of suspicion and low threshold for obtaining diagnostic tests and specialist consultation must be maintained.

Ophthalmologic examination should occur within 48 hours, preferably within 24 hours, because RH can begin to resolve within days. A dilated fundus examination with an indirect ophthalmoscope and, when indicated, scleral depression are required to adequately visualize the retina. Ophthalmologic consultation should not be delayed because of an inability to pharmacologically dilate the pupils due to neurologic pupil exam checks; the ophthalmologist can still attempt to view a portion of the retina and return for a dilated examination later. It is very important to document the type(s), number, location(s), and laterality of all RHs, both using explicit descriptive terms and through diagrams. Fundus photographs, for example with a RetCam camera, should be obtained when possible (Nakagawa and Skrinska, 2001; Saleh et al, 2009). Such photographs are important documentation and are often easily obtained at the time of sedation administered for MRI or other tests. However, the authors stress that the presence of RH is not descriptive enough, and the extent and detailed characteristics of the hemorrhages are vitally important. Such cameras may identify and characterize some posterior pole RH, but they do not consistently provide adequate visualization of the retinal periphery and are not a substitute for an indirect exam. RH have been reported as a result of RetCam use in a premature infant undergoing ROP screening (Adams et al, 2004). Notably, this 25-week-gestational-age infant was less than 34 weeks postmenstrual age at the time of exam and had immature retinal vasculature, without smooth muscle, elastin, or collagen layers and poor autoregulation, unlike the mature vasculature of a few-months-old infant evaluated for AHT (Adams et al, 2004). Further, other investigators have failed to identify any RH with the routine use of the RetCam for ROP screening (Azad et al, 2005). Nevertheless, whenever possible an indirect ophthalmoscopic exam should be completed and documented before using a contact fundus camera.

Visual impairment in children with AHT is most often related to cortical damage. However, persistent macular or vitreous hemorrhage, retinoschisis, and other scarring conditions may result in significant deprivation amblyopia, induced myopia and anisometropic amblyopia, or photoreceptor damage limiting visual function. The overall mortality rate in AHT has been reported to be between 13% and 36% (Barlow et al, 2005; Duhaime et al, 1987). Approximately two-thirds of the survivors have long-term neurologic deficits. In a prospective study of 25 children with a mean 5 years follow-up, Barlow et al found that 68% had neurologic and cognitive impairment, and one-half of these had severe disabilities and were totally dependent (Barlow et al, 2005).

RETINOPATHY OF PREMATURITY

Retinopathy of prematurity, a disease of the developing retinal vasculature, first became a significant cause of blindness in children in the 1940s and 1950s with increased survival of premature infants due to improved neonatal care, in particular the use of supplemental oxygen in industrialized countries (Patz, 1952, 1954, 1969, 1975). This episode has been termed the "first epidemic," and hyperoxia was determined to be the dominant risk factor (Campbell, 1951), a finding that was substantiated by both basic science and clinical trials (Flynn et al, 1992; Lanman and Guy, 1954). With restriction of oxygen in the mid-1950s, there was a reduction in the blindness from ROP, but this was associated with increased rates of mortality and cerebral palsy in premature babies (Cross, 1973). During the late 1960s, NICUs were introduced with use of oxygen with increasingly accurate methods of monitoring supplementation and improved management of neonatal and perinatal complications. However, because smaller and less mature babies were surviving, blindness from ROP began to reemerge (the "second epidemic) (Flynn et al, 1992). Surgical treatment of established disease (Cryotherapy for Retinopathy of Prematurity Cooperative Group 1988, 1990a; Tasman, 1985;) and improved neonatal care are probably the major factors responsible for reduction of blinding ROP observed during the 1980s and 1990s (Gibson et al, 1989).

Classification of Retinopathy of Prematurity

The International Classification of Retinopathy of Prematurity (ICROP) was published in 1984 (ICROP, 1984) and revised in 1987 (ICROP, 1987), providing a standard nomenclature for clinical findings in acute-phase ROP. As shown in Table 102-2, this classification takes into account four components of the ocular findings: anterior-posterior location of the retinopathy (zone), severity (stage), extent of the disease at the circumference of the vascularized retina (in clock hours), and the presence or absence of so-called plus disease. *Plus disease* is defined as engorged and tortuous vessels of the posterior pole and indicates a more serious form of ROP. The ROP status of an eye is determined by the highest stage and the lowest zone observed, along with noting the presence or absence of plus disease.

In ICROP, the retinal surface is divided into three concentric "zones" centered on the optic nerve (Figure 102-5). Most severe retinopathy occurs in zone I or posterior zone II, most retinopathy occurs in zone II, and ROP that occurs in zone III tends to be mild. The zone in which ROP occurs has important prognostic significance (Good et al, 2005; Palmer et al, 1991). Severity of retinopathy is designated on a scale of 1 to 3 by "staging" the retinopathy at the junction between vascular and avascular retina (Figure 102-6). The first two stages indicate mild disease; the extension of vessels into the vitreous indicates stage 3 ROP, a more serious disease. Stages 4 and 5 indicate the

TABLE 102-2 International Classification of Retinopathy of Prematurity—Revisited (2005)

Anterior-posterior location		Zone I: retinal area within a circle centered on the disk and with a radius of twice the estimated disk-foveal distance Zone II: retinal area extending from the edge of zone I to a circle with a radius from the disk to the nasal ora serrata Zone III: a crescent-shaped retinal area extending beyond zone II to the ora serrata
Severity	Stage of ROP	Stage 1: a thin, sharp line of demarcation between vascularized central retina and more peripheral avascular retina Stage 2: an intraretinal elevation (ridge) at the junction between vascularized and avascular retina Stage 3: a ridge with fibrovascular extension into the vitreous Stage 4: partial retinal detachment; 4A, does not involve the fovea; 4B: involves the fovea Stage 5: total retinal detachment
	AP-ROP	Aggressive posterior ROP recognized by: 1. marked dilation and tortuosity of posterior pole vessels 2. difficulty in documenting the stage of ROP at junction between vascularized and avascular retina 3. occurs in zone I or zone II
Extent		Number of clock hours of ROP along the circumference of the vascularized retina
Posterior pole vascular abnormalities	Plus disease	Presence of dilated and tortuous vessels of the posterior pole present in two or more quadrants
	Preplus disease	Abnormal vascular dilation and tortuosity that is insufficient for diagnosis of plus disease present in two or more quadrants

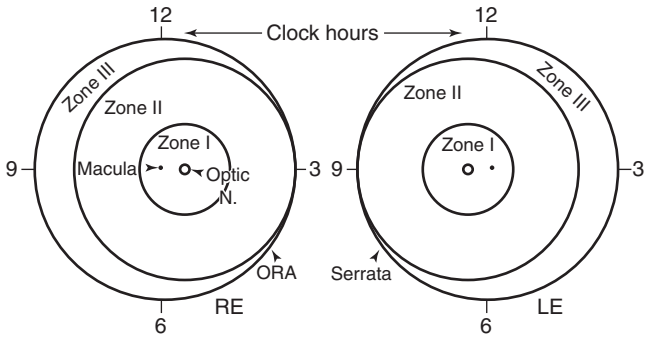

FIGURE 102-5 Scheme of retina of right eye *(RE)* and left eye *(LE)* showing zone borders and clock hours used to describe location and extent of retinopathy of prematurity. *(Reproduced from* Archives of Ophthalmology, *with permission.)*

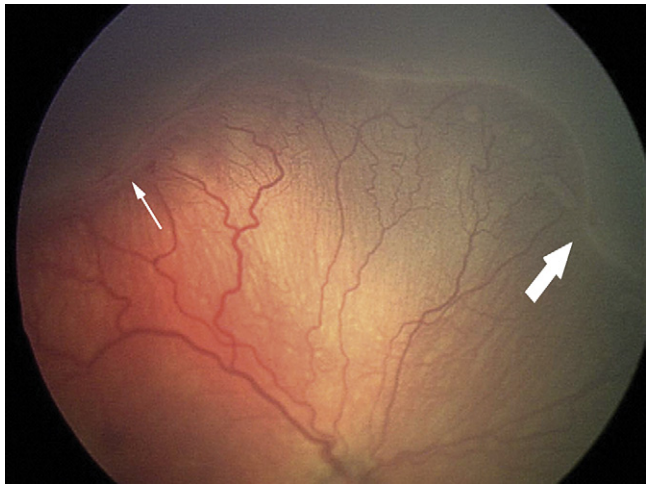

FIGURE 102-6 Fundus photograph showing the ridge between vascularized and avascular retina characteristic of stage 2 retinopathy of prematurity (*large arrow*). Stage 3 retinopathy of prematurity is present in the left-hand portion of the photograph (*small arrow*).

presence of retinal detachment. The term plus disease, a clinical diagnosis made by comparing to reference photographs used in clinical treatment trials in the United States (Cryotherapy for Retinopathy of Prematurity Cooperative Group, 1988; Good et al, 2005) indicates marked tortuosity and/or dilation of the peripapillary arterioles and venules in at least two quadrants. Preplus disease designates the presence of vessels that are not normal appearing but are not sufficiently abnormal to be designated as plus disease. Other signs that frequently accompany serious ROP include vitreous haze, iris vascular engorgement, and pupillary rigidity, but these signs are not required to make the diagnosis of plus disease.

In 2005 aggressive posterior ROP (AP-ROP) was added to ICROP, defining the observation of a particularly aggressive form of ROP observed with increasing frequency in the smallest premature babies and that may be more difficult to recognize, because the peripheral retinopathy is not as remarkable even though the posterior pole vascular abnormalities of dilation and tortuosity are quite marked (International Committee for the Classification of ROP, 2005).

Prevalence and Incidence of Retinopathy of Prematurity

Large natural history studies have shown that, in most cases, ROP begins at 31 to 32 weeks postmenstrual age (Fielder et al, 1992; Good et al, 2005; Palmer et al, 1991; Reynolds et al, 2002) with progression over the next 2 to 5 weeks. Spontaneous regression commonly occurs in eyes with stages 1 and 2 and early stage 3 (Palmer et al, 1991; Repka et al, 2000). Blindness or severe visual impairment commonly results from progression of the retinopathy to retinal detachment or severe distortion of the posterior retina (Dobson et al, 1995; Gilbert et al, 1992a, 1992b, 1996; Reynolds et al, 1993).

ROP occurs in a majority of babies with birthweights of less than 1500 g (very low-birthweight [VLBW]) with an even greater proportion of babies developing ROP in the less than 1000 g birthweight category (extremely low-birthweight, ELBW) and in the less than 750 g birthweight

infants (Cryotherapy for Retinopathy of Prematurity Cooperative Group, 1991; Darlow et al, 1992, 2005; Fielder et al, 1992; Good et al, 2005). ROP is also more likely to occur in males than females (Darlow et al, 2005) As neonatal services continue to improve, a greater proportion of VLBW and ELBW babies survive, with a resultant increase in the population of babies at risk (Gilbert et al, 2005).

Many case control studies have been undertaken to elucidate risk factors for ROP, and all identify preterm birth and low birthweight as the major risk factors. Other factors associated with the development of ROP (but not necessarily causally associated) include hyperoxia, hypoxia, acidosis, intraventricular hemorrhage, exposure to light, vitamin E deficiency, and septicemia. Progression to advanced, blinding disease seems to be determined by immaturity of the retina and the degree of early insult.

Prevention of Retinopathy of Prematurity

Medical treatment to prevent ROP holds the promise to markedly decrease development of serious ROP. Interventions such as systemic steroids given immediately before preterm birth and surfactant administered shortly after birth decrease the incidence of respiratory distress syndrome, which would be expected to decrease the incidence of serious ROP. However, these medical advances also increase the survival rate of low-birthweight babies (Soll, 2000). Several randomized clinical trials were undertaken in the 1970s and 1980s to determine whether supplementation with the antioxidant vitamin E might prevent development of ROP. Individually, these studies do not demonstrate a significant positive benefit, but a detailed metaanalysis of randomized trials suggested that more investigation is warranted (Raju et al, 1997).

In 2001, Hellstrom and co-investigators showed in a cohort of babies in Sweden that insulin-like growth factor-1 (IGF-1) was deficient in premature infants almost immediately after birth, and they observed that children who were slow to recover to normal serum levels of IGF-1 were more likely to develop ROP (Hellstrom et al, 2001). In several careful follow-up studies, these investigators demonstrated that determining the rate of weight gain, essentially a noninvasive surrogate for growth hormone level, was effective in stratifying the risk of developing serious ROP even before the retinopathy is manifest (Hellstrom et al, 2003; Lofqvist et al, 2006, 2009). Using a risk model (WINROP) (Lofqvist et al, 2009), individual infants could be targeted for more intensive examinations, and infants at little risk would require fewer diagnostic examinations. These approaches, supplemented by extensive work in murine models of oxygen-induced retinopathy by Smith et al (2003, 2008), open the way for potential medical therapies that can be offered to high-risk babies that may prevent ROP or at least modulate its severity (Chen and Smith, 2007; Heidary et al, 2009; Lofqvist et al, 2009; Mantagos et al, 2009).

Detection of Serious Disease

Because the benefit of treatment of serious ROP (as variously defined in clinical trials) has been shown in randomized clinical trials (Cryotherapy for Retinopathy of Prematurity Cooperative Group, 1988; Early Treatment for Retinopathy of Prematurity Cooperative, 2003), it is essential to identify the at-risk baby so that timely examinations can be performed to prevent blindness, or at least decrease its likelihood. In the United States, the recommended guidelines for detection of serious ROP indicate that diagnostic examinations should be performed on infants with birthweights <1500 g or 30 weeks' gestation, along with those high-risk babies in the 1501 to 2000 g birthweight group (American Academy of Pediatrics, 2006). In Latin American countries and in urban centers of newly industrializing countries in Asia and Eastern Europe, the same screening criteria likely do not apply, because evidence suggests that larger, older babies are also at risk in these settings, and national or regional guidelines need to be developed (Azad and Chandra, 2003; Fortes Filho et al, 2007; Trinavarat et al, 2004; Varughese et al, 2008; Vedantham, 2007).

The first examination should generally occur between 31 and 33 weeks postmenstrual age, but not before age 4 weeks (American Academy of Pediatrics, 2006; Reynolds et al, 2002). Examinations usually continue on an every-other-week basis unless ROP develops, at which time examination frequency may be increased. The indications for discontinuing surveillance are not clear at this point, but, in general, examinations continue until ROP is observed to regress, ROP progresses to treatment severity, or vessels are observed on at least two occasions to have progressed into zone III in the absence of ROP. Coordination of this schedule among neonatology, ophthalmology, and nursing is essential. If outpatient appointments are not kept or proper information is not conveyed when the baby is transferred to another facility, potentially treatable disease may be missed, with disastrous consequences (Mills, 2009).

Treatment of Established Retinopathy of Prematurity

Peripheral retinal ablation for eyes with serious ROP can prevent progression to blinding disease. The multicenter Cryotherapy for ROP (CRYO-ROP) study, which enrolled babies in 1986 and 1987, randomly assigned babies with bilateral "threshold" disease (i.e., 5 or more contiguous clock hours of stage 3 "plus" disease, or 8 or more clock hours of noncontiguous disease) to receive cryotherapy in one eye, and the fellow eye served as a control. For those babies with threshold ROP in one eye as the worst ROP, that eye was randomly assigned to undergo cryotherapy or not. During the study, approximately 15% of all babies born in the United States with birthweights of less than 1251 g were enrolled. Results documented a beneficial effect on both visual function and structure in eyes assigned to receive cryotherapy (Cryotherapy for Retinopathy of Prematurity Cooperative Group, 1988a, 1988b), a benefit that persisted through the last study examination at age 15 years (Cryotherapy for Retinopathy of Prematurity Cooperative Group, 1990b, 1990c, 1993, 1996, 2001; Palmer et al, 2005).

Still, almost half of eyes treated with cryotherapy had a visual acuity of worse than 20/200 at age 15 years (Palmer et al, 2005), and earlier intervention was considered in the multicenter Early Treatment for ROP trial (ETROP)

(Early Treatment for Retinopathy of Prematurity Cooperative, 2003). A risk model was based on the results of the CRYO-ROP study to determine which eyes were "high risk" for developing a poor outcome (Hardy et al, 2003). The model included not only the ROP status of the eye but also demographic characteristics and pace of ROP development. The ETROP was a randomized, controlled clinical trial with eyes that were determined to be at high risk for poor outcome assigned either to receive retinal ablative therapy at the diagnosis of high-risk retinopathy or to be followed and treated if the eye developed classic "threshold" ROP. A beneficial effect in both visual acuity and retinal structure was documented in high-risk eyes that underwent peripheral retinal ablation at the diagnosis of high risk compared to the cohort of eyes that were treated at "threshold" ROP if it developed (Early Treatment for Retinopathy of Prematurity Cooperative, 2003).

In the ETROP study, laser photocoagulation was more likely to be used than cryotherapy because of the advantages of using laser, including less discomfort intraoperatively and postoperatively, less pigmentation resulting from the therapy, and direct visualization of the area during treatment (Foroozan et al, 2001; McNamara, 1993; Tasman, 1995).

Follow-up studies of vitreoretinal surgical treatment for advanced disease (i.e., stages 4 and 5) have shown mixed results that very likely depend on whether the detachment is total and/or long-standing (Andrews et al, 1999; Hirose et al, 1993; Jabbour et al, 1987; Trese, 1994;). For eyes with total detachment, it appears that although surgery may give good anatomic results, good functional outcome is not likely to be achieved (Hirose et al, 1993; Quinn et al, 1991, 1996).

There has been a recent and serious interest in the use of anti–vascular endothelial growth factor (VEGF) drugs, with good results reported in babies with ROP (Mintz-Hittner and Best, 2009; Mintz-Hittner and Kuffel, 2008; Quiroz-Mercado et al, 2008). However, clinical trials must be undertaken before this modality is used in babies in whom vasculogenesis is incomplete not only in the eye but in other organs. Long-term systemic effects must be monitored in these children (Darlow et al, 2009).

COMMON OPHTHALMIC MANIFESTATIONS OF SYSTEMIC DISEASES

See Tables 102-3 through 102-5.

Role of the Neonatologist and Pediatrician

Neonatal health care providers clearly play a central role in the ophthalmologic care of the newborn and young infant. The first few weeks of life constitute a critical period of visual development in the brain, and the opportunity and responsibility to screen for ocular disease rests in the hands of the neonatologist and primary medical provider, whether pediatrician, family physician, or nurse practitioner. Using the I-ARM (Inspection, Acuity, Red Reflex, Motility) framework described previously as a guide, referral to a pediatric ophthalmologist should be made for any abnormality or asymmetry in an atomic structure or visual function. Some conditions require particularly urgent referral, such as an abnormal red reflex, cloudy cornea, and ocular infection or trauma. Identification of a sight-threatening cataract or life-threatening retinoblastoma is most commonly made by an astute pediatric clinician in the NICU, nursery, or primary care office who carefully evaluates the red reflex in both eyes. In the case of neonatal conjunctivitis, diagnostic cultures and treatment should be undertaken without delay, but ophthalmology consultation is still necessary to rule out intraocular involvement. Premature infants at risk for ROP represent a particularly vulnerable population. It is the neonatologist's clinical and medicolegal responsibility to arrange timely diagnostic ROP examinations in the NICU and to communicate to parents the absolute necessity of keeping ophthalmologist outpatient appointments after the infant is discharged from the hospital. Such appointments should be scheduled before discharge. A delay in care by even a week could result in a visually disastrous outcome. ROP examinations should be performed by an ophthalmologist with experience in ROP.

The neonatal health and primary care pediatric health teams should provide ongoing eye-related education and support. Reducing the risk of pediatric abusive head trauma is one important topic to be discussed with all parents and caregivers. Viewing of educational videos on shaken baby syndrome is mandatory in an increasing number of municipalities, and reductions in AHT incidence have been demonstrated. Pediatricians should discuss crying and parental stress at office visits during the first few months of life; the Period of PURPLE Crying educational materials (see Additional Resources, later) are very useful in this regard. Pediatricians can also provide support for the families of children with visual impairment, ensuring early, anticipatory referral to state commissions for the blind and early intervention services, and ongoing encouragement for parents to maximally utilize such resources when available.

Rapid visual development occurs in the months following the neonatal period. Primary care eye examinations and vision assessments continue to be vital for the detection of conditions that may result in visual impairment or blindness, lead to problems with school or social performance, signal the presence of a serious systemic disease, or threaten the child's life (American Academy of Pediatrics, 2003). Children should have an eye examination at each well-child visit. Children at high risk for eye disease should be referred for examination by a pediatric ophthalmologist, including children with a history of prematurity or metabolic or genetic diseases; significant developmental delay or neurologic problems; systemic diseases associated with eye abnormalities; a family history positive for retinoblastoma, childhood cataracts or glaucoma, inherited retinal disorders, or blindness in childhood; and those whose parents needed glasses at a very young age.

Additional Resources

In addition to texts, clinical guidebooks, and online medical literature search engines (such as www.pubmed.org), the following Web-based resources can provide useful information related to newborn eye disease.

Website of the American Academy of Pediatrics, for policy statements on eye-related topics and other

TABLE 102-3 Ophthalmic Manifestations of Systemic Diseases With Neonatal Findings

Etiologic Disorder	Inheritance	Ophthalmic Manifestations
Aicardi's syndrome	X-linked dominant disorder characterized by triad of callosal agenesis, infantile spasms, and chorioretinal lacunae OMIM #304050	Bilateral or unilateral, multiple, chorioretinal lacunae (most constant feature), optic disk/retinal/iris colobomas, optic nerve head hypoplasia, microphthalmos, retinal detachment (Aicardi, 2005)
Alagille syndrome (ALGS 1 and 2)	Autosomal dominant disorders characterized by neonatal jaundice secondary to hepatic cholestasis OMIM #118450 and OMIM #610205	Posterior embryotoxon, optic disk drusen, and retinal pigmentary changes sometimes in associations with rod-cone dystrophy
Albinism	Heterogenous disorder of melanin metabolism associated with abnormal development of the retina and visual pathways Ocular forms: OA1 (X-linked) Oculocutaneous forms: OCA1-4, ADOC, Hermansky-Pudlak and Chediak-Higashi syndromes (autosomal recessive, autosomal dominant) More than 13 genes involved	Reduced vision, delayed visual maturation, nystagmus, strabismus, iris transillumination, fundus hypopigmentation, foveal hypoplasia, misrouting of optic nerve fibers, anomalous optic chiasm
CHARGE syndrome (*c*oloboma, *h*eart defect, *a*tresia choane, *r*etarded growth, *g*enital hypoplasia, and *e*ar anomalies)	Nonrandom cluster of congenital abnormalities Mutation of CHD7 on 8q12.1 (Vissers et al, 2004; Jongmans et al, 2006) OMIM #214800	Unilateral or bilateral uveal colobomas (retinal more frequent than iris), microphthalmos, Bell's palsy
Chromosome 22q11.2 deletion syndrome	Contiguous gene deletion syndrome (encompasses DiGeorge syndrome, velocardiofacial syndrome, conotruncal-anomaly-face syndromes) Autosomal dominant	Posterior embryotoxon, tortuous retinal vessels, eyelid hooding, strabismus, ptosis, sclerocornea (Binenbaum et al, 2008; Forbes et al, 2007)
Down syndrome	Trisomy 21 OMIM #19605	NLDO, refractive errors, nystagmus, strabismus, retinal abnormalities, keratoconus, cataracts (Creavin and Brown, 2009)
de Morsier's syndrome (septo-optic dysplasia)	Heterogeneous disorder defined by the combination of optic nerve hypoplasia, pituitary dysfunction, and midline abnormalities of the brain (absence of the corpus callosum and septum pellucidum) OMIM #182230	Optic nerve hypoplasia (unilateral or bilateral), strabismus, nystagmus, optic chiasm hypoplasia. Severe cases may have microphthalmos or anophthalmos
Galactosemia (classic)	Metabolic disorder due to mutation in the galactose-1-phosphate uridyltransferase gene OMIM#230400	Congenital cataracts ("oil-droplet cataracts")
Goldenhar's syndrome (oculo-auriculovertebral dysplasia, hemifacial microsomia)	Craniofacial birth defect involving first and second branchial arch derivatives OMIM #164210	Epibulbar dermoid (unilateral or bilateral), coloboma of the upper lid, ptosis, strabismus, microphthalmos, nasolacrimal duct obstructions
Homocystinuria	Autosomal recessive metabolic disorder due to cystathionine beta-synthetase deficiency OMIM #236200	Progressive ectopia lentis (lens subluxation), pupil block glaucoma, progressive myopia, optic atrophy, retinal detachment (Harrison et al, 1998)
Kabuki syndrome	Congenital mental retardation syndrome OMIM #147920	Long palpebral fissures with eversion of the lateral third of the lower eyelids, ptosis, strabismus
Möbius sequence	Sporadic disorder characterized by congenital facial weakness and abduction deficits OMIM #157900	Abnormal tearing, esotropia with limited abduction (unilateral or bilateral), horizontal gaze palsy, other CN palsies (III, IV,V), ptosis
Myasthenic syndromes (congenital and neonatal myasthenia gravis)	Neuromuscular disorders. The congenital form is a nonautoimmune autosomal dominant disorder. The neonatal form is secondary to maternal antibodies.	Bilateral ptosis, strabismus, limited ocular motility
Incontinentia pigmenti (Bloch-Sulzberger syndrome)	X-linked dominant disorder with characteristic skin lesions OMIM #308300	Strabismus, nystagmus, cataracts, optic atrophy, corneal abnormalities, retinovascular abnormalities (may resemble ROP), retinal detachment
PHACES syndrome (*p*osterior fossa brain malformations, *h*emangiomas of the face, *a*rterial cerebrovascular anomalies, *c*ardiovascular anomalies, *e*ye anomalies, *s*ternal defects)	Heterogeneous associations that occur in patients with large segmental cervicofacial hemangiomas OMIM #606519	Microphthalmos, Horner's syndrome, retinal vascular abnormalities, optic nerve atrophy, iris hypoplasia, cataracts, sclerocornea, lens coloboma, strabismus, choroidal hemangiomas, congenital 3rd nerve palsy, morning glory deformity, and glaucoma (Coats et al, 1999; Hartemink et al, 2009)
Stickler's syndrome (hereditary arthro-ophthalmopathy) (STL1 and 2)	Autosomal dominant disorder of collagen synthesis OMIM #108300 and #604841	Congenital myopia, vitreous abnormalities, cataracts, retinal detachment
Trisomy 13 (Patau's syndrome)	Chromosomal abnormality most consistently associated with severe ocular defects	Anophthalmos, cyclopia, microphthalmos, uveal colobomas, cataracts, corneal opacities, retinal dysplasia, intraocular cartilage

Continued

TABLE 102-3 Ophthalmic Manifestations of Systemic Diseases With Neonatal Findings—cont'd

Etiologic Disorder	Inheritance	Ophthalmic Manifestations
Trisomy 18	Chromosomal abnormality with frequent ocular defects	Microphthalmos, short palpebral fissures, ptosis, hypertelorism, iris coloboma, corneal opacities, cataracts
Tuberous sclerosis	Autosomal dominant multisystem disease characterized by hamartomatous growths in multiple organs OMIM #191100, #605284	Retinal hamartomas, vitreous hemorrhage, chorioretinal punched-out lesions, papilledema, optic nerve atrophy, strabismus (Rowley et al, 2001)

TABLE 102-4 Eye Manifestations of Intrauterine and Perinatal Infections

Infection	Ophthalmic Findings		Diagnosis
Toxoplasmosis (*Toxoplasma gondii*)	Retinitis, vitritis, choroiditis and anterior uveitis; flat atrophic retinal scars	Present in 75% of newborns with toxoplasmosis, 10% have only ocular findings	Clinical ELISA Positive IgM assay (maternal IgM does not cross the placenta)
Syphilis (*Treponema pallidum*)	Chorioretinitis (salt-and-pepper appearance or pseudoretinitis pigmentosa), anterior uveitis, glaucoma, interstitial keratitis	Bilateral interstitial keratitis is the classic ophthalmic finding, it occurs in 10% of patients but manifests later in childhood or adulthood.	Positive VDRL, FTA-ABS tests
Rubella virus	Nuclear cataracts, glaucoma, uveitis, microphthalmos, retinopathy with "salt-and-pepper" appearance, pseudoretinitis pigmentosa	50% of children with rubella have ocular findings, bilateral 70% Severe postoperative inflammation after cataract surgery	
Cytomegalovirus	Retinochoroiditis, optic nerve atrophy, microphthalmos, cataracts, uveitis, strabismus (Coats et al, 2000)	Most common intrauterine viral infection in the United States Only 10% of infants show clinical features of CMV infection with ophthalmologic abnormalities in lessthan 30% of these	CMV IgM, urine culture, PCR detection of CMV DNA in blood
Herpesvirus (HSV 1 and 2, EBV)	Vesicular skin lesions, keratoconjunctivitis, retinochoroiditis, cataracts		Cultures from conjunctival or corneal swabs

CMV, cytomegalovirus; *EBV*, Epstein-Barr virus; *ELISA*, enzyme-linked immunosorbent assay; *FTA-ABS*, fluorescent treponemal antibody absorption; *HSV*, herpes simplex virus; *PCR*, polymerase chain reaction; *VDRL*, Venereal Disease Research Laboratory.

TABLE 102-5 Eye Findings after in Utero Exposure to Teratogens

Teratogen	Ophthalmic Manifestations
Alcohol (fetal alcohol syndrome)	Short palpebral fissures, microphthalmos, epicanthal folds, optic nerve head hypoplasia, tortuosity of retinal vasculature, strabismus, cataracts (Stromland and Hellstrom, 1996)
Cocaine	Optic nerve abnormalities, delayed visual maturation, ROP-like fundus abnormalities (Teske and Trese, 1987), prolonged eyelid edema (Good et al, 1992)
Anticonvulsants (fetal hydantoin syndrome)	Ptosis, trichomegaly, hypertelorism, strabismus, retinal coloboma, microphthalmos, optic nerve head hypoplasia
Warfarin	Optic atrophy, cataracts, microphthalmos
Thalidomide	Strabismus, Duane's syndrome, ptosis, paradoxic gustolacrimal tearing, Möbius sequence (Miller et al, 2009)
Misoprostol	Möbius sequence (Miller et al, 2009)

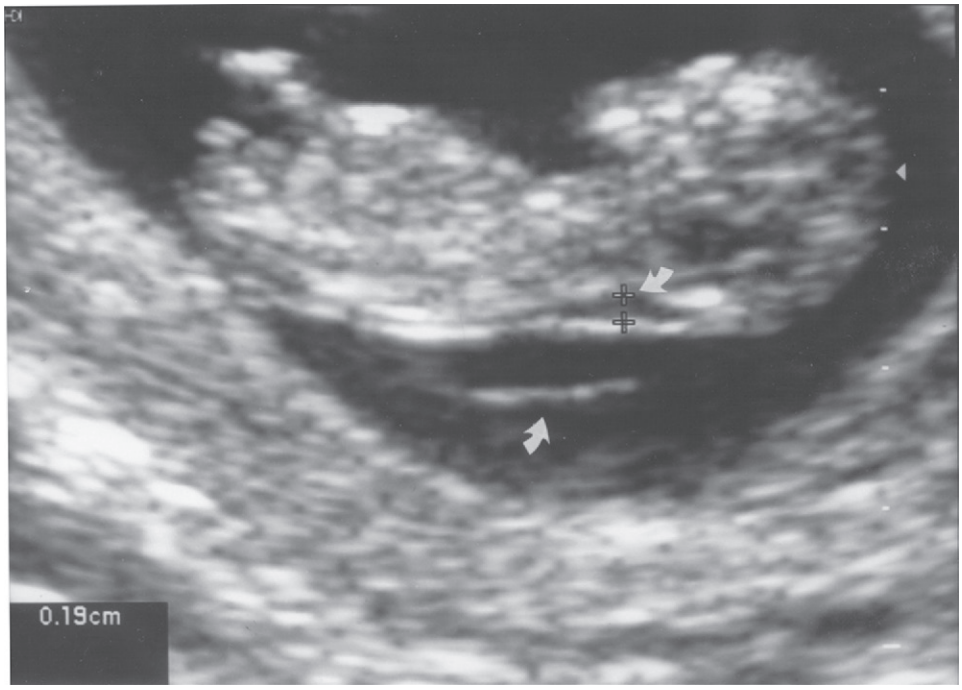
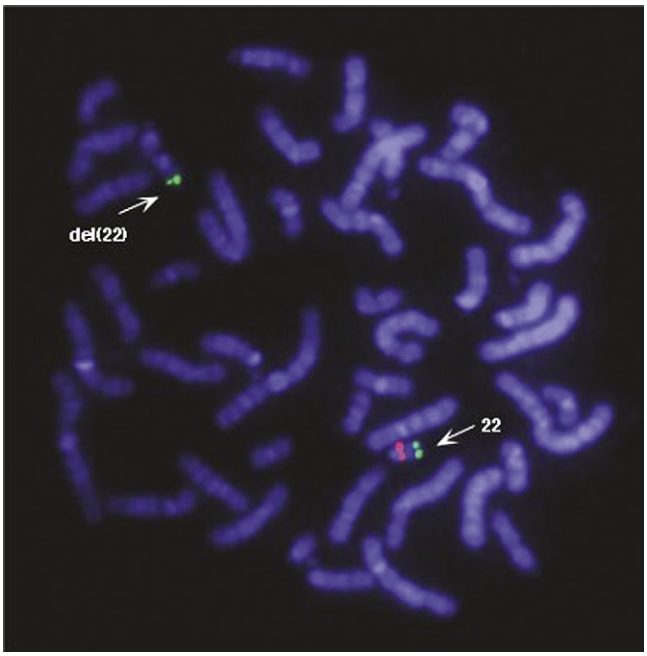
COLOR PLATE 1 *(See Chapter 5, p. 46.)* Angiogenic features of natural killer (NK) cells render them immune tolerant at the maternal-fetal interface. Vascular endothelial growth factor (VEGF) C-producing noncytotoxic uterine NK cell clones similar to decidual NK cells support endovascular activity in a coculture of endothelial cells (*red*) and first-trimester trophoblast HTR8 cells (*green*) on matrigel. By contrast, cytotoxic uterine NK cell clones similar to peripheral blood NK cells disrupted the endovascular activity because of endothelial and trophoblast cell lysis. This distinct functional feature determines whether optimal trophoblast invasion takes place and can result in normal or adverse pregnancy outcomes.

COLOR PLATE 2 *(See Chapter 15, p. 158.)* A 28-year-old woman was admitted to the labor and delivery department with an intrauterine demise. Examination of the fetus shows the cord wrapped tightly around the torso, leg, and ankle, suggesting cord accident as a cause of death. No other pathologic abnormalities were found on autopsy. *(Courtesy Thomas R. Easterling.)*



COLOR PLATE 3 *(See Chapter 18, p. 182.)* **Sagittal ultrasonographic image of a first-trimester fetus.** The nuchal translucency measurement is the distance between the two crosses. A measurement larger than normal standards for gestational age indicates that the fetus is at high risk for Down syndrome, congenital heart disease, or both. *(Courtesy Dr. Fergal Malone.)*



COLOR PLATE 4 *(See Chapter 20, p. 205.)* Fluorescence in situ hybridization study of a 22q deletion. *(Courtesy Beverly S. Emanuel.)*

COLOR PLATE 5 *(See Chapter 24, p. 262.)* **Osteogenesis imperfecta type II.** A 20-week fetus with limbs that are angulated and deformed from multiple fractures.

COLOR PLATE 6 *(See Chapter 24, p. 267.)* **Thanatophoric dysplasia.** Radiograph of an infant with thanatophoric dysplasia demonstrates a large calvarium, short ribs with anterior splaying, flat vertebral bodies (platyspondyly), and short bowed femurs with medial metaphyseal spike.

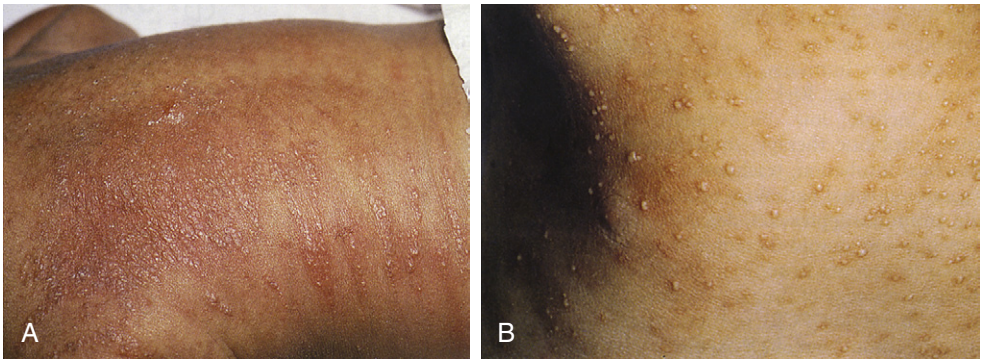
COLOR PLATE 7 *(See Chapter 24, p. 268.)* **Spondyloepiphyseal dysplasia congenita.** A 2-month-old infant demonstrating short neck, trunk, and limbs. Note the flat facial profile and normal size of hands and feet.

COLOR PLATE 8 *(See Chapter 24, p. 276.)* **Menkes syndrome.** Note blonde hair, fair complexion, and epicanthal folds in this 11-month-old Hispanic boy.

COLOR PLATE 9 *(See Chapter 25, p. 284.)* **Erythema toxicum neonatorum with erythematous macules, wheals, and pustules.** Pustules predominate in this example. At times, patchy or confluent areas of erythema occur without pustules. *(Reprinted from Eichenfield LF, et al, editors:* Neonatal dermatology, *Philadelphia, 2008, Saunders, p 88.)*

COLOR PLATE 10 *(See Chapter 25, p. 285.)* **Miliaria crystallina.** The tiny, clear vesicles resemble water droplets, with no signs of inflammation. *(Reprinted from Rudolph AJ:* Atlas of the newborn, *vol 4, Hamilton, Ontario, Canada, 1997, BC Decker, p 13.)*

COLOR PLATE 11 *(See Chapter 25, p. 285.)* **Neonatal cephalic pustulosis (neonatal acne).** Small red papules and pustules are seen on the cheeks and forehead, with some extension into the scalp. Comedones are absent. *(Reprinted from Eichenfield LF, et al, editors:* Neonatal dermatology, *Philadelphia, 2008, WB Saunders, p 90.)*



COLOR PLATE 12 *(See Chapter 25, p. 286.)* **Congenital candidiasis.** The rash may be a diffuse, erythematous pustular eruption **(A)** or have diffusely distributed but distinct pustules **(B)**. In premature infants, a diffuse scaldlike erythematous dermatitis may be seen (not shown). *(Reprinted from Eichenfield LF, et al, editors:* Neonatal dermatology, *Philadelphia, 2008, Saunders, p 214.)*

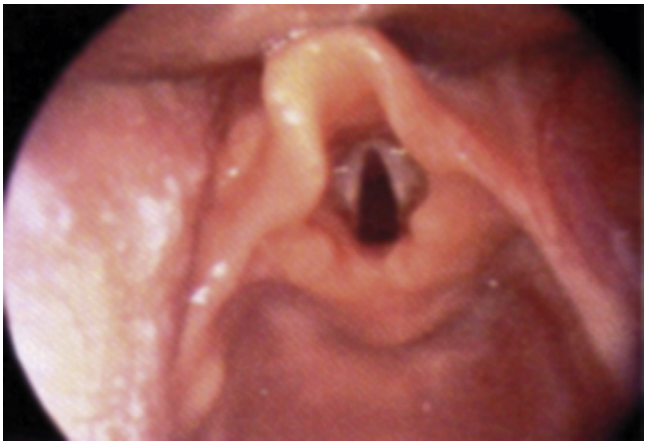
COLOR PLATE 13 *(See Chapter 25, p. 286.)* **Herpes simplex. A,** The first signs of herpes infection in this neonate were eroded vesicles at the corner of the mouth. **B,** Herpetic vesicles on the face, scalp, and ear of an infant with respiratory distress and hepatitis. *(Reprinted from Cohen B:* Pediatric dermatology, *ed 3, Philadelphia, 2005, Mosby, p 36.)*

COLOR PLATE 14 *(See Chapter 25, p. 286.)* Desquamation on the palms **(A)** and soles **(B)** of an infant with congenital syphilis. *(Reprinted from Rudolph AJ:* Atlas of the newborn, *vol 4, Hamilton, Ontario, Canada, 1997, BC Decker, p 108.)*

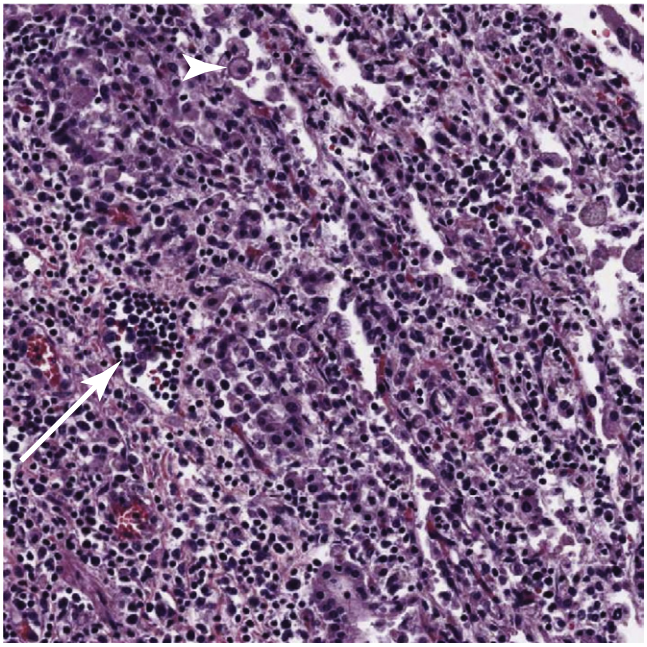
COLOR PLATE 15 *(See Chapter 25, p. 288.)* Salmon patches are commonly seen on the glabella, eyelids, nose, or upper lip, either singly or in all these locations **(A)**, and on the nape of the neck (**B)**. *(Reprinted from Eichenfield LF, et al, editors:* Neonatal dermatology, *Philadelphia, 2008, Saunders, p. 95.)*

COLOR PLATE 16 *(See Chapter 25, p. 289.)* Posterior view of a large cephalohematoma under the periosteum of the right parietal bone. *(Reprinted from Fletcher MA:* Physical diagnosis in neonatology, *Philadelphia, 1998, Lippincott-Raven, p 185.)*

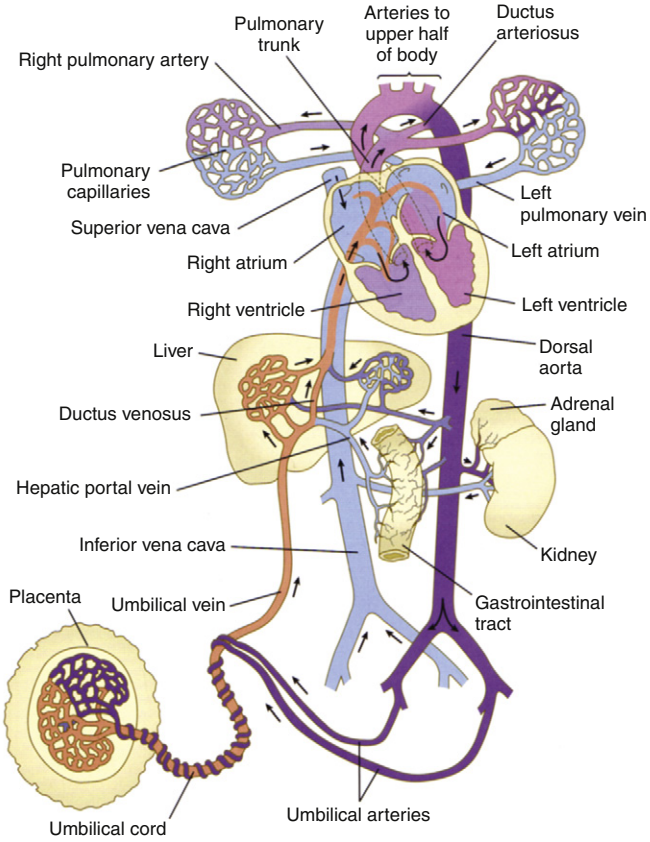
COLOR PLATE 17 *(See Chapter 25, p. 299.)* **Unilateral facial weakness.** There are obvious asymmetries of the grimace and eye closing during crying; the weakness is shown on the right side here. *(Reprinted from Fletcher MA:* Physical diagnosis in neonatology, *Philadelphia, 1998, Lippincott-Raven, p 457.)*



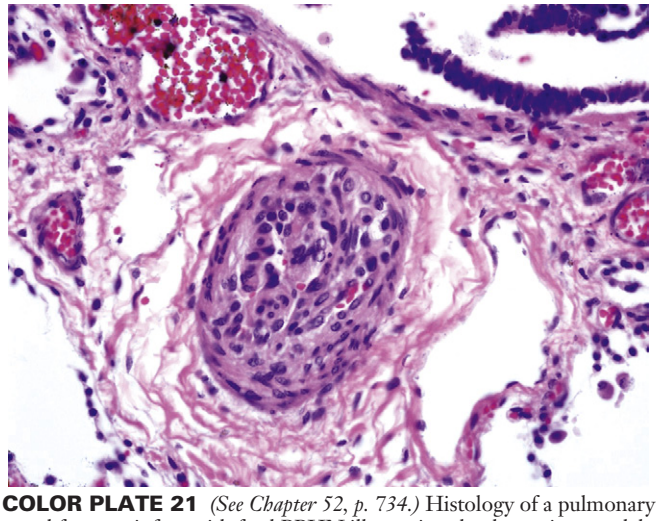
COLOR PLATE 18 *(See Chapter 28, p. 336.)* View of the glottis and vocal cords as the laryngoscope is gently lifted. *(From American Heart Association, American Academy of Pediatrics: Kattwinkel J, editor:* Neonatal resuscitation textbook, *ed 5, Elk Grove Village, Ill, 2006, American Academy of Pediatrics.)*



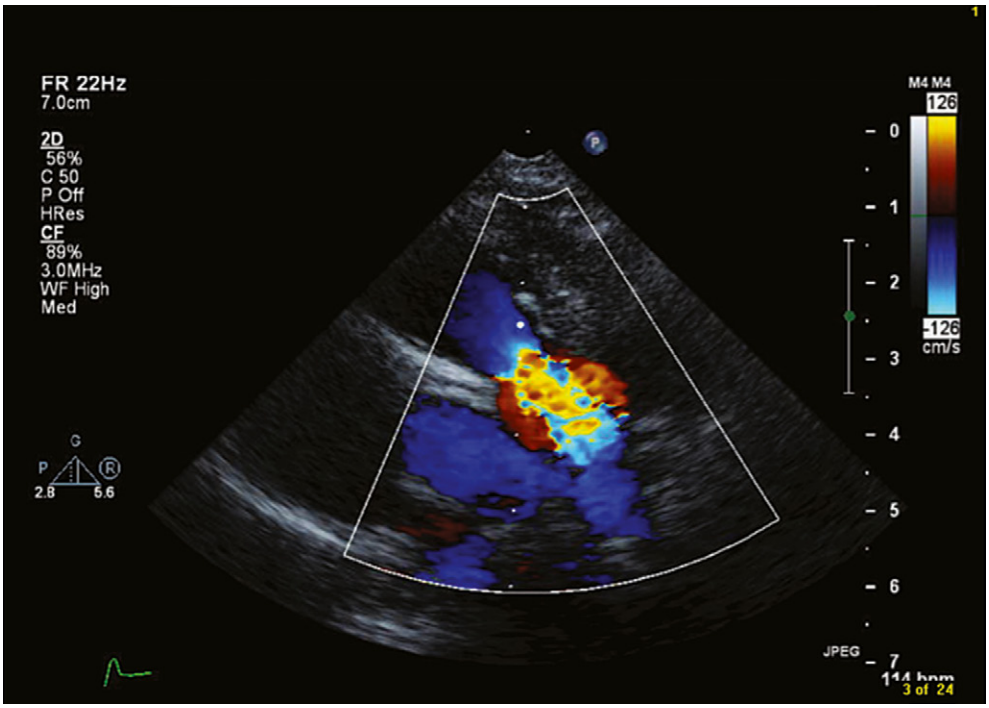
COLOR PLATE 19 *(See Chapter 37, p. 503.)* Postmortem histology from infant who expired from disseminated adenovirus infection at 2 weeks of age. H & E stain of lung demonstrating inflammatory infiltrates (*arrow*) and intranuclear inclusions (*arrowhead*). This infant had a viral sepsis syndrome characterized by hepatic failure, DIC, and pneumonitis from adenovirus infection, presumed to have been acquired intrapartum.



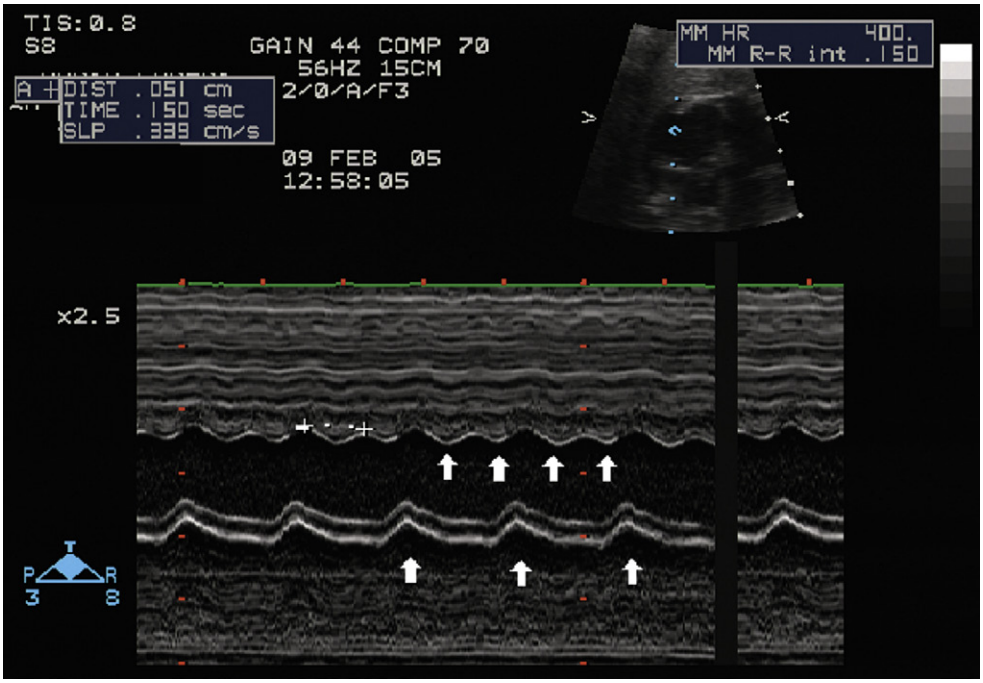
COLOR PLATE 20 *(See Chapter 50, p. 712.)* **The fetal circulation at term.** The path of oxygenated blood returning from the placenta is shown in orange. It mixes with deoxygenated blood returning from the fetal systemic veins shown in light blue. There is intracardiac mixing of blood as shown. The upper body receives higher oxygen content than the lower body, as deoxygenated blood enters the descending aorta via right-to-left flow at the ductus arteriosus. *(From Carlson BM:* Human embryology and developmental biology, *ed 4, Philadelphia, 2009, Mosby, p 466.)*



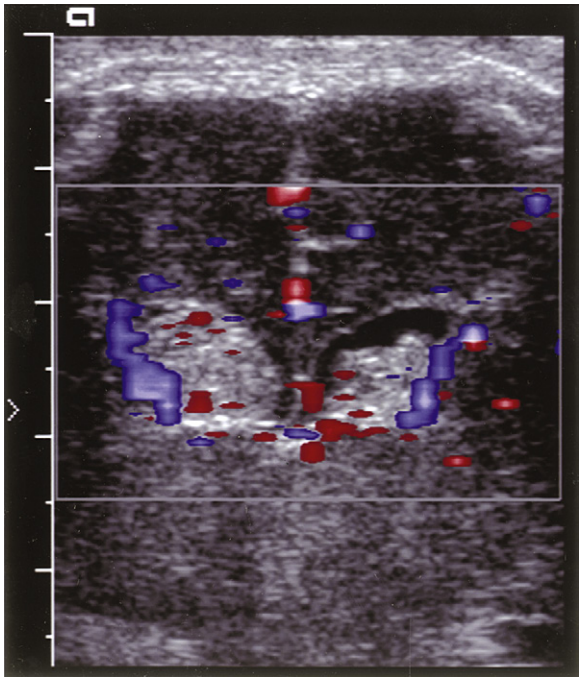
COLOR PLATE 21 *(See Chapter 52, p. 734.)* Histology of a pulmonary vessel from an infant with fatal PPHN illustrating the dramatic remodeling that can be associated with severe PPHN.



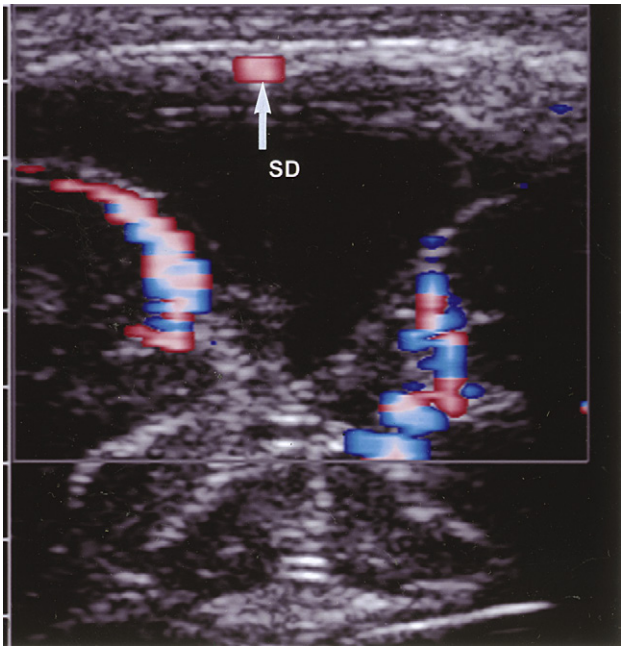
COLOR PLATE 22 *(See Chapter 55, p. 771.)* **Pulmonic stenosis.** Using color Doppler imaging, turbulence in the main pulmonary artery is seen above the pulmonic valve.



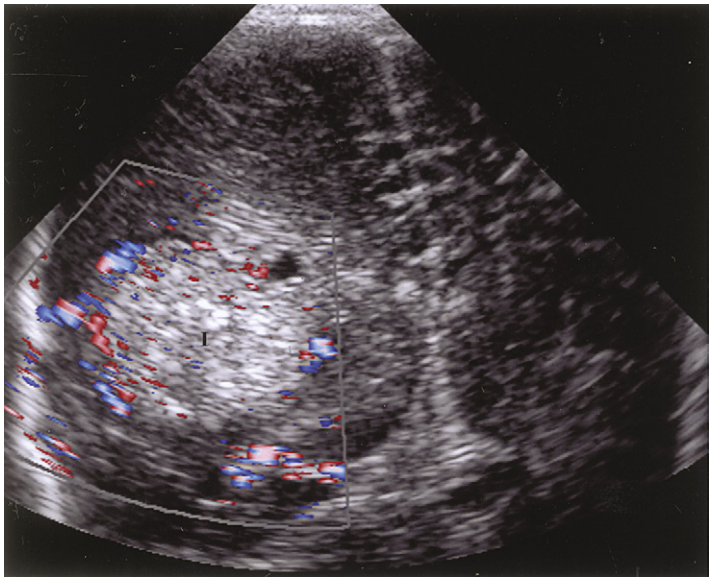
COLOR PLATE 23 *(See Chapter 56, p. 797.)* **Fetal m-mode echocardiogram recording of a late second-trimester fetus with atrial flutter.** The ultrasound cursor is positioned through the right atrium, tricuspid valve, and the right ventricle (*upper right corner*). The top row of four arrows delineates the mechanical right atrial contraction rate, which is faster than the tricuspid valve/right ventricle contraction rate (*bottom three arrows*).



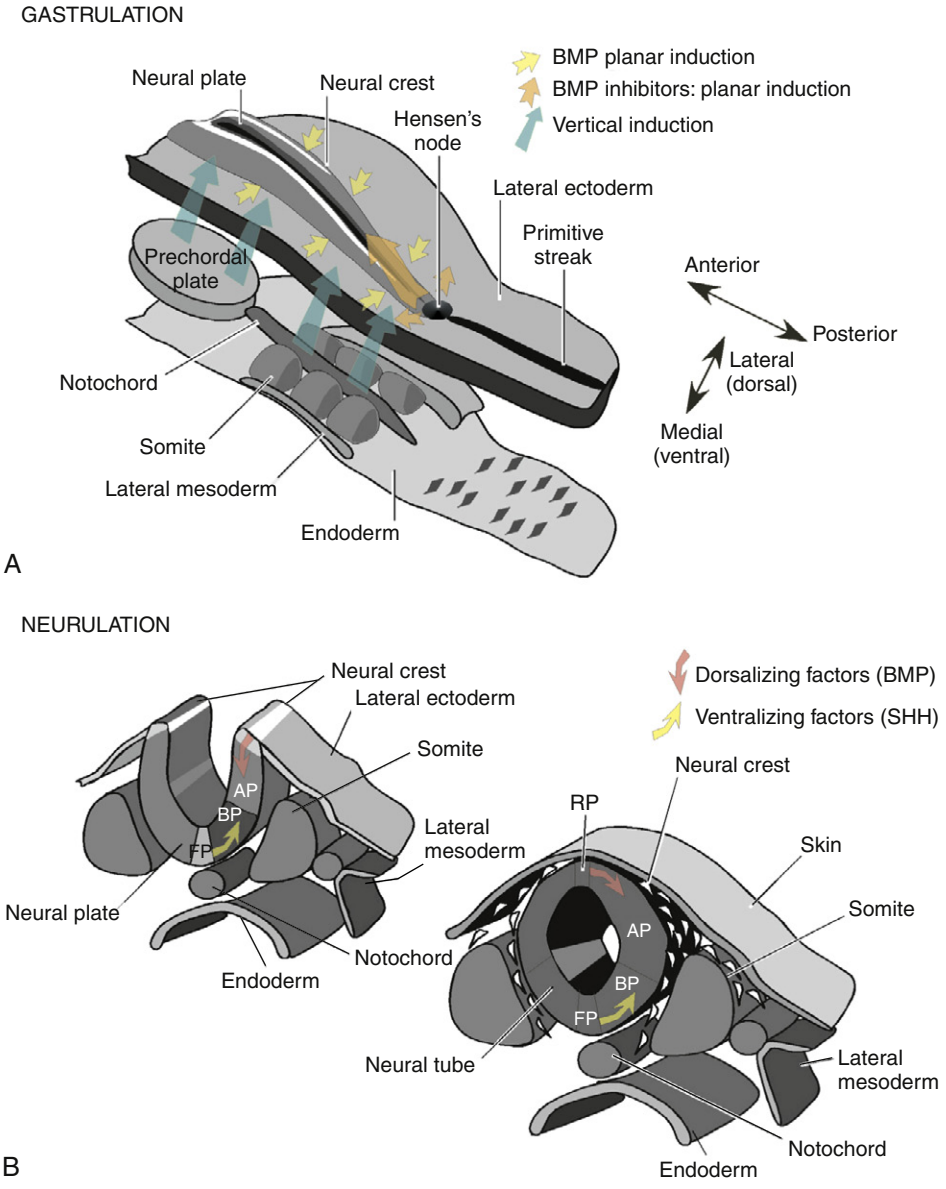
COLOR PLATE 24 *(See Chapter 59, p. 828.)* **Coronal color Doppler image of bilateral grade I germinal matrix hemorrhages.** The hemorrhages are echogenic. Although flow is confirmed within the terminal veins (*blue*), the veins are laterally displaced by the subependymal hemorrhages.



COLOR PLATE 25 *(See Chapter 59, p. 830.)* Coronal color Doppler ultrasound study shows that the vessels (color) are displaced toward the brain parenchyma by the subdural fluid (SD). Note flow in the superior sagittal sinus (*arrow*).

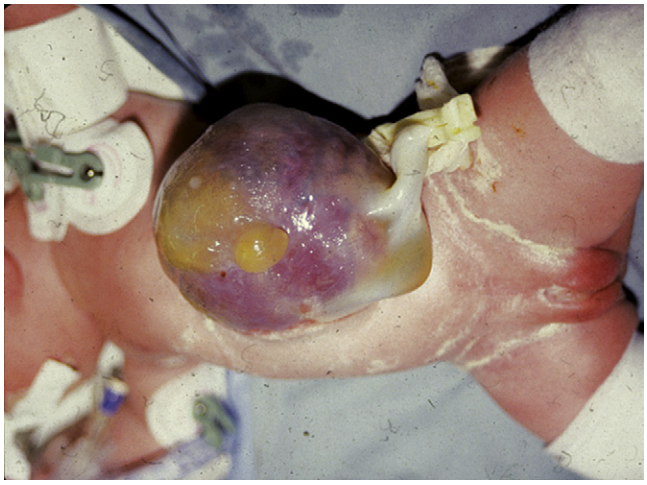


COLOR PLATE 26 *(See Chapter 59, p. 832.)* **The patient was a neonate with a focal right occipital infarction with surrounding "luxury perfusion."** A coronal ultrasound image obtained through the anterior fontanel shows a hyperechoic right occipital infarction (I) surrounded by increased flow on color Doppler examination.

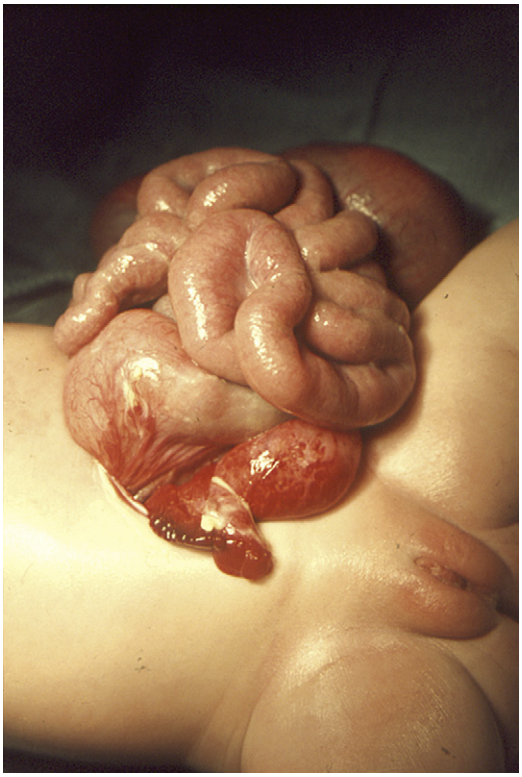


COLOR PLATE 27 *(See Chapter 60, p. 846.)* **Formation of the neural tube. A,** During gastrulation, at the neural plate stage, dorsoventral polarity and early anteroposterior regionalization is defined by a process of vertical induction by fibroblast growth factor-8 (FGF-8) and other factors (*long gray arrows*) derived from mesendoderm (notochord and prechordal plate). Planar induction occurs via BMPs and BMP inhibitors that are derived from lateral ectoderm (*short light gray arrows*) and Hensen's node (*short dark gray arrows*), respectively. **B**, The process of neurulation proceeds with the approximation of the neural folds toward the dorsal midline. Before closure of the neural tube, neural crest cells delaminate and migrate from the neural folds. Dorsalizing factors (BMPs; *dark gray arrow*) derived from the dorsal midline roofplate (RP) and ventralizing factors (SHH; *light gray arrow*) from the floor plate (FP) establish dorsal-ventral gradients of these key signaling molecules that induce formation of the alar plate (AP) and the basal plate (BP) from the lateral wall of the neural tube. *(From: Vieira C, Pombero A, Garcia-Lopez R, et al: Molecular mechanisms controlling brain development: an overview of neuroepithelial secondary organizers, Int J Dev Biol 54:7-20, 2010; courtesy Dr. Salvador Martinez, Institute of Neuroscience, Universidad Miguel Hernandez, San Juan de Alicante, Spain.)*

COLOR PLATE 28 *(See Chapter 69, p. 980.)* **Cystic hygroma of the face and neck.** Prenatal diagnosis of this large lesion led to the delivery of this infant using EXIT. *(From American Medical Association:* Archives of pediatrics and adolescent medicine, *155:1271–1272, 2001. All rights reserved.)*



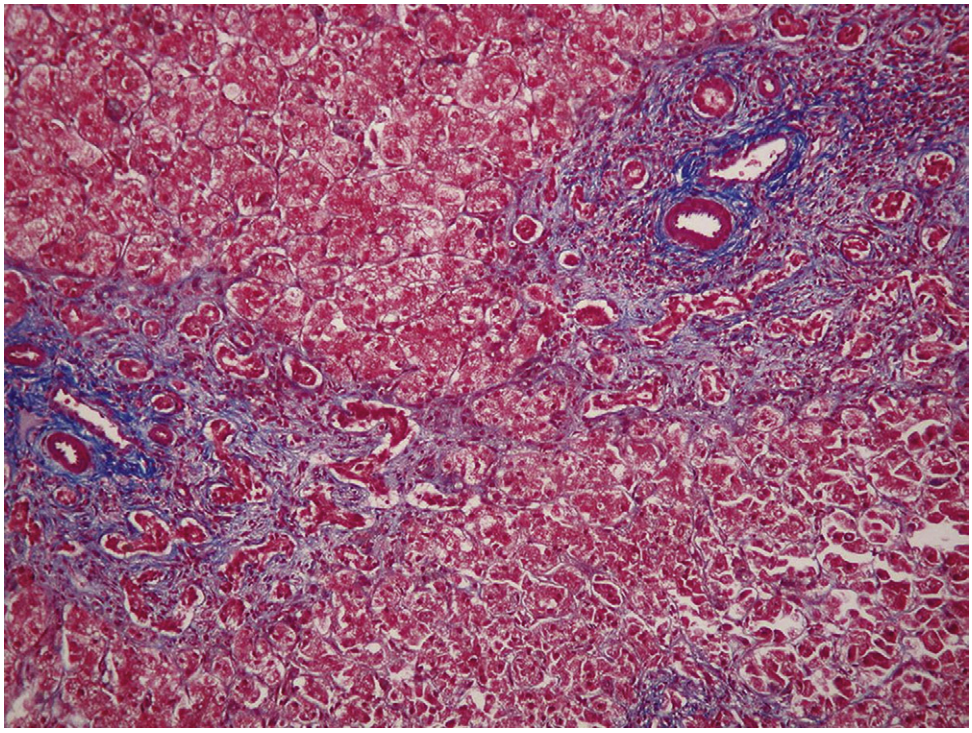
COLOR PLATE 29 *(See Chapter 71, p. 1008.)* **Female newborn with omphalocele.** The fascial defect is large, situated at the base of the umbilical cord, covered by a glistening membrane, and contains both liver and bowel.



COLOR PLATE 30 *(See Chapter 71, p. 1010.)* **Female newborn with gastroschisis.** The fascial defect is relatively small, situated to the right of the umbilical cord, and contains exposed bowel (as well as an ovary in this instance).

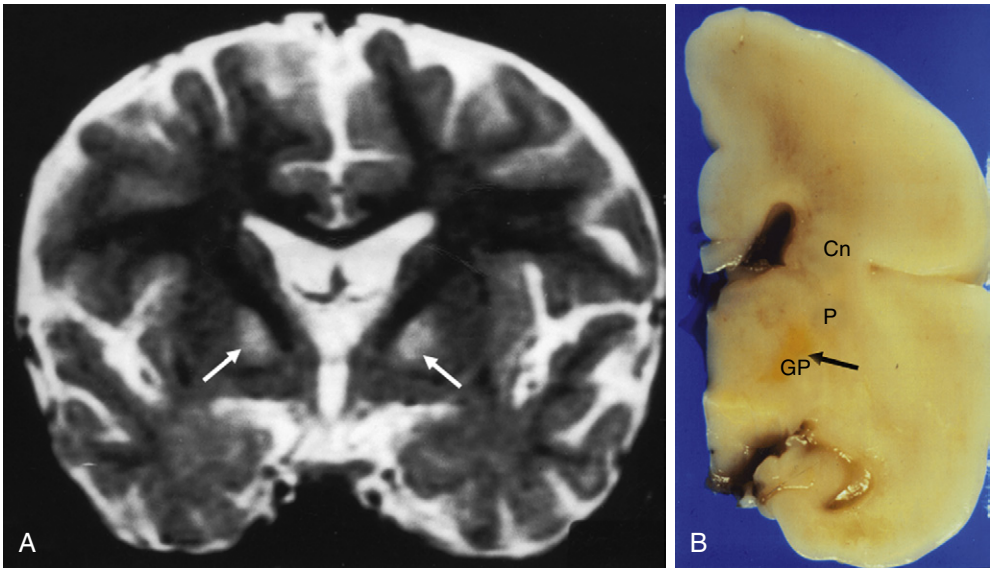
COLOR PLATE 31 *(See Chapter 71, p. 1011.)* **Newborn with prune belly syndrome.** The laxity of the abdominal wall musculature is obvious.

COLOR PLATE 32 *(See Chapter 71, p. 1012.)* **Bilateral infantile hydroceles.** The scrotum is distended by fluid, while the inguinal canals are normal.



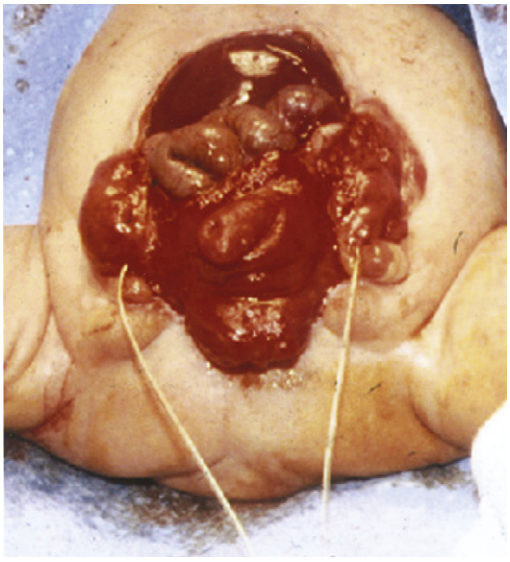
COLOR PLATE 33 *(See Chapter 74, p. 1035.)* **Liver biopsy from an infant with biliary atresia.** Trichrome stain demonstrates portal tract fibrosis.

COLOR PLATE 34 *(See Chapter 76, p. 1078.)* Arterial thrombosis with skin necrosis.

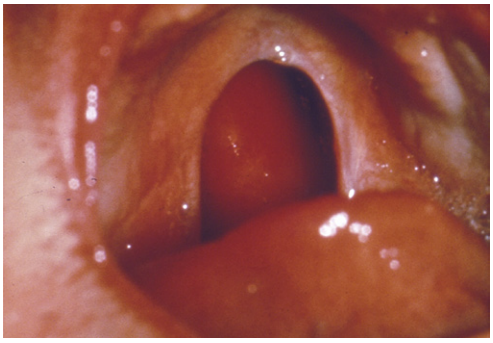


COLOR PLATE 35 *(See Chapter 79, p. 1135.)* **A,** Coronal T1-weighted magnetic resonance image at the level of the basal ganglia in one infant is shown on the left, demonstrating bilateral, symmetric high-intensity globus pallidus *(GP)* signals *(arrows)*. **B,** Deep orange-yellow staining of the globus pallidus (GP) of the coronal section at postmortem in another neonate. Note unstained putamen *(P)* and caudate nucleus *(Cn)*. These findings illustrate the selective vulnerability and regional nature of kernicterus and concordancy of neuroimaging and neuropathology in this disorder. (**A,** *Reprinted with permission from Coskun A, Yikilmaz A, Kumandas S, et al: Hyperintense globus pallidus on T1-weighted MR imaging in acute kernicterus: is it common or rare?* Eur Radiol *15:1263-1267, 2005;* **B,** *reprinted with permission from* Monographs in Clinical Pediatrics *11:78, 2000. Available at www.tandf.co.uk.)*

COLOR PLATE 36 *(See Chapter 84, p. 1197.)* The classic wrinkled abdominal wall seen in the prune-belly syndrome is accompanied by bilateral undescended testes.



COLOR PLATE 37 *(See Chapter 84, p. 1198.)* **Dramatic appearance of cloacal exstrophy.** In cloacal exstrophy, the bladder halves are separated by the presence of a large cecal plate and a protruding ileal stump. In this intraoperative photograph, the omphalocele has been removed to expose the small bowel and liver.



COLOR PLATE 38 *(See Chapter 95, p. 1332.)* U-shaped cleft palate.

COLOR PLATE 39 *(See Chapter 95, p. 1344.)* A child with an epibulbar lipodermoid and craniofacial microsomia.

COLOR PLATE 40 *(See Chapter 95, p. 1348.)* A premature newborn with Beckwith-Wiedemann syndrome, macroglossia, and rectus diastasis.

INDEX

A

Aarskog syndrome, cleft lip and/or palate with, 1336t–1337t
ABCA3 gene, in neonatal lung disease, 735
Abdomen
  assessment of, 294–295, 294f
  examination of, for dysmorphology, 189–190
Abdominal mass, postnatal evaluation of, 1178
Abdominal wall defects, 1007–1012. *See also specific defect.*
  transport of neonate with, 355
Abnormal ductus venosus blood flow, prenatal screening for, 182–183
ABO blood group incompatibility, 311, 1126
  hemolytic anemia due to, 1091, 1091t
  hemolytic disease related to, 1131–1132
Abrasion, corneal, 1431
Abruptio placentae, 1086–1087
Abscess, *Citrobacter*, neonatal
  neuroimaging of, 838, 840f
Absent nasal bone, 182
Absorption of drugs, 417–418
Abuse, substance. *See* Substance abuse; *specific substance.*
Abusive head trauma (AHT), 1431–1433
  visual impairment in, 1433
Acetaminophen
  for circumcision, 437
  for pain and stress, 438
Achondrogenesis
  type IB, 270, 271f
    features of, 259t–261t
  type II–hypochondrogenesis, 268–269, 269f
    features of, 259t–261t
Achondroplasia
  differential diagnosis of, 266
  etiology of, 266
  features of, 259t–261t
  inheritance of, 266
  management of, 266
  presentation of, 264, 265f
  radiologic features of, 264–265, 265f
Acid-base balance, 383–389
  disturbances of, 384–389. *See also* Metabolic acidosis; Metabolic alkalosis; Respiratory acidosis; Respiratory alkalosis.
Acid-base balance *(Continued)*
    general principles in, 384–385, 385f, 385t
    simple, 384
    transitional, after birth, 385
  regulation of, 383–384, 1172
Acidemia
  glutaric, type2, 230–231
  isovaleric, 228–229
  methylmalonic, 226–228
  propionic, 228
Acidosis
  lactic
    early lethal, 238
    primary, 234–238
  metabolic. *See* Metabolic acidosis
  renal tubular. *See* Renal tubular acidosis
Aciduria, glutaric, type II, 1190
Acne, 1399–1400, 1400f
  neonatal, 285, 285f
Acquired immunodeficiency syndrome (AIDS). *See* HIV/AIDS.
Acuity, 1424
Acute kidney injury (AKI), 1205–1215
  AKIN classification of, 1205
  causes of, 1208b
  chronic kidney disease due to, 1215
  definition of, 1205–1206, 1206f, 1206t
  epidemiology of, 1206–1208
  evaluation of, 1210–1211, 1210t
  in neonatal population, 1207
  intrinsic, 1208
    vs. prerenal azotemia, 1210t
  ischemic, 1208–1209, 1209f
  management of, 1211–1214, 1213t
    dialysis in, 1213–1214
    hemodialysis in, 1214
    peritoneal dialysis in, 1214
  nephrotoxic, 1209–1210
  obstructive, 1210
  pathophysiology of, 1208–1210, 1208b, 1209f
  RIFLE classification of, 1205
Acute Kidney Injury Network (AKIN) classification, of acute kidney injury, 1205
Acute phase reactants, in bacterial sepsis, 544–546
Acyclovir
  for conjunctivitis, 1429t
  for HSV infection, 473, 474t, 1396
  for VZV infection, 474t, 477
  nephrotoxic effects of, 1210
Acylcarnitine translocase deficiency, 233
Acyl-CoA dehydrogenase deficiency(ies), multiple, 1190
Adaptive immunity, 454–461
  B cells in, 457
  immunoglobulins in, 458–461, 458t, 459f, 460t. *See also* Immunoglobin *entries.*
  T cells in
    adaptive, 454–456, 454f–455f
    regulatory, 456–457
Adefovir, for hepatitis B, 474t
Adenosine, for supraventricular tachycardia, 794, 795f
Adenovirus infection, 503, 503f
Adhesives, application and removal of, in extremely-low-birth-weight infants, 395, 396t
Administration, of neonatal transport program, 345
Admission criteria, for late preterm infants, 414, 415b
Adolescence, function in, neurodevelopmental outcome and, 928
Adrenal crisis, management of, 1284–1285
  initial, 1284
  maintenance therapy in, 1284
  stress replacement therapy in, 1284–1285
Adrenal enzyme deficiency, steroidogenic defects caused by, 1277–1282
Adrenal gland(s), 1274–1277
  development of, 1250, 1250f
    abnormalities of, 1282–1284
    molecular basis for, 1276
  disorders of. *See also specific disorder.*
    primary, 1277–1285
    secondary and tertiary, 1283–1284
  embryology of, 1274
  function of
    assessment of, in neonate, 1276–1277
    fetal and adult, 1274–1276, 1275f
  glucocorticoid production and, control of, 1276
  mineralocorticoid production and, control of, 1276
  morphology of, 1274

Page numbers followed by *b*, indicate box; *f*, figure; *t*, table.

Adrenal hemorrhage, 1283
neonatal, 1238–1239
serum bilirubin levels and, 1132
Adrenal hyperplasia, congenital. *See* Congenital adrenal hyperplasia (CAH).
Adrenal hypoplasia congenita, 1282
Adrenal insufficiency
associated with syndromic disorders, 1282
bronchopulmonary dysplasia and, 664–665, 664f
developmental, 1283–1284
iatrogenic, 1283
primary, 1277–1285
management of, 1284–1285
secondary and tertiary, 1283–1284
management of, 1285
Adrenocortical steroidogenesis, 1296
Adrenocorticotropic hormone (ACTH), adrenal gland and, 1276
Adrenocorticotropic hormone (ACTH) stimulation test, for ambiguous genitalia, 1291–1292
Adrenoleukodystrophy, neonatal, 253t, 254, 1281
Adulthood, function in, neurodevelopmental outcome and, 928
Afferents, in cold response, 357–358
African Americans, perinatal outcome among, 5t
Afterload
increases in, 716–717
ventricular, 714–715
Aglossia congenita, 979
Aicardi's syndrome, ophthalmic manifestations of, 1436t–1437t
Air leaks, respiratory distress syndrome causing, 639
Air transport, of neonates, 343. *See also* Neonatal transport medicine.
Airway(s)
anomalies of, 672–677. *See also specific anomaly*.
complications of, with mechanical ventilation, 631
composition of, 572–574
development of, 571–572
in achondrodysplasia, 266
maintenance of, in delivery room resuscitation, 332–334
maternal, during pregnancy, 160
obstruction of, complicating resuscitation, 339
resistance of, 598
during positive pressure ventilation, 621, 622f
Airway compromise, in craniosynostosis syndromes, 1341t
Alagille syndrome, ophthalmic manifestations of, 1436t–1437t
Albinism
oculocutaneous, 1379–1380
ophthalmic manifestations of, 1436t–1437t
Albumin, 1309
production of, 1309–1310
Albuterol, for hyperkalemia, 379t
Alcohol
abuse of, during pregnancy, 6, 54, 112, 113t. *See also* Fetal alcohol syndrome.
complications associated with, 113–114
for hand hygiene, 561, 561t
in utero exposure to, ophthalmic manifestations of, 1438t
pharmacology and biologic actions of, 113
Alcoholism, 113
Alignment, ocular, 1425
Alkalosis
metabolic, 388–389
cerebral blood flow and, 814–815
respiratory, 389
Allagille syndrome, 1037–1038
Allgrove syndrome, 1281
Alloimmune neonatal neutropenia, 1111
Alpha-dystroglycanopathies, 892–894
Alpha-fetoprotein (AFP), 180
maternal serum
anencephaly and, 848
for prenatal genetic diagnosis, 180, 181b
with omphalocele, 1009
Alpha-thalassemia, 1096–1097, 1097t, 1125
homozygous, 1097, 1097t
Alpha-thalassemia trait, 1097, 1097t, 1125
Altitude, effect of, on fetal growth, 53
Alveolar capillary dysplasia with misalignment of pulmonary vessels (ACD/MPV), 735
Alveolar hypoplasia, 659
Alveolar ventilation, 602–604, 603f
Alveolarization
in lung development, 578, 579f
late, 572
postnatal, 572
Alveolus(i)
collapse of, in respiratory distress syndrome, 623f, 635
epithelial development in, 573–574
Amantadine, for influenza A, 474t
Ambiguous genitalia. *See* Genitalia, ambiguous.
AmBisome, for systemic *Candida* infections, 567
Amblyopia, 1424
definition of, 1424
American Recovery and Reinvestment Act (2009), 10
American Society for Reproductive Medicine (ASRM) guidelines, 65
Amiloride, for congenital nephrogenic diabetes insipidus, 1227
Amines, biogenic, genetic mutations affecting, 587–588
Amino acid(s)
branched-chain, 221–222
requirements for, 223
commercial parenteral, composition of, 964t
Amino acid metabolism, inborn errors of, 215b, 221–226. *See also specific disorder*.
screening for, 317t, 321–322
Aminoglycosides, nephrotoxic effects of, 1210
Amiodarone, for supraventricular tachycardia
in fetus, 799
in neonate, 794–795
Amish infantile epilepsy, 250
Amlodipine, for neonatal hypertension, 1243t
Ammonia, production of, 384
Ammonia metabolism, inborn errors of, 215b, 219–221, 220f. *See also specific disorder*.
Amniocentesis, 183–184
fetal anemia screening with, 96
Amnion, 49
Amnion rupture sequence, cleft lip and/or palate with, 1336t–1337t
Amniotic fluid
assessment of, 137
composition of, 996b
role of, in gastrointestinal development, 994–995
sampling of, prenatal, 1176–1177
Amniotic fluid index (AFI), 137, 137f
Amoxicillin, prophylactic
for hydronephrosis, 1191
for urinary tract infections, 1229
Amphetamines
abuse of, during pregnancy, 112, 113t
complications associated with, 119
pharmacology and biologic action of, 119
Amphotericin B
for aspergillosis, 569
for *Candida* urinary tract infection, 566
for invasive fungal dermatitis, 568
for systemic *Candida* infections, 567
nephrotoxic effects of, 1209
Analgesia
definition of, 161
obstetric, 161–164
combined spinal-epidural, 166
dissociative, 163
epidural, 165–166, 165f
inhalation, 163
neonatal response to, 338–339

Analgesia *(Continued)*
neuraxial (regional), 163–164
contraindications and complications of, 167–168
techniques of, 164–168
nonpharmacologic, 161
paracervical block, 168
pudendal block, 168
spinal, 166
systemic medications for, 161
techniques of, 161, 161b
regional, definition of, 161
Analgesics, for pain and stress
nonopioid, 438
opioid, 438–439
long-term consequences of, 439–440
Anastomotic leak, after esophageal atresia/tracheoesophageal fistula repair, 982–983
Androgen(s), maternal, increased, virilization of female and, 1254, 1297
Androgen factory, 1274–1275
Androgen insensitivity, 1204, 1297–1299
complete, 1297–1298, 1298f
partial, 1298–1299
Anemia, 1082–1085
antiretroviral therapy–induced, 511
blood transfusions for, 1084–1085
hemolytic. *See* Hemolytic anemia.
hemorrhagic, 1085–1087, 1086t, 1107b
after delivery, 1087
fetal, 1086
placental blood loss and, 1086–1087
twin-twin transfusion and, 1086
umbilical cord bleeding and, 1087
history and physical examination in, 1082
hypoplastic, 1099–1100
in chronic kidney disease, 1216, 1216t
in nonimmune hydrops, 68t, 69
treatment of, 71
laboratory evaluation of, 1083–1084, 1083t, 1084f
physiologic
of infancy, 1100–1101, 1100t
of pregnancy, anesthesia and, 160
of prematurity, 1100–1101, 1101f
treatment of, 1101–1102
Anemic hypoxia, cerebral blood flow in, 813
Anencephaly, 847–848, 848f
Anesthesia
general, definition of, 161
obstetric
anatomy of labor pain and, 159, 160f
epidural, 168
for cesarean delivery, 168–171
general, 169–171
history of, 159
local, 169
Anesthesia *(Continued)*
maternal physiologic changes and, 159–161
neonatal response to, 338–339
spinal, 168–169
regional, definition of, 161
Aneuploidy, 196
partial, 196–197
screening for, 180–181, 181b
Angiogenic factors, in preeclampsia, 108
Angiotensin-converting enzyme (ACE) inhibitors, for neonatal hypertension, 1243, 1243t–1244t
Angleman syndrome, 207
Animal studies, for control of breathing, 584
Anion gap, in metabolic acidosis, 385–386
Ankyloglossia inferior, 979
Ankyloglossia superior, 979
Anorectal malformations, 990–991
Anorectal syndromes, 1185
Anosmia, hypogonadotropic hypogonadism and, 1185
Antenatal steroids
for bronchopulmonary dysplasia prevention, 665
prophylactic
for intraventricular hemorrhage, 872
for respiratory distress syndrome, 380, 639
Antibiotics
for bacterial sepsis, 547–548
for nosocomial infections, 563
influence of, on intestinal microbiota, 1002
intrapartum, for group B *Streptococcus* (GBS) infection, 540
prophylactic, 540–541
topical, for conjunctivitis, 1429t
Anticoagulation agents, for deep vein thrombosis, 1075
Anticonvulsants, in utero exposure to, ophthalmic manifestations of, 1438t
Antidiuretic hormone (ADH), body composition and fluid compartment regulation and, 371
Antiepileptic agents, 915–917
discontinuation of, 917
efficacy of, 915–916
in pregnancy, 93
new alternatives to, 916–917
Antiexcitotoxicity, for neuroprotection, 889–890
Antifibrinolytic agents, for thrombocytopenia, 1061–1062
Antifungal agents, for systemic *Candida* infections, 567–568
Antifungal creams, for *Candida* infections, 565
Antigen sampling, 998–1000, 999f
Antihypertensive agents, in pregnancy, 105–106, 106t
Anti-inflammatory agents
for neuroprotection, 890
nonsteoidal. *See* Nonsteroidal anti-inflammatory drugs (NSAIDs).
Antioxidant therapy
for bronchopulmonary dysplasia prevention, 667
for neuroprotection, 889
lungs and, 581
Antiphospholipid antibodies, maternal, prothrombotic disorders and, 1074
Antiplatelet therapy, for stroke, 1077
Antiretroviral therapy, for HIV/AIDS
breastfeeding and, 509
maternal, 507, 508f
resistance to, 507–509
side effects of, in exposed infants, 511
Anti-SSA antibodies, in immune-mediated congenital AV block, 794
Anti-SSB antibodies, in immune-mediated congenital AV block, 794
Antithrombin deficiency, prothrombotic disorders and, 1074
Antithyroid agents
for hyperthyroidiam, 1319
placental transfer of, 1307–1308
A_1-Antitrypsin deficiency, 1040–1041
Antiviral agents, common, 474t
Antley-Bixler syndrome, 1281
Anus, imperforate, 1199
Anxiety disorders, impact of, on pregnancy outcome, 102t
Anxiolytics, for obstetric analgesia, 163
Aorta, coarctation of, 784–785
Aortic arch
development of, 709–710, 711f
interrupted, 785–786, 786f–787f
Aortic stenosis, 771–772
critical, 783–784, 784f–785f
supravalvular, in Williams-Beuren syndrome, 203
Aortic thrombosis, abdominal
clinical presentation of, 1236b
risk factors for, 1236b
Aorto-gonado-mesonephron, as primary site of erythropoiesis, 1050
Aortopulmonary window, 766–767
Apert's syndrome, 1339, 1339f, 1341t
Apgar score, 332, 333t
in hypoxic-ischemic encephalopathy, 879–880
in small-for-gestational-age infants, 55
Aplasia cutis congenita, 283–284, 283f
causes of, 1380–1381
clinical findings in, 1381–1382, 1381f
prognosis and treatment of, 1382
skull defect associated with, 283–284, 283f, 290

Apnea
classification of, 594–595
detection of, 612
gastroesophageal reflux–associated, 596
of prematurity, 594–595, 595f
resolution and consequences of, 596–597, 597f
therapeutic approach(es) to, 595–596
continuous positive airway pressure as, 595
xanthine as, 595–596, 596f
post-extubation continuous positive airway pressure for, 398
Apocrine glands, formation of, 1364
Apoptosis, 879
Aquaporin water channels, 1169
Argininosuccinate lyase deficiency, 219–221
Argininosuccinate synthetase deficiency, 219–221
Arias syndrome, hyperbilirubinemia due to, 1127, 1127t
Arnold-Chiari malformation, 850–851, 851f
Arrhythmia(s), 789
fetal, 796–798
bradycardias as, 799
management of, 800
irregular rhythms in, 796
management of, 798
tachycardias as, 796–798, 796f–797f
echocardiographic diagnosis of, 793t
management of, 798–799, 798f–799f
neonatal, 789–794
bradycardias as, 793–794, 793f–794f, 793b
management of, 795–796
tachycardias as, 789–793, 789f–792f
management of, 794–795, 795f
pathophysiology of, 789
nonimmune hydrops associated with, 68t
Arterial malformation, 1411
Arterial puncture, pain management strategies for, 437
Arterial spin labeling (ASL), cerebral perfusion assessment with, 823–824
Arterial thrombosis, not related to central nervous system, 1077–1079. *See also* Thrombosis, arterial.
Arteriovenous fistulas (AVFs), 786–787
Arteriovenous malformations (AVMs), 786–787
Arthritis, septic, neonatal, 1360–1361, 1361f
Ascites, postnatal evaluation of, 1178
Ash-leaf macules, 190–191, 1412–1413, 1413f
Asphyxia
infants with, transient hyperinsulinism in, 1322
neonatal, 31–32
therapeutic hypothermia after, 365–366
physiologic responses to, 329–330, 329f, 331f
prevention of, respiratory distress syndrome and, 639
Asphyxiating thoracic dystrophy (Jeune's syndrome), 681, 682f
features of, 259t–261t
Aspirin, for stroke, 1077
Assist-control ventilation, 623–624
weaning from, 628
Assisted reproductive technology (ART). *See also* In vitro fertilization (IVF).
costs associated with, 65
increase in monozygotic twins with, 61–63
preterm birth associated with, 142
psychosocial factors associated with, 64–65
Associations, definition of, 193
Atelectasis, with mechanical ventilation, 631
Atelosteogenesis, types I and II, features of, 259t–261t
Atopic dermatitis, 1370, 1401–1402
Atopic diseases, incidence of, 1004–1005
Atosiban, for preterm labor, 144t
ATP7A gene, in cutis laxa, 274–275
ATP-binding cassette A3 (ABCA3) gene deficiency, 654
Atresia, 986–989. *See also at anatomic site.*
definition and etiology of, 986–987
vs. stenosis, 986–987
Atrial flutter
fetal, 797–798
neonatal, 790, 790f
management of, 794–795
Atrial natriuretic peptide (ANP), body composition and fluid compartment regulation and, 371
Atrial septum
defects of, 769
development of, 708–709
Atrioventricular block, congenital
associated with structural heart disease, 793–794
immune-mediated, 794, 794f
Atrioventricular canal defects, in Down syndrome, 198
Atrioventricular septal defects, 769–770, 770f
Atrioventricular valves, anatomy of, 763
Atrium (atria)
characterization of, 763
development of, 708–709
Atropine, for tracheal intubation, 437
Autoimmune disease, 1005
Autoimmune hemolytic anemia, maternal, 1092
Autoimmune neonatal neutropenia, 1111–1112
Autoregulation, cerebral, 812–813
Autosomal dominant polycystic kidney disease, 1187, 1187f
Autosomal recessive inheritance, cystic kidneys with, 1188–1189, 1188t
Autosomal recessive polycystic kidney disease, 1186–1188, 1186f
Azithromycin, for conjunctivitis, 1429t
Azotemia, prerenal, 1208, 1208b
vs. intrinsic acute kidney injury, 1210t

programmed, 879
Cellulitis, orbital and preseptal, 1429
Centers for Disease Control (CDC) and Prevention definition
of central line–associated bloodstream infections, 551, 552b
of nosocomial infections, 551, 552b
Central core disease, 896
Central nervous system (CNS). *See also* Brain *entries;* Spinal cord.
anomalies of
associated with infantile hemangioma, 1406–1407
in fetal alcohol syndrome, 114, 115f
neurodevelopmental disabilities and, 931
prenatal ultrasound screening for, 302–303
seizures and, 912
bacterial infections of, neonatal neuroimaging of, 838, 840f
cerebral blood flow regulation in, 812–815
cerebrovascular and metabolic care guidelines for, in neonates, 815
congenital malformations of, 844, 845t. *See also specific malformation*.
development of
in postembryonic period, 860–868
vascular, 811–812

Central nervous system *(Continued)*
diseases of, in neonatal HSV infection, 472, 472f
energy metabolism and, 812–815
injury to, 869 . *See also specific injury*.
bilirubin-induced, 1135–1137, 1135f, 1136t–1137t
congenital heart disease and, 801–804
genetic susceptibility to, 807
in postoperative period, 806–807
lesions of, nonimmune hydrops associated with, 68t
neuroprotection of, strategies for, 886–890, 887b. *See also* Neuroprotection.
physiology of, 811
tumors of, 1158–1159
Central pattern generator, in respiratory control, 584
Central venous catheter(s)
candidemia associated with, 567
placement of, pain management strategies for, 437
Central venous pressure, elevated, 69
Cephalhematoma, serum bilirubin levels and, 1132
Cephalic pustulosis, neonatal, 285, 285f
Cephalohematoma, 289–290, 289f
perinatal, 884
with vacuum extractor, 150
Cerclage, cervical, for preterm birth prevention, 144
Cerebellar hypoplasia, lissencephaly with, 866
Cerebellar malformations, 858–860, 858f–859f
Cerebral blood flow (CBF), regulation of, 812–815
Cerebral energy, decreased, membrane depolarization and, 877–878
Cerebral hemispheres, venous drainage from, 811–812
Cerebral infarction
neonatal neuroimaging of, 830–834, 832f–834f
seizures and, 911
Cerebral necrosis, focal and multifocal, 876
Cerebral oxygen consumption, alterations in, 814
Cerebral oxygen demand-delivery coupling, developmental regulation of, 719
Cerebral palsy
in growth-restricted infants, 55–56
motor impairment in, 922–927, 923t–926t
prevalence of, by gestational age and birthweight, 922, 923t
Cerebral perfusion, assessment of
arterial spin labeling in, 823–824
MR imaging in, 823
Cerebral sinus thrombosis, diagnosis of, 1072
Cerebrosides, 239
Cerebrospinal fluid (CSF), in bacterial sepsis, 544
Cerebrovascular lesions, seizures and, 910–911, 911f
Cerebrovascular physiology, fetal, congenital heart disease and, 801–804, 804b
Cervical cerclage, for preterm birth prevention, 144
Cervix
cancer of, in pregnancy, 99–100, 100t
short, associated with preterm birth, 142
Cesarean section, 146–147
for macrosomia, 59
obstetric indications for, 146
rates of, 3–4
vaginal delivery after, 157–158
C-fiber receptors, in respiration, 589–590
CHARGE syndrome, 193, 672, 1346–1347
cleft lip and/or palate with, 1336t–1337t
epidemiology and genetics of, 1346
ICU concerns and, 1347
management of, 1347
ophthalmic manifestations of, 1436t–1437t
phenotype in, 1346, 1346f
CHD7 gene, 193
Chemical(s)
exposure to, during pregnancy, 1145
neonatal neutropenia due, 1112
Chemical barriers, in intestinal immunity
inadequate, 1003–1004
nonspecific, 998
Chemical control, of breathing, 590–593
Chemoceptor(s), development of, genetic regulation of, 593
Chemoprophylaxis, for group B *Streptococcus* (GBS) infection, 540
Chemosensitivity
CO_2/H^+, maturation of, 592
hypoxic, maturation of, 592–593
Chemotherapy
common agents in, 98t
dosing in, 1161
during pregnancy, 98, 98t
for congenital leukemia, 1153–1154
for Wilms tumor, 1157
late effects of, 1162
Chest. *See also* Thoracic *entries*.
assessment of, 282
examination of, for dysmorphology, 189–190, 190f
Chest wall
assessment of, 292
disorders of, 680–681
neuromuscular, 681
skeletal, 680–681, 682f
Chest wall compliance, 598, 599f
Child Abuse and Treatment Act, 20
Child Epidemiology Reference Group (CHERG), 33
Child Survival Series (United Nations Children's Fund 2007), 33
CHILD syndrome, 1378
Childhood cancer, survivors of, 101
Chloramphenicol, toxicity of, 427
Chlorhexidine gluconate, for hand hygiene, 561, 561t
Chloride
in body fluids, 374t
intake of, for healthy children, 1218t
reabsorption of, 1169–1170
Chloroma, 1151
Chloroquine, for malaria, 528
Chlorothiazide
for hyperinsulinism, 1325t
for neonatal hypertension, 1243t
Choanal atresia, congenital, 672
Cholangitis, sclerosing, neonatal, 1036–1037
Cholecystitis, calculous, 1044
Choledochal cysts, 1036
Cholelithiasis, prenatal ultrasound screening for, 303
Cholestasis
and congenital hypopituitarism, 1042
parenteral nutrition associated with, 1038
progressive familial intrahepatic, 1039–1040
Cholestatic jaundice
bacterial infections associated with, 1032
parenteral nutrition causing, 968
Cholesterol
for Smith-Lenli-Opitz syndrome, 256–257
metabolism of, defective, 1281–1282
Chondrodysplasia, Jansen metaphyseal, 1268
Chondrodysplasia puncta, types of, 258, 259t–261t
Chondrodysplasia punctata syndromes, 1378
Chordee, congenital, 295
Choreoathetosis, neonatal, without coincident electrographic seizures, 906
Chorioamnion, 137
Chorion, 49
Chorionic villous sampling (CVS), 184–185, 184f
advantages and disadvantages of, 184, 185b
prenatal, 1176–1177
Chorionicity, in multiple-fetus pregnancies, 60–61
complications associated with, 63–64, 64t
diagnosis of, 60

Chorioretinitis, in toxoplasmosis, 514, 514t
Choroid, inspection of, 1423
Choroid plexus cysts, ultrasound screening for, 302–303
Chromosomal abnormality(ies), 196. *See also specific abnormality*.
  deletion syndromes as, 201–202, 201f
  genomic imprinting and, 206
  human karyotype and, 196–197, 197f
  imprinted disorders as, 206–208, 207f
  in nonimmune hydrops, 67, 68t
  segmental duplications and microdeletion syndromes as, 202–206, 203f–205f
  trisomies as, 197–201, 197f, 199f–200f
  uniparental disomy and, 206
Chromosomal sex determination, 1286
Chromosome 1p deletion syndrome, 201, 201f
Chromosome 6q24 anomalies, in transient neonatal diabetes mellitus, 1328
Chronic diseases of childhood, breastfeeding and, 943
Chronic kidney disease (CKD), 1215–1221
  acid-base and electrolytes in, 1216–1217
  acute kidney injury causing, 1215
  anemia in, 1216, 1216t
  epidemiology of, 1215
  growth and development associated with, 1220–1221
  hemodialysis for, 1219–1220
  hospitalization for, 1221
  nutrition and, 1217–1218, 1217t–1218t
  outcome of, 1220–1221
  peritoneal dialysis for, 1219
  renal osteodystrophy associated with, 1221
  renal replacement therapy for, 1219
    ethics of initiating or withdrawing, 1218–1219
  renal transplantation for, 1220
  survival with, 1221
Chylothorax
  congenital, 682–684
  management of, 683–684
Chylous effusions, characteristics of, 683, 683t
Cigarette smoke (smoking), 116–117
  compounds in, 116
  during pregnancy, 6, 54, 111–112, 113t
    complications associated with, 116
  fetal growth restriction related to, 52t, 54–55, 116–117
Ciliary body, inspection of, 1423
Ciliated cells, in proximal airways, 572–573
Ciliopathy(ies), 1185–1186
Circadian rhythms, fetal and neonatal, 1252–1253
Circulation
  abnormal, pathogenesis of, 718
  assisted, in delivery room resuscitation, 337–338
  cerebral, regulation of, 812–815
  compromise of. *See also* Shock.
    diagnosis of, 721–724, 722f
    organ blood flow and, 723
    transitional blood flow and, 720–721
  fetal. *See* Fetal circulation.
  maternal, 160
    cell-free nucleic acids in, 183
  organ, autoregulation of, 718
  placental, 38, 40f
  systemic, echocardiographic measurement of, 724
  uterine, during pregnancy, 160–161
Circulatory arrest, deep hypothermic, 805–806
Circumcision, 305, 1202–1204
  bleeding after, 1203–1204
  contraindications to, 1203, 1203f
  pain and stress management strategies for, 437
  techniques of, 1202–1203
Citrin deficiency, 1042
Citrobacter infection, neonatal neuroimaging of, 838, 840f
Clara cells, in distal airways, 573
Clavicle fractures, at birth, 1358–1359
Clearance of drugs, 424–425, 425t
Cleft(s)
  laryngotracheoesophageal, 983, 983f, 1334
  orofacial, 1333–1338, 1334f, 1335b
    syndromes associated with, 1335–1338, 1336t–1337t
Clinodactyly, 190
Clitoral reduction, 1304
Clitoris, examination of, 1289
Cloaca, 1199–1200
Cloacal anomalies, 1199–1200, 1199f
Cloacal exstrophy, 1197–1198, 1198f
Clonic seizure(s). *See also* Seizure(s).
  neonatal, 902, 903f
    multifocal (fragmentary), 903
Clonidine, for neonatal abstinence syndrome, 125
Cloverleaf skull, 1341
Clubfoot (talipes equinovarus), 1355, 1355f
  nonoperative approach to, 1355–1356
Clunk, vs. click, 296
Coagulase-negative *Staphylococcus* (CONS) infection, nosocomial, 555–556, 555t
Coagulation, plasma phase of, 1056
Coagulation factors, 1056. *See also specific factor*.
  deficiencies of
    hemophilia A and B and, 1065–1067
    rare factors and, 1067–1070, 1068t–1069t
Coarctation of aorta, 784–785
Cobb syndrome, 1411
Cobblestone complex syndromes, 866–867
Cocaine
  abuse of, during pregnancy, 6, 112, 113t
    complications associated with, 118–119
  forms of, 118
  in utero exposure to, ophthalmic manifestations of, 1438t
  infants exposed to, 123
    childhood behavioral problems associated with, 127–128
  pharmacology and biologic actions of, 118
Coenzyme Q disorders, 236
Cognitive impairment, in preterm infants, 927–928
COL1A1 gene, in osteogenesis imperfecta, 262
COL1A2 gene, in osteogenesis imperfecta, 262
COL2A1 gene
  in achondrogenesis type II–hypochondrogenesis, 268–269
  in skeletal dysplasias, 258
  in spondyloepiphyseal dysplasia congenita, 268
COL5A1 gene, in Ehlers-Danlos syndrome, 274
Cold response
  afferents and, 357–358
  central regulation and, 358
  efferents and, 358
  physiology of, 357–358
Cold stress, 357, 358t
Collagen type II (COLA21) spectrum, 267–269
Collectins, 580
Collodion baby, 1370
  clinical findings in, 1373–1374, 1375f
  diagnosis of, 1374–1375
  differential diagnosis of, 1374, 1375t
  treatment of, 1375
Coloboma, ocular, 291, 1427, 1427f
Colon
  atresia of, 988–989, 989f
  development of, structural and functional, 975–976
  mechanical obstruction of, 985–986, 986t
Colostrum, intake of, 306–307
Comedones, 1399, 1400f
Communications, centralization of, in neonatal transport medicine, 342
Community contributors, to preterm birth, 140–142, 141t
Community health worker, home visits by, 32–33
Comparative genomic hybridization (CGH), 176–177

Compartment, in pharmacokinetics, 420
Complement, 449–452
Complement cascade, activation of, 449–450
  pathways in, 450–451, 450f
Computed tomography (CT)
  neonatal neuroimaging with, 819–820, 820f
    advantages and disadvantages of, 842–843
    clinical indications for, 820
    radiation risks in, 820
    techniques of, 820
  of congenital cystic adenomatoid malformation of lung, 687, 687f
  renal, postnatal, 1180
Conduction, heat loss through, 357
Conduction system, development of, 711
Condylomata, syphilitic, 519–520
Congenital adrenal hyperplasia (CAH)
  ambiguous genitalia in, 1204, 1293–1294, 1293f
  lipoid, 1280–1281, 1300, 1300b
  rare form of, with variable phenotypes, 1281
  screening for, 324
  virilizing form(s) of, 1277–1282
    3β-hydroxysteroid dehydrogenase Type II deficiency as, 1280
    11β-hydroxylase deficiency as, 1278–1279
    17-hydroxylase deficiency as, 1279–1280
    21-hydroxylase deficiency as, 1277–1278, 1293–1294
    treatment of, 1295
Congenital contractual arachnodactyly (Beals syndrome), 273–274, 275f
Congenital cystic adenomatoid malformation (CCAM)
  of lung, 684–687, 684t
    diagnosis and natural history of, 685–686
    postnatal management of, 686–687, 687f
    prenatal management of, 686
    types of, 684–685
  surgery for, 71
Congenital heart disease (CHD), 313, 719, 762
  anomalies associated with, 931
  fetal-to-postnatal transition in, 762, 763f

thalassemia syndromes as, 1096–1098, 1097t
hereditary disorder(s) causing
elliptocytosis as, 1094
G6PD deficiency as, 1094–1095, 1094f
membrane defects as, 1092, 1093f
pyruvate kinase deficiency as, 1095
red blood cell enzyme abnormalities as, 1094
spherocytosis as, 1092–1093
immune hemolysis and, 1087–1092, 1088f
ABO incompatibility and, 1091, 1091t
maternal disease causing, 1092
minor blood group incompatibility and, 1091–1092
Hemolytic anemia *(Continued)*
Rh hemolytic disease and, 1088–1091, 1090f
mild, 1089
moderate, 1089
severe, 1089
nonimmune
infection and, 1092
schistocytic, 1092
nonimmune hydrops associated with, 68t, 69
severity of, classification of, 94–95, 95t
Hemolytic disease, ABO incompatibility and, 1131–1132
Hemophagocytic lymphohistiocytosis, 1042–1043, 1159–1160, 1161b
Hemophilia A (factor VIII deficiency), 1065–1067
Hemophilia B (factor IX deficiency), 1065–1067
Hemorrhage, 1058–1070
adrenal, 1283
neonatal, 1238–1239
after circumcision, 1203–1204
fetomaternal, 1086
intracranial
neonatal neuroimaging of, 826–830, 827f, 831f
prophylactic indomethacin for, 760
intraventricular. *See* Intraventricular hemorrhage.
postnatal, 719
pulmonary, 610–611
retinal, 1431–1433
serum bilirubin levels and, 1132
subarachnoid, 885
subconjunctival, 1429, 1431
subdural, 884–885
subgaleal, 883
with vacuum extractor, 150–151
transplacental, obstetric events increasing risk of, 94, 94b
vitamin K–deficient, 304–305
Hemorrhagic anemia, 1085–1087, 1086t, 1107b. *See also* Anemia, hemorrhagic.
Hemostasis
developmental, 1057
disorders of, 1056. *See also* Hemorrhage; Thromboembolic disorder(s); *specific disorder*.
overview of, 1056–1057
Henderson-Hasselbalch equation, 383
Heparin
for renal artery thrombosis, 1235–1236
low-molecular-weight
for deep vein thrombosis, 1075
for renal artery thrombosis, 1236
Hepatic calcifications, prenatal ultrasound screening for, 303
Hepatic hemangioendothelioma, 1044, 1161
Hepatitis A virus (HAV) infection, during pregnancy, 1033
Hepatitis B vaccine, 305–306
Hepatitis B virus (HBV), materno-fetal transmission of, 1033
Hepatitis B virus (HBV) infection, 498–501, 499t
clinical spectrum and laboratory evaluation of, 500
etiology and pathogenesis of, 499–500
incidence of, 498–499
prevention of, 499t, 500
treatment of, 474t, 500–501
Hepatitis C virus (HCV), transmission of, 1033
Hepatitis C virus (HCV) infection, 501–503
clinical spectrum and laboratory evaluation of, 502
etiology and pathogenesis of, 501–502
incidence of, 501
maternal drug abuse and, 122
prevention of, 503
prognosis of, 502
treatment of, 474t, 502
Hepatitis E virus (HEV), materno-fetal transmission of, 1033
Hepatitis virus(es), liver disease and, 1032–1033
Hepatobiliary scintigraphy, 1035
Hepatoblastoma, 1160–1161
Hepatocellular carcinoma, tyrosinemia type 1 and, 224
Hepatoportoenterostomy, Kasai, for biliary atresia, 1035–1036
Hepatopulmonary fusion, associated with congenital diaphragmatic hernia, 696–697
Hepatorenal tyrosinemia, 224
Hepatosplenomegaly, in neuroblastoma, 1148
Hereditary elliptocytosis, 1094
Hereditary fructose intolerance, 218, 1224, 1326
Hereditary galactosemia, 215–217, 215b
Hereditary spherocytosis, 1092–1093
Hereditary tyrosinemia
type1, 223–224
type I, 1040
Hermansky-Pudlack syndrome, type2, 1121
Hernia, 1202
diaphragmatic. *See* Diaphragmetic hernia.
inguinal, 1012, 1012f
umbilical, 1007
Heroin abuse, during pregnancy, 112
Herpes simplex virus (HSV) infection, 470–489
clinical findings in, 470–471, 470t
epidemiology of, 470–471
hepatitis due to, 1032

Herpes simplex virus *(Continued)*
neonatal, 285–286, 286f
clinical findings in, 471–476, 472f
diagnosis of, 472–473
neuroimaging of, 838, 839f
prevention of, prospects for, 475–476
treatment of, 473–475, 474t
of skin, 1395–1396
treatment of, 1396
Herpes simplex virus-1 (HSV-1), 470
genital herpes associated with, 471
Herpes simplex virus-2 (HSV-2), 470
genital herpes associated with, 471
Herpesvirus(es), type 1 and 2, ophthalmic manifestations of, 1437t
HESX1 gene
in septo-optic dysplasia, 857
mutations of, 1245–1246, 1246t
Heterochromia, 1423
Heterotopia, neuronal, 867–868, 867f
Hexachlorophene, for hand hygiene, 561
High-frequency ventilation (HFV), 625–627
clinical experience with, 626
devices for, 626
for extremely-low-birth-weight infants, 397–398
for persistent pulmonary hypertension of newborn, 627
for respiratory distress syndrome, 626
gas transport during, 626
indications for, 627
oscillatory, bronchopulmonary dysplasia and, 662
side effects of, 627
ventilator settings for, 627
weaning from, 629
High-order multiples (HOMs), 60. *See also* Multiple-fetus pregnancies.
maternal complications associated with, 64
High-risk infant(s), neurodevelopmental outcome in, 932–934
comprehensive developmental follow-up evaluation of, 932–933
discharge planning and, 932
referral for multidisciplinary evaluation and early interventions services for, 933–934
Hindbrain, normal development of, 858
Hindgut, development of, structural and functional, 974–977
Hip(s)
assessment of, 295–296
developmental dysplasia of, 1351–1353, 1352f
syndromic, 1351
treatment of, 1352–1353, 1352f
typical, 1351
Hirschsprung's disease, 853
Hispanics, perinatal outcome among, 5t
Histamine-blocking agents, nosocomial infections associated with, 555
Histiocytosis, 1159–1160
classification of, 1160t
HIV/AIDS, 505–512
changing epidemiology of, 505–506, 505f
congenital, vs. leukemia, 1152
maternal
and uninfected infants, 511–512
congenital syphilis associated with, 518
infant feeding and, 509
infants exposed to
testing of, 509–510, 510t
treatment of, 510–511, 511t
side effects of, 511
intravenous drug abuse and, 122
method of delivery in, 509
treatment of, 507, 507b
antiretroviral therapy in, 507, 508f
resistance to, 507–509
mother-infant transmission of, 506
prevention of, 506–507
neonatal, 31
circumcision and, 305
neuroimaging of, 838
pathogenesis of, 506–512
perinatal exposure to, 122–123
viral transmission of, 506–507
HNF4α gene mutations, in congenital hyperinsulinism of infancy, 1324
Holocarboxylase synthetase deficiency, 229
Holoprosencephaly, 853–856, 854f–855f
alobar, 853, 855f
clinical features of, 854–855
etiology and epidemiology of, 855
molecular genetic events related to, 855–856
Homocysteine, prothrombotic disorders and, 1074
Homocysteine remethylation disorders, 224–225
Homocystinemia, classic, 225
Homocystinuria
ophthalmic manifestations of, 1436t–1437t
screening for, 321–322
Hormonal contraception, affecting milk supply, 949
Hormonal deficiency, counterregulatory, 1326
Hormone(s). *See also specific hormone*.
end-organ responsiveness to, maturation of, body composition and fluid compartment regulation and, 370–372
in lung maturation, 575, 576t
Horseshoe kidney, 1182
Hospital, breastfeeding support in, 946–947
Hospital-acquired infections. *See* Nosocomial infections.
Hospitalization
for chronic kidney disease, 1221
of late preterm infants, 413–414
readmission and, 416
Host defenses
breastfeeding and, 941–943, 942t, 943b
gastrointestinal, 998–1000
in necrotizing enterocolitis, 1023
pulmonary, development of, 580
Host susceptibility, bronchopulmonary dysplasia and, 659–660
Human chorionic gonadotropin (hCG)
in ambiguous genitalia, 1292
placental production of, 39–41
Human chorionic somatomammotropin (hCS), placental production of, 39–41
Human genome project, 173
comparative hybridization and, 176–177
copy number variants and, 175
epigenetic regulation and, 178
ethical, legal, and social aspects of, 179
gene identification in, 175
gene therapy and, 178–179
hapnap and genome-wide association of, 175–176
historical background of, 173–174
individualized information in, 177
microbial genomes and virulence factors in, 178
mitochondrial DNA in, 175
pharmacogenetics and, 177
scientific basis of, 174–179
single nucleotide polymorphisms in, 174
Human herpes virus-6 (HHV-6), 485–486
Human herpes virus-7 (HHV-7), 485–486
Human herpes virus-8 (HHV-8), 486–487
Human karyotype, 196–197, 197f
Human leukocyte antigen B12 (HLA-B12), in biliary atresia, 1034
Human milk. *See* Breast milk.
Human parechovirus infection, 498
Human parvovirus B19 infection, 487–489
clinical findings in, 470t
clinical spectrum of, 488
epidemiology of, 487
laboratory evaluation of, 488–489
pathogenesis of, 487–488
prevention of, 489
prognosis of, 489
treatment of, 489
Hyaline membrand disease. *See* Respiratory distress syndrome.
Hybrid incubator-radiant warmer technology, 360–362

Hybridization, array-based, 176–177
Hydantoin syndrome, fetal, 93, 94t
Hydralazine
  for hypertension
    in preeclampsia, 109t
    in pregnancy, 106, 106t
  for neonatal hypertension, 1243t–1244t
Hydrocele, 295, 1012, 1013f, 1201
Hydrocephalus
  in achondrodysplasia, 266
  in craniosynostosis syndromes, 1342
  in toxoplasmosis, 514, 514t
  neonatal, neuroimaging of, 836–837, 837f–839f
Hydrochlorothiazide
  for congenital nephrogenic diabetes insipidus, 1227
  for neonatal hypertension, 1243t
Hydrocortisone
  effect of, on blood pressure, vasopressor-resistant shock and, 729, 730f–731f
  for acute kidney injury, 1211–1212
  for adrenal crisis, 1284
  for primary adrenal insufficiency, 1284
Hydrolases, 239
Hydronephrosis, 1191–1192, 1192f
  prenatal diagnosis of, 1176
Hydrops
  hemolytic anemia and, 1090–1091
  immune-mediated, 93, 94f
  in human parvovirus B19 infection, treatment of, 489
  nonimmune, 67
    clinical course and outcome of, 72–73
    etiology of, 67, 68t
    incidence of, 67
    management of
      cardiovascular, 72
      fluid and electrolyte, 72
      intensive care in, 71–72
      prenatal, 70–71
      respiratory, 72
    neonatal evaluation of, 71, 72t
    pathophysiology of, 67–70
      fluid homeostasis derangements in, 69–70
      normal fluid homeostasis and, 67–69, 69f
    prenatal diagnosis of, 70, 70t
  with congenital cystic adenomatoid malformation of lung, 686
Hydrostatic pressure
  interstitial, 369, 369b
  intracapillary, 369, 369b
  intravascular, increased, in heart-lung interactions, 607–608, 608f, 608b
11β-Hydroxylase deficiency, 1278–1279
17-Hydroxylase deficiency, 1279–1280
21-Hydroxylase deficiency, 1277–1278, 1293–1294
  diagnosis of, 1294
17α-Hydroxylase/17,20-lyase deficiency, 1301
3β-Hydroxysteroid dehydrogenase Type II deficiency, 1280, 1300–1301
17-Hydroxysteroid dehydrogenase-3 deficiency, 1299–1300
Hygiene, hand. *See* Hand hygiene.
Hygiene hypothesis, in atopic diseases, 1004–1005
Hygroma, cystic, 980, 980f
  prenatal screening for, 182
Hyperammonemia
  transient, of newborn, 221
  with coma, continuous arteriovenous hemofiltration for, 219
Hyperbilirubinemia
  after intrauterine transfusion, 1091
  clinical relevance of, 1128–1142
  development of, risk factors for, 1128, 1128b
  in infants of diabetic mothers, 81
  in late preterm infants, 411, 1128–1129, 1129f
  neonatal, 311–312
    decreased bilirubin clearance causing, 1124b, 1126–1128
      hepatic bilirubin conjugation and, 1126–1128, 1127t
      hepatic bilirubin uptake and, 1126
    East Asian ethnicity and, 1132
    G6PD deficiency and, 1130–1131, 1130t
    increased bilirubin load causing, 1123–1126, 1124b
      hemoglobinopathies and, 1125
      immune-mediated hemolytic disease and, 1125–1126
      red cell enzyme deficiencies and, 1124–1125, 1125b
      red cell membrane defects and, 1123–1124
    neuroimaging in, 841
    prediction of, 1133, 1133f
    treatment of
      considerations in, 1137–1142, 1139f–1140f
      exchange transfusion in, 1141–1142, 1141f
      phototherapy in, 1140–1141
Hypercalcemia, neonatal, 1265–1269, 1266b
  definition of, 1265
  hyperparathyroid syndromes and hypocalciuric, 1266
  with maternal hypoparathyroidism, 1266–1267
  other causes of, 1268
  treatment of, 1268–1269
  vitamin D toxicity and, 1268
Hypercalcemia, neonatal *(Continued)*
  Williams syndrome and, 1267
  with blue diaper syndrome, 1268
  with phosphate depletion, 1268
  with skeletal dysplasias, 1268
  with subcutaneous fat necrosis, 1267–1268
Hypercapnia, 814
  cerebral effects of, 814
  permissive, 628
Hyperglycemia
  maternal, fetal effects of, 75–78, 76f, 76t
  neonatal, 1327
    transient, treatment of, 1329
Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study, 78, 78f
Hyperglycinemia, nonketotic, 224
Hyperinflation, in chronic lung disease, 690
Hyperinsulinemia, fetal, 77
Hyperinsulinism
  congenital, 1322–1325. *See also* Congenital hyperinsulinism of infancy (CHI).
  transient, in asphyxiated or small-for-gestational age infants, 1322
Hyperkalemia, 378
  circulatory compromise and, 723
  renal tubular, 1226–1227
  transient, 1173
  treatment of, 378, 379t, 1212, 1213t
Hyperkeratosis, epidermolytic, 1376–1377, 1418
Hyperlactemia, antiretroviral therapy–induced, 511
Hypermagnesemia, neonatal, 1269
Hypernatremia, 375–377, 376b
  seizures and, 910
  treatment of, 377
Hypernephronic nephromegaly, congenital, with tubular dysgenesis, 1189
Hyperoxia, cerebral blood flow and, 813
Hyperparathyroidism
  maternal, neonatal hypocalcemia associated with, 1262–1263
  neonatal
    hypocalciuric hypercalcemia and, 1266
    maternal hypoparathyroidism associated with, 1266–1267
Hyperphenylalaninemia, 226
Hyperphosphatemia
  hypocalcemia and, 1261, 1264
  management of, 1212
Hyperprostaglandin E syndrome, 1226
Hypertelorism, 290–291, 1349

Hypertension
definition of, 105
familial hyperkalemic, 1227
maternal, neutropenia associated with, 1112
neonatal, 1239–1244
blood pressure measurement in
invasive (direct), 1239–1240
noninvasive (indirect), 1240–1241
clinical signs of, 1241, 1242b
definition of, 1239
epidemiology of, 1239
etiology of, 1241, 1242b
evaluation of, 1241–1242
in acute kidney injury, management of, 1212
prognosis of, 1244
treatment of, 1242–1244, 1243t–1244t
postnatal evaluation of, 1178
pregnancy-associated, 47, 105
chronic, 105–107
antenatal fetal surveillance in, 106–107
antihypertensive therapy for, 105–106, 106t
classification of, 105, 106t
gestational, 107
preeclampsia-eclampsia and, 107–110. *See also* Eclampsia; Preeclampsia.
pulmonary. *See* Pulmonary hypertension.
Hyperthermia
in premature infants, 364
neonatal, 310
Hyperthyroidism
in pregnancy, 88
diagnosis of, 88–89
neonatal, 1318–1319
Hyperthyrotropinemia, in Down syndrome, 1315
Hyperthyroxinemia, dysalbuminemic, familial, 1317
Hypertrophic cardiomyopathy, in infants of diabetic mothers, 81–82
Hyperventilation, 603
Hyperviscosity
cerebral blood flow and, 813–814
in infants of diabetic mothers, 81
Hyphema, 1431
Hypoalbuminemia, 1255
Hypocalcemia
incidence of, acute kidney disease and, 1212–1213
neonatal, 1259–1265
clinical findings in, 1260
definition of, 1259
early-onset, 1259b, 1260
hypomagnesemia associated with, 1259b, 1263
hypoparathyroid syndromes causing, 1259b, 1261–1262
Hypocalcemia *(Continued)*
late-onset, 1259b, 1260–1261
maternal hyperparathyroidism associated with, 1262–1263
other causes of, 1259b, 1264
phosphate-induced, 1259b, 1264
renal tubular acidosis associated with, 1259b, 1263
treatment of, 1264–1265
magnesium administration in, 1265
nonemergency, 1265
vitamin D therapy in, 1265
vitamin D disorders causing, 1259b, 1263–1264
seizures and, 910
treatment of, 915
Hypocalcemic crisis, 1265
Hypocapnia, cerebral effects of, 814
Hypoglycemia
cerebral effects of, 814
definition of, 410, 1320
in late preterm infants, 410–411
causes of, 410b
in premature infants, 1322
in small-for-gestational-age infants, 1322
neonatal
classification of, 1321–1329, 1321b
in infants of diabetic mothers, 81, 1322
increased risk of, 1321b
intrauterine growth restriction associated with, 55
neuroimaging in, 840–841, 841f
normoinsulinemic, 1326
persistent, 1322–1326
persistent hyperinsulinemic, 1322–1325. *See also* Congenital hyperinsulinism of infancy.
signs and symptoms of, 1320–1321
transient, 1321–1322
transient hyperinsulinism causing, 1322
seizures and, 910
treatment of, 915
Hypoglycemic therapy, prenatal, for diabetic mothers, 84–85
Hypogonadotropic hypogonadism and anosmia, 1185
Hypokalemia, 378
treatment of, 378
Hypomagnesemia, neonatal hypocalcemia associated with, 1259b, 1263
Hypomelanosis of Ito, 1413
Hyponatremia, 375, 376f
management of, 1212
seizures and, 910
Hypoparathyroidism
maternal, neonatal hyperparathyroidism associated with, 1266–1267
neonatal hypocalcemia with, 1259b, 1261–1262
Hypoparathyroidism-deafness-renal dysplasia syndrome, 1185
Hypoparathyroidism-retardation-dysmorphism syndrome, 1262
Hypoperfusion, impact of, on neurodevelopmental impairment, 725
Hypophosphatasia, perinatal, 264, 1268
Hypophosphatemia
hypercalcemia associated with, 1268
X-linked dominant, 1272
Hypopigmented lesions, cutaneous, 1412–1413, 1413f
definition of, 1412
Hypopituitarism, congenital, cholestasis and, 1042
Hypoplastic anemia, 1099–1100
Hypoplastic kidney, 1184
Hypoplastic left heart syndrome (HLHS), 780–781, 782f–783f
surgical intervention for, neurodevelopmental outcome after, 807–808
Hypoplastic vasculature, in persistent pulmonary hypertension of newborn, 733
Hypoproteinemia, nonimmune hydrops associated with, 69
Hypospadias, 1202, 1303–1304
examination of, 1290
Hypotelorism, 290–291
Hypotension
impact of, on neurodevelopmental impairment, 725
in first postnatal day, definition of, 722
in pregnancy, 160
vasopressor-resistant, 721
Hypothalamic-pituitary-adrenal axis, 1248–1250, 1249f–1250f
Hypothalamic-pituitary-thyroid axis, 1250–1251
embryogenesis of, 1307
Hypothalamo-pituitary development, abnormal, gene mutations causing, 1246t
Hypothalmic-pituitary-adrenal (HPA) axis
activation of, 48
components of, 1276
Hypothermia
for neuroprotection, 887
neonatal, 310
intrauterine growth restriction associated with, 55
therapeutic, 890–891
following neonatal asphyxia, 365–366
for hypoxic-ischemic encephalopathy, 346
Hypothermia therapy, after significant resuscitation, 340
Hypothermic circulatory arrest, deep, 805–806

Hypothyroidism
central, 1314–1315
congenital, 1310–1312
clinical manifestations of, 1311–1312, 1311t
screening for, 324, 1312–1314, 1312t
treatment of, 1317–1318, 1318b
consumptive, 1315
in pregnancy, 90–91
diagnosis of, 90
management of, 90
neonatal neurologic development and, 90–91
primary, transient, 1315
Hypothyroxinemia, transient, of prematurity, 1316
Hypoventilation, 603
Hypoventilation syndrome, congenital, sleep state and, 594
Hypovolemia, shock and, 719
Hypoxemia
fetal, 132
in persistent pulmonary hypertension of newborn, 735
in uncorrected congenital heart disease, 804
pulse oximetry detection of, 614
respiratory failure and. *See* Respiratory failure, hypoxemic.
Hypoxia
cerebral response to, 813
neonatal breathing and, 593
perinatal, 1206–1207
Hypoxia-inducible factor1α, for neuroprotection, 888
Hypoxia-ischemia, seizures and, 908–909
Hypoxic hypoxia, cerebral blood flow in, 813
Hypoxic stress, maternal diabetes mellitus and, 78
Hypoxic-ischemic encephalopathy, 874
clinical staging of, 875t
diagnosis of, 875–876
management of, 879
neuroimaging in, 880, 881f
prognosis of, 879–880
seizures in, 908–909
other causes of, 909–910
therapeutic hypothermia for, 346
Hypoxic-ischemic reperfusion injury, perinatal, 874–881
cell death in, 879
cellular mechanisms of, 877, 877f, 878b
clinical signs and symptoms of, 874–875, 875t
decreased cerebral energy in, 877–878
diagnosis of, 875–876
etiology of, 874
excitotoxicity in, 878
management of, 879
membrane depolarization in, 877–878
Hypoxic-ischemic reperfusion injury *(Continued)*
outcome of, 880–881
oxidative stress in, 878–879
pathology of, 876
patterns of, 876
prognosis of, 879–880

I

Ibuprofen, for patent ductus arteriosus, 759–760
I-cell disease (mucolipidosis type II), 243t, 247
Ichthyosis(es), 1373–1379
cutaneous, primary, 1379
harlequin, 1375–1376, 1376f
ichthyosiform syndromes as, 1378–1379
lamellar, 1377–1378, 1377f
manifesting in neonatal period, 1373–1378, 1375f
recessive, X-linked, 1378
resources for, 1374b
Ichthyosis linearis circumflexa, 1378
Ichthyosis vulgaris, 1379
IGF2 gene
in Beckwith-Wiedermann syndrome, 207–208
in Russell-Silver syndrome, 208
Illicit drug(s). *See also* Substance abuse; *specific drug*.
breastfeeding and, 103t, 123
Illness, drug-induced, in neonatal intensive care unit, 426–427
Imiglucerase, for lysosomal storage diseases, 248
Immigrant cells, of skin, 1364
Immune cells, epithelial, specialized, 997–998
Immune hemolysis, 1087–1092, 1088f
ABO incompatibility and, 1091, 1091t
maternal disease causing, 1092
minor blood group incompatibility and, 1091–1092
Rh hemolytic disease and, 1088–1091, 1090f
mild, 1089
moderate, 1089
severe, 1089
Immune-mediated congenital AV block, 794, 794f
Immunity
adaptive. *See* Adaptive immunity.
innate. *See* Innate immunity.
intestinal microbiota and, 1002, 1018
mucosal, of gastrointestinal tract, 976–977, 996
impact of altered, 1003–1005
Immunization, 465–467
CMV human immunoglobulin, 483
during pregnancy, 465–466, 465b
hepatitis B, 500, 500t
in neonates, 305–306
Immunization *(Continued)*
in neonates, 466–467
with malignant disorders, 1162
rubella, 492
varicella, 478
Immunoglobulin(s), 458–461
characteristics and functions of, 458t
classes of, 458
RSV-specific, 504–505
structure of, 454, 459f
therapy with, 461
Immunoglobulin A (IgA), 458t, 460
Immunoglobulin D (IgD), 458t, 461
Immunoglobulin E (IgE), 458t, 460–461
Immunoglobulin G (IgG), 458–460, 458t
intravenous
for neonatal alloimmune thrombocytopenia, 1061
for nosocomial infections, 563–564
Immunoglobulin M (IgM), 458t, 460
Immunoglobulin M (IgM)
immunosorbent agglutination assay, for toxoplasmosis, 515
Immunologic disorders, associated with erythroderma, 1370
Immunology, 445
fetal-neonatal, 449–461
adaptive immunity in., 454–461. *See also* Adaptive immunity.
innate immunity in., 449–454. *See also* Innate immunity.
maternal and placental, 445–449
cytokine secretion during pregnancy and, 448
evasion strategies at maternal-fetal interface and, 446–448, 446t
regulatory T cells in pregnancy and, 448–449
specific immunologic deficiencies and, 461–465. *See also named deficiency.*
Immunophenotypic classification, of childhood leukemia, 1152t, 1153
Immunoreactive trypsinogen, in sickle cell disease, 325
Immuno-vascular balance, during placentation, 42–45, 43t, 44f, 45t, 46f
Imperforate anus, 1199
Impetigo, bullous, 1390–1391, 1391f
In utero exposure to teratogens
ocular findings associated with, 1438t
renal disorders associated with, 1190
In utero fetal demise (IUFD), 158
In utero regulation, of patent ductus arteriosus, 752–753
In vitro fertilization (IVF), 60. *See also* Assisted reproductive technology (ART).
costs associated with, 65
zona pellucida manipulation in, 61–62

Inborn errors of metabolism, 209
amino acids, 215b, 221–226
screening for, 317t, 321–322
ammonia, 215b, 219–221, 220f
associated with metabolic acidosis, 386b
bile acid, 1041
carbohydrates, 215–221, 215b
classification of, 210–213, 210b
common types of, 210, 210b
diagnostic testing outcomes in, 212t
emergency treatment for, 213
hypoglycemia associated with, 1326, 1327f
organic acid, 216b, 222f, 226–238
screening for, 317t, 323
physical findings in, 211t
renal disorders associated with, 1190
screening for, 317t, 321–323
seizures and, 912–913
signs and symptoms of, 213, 213b
with neonatal hepatic phenotype, 1031t
Incisions, for cesarean section, 146
Incontinentia pigmenti
causes of, 1382
clinical findings in, 1382–1383, 1382f
diagnosis of, 1383
ophthalmic manifestations of, 1436t–1437t
prognosis and treatment of, 1383
Incubation
hybrid incubator-radiant warmer technology in, 360–362
partitioning of heat losses and gains and, 359–360, 360f
thermal neutral zone and, 358–359, 359f, 359t
Incubator-radiant warmer technology, hybrid, 360–362
India
child deaths in, 23, 24t
child nutrition in, 26
Indomethacin
for intraventricular hemorrhage, prophylactic, 872
for patent ductus arteriosus, 759
prophylactic, 760
for preterm labor, 144t
nephrotoxic effects of, 1209
Induction agents, for obstetric anesthesia, 169–170
Inertance, in lung mechanics, 599
Infant formula(s). *See also* Breast milk.
cow milk–based, 308
for premature infants, composition of, 956t–957t
postdischarge, 962t
protein hydrolysate, 308
soy, 308
vs. breast milk, 999
Infant heart donors, availability of, 788t
Infant mortality
definition of, 1
international comparisons of, 4
Infant pain scores, 432–434, 433t–434t
Infant serum, drug concentrations in, 103t
Infantile cardiomyopathy, lethal, 237
Infantile epileptic encephalopathy, early, 913
Infantile hemangioma, 1405. *See also* Hemangioma, infantile.
Infantile mitochondrial myopathy
benign, 236
lethal, 236–237
Infantile nystagmus syndrome, 1430
Infantile Refsum syndrome, 253t, 254
Infantile sialic acid storage disease, 243t, 246–247
Infants of diabetic mothers (IDMs)
congenital anomalies in, 75–76, 76f, 76t
pathogenesis of, 76
prevention of, 76
hypocalcemia in, 1260
hypoglycemia in, 81, 1322
macrosomia in, 77
childhood effects of, 77
transitional management of, 87
Infarction, cerebral
neuroimaging of, 830–834, 832f–834f
seizures and, 911
Infection(s). *See also specific infection.*
bronchopulmonary dysplasia and, 660–661
congenital, vs. leukemia, 1151–1152
control of, in hospital setting, 559, 559b
hemolytic anemia due to, 1092
in extremely-low-birth-weight infants
early-onset, 400–401, 401t
late-onset, 401–402, 401t
prevention of, 402
in late preterm infants, 411–412
maternal, associated with preterm birth, 142
neonatal, 29–31
neuroimaging of, 837–838, 839f–840f
nonimmune hydrops associated with, 68t
protective effect of breastfeeding against, 942–943
seizures and, 912
Inferior vena cava
development of, 709, 710f
venous connections of, 763
Infertility
associated with cryptorchidism, 1200–1201
treatment of. *See* Assisted reproductive technology (ART); In vitro fertilization (IVF).
Inflammation
in bronchopulmonary dysplasia, 660, 661b
intestinal microbiota and, 1002
Inflammatory bowel disease, 1005, 1018
Influenza virus infection, nosocomial, 557–558
Informatics
biomedical, 11
health, 10–11
Information retrieval, online, 16–17
Infusion drug doses, calculation of, 423
Inguinal hernia, 1012, 1012f
Inhalation analgesia, obstetric, 163
Inhaled halogenated agents, for obstetric anesthesia, 170
Inhaled nitric oxide therapy
during transport, for hypoxic respiratory failure, 349
for bronchopulmonary dysplasia, 669
prophylactic, 667–668, 668f
in extremely-low-birth-weight infants, 398–399
for hypoxic respiratory failure, 929–930
for persistent pulmonary hypertension of newborn, 737–738, 738t
Innate immunity, 449–454
complement in, 449–452, 450f
monocytes and macrophages in, 453–454
natural killer cells in, 452–453
of gastrointestinal tract, 976–977, 996
antigen sampling and presentation in, 998–1000, 999f
nonspecific physical and chemical barriers in, 998
polymorphonuclear neutrophils in, 453
Inotropic therapy, for congenital heart disease, 353–354
INS gene mutations, in permanent neonatal diabetes mellitus, 1328
Inspiration, duration of, intermittent mandatory ventilation and, 621–622, 622f
Inspired gas conditioning, in mechanical ventilation, 619
Insula of Reil, 804
Insulin
fetal development and, 57
for diabetic mothers
dosing regimen of, 83
principles of, 84
for hyperkalemia, 1213t
Insulin plus dextrose, for hyperkalemia, 379t
Intellectual disability, 920
Intelligence quotient (IQ) scores
breastfeeding and, 944
in preterm infants, 927–928

Intensive care. *See also* Neonatal intensive care unit (NICU).
for infant with nonimmune hydrops, 71–72
Interagency Group for Child Mortality Estimation, *State of the World's Children* based on, 33
Interfacility transport, of neonates., 341. *See also* Neonatal transport medicine.
mode of, 343
Interferon γ release assays (IGRAs), for tuberculosis, 532
Interferon-α
for hepatitis B, 474t, 500–501
for hepatitis C, 474t, 502
Interleukin-6, in bacterial sepsis, 545
Interleukin-10, in pregnancy, 44–45
Interleukin-12, monocyte physiology and dysfunction and, 1116t, 1117
Interleukin-15, monocyte physiology and dysfunction and, 1116t, 1117
Interleukin-18
monocyte physiology and dysfunction and, 1116t, 1117
urinary, as marker of acute kidney injury, 1205–1206, 1206f
Intermittent mandatory ventilation (IMV), 621–622, 622f–623f
extubation from, 629
synchronized, 622–623
International Staging System (INSS), for neuroblastoma, 1149–1150, 1149t
Internipple distance, 189–190, 190f
Interpupillary distance, 188–189, 189f
Interstitial compartment, regulation of, 369, 369b
Interstitial emphysema, pulmonary, with mechanical ventilation, 630, 630f
Intervention services, early, for high-risk infants, 933–934
Intestine(s). *See also specific part*.
atresias of, 986–989
bacterial colonization of, 1000–1002
abnormal, in preterm infant, 1004
immunity and inflammation and, 1002
duplications of, 991
epithelial cell layer and tight junctions of, 996–997, 997f
intussusception of, 992–993
malformations of, 990–991
malrotation of, 992
mechanical obstruction of, 985–986, 986t, 987f
meconium ileus of, 989–990, 990f
strictures of, necrotizing enterocolitis and, 1026–1027, 1027f
Intoxication, with anesthetic agent, seizures and, 913
Intracardiac echocardiography, 748–749, 749f. *See also* Echocardigraphy (ECHO).
Intracellular fluid compartment, regulation of, 368–369
Intracellular-extracellular interface, regulation of, 369, 369b
Intracranial hemorrhage
neonatal neuroimaging of, 826–830, 827f, 831f
prophylactic indomethacin for, 760
Intracranial injury, risk of, according to type of delivery, 149, 149t
Intralobar sequestrations, bronchopulmonary, 687–688
Intrathoracic pressure, on heart
negative, 605–606, 606f
positive, 606–607, 606f
Intrauterine development, body composition and fluid compartment changes during, 367, 368f
Intrauterine growth restriction (IUGR), 49
adrenal insufficiency associated with, 1282
alcohol abuse and, 116
asymmetric, 136
cigarette smoking and, 52t, 54–55
definition of, 51
diagnosis of, 136
etiologies of, 52
fetal causes of, 52, 52t
fetal origins of adult disease hypothesis and, 1253
long-term consequences of, 56–58
birth weight and, 57
catch-up growth and, 56
cellular mechanisms in, 58
epidemiology of, 56–57
genetics vs. environment in, 57–58
glucose homeostasis in, 57
programming and, 56
maternal causes of, 52t, 53–54
placental causes of, 52–53, 52t
short-term outcomes of, 55–56
symmetric, 136
Intrauterine stress, chronic, persistent pulmonary hypertension of newborn and, 733
Intravascular hydrostatic pressure, increased, in heart-lung interactions, 607–608, 608f, 608b
Intravenous access, for neonates, with malignant disorders, 1162
Intravenous drug abusers, HIV infection in, 122
Intraventricular hemorrhage
in extremely-low-birth-weight infants, 402–403
in preterm infants, 869–873
clinical presentation of, 870
diagnostic imaging for, 874
grading of, 870, 870f, 871t
management of, 872–873
outcome and prognosis of, 870–871
Intraventricular hemorrhage *(Continued)*
pathogenesis of, 869, 870b
prevention of, 871–872
site, incidence, and timing of, 869–870
Intussusception, 992–993
Intussusceptive microvascular growth, lung volume and, 576
Iodine
deficiency of, 1316–1317
for hand hygiene, 561, 561t
Iodophors, for hand hygiene, 561, 561t
IPEX syndrome, in permanent neonatal diabetes mellitus, 1329
IPF-1 gene mutation, in permanent neonatal diabetes mellitus, 1328–1329
Iris
coloboma of, 291, 1427
inspection of, 1423
Iron, in enteral nutrition, 960–961
Irregular rhythms. *See also* Arrhythmia(s).
in fetus, 796
management of, 798
Ischemia
bowel, in necrotizing enterocolitis, 1022–1023
cell death after, 879
focal, 876
spinal cord, 876
Isoflurane, for obstetric anesthesia, 170
Isoimmunization, red blood cell, 93–97. *See also* Rh isoimmunization.
Isoniazid, for tuberculosis, 534, 534t
Isovaleric acidemia, 228–229
Isovaleryl-coenzyme A dehydrogenase deficiency, 228–229
Isradipine, for neonatal hypertension, 1243t
Ivemark's syndrome (renal-hepatic-pancreatic dysplasia), 1189

J

Jackson-Weiss syndrome, 1336t–1337t
Jansen metaphyseal chondrodysplasia, 1268
Jaundice, 311–312
breastfeeding and, 949
cholestatic
bacterial infections associated with, 1032
parenteral nutrition causing, 968
clinical evaluation of, 1133–1136
in first 24 hours of life, 1132
in full-term infant, 1128–1129
neonatal, 283
Jejunoileal atresia, 987–988, 988f–989f
Jet ventilators, 626
Jeune asphyxiating thoracic dystrophy syndrome, 1188–1189
Jeune's syndrome (asphyxiating thoracic dystrophy), 681, 682f
features of, 259t–261t

Jitteriness, neonatal, 904
Junctional ectopic tachycardia (JET)
  fetal, 798
  neonatal, 791
    management of, 795
Juvenile xanthogranuloma, 1160, 1418–1419, 1419f

K

Kabuki syndrome
  cleft lip and/or palate with, 1336t–1337t
  ophthalmic manifestations of, 1436t–1437t
Kallmann's syndrome, 1185
Kangaroo care
  in pain and stress management, 441
  of premature infants, 362–363
Kaposi's sarcoma herpes virus, 486–487
Karyotype, human, 196–197, 197f
Kasabach-Merritt phenomenon, 287–288
Kasabach-Merritt syndrome, 1068–1070
  associated with infantile hemangioma, 1406
Kasai hepatoportoenterostomy, for biliary atresia, 1035–1036
K_{ATP} channel defects
  in congenital hyperinsulinism of infancy, 1322–1323, 1323f–1324f
  in permanent neonatal diabetes mellitus, 1328
  in transient neonatal diabetes mellitus, 1328
Kayexalate, for hyperkalemia, 379t
Keeping Children and Family Safe Act (2003), 120
Kenny-Caffrey syndrome, 1262
Keratitis, infectious, 1428
Keratitis-ichthyosis-deafness syndrome, 1378–1379
Kernicterus, 1134–1136
  prevention of, clinical efforts at, 1137, 1138f–1139f
Ketamine
  for obstetric analgesia, 163
  for obstetric anesthesia, 170
Ketogenesis, disorders of, 1326
Ketone metabolism, defects in, 233–234
17-Ketosteroid reductase deficiency, 1299–1300
Ketotic hyperglycinemia syndrome, 224, 228
Kidney(s). *See also* Nephro-; Renal *entries*.

    laboratory manifestations of, 1151, 1152f
    treatment of, 1153–1154

Leukemia cutis, 1151
Leukocoria (white pupil), 1425
Leukodystrophy, globoid cell (Krabbe disease), 243t, 244–245
Leukomalacia, periventricular
  congenital heart disease and, 804
  neonatal neuroimaging of, 834, 835f
Levothyroxine, for hypothyroidism, 90, 1317–1318
Leydig cell hypoplasia, 1301
Ligamentum venosum, 50
Limb abnormalities, chorionic villous sampling associated with, 185
Limb-girdle muscular dystrophy, 895
Limits of viability
  in premature infants, 347
  resuscitation and, 339
Line infections, lipophilic organisms causing, in neonatal intensive care unit, 568–569
Lines of Blaschko, 1373, 1374f
Lip(s), clefting of. *See* Orofacial clefting.
Lipid(s), in parenteral nutrition, 966–967, 966t
  in neonatal intensive care unit, 970
Lipid emulsions, intravenous, nosocomial infections associated with, 554–555
Lipid storage disease, neutral, 1379
Lipogranulomatosis, Farber, 243t, 245
Lipoid adrenal hyperplasia, congenital, 1280–1281, 1300, 1300b
Lipoprotein(a), prothrombotic disorders and, 1074
LIS1 gene, in lissencephaly, 864–865
Lissencephaly
  cobblestone, 866
  pachygyria and, 864–866, 864f–865f
  with cerebellar hypoplasia, 866
Listeria monocytogenes infection, sepsis due to, 542
Liver. *See also* Hepatic: Hepatitis; Hepato- *entries*
  as primary site of erythropoiesis, 1050
  development of, structural and functional, 974, 976f
  herniation of, with congenital diaphragmatic hernia, 691–692
Liver biopsy, in biliary atresia, 1035, 1035f
Liver disease. *See also specific disease*.
  metabolic, 1031t, 1040–1044
  neonatal
    approach to, 1030–1031, 1030b, 1031t
    infections associated with, 1030b, 1031–1033
  parenteral nutrition–associated, 968–969
Liver failure, secondary to mitochondrial disorders, 1042
Liver tumors, 1044
Lobar emphysema, congenital, 689
Local anesthesia, obstetric, 169
Local anesthetics
  for pain and stress, 440
  obstetric, 164
Long QT syndrome (LQTS), 791–792
Long-chain 3-hydroxy acyl-coenzyme A dehydrogenase deficiency, 232
Low birth weight (LBW), consequences of, 29
Low triiodothyronine syndrome, in premature infants, 1316
Low-birth-weight (LBW) infant(s). *See also* Extremely-low-birth-weight (ELBW) infant(s); Very-low-birth-weight (VLBW) infant(s).
  tertiary care for, 341–342
Lower extremities. *See also specific part*.
  angular deformities of, 1356–1358, 1356f
  assessment of, 282
Low-molecular-weight heparin (LMWH)
  for deep vein thrombosis, 1075
  for renal artery thrombosis, 1236
Low-protein diet, for phenylketonuria, 226
Lugol's solution, for hyperthyroidism, 1319
Lumbar puncture, pain management strategies for, 437–438
Lung(s). *See also* Pulmonary; Respiratory *entries*.
  assessment of, 292
  congenital cystic adenomatoid malformation of, 684–687, 684t
    diagnosis and natural history of, 685–686
    postnatal management of, 686–687, 687f
    prenatal management of, 686
    types of, 684–685
  development of, 571
    alveolarization in, 578, 579f
    branching morphogenesis in, 577
    detoxification systems in, 581
    epithelial cell differentiation in, 572–574
      alveolar, 573–574
      in distal airways, 573
      in proximal airways, 572–573
    epithelial to mesenchymal transition in, 581
    gas exchange surfaces in, 571–572
      alveolar phase of, 572
      canalicular phase of, 572
      embryonic phase of, 571
      pseudoglandular phase of, 571
    growth factors in, 579
    inhibition of, in bronchopulmonary dysplasia, 665
    interdependence of alveolar and vascular development in, 578
Lung(s) *(Continued)*

postnatal maturation of, 1166–1167, 1167f
Renal cortex, necrosis of, 1238
Renal cysts, prenatal diagnosis of, 1176
Renal disorder(s)
chronic. *See* Chronic kidney disease (CKD).
in utero exposure to teratogens and, 1190
inborn errors of metabolism and, 1190
nonimmune hydrops associated with, 68t
postnatal evaluation of, 1177–1180
family history in, 1178
imaging in, 1180
laboratory tests in, 1178–1180
physical examination in, 1178
prenatal and perinatal history in, 1177–1178
prenatal diagnosis of, 1176, 1177f
prenatal management of, 1177
Renal dysplasia, 1183–1185
in regional defects, 1184, 1184f
isolated, 1183–1184
with multiple congenital anomalies, 1184–1185
Renal ectopia, crossed fused, 1182
Renal failure, acute. *See* Acute kidney injury (AKI).
Renal function
in utero, 1166, 1166f, 1166t
maturation of, body composition and fluid compartments regulation and, 370
Renal glycosuria, 1225
Renal hamartoma, 1189–1190
Renal medulla, necrosis of, 1238
Renal neoplasm(s), congenital, 1155–1158
cystic partially differentiated nephroblastoma as, 1157
mesoblastic nephroma as, 1155–1156, 1155f
persistent renal blastema as, 1157
rhabdoid tumor as, 1157
Wilms tumor as, 1156–1157, 1157f, 1157t
Renal osteodystrophy, 1272
chronic kidney disease associated with, 1221
Renal replacement therapy, 1219
continuous, for acute kidney injury, 1214
initiating or withdrawing, ethics of, 1218–1219
Renal transplantation, for chronic kidney disease, 1220
Renal tubular acidosis, 1225–1226
caused by maternal toluene sniffing, 1226
distal, 1225–1226
neonatal hypocalcemia associated with, 1259b, 1263
proximal, 1225
Renal tubular disorders, 1224–1226
hypokalemic, inherited, 1226
Renal tubular dysgenesis, 1189
Renal tubular hyperkalemia, 1226–1227
Renal vascular disease, neonatal, 1235
adrenal hemorrhage as, 1238–1239
arterial obstruction as, 1235–1237, 1236b
cortical and medullary necrosis as, 1238
hypertension as., 1239–1244. *See also* Hypertension, neonatal.
venous obstruction as, 1237–1238, 1237b
Renal vein thrombosis, 1071
neonatal, 1237–1238, 1237b
Renal-coloboma syndrome, 1185
Renal-hepatic-pancreatic dysplasia (Ivemark's syndrome), 1189
Renin-angiotensin-aldosterone system, body composition and fluid compartment regulation and, 371
Repetitive dosing, plateau principle and, 424, 424f
Residual volume (RV), definition of, 598
Respirations. *See* Breathing.
Respiratory acidosis, 388
Respiratory alkalosis, 389
Respiratory center, neuroanatomy of, 585f–586f, 586–588
Respiratory distress syndrome
fluid and electrolyte disturbances in, 380
in infants of diabetic mothers, 82
in late preterm infants, 408
in neonates, 312
in preterm infant, 633–642
causes of, 633
clinical signs of, 636–637, 637b
complications of, 639
diagnostic evaluation of, 633t, 638, 638b
differential diagnosis of, 636–637
incidence of, 620f
laboratory features of, 637–638
pathophysiology of, 620f, 633
prevention of, 639b
antenatal steroids in, 380, 639
asphyxia prophylaxis in, 639
radiographic features of, 638
risk factors for, 633
supportive care for, 638–639
treatment of, 638b, 639–642
continuous positive airway pressure in, 640
surfactant preparations in, 640–642
clinical care after, 642
dosing methods of, 642
dosing numbers and intervals for, 642
historical summary of, 640
selection of, 641
timing of administration of, 641–642, 641t
types of, 640–641, 640t
management of
high-frequency ventilation in, 626
nasal continuous positive airway pressure in, 616
post-extubation continuous positive airway pressure in, 398
symptoms of, 292
Respiratory failure
hypoxemic, 647–650
echocardiographic assessment of, 649–650, 649b
history of, 647, 648b
laboratory and radiologic evaluation of, 649, 649b
physical examination in, 647–648, 648b
pulse oximetry measurements in, 648, 648t
supplemental oxygen response in, 649

Respiratory failure *(Continued)*
hypoxic
neurodevelopmental outcome and, 929–930

serum concentration of, 374t
Sodium acetate, for metabolic acidosis, 387

Sodium balance, negative, growing premature infant with, 381–382
Sodium bicarbonate
for hyperkalemia, 379t, 1213t
for metabolic acidosis, 387
Sodium homeostasis. *See also* Hypernatremia; Hyponatremia
fluid and electrolyte management in, 374–378, 376f, 376b, 379t
Sodium nitroprusside, for neonatal hypertension, 1244t
Sodium polystyrene sulfonate, for hyperkalemia, 1213t
Sodium thiopental, for obstetric anesthesia, 169
Soft tissue sarcoma, 1159
Sole "open field" pattern, in Down syndrome, 190, 192f
Solute, regulation of
extracellular, 369–370
intracellular, 368–369
Somatostatin, for chylothorax, 683–684
Sotalol, for supraventricular tachycardia, in fetus, 798f–799f, 799
South Asia, child deaths in, 23, 24t
Soy formulas, 308. *See also* Infant formula(s).
Spastic diplegia, in preterm infants, 922
Spectroscopy, near-infrared, in circulation compromise assessment, 723–724
Spermatogenesis, 196
Spherocytosis, hereditary, 1092–1093
Sphingolipids, 239
Spina bifida, 1198–1199
Spinal analgesia, obstetric, 166
Spinal anesthesia, obstetric, 168–169
Spinal cord
compression of, in Down syndrome, 198
injury to, perinatal, 885
ischemia of, 876
Spinal dysraphism
associated with infantile hemangioma, 1407
occult, 851, 852f
Spinal muscular atrophy, 897–898, 897f
diaphragmatic, 898
Spinal-epidural analgesia, combined, obstetric, 166
Spiral arteries, remodeling of, 41–42
Spiramycin, for toxoplasmosis, 517t
Spironolactone, for neonatal hypertension, 1243t
Spondyloepiphyseal dysplasia congenita
differential diagnosis of, 268
etiology of, 268
features of, 259t–261t
inheritance of, 268
management of, 268
presentation of, 267
radiologic features of, 267–268, 268f
Spontaneous pneumothorax, 312
Staphylococcal scalded skin syndrome, 1391–1392, 1391f
Staphylococcus, coagulase-negative, in nosocomial infections, 555–556, 555t
Staphylococcus aureus
in atopic dermatitis, 1401
methicillin-resistant, 1390
Staphylococcus aureus infection
nosocomial, 556
of skin, 1390–1392, 1391f
Starling equation, 67–68
Starling forces, in fluid homeostasis, 67–68, 69f
Status marmoratus, 876
Stem cell(s)
biology of, 1047–1048
harvesting of, 1047–1048
in lung development, 581–583
neuronal, 890
pluripotent, 1047, 1108
Stem cell therapy, 890
Stem cell transplantation, hematopoietic, 1048
Stenosis. *See also at anatomic site*.
vs. atresia, 986–987
Stepping reflex, 297
Sternal fusion, defects of, 680
Sternomastoid tumor, 980
Steroidogenesis
adrenocortical, 1296
and maternal-placental-fetal unit, 1247–1248, 1247f
Steroids. *See also specific steroid*.
antenatal. *See* Antenatal steroids.
for neonatal shock, 728–730, 730f–731f
Stickler syndrome, 192–193, 1332–1333, 1333f
cleft lip and/or palate with, 1336t–1337t
Stillbirth, 28
asphyxia-induced, 31
definition of, 28
Stimulants, respiratory, 628
Stomach. *See also* Gastric; Gastro- *entries*.
development of, structural and functional, 973–974

Tricuspid valve
  anatomy of, 763
  Ebstein's anomaly of, 779–780, 779f–780f
Triiodothyronine (T_3)
  fetal, 88, 90, 1307–1309, 1309f
  maternal, 87–88
  postnatal secretion of, 1310, 1311f
  structure of, 1310f
  synthesis of, 1309
  transport of, 1309–1310
Triiodothyronine (T3) syndrome, low, in premature infants, 1316
Trimethoprim-sulfamethoxazole, prophylactic, for urinary tract infections, 1229
Triplets, fetal morbidity and mortality for, 63, 63t
Triploidy (69,XXX or 69,XXY), 201
Trisomy13. *See* Patau syndrome (trisomy 13).
Trisomy18. *See* Edwards syndrome (trisomy 18).
Trisomy21. *See* Down syndrome (trisomy 21).
Tromethamine
  for hyperkalemia, 379t
  for metabolic acidosis, 387

Trophoblast, 37–38
differentiation of, 41–42, 41f, 43f
Truncal incurvation reflex, 297
Truncus arteriosus, 774–775
classification of, 774, 774f–775f
Trypsinogen, immunoreactive, in sickle cell disease, 325
TUBA1A gene, in lissencephaly, 864–865
Tuberculin skin test (TST), for tuberculous, 532
Tuberculosis
congenital, 529–535
clinical presentation of, 531, 531t, 532f
definition of, 529–530
diagnosis of, 532–533, 533f, 534t
epidemiology of, 530, 530t
pathophysiology of, 530–531
prevention of, 535
prognosis of, 535
treatment of, 534–535, 534t
latent, management of, 535, 536f
perinatal, 531
Tuberous sclerosis, 1187–1188
neonatal, neuroimaging of, 841, 842f
ophthalmic manifestations of, 1436t–1437t
Tumor(s). *See also at anatomic site; specific tumor*.
malignant. *See* Malignant disorder(s); *specific neoplasm*.
nonimmune hydrops associated with, 68t
Tumor biology, in neuroblastoma, 1149, 1149t
Tumor necrosis factor-α (TNF-α), in bacterial sepsis, 544–545
Turner syndrome (45,X), 200–201
clinical features of, 200–201
22q11 deletion syndrome(s), 204–205, 205f, 464–465, 1337–1338. *See also* DiGeorge syndrome; Velocardiofacial syndrome.
cleft lip and/or palate with, 1336t–1337t
ophthalmic manifestations of, 1436t–1437t
Twins
delivery of, 155–156
monochorionic, monoamniotic, 156
nonvertex-nonvertex, 156
vertex-nonvertex, 155–156
vertex-vertex, 155
dizygotic, 60, 60t, 61f
fetal morbidity and mortality for, 63, 63t
maternal age and, 61
monozygotic, 60–61, 60t, 61f–62f
nonimmune hydrops in, 67, 68t
Twin-twin transfusion syndrome
anemia associated with, 1086
in monochorionic twins, 64
with hydrops, 71
Twin-twin transmission, of malignant disorders, 1144
Two-dimensional echocardiography., 741. *See also* Echocardiography (ECHO).
Tyrosinemia, type I, 1225
hereditary, 223–224, 1040
screening for, 322
Tyson's algorithm, 18

U

UBE3A gene, in Angleman syndrome, 207
Ulceration, in infantile hemangioma, 1406, 1406f
Ultrasonography
basic components of, 741–743
cardiovascular. *See* Echocardiography (ECHO).
Doppler
fetal anemia screening with, 96–97, 96f
neonatal neuroimaging with, 816
compression, 819
for prenatal genetic diagnosis
during first trimester, 181
abnormal ductus venosus blood flow and, 182–183
absent nasal bone and, 182
cystic hygroma and, 182
nuchal translucency measurement and, 181–182
in second trimester, 182–183
genetic sonogram, 183
three-dimensional, 183
in high-risk pregnancy, 134–135
in neonatal screening, 302–303
cardiac findings in, 303
central nervous system findings in, 302–303
gastrointestinal findings in, 303
urinary tract findings in, 303
in nonimmune hydrops, 70
in pregnancy dating, 131
in second and third trimesters, 131–132
neonatal neuroimaging with, 816–819
advantages and disadvantages of, 842
anatomic (gray scale), 816
clinical indications for, 819
Doppler, 816
compression, 819
scanning technique of, 816–819, 817f–819f
transducers in, 816
pelvic, of ambiguous genitalia, 1290, 1291f–1292f
physics of, 741
renal
postnatal, 1180
prenatal, 1176
two-dimensional, 741
Umbilical artery(ies), 38, 40f
Doppler velocimetry of, 139
single, 306, 1007
Umbilical artery catheters, in respiratory failure, 612
Umbilical cord, 50
bleeding from, anemia associated with, 1085b, 1087
care of, 306
infection prevention with, 562–563
cord accidents and, 158, 158f
lesions of, 1007
separation of, delay in, 1007
Umbilical cord blood, hematopoietic stem cells from, 1047–1048
Umbilical cord blood vessels
noncoiled, 1007
percutaneous sampling of, 185, 185b
Umbilical granuloma, 1007
Umbilical hernia, 1007, 1008f
Umbilical ligaments, medial, 50
Umbilical polyp, 1007, 1008f
Umbilical region, disorders of, 1007
Umbilical stump, infection of, 1392
Umbilical veins, 40f
development of, 709, 710f
Undernutrition. *See* Malnutrition.
Undervirilization, disorders leading to, 1279–1281
Underweight, maternal, associated with preterm birth, 142
Uniparental disomy (UPD), 184–185, 206
in Prader-Willi syndrome, 206–207
United Nations Children's Fund (2005, 2008a), 33
United Nations Children's Fund (2007), 33
Upper extremities. *See also specific part*.
assessment of, 282
Urachal cyst, 1013
Urachal lesions, 1012–1013, 1013f
Urachus
blind
external, 1012–1013, 1013f
internal, 1013, 1013f
completely patent, 1012, 1013f
Urea cycle defects, 219–221
screening for, 322
Ureter(s), ectopic, 1195–1196
Ureterocele, 1195, 1196f
Ureteropelvic junction obstruction, 1192–1193, 1192f–1193f
Ureterovesical junction obstruction, 1193–1194, 1194f
Urethral mobilization, total, 1305
Urethral valves, posterior, 1194–1195, 1195f
renal adysplasia in, 1184
Uricosuria, postnatal, 1180

Uridine diphosphate-glucouronosyltransferase (UGT) system, 1126–1128
Urinary tract, prenatal ultrasound screening of, 303
Urinary tract disease
  postnatal evaluation of, 1177–1180
    family history in, 1178
    imaging in, 1180
    laboratory tests in, 1178–1180
    physical examination in, 1178
    prenatal and perinatal history in, 1177–1178
  prenatal diagnosis of, 1176, 1177f
  prenatal management of, 1177
Urinary tract infection(s)
  Candida, in neonatal intensive care unit, 566
  neonatal, 1228–1231
    circumcision and, 305
    diagnosis of, 1228–1229, 1229f
    epidemiology of, 1228
    obstructive uropathy complicating, 1231, 1232f
    pathophysiology of, 1230–1231, 1231f
    radiographic work-up of, 1229–1230, 1230f
    treatment of, 1229
  postnatal evaluation of, 1179
Urine
  concentration of, 1170–1171, 1171f
  fetal, hypotonic, 1177
  neonatal, concentration/dilution of, 1179
  postnatal evaluation of, 1179–1180
Urine analysis, for lysosomal storage diseases, 248
Urine cultures, for bacterial sepsis, 544
Urine output
  low, circulatory compromise and, 723
  water loss through, 372–373
Urine toxicology testing, for maternal substance abuse, 120
Urogenital sinus, 1199–1200, 1290
Uropathy, obstructive, 1192–1200
  urinary tract infections complicated by, 1231, 1232f
Ursodeoxycholic acid, for cystic fibrosis, 1038–1039
Urticaria pigmentosa, 1419, 1419f
U.S. national standard birth certificate, 7f
Uterine circulation, during pregnancy, 160–161
Uterine natural killer (NK) cells, phenotypic and functional features of, 42–45, 44f, 45t, 46f
Uterine tissue, inflammatory mediators and cytokines produced by, 446
Uvea, inspection of, 1423
Uvula, clefting of, 1333

V

Vaccine(s). *See* Immunization; *specific vaccine*.
VACTERL association, 193, 982
VACTERL/VATER association, 1185
Vacuum extractor, for vaginal delivery, 149–152, 150f
  complications associated with, 150–151
Vagally-mediated reflexes, in respiration, 588
Vaginal delivery. *See* Delivery, vaginal.
Vaginal infections, treatment of, in preterm birth prevention, 144
Vaginoplasty, 1304
  flap, 1305
  pull-through, 1305
Valganciclovir, for CMV infection, 474t
Van der Woude's syndrome, cleft lip and/or palate with, 1336t–1337t
Vanishing testis syndrome, 1302
Varicella zoster virus (VZV) infection, 476–478
  maternal and perinatal
    clinical manifestations of, 476–477
    diagnosis of, 477
    epidemiology of, 476
    pathogenesis of, 476–477
    prevention of, 477–478
    treatment of, 477
  nosocomial, 558
VariZIG, after exposure to varicella zoster, 477–478, 478b
Vasa previa, 1086–1087
Vascular access
  in congenital heart disease, 354
  in extremely-low-birth-weight infants, 395
Vascular accidents, nonimmune hydrops associated with, 68t
Vascular anomalies., 1405–1409. *See also* Hemangioma.
  characteristics of, 1407t
  classification of, 1405
Vascular endothelial growth factor (VEGF)
  for neuroprotection, 888
  in lung development, 579
  in preeclampsia, 108
  placental production of, 39–41, 47–48
  poor expression of, 41–42
Vascular malformations
  cutaneous, 1371
    characteristics of, 1407t
    clinical findings in, 1409–1412
    treatment of, 1412
  neonatal neuroimaging of, 835–836
  nonimmune hydrops associated with, 68t
Vascular rings, tracheal compression by, 676
Vascular system, development of
  in central nervous system, 811–812
  inhibition of, in bronchopulmonary dysplasia, 665
Vasculitis, umbilical, 50
Vasculogenesis, pulmonary, 575
Vasoconstriction, in patent ductus arteriosus
  balance between vasorelaxation and, 752–755
  relationship between anatomic closure and, 756–757
Vasodilators, for neonatal hypertension, 1243, 1243t–1244t
Vasopressin, body composition and fluid compartment regulation and, 371
Vasoregulation, peripheral, abnormal, 719
Vecuronium, for tracheal intubation, 437
Vein of Galen malformation, neonatal neuroimaging of, 827, 827f
Velocardiofacial syndrome, 192–193, 1337
Venereal Disease Research Laboratory (VDRL) test, for syphilis, 520
Venous malformation, 1411
Ventilation
  alveolar, 602–604, 603f
  assisted
    during neonatal transport, 349
    in delivery room resuscitation, 334–336, 336f
  high-frequency. *See* High-frequency ventilation (HFV)
  mechanical. *See* Mechanical ventilation (MV).
  monitoring of, 612
  noninvasive
    clinical application of, 617–618
    devices for, 617
    potential drawbacks of, 618
Ventilation-perfusion imbalance, in neonates, 605, 606t
Ventilation-perfusion relationships, 604–605, 605f, 606t
Ventilator(s), high-frequency
  jet, 626
  oscillatory, 626
  settings for, 627
Ventilatory depression, hypoxic, in neonate, 593
Ventricle(s)
  common, definition of, 763
  development of, 708, 708f
  left, 708
  morphology of, 763
  right, 708
    double-outlet. *See* Double-outlet right ventricle (DORV).
Ventricular septal defect(s), 313, 767–769
  classification of, 767, 767f
  transposition of great arteries associated with, 773

Ventricular septum, development of, 708, 708f
Ventricular tachycardia (VT), neonatal, 791–793, 792f
  management of, 795
Ventriculoarterial connections, concordant and discordant, 764
Ventriculomegaly, prenatal ultrasound screening for, 303
Vermont-Oxford Network, interventions and outcomes of extremely-low-birth-weight infants in, 392t
Versalet incumarmer, 361
Vertebral malformations, congenital, 1358
Vertex-nonvertex twins, delivery of, 155–156
Vertex-vertex twins, delivery of, 155
Very-long-chain acyl-coenzyme A dehydrogenase deficiency, 231–232
Very-long-chain fatty acid(s), in peroxisome disorders, 254–255
Very-long-chain fatty acid oxidation defects, 231–233
Very-low-birth-weight (VLBW) infant(s)
  CMV-seropositive breast milk and, 484
  left-to-right shunting in, 717, 717f
  management of
    parenteral intakes in, 964t
    pharmacologic principles and pitfalls in, 418b
  skin care for, 563
Vesicles, 1368–1369
Vesicostomy, for hostile bladder, 1199
Vesicoureteral reflux, 1231–1234, 1232f–1234f
  grading scale of, 1231–1232, 1233f
  primary, 1231
  secondary, 1231
Viability, limits of
  in premature infants, 347
  resuscitation and, 339
Video-assisted thorascopic surgery (VATS), 689–690
Villi, placental, 37–38, 40f
Viral infections. *See also specific infection*.
  nosocomial, 557–558
  of fetus and newborn, 468, 469f
    diagnostic approach to, 468–470, 469b, 470t
Viral pathogens, causing congenital infections, 469b
Virchow's triad, 1070
Virilization, of female, 1293, 1293f
  disorders leading to, 1277–1279
Viscera, involvement of, in infantile hemangioma, 1407
Visceral sidedness, of organs, definition of, 763
Viscous tissue resistance, 598
Vision
  assessment of, 296
  development of, 1424
  impaired, 1424
    abusive head trauma and, 1433
Visitation policies, for infection control, 559, 559b
Vitamin(s)
  in breast milk and fortifiers, 955t
  in enteral nutrition, 961
  in parenteral nutrition, 968, 969t
  in premature formulas, 956t–957t
    postdischarge, 962t
  recommended intake of, 959t
  supplemental, 961
Vitamin A
  for bronchopulmonary dysplasia prevention, 666, 666f
    in extremely-low-birth-weight infants, 398
  supplementation with, 26
Vitamin B_6 dependency, seizures and, 912
  treatment of, 915
Vitamin B_{12}, for L-methylmalonyl-coenzyme A mutase deficiency, 228
Vitamin C, birth weight and, 54
Vitamin D
  disorders of, hypocalcemia resulting from, 1259b, 1263–1264
  for hypocalcemia, 1265
  parathyroid-renal hormonal axis and, 1257–1258
  supplemental, for preterm breast-fed infants, 1271
  toxicity of, hypercalcemia associated with, 1268
Vitamin D deficiency. *See also* Rickets.
  breastfeeding and, 940
  maternal, 1263–1264
Vitamin E, for premature infants, 1101
Vitamin E deficiency, hemolytic anemia and, 1101
Vitamin K, to prevent bleeding, 304–305, 1068
Vitamin K deficiency
  bleeding and, 1068, 1068t
  breastfeeding and, 940
Vitelline veins, development of, 709, 710f
Vitreous
  inspection of, 1424
  primary, persistent hyperplastic, 1427
Vocal cord paralysis, 674
Voiding
  delayed, definition of, 310
  in neonate, 310
Voiding cystourethrography (VCUG)
  of urinary tract infections, 1229–1230, 1229f
  of vesicoureteral reflux, 1231–1232, 1234f
  postnatal, 1180
Volume administration, for neonatal shock, 725
Volume of distribution, apparent, 420
Volume-controlled ventilation, 624
Volume-targeted ventilation, 624–625
  weaning from, 628
Volutrauma, bronchopulmonary dysplasia and, 661–663, 663f
Volvulus, midgut, 992, 992f
  transport of neonate with, 356
Vomiting. *See* Emesis.
Von Willebrand disease, 1064–1065
  acquired, 1065
  classification of, 1064t
  etiology and pathophysiology of, 1064–1065
  treatment of, 1065
Von Willebrand factor (VWF), 1056, 1064–1065

W

Walker-Warburg syndrome, 866, 893, 893f
Warfarin, in utero exposure to, ophthalmic manifestations of, 1438t
Warmers, radiant, 358–360
Waste nitrogen therapy, 219–221
Water
  free, excretion of, 1170
  reabsorption of, 1169–1170
  requirements for, management of, 368f, 373–374, 373t
Water deficit/excess, free, calculation of, 374
Water loss(es), 372–373
  insensible, 372–373
    formula estimating, 373
  sensible, 372–373
  surgical, 382
  transepidermal, 373
    neonatal rates of, 1365, 1365f
Weaning
  from high-frequency ventilation, 629
  from mechanical ventilation, 627–629
    automated and computer-assisted, 629
Well baby nursery, nosocomial infections in
  anatomic sites of, 552
  incidence of, 551–552
Wet lung disease, 543
WHIM syndrome, 1113t, 1114
White blood cell count, in bacterial sepsis, 544, 544t
White matter
  injury to, 873–874, 873f
    clinical factors in, 873–874
    diagnostic imaging for, 874
    pathogenesis of, 874
  periventricular, vascular development in, 811

White pupil (leukocoria), 1425
White reflex, 291
Williams-Beuren syndrome, 203, 204f, 1267
Wilms tumor, 1156–1157
  clinical manifestations of, 1156
  evaluation and staging of, 1156–1157, 1157f, 1157t
  hereditary associations and congenital anomalies with, 1156
  prognostic factors for, 1156
  treatment of, 1157
Wiskott-Aldrich syndrome, 464
Wolcott-Rallison syndrome, in permanent neonatal diabetes mellitus, 1329
Wolf-Hirschhorn syndrome, 201–202
  cleft lip and/or palate with, 1336t–1337t
Wolman disease, 243t, 246
  diet therapy for, 249
Woods-Screw maneuver, for shoulder dystocia, 152–153
World Health Organization (WHO), Essential Newborn Care package developed by, 29
World Health Organization (WHO) approach, to malaria prevention, 529
World Health Organization (WHO) definition
  of maternal mortality, 1
  of preterm birth, 140
Wound(s)
  healing of, fetal vs. adult, 1364, 1364t
  occlusive dressing materials for, 1368t
WT1 gene, 1144, 1276
  in genital tract development, 1303
Wyburn-Mason syndrome, 1411

X

Xanthine, for apnea of prematurity, 595–596, 596f
Xanthogranuloma, juvenile, 1160, 1418–1419, 1419f
Xenon, for neuroprotection, 891
X-linked dominant hypophosphatemia, 1272
X-linked recessive ichthyosis, 1378
XPB gene, mutations of, 1379
XPD gene, mutations of, 1379
46,XX karyotype, 196
46,XY gonadal dysgenesis
  complete, 1301
  partial, 1301–1302
46,XY karyotype, 196, 197f

Y

Yolk sac, as primary site of erythropoiesis, 1049–1050
Yolk sac tumor (endodermal sinus tumor), 1154

Z

Zanamivir, for influenza A and B, 474t
Zavanelli maneuver, for shoulder dystocia, 152–153
Zellweger cerebro-hepato-renal syndrome, 1190
Zellweger syndrome, 253–254, 253t
  renal disorders associated with, 1190
Zero-order kinetics, of drugs, 422, 422f, 422b
Zinc, in enteral nutrition, 960
Zinc deficiency, fetal growth restriction related to, 54
Zinc supplements, 26
Zona pellucida manipulation, 61–62
Zoster. *See* Varicella zoster virus (VZV) infection.
Zygosity, in multiple-fetus pregnancies, 60–61, 60t, 61f–62f
  complications associated with, 63–64, 64t
  diagnosis of, 60
