Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

CONTRIBUTORS

Steven H. Abman, MD
Professor
Department of Pediatrics
University of Colorado School of Medicine
Director
Pediatric Heart Lung Center
Co-Director
Pulmonary Hypertension Program
The Children's Hospital
Aurora, Colorado

Amina Ahmed, MD
Pediatric Infectious Disease
Department of Pediatrics
Carolinas Medical Center
Levine Children's Hospital
Charlotte, North Carolina
Adjunct Clinical Associate Professor
Department of Pediatrics
University of North Carolina
Chapel Hill, North Carolina

Marilee C. Allen, MD
Professor of Pediatrics
Johns Hopkins University School of Medicine
Co-Director
Neonatal Intensive Care Unit Developmental Clinic
Kennedy Krieger Institute
Baltimore, Maryland

David Askenazi, MD, MSPH
Assistant Professor
Division of Nephrology and Transplantation
Department of Pediatrics
University of Alabama at Birmingham
Birmingham, Alabama

Stephen A. Back, MD, PhD
Associate Professor of Pediatrics and Neurology
Oregon Health and Science University
Clyde and Elda Munson Professor of Pediatric Research
Director
Neuroscience Section
Papé Family Pediatric Research Institute
Portland, Oregon

H. Scott Baldwin, MD
Professor of Pediatrics and Cell and Developmental Biology
Vanderbilt University Medical Center
Chief
Division of Pediatric Cardiology
Co-Director
Pediatric Heart Institute
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennessee

Roberta A. Ballard, MD
Professor
Department of Pediatrics and Neonatology
University of California, San Francisco School of Medicine
San Francisco, California

Eduardo Bancalari, MD
Professor of Pediatrics
Director
Division of Neonatology
University of Miami Miller School of Medicine
Chief
Newborn Service
Jackson Memorial Hospital
Miami, Florida

Carlton M. Bates, MD
Associate Professor
Department of Pediatrics
University of Pittsburgh School of Medicine
Chief and Program Director
Pediatric Nephrology
Children's Hospital of Pittsburgh
Rangos Research Building
Pittsburgh, Pennsylvania

Donald L. Batisky, MD
Associate Professor of Pediatrics
Division of Pediatric Nephrology
Emory University School of Medicine
Director
Pediatric Hypertension Program
Children's Healthcare of Atlanta
Atlanta, Georgia

Stephen Baumgart, MD
Professor of Pediatrics
Department of Neonatology
George Washington University School of Medicine and Health Sciences
Children's National Medical Center
Washington, DC

Thomas J. Benedetti, MD, MHA
Professor
Department of Obstetrics and Gynecology
University of Washington School of Medicine
Seattle, Washington

Gerard T. Berry, MD
Professor
Department of Pediatrics Harvard Medical School
Director
Metabolism Program
Division of Genetics
Children's Hospital Boston
Boston, Massachusetts

Diana W. Bianchi, MD
Natalie V. Zucker Professor of Pediatrics, Obstetrics and Gynecology
Tufts University School of Medicine
Vice Chair for Research
Department of Pediatrics
Floating Hospital for Children
Boston, Massachusetts

Gil Binenbaum, MD, MSCE
Assistant Professor
Department of Ophthalmology
University of Pennsylvania School of Medicine
Attending Surgeon
Department of Ophthalmology
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Sureka Bollepalli, MD
Assistant Professor
Department of Pediatrics
University of South Florida Diabetes Center
Tampa, Florida

Sonia L. Bonifacio, MD
Assistant Adjunct Professor
Department of Pediatrics and Neonatology
University of California, San Francisco School of Medicine
Co-Director
Neurological Intensive Care Nursery
University of California, San Francisco Medical Center
Benioff Children's Hospital
San Francisco, California

Mitchell S. Cairo, MD
Professor of Pediatrics and Medicine and Pathology
Chief
Division of Blood and Marrow Transplantation
Department of Pediatrics
New York-Presbyterian Morgan Stanley Children's Hospital
Columbia University Medical Center
New York, New York

Katherine H. Campbell, MD, MPH
Fellow
Department of Obstetrics, Gynecology, and Reproductive Sciences
Yale School of Medicine
New Haven, Connecticut

Michael Caplan, MD
Chairman
Department of Pediatrics
NorthShore University HealthSystem
Evanston, Illinois
Professor
Department of Pediatrics
University of Chicago Pritzker School of Medicine
Chicago, Illinois

Stephen Cederbaum, MD
Professor Emeritus
Departments of Psychiatry and Pediatrics and Human Genetics
University of California, Los Angeles
Attending Physician
Department of Pediatrics
Ronald Reagan UCLA Medical Center
Los Angeles, California
Consulting Physician
Department of Pediatrics
Santa Monica UCLA Medical Center
Santa Monica, California

Sudhish Chandra, MD, FAAP
Medical Director
Department of Neonatology
Neonatal Intensive Care Unit
St. Anthony Medical Center
Crown Point, Indiana

Ming Chen, MD, PhD
Assistant Professor
Department of Pediatrics
University of Michigan
Ann Arbor, Michigan

Nelson Claure, MSc, PhD
Research Associate Professor of Pediatrics
Director
Neonatal Pulmonary Research Laboratory
Department of Pediatrics
Division of Neonatology
University of Miami Miller School of Medicine
Miami, Florida

Ronald I. Clyman, MD
Professor
Department of Pediatrics
Senior Staff
Cardiovascular Research Institute
University of California, San Francisco
San Francisco, California

Bernard A. Cohen, MD
Professor of Pediatrics and Dermatology
Johns Hopkins University School of Medicine
Director
Pediatric Dermatology
Johns Hopkins Children's Center
Baltimore, Maryland

F. Sessions Cole, MD
Park J. White, MD, Professor of Pediatrics
Assistant Vice Chancellor for Children's Health
Director
Division of Newborn Medicine
Washington University School of Medicine
Chief Medical Officer
St. Louis Children's Hospital
St. Louis, Missouri

Lawrence Copelovitch, MD
Assistant Professor
University of Pennsylvania School of Medicine
Attending in Nephrology
Department of Pediatrics
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Michael Cunningham, MD, PhD
Professor and Chief
Division of Craniofacial Medicine
Department of Pediatrics
University of Washington
Medical Director
Craniofacial Center
Seattle Children's Hospital
Seattle, Washington

Alejandra G. de Alba Campomanes, MD, MPH
Assistant Professor of Ophthalmology
Division of Pediatric Ophthalmology and Strabismus
University of California, San Francisco
Director
Department of Pediatric Ophthalmology and Strabismus
San Francisco General Hospital
San Francisco, California

Ellen Dees, MD
Assistant Professor of Pediatrics
Division of Pediatric Cardiology
Monroe Carell Jr. Children's Hospital at Vanderbilt
Nashville, Tennessee

Scott C. Denne, MD
Professor of Pediatrics
Indiana University School of Medicine
Riley Hospital for Children
Indianapolis, Indiana

Sherin U. Devaskar, MD
Mattel Endowed Executive Chair and Distinguished Professor
Department of Pediatrics
David Geffen School of Medicine
Assistant Vice Chancellor for Children's Health
University of California, Los Angeles Health System
Physician in Chief
Mattel Children's Hospital
Los Angeles, California

Robert M. DiBlasi, RRT-NPS, FAARC
Respiratory Research Coordinator
Center for Developmental Therapeutics
Seattle Children's Research Institute
Seattle, Washington

Reed A. Dimmitt, MD, MSPH
Associate Professor of Pediatrics and Surgery
Director
Division of Neonatology and Pediatric Gastroenterology and Nutrition
University of Alabama at Birmingham
Birmingham, Alabama

Eric C. Eichenwald, MD
Associate Professor
Vice Chair and Division Director
Neonatology
Department of Pediatrics
University of Texas Health Science Center
Texas Children's Hospital
Houston, Texas

Eli M. Eisenstein, MD
Senior Pediatrician
Department of Pediatrics
Hadassah-Hebrew University Medical Center
Mount Scopus, Jerusalem, Israel

Jacquelyn R. Evans, MD
Medical Director
Newborn/Infant Intensive Care Unit
The Children's Hospital of Philadelphia
Associate Division Chief
Department of Neonatology
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Kelly Evans, MD
Fellow
Division of Craniofacial Medicine
Department of Pediatrics
University of Washington
Craniofacial Center
Seattle Children's Hospital
Seattle, Washington

Diana L. Farmer, MD, FAAP, FACS, FRCS
Professor of Surgery, Pediatrics, and Obstetrics, Gynecology, and Reproductive Sciences
Chief
Division of Pediatric Surgery
Vice Chair
Department of Surgery
University of California, San Francisco School of Medicine
Surgeon-in-Chief
University of California, San Francisco Medical Center
Benioff Children's Hospital
San Francisco, California

Patricia Ferrieri, MD
Professor
Chairman's Fund Endowed Chair in Lab Medicine and Pathology
Division of Infectious Diseases
Department of Pediatrics
University of Minnesota Medical School
Minneapolis, Minnesota

Donna M. Ferriero, MS, MD
Professor and Interim Chair of Pediatrics
Professor of Neurology
Co-Director
Newborn Brain Research Institute
University of California, San Francisco School of Medicine
Physician-in-Chief
University of California, San Francisco Medical Center
Benioff Children's Hospital
San Francisco, California

Neil N. Finer, MD
Division of Neonatal-Perinatal Medicine
Department of Pediatrics
University of California, San Diego
San Diego, California

Maria Victoria Fraga, MD
Fellow
Division of Neonatology and Pediatrics
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Lydia Furman, MD
Associate Professor of Pediatrics
Case Western Reserve University School of Medicine
Rainbow Babies and Children's Hospital
Cleveland, Ohio

Susan Furth, MD, PhD
Associate Professor
Department of Pediatrics
Johns Hopkins University School of Medicine
Associate Professor
Department of Epidemiology
Johns Hopkins Bloomberg School of Public Health
Baltimore, Maryland

Estelle B. Gauda, MD
Professor
Department of Pediatrics
Division of Neonatology
Johns Hopkins University School of Medicine
Baltimore, Maryland

Bertil Glader, MD, PhD
Professor of Pediatrics (Hematology/Oncology) and Pathology
Stanford University School of Medicine
Stanford, California

Christine A. Gleason, MD
W. Alan Hodson Endowed Chair in Pediatrics
Professor of Pediatrics
Head, Division of Neonatology
Department of Pediatrics
University of Washington
Seattle Children's Hospital
Seattle, Washington

Michael J. Goldberg, MD
Clinical Professor
Department of Orthopedics and Sports Medicine
University of Washington
Director
Skeletal Health Program
Department of Orthopedics
Seattle Children's Hospital
Seattle, Washington

Fernando Gonzalez, MD
Assistant Professor
Department of Pediatrics
Division of Neonatology
University of California, San Francisco Medical Center
Benioff Children's Hospital
San Francisco, California

Sameer Gopalani, MD
Clinical Assistant Professor
Department of Obstetrics and Gynecology
University of Washington School of Medicine
Division of Perinatal Medicine
Swedish Medical Center
Seattle, Washington

P. Ellen Grant, MD
Associate Professor
Department of Radiology
Harvard Medical School
Founding Director
Center for Fetal-Neonatal Neuroimaging and Developmental Science Center
Chair
Department of Neonatology
Children's Hospital Boston
Boston, Massachusetts

Carol L. Greene, MD
Professor
Departments of Pediatrics and Obstetrics, Gynecology, and Reproductive Sciences
Division of Genetics
University of Maryland School of Medicine
Baltimore, Maryland

Salvador Guevara-Gallardo, MD
Surgeon
University of California, San Francisco Medical Center
Benioff Children's Hospital
San Francisco, California

Jean-Pierre Guignard, MD
Honorary Professor of Pediatrics
Lausanne University Medical School
Lausanne, Switzerland

Susan Guttentag, MD
Associate Professor
Department of Pediatrics
University of Pennsylvania School of Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Chad R. Haldeman-Englert, MD
Assistant Professor
Department of Pediatrics
Section on Medical Genetics
Wake Forest University School of Medicine
Winston-Salem, North Carolina

Thomas Hansen, MD
Professor
Department of Pediatrics
University of Washington School of Medicine
Chief Executive Officer
Seattle Children's Hospital
Seattle, Washington

Anne V. Hing, MD
Associate Professor
Division of Craniofacial Medicine
Department of Pediatrics
University of Washington
Craniofacial Center
Seattle Children's Hospital
Seattle, Washington

A. Roger Hohimer, PhD
Associate Professor
Department of Obstetrics
Division of Perinatology
Oregon Health and Science University
Portland, Oregon

Margaret K. Hostetter, MD
Professor and Chair
Department of Pediatrics
Yale School of Medicine
New Haven, Connecticut

Andrew D. Hull, MD, FRCOG, FACOG
Professor of Clinical Reproductive Medicine
University of California, San Diego
Director
Maternal Fetal Medicine Fellowship
University of California, San Diego Medical Center
La Jolla, California

J. Craig Jackson, MD, MHA
Professor
Department of Pediatrics
Division of Neonatology
University of Washington
Neonatal Intensive Care Unit Medical Director
Seattle Children's Hospital
Seattle, Washington

Lucky Jain, MD, MBA
Executive Vice Chairman
Department of Pediatrics
Emory University
Medical Director
Emory Children's Center
Atlanta, Georgia

Vandana Jain, MD
Associate Professor
Division of Pediatric Endocrinology
Department of Pediatrics
All India Institute of Medical Sciences
New Delhi, India

Halima Saadia Janjua, MD
Pediatric Nephrology Fellow
Department of Pediatrics
Ohio State University
Nationwide Children's Hospital
Columbus, Ohio

Sandra E. Juul, MD, PhD
Professor
Department of Pediatrics
University of Washington
Seattle, Washington

Satyan Kalkunte, MPharm, PhD
Research Associate
Superfund Basic Research Program
Department of Pediatrics
Women and Infants' Hospital of Rhode Island
Warren Alpert Medical School of Brown University
Providence, Rhode Island

Bernard S. Kaplan, MB, BCh
Professor of Pediatrics
University of Pennsylvania School of Medicine
Attending in Nephrology
Department of Pediatrics
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Roberta L. Keller, MD
Assistant Professor of Clinical Pediatrics
University of California, San Francisco
Director
Neonatal Extracorporeal Membrane Oxygenation Program
University of California, San Francisco Medical Center
Benioff Children's Hospital
San Francisco, California

Thomas F. Kelly, MD
Clinical Professor and Chief
Division of Perinatal Medicine
Department of Reproductive Medicine
University of California, San Diego School of Medicine
La Jolla, California
Director
Maternity Services
University of California, San Diego Medical Center
San Diego, California

Steven E. Kern, PhD
Associate Professor of Pharmaceutics, Anesthesiology, and Bioengineering
University of Utah
Salt Lake City, Utah

Nanda Kerkar, MD
Department of Pediatrics
Division of Pediatric Hepatology
Recanati-Miller Transplantation Institute
The Mount Sinai Medical Center
New York, New York

John P. Kinsella, MD
Professor of Pediatrics
Section of Neonatology
University of Colorado School of Medicine
Medical Director
Newborn/Young Child Transport Service
Co-Director
Newborn Extracorporeal Membrane Oxygenation Service
The Children's Hospital
Aurora, Colorado

Roxanne Kirsch, MD, FRCPC, FAAP
Cardiac Intensivist
Departments of Anesthesia and Critical Care
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Monica E. Kleinman, MD
Associate Professor of Anesthesia
Department of Pediatrics Harvard Medical School
Clinical Director
Medical-Surgical Intensive Care Unit
Department of Anesthesia
Division of Critical Care Medicine
Department of Anesthesia, Perioperative, and Pain Medicine
Medical Director
Critical Care Transport Program
Children's Hospital Boston
Boston, Massachusetts

Thomas S. Klitzner, MD, PhD
Jack H. Skirball Professor and Chief
Pediatric Cardiology
David Geffen School of Medicine
University of California, Los Angeles
Los Angeles, California

Sarah M. Lambert, MD
Assistant Professor of Surgery in Urology
University of Pennsylvania School of Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

John D. Lantos, MD
Professor of Pediatrics
University of Missouri at Kansas City
Director
Children's Mercy Bioethics Center
Children's Mercy Hospital
Kansas City, Missouri
Visiting Professor of Pediatrics
University of Chicago
Chicago, Illinois

Tina A. Leone, MD
Assistant Professor of Pediatrics
University of California, San Diego
San Diego, California

Mary Leppert, MB, BCh
Assistant Professor of Pediatrics
Johns Hopkins University School of Medicine
Attending Physician
Neurodevelopmental Medicine
Kennedy Krieger Institute
Baltimore, Maryland

Harvey L. Levy, MD
Professor
Department of Pediatrics
Harvard Medical School
Senior Physician in Medicine and Genetics
Department of Medicine
Children's Hospital Boston
Boston, Massachusetts

Mark Lewin, MD
Professor and Chief
Pediatric Cardiology
University of Washington School of Medicine
Co-Director
Heart Center
Seattle Children's Hospital
Seattle, Washington

Karen Lin-Su, MD
Clinical Associate Professor of Pediatrics
Pediatric Endocrinology
Weill Cornell Medical College
New York, New York

Mignon L. Loh, MD
Professor of Clinical Pediatrics
Department of Pediatrics
University of California, San Francisco
Pediatric Hematological Oncologist
University of California, San Francisco Medical Center
Benioff Children's Hospital
San Francisco, California

Scott A. Lorch, MD, MSCE
Assistant Professor
Department of Pediatrics
University of Pennsylvania School of Medicine
Attending Neonatologist
Division of Neonatology and Center for Outcomes Research
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Ralph A. Lugo, PharmD
Professor and Chair
Department of Pharmacy Practice
Bill Gatton College of Pharmacy
East Tennessee State University
Johnson City, Tennessee

Volker Mai, PhD
University of Florida Microbiology and Cell Sciences
Emerging Pathogens Institute
Gainesville, Florida

Bradley S. Marino, MD, MPP, MSCE
Associate Professor of Pediatrics
University of Cincinnati College of Medicine
Director
Heart Institute Research Core
Attending Physician
Cardiac Intensive Care Unit
Divisions of Cardiology and Critical Care Medicine
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio

Barry Markovitz, MD, MPH
Professor of Clinical Anesthesiology and Pediatrics
University of Southern California Keck School of Medicine
Director
Critical Care Medicine
Children's Hospital Los Angeles
Los Angeles, California

Kerri Marquard, MD
Clinical Fellow
Reproductive Endocrinology and Infertility
Department of Obstetrics and Gynecology
Division of Reproductive Endocrinology and Infertility
Washington University School of Medicine
St. Louis, Missouri

Camilia R. Martin, MD, MS
Assistant Professor of Pediatrics
Harvard Medical School
Associate Director
Neonatal Intensive Care Unit
Director
Cross-Disciplinary Research Partnerships
Division of Translational Research
Beth Israel Deaconess Medical Center
Boston, Massachusetts

Richard J. Martin, MD
Drusinsky-Fanaroff Chair in Neonatology
Professor
Rainbow Babies and Children's Hospital
Professor of Pediatrics
Case Western Reserve University
Cleveland, Ohio

Katherine K. Matthay, MD
Mildred V. Strouss Professor of Translational Research
Chief of Pediatric Hematology-Oncology
University of California, San Francisco Medical Center
Benioff Children's Hospital
San Francisco, California

Dana C. Matthews, MD
Associate Professor
University of Washington School of Medicine
Director
Clinical Hematology
Pediatric Hematology and Oncology
Seattle Children's Hospital
Seattle, Washington

Dennis E. Mayock, MD
Professor
Division of Neonatology
Department of Pediatrics
University of Washington School of Medicine
Seattle, Washington

William L. Meadow, MD, PhD
Professor
Department of Pediatrics
University of Chicago
Chicago, Illinois

Ram K. Menon, MD
Professor of Pediatrics and Molecular and Integrative Physiology
Director
Division of Endocrinology
Department of Pediatrics
University of Michigan Medical School
Ann Arbor, Michigan

Eugenio Mercuri, MD, PhD
Professor of Pediatric Neurology
Department of Pediatrics
Catholic University
Rome, Italy

Sowmya S. Mohan, MD
Neonatal-Perinatal Medicine Fellow
Department of Pediatrics
Division of Neonatology
Emory University
Atlanta, Georgia

Kelle Moley, MD
James P. Crane Professor of Obstetrics and Gynecology
Division of Reproductive Endocrinology and Infertility
Vice Chair
Basic Science Research
Washington University School of Medicine
St. Louis, Missouri

Thomas J. Mollen, MD
Associate Medical Director
Infant Breathing Disorder Center
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Jeremy P. Moore, MD
Assistant Professor of Pediatrics
Division of Pediatric Cardiology
Mattel Children's Hospital
David Geffen School of Medicine
University of California, Los Angeles
Los Angeles, California

Thomas R. Moore, MD
Professor and Chairman
Department of Reproductive Medicine
University of California, San Diego
San Diego, California

David A. Munson, MD
Assistant Professor of Clinical Pediatrics
University of Pennsylvania School of Medicine
Associate Medical Director
Newborn and Infant Intensive Care Unit
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Jeffrey C. Murray, MD
Professor
Departments of Pediatrics, Biology, Nursing, and Epidemiology
University of Iowa
Iowa City, Iowa

Josef Neu, MD
Professor of Pediatrics
Division of Neonatology
University of Florida College of Medicine
Gainesville, Florida

Maria I. New, MD
Professor of Pediatrics
Director
Adrenal Steroid Disorders Program
Mount Sinai School of Medicine
New York, New York

Annie Nguyen-Vermillion, MD, FAAP
Department of Neonatology
Northwest Permanente, PC
Providence St. Vincent Medical Center
Neonatal Intensive Care Unit
Portland, Oregon

Victoria Niklas, MD
Associate Professor of Pediatrics
Division of Neonatal Medicine
University of Southern California Keck School of Medicine
Children's Hospital Los Angeles
Los Angeles, California

Saroj Nimkarn, MD
Assistant Professor of Pediatrics
Associate Director
Pediatric Endocrinology
Weill Cornell Medical College
New York, New York

James F. Padbury, MD
Oh-Zopfi Professor of Pediatrics and Perinatal Biology
Vice Chair for Research
Department of Pediatrics
Warren Alpert Medical School of Brown University
Women and Infants' Hospital of Rhode Island
Providence, Rhode Island

Marika Pane, MD, PhD
Institute of Neurology
Catholic University
Rome, Italy

Nigel Paneth, MD, MPH
University Distinguished Professor
Departments of Epidemiology and Pediatrics and Human Development
College of Human Medicine
Michigan State University
East Lansing, Michigan

Thomas A. Parker, MD
Associate Professor of Pediatrics
Director
Training Program in Neonatal-Perinatal Medicine
University of Colorado School of Medicine
Aurora, Colorado

Janna C. Patterson, MD, MPH
Assistant Instructor
Department of Pediatrics
Division of Neonatology
University of Washington
Seattle, Washington

Christian M. Pettker, MD
Assistant Professor
Department of Obstetrics, Gynecology, and Reproductive Sciences
Yale School of Medicine
New Haven, Connecticut

Lauren L. Plawner, MD
Acting Assistant Professor of Neurology
University of Washington
Pediatric Neurologist
Seattle Children's Hospital
Seattle, Washington

Dan Poenaru, BSc, MD, MHPE
Adjunct Professor
Department of Surgery
Queen's University
Kingston, Ontario, Canada
Medical Director
BethanyKids at Kijabe Hospital
Kijabe, Kenya

Brenda B. Poindexter, MD, MS
Associate Professor of Pediatrics
Section of Neonatal-Perinatal Medicine
Indiana University School of Medicine
Indianapolis, Indiana

Michael A. Posencheg, MD
Assistant Professor of Clinical Pediatrics
University of Pennsylvania School of Medicine
Associate Medical Director
Intensive Care Nursery
Medical Director
Newborn Nursery
Division of Neonatology and Newborn Services
Hospital of the University of Pennsylvania
Attending Neonatologist
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Sanjay P. Prabhu, MBBS, DCH, MRCPCH, FRCR
Instructor
Department of Radiology
Harvard Medical School
Director
Advanced Image Analysis Lab
Department of Radiology
Children's Hospital Boston
Boston, Massachusetts

Katherine B. Püttgen, MD
Assistant Professor
Departments of Dermatology and Pediatrics
Johns Hopkins University School of Medicine
Baltimore, Maryland

Graham E. Quinn, MD, MSCE
Professor of Ophthalmology
Division of Pediatric Ophthalmology
The Children's Hospital of Philadelphia
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Tonse N.K. Raju, MD, DCH
Medical Officer
Eunice Kennedy Shriver National Institute of Child Health and Human Development
National Institutes of Health
Bethesda, Maryland

Gladys A. Ramos, MD
Associate Physician
Department of Reproductive Medicine
Division of Perinatology
University of California, San Diego
San Diego, California

Benjamin E. Reinking, MD
Clinical Assistant Professor
Department of Pediatrics
University of Iowa
Iowa City, Iowa

C. Peter Richardson, PhD
Associate Research Professor
Department of Pediatrics
University of Washington
Associate Research Professor
Department of Pulmonary and Newborn Care
Seattle Children's Hospital
Principal Investigator
Center for Developmental Therapy
Seattle Children's Research Institute
Seattle, Washington

David L. Rimoin, MD, PhD
Professor of Pediatrics, Medicine, and Medical Genetics
David Geffen School of Medicine
University of California, Los Angeles
Director
Medical Genetics Institute
Steven Spielberg Chair
Cedars-Sinai Medical Center
Los Angeles, California

Elizabeth Robbins, MD
Clinical Professor
Department of Pediatrics
University of California, San Francisco
San Francisco, California

Richard L. Robertson, MD
Associate Professor of Radiology
Harvard Medical School
Radiologist-in-Chief
Children's Hospital Boston
Boston, Massachusetts

Mark D. Rollins, MD, PhD
Associate Professor
Department of Anesthesia and Perioperative Care
University of California, San Francisco
San Francisco, California

Susan R. Rose, MEd, MD
Professor of Pediatrics and Endocrinology
University of Cincinnati
Pediatric Endocrinologist Cincinnati
Children's Hospital Medical Center
Cincinnati, Ohio

Mark A. Rosen, MD
Professor
Departments of Anesthesia and Perioperative Care and Obstetrics, Gynecology, and Reproductive Sciences
University of California, San Francisco
Director
Obstetric Anesthesia
University of California, San Francisco
San Francisco, California

Lewis P. Rubin, MPhil, MD
Pamela and Leslie Muma Endowed Chair in Neonatology
Professor of Pediatrics, Obstetrics and Gynecology, Pathology and Cell Biology, and Community and Family Health
University of South Florida
Medical Director
Newborn Service Line
Tampa General Hospital
Tampa, Florida

Inderneel Sahai, MD, FACMG
Assistant Professor
Department of Pediatrics
University of Massachusetts
Chief Medical Officer
New England Newborn Screening Program
Division of Genetics and Metabolism
Massachusetts General Hospital
Department of Pediatrics
Harvard Medical School
Boston, Massachusetts

Sulagna C. Saitta, MD, PhD
Assistant Professor of Pediatrics
Division of Genetics
The Children's Hospital of Philadelphia
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Pablo J. Sánchez, MD
Professor of Pediatrics
University of Texas Southwestern Medical Center
Children's Medical Center Dallas
Dallas, Texas

Gary M. Satou, MD
Associate Clinical Professor
David Geffen School of Medicine
University of California, Los Angeles
Director
Pediatric Echocardiography
Co-Director
Fetal Cardiology Program
Mattel Children's Hospital
Los Angeles, California

Richard J. Schanler, MD
Professor
Department of Pediatrics
Hofstra North Shore-LIJ School of Medicine
Hempstead, New York
Associate Chairman
Department of Pediatrics
Chief
Neonatal-Perinatal Medicine
Steven and Alexandra Cohen Children's Medical Center of New York
New Hyde Park, New York

Mark S. Scher, MD
Professor of Pediatrics and Neurology
Case Western Reserve University School of Medicine
Chief of Pediatric Neurology
Rainbow Babies and Children's Hospital
University Hospitals of Cleveland
Cleveland, Ohio

Mark R. Schleiss, MD
Professor of Pediatrics
Director
Division of Pediatric Infectious Diseases and Immunology
Associate Chair for Research
Department of Pediatrics
University of Minnesota Medical School
American Legion Endowed Chair in Pediatric Infectious Diseases
Co-Director
Center for Infectious Diseases and Microbiology Translational Research
Minneapolis, Minnesota

Thomas D. Scholz, MD
Children's Miracle Network Professor of Pediatrics
Director
Division of Pediatric Cardiology
University of Iowa Carver College of Medicine
Iowa City, Iowa

Andrew L. Schwaderer, MD
Assistant Professor
Department of Pediatrics
Ohio State University
Columbus, Ohio

Istvan Seri, MD, PhD, HonD
Professor and Chief
Division of Neonatal Medicine
Department of Pediatrics
University of Southern California Keck School of Medicine
Director
Center for Fetal and Neonatal Medicine
Children's Hospital Los Angeles
Los Angeles, California

Surendra Sharma, MD, PhD
Professor
Department of Pediatrics
Warren Alpert Medical School of Brown University
Women and Infants' Hospital of Rhode Island
Providence, Rhode Island

Evan B. Shereck, MD
Assistant Professor of Pediatrics
Division of Pediatric Hematology and Oncology
Oregon Health and Science University
Doernbecher Children's Hospital
Portland, Oregon

Eric Sibley, MD, PhD
Associate Professor of Pediatrics
Stanford University School of Medicine
Stanford, California

Caroline Signore, MD, MPH
Medical Officer
Pregnancy and Perinatology Branch
Eunice Kennedy Shriver National Institute of Child Health and Human Development

Preface

"The neonatal period … represents the last frontier of medicine, territory which has just begun to be cleared of its forests and underbrush in preparation for its eagerly anticipated crops of saved lives."

Introduction from the first edition of
Schaffer's Diseases of the Newborn

The first edition of *Diseases of the Newborn* was published in 1960 by Dr. Alexander J. Schaffer, a well-known Baltimore pediatrician who coined the term *neonatology* to describe this emerging pediatric subspecialty that concentrated on "the art and science of diagnosis and treatment of disorders of the newborn infant." Schaffer's first edition was used mainly for diagnosis, but also included reference to neonatal care practices (i.e., the use of antibiotics, temperature regulation, and attention to feeding techniques)—practices that had led to a remarkable decrease in the infant mortality rate in the United States, from 47 deaths per 1000 live births in 1940 to 26 per 1000 in 1960. But a pivotal year for the new field of neonatology came 3 years later in 1963, with the birth of President John F. Kennedy's son, Patrick Bouvier Kennedy, at 36 weeks' gestation (i.e., late preterm). His death at 3 days of age, from complications of hyaline membrane disease, accelerated the development of infant ventilators that, coupled with micro-blood gas analysis and expertise in the use of umbilical artery catheterization, led to the development of intensive care for newborns in the 1960s on both sides of the Atlantic. Advances in neonatal surgery and cardiology, along with further technological innovations, stimulated the development of neonatal intensive care units and regionalization of care for sick newborn infants over the next several decades. These developments were accompanied by an explosion of neonatal research activity that led to improved understanding of the pathophysiology and genetic basis of diseases of the newborn, which in turn has led to spectacular advances in neonatal diagnosis and therapeutics—particularly for preterm infants. These efforts led to continued improvements in the infant mortality rate in the United States, from 26 deaths per 1000 livebirths in 1960 to 6.5 per 1000 in 2004. Current research efforts are focused on decreasing the striking global disparities in infant mortality rates, decreasing neonatal morbidities, advancing neonatal therapeutics, and preventing prematurity and newborn diseases. We neonatologists would like to be put out of business one day!

Dr. Mary Ellen Avery joined Dr. Schaffer for the third edition of *Diseases of the Newborn* in 1971. For the fourth edition in 1977, Drs. Avery and Schaffer recognized that their book now needed multiple contributors with subspecialty expertise and they became co-editors, rather than sole co-authors, of the book. In the preface to that fourth edition, Dr. Schaffer wrote, "We have also seen the application of some fundamental advances in molecular biology to the management of our fetal and newborn patients"—referring to the new knowledge of hemoglobinopathies. Dr. Schaffer died in 1981, at the age of 79, and Dr. H. William Taeusch joined Dr. Avery as co-editor for the fifth edition in 1984. Dr. Roberta Ballard joined Drs. Taeusch and Avery for the sixth edition in 1991, with the addition of Dr. Christine Gleason for the eighth edition in 2004. Drs. Avery, Taeusch, and Ballard retired from editing the book in 2009, and became "editors emeriti." Dr. Gleason was joined by Dr. Sherin Devaskar as co-editor for this, the ninth edition.

What's new and different about this edition? The book has been completely (and often painfully) revised and updated by some of the best clinicians and investigators in their field. Some chapters required more extensive revision than others, particularly those that deal with areas in which we have benefitted from new knowledge and/or its application to new diagnostic and therapeutic practices. This is particularly true in areas such as the genetic basis of disease, neonatal pain management, information technology, and the fetal origins of adult disease—an area that is now embedded within many of the chapters of this book. Some of the book's sections were reorganized to reflect our field's continued evolution. For example, Chapter 52, Persistent Pulmonary Hypertension, previously in Part X, Respiratory System, has found a new home in Part XI, Cardiovascular System. Finally, we've added new chapters that reflect the continued growth and development of our subspecialty. These include Chapter 4, Global Neonatal Health; Chapter 29, Stabilization and Transport of the High-Risk Infant; Chapter 33, Care of the Late Preterm Infant; Chapter 74, Disorders of the Liver; and Chapter 95, Craniofacial Malformations.

With the incredible breadth and depth of information immediately available to neonatal caregivers and educators on multiple internet sites, what's the value of a textbook? We, the co-editors of this ninth edition, believe that textbooks such as *Diseases of the Newborn* and all forms of integrative scholarship, will always be needed—by clinicians striving to provide state-of-the-art neonatal care, by educators striving to train the next generation of caregivers, and by investigators striving to advance neonatal scholarship. A textbook's content is only as good as its contributors and this textbook, like the previous editions, has awesome contributors. They were chosen for their expertise and ability to integrate their knowledge into a comprehensive, readable, and useful chapter. They did this despite the demands of their day jobs in the hopes that their syntheses could, as Ethel Dunham wrote in the foreword to the first edition, "spread more widely what is already known … and make it possible to apply these facts." Textbooks of the future will undoubtedly take advantage of online,

interactive publishing technologies, making their content readily accessible and more real-time, with continued revision and updating. However, in 2011—a full 50 years after the publication of the first edition of this book—we continue to find copies of this and other textbooks important to our subspecialty lying dog-eared, coffee-stained, annotated, and broken-spined in all of the places where neonatal caregivers congregate. These places, these congregations of neonatal caregivers, are now present in every country around the world. The tentacles of neonatal practice and education are spreading—ever deeper, ever wider—to improve the outcome of pregnancy worldwide. Textbooks connect us to the past, bring us up to date with the present, and prepare and excite us for the future. We will always need them, in one form or another, at our sites of practice. To that end, we have challenged ourselves to meet, and hopefully exceed, that need—for our field, for our colleagues, and for the babies.

We wish to thank key staff at Elsevier—Deidre Simpson, senior developmental editor, and Judith Fletcher, publishing director, both of whom demonstrated patience, guidance, and persistence, and Jessica Becher, associate project manager, for our book. We also wish to thank our academic institutions and our administrative assistants, Mildred Hill at the University of Washington and Kristie Smiley at the University of California, Los Angeles. They kept us grounded, on track, and basically saved our lives! We are indebted to our contributors, who actually *wrote* the book and did so willingly, enthusiastically, and (for the most part) in a timely fashion—despite the myriad of other responsibilities in their lives. And we are deeply grateful for the support of our families throughout the long, and often challenging, editorial process. Finally, we thank the editors emeriti of this book, Drs. Mary Ellen Avery, Bill Taeusch, and Roberta Ballard, for their enormous contributions to the field of neonatology and to the lives of babies throughout the world, and their wise influence on us, the editors of the ninth edition of this text.

PART I

Overview

CHAPTER 1

Neonatal and Perinatal Epidemiology

Nigel Paneth

EPIDEMIOLOGIC APPROACHES TO THE PERINATAL AND NEONATAL PERIODS

The period surrounding the time of birth (the perinatal period) is a critical episode in human development, rivaling only the period surrounding conception in its significance. During this period, the infant makes the critical transition from its dependence on maternal and placental support—oxidative, nutritional, and endocrinologic—and establishes independent life. The difficulty of this transition is indicated by mortality risks that are higher than any occuring until old age (Kung et al, 2008) and by risks for damage to organ systems, most notably the brain, that can be lifelong. Providers of care in the perinatal period recognize that the developing human organism cannot always demonstrate the immediate effects of even profound insults. Years must pass before the effects on higher cortical functions of insults and injuries occurring during the perinatal period can be detected reliably. Epidemiologic approaches to the perinatal period must therefore be bidirectional—looking backward to examine the causes of adverse health conditions that arise or complicate the perinatal period, and looking forward to see how these conditions shape disorders of health found later in life.

Traditionally the perinatal period was described as from 28 weeks' gestation until 1 week of life, but the World Health Organization has more recently antedated the onset of the perinatal period to 22 weeks' gestation (World Health Organization, 2004). For this discussion we will view the term *perinatal* more expansively, as including the second half of gestation—by which time most organogenesis has occurred, but growth and maturation of many systems have yet to occur—and the first month of life. The neonatal period, usually considered as the first month of life, is thus included in the term *perinatal*, reflecting the view that addressing the problems of the neonate requires an understanding of intrauterine phenomena.

HEALTH DISORDERS OF PREGNANCY AND THE PERINATAL PERIOD

KEY POPULATION MORTALITY RATES

Maternal and child health in the population have traditionally been assessed by monitoring two key rates—maternal mortality and infant mortality. Maternal mortality is defined by the World Health Organization as the death of a woman from pregnancy-related causes during pregnancy or within 42 days of pregnancy, expressed as a ratio to 100,000 live births in the population being studied (World Health Organization, 2004). Because pregnancy can contribute to deaths beyond 42 days, some have argued for examining all deaths within 1 year of a pregnancy (Hoyert, 2007). When the cause of death is attributed to pregnancy-related causes, it is described as *direct*. When pregnancy has aggravated an underlying health disorder, the death is termed an *indirect maternal death*. Deaths unrelated to pregnancy that occur within 42 days of pregnancy are termed *incidental maternal deaths* or sometimes *pregnancy-related deaths* (Khlat and Guillaume, 2006). These distinctions are not always easy to make. Homicide and suicide, for example, are sometimes found to be more common in pregnancy, and thus might not be entirely incidental (Samandari et al, 2010; Shadigian and Bauer, 2005).

Since 2003, the U.S. Standard Certificate of Death has included a special requirement for identifying whether the decedent, if female, was pregnant or had been pregnant in the previous 42 days, or from 43 days to 1 year before the death, thus enhancing the monitoring of all forms of maternal death (Centers for Disease Control and Prevention, 2003). This addition has added to the number of recorded maternal deaths.

In most geographic entities, *infant mortality* (IM) is defined as all deaths occurring from birth to 365 days of age in a calendar year divided by all live births in the same year. This approach is imprecise, because some deaths in the examined year occurred to the previous year's birth cohort, and some births in the examined year may die as infants in the following year. In recent years, birth-death linkage has permitted vital registration areas in the United States to provide IM rates that avoid this imprecision. The standard IM rate reported by the National Center for Health Statistics links deaths for the index year to all births, including those taking place the previous year. This form of IM is termed *period infant mortality*. An alternative procedure is to take births for the index year and link them to infant deaths, including those taking place the following year; this is referred to as *birth cohort infant mortality*, and it is not used for regular annual comparisons because it cannot be completed in as timely a fashion as period IM (Mathews and MacDorman, 2008).

Infant deaths are often divided into deaths in the first 28 days of life (neonatal death) and deaths later in the first year (postneonatal death). Neonatal deaths, which are largely related to preterm birth and birth defects, tend to reflect the circumstances of pregnancy. Postneonatal

deaths, when frequent, commonly result from infection, often in the setting of poor nutrition. Thus in underdeveloped countries, postneonatal deaths predominate; in industrialized countries the reverse is true. In the United States, neonatal deaths have been more frequent than postneonatal deaths since 1921. In recent years, the ratio of neonatal to postneonatal deaths in the United States has consistently been approximately 2:1.

Perinatal mortality is a term used for a rate that combines stillbirths and neonatal deaths in some fashion (World Health Organization, 2004). Stillbirth reporting before 28 weeks' gestation is probably incomplete, even in the United States, where such stillbirths are required to be reported in every state. Nonetheless, stillbirths continue to be reported at a levels not much lower those of neonatal deaths, and our understanding of the causes of stillbirth remains very limited.

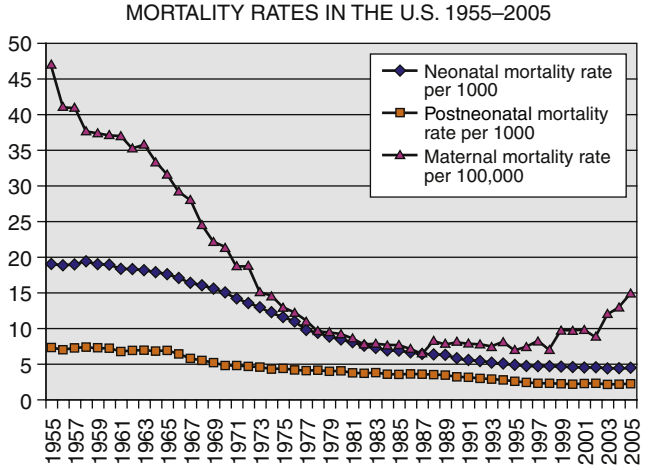

FIGURE 1-1 Neonatal, postneonatal, and maternal mortality, 1955 to 2005.

TIME TRENDS IN MORTALITY RATES IN THE UNITED STATES

Maternal mortality and IM declined steadily through the twentieth century. By 2000, neonatal mortality was 10% of its value in 1915, and postneonatal mortality less than 7%. Maternal mortality in this interval declined 74-fold; the rate in 2000 was less than 2% of the rate recorded in 1915. The contribution to these changes of a variety of complex social factors including improvements in income, housing, birth spacing, and nutrition have been documented widely, as has the role of ecologic-level public health interventions that have produced cleaner food and water (Division of Reproductive Health, 1999). Public health action at the individual level, including targeted maternal and infant nutrition programs and immunization programs, have made a lesser but still notable contribution. Medical care was, until recently, less critically involved, except for the decline in maternal mortality, which was highly sensitive to the developments in blood banking and antibiotics that began in the 1930s. To this day, hemorrhage and infection account for a large fraction of the world's maternal deaths (Khan et al, 2006).

A notable feature of the past 50 years is the sharp decline in all three mortality rates, beginning in the 1960s after a period of stagnation in the 1950s (Figure 1-1). The decline began with maternal mortality, followed by postneonatal and then by neonatal mortality. The contribution of medical care of the neonate was most clearly seen in national statistics in the 1970s, a decade that witnessed a larger decline in neonatal mortality than in any previous decade of the century (Division of Reproductive Health, 1999). All of the change in neonatal mortality between 1950 and 1975 was in mortality for a given birthweight; no improvement was seen in the birthweight distribution (Lee et al, 1980). The effect of newborn intensive care on mortality in extremely small babies has been striking. In 1960, 142 white singletons weighing less than 1000 g in the United States survived to age 1, less than 1% of births of that weight. In 2005, the survival rate for infants weighing 501 to 999 g was 70%, and the number of survivors at age 1 was almost 18,000 (Mathews and MacDorman, 2008).

In retrospect, three factors seem to have played critical roles in the rapid development of newborn intensive care programs. These programs that largely accounted for the rapid decline in birthweight-specific neonatal mortality that characterized national trends in the last third of the twentieth century. The first factor was the willingness of medicine to provide more than nursing care to marginal populations such as premature infants. It has often been noted that the death of the mildly premature son of President John F. Kennedy in 1963 provided a stimulus to the development of newborn intensive care, but it should be noted that the decline in IM that began in the 1970s was paralleled by a similar decline in mortality for the extremely old (Rosenwaike et al, 1980). A second factor was the availability of government funds, provided by the Medicaid program adopted in 1965, to pay for the care of premature newborns, among whom the poor are overrepresented. Whereas these two factors were necessary, they would have been insufficient to improve neonatal mortality had not new medical technologies, especially those supporting ventilation of the immature newborn lung, been developed at approximately the same time (Gregory et al, 1971).

Advances in newborn care have ameliorated the effects of premature birth and birth defects on mortality. Unfortunately, the underlying disorders that drive perinatal mortality and the long-term developmental disorders that are sometimes their sequelae have shown little tendency to abate. With the important exception of neural tube defects, whose prevalence has declined with folate fortification of flour in the United States and programs to encourage intake of folate in women of child-bearing age (Mathews et al, 2002), the major causes of death—preterm birth and birth defects—have not declined, nor has the major neurodevelopmental disorder that can be of perinatal origin, cerebral palsy (Paneth et al, 2006). Progress has come from improved medical care of the high-risk pregnancy and the sick infant, rather than through understanding and preventing the disorders themselves.

The period since 1990 has witnessed much less impressive mortality improvement. While infant, neonatal, and postneonatal mortality have declined since 1990, in the 1995-2005 decade these rates were at a near standstill

TABLE 1-1 U.S. Perinatal Mortality, Morbidity, Interventions, Health Conditions, and Behaviors, 1990 to 2005

	1990	1995	2000	2005	Net Change 1990-2005 (%)
Death Rates and Ratios					
Maternal mortality ratio (per 100,000 live births)	8.2	7.1	9.8	15.1	+84%
Infant mortality rate (per 1000 live births)	9.2	7.6	6.9	6.9	–25%
Neonatal mortality rate (per 1000 live births)	5.8	4.9	4.6	4.5	–22%
Postneonatal mortality rate (per 1000 live births)	3.4	2.6	2.3	2.3	–32%
Fetal mortality ratio (per 1000 live births)*	7.5	6.9	6.6	6.2	–17%
Morbidity Rates					
Preterm birth (<37 weeks' gestation) per 100 live births	10.6%	11.0%	11.6%	12.7%	+20%
Very preterm birth (<32 weeks' gestation) per 100 live births	1.9%	1.9%	1.9%	2.0%	+5%
Extremely preterm birth (<28 weeks' gestation) per 1000 live births	7.1	7.0	7.2	7.6	+7%
Low birthweight (<2500 g) per 100 live births	7.0%	7.3%	7.6%	8.2%	+12%
Very low birthweight (<1500 g) per 100 live births	1.3%.	1.4%	1.4%	1.5%	+15%
Extremely low birthweight (<1000 g) per 1000 live births	6.3	6.6	7.1	7.3	+16%
Cesarean Section					
Per 100 live births	22.6%	20.8%	22.9%	30.3%	+34%
Health Behaviors (per 100 live births)					
Cigarette smoking†	17.7%	13.7%	12.2%	10.7%	–40%
Alcohol intake‡	3.2%	1.5%	0.9%	0.7%	–78%
Late or no prenatal care	6.1%	4.2%	3.9%	3.5%	–42%
Inadequate weight gain (<16 lb) at 40 weeks' gestation§	7.9%	9.3%	11.6%	11.4%	+44%
Unmarried	28.0%	32.1%	33.2%	36.9%	+32%
Multiple Births					
Per 1000 live births	23.3	26.1	31.1	33.8	+45%
Fertility Rate					
Per 1000 women aged 15-44 years	70.9	64.6	65.3	66.7	–5.9%

*Fetal deaths with stated or presumed period of 20 weeks' gestation or more.
†1990-2000 smoking data based on 45 states and Washington, D.C.; 2005 data based on 36 states, New York City, and Washington, D.C., which used pre-2003 smoking definitions.
‡1990-2000 alcohol data based on 46 states and Washington, D.C.; 2005 data based on 36 states, New York City, and Washington, D.C., which used pre-2003 drinking definitions.
§1990 weight gain data based on 48 states and Washington, D.C. Remaining data based on 49 states and Washington, D.C.

(Table 1-1). Infant mortality actually rose in 2002, the first 1 year since 1958. Data from the Vermont Oxford Neonatal Network encompassing hundreds of neonatal units show stability in weight-specific mortality rates for all categories of infants weighing less than 1500 g, beginning in approximately 1995 (Horbar et al, 2002). It appears that the pace of advancement in newborn medicine and the expansion of newborn intensive care to previously underserved populations, factors that have exerted a constant downward pressure on infant mortality since the 1960s, have lessened greatly in the past decade.

Maternal mortality has actually climbed substantially, but this is almost certainly the effect of improved reporting (Hoyert, 2007). Two key changes were the implementation of the *International Classification of Diseases, Tenth Revision*, in 1999, which was less restrictive in including indirect maternal deaths, and the introduction of the separate pregnancy question on the U.S. Standard Certificate of Death in 2003.

The risk of preterm birth has been increasing in recent years. This increase is mostly noted in moderately preterm babies, and is likely to reflect increased willingness on the part of obstetricians to deliver fetuses earlier in gestation who are not doing well in utero, in addition to the increased prevalence of twins and triplets, who are generally born preterm, resulting from in vitro fertilization. The small rise in extremely small and preterm babies is likely to reflect trends toward increased reporting of marginally viable immature babies as live births rather than stillbirths (MacDorman et al, 2005).

The cesarean section rate continues its long-term increase, from 5% in 1970 to 23% in 1990 to 32% in 2005. The reasons for this unprecedented trend are multifactorial and include pressures from patients, physicians, and the medical malpractice system. The steady reduction in smoking during pregnancy is likely to be real, whereas trends in the self-reporting of alcohol use in pregnancy may be influenced by societal norms and expectations. Fewer women seem to have late or no prenatal care in recent years, but more women have been found to have inadequate pregnancy weight gain at term. A slight increase in the fertility rate follows a long-term (since approximately

1960) decline in fertility in the United States. One third of mothers in the United States are now unmarried when they give birth.

International Comparisons

The United States lags in IM compared with other developed nations; the United States ranked thirtieth in the world in IM in 2005 (MacDorman and Mathews, 2009). This surprising finding, in light of more favorable socioeconomic and medical care circumstances in the United States than in many nations with lower IM, cannot be attributed to inferior neonatal care. Mortality rates for low-birthweight infants are generally lower in the United States than in European and Asian nations, although mortality at term may be higher. The key difference, however, is that the United States suffers from a striking excess of premature births. Whereas the U.S. African American population is especially vulnerable to premature birth, and especially severe prematurity, premature birth rates are also considerably higher in white Americans than in most European populations. It is likely that the recording of marginally viable small infants as live births rather than stillbirths is more pronounced in the United States than in Europe (Kramer et al, 2002). Although this practice makes a contribution to our higher prematurity and IM rates, it cannot fully explain them.

Premature birth, fetal growth retardation, and IM are tightly linked, in every setting in which they have been studied, to most measures of social class and especially to maternal education; however, uncovering precisely why lower social class drives these important biologic differences has been elusive. Factors such as smoking have at times been implicated, but can only explain a small fraction of the social class effect. It is unlikely that this situation will change until a better understanding of the complex social, environmental, and biologic roots of preterm birth is achieved.

Health Disparities in the Perinatal Period

In 2005, 55.1% of all U.S. births were to non-Hispanic white mothers, 23.8% were to Hispanic mothers, 14.1% were to African American mothers, and 7% were to mothers of other ethnic groups. Health disparities are especially prominent in the perinatal period, with African American IM stubbornly remaining about double that of white IM in the United States, even as rates decline in both populations (Table 1-2). Preterm birth is the central contributor to this racial disparity in IM, and the more severe the degree of prematurity, the higher the excess risk for African American infants. The risk of birth before 37 weeks' gestation was 76% higher in African American mothers than among non-Hispanic whites in 2005, but the risk of birth before 32 weeks' gestation was 310% higher. Reduction in IM disparities in the United States thus requires a better understanding of the causes and mechanisms of preterm birth. Birth defect mortality shows a less pronounced gradient by ethnic group, and it does not contribute in a major way to overall IM disparities (Yang et al, 2006).

The *Hispanic paradox* is a term often used to describe the observation that IM is the same or lower in U.S. citizens classified as Hispanic than in non-Hispanic whites, despite the generally lower income and education levels of U.S. Hispanics (Hessol and Fuentes-Afflick, 2005). The IM experience of Hispanic mothers in the United States reflects the principle that premature birth and low birthweight are key determinants of IM, because these parameters are also favorable in Hispanics. Smoking is much less common among Hispanics in the United States, but this factor alone does not fully explain the paradox.

MAJOR CAUSES OF DEATH

Analyzing the cause of death, a staple of epidemiologic investigation, has limitations when applied to the perinatal period. Birth defect mortality is probably reasonably accurate, but causes of deaths among premature infants are divided among categories such as respiratory distress syndrome, immaturity, and a variety of complications of prematurity. Choosing which particular epiphenomenon of preterm birth to label as the primary cause of death is arbitrary to some extent. Some maternal complications, such as preeclampsia, are also occasionally listed as causes of newborn death. However categorized, prematurity accounts for at least one third of infant deaths (Callaghan et al, 2006).

Before prenatal ultrasound examination could be used to estimate gestational age with reasonable accuracy, a high fraction of neonatal deaths were attributed to low birthweight, but most of these deaths occurred in premature infants, because premature birth is much more important as a cause of death than is fetal growth restriction. Extreme prematurity makes a contribution to IM well beyond its frequency in the population; 1.9% of births, that occurred before 32 weeks' gestation, accounted for 54% of all infant deaths in 2005.

Following premature birth, another important group of causes of death is congenital anomalies (Mathews and MacDorman, 2008). With the exception of folate supplementation to prevent neural tube defects, there is no clearly effective primary prevention program for any birth defect. Pregnancy screening and termination of severe defects, however, is an option for many mothers, and there is evidence that this practice contributes to a reduced prevalence of chromosomal anomalies at birth (Khoshnood et al, 2004).

The major postneonatal cause of death since the 1970s in the United States is sudden infant death syndrome. This cause of death has declined substantially in the United States in parallel with successful public health efforts to discourage sleeping in the prone position during infancy (Ponsonby et al, 2002).

MAJOR MORBIDITIES RELATED TO THE PERINATAL PERIOD

The principal complications of preterm birth involve five organs: the lung, heart, gut, eye, and brain. Management of respiratory distress syndrome and its short- and long-term complications is the centerpiece of neonatal

TABLE 1-2 Ethnic Disparities in Key Perinatal Outcomes and Exposures in 2005

	Non-Hispanic White	African American		Hispanic	
	Prevalence rate	*Prevalence rate*	*RR**	*Prevalence rate*	*RR**
Deaths Rates and Ratios					
Maternal mortality ratio (per 100,000 live births)	11.7	39.2	3.4	9.6	0.8

medicine. Surgical or medical management of symptomatic patent ductus arteriosus is the major cardiac challenge in premature infants, and there is limited understanding of the striking variations, by time and place, of necrotizing enterocolitis—a disorder that in its most extreme forms can cause death or substantial loss of bowel function. Retinopathy of prematurity is closely related to arterial oxygen levels. The epidemic level of this disorder encountered in the 1950s, when oxygen was freely administered without monitoring, was a major setback for neonatal medicine (Silverman, 1980). However, even with more careful management of oxygen, retinopathy of prematurity continues to occur.

The largest unsolved problem in neonatal medicine remains the high frequency of brain damage in survivors of premature birth. The extraordinary decline in mortality rates has not been paralleled by similar declines in rates of neurodevelopmental disabilities in survivors. The key epidemiologic feature of cerebral palsy rates in population registries toward the end of the twentieth century was a modest overall increase in the prevalence of that disorder, which was attributable entirely to the increasing number of survivors of very low birthweight. There are suggestions that this rise may now be leveling (Paneth et al, 2006).

FACTORS AFFECTING PERINATAL HEALTH

HEALTH STATES IN PREGNANCY

The major causes of neonatal morbidity, prematurity and birth defects, generally occur in pregnancies free of antecedent complications. Having a previous birth with an anomaly or a previous preterm birth raises the risk for recurrence of the condition. For preterm birth, no other known risk factor carries as much risk for the mother as having previously delivered preterm.

More than a quarter of preterm birth is iatrogenic, the result of induced labor in pregnancies in which the fetus is severely compromised (Morken et al, 2008). Generally the reason is preeclampsia with attendant impairments in uterine blood flow and poor fetal growth, but poor uterine blood flow and impaired fetal growth can also occur independently of diagnosed preeclampsia; the other major complication of pregnancy is diabetes, most often gestational but sometimes preexisting. Insulin resistance in the mother promotes the movement of nutrients towards the fetus, and typically the infant of the diabetic mother is large for gestational age. Severe diabetes, however, can be accompanied by fetal growth retardation.

HEALTH BEHAVIORS

The most carefully studied and well-established health behavior affecting newborns is maternal cigarette smoking, which has a consistent effect in impairing fetal growth (Cnattingius, 2004). Infants with growth retardation from maternal cigarette smoking paradoxically survive slightly better than do infants of the same weight whose mothers did not smoke, but the net effect of smoking, which also shortens gestation slightly, is to increase perinatal mortality. Although the subject is much debated, it has not been conclusively shown that prenatal maternal smoking has independent long-term effects on children's cognitive capacity (Breslau et al, 2005).

Alcohol is less clearly a growth retardant, but mothers who drink heavily during pregnancy are at risk of having infants with the cluster of defects known as *fetal alcohol syndrome*. Cocaine use in pregnancy is almost surely a severe growth retardant, and it may affect neonatal behavior, but the long-term effects of this exposure on infant cognition and behavior are not as grave as initially feared (Bandstra et al, 2010).

PERINATAL MEDICAL CARE

In light of the potent effects of medical care on the neonate, it has been important to develop systems of care that ensure, or at least facilitate, provision of care to neonates in need. This concept was first promoted by the March of Dimes Foundation, which in its committee report of 1976 recommended that all hospitals caring for babies be classified as level 1 (care for healthy and mildly sick newborns), level 2 (care for most sick infants born in the hospital, but not accepting transfers), or level 3 (regional centers caring for complex surgical disease and receiving transfers) (The Committee on Perinatal Health, 1976). This concept of a regional approach to neonatal care, with different hospitals playing distinct roles in providing care, was endorsed by organizations such as American College of Obstetricians and Gynecologists and the American Academy of Pediatrics and by many state health departments. Whereas it is important to transfer sick babies to level 3 centers when needed, it is preferable to transfer mothers at risk of delivering prematurely or of having a sick neonate, because transport of the fetus in utero is superior to any form of postnatal transport. Birth at a level 3 center has been shown consistently to produce lower mortality rates than birth in other levels of care (Paneth, 1992). The overall system of care, which includes selecting mothers and babies for transfer to other hospitals, is highly dependent on cooperative physicians and health systems. Concern has been raised that economic considerations may threaten ideal systems of regionalization of newborn intensive care (Bode et al, 2001).

EPIDEMIOLOGIC STUDY DESIGNS IN THE PERINATAL PERIOD

Epidemiologic studies have contributed substantially to better understanding the patterns of risk and prognosis in the perinatal period, to tracking patterns of mortality and morbidity, to assessing regional medical care, and to assisting physicians and other providers in evaluating the efficacy of treatments. A variety of study designs have been used in this research.

VITAL DATA ANALYSES

Routinely collected vital data serve as the nation's key resource for monitoring progress in caring for mothers and children. All data presented in this chapter's figures and tables are derived from the annual counts of births and deaths collected by the 52 vital registration areas of the United States (50 states, Washington, D.C., and New York City) and then assembled into national data sets by the National Center for Health Statistics. Unlike data collected in hospitals, in clinics, or from nationally representative surveys, birth and death certificates are required by law to be completed for each birth and death. Birth and death registration has been virtually 100% complete for the entire United States since the 1950s. The universality of this process renders the findings from vital data analyses stable and generalizable. Figure 1-2 illustrates the most recent nationally recommended standard for birth certificate data collection, which has been adopted by most states. Birth certificates contain valuable information for neonatologists. Especially of note are variables such as to whether the mother or infant was transferred for care (not shown), breastfeeding plans, alcohol and cigarette smoking histories, and patterns of maternal weight gain and prenatal care.

The limitations of vital data are well known. Causes of death are subject to certifier variability and, perhaps more importantly, to professional trends in diagnostic categorization. The accuracy of recording of conditions and measures on birth certificates is often uncertain and variable from state to state and hospital to hospital; however, the frequencies of births and deaths in subgroups defined objectively, such as birthweight, are likely to be valid.

COHORT STUDIES IN PREGNANCY AND BIRTH

Studies that follow populations of infants over time, beginning at birth or even before birth and continuing to hospital discharge, early childhood, and adult life, are the leading sources of information about perinatal risk factors for disease and adverse outcomes. As with all observational studies, cohort studies produce associations of exposures and

28. MOTHER TRANSFERRED FOR MAXIMAL MEDICAL OR FETAL INDICATIONS FOR DELIVERY? ☒ Yes ☒ No

58. IS THE INFANT BEING BREASTFED AT DISCHARGE?
☒ Yes ☒ No

FIGURE 1-2 U.S. national standard birth certificate, 2003 revision.

outcomes whose strength and consistency must be carefully judged in the light of other biologic evidence, and with attention to confounding and bias. Collaborations across centers in assembling such data are highly valuable. One noteable collaboration is the Vermont-Oxford Network, which provides continuous information on the frequency of conditions observed and diagnoses made in hundreds of U.S. and overseas hospitals, with a particular emphasis on using these data for improving care (Horbar et al, 2010). The neonatal network supported by the National Institute of Child Health and Human Development (NICHD) has been a rich source of randomized trials and has produced observations about prognosis based on large samples of low-birthweight babies (Fanaroff, 2004). These collaborations focus mainly on the period until hospital discharge.

Multicenter cohort studies focusing on diagnosis and follow-up of brain injury in premature infants—such as the Developmental Epidemiology Network (Kuban et al, 1999), Neonatal Brain Hemorrhage (Pinto-Martin et al, 1992), and Extremely Low Gestational Age Newborns (O'Shea et al, 2009) studies—have contributed to our understanding of the prognostic value of brain injury imaged by ultrasound in the neonatal period, because they include follow-up to the age of 2 years or later. Of particular value have been regional or population-wide studies of low-birthweight infants with follow-up to at least school age, among which are included the Neonatal Brain Hemorrhage study from the United States and important studies from Germany (Wolke and Meyer, 1999), the Netherlands (Veen et al, 1991), the United Kingdom (Wood et al, 2000), and Canada (Saigal et al, 1990).

Newborn intensive care has been in place long enough that the first reports of adult outcomes in small infants are now emerging (Saigal and Doyle, 2008). These reports paint a picture that is perhaps less dire than anticipated.

From 1959 to 1966, the National Collaborative Perinatal Project assembled data on approximately 50,000 pregnancies in 12 major medical centers and followed them to age 7 (Niswander and Gordon, 1972). This highly productive exercise, one of whose major contributions was to show that birth asphyxia is a rare cause of cerebral palsy, has now been followed by the development of even larger birth cohort studies starting in pregnancy. For reasons that are not entirely clear, a sample size of 100,000 has been adopted in studies in Norway (Magnus et al, 2006), Denmark (Olsen et al, 2001), and the United States (Lyerly et al, 2009). A major difference from the National Collaborative Perinatal Project is that each of the studies aims to obtain some degree of national representativeness. The U.S. National Children's Study, currently underway, plans to enroll women in early pregnancy and possibly before conception and to follow the offspring to age 21 in 105 locations in the United States, selected by a stratified random sampling of all 3141 U.S. counties.

RANDOMIZED CONTROLLED TRIALS

Few areas of medicine have adopted the randomized trial as wholeheartedly as has newborn medicine. The number of trials mounted has been large and have created a strong influence on practice. A notable influence on this field has been the National Perinatal Epidemiology Unit at Oxford University, established in 1978, which prioritized randomized trials among their several investigations of perinatal care practices and other circumstances affecting maternal and newborn outcomes. The NICHD neonatal research network was established in 1986, principally to support trials. Hundreds of trials have been mounted by these two organizations, but many other centers have contributed to the trial literature.

Trials in pregnancy or in labor have also been supported by the National Perinatal Epidemiology Unit and by NICHD, who support a network of obstetric centers to conduct trials in pregnancy and labor, the NICHD maternal-fetal research network. These trials have often had important implications for newborns and mothers, most notably for showing that the risk of preterm birth can be reduced by administering 17-OH hydroxyprogesterone caproate in midgestation to high-risk women (Meis et al, 2003).

Most newborn trials have focused on outcomes evident in the newborn period, such as mortality, chronic lung disease, brain damage visualized on ultrasound exam, and duration of mechanical ventilation or hospital stay. Recently however, trials extending into infancy or early childhood that incorporate measures of cognition or neurologic function have been a welcome addition to the trial arena. In the past few years, such trials have shown that moderate hypothermia can reduce mortality and brain damage in asphyxiated term infants (Shankaran et al, 2005), and that both caffeine for apnea treatment (Schmidt et al, 2007) and magnesium sulfate administered during labor can reduce the risk of cerebral palsy (Rouse et al, 2008).

Trials in which both mortality and later outcome are combined raise complex methodologic issues. Imbalance in the frequency of the two outcomes being combined can result in a random variation in the more common outcome, overwhelming a significant finding in the other. Precisely how best to conduct such dual- or multiple-outcome trials is the subject of discussion and debate in the neonatal and epidemiology communities.

As the number of trials increases, not all of them sufficiently powered, the methodology for summarizing them and drawing effective conclusions has become increasingly important to neonatologists. The terms *systematic review* and *metaanalysis* have firmly entered the research lexicon, especially the randomized trial literature. The Cochrane Collaboration is an international organization that uses volunteers to systematically review trial results in all fields of medicine. The collaboration, established in 1993, began in the field of perinatal medical trials. Systematic reviews of neonatal trials reviewed by the Cochrane Collaboration are hosted on the website of the NICHD (http://www.nichd.nih.gov/cochrane).

SUMMARY

The patterns of disease, mortality, and later outcome in the perinatal period are complex. Some factors are reasonably stable (e.g., long-term trends in preterm birth and birthweight), whereas others can undergo rapid change (e.g., the rates of cesarean section and twinning). The success of

newborn intensive care is well established. No other organized medical care program, targeted at a broad patient population, has had such remarkable success in lowering mortality rates in such a short period of time. Much of that success is due to the evidence-based nature of neonatal practice.

Nonetheless, this success has opened the door to new problems as survivors of intensive care face the challenges of the information age. Resource allocations similar to those that permitted the development of newborn intensive care are now needed to address the educational and rehabilitative needs of survivors. A hopeful sign is the success of some recently studied interventions in reducing the burden of brain damage.

On the nontechnologic front, targeted epidemiologic efforts to address perinatal disorders have yielded progress. Careful study of the circumstances surrounding infant sleep patterns led to active discouragement of sleeping in the prone position, which has reduced mortality from sudden infant death syndrome by half (The Committee on Perinatal Health, 1976). Observational research, followed by two important randomized trials in Europe, led to interventions that increased folate intake in women of child-bearing age and a substantial reduction in the birth prevalence of neural tube defects (Czeizel and Dudás, 1992; Medical Research Council, 1991).

The population-level study of health events occurring in pregnancy and infancy, their antecedents, and their long-term consequences have been an important component to the success of newborn care. Careful self-evaluation through monitoring of vital data and collaborative clinical data, rigorous assessment of new treatments through randomized trials, and alertness to opportunities to implement prevention activities after discovering important risk factors should continue to guide the care of the newborn.

CHAPTER 2

Evaluation of Therapeutic Recommendations, Database Management, and Information Retrieval

Peter Tarczy-Hornoch

BACKGROUND

At a fundamental level, the practice of neonatology can be considered an information management problem. The care provider is combining patient-specific information (history, findings of physical examination, and results of physiologic monitoring, laboratory tests, and radiologic evaluation) with generalized information (medical knowledge, practice guidelines, clinical trials, and personal experience) to make medical decisions (diagnostic, therapeutic, and management). The Internet has made possible a revolution in the sharing and disseminating of knowledge in all fields, including medicine, with continued growth and maturation of online clinical information resources and tools. Although medicine remains a quintessentially human endeavor, computers are playing a growing role in information management, particularly in neonatology. Patient-specific and generalized information (medical knowledge) are becoming increasingly available in electronic form. In the United States, a growing number of hospitals are adopting electronic medical record systems to manage patient-specific information, with the approaches ranging from electronic flow sheets in the intensive care unit to entirely paperless hospitals. The American Recovery and Reinvestment Act of 2009 (ARRA; i.e., the federal economic stimulus plan) has a provision for the investment of $19 billion in health information technology to motivate physicians to adopt electronic health records (in the Health Information Technology for Economic and Clinical Health [HITECH] act, a part of AARA) and $1.1 billion to research the effectiveness of certain health care treatments. These ARRA provisions are predicated on the belief that quality, safety, and efficiency of clinical care can be improved through electronic medical records and through evidence-based practice.

Parallel with and related to the adoption of information technology is the growth of societal pressures to improve the quality of medical care while controlling costs. These changes are beginning to affect the way in which medicine and neonatology are practiced. In turn, it is becoming important for neonatologists to understand basic principles related to biomedical and health informatics, databases and electronic medical record systems, evaluation of therapeutic recommendations, and online information retrieval.

This expansion of information technology in clinical practice and the concurrent growth of medical knowledge have great promise in addition to potential pitfalls. One pitfall that must not be underestimated, and which is as great a danger today as when Blois (1984) first cautioned against it, is the unquestioning adoption of information technology: "And, since the thing that computers do is frequently done by them more rapidly than it is by brains, there has been an irresistible urge to apply computers to medicine, but considerably less of an urge to attempt to understand where and how they can best be used." A present and real challenge is information overload. Bero and Rennie (1995) observed, "Although well over 1 million clinical trials have been conducted, hundreds of thousands remain unpublished or are hard to find and may be in various languages. In the unlikely event that the physician finds all the relevant trials of a treatment, these are rarely accompanied by any comprehensive systematic review attempting to assess and make sense of the evidence." The potential of just-in-time information at the point of care is thus particularly appealing, especially considering that the growth in published literature continues at an accelerating rate, with a flood of new knowledge coming from the latest research in genomics, proteomics, metabolomics, and systems biology. A vision to address this was articulated by one of the editors of the *British Medical Journal:* "New information tools are needed: they are likely to be electronic, portable, fast, easy to use, connected to both a large valid database of medical knowledge and the patient record" (Smith, 1996). Although these goals are close to being achieved, there is still progress to be made before this vision is a reality. This chapter aims to provide an overview of the current progress in this direction.

BIOMEDICAL AND HEALTH INFORMATICS

In the 1970s, clinicians with expertise in computers became intrigued by the potential of these tools to improve the practice of medicine, and thus the field of medical informatics was born. The importance of this field addressing the issues of information management in health care is growing rapidly, as seen in the activities of the American Medical Informatics Association (AMIA; www.amia.org). *Medical informatics* can be concisely defined as "the rapidly developing scientific field that deals with storage, retrieval, and optimal use of biomedical information, data, and knowledge for problem solving and decision making" (Shortliffe and Blois, 2006). A more extensive definition can be found at the AMIA Web site under About AMIA, including professional and training opportunities. The University of Washington

Web site (www.bhi.washington.edu) contains a review of the discipline (found under History, About Us, Vision). The field includes both applied and basic research, with the focus in this chapter being on the applied aspects. Examples of basic research are artificial intelligence in medicine, genome data analysis, and data mining (sorting through data to identify patterns and establish relationships). As our knowledge of the genetic mechanisms of disease expands and more data about patients and outcomes are available electronically, the role of informatics in medicine will expand, particularly in the field of neonatology.

The applied focus of the field in the 1960s and 1970s was data oriented, focusing on signal processing and statistical data analysis. In neonatology, the earliest applications of computers were for physiologic data monitoring in the neonatal intensive care unit (NICU). As the field matured in the 1980s, applied work focused on systems to manage patient information and medical knowledge on a limited basis. Examples are laboratory systems, radiology systems, centralized transcription systems, and, probably the best-known medical knowledge management system, the database of published medical articles maintained by the National Library of Medicine known first as MEDLARS, then as MEDLINE and currently as PubMed (www.ncbi.nlm.nih.gov/pubmed). For example, neonatologists began to develop tools to aid in the management of patients in the NICU, such as computer-assisted algorithms to help manage ventilators, although the algorithms have not been successfully deployed on a large scale in the clinical setting.

As computers and networking became mainstream in the workplace and home in the 1990s, informatics researchers began to develop integrated and networked systems (Fuller, 1992, 1997). With the explosion of information from the Human Genome Project, the intersection between bioinformatics and medical informatics began to blur, leading to the adoption of the term *biomedical informatics*. The 1990s saw the development of a number of important systems. In terms of patient-specific information retrieval, these systems included integrated electronic medical record systems that in their full implementation can encompass—in a single piece of easy-to-use software—interfaces to physiologic monitors; electronic flow sheets; access to laboratory and radiology data; tools for electronic documentation (charting), electronic order entry, and integrated billing; and modules to help reduce medical errors. The Internet has permitted ready access and sharing of this information within health care organizations and limited secured remote access to this information from home. In terms of patient population information retrieval, a number of tools were developed to help clinicians and researchers examine aggregate data in these electronic medical records to document outcomes and help to improve quality of care. The Internet, particularly the World Wide Web, has transformed access to medical knowledge (Fuller et al, 1999). Health sciences libraries are becoming digital and paper repositories. Journals are available online. Knowledge is now available at the point of care in ways that were not previously possible (Tarczy-Hornoch et al, 1997). In 2004, in recognition of the unfulfilled potential of health care information technology, the Office of the National Coordinator for Health Information Technology (ONC) was established (www.healthit.hhs.gov) to achieve the following vision:

> *Health information technology (HIT) allows comprehensive management of medical information and its secure exchange between health care consumers and providers. Broad use of HIT has the potential to improve health care quality, prevent medical errors, increase the efficiency of care provision and reduce unnecessary health care costs, increase administrative efficiencies, decrease paperwork, expand access to affordable care, and improve population health.*

In the upcoming decade, the focus will be shifting from demonstrating the potential of electronic medical record and information systems toward implementing them more broadly to realize their benefit (e.g., the ARRA legislation). Evidence-based medicine is considered by many as a part of informatics as an approach to the evaluation of therapeutic recommendations and their implementation (see later discussion), and it is part of the ARRA and some approaches to health care reform being proposed in 2009.

Neonatologists have been involved in informatics for a long time. Duncan (2010) maintains an excellent continually updated bibliographic database on the literature about computer applications in neonatology. In 1988, as one of the earlier groups to develop national databases of clinical care, neonatologists established and expanded the Vermont Oxford Network (www.vtoxford.org) to improve the quality and safety of medical care for newborn infants and their families. As part of the activities, the Vermont established and maintained Oxford Network a nationwide database about the care and outcome of high-risk newborn infants. In 1992, Sinclair et al (1992) published one of the earlier evidence-based textbooks, *Effective Care of the Newborn Infant*.

DATABASES

In broad terms, a database is an organized, structured collection of data designed for a particular purpose. Thus, a stack of 3 × 5 cards with patient information is a database, as is the typical paper prenatal record. Most frequently, the term *database* is used to refer to a structured electronic collection of information, such as a database of clinical trial data for a group of patients in a study. Databases come in a variety of fundamental types, such as single-table, relational, and object-oriented.

A simple database can be built using a single table by means of a spreadsheet program such as Microsoft Excel, or a database program such as Microsoft Access (Microsoft, Redmond, Washington). The advantage of such a database is that it is easy to build and maintain. For an outcomes database in a neonatology unit, each row can represent a patient and each column represents information about the patients (e.g., name, medical record number, gestational age, birth date, length of stay, patent ductus arteriosus [yes/no], necrotizing enterocolitis [NEC; yes/no]). The major limitation of such a database is that a column must be added to store the information each time the researcher wants to track another outcome (e.g., maple syrup urine disease [MSUD]). This limitation can result in tables with dozens to hundreds of columns, which then become difficult to maintain. The challenges can be illustrated with a few examples. The first

example of a challenge is that which results from adding a new column (e.g., MSUD); one must either review all records (rows) already in the spreadsheet for the presence or absence of MSUD or flag all existing records (rows) in the spreadsheet as *unknown* for MSUD status. The second example of a challenge results from the logistics of managing an extremely wide spreadsheet—imagine not adding the tenth column but the 1000th column.

The majority of databases and electronic medical records in neonatology are built using relational database software. To build a simple outcomes relational database that permits easy adding of new outcome measures, one could use a three-table database design (Figure 2-1). The first table contains all the information for each patient (e.g., name, medical record number, gestation in weeks, birth date, admit date, discharge date). The second table is a dictionary that assigns a code number to each diagnosis or outcome being tracked (e.g., patent ductus arteriosus = 1; NEC = 2; MSUD = 10234). The third table is the diagnosis-tracking table; it links a patient number to a particular code and assigns a value to that code. Adding a new diagnosis to track would require adding an entry to the diagnosis dictionary table. To add a diagnosis to a patient, one would add an entry to the tracking table. For example, Girl Smith (medical record number 00-00-01) has a diagnosis of NEC. To add the diagnosis, add to the diagnosis table an entry that has a value of 00-00-01 in the medical record column, a value of 2 (the code for NEC) in the code column, and a value of 2 in the value column (the code for surgical). Although relational databases are harder to build, they provide greater flexibility for expansion and maintenance and thus are the preferred implementation for clinical databases. They address the challenges in a simple spreadsheet by tracking dates that new diagnostic codes were added and by user interfaces that allow one to easily view only diagnoses present for a given patient rather than all potential diagnoses for a patient.

The distinction between an NICU quality assessment–quality improvement (i.e., outcomes) database and an electronic medical record is largely a matter of degree. Some characteristics typical of a neonatal outcomes database are data collection and data entry after the fact, limited amount of data collected (a small subset of the information needed for daily care), lack of narrative text, lack of interfaces to laboratory and other information systems, and the episodic (e.g., quarterly) use of the system for report generation. Some characteristics typical of an electronic medical record are real-time (daily or more frequent) data entry, a large amount of data collected (approximating all the information needed for daily care in a fully electronic care environment), narrative text (e.g., progress notes, radiology reports, pathology reports), interfaces to laboratory and other information systems, and, most important, the use of the system for daily patient care, including features such as results review, messaging or alerting for critical results, decision support systems (drug dosage calculators, drug-drug interaction alerts, among others), and computerized electronic order entry.

In the past, the majority of neonatal databases and first-generation NICU electronic medical record systems were

Tables in the database:

DEMOGRAPHIC DATA
- Name
- Hospital_Number
- Gestational_Age
- Birthdate
- Admit_Date
- Discharge_Date

DIAGNOSES
- Hospital_Number
- Diagnosis_Code
- Value

DIAGNOSIS DICTIONARY
- Diagnosis_Code
- Description

Example Entries in the Tables:

DEMOGRAPHIC DATA

Name	Hospital_Number	Gestational_Age	Birthdate	Admit_Date	Discharge_Date
John Smith	00-00-01	27	1/1/2003	1/1/2003	3/21/2003
Jane Doe	00-00-02	24	1/2/2003	1/3/2003	4/15/2003

DIAGNOSES

Hospital_Number	Diagnosis_Code	Value
00-00-01	1	1
00-00-01	2	1
00-00-02	1	2
00-00-02	10234	

DIAGNOSIS DICTIONARY

Diagnosis_Code	Description
1	PDA (1=small, 2=large)
2	NEC (1=medical, 2=surgical)
....	
10234	Maple Syrup Urine Disease

FIGURE 2-1 Example of a relational database.

developed locally by and for neonatologists. The literature describing these efforts is available online (Duncan, 2010). Unfortunately the majority of these systems were never published or publicly documented, and thus a number of important and useful innovations are lost or must be repeatedly rediscovered. Anybody thinking about building their own neonatology database would be well advised to review the existing literature and existing commercial products before embarking on this path. That said, there is room for improvement of the existing products, and neonatologists continue to develop their own databases today. With the national push toward interoperable electronic medical records through U.S. Department of Health and Human Services Office of the National Coordinator for Health Information Technology (ONC; since 2004) and ARRA HITECH (since 2009), it is likely that the market will consolidate into a smaller number of neonatology practice tailored systems that are certified and that interoperate with the National Health Information Network (2010). The largest neonatal outcomes database is the centralized database maintained by the Vermont Oxford Network with the mission of improving the quality and safety of medical care for infants and their families. One of the key activities of the network is their outcomes database, which involves more than 800 participating intensive care nurseries both in the United States and internationally collecting data on approximately 55,000 low-birthweight infants each year. Other activities of the network are clinical trials, follow-up of extremely low–birthweight infants, and NICU quality and safety studies. The focus of the database initially was very low–birthweight infants (401 to 1500 g), but this focus has expanded to include data on infants weighing more than 1500 g. Presently the network collects data on more than two thirds of the very low–birthweight infants born in the United States. Participants in the network submit data and in return receive outcome data for their own institution and comparative data from other nurseries nationwide, including custom reports, comparison groups, and quality management reports. Members also have the ability to participate in collaborative research projects and collaborative multicenter quality-improvement collaborations. All data except their own are anonymous for all participants. The network does have access to both the individual and aggregate data. The network database is maintained centrally, and data quality monitoring and data entry are centralized. Initially the process involved paper submission of data by participating nurseries. Currently a number of the commercial and custom NICU databases and electronic medical record systems can export their data in the format required by the Vermont Oxford Network as well as the option to submit data directly using the custom eNICQ software developed by Vermont Oxford. Submissions of data are thus a combination of paper forms and reports generated by commercial and custom software packages.

The database focuses on tracking outcomes. With the passage of the Health Insurance Portability and Accountability Act of 1996 (HIPAA) and federal regulations governing the confidentiality of electronic patient data, some of the anonymous demographic data that were collected by the network in the past have decreased. This change has grown from concerns that, in combination with identity of the referring center, these data could be used to uniquely identify patients, which is a violation of the HIPAA.

ELECTRONIC HEALTH RECORD

An electronic health record (EHR; also known as an *electronic medical record*) is much more complex than an outcomes database, because the system is intended to be used continually on a daily basis to replace electronically some, if not all, of the record keeping, laboratory result review, and order writing that occur in a neonatal intensive care nursery (or more generically in any inpatient or outpatient clinical setting). The complexity of this task becomes evident if one imagines that, for a paperless medical record environment, every paper form in a nursery would need to be replaced with an electronic equivalent, which is also true for every paper-based workflow and process. Organizations are moving in this direction because of a combination of forces, such as the desire to reduce error and to control the spiraling costs of health care. These reasons are addressed at great length in two reports from the Institute of Medicine (Institute of Medicine Committee on Improving the Patient Record, 1997; Kohn et al, 2000). These benefits are typically achieved when information is available electronically (e.g., results of laboratory tests, radiology procedures, transcription) and input into the system (e.g., problem lists, allergies), and when both sets of information are combined and checked against electronic orders. Only with electronic orders has it been shown that errors can be reduced and care provider behavior clearly changed. Combining just electronic laboratory results (e.g., creatinine level) and electronic order entry (e.g., a drug order), for example, enables one to verify that drug dosages have been correctly adjusted for renal failure. This approach would work well in adults, but in neonates, whose renal function is more difficult to assess and for whom drug dosage norms depend on gestational age and post-delivery age, additional information must be entered into the system (e.g., urine output, gestational age), requiring a more sophisticated EHR. Despite more than one decade of work deploying EHRs, the proportion of acute care hospitals that are members of the American Hospital Association and have a comprehensive EHR is remarkably low (1.5%), and computerized order entry has been implemented in only 17% of hospitals (Jha et al, 2009).

Results review systems include basic demographic data, such as name, age, and address from the hospital registration system. These systems require a moderate amount of work to tie them to the various laboratory, radiology, and other systems and to train users. The benefits are hard to quantify, but users typically prefer them to the paper alternative because of the more rapid access to information. The challenge in moving beyond the results review level to the integrated system level is that the documentation level and order entry level are essentially prerequisites for the integrated system level, but they have marginal benefit, particularly given the human and financial costs. Integrated systems require significant work to implement, including the presence of computers at each bedside, as well as significant work to train users. The benefits accrue mainly to the organization, in the form of reduced costs of filing, printing, and maintaining paper records and, if providers are forced to enter notes instead of dictate them, significant savings in transcription costs.

The challenge is that the end users often find that it takes much longer to do their daily work with electronic documentation. Without moving to electronic order entry, if not an integrated system, the users do not realize major day-to-day benefits. The ARRA HITECH provisions noted earlier essentially are designed to create incentives for provider adoption of EHRs to overcome this activation barrier.

The benefits start to accrue more clearly at the next level—electronic order entry. The complexity of implementing and deploying an electronic order entry system cannot be overstated. Interfaces need to be built with all the systems that are part of results review in addition to other systems. Furthermore, a huge database of possible orders must be created to allow users to pick the right orders. This database and the menu of choices are needed because computers are poor at recognizing and interpreting a narrative text typed by a human. Finally and most important, there is a huge training challenge, because writing orders electronically is more complex and time consuming than writing them by hand. The change management issues become apparent when one considers that typically these systems take the unit assistant out of the loop; therefore much of the oversight that can occur at the unit assistant level does not, or the burden of oversight is borne by the person entering the orders.

After overcoming the barriers to electronic order entry, organizations can start to benefit from integrated systems. For this reason, the trend today is not a stepwise move from results review to documentation of integrated systems. Instead, organizations are moving from results review directly to integrated systems. Interestingly, the technical complexities and the training and usage complexities of integrated systems are not much higher than those for order entry. Integrated systems add tools to make life easier for care providers using all the data in the system. As an analogy, an integrated EHR system is like an office software suite that encompasses a word processor, a spreadsheet, a slide presentation tool, a graphic drawing tool, and a database, all of which can communicate with one another, making it easy to put a picture from the drawing tool or a graph from a spreadsheet into a slide show. Integrated systems include (1) checking orders for errors, (2) alerts and reminders triggered by orders or by problems on the problem list or other data in the system, (3) care plans tied to patient-specific information, (4) charting modules customized to the problem list, (5) charting and progress notes that automatically import information (e.g., from laboratory tests, flow sheets) and that help generate orders for the day as the documentation occurs, (6) modules to facilitate hyperalimentation ordering, and (7) modules to assist in management. For example it is possible to imagine a system in which reminders for screening studies (e.g., for retinopathy of prematurity, intraventricular hemorrhage, and brainstem auditory evoked response) were triggered by gestational age, a problem list, and previous results of screening studies. Similarly, admitting a neonate at a particular gestational age with a particular set of problems could trigger pathways, orders, and reminders specific to that clinical scenario. An important caveat is that all such systems are only as good as the data and rules put into them. The issues raised in the section on evaluation of therapeutic recommendations are important to consider in the context of electronic order entry and integrated systems.

The EHR market is still relatively young and continually evolving; this is true of products designed specifically for the NICU and more generic products designed to be used throughout a hospital or health care system. The ONC was established in part to address this young marketplace by creating standards and certification bodies. In particular, the ONC created the Certification Commission for Healthcare Information Technology (CCHIT) and the Health Information Technology Standards Panel to begin to bring more standardization to the marketplace. The CCHCIT examines criteria for certifying systems, including functionality, security, and interoperability. Order entry and documentation systems are beginning to be more widely adopted, however truly integrated systems are much less broadly implemented. The major reason for this situation is that the needs of different health care systems vary significantly, and the existing products are not flexible enough to meet all these needs in one system. Furthermore, there is a trend among health care organizations, EHR developers, and vendors to move away from niche systems tailored to particular subsets of care providers, such as neonatology, and toward a focus on systems that are generically useful. There are two important drivers behind this trend.

The first and most important reason for adopting a single integrated system is that the benefits of an EHR system begin to accrue only when an entire organization uses the same one. Consider the following scenario: a woman receives prenatal care in the clinic of an institution and is then admitted to the emergency department in preterm labor. Her infant is delivered in the labor and delivery department, hospitalized in the neonatal intensive care nursery, and discharged to an affiliated pediatric follow-up clinic. In the current era of paper medical records, paper is used to convey information from one site to the other. In an integrated EHR system, all the information for both mother and infant is in one place for all providers to see. Interoperability is important as well if the care described crosses organizational boundaries, such as an outpatient-focused health maintenance organization contracting inpatient obstetric care to one hospital system and neonatal or pediatric care to a children's hospital in a different health care system. If a single unified institution were to adopt niche software tailored to the needs of each site, a provider caring for the infant might need to access an emergency department system, an obstetric system, an NICU system, and an outpatient pediatric system to gather all the pertinent information. Each system would require the user to learn a separate piece of software. Learning a site-specific piece of software is a considerably greater burden on care providers than learning to use a site-specific paper form. If care crosses organizations and electronic systems are not interoperable, then care transitions most often remain on paper.

The second factor driving adoption of integrated systems is economies of scale. The ideal EHR system contains electronic interfaces that automatically import the system data from laboratory, pharmacy, radiology, transcription, integrated electronic orders, error checking, and electronic

documentation by care providers. Given that development of these interfaces, training, and maintenance cost more than the purchase of the system itself, it is far more cost effective to install one system with one set of interfaces and one set of training and maintenance issues than to replicate the process multiple times.

The neonatal intensive care environment poses some unique challenges for EHRs. As a result, it is important to ensure that when health care systems are making decisions about the purchase of an EHR, neonatologists and other neonatal health care providers are involved in the process. An excellent source of information about NICU medical record systems and databases is an article by Stavis (1999). Neonatologists in the position of helping to select an EHR system must acquire the necessary background through reading some basic introductory texts on medical informatics, focusing on EHRs. It is then critical that they survey other organizations similar to their own to discover which systems have worked and which ones have not. For example, the needs of a level III academic nursery that performs extracorporeal membrane oxygenation are different from those of a community level II hospital that does not perform mechanical ventilation. Systems that work well in teaching hospitals with layers of trainees may not work well in private practice settings and vice versa. Most important, when using a medical informatics framework, the neonatologists must develop a list of prioritized criteria specific to their institution and compare available products in the marketplace with this list, while also considering the recommendations of the CCHIT as described earlier.

All end user needs must also be considered. If residents, nurse practitioners, nutritionists, pharmacists, and respiratory therapists are expected to use the system, their input must be solicited. Ensuring broad-based input is especially relevant if the goal is an EHR system into which a lot of data will be entered by health care providers (e.g., electronic charting, note writing, medication administration records, order entry). The reason to ensure acceptance by all users of systems that require data entry is that a significant percentage of systems requiring data entry has ultimately been unsuccessful because of lack of user acceptance. Unfortunately there is little literature on this issue, because institutions rarely publicize and publish their failures in this arena, although the situation is beginning to change. A review of some of these challenges and a theoretical framework for looking at them is provided by Pratt et al (2004).

The final step in evaluating a potential system is to develop a series of scenarios and to have potential users test the scenarios. Evaluating usage scenarios typically involves visits to sites that have installed the EHR system under consideration. An example of a scenario might be for a nurse, a respiratory therapist, a resident, and an attending physician to try to electronically replicate, on a given system under consideration, the bedside charting, progress note charting, and order writing for a critically ill patient who undergoes extracorporeal membrane oxygenation and then decannulation. The reason for developing and testing such scenarios is that this approach is the best way to ensure that aspects of charting, note writing, and documentation unique to the NICU are supported by the system.

EVALUATING THERAPEUTIC RECOMMENDATIONS

Once all the data about a patient, whether in electronic or paper form, are in hand, the clinician is faced with the challenge of medical decision making and applying all that he or she knows to the problem. It is vital that the clinician understand what is known and what is still uncertain in terms of the validity of therapeutic recommendations. The evaluation of new recommendations arising from a variety of sources, including journal articles, metaanalyses, and systematic reviews, is a critical skill that all neonatologists must master. Broadly speaking, this approach has been termed *evidence-based medicine*. A full discussion of this approach to evaluation of new approaches in clinical medicine is beyond the scope of this chapter. Two outstanding sources of information are the works by Guyatt and Rennie (2002) and Straus et al (2005). An excellent overview of the progress in evidence-based medicine over the last 15 years is provided by Montori and Guyatt (2008). An important caveat is that evidence-based medicine is not a panacea. It is not helpful when the primary literature does not address a particular clinical situation, such as one that is rare or complex. This approach also does not necessarily address broader concerns, such as clinical importance or cost effectiveness, although it sometimes does. There are potential challenges when combining evidence-based medicine with the emerging humanistic approach to health care, which can heavily weight patient preferences potentially over the evidence base.

In the early days of medicine, the standard practice was observation of individual patients and subjective description of aggregate experiences from similar patients. As the science of medicine evolved, formal scientific methods were applied to help to assess possible therapeutic and management interventions. Important tools in this effort are epidemiology, statistics, and clinical trial design. Currently medicine in general and neonatology in particular are faced with an interesting paradox. For some areas, there is a wealth of information in the form of randomized controlled clinical trials, whereas there is scant information to guide clinical practice for others. A wealth of well-designed clinical trials on the use of surfactant has been published, for example, but there are essentially no trials addressing the management of chylothorax. One might assume that the practice of medicine reflects the available evidence, but this is not the case. McDonald (1996) summarized the problem as follows: "Although we assume that medical decisions are driven by established scientific fact, even a cursory review of practice patterns shows that they are not." A study of 2500 treatments in the British Medical Journals Clinical Evidence Database (http://clinicalevidence.bmj.com), shows that, as of the summer of 2009, 49% of treatments are of unknown effectiveness, 12% are clearly beneficial, 23% are likely to be beneficial, 8% are a tradeoff between beneficial and harmful, 5% are unlikely to be beneficial, and 3% are likely to be ineffective or harmful. As a result, neonatologists have a responsibility to identify what knowledge is available in the literature and elsewhere and to critically evaluate this information before applying it to practice. Furthermore, because this information is constantly evolving, practitioners must continually revisit the underlying literature as it expands (e.g., the recommendations regarding the use of steroids for chronic lung disease).

The evidence-based practice of medicine is an approach that addresses these issues. It is helpful to consider the process as involving two steps—the critical review of the primary literature and the synthesis of the information offered in the primary literature. Critical review of the primary literature is an area in which most neonatologists have significant experience, with journal clubs and other similar forums. The approach involves systematically reviewing each section of an article (i.e., background, methods, results, discussion) and asking critical questions for each section (e.g., for the methods section: Is the statistical methodology valid? Were power calculations made? Was a hypothesis clearly stated? Do the methods address the hypothesis? Do the methods address alternative hypotheses? Do the methods address confounding variables?). The formal evaluation of each section must then be synthesized into conclusions. A helpful question to ask is, "Does this paper change my clinical practice, and if so, then how?" Additional resources for systematic review of the primary literature are listed in the Suggested Readings. It is important to note that guidelines for systematic review of a single article differ according to whether it describes a preventive or therapeutic trial (e.g., use of nitric oxide for chronic lung disease), evaluation of a diagnostic study (e.g., use of C-reactive protein level for prediction of infection), or prognosis (e.g., prediction of outcome from a Score for Neonatal Acute Physiology score).

The second, and arguably more important, step is to determine not the effect of one article on one's practice, but the overall effect of the body of relevant literature on one's practice. For example, if the preponderance of the literature favors one therapeutic recommendation, then a single article opposing the recommendation must be weighed against the other articles that favor it. This task is complex, and the most complete and formal statistical approach to combining the results of multiple studies (i.e., metaanalysis) requires significant investment of time and effort. Part of the evidence-based practice of medicine approach therefore involves the collaborative development of evidence-based systematic reviews and metaanalyses by communities of care providers. Within the field of neonatology, Sinclair et al (1992) laid the seminal groundwork for this approach; their textbook *Effective Care of the Newborn* remains an important milestone, but it illustrates the problem of information currency. Because the book was published in 1992, none of the clinical trials in neonatology in the last decade and a half are included. The Internet has permitted creation and continual maintenance of up-to-date information by a distributed group of collaborators, lending itself well to the maintenance of a database of evidence-based medicine reviews of the literature. This international effort is the Cochrane Collaboration, and the *Cochrane Neonatal Review* is devoted to neonatology (Cochrane Neonatal Collaborative Review Group). A limitation of the Cochrane approach is illustrated by the relatively restricted scope of topics covered at the National Institute of Child Health and Human Development Web site (www.nichd.nih.gov/cochrane/cochrane.htm). The existence of a review requires adequate literature on a topic and a dedicated and committed clinician to create and update the review.

It is important to distinguish between these formal approaches to reviewing the literature (i.e., systematic literature reviews and metaanalyses) that have specific methodologies and more ad hoc reviews of the literature. Evidence-based medicine aggregate resources such as the Cochrane Collaboration take a more systematic approach, but review articles published in the literature vary in their approach. Metaanalyses are easy to distinguish, but systematic reviews versus ad hoc reviews are harder to distinguish. Systematic reviews focus on quality primary literature (e.g., controlled studies rather than case series or case reports) and must include (1) a methods section for the review article that explicitly specifies how articles were identified for possible inclusion and (2) what criteria were used to assess the validity of each study and to include or exclude primary literature articles in the systematic review. Systematic reviews also tend to present the literature in aggregate tabular form, even when metaanalyses of statistics of all the articles cannot be done. One commonly used source of overview information in neonatology—the *Clinics in Perinatology* series—is a mix of opinion (written in the style of a book chapter), ad hoc literature review, systematic literature review, and metaanalysis. Guidelines (e.g., screening recommendations for group B streptococcal infection), although based on primary literature review, are typically neither metaanalyses nor systematic reviews of the literature. Whereas formal methods are used to derive conclusions with metaanalyses and systematic reviews, guidelines are developed frequently instead by consensus among committee members; this is true of both national and local practice guidelines. General textbooks of neonatology are typically based on ad hoc literature review that includes both primary literature and systematic literature review. When reading overviews of the aggregate state of current knowledge on a given topic in neonatology, it is important to keep these distinctions in mind.

Anyone interested in developing evidence-based reviews on a particular topic should review some of the textbooks on evidence-based practice listed at the end of this chapter. Initially, it is a good idea to collaborate with someone who has experience in systematic review and metaanalysis. The process consists of the following steps: (1) identifying the relevant clinical question (e.g., management of bronchopulmonary dysplasia); (2) narrowing the question to a focus that enables one to determine whether a given article in the primary literature answers it (e.g., does prophylactic high-frequency ventilation have positive or negative effects on acute and chronic morbidity—pulmonary and otherwise?); (3) extensively searching the primary literature (frequently in collaboration with a librarian with expertise searching the biomedical literature) and retrieving the articles; (4) critically, formally, and systematically reviewing each article for inclusion, validity, utility, and applicability; and (5) formally summarizing the results of the preceding process, including conclusions valid throughout the body of included primary literature.

ONLINE INFORMATION RETRIEVAL

Because of the rapid growth of biomedical information and because it changes over time, investigators in informatics and publishers believe that print media will soon

no longer be used for sharing and distributing biomedical information (Smith, 1996; Weatherdall, 1995). Economic realities will dictate, however, that quality information will generally come at a price. The medical digital library at the University of Washington (www.healthlinks.washington.edu, under Care Provider) serves to illustrate the current state of the art. The information available is a combination of locally developed material (e.g., University of Washington faculty writing practice guidelines), material developed by institutions elsewhere (faculty elsewhere writing such guidelines), material developed by organizations (e.g., the neonatal Cochrane Collaboration), and electronic forms of journals, textbooks, and evidence-based medicine databases. The last (journals, textbooks, databases) generally are not free, and the University of Washington pays a subscription fee (termed a *site license*) to provide access to these resources for their faculty, staff, and students. Libraries will likely remain the primary source of information, but will shift their attention from paper to electronic records. Health sciences libraries can provide invaluable training in the efficient use of online medical resources, and most offer training sessions and consultation.

A number of online resources are valuable for neonatologists. For accessing the primary literature, the most valuable resource is the National Library of Medicine's database of the published medical literature accessible (PubMed; www.ncbi.nlm.nih.gov/entrez) along with many other databases accessible from the Health Information Web site (www.nlm.nih.gov/hinfo.html). The PubMed system is continually being enhanced; therefore it is useful to review the help documentation online and regularly check the New/Noteworthy section to see what has changed. One of the most powerful yet underused tools is the Find Related Link that appears next to each article listed on PubMed. This link locates articles that are related to the one selected (Liue and Altman, 1998). The PubMed system applies a powerful statistical algorithm with complex weightings to the article selected to each word in the title, to each author, to each major and minor keyword (Medical Subject Heading terms), and to each word in the abstract and then finds statistically similar articles in the database. In general, this system outperforms novice to advanced health care providers performing a complex search, and it begins to approach the accuracy of an experienced medical librarian. Another powerful search tool within PubMed is the Clinical Query (www.ncbi.nlm.nih.gov/corehtml/query/static/clinical.shtml). This tool facilitates searches for papers by clinical study category (e.g., etiology, diagnosis, therapy, prognosis), focuses on systematic reviews, and performs medical genetics searches—the last of which is useful in the context of neonatology. All the major pediatric journals are available online either through a package at local hospital libraries or by subscription, instead of or in addition to a print subscription. The value of having an electronic subscription to a journal is that it provides access to current and past issues. The best free online source of information on evidence-based practice is the *Cochrane Neonatal Review*. Subscriptions to the full Cochrane database can be purchased online as well.

Given the growing role of genetics in health care, and in particular the importance of genetic diseases in infants, there are two notable genetics databases that are available free of charge online (in addition to the Medical Genetics Searches mentioned previously). The first is Online Mendelian Inheritance in Man (www.ncbi.nlm.nih.gov/omim). This database, which is a catalog of human genes and genetic disorders, is an online version of the textbook by the same name. It is a diachronic collection of information on genetic disorders, meaning that each disease entry chronologically cites and summarizes key papers in the field. The second is the GeneTests database (www.genetests.org), which is a directory of genetic testing (what testing is available on a clinical and research basis, where, and how one sends a specimen) and a user's manual (how to apply genetic testing). The user's manual section consists of entries for a growing number of diseases or clinical phenotypes of particular importance. Entries are written by experts, peer reviewed both internally and externally, subjected to a formal process similar to a systematic review, and updated regularly online. As of the winter of 2011, the GeneTests database includes GeneReviews (user's manual entries) for 527 diseases, and the directory includes 1189 genetics clinical, 595 laboratories, and information on testing for 2270 diseases (2005 clinically and 265 on a research basis). An excellent site that maintains links to the majority of locally developed, neonatology-specific content around the country is the site maintained by Duncan (2010). In addition to a database of links to clinical resources around the country, the site also has a job listing and a database of the literature on computer applications in medicine.

The clinician must realize that, unlike journals, textbooks, and guidelines, the material on the World Wide Web (whether accessed from Duncan's site or based on a search) is not necessarily subject to any editorial or other oversight as to what is published; therefore, as stated by Silberg et al (1997), "caveat lector" (reader beware). A number of articles and Web sites address criteria for assessing the validity and reliability of material on a Web site. (Health on the Net Foundation, www.hon.ch Mitretek Systems). With caution in mind, a search on the entire World Wide Web using a sophisticated search engine (e.g., Google, Google Scholar) can yield valuable information, though search results typically include a lower proportion of quality resources compared with curated resources. Google also has a sophisticated statistical algorithm that allows a user to find similar Web pages after identifying a particular one of interest.

CHAPTER 3

Ethics, Data, and Policy in Newborn Intensive Care

William L. Meadow and John D. Lantos

PHILOSOPHY

Ethics in the neonatal intensive care unit (NICU), as in all clinical contexts, starts with the traditional triangular framework of autonomy (do what the patient, or in this case the parent, thinks is right), paternalism (do what the doctor thinks is right), and beneficence and nonmaleficence (do the right thing). These concepts, independent of context or data, are timeless.

The problem with timeless concepts, of course, comes in knowing what to do in real time. What exactly is the right thing? What facts should be brought to bear in the decision? What weight should each fact be given? And whose opinion should count in the end? Nonetheless, some applications of traditional ethical concepts in the NICU are already universally adopted (e.g., avoid futility, do not torture, and intervene when the data provide compelling evidence to do so).

Unfortunately, much of NICU care falls between not resuscitating 21-week births, obligatory support of 28-week births, and not performing cardiopulmonary resuscitation on infants with lethal anomalies. The traditional ethical solution to medical dilemmas is to ground concerns in context, take data into account, and be sympathetic to patient preferences when the balance of benefits and burdens is not clear. The precise problem in the NICU is that the burdens are real, immediate, long term, and significant—months of painful procedures such as intubation, ventilation, intravenous catheterization, and any permanent sequelae that might ensue—whereas the benefits of NICU interventions are distant, statistical, and unpredictable. Moreover, NICU success is often viewed as "all or none"—that is, in most of the NICU follow-up literature a Bayley mental developmental index MDI or psychomotor developmental index PDI greater than 70 is classified as *normal*, whereas an MDI or PDI less than 70 is classified as an *adverse outcome*.

Faced with a difficult case, it is rare that simply applying principles will help to devise a solution. Difficult cases are usually ones in which the principles themselves are in conflict, or their application to the case is ambiguous.

DATA

What kind of information would parents, physicians, or judges want to know about the NICU? The essential truth at the intersection of NICU epidemiology and ethics is that survival depends sharply on gestational age (GA), within relatively precise boundaries. In the United States, as in virtually all the industrialized world, infants born after 27 weeks' gestation have, from any ethical perspective, no increased mortality over infants born at term. Consequently, for these infants, the ethical principle of best interests requires their resuscitation, in the same way that sick children born at term deserve resuscitation.

Conversely, for infants born before 22 weeks' gestation, survival is essentially zero. Consequently, these infants and their parents deserve our compassion, but not our interventions, on the ethical grounds of strict futility.

In between, spanning roughly one gestational month, from 23 to 26 weeks, we will require not just data, but interpretation. First, there is the intriguing finding that GA-specific mortality for infants resuscitated in this gestational range has more or less reached a plateau. Within 10 to 20 years ago, the "border of viability" was steadily decreasing, thus improving outcomes for infants in the gray zone. Not so much, recently, and there is little reason to think that things will change for infants born in this gestational range in the foreseeable future.

Nonetheless, epidemiologic progress has been made. Tyson et al (2008), using the vast data base of the National Institute of Child Health and Human Development network, attempted to go "beyond gestational age" and quantify additional risk factors for both mortality and neurologic morbidity in infants born on the cusp of viability. The analysis revealed that singleton status, appropriate in utero growth, antenatal steroids, and female gender all improve the likelihood of survival and intact neurologic outcome, independent of GA. Tyson's algorithm, using information available at the time of birth, significantly improved predictive value and sensitivity of prognostication over GA alone.

However, two problems remain. First, for many infants the predictive value of the Tyson algorithm is still not very good—that is, many of the lower-risk patients will still die, and many of the higher-risk patients will survive. Second, the Tyson algorithm, like GA, ignores a potentially important feature of NICU care—time. The algorithm stops accumulating data at the time of birth, and it does not account for prognostic features that might become available as the infant's course unfolds in the NICU. In theory, making decisions over the course of time offers two advantages over prognostication in the delivery room. First, parents often appreciate the opportunity to get to know their baby as an individual, as opposed to evaluating anonymous population-based prognostications at the time of birth. Second, there is valuable information to learn while the baby is in the NICU.

Two time-sensitive prognostic features have been evaluated in the context of infants born at the border of viability—serial illness severity algorithms (Score for Neonatal Acute Physiology [SNAP] scores) and serial that intuitions that the patient would "die before NICU discharge" (Meadow et al, 2008). Unfortunately, although SNAP scores on the first day of life have good prognostic power for death or survival, their power diminishes over time. Intriguingly, serial intuitions that an individual baby will die before discharge—offered by medical caretakers for

patients who require mechanical ventilation and for whom there is an ethical alternative to continued ventilation, namely extubation and palliative care—are remarkably accurate in predicting a combined outcome of either death or survival with neurologic impairment (MDI or PDI <70). Children with abnormal results from a cranial ultrasound examination and corroborated predictions of death have a less than 5% chance of surviving with both MDI and PDI greater than 70 at 2 years, independent of their gestational age. The predictive power of these data, acquired over time during an individual infant's NICU course, though not perfect, is greater than any algorithm available at the time of birth.

What do prospective parents or medical caretakers consider when they are asked to decide whether or not to resuscitate their micro-premie? A fascinating insight has been offered by Janvier et al, (2008), who have done extensive surveys comparing responses to requests for resuscitation of sick micro-premies with resuscitation of comparably sick patients at other ages (from term infants to 80-year-olds). Consistently, it appears that micro-premies are devalued—that is, for comparable likelihood of survival and comparable likelihood of neurologic morbidity in survivors, more people would let a micro-premie die first, or at least offer to resuscitate them last. There is no theory to account for these findings.

Indeed, for male infants born at 23 weeks' gestation, the likelihood of intact survival (i.e., neither death in the NICU nor permanent neurologic morbidity) is less than 10%. Given that the likelihood of burdensome therapy is 100%, how can resuscitation be justified? Intriguingly, combining the outcomes of death in the NICU with abnormal neurologic function in later life may not reflect the emotional reality of many NICU parents. For these parents, death in the NICU is not necessarily the worst outcome, because acknowledging that the baby was too small might be better consolation than not ever giving the baby a chance at life.

If trying and failing is seen as a positive process, then the long-term burden of NICU care for parents should perhaps be calculated not as a function of all live births (the current practice), but as a function of infants who survive to discharge. Numerous studies analyzing various populations in several countries have converged on the same surprising observation: the incidence of neurologic morbidity in NICU survivors is not very different when comparing infants at 23, 24, 25, and 26 to 27 weeks' gestation. The essential epidemiologic difference for infants born in this gestational range appears to be whether the baby will survive at all. Once the baby leaves the NICU, the risk of severe morbidity is largely the same; this is true in single-center and multicenter studies, in the United Kingdom, Canada, Europe, and the United States (Johnson et al, 2009; Tyson et al, 2008). Paradoxically, if avoiding survival with permanent crippling neurologic injury is the driving force behind resuscitation decisions, it appears that we should not be worrying about 23- and 24-weekers–rather we should not be resuscitating 26- or 27-weekers, since many more of them will survive, and survive with disability. But that seems very odd.

Finally, there is epidemiologic difficulty in assigning value to morbidity in surviving infants in the NICU. Verrips et al (2008) have attempted to assess the effects of permanent residual disability for NICU survivors and their immediate families; they have demonstrated consistently that children with disabilities and their parents place a much higher value on their lives, and the quality of those lives, than do either physicians or NICU nurses. The vast majority of infants who survive the NICU, even those with significant permanent neurologic compromise, have "lives worth living," as judged by the people most affected by those lives.

GA-specific mortality seems to preclude resuscitation for infants born before 22 weeks' gestation and require resuscitation for infants born after 27 weeks' gestation. In between, the outcomes are murky, prognostic indices are imperfect, and sociologic analyses of human behaviors (of parents and physicians) appear inadequate to develop any uniform approach that is satisfactory.

POLICY

Neonatologists in the United States are sued for medical negligence approximately once every 10 years, and the average U.S. neonatologist will be sued more than once during his or her career (Meadow et al, 1997). Other than case-specific failures or oversights, are there any overarching themes that have arisen from medical malpractice cases in neonatology?

In the United States most malpractice allegations are state based, as opposed to federal cases. Consequently, the decisions of lower state courts, or even state supreme courts, are not binding in any other state, but they can be informative. The first important legal case in neonatology in the United States was *Miller v HCA* (2003). In 1990, Mrs. Miller came to the Hospital Corporation of America (HCA) in Texas in labor at 23 weeks' gestation. The fetus was estimated to weigh 500 to 600 g. No baby born that size had ever survived at that hospital. Mrs. Miller, her husband, and the attending physicians agreed that the baby was previable and that no intervention was indicated. The baby was born, but a different physician performed resuscitation, and the infant survived with brain damage. As a result, the Millers sued the hospital for a breach of informed consent, and they were awarded $50 million by a trial jury. The case wound its way to the Texas Supreme Court, which dismissed the verdict and articulated an "emergency exception" for physicians—that is, if a Texas physician finds himself or herself in the emergency position of needing to resuscitate a patient to prevent immediate death, the physician can try to perform resuscitation without being obligated to obtain consent from anyone. Whether it would be acceptable for a physician not to perform resuscitation in an emergency was left unarticulated by the Texas court.

In Wisconsin, the case of *Montalvo v Borkovec* (2002) took the legal obligations of neonatologists and parents to a different place. The case derived from the resuscitation of a male infant born between 23⅙ and 24⅙ weeks' gestation, weighing 679 g. The parents claimed a violation of informed consent, arguing that the decision to use "extraordinary measures" should have been relegated to the parents. The Wisconsin Appellate Court disagreed, holding that "in the absence of a persistent vegetative state, the right of a parent to withhold life-sustaining treatment from a child does not exist." Because virtually no infant is

born in a persistent vegetative state, this decision would apparently eliminate the ethical possibility in Wisconsin of a "gray zone" of parental discretion. No other jurisdiction in the United States has adopted this position. The Wisconsin Appellate Court, like the Texas Supreme Court, was silent on whether physicians have discretion not to resuscitate. However, in Texas and Wisconsin, physicians are apparently not liable if they choose to do so.

A number of other state courts have addressed issues of treatment or nontreatment. In general, the courts are permissive of physicians who resuscitate infants. If courts are asked to sanction decisions to allow infants to die, most will do so only if there is consensus among physicians and parents, and occasionally ethics committees. Courts are not eager to punish physicians who treat infants over parental objections or to empower physicians to stop treatment when parents want it to continue.

BABY DOE REGULATIONS

Of course, state-by-state civil malpractice cases are not the only administrative means for redrawing the interface between neonatal medicine and the law. The federal government has contributed as well. The Baby Doe Regulations were one of the first attempts to codify and impose a federal vision of appropriate ethical behavior in the NICU.

In 1982, a baby with Down syndrome and esophageal atresia was born in Bloomington, Indiana. At that time, the standard of care for babies with Down syndrome was shifting. A decade or two earlier, most babies with Down syndrome who survived infancy were institutionalized. If babies needed surgery for an anomaly like Baby Doe's atresia, the parents were given the option. Approximately half chose surgery and half chose palliative care (Shaw, 1973). Similarly, half of pediatricians thought that palliative care, rather than surgery, was the better option (Todres et al, 1977). By the early 1980s, this practice had started to change. More parents opted for active intervention to save their babies (Shepperdson, 1983), and more physicians believed that withholding treatment was medical neglect (Todres et al, 1988). Baby Doe was born into this shifting cultural milieu.

Baby Doe's parents refused to consent to surgery and chose palliative care instead. The pediatrician alerted the state child protection agency, which investigated the case. At a court hearing, the parents claimed that they were following the advice of their obstetrician and not their pediatrician. The court found that parents only had to follow the advice of a licensed physician and that, since they were doing so, they were not neglectful. The court did not take protective custody. The doctor and hospital appealed. The Indiana Supreme Court refused to hear the appeal, and the baby died after 8 days (Lantos, 1987).

These facts became publicly known and led to a national controversy that eventually reached the Oval Office. President Reagan demanded federal action. It was difficult to decide which action should be taken, because the federal government has no jurisdiction over child abuse and neglect; it is the domain of the states. The federal government oversees civil rights enforcement, however, and the Reagan administration devised a legal strategy that defined not treating babies with Down syndrome or other congenital anomalies as discrimination against people with disabilities, rather than medical neglect. This strategy gave the federal government a justification for oversight. The new regulations were implemented, and bright red signs containing federal hotline telephone numbers were posted in NICUs across the country. These signs proclaimed that withholding treatment on the basis of disability was a federal civil rights violation (Annas, 1984) and that federal investigative squads could review medical records to determine whether discrimination had taken place. These regulations were challenged and eventually struck down by the U.S. Supreme Court (Annas, 1984).

A diluted version of the original Baby Doe guidelines was eventually incorporated into the federal Child Abuse and Treatment Act (Annas, 1986; Kopelman, 1988). That law, however, is primarily a funding mechanism to channel federal funds to state child protection agencies; it is not a regulation that can be enforced for physicians or hospitals. The Baby Doe regulations do not exist today and have not existed since 1984; however, they still hold symbolic power. The mention of Baby Doe strikes fear in the hearts of pediatricians who lived through the events, in part because pediatricians had made pediatricians into villains in the societal battle over child protection.

There is a certain irony in the controversy over Baby Doe regulations. The original goal—to decrease the range of cases in which withholding treatment of newborns is permissible—did not need federal input. Progress was already being made. Many diseases that used to be considered incompatible with life or that were seen as leading to an unacceptable quality of life were being treated routinely. Metabolic therapies for genetic diseases (phenylketonuria [PKU], hypothyroidism, Gaucher disease) and surgical therapies for organ dysgenesis (congenital heart corrections, congenital diaphragmatic hernia (CDH) repair, extra corporeal membrane oxygenation (ECMO), dialysis) have been forcefully advanced by medical subspecialists in their corresponding fields (e.g., genetics, cardiac surgery, general surgery). With few exceptions (hypoplastic left ventricle being one of the best recognized), these advances have been relatively uncontroversial. Once sufficient data are gathered to demonstrate moderate efficacy, the innovations are widely and rapidly adopted.

There is still controversy when treatments enable survival but have a high likelihood, or certainty, that survival will be accompanied by severe neurologic impairment. As a result, two questions must be asked. First, how severe will the neurologic impairment be? Second, what is the likelihood that the child will have the most severe possible impairment? The prognostic spectrum of Down syndrome is broad, but few infants with trisomy 21 are severely impaired. In contrast, almost all infants with trisomy 13 or 18 either die in infancy or are left with profound neurologic impairment. The outcomes for these chromosomal anomalies can be used to define the spectrum within which clinical decisions are made. For babies whose outcomes are likely to be similar to those seen in trisomy 21, it is no longer permissible to withhold life-sustaining treatment. For babies whose outcomes are likely to be similar to babies with trisomy 13, it is permissible to withhold or withdraw life-sustaining treatment and offer palliative care instead. The calculus becomes more complex in conditions associated with a wider range of outcomes, such as extreme prematurity or high myelomenigocele with hydrocephalus.

The shift in moral standards regarding babies with Down syndrome was not related to technology, but rather sociology. The capacity to repair Arnold–Chiari malformation and duodenal atresia existed long before it was applied to children with myelomeningocele and Down syndrome. What has changed the mood of the country is a growing recognition that disability is as much a social construct as a medical construct, although it is always both and not one or the other.

BORN ALIVE INFANT PROTECTION ACT

In 2002, the U.S. Congress passed a law called the *Born Alive Infant Protection Act* (BAIPA). BAIPA, like the discredited Baby Doe regulations, was an attempt to insert federal values into medical deliberations. There are some interesting similarities and distinctions between Baby Doe and BAIPA. The Baby Doe regulations addressed disability, whereas BAIPA applies to abortion. BAIPA declares that "for the purposes of Federal law, the words 'person', 'human being', 'child', and 'individual' shall include every infant who is born alive at any stage of development." As Sayeed (2005) noted, "The agency arguably substitutes a nonprofessional's presumed sagacious assessment of survivability for reasonable medical judgment." It is unclear what the implications of this law have been. On the one hand, all infants born alive before BAIPA were also treated as human beings; however, that did not necessarily mean that they received all available life support and resuscitation. After all, patients can have do-not-resuscitate orders or receive palliative care rather than intensive care. Still, the purpose of BAIPA seemed to be less about the treatment of babies and more about restrictions on abortion. Although some authors have expressed concern that the influence of BAIPA may transform neonatal care of infants born at, or even below, the threshold of viability, it appears to have had little measurable effect to date. Partridge et al (2009) surveyed neonatologists in California and found that they were concerned about the implications of BAIPA. They write, "If this legislation were enforced, respondents predicted more aggressive resuscitation potentially increasing risks of disability or delayed death." There have been no cases to date in which BAIPA has been invoked or in which physicians and hospitals have been found to be in violation of its requirements.

FUTURE DIRECTIONS

There is no new technology in development that appears likely to affect outcomes significantly. Consequently, for infants who receive resuscitation in the delivery room, birthweight-specific mortality and morbidity are unlikely to change much in the near future. Nonetheless, three developments may change the way we think about newborns, and consequently shift the terrain of neonatal bioethics.

HIGH RISK MATERNAL-FETAL MEDICINE CENTERS

Many children's hospitals are now developing high-risk, maternal-fetal medicine centers. The goal of these centers is to identify fetuses at risk—particularly those with congenital anomalies—and to care for those fetuses and their mothers in centers where there is expertise in fetal diagnosis, therapy, and neonatal care. The hope is that such centers will allow more timely, and therefore more effective, intervention for babies with congenital heart disease, congenital diaphragmatic hernia, or other anomalies.

The medical effectiveness of fetal centers will depend on two distinct developments. First, on a population basis, these centers will only be as effective as fetal screening and diagnosis. The existence of these centers will almost certainly create an expectation and a demand for better fetal screening. Such screening is likely to include both better imaging and better screening tests that can be performed on maternal blood; both will lead to earlier diagnosis of fetal anomalies. These diagnoses will create more complex dilemmas for perinatologists and parents who will need to decide, in any particular case, whether to terminate the pregnancy, offer fetal therapy, or offer either palliative care or interventions after birth. Ironically, better fetal diagnosis may increase the likelihood of pregnancy termination, even when postnatal treatment is possible, such as in hypoplastic left heart syndrome.

Second, the effectiveness of fetal centers will depend on the effectiveness of fetal interventions. Perhaps surprisingly, other than in utero transfusion for Rhesus disease or vascular ablation for twin-twin transfusion syndromes—neither of which are particularly new and neither of which is performed by pediatric surgeons or pediatricians—there is little evidence that any fetal intervention has had any effect on any neonatal outcome. This lack of demonstrated effectiveness has, thus far, not suppressed the proliferation of fetal intervention centers. There may be other factors, including institutional prestige, finances, and recruitment of "desirable" patients.

EXPANDED NEWBORN SCREENING

In recent years, the number of diseases and conditions that can be diagnosed through newborn screening has expanded dramatically. Such screening is under the purview of states, rather than the federal government, and there is wide variation in the number of tests that are performed. In 1995 the average number of tests per state was five (range: zero to eight disorders). Between 1995 and 2005 most states added tests, so that the average number of screening tests done by 2005 was 24 (Tarini et al, 2006). The expansion of newborn screening raises three problems. First, even the most accurate test has false positives. For rare conditions, the percentage of positive tests that are false positives is increased. Thus, the more rare conditions that are added to a newborn screening panel, the more false positives there will be. False positives are associated with considerable parental anxiety and can lead to potentially dangerous and unnecessary diagnostic procedures or treatments. Second, expanded newborn screening costs money. Interestingly, the tests themselves are astoundingly inexpensive, which is why policy makers are tempted to add more to the panels. However, the follow-up counseling and testing after positive tests are expensive, and without such follow-up the screening programs will not work. The Centers for Disease Control and Prevention has recently expressed concern about these costs (Centers for Disease Control

and Prevention, 2008). Finally, there is the potential for discrimination against patients for whom documented heterozygous carrier status conveys no recognized medical infirmity, but social or psychological stigma may be real. There is little funding available to assist or counsel these patients.

FINANCIAL CONSTRAINTS

The American Academy of Pediatrics guidelines on neonatal resuscitation suggest that resuscitation should be obligatory at 25 weeks' gestation or greater, optional at 24 weeks' gestation, and unusual at 23 weeks' gestation. These recommendations are thought to reflect the best understanding of both the ethical discussion and the epidemiologic facts surrounding NICU outcomes. The recommendations purport to reflect the traditional paradigm that data drive policy. However, particularly in the context of NICU survival for infants at 23 to 25 weeks' gestation, there is good evidence that causation can work in the reverse direction—that is, policy drives data. In the Netherlands, Canada, and some parts of Oregon, survival at 25 weeks' gestation is comparable and comparably good; more than 50% of infants born at 25 weeks' gestation will survive to discharge. However, in the Netherlands, virtually no infant survives birth at 24 weeks' gestation, whereas in Canada and Oregon the survival rate is 40%. In addition, in Oregon and some parts of Canada, survival at 23 weeks' gestation is close to zero, whereas in other parts of Canada and the United States the survival rate is 20% or greater. Why? Certainly not because the Dutch, Canadians, or Oregonians have forgotten how to resuscitate small infants. Rather, they have chosen not to. Why not? Perhaps it is non-maleficence–the fear that survival with permanent neurologic morbidity may be cruel to the child, the family, or society at large. However, the incidence of neurologic morbidity in survivors is not different when comparing infants at 23, 24, 25, and 26 to 27 weeks' gestation. If the fear of a permanent crippling neurologic injury is the driving force, we should not be resuscitating 26 or 27 weekers, since many more of them will survive, and survive with disability. But that seems odd.

The approach in the Netherlands is consistent; there is a limited budget and a communitarian ethic. There is a certain rationale behind spending money on all pregnant women, instead of 1% of micro-premies. The United States appears ambivalent–we value individuals over community, are fascinated with high-technology, and claim to prize our children. On the other hand, we will not spend money to prevent unwanted teen pregnancy or to provide visiting nurses for new mothers.

Finally the concept of generational conflict must be considered. We appear quite comfortable calling delivery-room resuscitation of 24 weekers "optional," based on gestational age alone. It is difficult to imagine the AMA recommending that resuscitation for 85-year-olds who come to the emergency department is "optional," based on age alone. NICU care is often criticized as "too expensive." We ask, "Compared to what?"

Fewer than 5% of infants will be in the NICU for more than a short stay. The vast majority of these patients will survive. Only 24,000 infants of 4 million births die each year in the United States, and half of these will die within fewer than 7 days. In contrast, nearly 3 million adults will die in the United States each year and one third of these will have been admitted to an medical intensive care unit (MICU) in the 6 months before dying. MICU costs outpace NICU costs by at least 100 to 1.

SUMMARY

Ethical philosophy is a place to start, not a place to finish. Data are relatively easy to acquire and agree on. Policy is intriguingly insensitive to data, but that may reflect social and political realities that exist beyond the NICU—perceptions of disability, abortion politics, individual versus communitarian emphasis, fascination with technology, discrimination, publicity, financial constraints—so that an ethical course of action in one country, one city, or one family might seem perverse elsewhere.

CHAPTER 4

Global Neonatal Health

Linda L. Wright

CHILD MORTALITY

In 2000, the 192 United Nations member states and many international partners adopted the Millennium Development Goals (MDGs) in response to morbidity and mortality rates in the developing world that were alarmingly high. These eight international development goals were to eradicate extreme hunger and poverty; achieve universal primary education; promote gender equality and empower women; reduce child mortality; improve maternal health; combat HIV/AIDS, malaria, and other diseases; ensure environmental sustainability; and develop a global partnership for development. The agreement included 18 specific targets and 48 technical indicators to measure progress toward the MDGs between 1990 and 2015 (United Nations General Assembly, 2001).

Although significant progress has been made toward achieving many of the MDGs, progress has been uneven, with huge disparities across the goals and among countries. This disparity is especially true for MDG 5 (i.e., improving indicators of maternal health, including maternal mortality during pregnancy or the 42 days following the end of pregnancy, per 100,000 deliveries) and MDG 4 (i.e., reducing child mortality, expressed as deaths before 5 years per 1000 live births). Regions and countries that have the highest maternal mortality rates also have the highest child mortality rates (Table 4-1).

Twenty percent of all deaths in the world are child deaths (Save the Children, 2007; United Nations Children's Fund, 2007), and greater than 99% of deaths occurring in children aged 5 years or younger are in the developing world. Of the 136 million babies born in 2007, an estimated 9.7 million died before the age of 5 years (approximately 26,000 per day) (Save the Children, 2007; United Nations Children's Fund, 2007). This staggering number equals approximately half of all U.S. children younger than 5 years (Save the Children, 2007; U.S. Census Bureau's American Community Survey, 2007). The latest estimates suggest that 8.8 million children died in 2008 (United Nations Children's Fund, 2008b). The rate of decline in mortality in children younger than 5 years is grossly insufficient to meet the MDG 4 goal by 2015, particularly in Sub-Saharan Africa and South Asia (United Nations Children's Fund, 2009). At the current rate, the target of fewer than 5 million annual child deaths will not be met until 2045. To meet the goal of fewer than 5 million child deaths in 2015, deaths in children younger than 5 years must be cut in half between 2008 and 2015 (Table 4-2) (United Nations Children's Fund, 2007, 2009a).

The regions with the highest numbers of child deaths are Sub-Saharan Africa (which has high fertility rates and the highest child mortality rates [144 deaths per 1000 live births], and 4.8 million children [1 in 7] dies before the age of 5 years) and South Asia (3.1 million deaths [1 in 13] before the age of 5 years) (United Nations Children's Fund, 2007). Sub-Saharan Africa accounts for 51% of all deaths among children younger than 5 years, followed by Asia with 42% (You et al, 2009).

In 2008, 75% of deaths in children younger than 5 years occurred in only 18 countries, and 40% occurred in only three countries: India, Nigeria, and the Democratic Republic of the Congo. Of the 34 countries with mortality rates exceeding 100 per 1000 live births in 2008, all were in Sub-Saharan Africa, except for Afghanistan (You et al, 2009). Equally troubling, only 10 of the 67 countries with high mortality rates (at least 40 per 1000 live births) were on track to meet MDG 4 before the 2009 economic crisis (You et al, 2009). However, a number of relatively poor countries with low gross national incomes have made considerable progress in improving survival, including Malawi, Tanzania, Madagascar, Nepal, Bangladesh (Save the Children, 2007), Eretria, the Lao People's Democratic Republic, Mongolia, and Bolivia (Figure 4-1) (You et al, 2009).

More than 70% of deaths in children younger than 5 years are caused by newborn problems, pneumonia, and diarrhea. Pneumonia kills more children than any other illness—more than HIV, malaria, and measles combined (Figure 4-2). Pneumonia results in death for more than 2 million children younger than 5 years each year, or approximately 20% of child deaths worldwide. More than 95% of all new pneumonia cases, representing an estimated 150 million episodes of pneumonia annually, occur in children younger than 5 years in developing countries. Sub-Saharan Africa and South Asia together have more than half the total number of pneumonia cases. Effective prevention strategies include immunization against measles, whooping cough, *Haemophilus influenzae* type b, and *Streptococcus pneumoniae;* exclusive breastfeeding and improved nutrition or low birthweight; zinc supplementation; reducing indoor air pollution; and prevention and management of HIV infection (Qazi et al, 2008); however, the protection afforded by immunizations will not prevent neonatal pneumonia. Universal use of simple standardized management guidelines for identifying and treating pneumonia in communities and primary health care centers, with the World Health Organization (WHO) Integrated Management of Childhood Illness (Niessen et al, 2009), may reduce the child pneumonia fatality rate (Niessen et al, 2009). Sazawal and Black (1992) suggested that community-based acute respiratory infection case management might reduce mortality by more than 20% in children younger than 4 years. Failing prevention, prompt diagnosis and treatment are necessary to improve pneumonia mortality and morbidity; however, prompt diagnosis and effective treatment of pneumonia and hypoxemia are often not available. Radiology, laboratory tests, and pulse oximetry, which can predict response to antibiotic therapy in cases of severe pneumonia (Fu et al, 2006), are not available in most first-level (i.e., rural)

TABLE 4-1 Countries With the Highest Numbers of Child Deaths Also Have High Rates of Maternal Death

Country	Ranking for Number of Child Deaths	Number of Child Deaths	Ranking for Number of Maternal Deaths	Number of Maternal Deaths
India	1	1,919,000	1	136,000
Nigeria	2	1,043,000	2	37,000
DR Congo	3	589,000	4	24,000
Ethiopia	4	509,000	4	24,000
Pakistan	5	473,000	3	26,000
China	6	467,000	9	11,000
Afghanistan	7	370,000	7	20,000
Bangladesh	8	274,000	8	16,000
Uganda	9	200,000	12	10,000
Angola	10	199,000	9	11,000
	6,043,000 child deaths Approximately 60 percent of global total		315,000 maternal deaths Approximately 60 percent of global total

World	**93**	**72**	**1.6**	**9.4**	Insufficient progress

United Nations Children's Fund: The state of the world's children 2008: child survival, 2007, New York.
*Progress towards MDG 4, with countries classified according to the following thresholds:
On track: U5MR is less than 40, or U5MR is 40 or more and the average annual rate of reduction (AARR) in under 5 mortality rate observed from 1990 to 2006 is 4.0% or more.
Insufficient progress: U5MR is 40 or more and AARR observed for the 1990-2006 period is between 1.0% and 3.9%.
No progress: U5MR is 40 or more and AARR observed for 1990-2006 is less than 1.0%.
Source: UNICEF estimates based on the work of the interagency Child Mortality Estimation Group.

hospitals, despite high mortality rates in children who have hypoxemia or HIV. Randomized controlled trials of parenteral antibiotic treatment in hospitals compared with home-based treatment have demonstrated the safety and efficacy of treating pneumonia with oral antibiotics outside of a hospital setting in older children. New evidence regarding home treatment of severe pneumonia is changing concepts about the need for hospitalization. The first randomized trial to compare outcomes of hospital treatment of severe pneumonia, without underlying complications, with home-based oral antibiotics in Pakistan demonstrated that home-based antibiotics are safe and effective. Of 2037 children with severe pneumonia aged 3 to 59 months, randomized to either parenteral ampicillin for 48 hours followed by 3 days of oral ampicillin or home-based oral amoxicillin for 5 days, there were equal numbers of failures in the hospitalized group (8.6%) and in the ambulatory group (7.5%) by day 6. Just 0.2% children died within 14 days of enrollment and none of the deaths were considered to be associated with treatment

allocation (Hazir et al, 2008). A small percentage (approximately 2% to 3%) of severely ill children will still require early community detection and transport to a hospital for evaluation of hypoxia, infection, pneumonia, malaria, and parenteral antibiotics with or without oxygen (Mwaniki et al, 2009). The WHO has spearheaded efforts to reduce the global burden of child pneumonia with the Integrated Management of Childhood Illness, a Global Action Plan for Control and Prevention of Pneumonia (GAPP) (Qazi et al, 2008), publication of new comprehensive global, regional, and national disease burden statistics for pneumococcal and hepatitis b disease, the Global Coalition against Childhood Pneumonia, and the first World Pneumonia Day on November 2, 2009 (United Nations Children's Fund, 2009b).

Diarrheal diseases are the second most common cause of child deaths globally. Worldwide, diarrhea accounts for 18% of deaths among children younger than 5 years, or an estimated 1.7 million child deaths every year, and it accounts for 10% to 80% of growth retardation in the first few years of life (Baqui and Ahmed, 2006). Exclusive breastfeeding provided significant protection from diarrheal diseases before the WHO-recommended introduction of complementary feeds at 6 months. Children in poverty are especially prone to diarrheal diseases after the introduction of complementary feeding, because diarrhea is spread by poor hygiene and sanitation facilities; contaminated water, formula, food, or utensils; low rates of vitamin A supplementation; low zinc intake; and limited access to rotavirus immunization. Most diarrhea-related deaths in children are due to dehydration. The WHO recommendations for oral rehydration therapy (ORT) for childhood diarrheal diseases have changed. Research has demonstrated that homemade fluids that contain lower concentrations of sodium and glucose, sucrose, or other carbohydrates (e.g., cereal-based solution) can be as effective as ORT. Current recommendations include increased fluid intake and continued feeding, as well as the use of zinc and low-osmolarity ORT to prevent and treat diarrheal episodes (Fischer-Walker et al, 2009; World Health Organization and United Nations Children's Fund, 2004). Lower-osmolarity ORT reduces stool output, vomiting, and unscheduled intravenous therapy (Baqui and Ahmed, 2006). In Sub-Saharan Africa there has been little progress in diarrhea prevention and treatment in the last decade—the percentage of children younger than 5 years who received the recommended treatment increased from 32% in 2000 to only 38% in 2008 (United Nations Children's Fund, 2009). Progress on case management of childhood

pneumonia, diarrhea, and malaria will depend on strengthening the integrated community-based prevention and treatment of these pervasive childhood diseases within the health system (United Nations Children's Fund, 2009).

Undernutrition is another major factor in mortality of children younger than 5 years; it is responsible for 7% of the total disease burden in any age group, making it the highest of any risk factor for overall global burden of disease (Black et al, 2008b). Undernutrition is a contributing factor in more than half of infectious disease deaths in children (Save the Children, 2007) and is the underlying cause of more than one third of all deaths among children younger than 5 years (United Nations Children's Fund, 2008a). The effects of undernutrition reach beyond the individual child. Maternal or child undernutrition is a complex intergenerational problem that includes intrauterine growth restriction, severe wasting, and stunting. Virtually no progress has been made toward overcoming undernutrition in the last 25 years (United Nations Children's Fund, 2008a). Wasting (weight-for-height Z score less than –2) is associated with acute weight loss. Of the estimated 55 million children younger than 5 years with wasting (10% of all children), more than half are in south central Asia or Sub-Saharan Africa; 19 million children have severe acute malnutrition or wasting (weight-for-height Z score less than –3) and are in need of urgent therapeutic feeding (United Nations Children's Fund, 2008a). Stunting (height-for-age Z score less than –2), which is more common, indicates chronic restriction of a child's potential growth. An estimated 178 million children younger than 5 years have stunting—almost one third of children in low- to middle-resource settings. Ninety percent of them (160 million) live in just 36 countries and represent almost half of the children in those countries. India's 61 million children with stunting represent more than half of all Indian children younger than 5 years and 34% of all children with stunting worldwide (Bhutta et al, 2008a). This urgent problem must be solved, because the period between birth and 24 months old is critical. If children do not grow appropriately before 2 years old, they are more likely to be short as adults, have lower educational achievement and economic productivity, and give birth to smaller infants who repeat the cycle in the next generation. Although the problem of undernutrition has been overshadowed by concerns over obesity, there is no evidence that rapid weight or linear growth in the first 2 years of life increases the risk of chronic disease in adults (fetal origin of adult disease), even in children with poor fetal growth (Victora et al, 2008).

A recent review of interventions that affect maternal and child undernutrition suggested that counseling about breastfeeding and supplementation with vitamin A and increased zinc intake have the greatest potential to reduce the burden of child morbidity and mortality (Bhutta et al, 2008a). The promotion of breastfeeding has had an effect on the improved survival of infants and young children, but its effect on stunting has been negligible. Among populations with inadequate food, food supplements are beneficial with or without educational interventions (increased height-for-age Z scores by 0.41; 95% confidence interval [CI], 0.05-0.76) and can reduce stunting and the related burden of disease. In populations with sufficient food, complementary feeding education increased height-for-age Z scores by 0.25 (95% CI, 0.01-0.49) compared with controls. Facility management of severe acute malnutrition, according to WHO guidelines, reduced the case fatality rate by 55% (relative risk [RR], 0.45; 95% CI, 0.32-0.62), and observational data suggest that ready-to-use prepared foods in treatment of severe malnutrition may be effective in community settings as well. Recommended micronutrient interventions for children include strategies for vitamin A supplementation, zinc supplements to prevent and treat diarrhea and lower respiratory tract infections, iron supplements in areas where malaria is not endemic, and universal promotion of iodized salt (Bhutta et al, 2008a). A subsequent metaanalysis of neonatal vitamin A supplementation concluded, on the basis of six trials in the developing world, that there was no evidence for a reduced risk of mortality and morbidity during infancy and thus no justification for neonatal vitamin A supplementation as a public health measure to reduce infant mortality and morbidity in developing countries (Gogia and Sachdev, 2009). The efficacy of zinc supplementation in reducing overall mortality in neonates has been questioned as well (Sazawal et al, 2007). Existing interventions designed to improve nutrition and prevent related disease may reduce stunting at 36 months old by as much as 36% and mortality between birth and 36 months old by approximately 25%. However, elimination of stunting will require long-term investment in improved nutrition and interventions to improve early childhood education, maternal education, and women's economic status (Black et al, 2008a). Growth (length, height, and weight) should be monitored routinely and regularly in view of its importance as a marker for undernutrition and stunting (Victora et al, 2009).

The nutrition of the children of India and Sub-Saharan Africa are of greatest concern. India is a concern because it represents 34% of the world's children with stunting, who often start life with intrauterine growth retardation and as adults are members of families with intergenerational stunting that live on less than $2 per day. In Africa, neonates are born with normal birthweight, but develop stunting and wasting because of poverty and civil unrest. Although exclusive breastfeeding protects the neonate, providing adequate amounts of nourishing food in early infancy is critical to the future of children from these two continents. Among the areas needing further research are assessments of the effectiveness and cost-effectiveness of a national health system's nutritional interventions on stunting rates and weight gain; long-term effects of maternal nutritional interventions on maternal and child health and cognitive outcome; research on the reversibility of stunting and cognitive impairment in children aged 36 to 60 months; studies of community-based prevention and treatment strategies for severe acute malnutrition; and studies of the effectiveness of various zinc delivery strategies.

EPIDEMIOLOGY OF NEONATAL MORTALITY (BEFORE 28 DAYS)

Developed countries have experienced significant declines in child mortality in the last 30 years, but only 1% of the world's neonatal deaths occur in 39 high-income countries whose average neonatal mortality rates are 4 to 6 per 1000

TABLE 4-3 Regional or Country Variations in Neonatal Mortality Rates and Numbers of Neonatal Deaths, Showing the Proportion of Deaths in Children Younger than Age 5 Years

	NMR per 1000 Livebirths (range across countries)	Number (%) of Neonatal Deaths (1000s)	Percentage of Deaths in Children Aged Younger than 5 Years in the Neonatal Period	Percentage Change in NMR between 1996 and 2005 Estimates*
Income groups				
High-income countries†	4 (1–11)	42 (1%)	63%	–29%
Low-income and middle-income countries	33 (2–70)	3956 (99%)	38%	–8%
WHO regions				
Africa	44 (9–70)	1128 (28%)	24%	5%
Americas	12 (4–34)	195 (5%)	48%	–40%

*The data inputs cover at least a 5-year period before each set of estimates. Period of change may be assumed to be up to 15 years.
†Thirty-nine countries with NMR data of 54 countries with gross national income per person of US$9386.10.

live births. In contrast, little progress has been made in reducing maternal and neonatal deaths in the developing world, where the disparity is large and growing (Lawn et al, 2005) and the average neonatal mortality rate (deaths in the first 28 days of life per 1000 live births) in 2000 was 33, with a range of 2 to 70. Together Africa and Southeast Asia account for approximately two thirds of neonatal deaths (Table 4-3) (Lawn et al, 2005).

More than half of all maternal and newborn deaths occur at birth or in the first few days after birth, when health coverage is the lowest. Cultural norms, financial constraints, and small fetuses that are considered nonviable also limit the reporting of neonatal deaths. As a consequence, the births of an estimated 51 million children per year go unrecorded in any formal registration system (United Nations Children's Fund, 2007). These children are often born in slums or rural poverty to very young or older mothers who lack access to education and basic health and reproductive services, and who also live in countries that have experienced recent political unrest (United Nations Children's Fund, 2007). As a result, fewer than 3% of neonatal deaths occur in countries that have high-coverage vital registration data or recent, reliable data on causes of neonatal death; therefore global analysis is based on estimates (Lawn et al, 2005) derived from statistical modeling. Until the middle to late 1990s, estimates of neonatal deaths were drawn from historical data. More rigorous estimates using demographic and health surveys of newborn deaths at a national level were available in 1995 and 2000 (Lawn et al, 2005; United Nations Children's Fund, 2008a), which produced more reliable neonatal mortality rates. The lack of reliable data from most high-risk countries, and the complex methods for developing estimates and for estimating uncertainty, makes even these improved neonatal mortality data inherently uncertain (United Nations Children's Fund, 2008a). As a result, data from different sources are difficult to compare and interpret; this will be especially true when comparing data from before and after 2008, when the Inter-agency Group for Child Mortality Estimation (IGME) incorporated a substantial amount of new data and developed a new method to adjust mortality related to HIV/AIDS (You et al, 2009).

The latest available data suggest that 3.7 million deaths (40% of deaths in children younger than 5 years) occur in the first month and that there are almost as many stillbirths per year worldwide (3.3 million) (Stanton et al, 2006; United Nations Children's Fund, 2008a; World Health Organization, 2006). The first hours and days of a baby's life are the most critical (Figure 4-3). Every year 2 million babies die on the day they are born (Save the Children, 2007), representing almost 50% of all neonatal deaths, and an astounding 75% of neonatal deaths occur within the first 7 days of life (Murray et al, 2007; Save the Children, 2007).

As a result, a neonate is approximately 500-fold more likely to die in the first day of life than at 1 month of age (United Nations Children's Fund, 2007). Without a major reduction in early (7 days) deaths in high-mortality countries, it will be impossible to meet the MDG 4 (Figure 4-4) (World Health Organization, 2006).

MATERNAL RISK FACTORS FOR NEONATAL DEATH

Because 40% to 90% of women in low-resource settings deliver their baby in the home without a skilled birth attendant or access to facility care for themselves or their newborn, intrapartum complications put the fetus or neonate at increased risk for death, especially maternal bleeding after the eighth month, hypertensive disorders, obstructed labor, prolonged second-stage of labor or malpresentation, maternal fever or rupture of membranes for longer than 24 hours, multiparity, malaria or syphilis, meconium staining, and maternal HIV (Lawn et al, 2005).

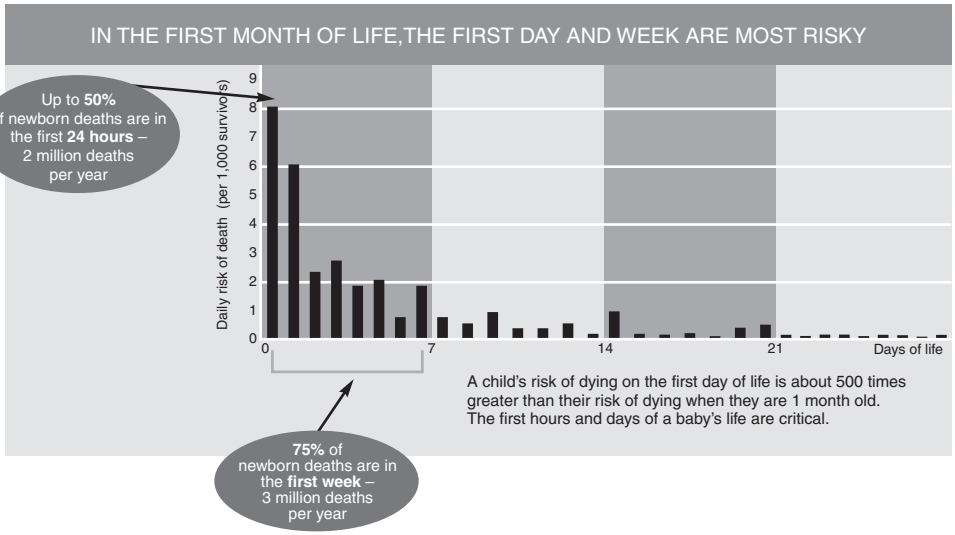

FIGURE 4-3 In the first month of life, the first day and week pose the highest risk. *(Modified from ORC Macro: Measure Demographic Health Survey STAT compiler, 2006. Available at www.measuredhs.com. Accessed April 6, 2006. Based on the analysis by J. Lawn of 38 DHS datasets [2000 to 2004] with 9022 neonatal deaths.)*

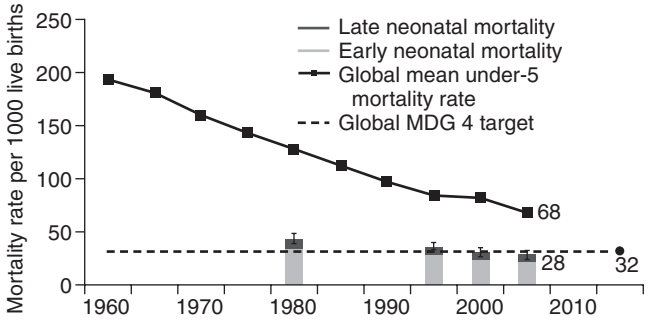

FIGURE 4-4 Progress toward Millennium Development Goal 4 for child survival showing the increasing proportion of deaths in children younger than 5 years. *(Modified from Lawn JE, Kerber K, Enweronu-Laryea C, et al: Newborn survival in low resource settings: are we delivering?* BJOG *116[Suppl 1]:49-59, 2009.)*

STILLBIRTHS

Current estimates attribute at least 3.2 million deaths worldwide to stillbirth—defined as having no signs of life at delivery in a fetus at 28 weeks' gestation or greater—ranging from 5 per 1000 in wealthy countries to 32 per 1000 in South Asia and sub-Saharan Africa (Lawn et al, 2009c; Stanton et al, 2006); however, stillbirths are largely unrecorded and uncounted. Although differentiating a macerated stillbirth from a recent stillbirth seems simple, differentiating a stillbirth from an early neonatal death is challenging, especially in community settings with weak health systems and limited access to facility care. The task requires training in monitoring fetal heart rate and early signs of life, prompt and appropriate resuscitation, and emergency caesarian section, as required (McClure et al, 2007). Lack of training of birth attendants in resuscitation and careful assessment for signs of life, variability in what is considered the lower limit of viability, gender bias, and the influence of financial or other burdens with an assignment can result in the misclassification of early deaths as stillbirths. Cultural norms that discourage the weighing of dead infants and dictate prompt burial may serve to perpetuate misclassification. *Stillbirth* is commonly defined as fetal death within the last 12 weeks of pregnancy (i.e., at least 28 weeks' gestation or weighing 1000 g); however, some community and national standards define *stillbirth* as fetal death after 22 weeks' gestation or weighing 500 g. Because most of these deaths occur in settings where women have limited access to skilled birth attendants, it is likely that the current estimates of stillbirth numbers are too low and that a cause of death may not be established in the majority of stillbirths that occur in the developing world. Better data on the number and causes of stillbirth are urgently needed to prioritize action to reduce avoidable stillbirths in high-mortality settings, where rates are at least 10-fold higher than in wealthy countries (Stanton et al, 2006). Stillbirths are included in the mortality tables of the 2009 *Global Burden of Disease* for the first time (Lawn et al, 2009c).

DIRECT CAUSES OF NEONATAL DEATH

The proportion of neonatal deaths among children younger than 5 years varies, but the absolute number of neonatal deaths is determined by the size of the population and the neonatal mortality rate (NMR). Africa and Southeast Asia represent approximately two thirds of neonatal deaths, with the largest number of newborn deaths in South Asia and the highest rates of neonatal mortality in Sub-Saharan Africa, similar to child deaths. India contributes 25% of the world's neonatal deaths (United Nations Children's Fund, 2007).

Three causes of neonatal death are responsible for approximately 75% of neonatal deaths: prematurity (28%), sepsis and pneumonia (26%), and asphyxia (23%) (Save the Children, 2007). Prematurity (birth before 37 weeks' gestation) and asphyxia (failure to initiate and sustain spontaneous respiration) can result in long-term neurologic injury and cognitive impairment among survivors

in countries and families that are least able to provide appropriate care. For every newborn that dies, another 20 suffer birth injury, preterm birth complications, or other neonatal conditions (United Nations Children's Fund, 2007). Determining cause-specific perinatal and neonatal mortality would allow the development of focused interventions and evaluation of their effects on perinatal and neonatal survival. However, establishing a primary cause of stillbirth and neonatal death in the 50% (2 million) of neonates that die in the first day—often in homes without access to health care systems, skilled birth attendants, or diagnostic techniques—is extremely challenging. To overcome these problems, verbal autopsy techniques have been developed to assign a cause of death in such cases, usually based on an interview with the infant's mother or caretaker within 6 months of the child's death. The cause of death is assigned by a panel of physicians or compared to a reference standard from prospective hospital-assigned causes of death. The diagnostic accuracy of verbal autopsy techniques to establish neonatal cause of death is limited because of the lack of standardization of case definitions, cause of death classifications, methods of assigning cause of death, and the limited generalizability of hospital reference standards to infants who die in the community (Edmond et al, 2008; World Health Organization, Development of Verbal Autopsy Standards). In the absence of critical vital registry data (Setel et al, 2007), global estimates of the causes of neonatal deaths are possible only through statistical modeling.

The cause-specific distribution of neonatal deaths correlates with the NMR. In high-mortality settings (>45 per 1000 live births), the risk of neonatal death because of severe sepsis and pneumonia is approximately 11-fold higher, and the risk of dying because of birth asphyxia is approximately eightfold higher than the risk in low-mortality countries (<15 per 1000 live births). The proportion of deaths as a result of prematurity drops in countries with a high NMR because of the deaths due to infection; however, the risk of death attributable to the complications of prematurity is still threefold higher than in low-mortality countries (Lawn et al, 2005). In addition to significant differences in cause-of-death distribution between countries, there is often substantial variation within countries (Lawn et al, 2005), especially between urban and rural areas.

CONSEQUENCES OF PRETERM DELIVERY AND LOW BIRTHWEIGHT

Prematurity and low birthweight are often not distinguished because of the lack of gestational age dating and failure to weigh all babies at birth. As many as 18 million babies worldwide may be born annually at a low birthweight (<2500 g). Although low birthweight affects approximately 15% of births, preterm delivery and low birthweight may account for up to 60% to 80% of neonatal deaths (Awasthi et al, 2006). South Asia contributes 50% of the world's babies with low birthweight, because 29% of babies have a low birthweight. In contrast, only 14% of Sub-Saharan African babies have a low birthweight (United Nations Children's Fund, 2007).

In developed countries, preterm birth is the leading cause of morbidity and mortality, and the percentage of deaths attributed to preterm delivery is more than twofold the percentage of deaths due to asphyxia, sepsis and pneumonia, and congenital anomalies (death from diarrhea does not occur) (Lawn et al, 2005). The current rate of 12.5% in the United States represents an increase of more than 30% since 1981 and is almost double the 5% to 9% frequency in other developed countries. The highest rates of preterm birth in the United States occur among racial and ethnic minorities and in older women who conceive by artificial reproductive technology (Preterm birth: crisis and opportunity, 2006). Whether the number of preterm deliveries is rising in the developing world is unknown.

Despite 30 years of research, little is known about the etiology and prevention of preterm delivery, but improved management in neonatal intensive care units has increased the survival of extremely immature fetuses in the developed world. Complex technology is not required to prevent deaths attributable to prematurity and birth asphyxia in the developing world. Low-cost interventions, including resuscitation training (Deorari et al, 2001), nutritional and thermal support through kangaroo-mother care (Charpak et al, 2005), and exclusive breastfeeding may reduce deaths attributable to asphyxia and preterm delivery after 34 weeks' gestation. The WHO has developed an Essential Newborn Care package, which includes clean delivery practices, neonatal delivery care (including prompt stimulation and bag-mask resuscitation as required), thermoregulation with skin-to-skin care, early initiation of exclusive breastfeeding, care of the moderately small baby at home, and recognition of common illnesses (World Health Organization and Department of Reproductive Health and Research, 1996). The addition of neonates to the WHO–United Nations Children's Fund *Integrated Management of Childhood Illnesses* package, which has been adopted by India, represents a significant resource to improved neonatal survival. The package provides skill-based training with elements similar to the Essential Newborn Care package, but it adds immunization and several postpartum home visits by health workers to help mothers recognize and manage minor conditions and refer severe cases in a timely manner (World Health Organization, 2003a). The Global Alliance to Prevent Prematurity and Stillbirth (GAPPS) has recently been launched to address stillbirth and prematurity with a comprehensive review of published and unpublished data on preterm birth and stillbirth research and interventions. In collaboration with diverse global partners in science, public health, and policy, GAPPS plans to advance research on the etiology of preterm delivery and stillbirth, accelerate delivery of low-cost effective interventions, and raise awareness of the effects of prematurity and stillbirth (www.gapps.org).

NEONATAL SEPSIS AND PNEUMONIA

Neonatal infections are responsible for more than 1 million of the 3.7 million annual deaths in the developing world. More than 95% of all deaths from birth to 2 months of age occur in developing countries. Risk factors include chorioamnionitis, low birthweight, unhygienic delivery, skin care, cord care, and environments. Ideally, simple preventive strategies such as clean delivery kits, hand washing, and cord care would be effective, but such data are not

available, and the effectiveness of using chlorhexidine to prevent community-acquired neonatal sepsis and mortality is still unsettled (Cutland et al, 2009; Mullany et al, 2006). The quality and quantity of data on neonatal deaths caused by infections in the developing world are extremely limited. The estimated total is at least 1.6 million annual deaths (26% for sepsis and pneumonia, excluding tetanus and diarrhea) (Lawn et al, 2005). The majority of births and deaths are thought to occur at home without coming to medical attention (Lawn et al, 2004), because of cultural norms that prescribe seclusion for mothers and neonates; lack of trained caretakers and facilities; high out-of-pocket costs for transport, hospitalization, and medications; and loss of wages for the mother, the father, and often another family member. As a result, the current WHO recommendation of 10 to 14 days of inpatient treatment with broad-spectrum parenteral antibiotics is unavailable or unacceptable to most families (Zaidi et al, 2005).

Among those babies born in hospitals, the risk of nosocomial infection is threefold to 20-fold higher (6.5 to 38 per 1000) than in industrialized countries because of poor intrapartum and postnatal infection-control practices (Zaidi et al, 2005). Many hospitals are overcrowded and understaffed and lack even basic infection control procedures, despite the guidelines of WHO–United Nations Children's Fund *Integrated Management of Pregnancy and Childbirth* and the *Newborn Problems Handbook: A Guide for Doctors, Nurses, and Midwives* (World Health Organization, 2003a, 2003b; Zaidi et al, 2005). The major pathogens among babies born in a hospital (11,471 isolates) are *Klebsiella pneumonae*, other gram-negative rods (*Escherichia coli*, *Pseudomonas* spp., *Acinetobacter* spp.), and *Staphylococcus aureus* (8% to 22%) (Zaidi et al, 2009). Newborns in a hospital often receive empiric therapy with broad spectrum parenteral antibiotics (imipenem and amikacin), because of the lack of culture facilities and concerns about resistance.

Data from community settings during the first week of life are almost nonexistent. A 2009 *Pediatric Infectious Disease* supplement (Qazi and Stoll, 2009) reviewed evidence on community-acquired neonatal sepsis in the developing world from 32 studies published since 1990. The tremendous heterogeneity in studies, suggesting that infections may be responsible for 8% to 80% of all neonatal deaths and up to 42% of deaths in the first week, make the data difficult to interpret. Among neonates from 0 to 60 days old, rates of clinically diagnosed neonatal sepsis were as high as 170 per 1000 live births versus 5.5 blood-culture confirmed sepsis cases per 1000 live births (Thaver and Zaidi, 2009). Gram-negative rods (*Klebsiella* spp. [25%], *E. coli* [15%]) and *S. aureus* were the major community-acquired pathogens. Group B streptococcus was relatively uncommon (7%) in the first week, but group B streptococcus, *S. aureus*, and nontyphoid *Salmonella* spp. infection rates increased to 12% to 14% after the first week. Only 170 isolates, predominantly gram negative, were reported among home-delivered babies. The authors concluded that hospital-based and community studies suggest that most infections in the first week are attributable to gram-negative pathogens that may be environmentally acquired during unhygienic deliveries, rather than maternally acquired. As with hospital-born infants, empiric therapy with broad spectrum antibiotics was the norm, based on clinical diagnosis or on algorithms, because advanced technology was neither available nor affordable. Because the signs and symptoms of neonatal sepsis and pneumonia are nonspecific and medical systems are weak, delays in recognition, referral, and treatment were common and were reflected in both the high mortality rate (22%) (Bang et al, 2005) and frequent prescription of broad-spectrum antibiotics.

A recent population-based nested observational study of community and hospital-born neonates randomized to a package of neonatal and maternal interventions in Mirzapur, Bangladesh, represents the difficulty of obtaining reliable infection data in the developing world. Of the 239 neonates who died without being enrolled, 59% and 87% died within the first 2 and 7 days, respectively, and were thought to be the result of birth asphyxia, prematurity, or both. Among the 7310 neonates who were assessed at least once by community health workers, the incidence of early neonatal sepsis was only 3 in 1000 live births. The 29 positive blood cultures represent an incidence of bacteremia of only 2.9 cases per 1000 live births; 38% of these cultures were obtained in the first three postnatal days. Fifty percent of the organisms were gram negative and 50% were gram positive; 10 in 15 gram-positive organisms were *S. aureus*, and one was group B streptococcus. The case fatality rate was 13% (2/15) in the gram-positive and 27% in the gram-negative infections. Seventy percent of the isolates were sensitive to the combination of ampicillin plus gentamicin or ceftriaxone. The authors noted that the incidence rate was roughly comparable to reported early-onset neonatal sepsis in the United States; however, the reported rates are likely to be low because infants who died early were not enrolled, parents were not compliant with referrals, and the intervention package may have prevented some infections.

For the many reasons noted, the current recommendations for hospitalization and parenteral therapy are simply not feasible in the developing world. Therefore several multicenter trials have been launched in Asia (2009) and (2010) Africa to test the safety and efficacy of simplified antibiotic regimens to treat possible serious bacterial infections in 0- to 59-day-old infants in the community or first-level facilities (S. Qazi, personal communication, 2010). Studies evaluating the effect of prenatal and postnatal home visits by community health workers to improve newborn care practices, and identification and referral of positive serious bacterial infection were completed in 2010 in Ghana and Uganda. Studies are ongoing in Tanzania (R. Bahl, personal communication, 2011). Such research is a priority to guide community management of infections and prevent unacceptably high neonatal mortality rates in developing countries.

Effective and simple interventions for the prevention and treatment of neonatal infections exist, but poor coverage of health services, a shortage of health care providers, access to referral services, and lack of knowledge on how to implement existing cost-effective interventions at scale in low-resource settings prevent them from reaching community neonates in the developing world. A methodology developed by the WHO Department of Child and Adolescent Health and Development (CAH) provides a systematic method, the Child Health and Nutrition Research Initiative (CHNRI) methodology, for setting priorities in health research investments at any level (institutional to global) (Rudan et al, 2007, 2008). Applying the CHNRI methodology to

the prevention and treatment of neonatal infection identified the need for health policy and systems research to understand the barriers to implementation, effectiveness, and optimized use of available interventions (Bahl et al, 2009). The need for point-of-care diagnostics for neonatal pneumonia, hypoxia, bacterial sepsis, and antibiotic resistance is urgent because standard laboratory and radiologic technology are not available. To clarify the contribution of vertical transmission to neonatal mortality, sepsis data during the first 3 days of life are also a high priority.

Malaria and HIV infection are threats to neonatal health in Sub-Saharan Africa. The burden of malaria in pregnancy is exacerbated by HIV, which increases susceptibility in pregnancy, in addition to reducing the efficacy of antimalaria interventions and complicating their use because of potential drug interactions. Important progress has been made in preventing malaria with intermittent preventive treatment in pregnancy and insecticide-treated nets, but coverage of these treatments with funds is still unacceptably low (Menendez et al, 2007). HIV has devastated Sub-Saharan Africa, but progress is being made. The latest guidelines are available on the WHO Web site (www.who.int/hiv). Other useful, sites for current recommendations for treating pregnant women, reducing mother-to-child transmission, and infant feeding include http://AIDSinfo.nih.gov (for U.S. guidelines and access to information on trials and drugs), http://unaidstoday.org, www.accessdata.fda-gov, and www.cdc.gov/hiv/dhap.htm.

ASPHYXIA

The major causes of stillbirth and early neonatal death (during the first 7 days after birth) are birth asphyxia (defined by the WHO as the failure to initiate and maintain spontaneous respiration), low birthweight, and preterm delivery. Concerns about identifying stillbirth prevention strategies, the appropriate timing for such interventions, misclassification of early neonatal deaths as stillbirths, and the limitations of verbal autopsy have led to proposals to use terms that describe the timing of an insult (*intrapartum deaths* and *intrapartum-related neonatal deaths*) and specific adverse outcome (*neonatal encephalopathy*) rather than the term *asphyxia* (Lawn et al, 2009b, 2009c). Classification of the timing of death as previable versus antepartum (macerated) or intrapartum (fresh stillbirth) may be possible, even among the 60 million annual home births; however, the consequences of intrapartum fetal organ damage caused by poor oxygenation are often difficult to distinguish from those associated with infection and trauma; therefore differentiating the specific outcomes associated with each condition might not be important. Intrapartum fetal organ damage caused by poor oxygenation may be the final common pathway for many stillbirths and early neonatal deaths (Goldenberg and McClure, 2009).

Several studies suggest that improved neonatal resuscitation skills reduce misclassification of stillbirths and improve neonatal survival (Cowles, 2007; Daga et al, 1992), including a before-and-after study that provided college-educated Zambian midwives equipment and training in essential newborn care and resuscitation. The training resulted in a reduction of stillbirths from 23 to 16 per 1000 births without an increase in neonatal deaths (Chomba et al, 2008), suggesting that resuscitation training of providers can decrease misclassification of stillbirths and improve neonatal survival.

Of the approximately 136 million babies born every year, approximately 10% (14 million) require only stimulation at birth to establish regular respiration. As many as 3% to 6% (4 million) require stimulation and basic resuscitation with room air and a self-inflating resuscitation bag and mask, and less than 1% (1.4 million) require advanced resuscitation and postresuscitation care (Wall et al, 2009). Because less than 1% of neonates require advanced resuscitation, and few of those would survive without mechanical ventilation, advanced neonatal resuscitation is not a priority unless neonatal intensive care is available. The 1997 *WHO Basic Newborn Resuscitation: A Practical Guide*, which will be revised and published in 2011, provides guidelines for resuscitation training that are appropriate for first-referral level facilities in low-resource settings. A new educational resuscitation training program, *Helping Babies Breathe*, by the American Academy of Pediatrics and others (Niermeyer, 2009), is designed to support resuscitation training in low-resources settings. It emphasizes the "golden moment," provides clear graphics for decision making in basic resuscitation and hands-on exercises. It is being rolled out globally by USAID and partners. New low-cost resuscitation bags and infant resuscitation models will facilitate hands-on resuscitation training initiatives.

A recent review of resuscitation in low-resource settings describes the available evidence for which newborns should be resuscitated, when resuscitation should not be initiated, and when it should be stopped; management of meconium-stained infants; equipment needed for ventilation during resuscitation; evidence to support resuscitation with room air; evidence of the effects of resuscitation training in facilities and communities; postresuscitation management; and considerations for improving neonatal resuscitation in low- and middle-income countries (Wall et al, 2009). Improvement will require providing essential newborn care to newborns in all settings and frequent retraining to maintain resuscitation knowledge and skills. The authors estimate that systematic implementation of personnel using standard neonatal and competency-based training could avert an estimated 192,000 intrapartum-related neonatal deaths per year and an additional 5% to 10% of deaths as a result of complications of preterm birth (Lawn et al, 2009; Wall et al, 2009).

Among critical issues neonatal resuscitation are:

- How to deliver neonatal resuscitation in settings with the highest burden, but the weakest health systems
- How to implement and sustain national vital registries
- How to document the actual number of births
- How to document the number of intrapartum stillbirths
- Whether improved survival is associated with increased numbers of disabled survivors
- How to improve monitoring of the proportion of infants requiring resuscitation and their outcome
- How to deliver cost-effective neonatal care, resuscitation training methods, and maintenance of resuscitation skills by different levels of providers in facilities and communities
- How to determine whether infants should be suctioned, including those with meconium staining

- Early infant stimulation methods to ameliorate the effects of perinatal hypoxia

Equally important are methods to improve the quality of care for mothers and neonates, including maternal and perinatal death reviews, criterion-based audits, and emergency drills (van den Broek and Graham, 2009). Dissemination of the new *Helping Babies Breathe* curriculum represents an important opportunity for implementation research to improve newborn survival in the developing world.

PROVIDING A CONTINUUM OF CARE

Early efforts to improve neonatal mortality focused on high coverage levels of a few simple and cost-effective interventions in low-resource settings. Because simple interventions did not decrease neonatal mortality, the emphasis has subsequently shifted to comprehensive packages of community interventions and to a continuum of levels of care from home to hospital.

Interventions that improve access to quality health care systems and can provide training, skilled birth attendants, transportation, timely emergency obstetric and neonatal care, and early postnatal care are likely to simultaneously reduce stillbirths and early neonatal deaths, as well as maternal morbidity and mortality; however, they have only been achieved in the context of research. The proposed components include:

- Empowerment of women
- Increased training of all levels of birth attendants in essential newborn care and resuscitation
- Emphasis on increased institutional deliveries
- Mobilization of communities to identify and transfer high-risk pregnancies and neonates
- Improved strategies for community treatment of postpartum hemorrhage, eclampsia, and sepsis
- Increased postpartum home visits
- The *Safe Childbirth Checklist* (World Health Organization, Safe Childbirth Checklist)

The joint statement from the WHO and United Nations Children's Fund recommending several early postpartum visits to deliver effective elements of care to newborns and their mothers is based on studies in Bangladesh and Pakistan, where such visits have been associated with reductions in newborn deaths and improved care practices. However, postpartum visits in a large-scale community-based integrated nutrition and health program in Uttar Pradesh, India, improved care practices but did not reduce the primary outcome (i.e., neonatal mortality) at the population level (Baqui et al, 2008a).

A 2007 review of the effects of packaged interventions on neonatal health (Haws et al, 2007) found no true effectiveness trials among 19 randomized controlled trials. No trial targeted women before pregnancy, and antenatal interventions were largely micronutrient supplementation. Intrapartum interventions were limited principally to clean delivery, and few increased the demand for care or improved the delivery of interventions to large populations. Subsequent trials using existing human and material resources and documenting external input are limited, but there is an increased emphasis on rural community-based interventions that could be improved. The early Bang Gadchiroli trial in Mahrashtra, India—which achieved a greater than 60% reduction in

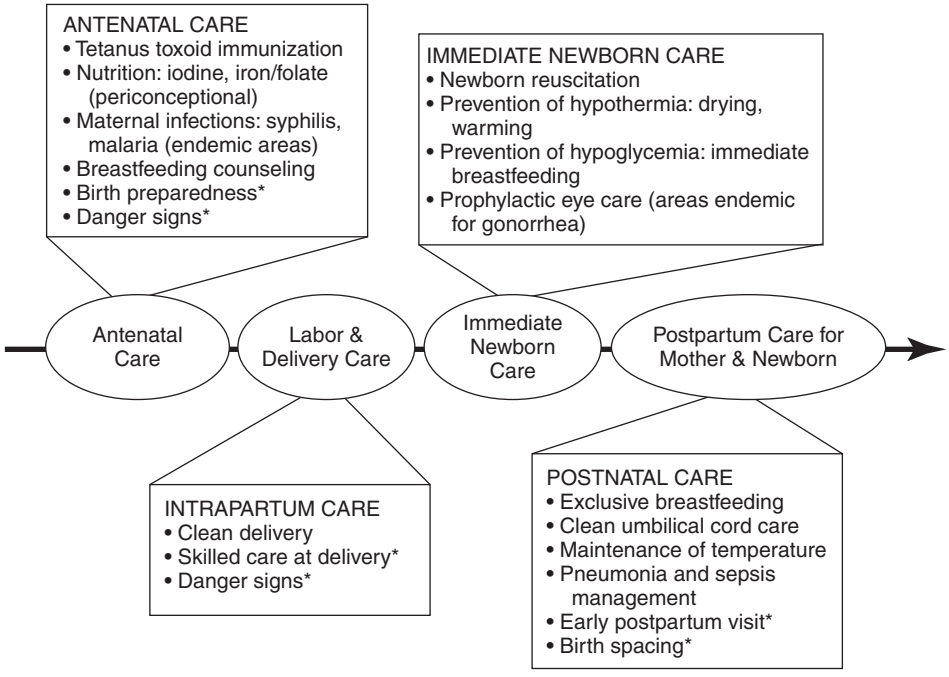

FIGURE 4-5 Summary of priority antepartum, intrapartum, and postnatal interventions. *(Modified from Bhutta ZA, Darmstadt GL, Hasan BS, et al: Community-based interventions for improving perinatal and neonatal health outcomes in developing countries: a review of the evidence,* Pediatrics *115[Suppl 2]:519-617, 2005.)*

neonatal mortality by intensive training of community health workers to resuscitate asphyxiated infants, manage infants with low birthweight, and treat suspected bacterial infections with oral and injectable antibiotics (Bang et al, 1999, 2005)—has not been replicated in other communities. However, community mobilization training (women's support groups with little additional input of health system strengthening) in rural Nepal between 2001 and 2003 reduced the neonatal mortality rate in intervention clusters by 30% (adjusted odds ratio, 0.70; 95% CI, 0.53–0.94) to 26.2 per 1000 (76 deaths per 2899 live births) compared with 36.9 per 1000 (119 deaths per 3226 live births) in controls (Manandhar et al, 2004). More recently, a community-based mobilization and education trial of care of newborn babies in rural India was associated with improved household care behaviors (early initiation of breastfeeding, delayed bathing, and skin-to-skin care) and a reduction of neonatal mortality (Kumar et al, 2008). This 30-month, community-based unmasked cluster randomized trial was conducted through government and nongovernmental organization infrastructures. The trial provided home care visits (two prenatal and four postnatal care home care and referral or treatment of sick neonates by a female community health worker [CHW]) or community-based promotion of care-seeking and birth or newborn care preparedness through group sessions with female and community mobilizers, in addition to a comparison arm. Neonatal mortality was reduced in the home-care arm by 34% (adjusted RR, 0.66; 95% CI, 0.47–0.93) over the last 6 months of the intervention versus the comparison arm. The community-care arm documented improved care practices, but no reduction in neonatal mortality. These favorable results were achieved despite a much lower community health worker (CHW) density and 30% of the CHW postnatal care visits, compared with the Gadcharoli trial (Bang et al, 2005). Improvement of the home care service delivery strategy for essential newborn care is underway in Bangladesh (Baqui et al, 2008b). Although it appears that community-based preventive strategies for newborn care can improve newborn survival and care practices, it is not clear that government health care workers and CHWs can duplicate these research results (Bhutta and Soofi, 2008). Because each setting is unique, such efforts are likely to be improved after local formative research with the communities, CHW, and birth attendants (Bahl et al, 2008).

Key research gaps in community management include:

- How best to create the political will to prioritize community maternal and neonatal health
- How to provide a continuum of care from home to hospital (effectiveness trials carefully tailored to local health needs and conducted at scale)
- How to mobilize communities to identify, stabilize, and transfer at-risk pregnancies and neonates
- What strategies should be used to ensure quality of care
- How to manage birth asphyxia, preterm delivery, and serious neonatal bacterial infections in the community

Finally, it is important to test whether the community strategies that were effective in rural Southern Asia will be equally effective in Africa and in urban slums (Bhutta and Soofi, 2008; Bhutta et al, 2008b; Kumar et al, 2008).

RESOURCES

Some of the key challenges to global health initiatives are information, communication, and assessment. Although the data are not always available or consistent, a number of important resources are available. The United Nations Children's Fund reports progress in maternal and child survival in the *The State of the World's Children*, based on the work of the Inter-agency Group for Child Mortality Estimation (United Nations Children's Fund, 2007). The *State of the World's Children* provides summary tables of basic, health, education, demographics, economics, and progress indicators with national rankings. The detailed text discusses when, where, and why mothers and neonates die, and it documents interventions to improve outcomes. The 2009 *State of the World's Children* emphasizes maternal health.

The WHO Department of Child and Adolescent Health and Development is the Secretariat for the Child Epidemiology Reference Group (CHERG) that quantifies the burden of child illnesses, supports and disseminates research to understand the determinants of childhood illnesses, and develops and evaluates interventions of new delivery strategies and large-scale interventions (Bryce et al, 2005; World Health Organization, 2009).

A number of other important partnerships publish current data, including *The Countdown to 2015* (United Nations Children's Fund, 2005, 2008a), which assembles and summarizes the latest published data on 68 priority countries that represent 97% of child and maternal mortality worldwide. A unique feature is data on coverage rates for interventions that are feasible for universal implementation in poor countries and have been empirically proven to reduce mortality in mothers, children, and neonates. The 2008 edition included approaches such as delivery care and reproductive health services, which can serve as platforms for delivering multiple, proven interventions to reduce maternal and neonatal mortality (United Nations Children's Fund, 2008a); it is intended to assist policy makers, development agencies, and donors in making performance-based policy and decisions. An explicit goal is to hold governments, development partners, and the international health community accountable for the lack of progress (United Nations Children's Fund, 2008a).

In 2003 a group of technical experts published The Child Survival Series in *The Lancet* (United Nations Children's Fund, 2007), which went on to become a unique series of special editions on perinatal health in the developing world. The series has played a critical role in drawing attention and resources to improved neonatal survival, which is important to the future of the developing world.

The comprehensive Disease Control Priorities Project (DCPP)—a joint effort of the National Institutes of Health Fogarty International Center, the WHO, and the World Bank—was launched in 2001 to identify policy changes and intervention strategies for the health problems of countries in need. The aim of the DCPP was to generate knowledge to assist decision makers in developing countries to realize the potential of cost-effective interventions to rapidly improve the health and welfare of their populations and to detail prevalent investments that are not cost

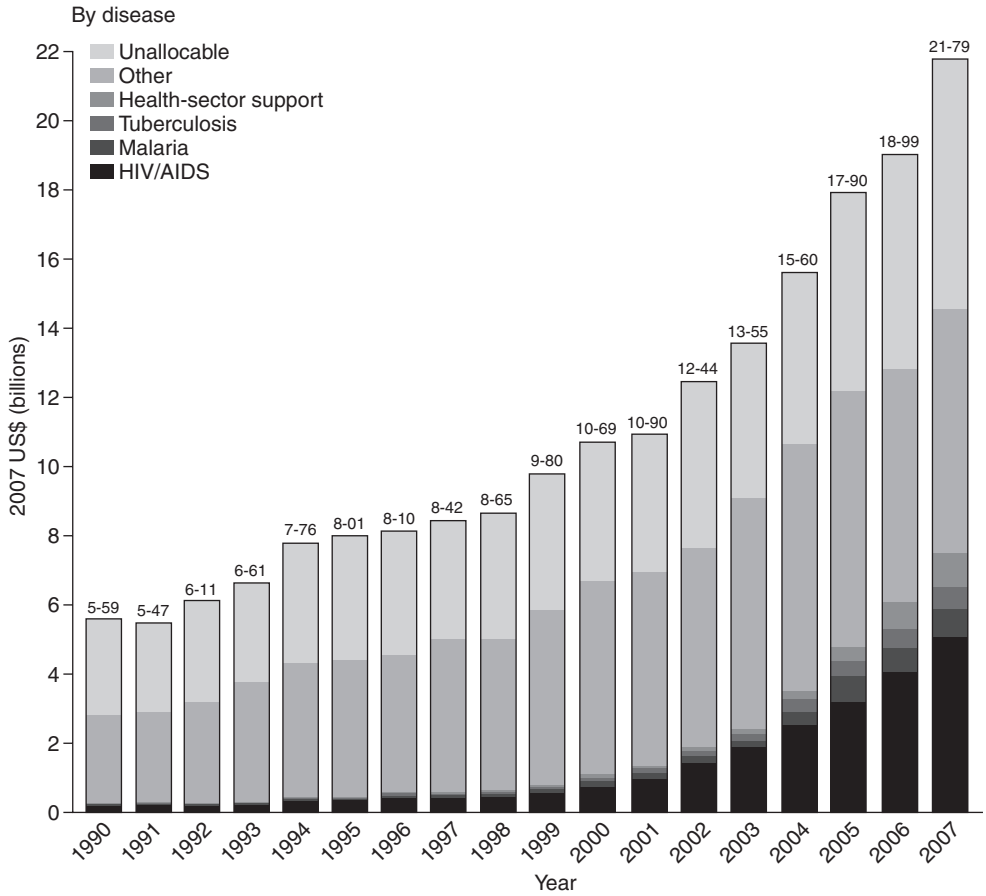

FIGURE 4-6 Development assistance for health from 1990 to 2007, by disease. (*Modified from Ravishankar N, Gubbins P, Cooley RJ, et al: Financing of global health: tracking development assistance for health from 1990 to 2007*, Lancet *373:2113-2124, 2009.*)

effective. The DCPP published an expanded and updated second edition that addresses disease conditions, their burdens and risk factors, strategy and intervention effectiveness and health systems, and financing (Laxminarayan et al, 2006).

FUNDING

There is no comprehensive system for tracking total amounts of developmental assistance for health or how they are spent. However, recent analyses have documented a fourfold increase in developmental assistance, from $5.6 billion in 1990 to $21.8 billion in 2007. The WHO estimated that the 10-year incremental global costs for universal health coverage of maternal and child health services ranged from $39.3 billion for a moderate improvement scenario to $551.7 billion for a rapid improvement scenario. These projections did not include the cost of health system reforms, such as recruiting, training, and retaining a sufficient number of personnel (Johns et al, 2007).

Global assistance rose sharply after 2002 because of increases in public funding, especially from the United States, and from increased philanthropic donations and in-kind contributions from corporations. (The Bill and Melinda Gates Foundation is the largest single source of private developmental health assistance.) Donor funding from the United States for HIV/AIDS has increased from $300 million in 1996 to $8.9 billion in 2006 (Oomman, et al, 2007). The proportion of developmental assistance from United Nations agencies and development banks decreased between 1990 and 2007 as targeted funding increased for the Global Alliance for Vaccines and Immunization; Medicines for Malaria, the Global Fund to Fight AIDS, Tuberculosis and Malaria; and the United States President's Emergency Plans for AIDS Relief (PEPFAR). The influx of funds has been accompanied by major changes in the institutional landscape of global health, with global health initiatives such as the Global Fund and the GAVI assuming a central role in mobilizing and channeling global health funds. Nongovernmental organizations have become a major conduit for an increasing share of developmental assistance (Ravishankar et al, 2009).

The pattern is similar for research and development for drugs: Global Funds and GAVI HIV/AIDS, tuberculosis, and malaria initiatives accounted for approximately 80% of the $2.5 billion that was spent on research and drug development in 2007 for neglected diseases in developing countries (Moran et al, 2009). Drugs and vaccines—rather than diagnostics, platform technologies, or country-specific products—are also funded preferentially (Moran et al, 2009). Research and development in neglected diseases—such as pneumonia and diarrheal illness, two major causes of mortality in developing countries–are severely underfunded at less than 6% of the budgeted funding. Increasing attention has been focused on the large amount of funding being earmarked for HIV, malaria, and tuberculosis and

TABLE 4-4 The Research Pipeline of Description and Determinants, Discovery, Development, and Delivery

	Description and Determinants	Discovery	Development	Delivery
Research aim	Descriptive epidemiology and understanding determinants, advancing definitions	New science for the discovery of mechanisms and causes of neonatal disease that provides foundation for developing new interventions	Developing new or adapting existing interventions to reduce the cost, increase effect, improve deliverability	Delivering existing interventions in new ways or in new settings. Includes monitoring and evaluation as feedback to additional discovery and development science
Types of research (research instrument)	Epidemiology	New drugs and vaccines. Biochemical and genetic basis for disease	Refining or adapting existing technology or drugs	Effectiveness trials or implementation research for scale-up in health systems
Typical timeline before impact is seen	Variable	5 to 15 years	5 to 10 years	2 to 5 years
Investment level	Variable	Very high	Moderate	Low to moderate depending on size of trial and rigor of evaluation
Probability of major impact	Variable, if new epidemiology leads directly to program or intervention	Very high	Moderate	Very high if high impact intervention and currently low coverage
Risk of failure	Low	High	Moderate	Low to moderate
Specific examples for global newborn health	Cohort studies to better delineate preterm birth and term small for gestational age and define short-and long-term outcomes	Discovering a marker for preterm birth amenable to intervention	Adapting technology for head or body cooling to be effective, lower cost, feasible and safe in low-income settings	Impact and cost to provide early postnatal care package using different cadres of workers in a range of varying health system contexts especially in Africa

From Lawn JE, Rudan I, Rubens C: Four million newborn deaths: is the global research agenda evidence-based? *Early Hum Dev* 84:809-814, 2008.

the missed opportunities to save more lives—especially young lives—at a lower cost by focusing on simpler interventions (Gostin, 2008).

CAREER OPPORTUNITIES

American universities are experiencing an unprecedented surge in interest in global health. Students and faculty have become actively engaged in operational research, project analysis, workforce training, and policy debates. A number of American universities have made long-term commitments to specific countries in the developing world, including formal opportunities for faculty and residents to work in targeted countries in low-resource settings. Opportunities range from in-depth experiences to volunteer research and service projects. The newly launched Consortium of University for Global Health 2009 survey of 37 universities found that the number of students enrolled in global health programs in universities across the United States and Canada doubled in just 3 years and that universities have established 302 training and education programs in 97 countries. Although there is currently no official "bulletin board" for international global opportunities at the faculty level, a number of Web sites offer a range of opportunities for individuals seeking additional training, career opportunities, and interaction with other global health professionals, including the American Medical Students Association (www.amsa.org); the Global Health Council career network (careers.globalhealth.org); the United States Agency for International Development (USAID) (www.usaid.gov); and the National Institutes of Health Fogarty International Center (www.nih.fogarty.org). A number of Web sites also provide research updates, including the WHO, USAID, Save the Children Newborn Research e*Updates*, and *Medical News Today*. The Federation of Pediatric Organizations is working in the areas of international certification, cataloging international rotations, creating a checklist of requirements for international rotations, and creating global partnerships.

THE WAY FORWARD: DATA, COLLABORATION, EVALUATION, AND INVOLVEMENT

There is a consensus in the global research community regarding the importance of providing a continuum of care from home to hospital for mothers and neonates and evaluating the effectiveness of packages of interventions that have proved effective in smaller trials (Madon et al, 2007). Much attention has been focused on the lack of quality data; social and cultural limitations; the need for large community randomized trials and their high cost; the lack of coordination of efforts to maximize current data by prioritizing and strengthening existing programs with proven, low-cost, high-impact interventions; and the need to systematically establish research priorities (Lawn et al, 2008, 2009a).

The need for a change in the design, implementation, and evaluation of programs has received less attention, to meet the needs of national governments and donors for rigorous assessment of child survival and health in general. Victora, Black, and Bryce (2009) emphasize the need for nationwide improvement and nationwide assessments of multiple programs, in collaboration with the government and other concurrent programs. They suggest three initial

steps for an ecologic evaluation platform: (1) develop and regularly update a district database from multiple sources, (2) conduct an initial survey to be repeated every 3 years to measure coverage for proven interventions and health status, and (3) establish a continuous monitoring system to document provision, use, and quality of interventions at the district level, with mechanisms for prompt and transparent reporting. Although this ambitious plan would support the analysis of combinations of interventions and delivery strategies with the ability to adjust for confounders, there is no precedent for undertaking such a massive effort. Short of their comprehensive strategy, there is increasing recognition of the need for national vital registries and recurrent surveys to provide the basis for changes in health policy. There is also clear evidence of the need for a new emphasis on implementation science and the urgency of strengthening the independent capacity for health research in the developing world (Whitworth et al, 2008), which will enable collaborators to solve their own national problems. Finally, everyone has the power to advocate for political change to support maternal and child health. Shiffman (2009) emphasizes the need to build a strong policy community to generate political attention for global maternal and neonatal health; to develop issue frames that resonate with politicians to move them to act; to cultivate strategic alliances within women's groups, key ministers, and congressional aides; to link the health of women and neonates in the developing world with other problems; and to remember that medical professionals carry great moral authority because of their expertise and pursuit of a humanitarian cause, if they choose to exert their political power in a strategic way.

PART II

Fetal Development

CHAPTER 5

Immunologic Basis of Placental Function and Diseases: the Placenta, Fetal Membranes, and Umbilical Cord

Satyan Kalkunte, James F. Padbury, and Surendra Sharma

Complex yet intricate interactions between maternal and fetal systems promote fetal growth and normal pregnancy outcomes. Throughout embryonic development, organogenesis and functional maturation are taking place. This period of development coincides with a high rate of cellular proliferation and organ development, which creates critical periods of vulnerability. Adverse factors, disruption, or impairment during these critical periods of fetal development can alter developmental programming, which can lead to permanent metabolic or structural changes (Baker, 1998). For example, triggers such as undernutrition can elicit placental and fetal adaptive responses that can lead to local ischemia and metabolic, hormonal, and immune reprogramming, resulting in small for gestational age (SGA) fetuses. Maternal health, dietary status, and exposure to environmental factors, uteroplacental blood flow, placental transfer, and fetal genetic and epigenetic responses likely all contribute to in utero fetal programming (Figure 5-1). Adult diseases such as coronary heart disorders, hypertension, atherosclerosis, type 2 diabetes, insulin resistance, respiratory distress, altered cell-mediated immunity, cancer, and psychiatric disorders are now thought to be a consequence of in utero life (Sallour and Walker, 2003). It is a matter of considerable interest that, in addition to maternal predisposing factors, cytokines, hormones, growth factors, and the intrauterine immune milieu also contribute to in utero programming. Adaptations of the maternal immune system exist to modulate detrimental effects on the fetus and additional mechanisms and factors actively cross the placenta and induce regulatory T cells in the fetus to suppress fetal antimaternal immunity. These effects persist at least through adolescence (Burlingham, 2009; Mold et al, 2008). Excessive restraint of maternal immune responses could lead to a lethal infection in the newborn. On the other hand, too little modulation of maternal immune response to the fetal allograft could lead to autoimmune-mediated fetal-placental rejection. Moreover, placental growth resembles that of a tumor, evading immune surveillance and initiating its own angiogenesis. Therefore a healthy mother with healthy placentation is critical to healthy fetal outcomes.

MAMMALIAN PLACENTATION

The immune tolerance of the semiallograft fetus and de novo vascularization are two highly intriguing processes that involve direct interaction of maternal immune cells, invading trophoblast cells, and arterial endothelial cells. Pregnancy is considered an immunologic paradox, in which paternal antigen-expressing placental cells interact directly with and coexist with the maternal immune system (Medawar, 1953). This anatomic distinction of the immunologic interface that arises from hemochorial placentation that occurs in humans and rodents is distinct from epitheliochorial placentation as seen in marsupials, horses, and swine or the endotheliochorial placentation seen in dogs and cats. Understanding the anatomic and physiologic events that occur during placentation is the key to appreciate the uniqueness of human placentation in the phylogenetic evolution. Typically, in hemochorial placentation, maternal uterine blood vessels and decidualized endometrium are colonized by trophoblast cells, derived from trophectoderm of the implanting blastocyst. These cells come in direct contact with maternal blood and uterine tissue. A similar phenomenon is evident in murine pregnancy, except the trophoblast invasion is deeper in humans (Moffett and Loke, 2006). In epitheliochorial placentation, trophoblast cells of the placenta are in direct contact with the surface epithelial cells of the uterus, but there is no trophoblast-cell invasion beyond this layer. In endotheliochorial placentation, the trophoblast cells breach the uterine epithelium and are in direct contact with endothelial cells of maternal uterine blood vessels.

EMBRYOLOGIC DEVELOPMENT OF THE PLACENTA

Shortly after fertilization takes place in the ampullary portion of the fallopian tube, the fertilized ovum or zygote begins dividing into a ball of cells called a *morula*. As the morula enters the uterus (by the fourth day after fertilization), it forms a central cystic area and is called a *blastocyst* (Figure 5-2). The blastocyst implants within the endometrium by day seven (Moore, 1988).

The blastocyst has two components: an inner cell mass, which becomes the developing embryo, and the outer cell layer, which becomes the placenta and fetal membranes. The cells of the developing blastocyst, which eventually become the placenta, are differentiated early in gestation (within 7 days after fertilization). The outer cell layer, the trophoblast, invades the endometrium to the level of the decidua basalis. Maternal blood vessels are also invaded. Once entered and controlled by the trophoblast, these

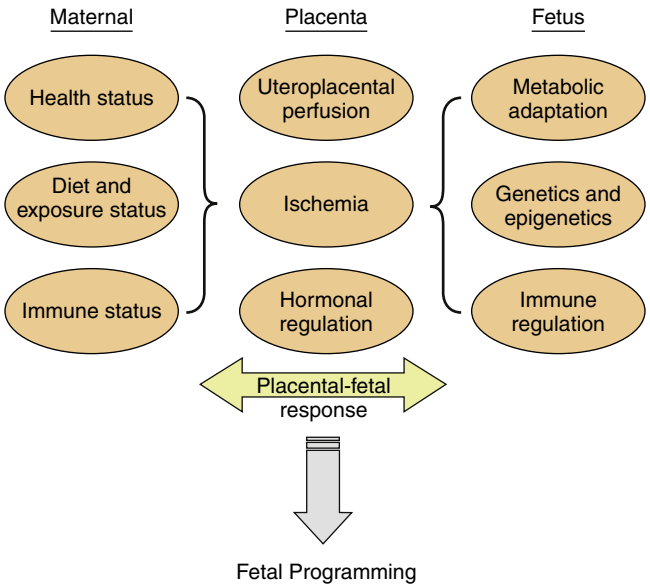

FIGURE 5-1 Fetal programming. Maternal health and the placenta influence fetal adaptations. Dietary status, exposure to environmental factors, uteroplacental blood flow, placental transfer, and genetic and epigenetic changes contribute to the in utero fetal programming.

maternal blood vessels form lacunae, which provide nutrition and substrates for the developing products of conception. The trophoblast differentiates into two cell types, the inner cytotrophoblast and the outer syncytiotrophoblast (Figure 5-3); the former has distinct cell walls and is thought to represent the more immature form of trophoblast. The syncytiotrophoblast, which is essentially acellular, is the site of most placental hormone and metabolic activity. Once the trophoblast has invaded the endometrium, it begins to form outpouchings called *villi*, which extend into the blood-filled maternal lacunae or further invade the endometrium to attach more solidly with the decidua, forming anchoring villi.

PLACENTAL ANATOMY AND CIRCULATION

At term, the normal placenta covers approximately one third of the interior portion of the uterus and weighs approximately 500 g. The appearance is of a flat circular disc approximately 2 to 3 cm thick and 15 to 20 cm across (Benirschke and Kaufmann, 2000). Placental and fetal weights throughout gestation are presented in Table 5-1. During the first trimester and into the second, the placenta weighs more than the fetus; after that period, the fetus outweighs the placenta. With the formation of the tertiary villi (19 days after fertilization), a direct vascular connection is made between the developing embryo and the placenta (Moore, 1988). Umbilical circulation between the placenta and the embryo is evident by 5½ weeks' gestation. Figure 5-4 demonstrates aspects of the maternal and fetal circulation in the mature placenta. The umbilical arteries from the fetus reach the placenta and then divide repetitively to cover the fetal surface of the placenta. Terminal arteries then penetrate the individual cotyledons, forming capillary beds for substrate exchange within the tertiary villi. These capillaries then reform into tributaries of the umbilical venous system, which carries oxygenated blood back to the fetus.

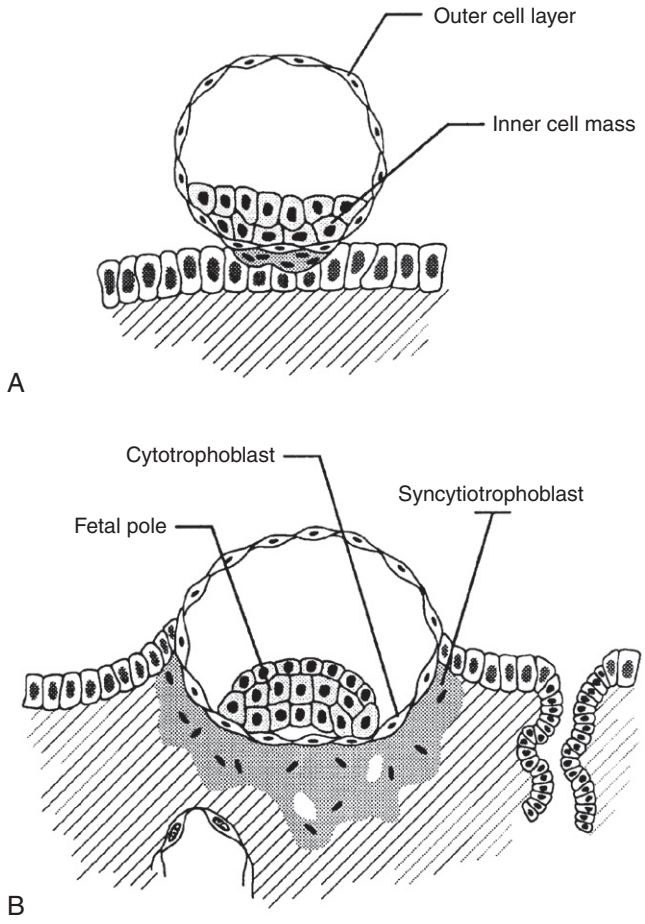

FIGURE 5-2 A, The human blastocyst contains two portions: an inner cell mass, which develops into the embryo, and an outer cell layer, which develops into the placenta and membranes. **B,** The outer acellular layer is the syncytiotrophoblast, and the inner cellular layer is the cytotrophoblast. (*From Moore TR, Reiter RC, Rebar RW, et al, editors:* Gynecology and obstetrics: a longitudinal approach, *New York, 1993, Churchill Livingstone.*)

EXAMINATION OF THE PLACENTA

A renaissance in placental pathology has led to a new relevance of the placenta to neonatology and early infant life, including issues of preterm birth, growth restriction, and cerebral, renal, and myocardial diseases. The placenta can give some clues to the timing and extent of important adverse prenatal or neonatal events as well as to the relative effects of sepsis and asphyxia on the causation of neonatal diseases. Placental disorders can be noted immediately in the delivery room, and others can be diagnosed through detailed gross and microscopic examinations over the ensuing 48 hours. Every placenta should be examined at the time of birth regardless of whether the newborn has any immediate problems. Most placentas invert with traction at the time of delivery, and the fetal membranes cover the maternal surface. It is important to reinvert the membranes and examine all surfaces of the placenta and membranes, looking for abnormalities. Table 5-2 lists pregnancy complications or conditions that are diagnosable at birth through examination of the placenta.

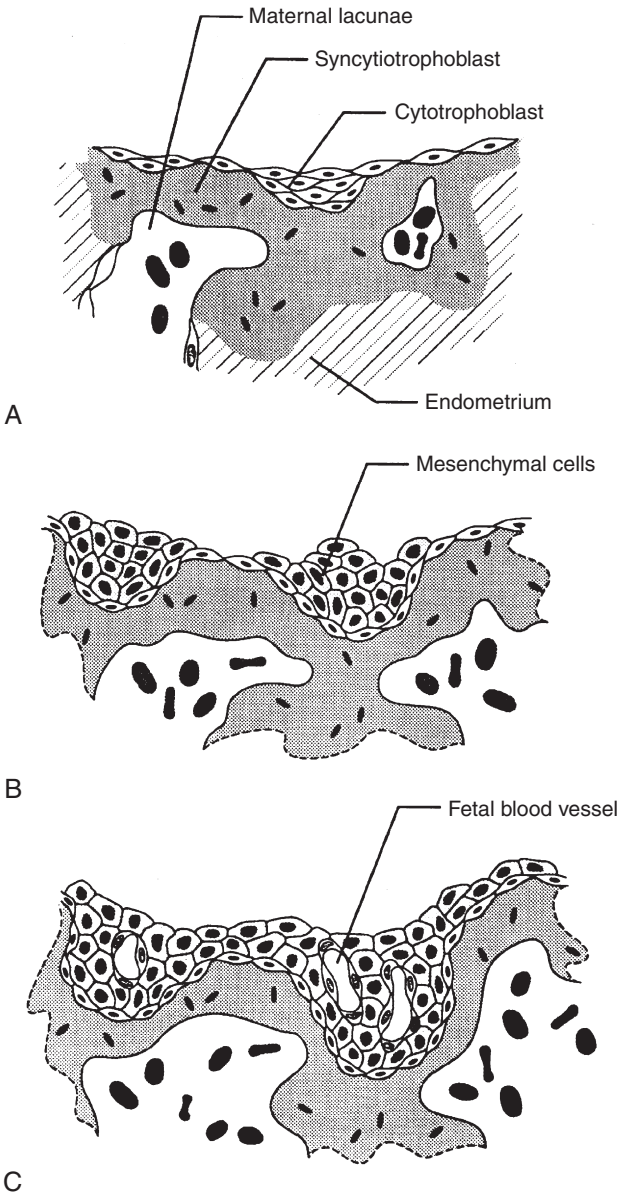

FIGURE 5-3 **A,** The cytotrophoblast indents the syncytiotrophoblast to form primary villi. **B,** Mesenchymal cells invade the cytotrophoblast 2 days after formation of the primary villi to form secondary villi. **C,** Blood vessels arise de novo and eventually connect with blood vessels from the embryo, forming tertiary villi. (*From Moore TR, Reiter RC, Rebar RW, et al, editors:* Gynecology and obstetrics: a longitudinal approach, *New York, 1993, Churchill Livingstone.*)

Gestational Age (wk)	Placental Weight (mg)	Fetal Weight (g)
14	45	—
16	65	59
18	90	155
20	115	250
22	150	405
24	185	560
26	217	780
28	250	1000
30	282	1270
32	315	1550
34	352	1925
36	390	2300
38	430	2850
40	470	3400

Adapted from Benirschke K, Kaufmann P: *Pathology of the human placenta*, ed 4, New York, 2000, Springer-Verlag.

The initial placental examination should include checking the edges for completeness. The membranes and fetal surface should be shiny and translucent. An odor may suggest infection, and cultures of the placenta may be beneficial (Benirschke and Kaufmann, 2000). Greenish discoloration may represent meconium staining or old blood; placentas with such discoloration should be sent to the pathologist for complete histologic examination. The finding of deep meconium staining of the membranes and umbilical cord suggests that the meconium was passed at least 2 hours before delivery; this fact may be helpful in cases of meconium aspiration syndrome, for which legal questions may arise as to whether the aspiration occurred before or during labor. If the membranes are deeply stained, the passage of meconium by the fetus may have predated onset of labor; therefore aspiration could have occurred before labor. The umbilical cord should also be examined for the number of vessels and their insertion into the placenta. Vessels on the fetal surface of the placenta should be examined for evidence of clotting or thrombosis.

FUNCTIONS OF THE PLACENTA

To ensure normal fetal growth and development, the placenta behaves as an efficient organ of gas and nutrient exchange and as a robust endocrine and metabolic organ. Besides mediating the transplacental exchange of gases and nutrients, the placenta also synthesizes glycogen with a significant turnover of lactate. Hormones secreted by the placenta have an important role for the fetus and the mother. Placental trophoblasts are a rich source of cholesterol and peptide hormones, including human chorionic gonadotrophin (HCG), human placental lactogen, cytokines, growth hormones, insulin-like growth factors, corticotrophin-releasing hormones, and angiogenic factors such as vascular endothelial growth factor (VEGF) and placental growth factor (PlGF). HCG, which is detected as early as day 8 after conception, is secreted by syncytiotrophoblasts into the maternal circulation, reaches maximal levels by week 8 of pregnancy and diminishes later during gestation. HCG is essential to promote estrogen and progesterone synthesis during different stages of pregnancy. Human placental lactogen mobilizes the breakdown of maternal fatty acid stores and ensures an increased supply of glucose to the fetus. VEGF and PlGF are secreted by trophoblasts and specialized natural killer (NK) cells in the decidua, and they promote angiogenesis and vascular activity, particularly during early stages of pregnancy when spiral

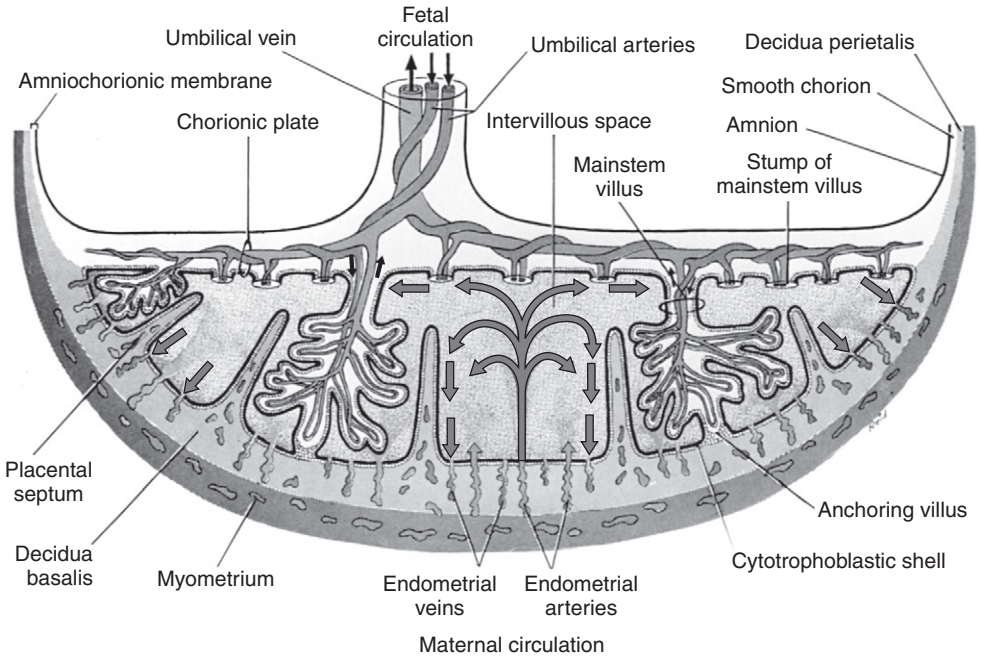

FIGURE 5-4 Schematic drawing of a section of a mature placenta showing the relation of the villous chorion (fetal part of the placenta) to the decidua basalis (maternal part of the placenta), the fetal placental circulation, and the maternal placental circulation. Maternal blood flows into the intervillous spaces in funnel-shaped spurts, and exchanges occur with the fetal blood as the maternal blood flows around the villi. Note that the umbilical arteries carry deoxygenated fetal blood to the placenta, and the umbilical vein carries oxygenated blood to the fetus. In addition, the cotyledons are separated from each other by decidual septa of the maternal portion of the placenta. Each cotyledon consists of two or more mainstem villi and their main branches. In this drawing, only one mainstem villus is shown in each cotyledon, but the stumps of those that have been removed are shown. TABLE 5-2 Pregnancy Conditions Diagnosable at Birth by Gross Placental Examination and Associated Neonatal Outcomes

Pregnancy Conditions	Fetal/Neonatal Outcomes
Monochorionic twinning	TTT syndrome donor/recipient status, pump twin in TRAP, survivor status after fetal demise, selective termination, severe growth discordance without TTT
Dichorionic twinning	Less likelihood of survivor brain disease in the event of demise of one fetus
Purulent acute chorioamnionitis	Risk of fetal sepsis, fetal inflammatory response syndrome, cerebral palsy
Chorangioma	Hydrops, cardiac failure, consumptive coagulopathy
Abnormal cord coiling	IUGR, fetal intolerance of labor
Maternal floor infarction	IUGR, cerebral disease
Abruption	Asphyxial brain disease
Velamentous cord	IUGR, vasa previa
Cord knot	Asphyxia
Chronic abruption oligohydramnios syndrome	IUGR
Single umbilical artery	Malformation, IUGR
Umbilical vein thrombosis	Asphyxia
Amnion nodosum	Severe oligohydramnios leading to pulmonary hypoplasia
Meconium staining	Possible asphyxia, aspiration lung disease
Amniotic bands	Fetal limb reduction abnormalities
Chorionic plate vascular thrombosis	Asphyxia, possible thrombophilia
Breus mole	Asphyxia, IUGR

IUGR, Intrauterine growth retardation; *TRAP*, twin-reversed arterial perfusion; *TTT*, twin-to-twin transfusion.

artery transformation and trophoblast invasion occurs. In addition, the placenta is a rich source of estrogen, progesterone, and glucocorticoids. Whereas progesterone maintains a quiescent, noncontractile uterus, it also has a role in protecting the conceptus from immunologic rejection by the mother. Glucocorticoids promote organ development and maturation. Placental transport is another important function, efficiently transferring nutrients and solutes that are essential for normal fetal growth. The syncytiotrophoblast covering the maternal villous surface is a specialized epithelium that participates in the transport of gases, nutrients, and waste products and the synthesis of hormones

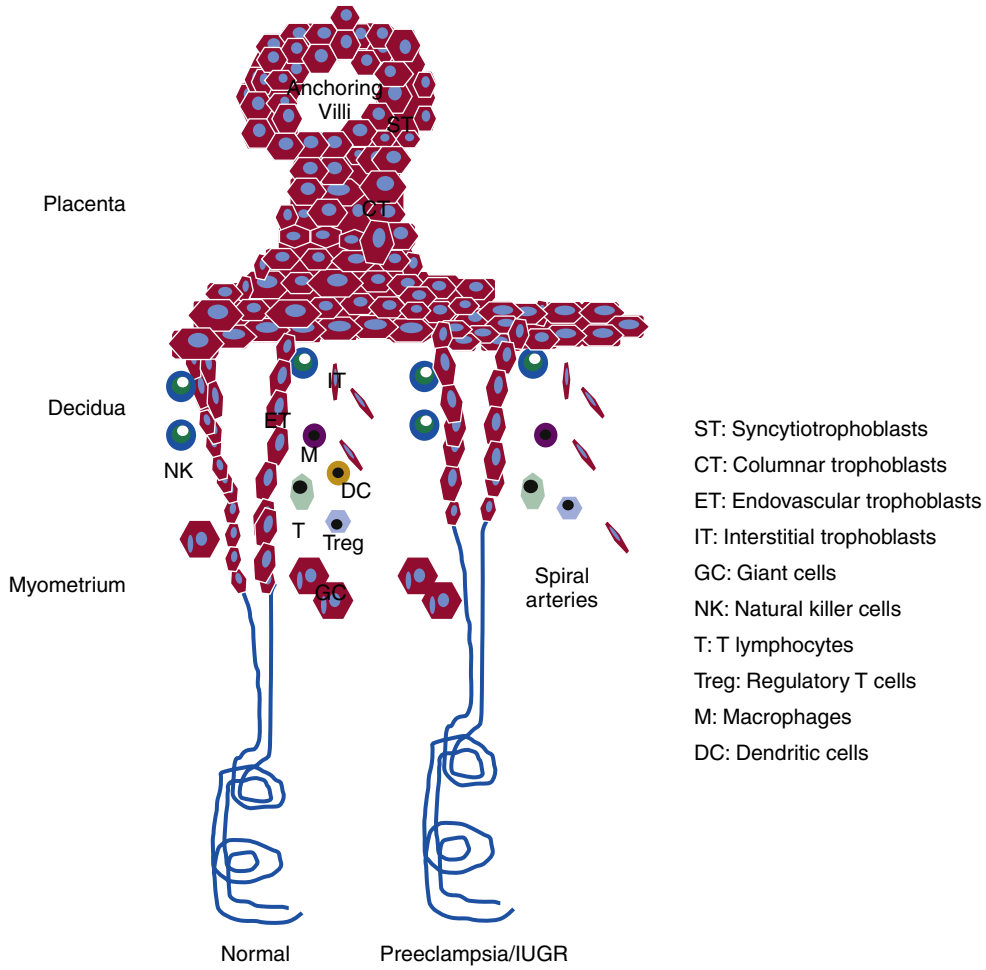

FIGURE 5-5 Trophoblast differentiation and spiral artery remodeling. Progenitor trophoblast cells from villi differentiate into syncytiotrophoblasts and the extravillous cytotrophoblasts (EVTs). EVTs migrate out in columns as columnar trophoblasts and anchor the placenta to the decidua. Further differentiation takes place into invasive or proliferative EVTs. The invasive EVTs invade the decidua known as *interstitial trophoblasts*, and some of them fuse to form the multinucleated gaint cells. Endovascular transformation ensues as endovascular trophoblasts migrate into and colonize the spiral arteries, almost reaching the myometrium. This results in wide-bore, low-resistant capacitance blood vessels as observed in normal pregnancy. In contrast, shallow trophoblast invasion and incomplete transformation of spiral arteries is a common feature of preeclampsia and intrauterine growth restriction.

that regulate placental, fetal, and maternal systems. The syncytiotrophoblast layer of the placenta is an important site of exchange between the maternal blood stream and the fetus. In addition to simple diffusion, syncytiotrophoblasts facilitate exchange by transcellular trafficking that utilizes transport proteins such as the water channels (aquaporins). Facilitated diffusion for molecules such as glucose and amino acids are performed by glucose transporters (GLUT) and amino acid transporters. In addition, adenosine triphosphate (ATP)-mediated active transport, such as the Na^+, K^+-ATPase or the Ca^{2+}-ATPase, besides endocytosis and exocytosis, participates in transplacental exchange (Hahn et al, 2001; Malassiné and Cronier, 2002; Randhawa and Cohen, 2005; Siiteri, 2005).

In healthy women who are not pregnant, uterine blood vessels receive approximately 1% of the cardiac output to maintain the uterus. During pregnancy, these same vessels must support the rapidly growing and demanding placenta and fetus. This evolutionary challenge is addressed by remodeling of the spiral arteries, converting them into large, thin-walled, dilated vessels with reduced vascular resistance.

TROPHOBLAST DIFFERENTIATION AND REMODELING OF SPIRAL ARTERIES

The placental-decidual interaction through invading trophoblasts determines whether an optimal transformation of the uterine spiral arteries is achieved. Trophoblast-orchestrated artery remodeling is an essential feature of normal human pregnancy. As shown in Figure 5-5, progenitor trophoblast cells from villi differentiate along two pathways: terminally differentiated syncytiotrophoblasts and the extravillous cytotrophoblasts (EVTs) that migrate out in columns and anchor the placenta to the decidua.

From these anchoring layers of EVTs further differentiation takes place into invasive or proliferative EVTs. The invasive EVTs invade the decidua and shallow parts of the myometrium and are known as interstitial EVTs. Thereafter endovascular transformation ensues as invasive EVTs migrate into and colonize the spiral arteries, almost reaching the myometrium. These trophoblasts are known as *endovascular EVTs*. Insufficient uteroplacental interaction characterized by shallow trophoblast invasion and

incomplete transformation of spiral arteries is a common feature of preeclampsia and intrauterine growth restriction (IUGR) (Brosens et al, 1977; Meekins et al, 1994). The precise period when trophoblast invasion of decidua and spiral arteries ceases is not clear. Nevertheless it is widely believed to be completed late in the second trimester.

Although our understanding of the molecular events underlying spiral artery remodeling in pregnancy remains poor, efficient trophoblast invasion is an essential feature. There are two waves of trophoblast invasion that follow implantation. The first wave is during the first trimester, when the invasion is limited to the decidual part of the spiral artery. The second wave is during the late second trimester involving deeper trophoblast invasion, reaching the inner third of myometrial segment. The initial invasion of EVTs into the endometrium initiates the decidualization process, which is characterized by replacement of extracellular matrix, loss of normal musculoelastic structure, and deposition of fibrinoid material. Displacement of the endothelial lining of spiral arteries by the invading trophoblasts further results in uncoiling and widening of the spiral artery, ensuring the free flow of blood and nutrients to meet the escalating demands of the growing fetus (Kham et al, 1999; Pijnenborg et al, 1983). A lack of spiral artery remodeling with shallow trophoblast invasion has been associated with preeclampsia. During the process of invasion in a normal pregnancy, cytotrophoblasts undergo phenotypic switching, with a loss of E-cadherin expression, and they acquire vascular endothelial-cadherin, platelet-endothelial adhesion molecule-1, vascular endothelial adhesion molecule-1, and α4 and αvβ3 integrins (Bulla et al, 2005; Zhau et al, 1997). Along with a repertoire of facilitators for invasion, trophoblasts express a nonclassic major histocompatibility complex (MHC) human leukocyte antigen (HLA) G, which has gained widespread interest because of providing noncytotoxic signals to uterine NK cells. It still needs to be evaluated whether intrinsic HLA-G inactivation by polymorphic changes influences the dysregulated trophoblast invasion seen in preeclampsia (Hiby et al, 1991; Le Bouteiller et al, 2007).

Although the exact gestational age at which trophoblast invasion ceases is not known, recent studies have shown that late pregnancy trophoblasts loose the ability to transform the uterine arteries. Using a novel dual-cell in vitro culture system that mimics the vascular remodeling events triggered by normal pregnancy serum, we have shown that first- and third-trimester trophoblasts respond differentially to interactive signals from endothelial cells when cultured on the extracellular matrix, matrigel. Term trophoblasts not only fail to respond to signals from endothelial cells, but they inhibit endothelial cell neovascular formation. In contrast, trophoblast cells representing first-trimester trophoblasts with invasive properties undergo spontaneous migration and promote endothelial cells to form a capillary network (Figure 5-6).

This disparity in behavior was confirmed in vivo using a matrigel plug assay. Poor expression of VEGF-C and VEGF receptors coupled with high E-cadherin expression by term trophoblasts contributed to their restricted migratory and interactive properties. Furthermore, these studies showed that the kinase activity of VEGF receptor 2 is essential for proactive crosstalk by invading first-trimester trophoblast cells (Kalkunte et al, 2008b). This unique maternal and fetal cell interactive model under the pregnancy milieu offers a potential approach to study cell-cell interactions and to decipher inflammatory components in the serum samples from adverse pregnancy outcomes (Kalkunte et al, 2010). One of the inimitable contributors to trophoblast cell invasion is the specialized NK cell of the pregnant uterus.

IMMUNE PROFILE AND IMMUNO VASCULAR BALANCE DURING PLACENTATION

During pregnancy, trophoblast cells directly encounter maternal immune cells at least at two sites. One site is the syncytiotrophoblasts covering the placental villi that are bathed in maternal blood, and the other is by the invading trophoblasts in the decidua. Although the syncytiotrophoblasts do not express MHC antigens, the invading trophoblasts express nonclassic HLA-G and HLA-C and would elicit immune responses in the decidua. The decidua is replete with innate immune cells including T cells, regulatory T cells, macrophages, dendritic cells and NK cells (Table 5-3). Interestingly, NK cells peak and constitute the largest leukocyte population in the early pregnant uterus, accounting for 60% to 70% of total lymphocytes. These cells diminish in proportion as pregnancy proceeds.

PHENOTYPIC AND FUNCTIONAL FEATURES OF UTERINE NATURAL KILLER CELLS

Peripheral blood NK (pNK) cells constitute 8% to 10% of the $CD45^+$ population in circulation. All NK cells are characterized by a lack of CD3 and expression of CD56 antigen. Based on the intensity of CD56 antigen, NK cells are further divided into $CD56^{bright}$ and $CD56^{dim}$ populations. The presence or absence of FcγRIII or CD16 further differentiates subpopulations of uterine NK (uNK) cells. Thus the majority of peripheral NK cells are of the $CD56^{dim}CD16^+$ phenotype (approximately 90%), and the remaining cells are $CD56^{bright}CD16^-$ (approximately 10%). The majority of uterine NK cells (approximately 90%) are $CD56^{bright}CD16^-$. In the uterine decidua, uNK cell numbers cyclically increase and decrease in tandem with the menstrual cycle—low in the proliferative phase (10% to 15%), which amplifies during the early, middle and late secretory phases (25% to 30%)—falling to a basal level with menstruation (Figure 5-7) (Kalkunte et al, 2008a; Kitaya et al, 2007).

With successful implantation, the uNK cell population further increases in the decidualized endometrium, reaches a peak in first-trimester pregnancy, and dwindles thereafter by the end of the second trimester. The origin of uNK cells that peak during the secretory phase of the menstrual cycle and early pregnancy is currently not well established, and the evidence indicates multiple different possibilities. These possibilities include recruitment of $CD56^{bright}CD16^-$ pNK cells, recruitment and tissue specific terminal differentiation of $CD56^{dim}CD16^+$ pNK cells, development of NK cells from $Lin^-CD34^+CD45^+$ progenitor cells, or proliferation of resident $CD56^{bright}CD16^-$ NK cells. Comparative surface expression of antigens, natural cytotoxicity receptors, inhibitory receptors, and

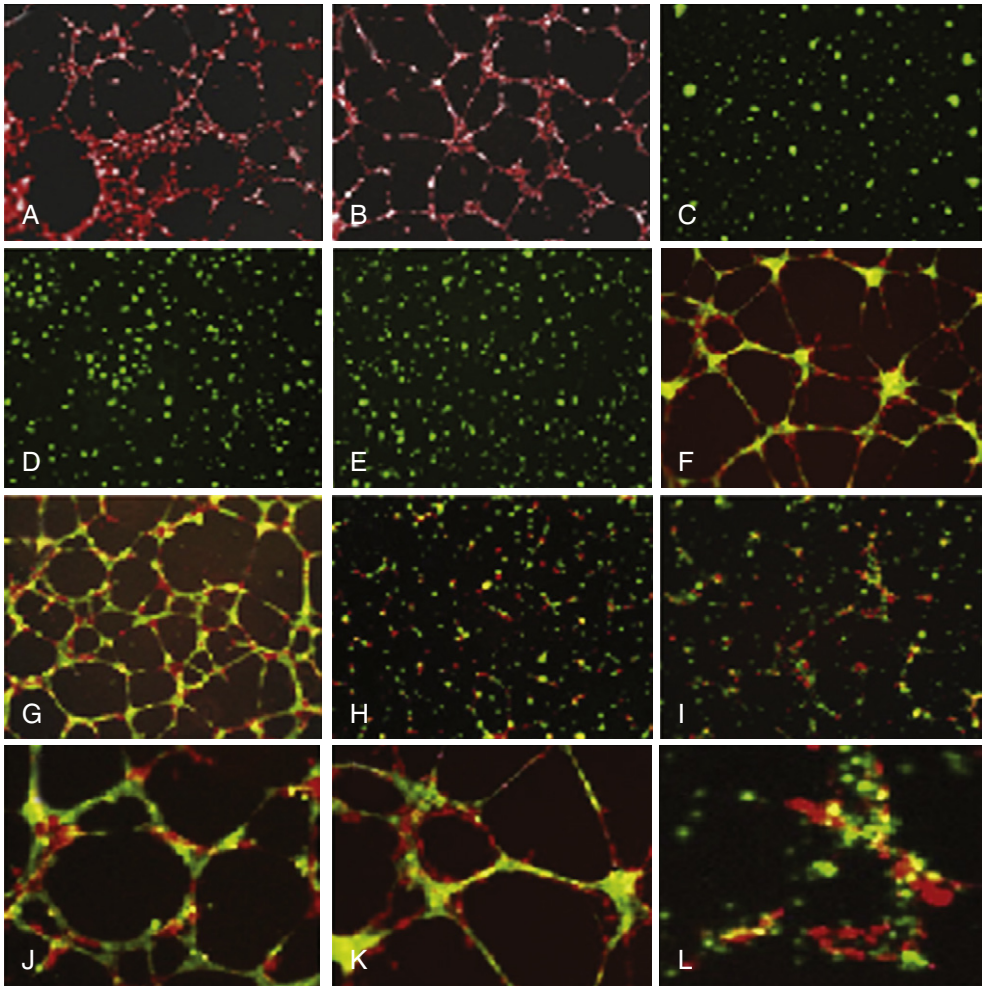

FIGURE 5-6 *(Supplemental color version of this figure is available online at www.expertconsult.com.)* **Differential endovascular activity of first- and third-trimester trophoblasts in response to normal pregnancy serum.** A representative micrograph of trophoblasts-endothelial cell interactions on matrigel is shown. Endothelial cells and trophoblasts are labeled with red and green cell tracker respectively, were independently cultured **(A** to **E)** or cocultured **(F** to **I)** on matrigel. Capillary-like tube structures were observed with human uterine endothelial cells (HUtECs) **(A)** and umbilical vein endothelial cells (HUVECs) **(B),** but not with first-trimester trophoblast HTR8 cells **(C),** third trimester trophoblast TCL1 cells **(D),** and primary term trophoblasts **(E).** However, in cocultures, HTR8 cells fingerprint the HUtECs **(F)** and HUVECs **(G),** while TCL1 cells **(H)** and primary term trophoblasts **(I)** inhibit the tube formation by endothelial cells (magnification ×4). Panels **J** to **L** show the cocultures of HTR8 with HUVECs **(J),** HUtECs **(K),** and term trophoblasts with HUVECs **(L)** at higher magnification (×10). *(Reproduced with permission from Kalkunte S, Lai Z, Tewari N, et al: In vitro and in vivo evidence for lack of endovascular remodeling by third trimester trophoblasts,* Placenta *29:871-878, 2008.)*

chemokines and cytokines on human pNK and uNK cells are provided in Table 5-4. Furthermore, $CD56^{bright}$ uNK cells are different from the $CD56^{bright}$ minor population of pNK cells because of the expression of CD9, CD103, and killer immunoglobulin-like receptors (KIRs). Despite being replete with cytotoxic accessories of perforin, granzymes A and B and the natural cytotoxicity receptors NKp30, NKp44, NKp46, NKG2D, and 2B4 as well as LFA-1, uNK cells are tolerant cytokine-producing cells at the maternal-fetal interface (Kalkunte et al, 2008a). The temporal occurrence around the spiral arteries and timed amplification of these specialized uNK cells observed during the first trimester implicate its role in spiral artery remodeling.

NK cell–deficient mice display abnormalities in decidual artery remodeling and trophoblast invasion, possibly because of a lack of uNK cell–derived interferon γ (Ashkar et al, 2000). Other studies have shown that unlike pNK cells, uNK cells are a major source of VEGF-C, Angiopoietins 1 and 2 and transforming grwoth factor (TGF-β1) within the placental bed that decrease with gestational age (Lash et al, 2006). These observations implicate uNK cells in promoting angiogenesis. Studies have provided further evidence that uNK cells, but not pNK cells, regulate trophoblast invasion both in vitro and in vivo through the production of interleukin-8 and interferon-inducible

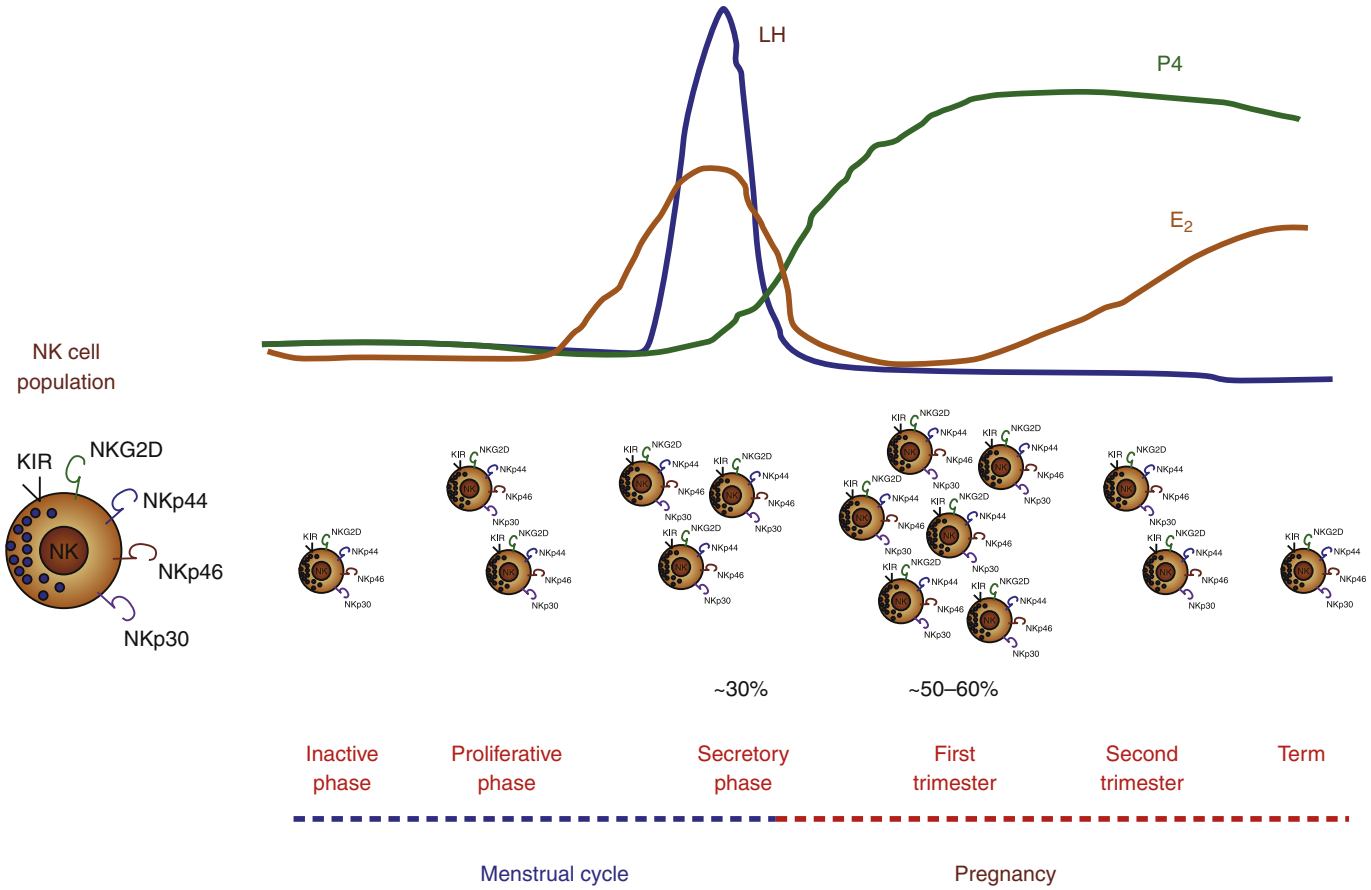

FIGURE 5-7 Biologic pattern of natural killer (NK) cells in the human endometrium and the decidua. The uterine NK cell population characterized by natural cytotoxicity receptors (Nkp30, NKp44, NKp46, NKG2D), killer immunoglobulin-like receptors, and cytolytic machinery (perforin and granzyme) cyclically increases and decreases in tandem with the hormonal changes during menstrual cycle. With successful implantation, uterine NK cells further increase in the decidua and dwindle thereafter by the end of second trimester. *E_2*, Estradiol; *LH*, luteinizing hormone; *P4*, progesterone.

protein-10, in addition to other angiogenic factors (Hanna et al, 2006). Recent studies suggest that VEGF-C, a pro-angiogenic factor produced by uNK cells, is responsible for the noncytotoxic activity (Kalkunte et al, 2009). As noted previously, VEGF-C–producing uNK cells support endovascular activity in a coculture model of capillary tube formation on matrigel (Figure 5-8). Peripheral blood NK cells fail to produce VEGF-C and remain cytotoxic. This function can be reversed by recombinant human VEGF-C. Cytoprotection by VEGF-C is related to induction of the transporter associated with antigen processing 1 and MHC assembly in target cells. Overall, these findings suggest that expression of angiogenic factors by uNK cells keeps these cells noncytotoxic, which is critical to their pregnancy compatible immunovascular role during placentation and fetal development (Kalkunte et al, 2009).

Although uNK cells seem to play a role that is compatible with pregnancy, retention of their cytolytic abilities suggests their role as sentinels at the maternal-fetal interface in situations that threaten fetal persistence. This facet of uNK cell function was elegantly demonstrated in animal models when pregnant mice were challenged with toll-like receptor (TLR) ligands that mimic bacterial and viral infections. These observations raise an important question whether uNK cells can harm the fetal placental unit and, if so, under what conditions?

The antiinflammatory cytokine interleukin (IL)-10 plays a critical role in pregnancy because of its regulatory relationship with other intrauterine modulators and its wide range of immunosuppressive activities (Moore et al, 2001). IL-10 expression by the human placenta depends on gestational age, with significant expression through the second trimester followed by attenuation at term (Hanna et al, 2000). IL-10 expression is also found to be poor in decidual and placental tissues from unexplained spontaneous abortion cases (Plevyak et al, 2002) and from deliveries associated with preterm labor (Hanna et al, 2006) and preeclampsia (S. Kalkunte et al, unpublished observations). However, the precise mechanisms by which IL-10 protects the fetus remains poorly understood. IL-$10^{-/-}$ mice suffer no pregnancy defects when mated under pathogen-free conditions (White et al, 2004), but they exhibit exquisite susceptibility to infection or inflammatory stimuli compared with wild type animals. It is then plausible that in addition to IL-10 deficiency, a "second hit" such as an inflammatory insult resulting from genital tract infections, environmental factors, or hormonal dysregulation during gestation can lead to adverse pregnancy outcomes (Tewari et al, 2009; Thaxton et al, 2009). Our recent studies provide direct evidence that uNK cells can become adversely activated and mediate fetal demise and preterm birth in response to low doses of TLR ligands

resulting in placental pathology (Murphy et al, 2005; Murphy et al, 2009). Moreover, spontaneous abortion is associated with an increase in $CD56^{dim}CD16^{+}$ cells and a decrease in $CD56^{bright}CD16^{-}$ NK cells in the preimplantation endometrium during the luteal phase (Michimata et al, 2002; Quenby et al, 1999). Therefore a fine balance between maternal activating and inhibitory KIRs and their ligand HLA-C on fetal cells seems to be maintained in normal pregnancy. Insufficient inhibition of uNK cells can activate the cytolytic machinery, resulting in spontaneous abortion, intrauterine growth restriction, or preterm labor, depending on the timing of the insult (Varla-Leftherioti et al, 2003). In the setting of IVF, the implantation failure has been associated with high uNK cell numbers, but direct evidence for their role in abnormal implantation is not clear (Quenby et al, 1999). Nevertheless current understanding strongly implies that uNK cells retain the ability to become foes to pregnancy under the axis of genetic stress and inflammatory trigger.

REGULATORY T CELLS AND PREGNANCY

The existence of regulatory mechanisms that suppress the maternal immune system was proposed in the early 1950 (Medawar, 1953). For several years, maternal tolerance toward fetal alloantigens was explored in the context of Th1/Th2 balance, with Th2 cells and cytokines proposed to predominate over Th1 cellular immune response under normal pregnancy. Recently the role of specialized T lymphocytes, termed *regulatory T cells* (Tregs), in tolerogenic mechanisms has emerged. Tregs are potent suppressors of T cell–mediated inflammatory immune responses and prevent autoimmunity and allograft rejection. Tregs act by controlling the autoreactive T cells that have escaped negative selection from the thymus, and they restrain the intensity of responses by T cells reactive with alloantigens and other exogenous antigens. This unique functional capability to suppress responses to tissue-specific self-antigens that escape recognition by T cells during maturation is due to tissue specific expression and alloantigens, particularly in the epithelial surfaces where tolerance to nondangerous foreign antigen is essential to normal function. This capability enables Tregs to play a unique role at the maternal-fetal interface. Tregs are typically characterized by a $CD4^{+}CD25^{+}$ surface phenotype and expression of the hallmark suppressive transcription factor Foxhead Box P3 ($Foxp3^{+}$). Their cell numbers increase in blood, decidual tissue, and lymph nodes draining the uterus during pregnancy. These cells are implicated in successful immune tolerance of the conceptus, mainly by producing IL-10 and TGF-β. Recent evidence suggests that fetal Tregs also play a vital role in suppressing fetal antimaternal immunity against maternal cells that cross the placenta (Mold et al, 2008).

In the absence of Tregs the allogeneic fetus is rejected, suggesting their critical role in normal pregnancy. Unexplained infertility, spontaneous abortion, and preeclampsia are associated with proportional deficience, functional Treg deficiency, or both. In the context of pregnancy, the local milieu, particularly during the first trimester, that includes hCG, TGF-β, IL-10, granulocyte-macrophage colony-stimulating factor, and indoleamine 2,3-dioxygenase expression has now been shown to induce $CD4^{+}CD25^{+}$ Tregs with Foxp3 expression with immunosuppressive features. This induction is thought to occur through the immature dendritic cells. In addition to immune suppressive and anti-inflammatory properties, TGF-β is recognized as inducing differentiation of naïve CD4 T cells into suppressor T-cell phenotype, expressing Foxp3, and promoting the proliferation of mature Tregs. In addition to the suppressive effects of cytokines produced by these cells, contact-mediated immune suppression by Tregs results from ligation of inhibitory cytotoxic T-lymphocyte antigen (CTLA-4) and its ability to induce tolerogenic dendritic cells and influence T-cell production of IL-10 (Aluvihare et al, 2004; Schumacher et al, 2009; Shevach et al, 2009). Therefore the pregnant uterus may be a natural depot for Tregs.

EPIGENETIC REGULATION IN THE PLACENTA

The regulation of gene expression is a crucial process that defines phenotypic diversity. Switching off or turning on genes as well as tissue-specific variation in gene expression contributes to this diversity. Besides the genetic make-up (i.e, sequence) of the individual, the regulation of gene expression is also influenced by epigenetic factors. Epigenetic changes include the noncoding changes in DNA and chromatin, or both, that mediate the interactions between genes and their environment. Epigenetic regulation generates a wider

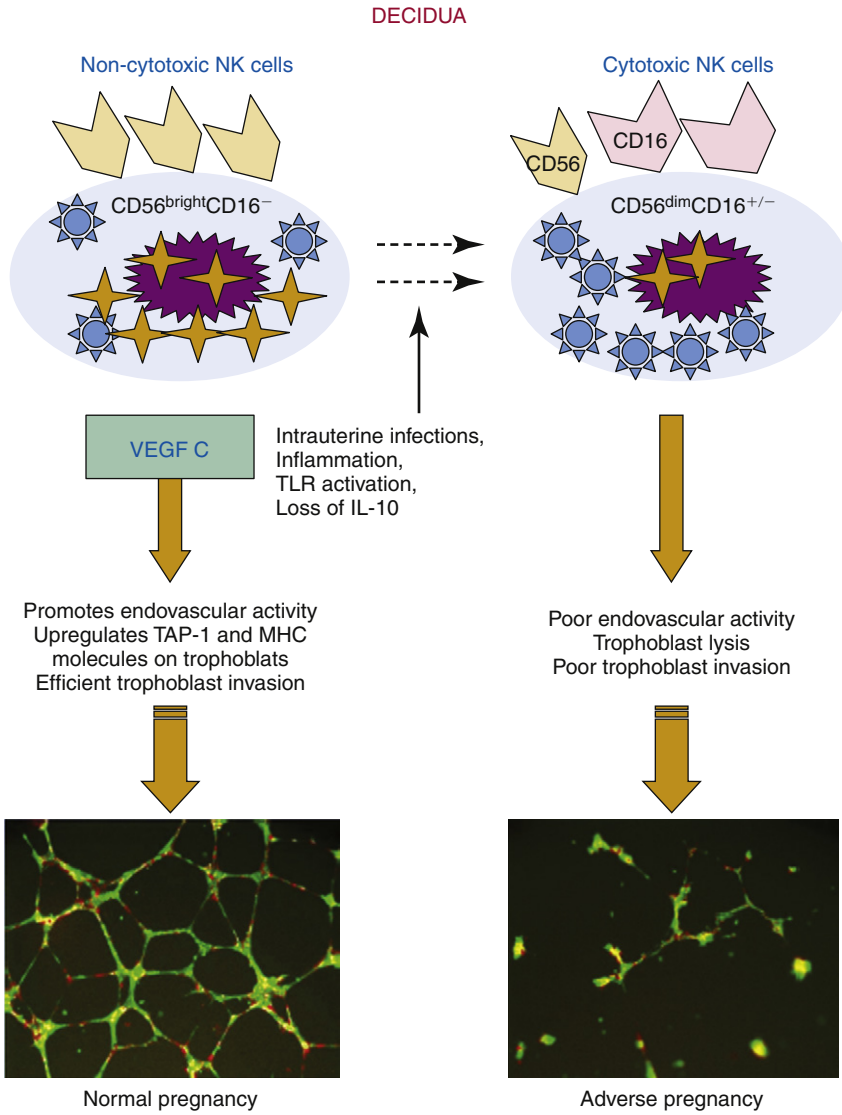

FIGURE 5-8 *(See also Color Plate 1.)* Angiogenic features of natural killer (NK) cells render them immune tolerant at the maternal-fetal interface. Vascular endothelial growth factor (VEGF) C–producing noncytotoxic uterine NK cell clones similar to decidual NK cells support endovascular activity in a coculture of endothelial cells and first-trimester trophoblast HTR8 cells on matrigel. By contrast, cytotoxic uterine NK cell clones similar to peripheral blood NK cells disrupted the endovascular activity because of endothelial and trophoblast cell lysis. This distinct functional feature determines whether optimal trophoblast invasion takes place and can result in normal or adverse pregnancy outcomes.

diversity of cell types during mammalian development and sustains the stability and integrity of the expression profiles of different cell types and tissues. This regulation is choreographed by changes in cytosine-phosphate-guanine (CpG) islands of the DNA promoter region by methylation, histone modification, genomic imprinting, and expression of noncoding RNAs such as micro RNA (miRNA).

Gene-environment interactions resulting in epigenetic changes in the placenta during the critical window of development can influence fetal programming in utero, with predisposing health consequences later in life. Using a microarray-based approach to compare chorionic villous samples from the first trimester of pregnancy with gestational age–matched maternal blood cell samples, recent studies show tissue-specific differential CpG methylation patterns that identify numerous potential biomarkers for the diagnosis of fetal aneuploidy on chromosomes 13, 18 and 21 (Chu et al, 2009). Human placentation displays many similarities with tumorigenesis, including rapid mitotic cell division, migration, angiogenesis and invasion, and escape from immune surveillance. Indeed, there are striking similarities in the DNA methylation pattern of tumor-associated genes between invasive trophoblast cell lines and first-trimester placenta and tumors (Christensen et al, 2009). This finding suggests that a distinct pattern of tumor-associated methylation can result in a series of epigenetic silencing events necessary for normal human placental invasion and function (Novakovic et al, 2008). Other studies using the placenta as a source suggest that the specific loss of imprinting because of altered methylation and subsequent gene expression can result in small for gestational age (SGA) newborns. Moreover, unbalanced expression of imprinted genes in IUGR placenta when compared with non-IUGR placenta was observed suggesting a differential expression pattern of imprinted genes as a possible biomarker for IUGR (Guo et al, 2008; McMinn et al, 2006).

The unique cytokine and hormonal milieu in utero may influence the trophoblast function and differentiation as well as immune cell regulation through histone posttranslational modification. In this regard, interferon γ produced by uNK cells and essential for spiral artery remodeling fails to induce MHC class II expression in trophoblast cells because of hypermethylation of regulatory class II MHC transactivator (CIITA) regions (Morris et al, 2002). This inability to upregulate classical MHC class II molecules by trophoblasts is essential for maintaining immune tolerance at the maternal-fetal interface. Moreover, the transcription factor regulating trophoblastic fusion protein syncytin, which is essential for the syncytialization of trophoblasts, is regulated by histone acetyl transferase and histone deacetylase activity (Chuang et al, 2006). miRNAs are small regulatory RNA molecules that can alter gene and protein expression without altering the underlying genetic code. Expression of miRNA is tissue specific, and several are expressed in the placenta. In placental pathology associated with preeclampsia, there is differential expression of miRNA (such as miR-210 and miR-182) compared with normal pregnancy placenta. This finding suggests that signature differences in placental miRNA and their detection in maternal serum may potentially be used as a biomarker for preeclampsia. Because implantation and early placentation is under the regulation of low oxygen tension, it is possible that miRNA are differentially expressed under different oxygen levels, as suggested by recent observations (Maccani and Marsit, 2009; Pineles et al, 2007).

PLACENTAL DISEASES

The placenta provides a wealth of retrospective information about the fetus and prospective information regarding the infant. Healthy development of the placenta requires efficient metabolic, immune, hormonal, and vascular adaptation by the maternal system as well as the fetus. Abnormal placentation and placental infections can lead to maternal or fetal anomalies as seen in preeclampsia, preterm birth, and SGA, which can have lifelong bearing on the development and health of infants. Maternal factors such as ascending infections, obesity, hypertension, genetic predisposition such as gene polymorphism of the pregnancy-compatible cytokine milieu, and environmental exposure could also contribute to the placental pathology. The following sections contain an abbreviated discussion of the pathogenesis of some of these placenta-associated disorders.

PREECLAMPSIA

Hypertensive disorders of pregnancy are enigmatic. They pose a major public health problem and affect 5% to 10% of human pregnancies. Preeclampsia is clinically associated with maternal symptoms of hypertension, proteinuria, and glomeruloendotheliosis. This disorder is strictly a placental condition because of its clearance after delivery. It causes morbidity and mortality in the mother, fetus, and newborn. *Pregnancy-associated hypertension* is defined as blood pressure greater than 140/90 mm Hg on at least two occasions and at 4 to 6 weeks apart after 20 weeks' gestation. *Proteinuria* is defined by excretion of 300 mg or more of protein every 24 hours or 300 mg/L or more in two random urine samples taken at least 4 to 6 hours apart (ACOG Committee on Practice Bulletins, 2002). The fetal problems most commonly associated with preeclampsia include fetal growth restriction, reduced amniotic fluid, and abnormal oxygenation (Sibai et al, 2005). However, the onset of clinical signs and symptoms can result in either near-term preeclampsia without affecting the fetus or its severe manifestation that is associated with low birthweight and preterm delivery (Vatten and Skjaerven, 2004). The heterogeneous manifestation of this disease is further confounded by preexisting maternal vascular disease, multifetal gestation, metabolic syndrome, obesity, or previous incidence of the disease. In addition, the pathophysiology of the disorder could differ from the onset before 24 weeks' gestation and its diagnosis at later stages of pregnancy:

Abnormal remodeling of spiral arteries and shallow trophoblast invasion are two hallmark features of preeclampsia. Preeclampsia is considered a two-stage disease where a poorly perfused placenta (stage I) causes the release of factors leading to maternal symptoms (stage II). However, it is also now being recognized that the maternal factors may contribute to programming of stage I of preeclampsia, suggesting that the intrinsic maternal factors stemming from genetic, behavioral, and physiologic conditions may contribute to placental pathology. Stage I initiated pathology may be particularly apparent in the oxidative stress-induced release of causative factors from the poorly perfused placenta and their effects on the maternal syndrome (Roberts and Hubel, 1999).

Despite a poor mechanistic understanding of placental pathology leading to preeclampsia, several critical features are common to this disease. Multiple studies have shown that reduced vascular activity could be a major factor contributing to preeclampsia. In normal pregnancy, the circulating PlGF levels steadily increase in the first and second trimesters, peak at 29 to 32 weeks, and decline thereafter. However, free VEGF remains low and unchanged during this window. Reduced placental expression of VEGF and PlGF is consistently observed in preeclampsia. Furthermore, preeclampsia is frequently accompanied by enhanced circulation and placental expression of the antiangiogenic soluble VEGF receptor 1 (sFlt-1), which is a decoy receptor titrating out VEGFs and PlGF (Levine et al, 2004; Romero et al, 2008; Thadhani et al, 2004). A lack of available VEGF and increased sFlt-1 expression has been associated with trophoblast injury. The soluble form of endoglin (CD105), a coreceptor involved in TGF-β signaling is reported to enhance the antiangiogenic effects of sFlt-1. Soluble endoglin has been found to be elevated in the serum of preeclamptic women and is accompanied by an increased ratio of sFlt-1:PlGF and correlates with the severity of the disease. Soluble endoglin is thought to inhibit TGF-β1 signaling in endothelial cells and blocks activation of endothelial nitric oxide synthase and vasodilatation (Venkatesha et al, 2006). Several recent studies have suggested an increase in apoptosis within villous trophoblast from preeclampsia and IUGR deliveries (Allaire et al, 2000; Heazell and Crocker, 2008; Levy et al, 2002). Unlike normal pregnancy, villous placental explants

from preeclamptic placenta have an increased sensitivity and susceptibility to apoptosis on exposure to proinflammatory cytokines, suggesting altered programming of apoptotic cascade pathway (Crocker et al, 2004; Levy et al, 2002). It is possible that incomplete spiral artery transformation resulting in reduced placental perfusion (stage I) in preeclampsia leads to focal regions of hypoxia with increase in apoptosis, oxidative stress, shedding of villous microparticles, and release of antiangiogenic factors such as sFlt-1.64 (Hung et al, 2002; Nevo et al, 2006; Redman and Sargent, 2000).

Another pathway that may contribute to the etiology of preeclampsia is unscheduled and excessive activation of the complement cascade; this is highly likely as a result of the maternal immune system responding to paternal antigens and inflammation. However, in normal pregnancy the placenta expresses complement regulatory proteins such as DAF, CD55, and CD59 and may control activation of complement factors (Tedesco et al, 1993). Despite the positioning of complement inhibitory proteins for protective roles, increasing evidence supports the involvement of complement activation in the pathogenesis of preeclampsia (Lynch et al, 2008). Interestingly, recent in vitro studies suggest that hypoxia enhances placental deposition of the membrane attack complex and apoptosis in cultured trophoblasts (Rampersad et al, 2008). The upstream factors that trigger complement activation are not yet known.

Recent studies also suggest increased serum levels of agonistic autoantibodies against angiotensin type 1 receptor (AT-1-AA) in preeclampsia as compared with healthy women (Zhou et al, 2008). Importantly, studies from our laboratory have shown that the full spectrum of preeclampsia-like symptoms can be reproduced in mice by injecting human preeclampsia serum containing subthreshold levels of AT-1-AA immunoglobulin G, suggesting that pregnancy serum contains some unknown causative factors. Therefore serum can be used as a blueprint to identify functional biomarkers for preeclampsia (Kalkunte et al, 2009).

PRETERM BIRTH

Preterm birth is the leading cause of infant morbidity and mortality in the world. Babies born before 37 weeks' gestation are considered premature. In the United States, approximately 12.8% of births are preterm, and the rate of premature birth has increased by 36% since early 1980s (Martin et al, 2009). Babies from preterm birth face an increased risk of lasting disabilities such as mental retardation, learning and behavioral problems, autism, cerebral palsy, bronchopulmonary dysplasia, vision and hearing loss, and risk for diabetes, hypertension, and heart disease in adulthood. The majority of preterm deliveries are due to preterm labor. Other factors leading to premature birth are preterm premature rupture of membranes (PPROM), intervention for maternal or fetal problems, preeclampsia, fetal growth restriction, cervical incompetence, and antepartum bleeding. Additional risk factors for preterm birth include stress, occupational fatigue, uterine distention by polyhydramnios or multifetal gestation, systemic infection such as periodontal disease, intrauterine placental pathology such as abruption, vaginal bleeding, smoking, substance abuse, maternal age (<18 or >40 years), obesity, diabetes, thrombophilia, ethnicity, anemia, and fetal factors such as congenital anomalies and growth restriction.

Activation of the hypothalamic-pituitary-adrenal (HPA) as a result of major maternal physical or psychological stress is thought to increase the release of corticotrophin-releasing hormone. In addition to the hypothalamus as a source of corticotrophin-releasing hormone, placental trophoblasts, amnion, and decidual cells also express this hormone during pregnancy. Corticotrophin hormone regulates the release of adrenocorticotropic hormone from pituitary and cortisol from adrenal glands, and it can also influence the activity of matrix metalloproteinases (MMPs). Premature activation of the HPA axis can eventually stimulate the prostaglandins, ultimately resulting in parturition via activation of proteases. In addition, activation of the HPA axis promotes the release of estrone, estradiol, and estriol that can activate the myometrium by increasing oxytocin receptors, prostaglandin activity, and enzymes such as myosin light chain kinase and calmodulin, which are responsible for muscle contraction. Concomitantly, progesterone withdrawal is expected with the raising concentration of myometrial estrogen receptors, further enhancing estrogen-induced myometrial activation and preterm birth (Dole et al, 2003; Grammatopoulos and Hillhouse, 1999; McLean et al, 1995).

There is increasing evidence that approximately 50% of preterm births are associated with infection of the decidua, amnion, or chorion and amniotic fluid caused by either systemic or ascending genital tract infection. Both clinical and subclinical chorioamnionitis are implicated in preterm birth. Maternal or fetal inflammatory responses to chorioamniotic infection can trigger preterm birth. Activated neutrophils and macrophages and the release of cytokines IL-1β, IL-6, IL-8, tumor necrosis factor alpha (TNF-α) and granulocyte colony-stimulating factor can lead to an enhanced cascade of signaling activity, causing release of prostaglandins and expression of various MMPs of fetal membranes and the cervix. Furthermore, elevated levels of TNF-α and apoptosis are associated with PPROM. Non–infection-related inflammation caused by placental insufficiency and apoptosis can also cause preterm birth. In addition to augmented inflammatory responses to infections, pathogenic microbes (e.g. *Staphylococcus*, *Streptococcus*, *Bacteroides*, and *Pseudomonas* spp.) are thought to directly degrade fetal membranes by releasing proteases, collagenases, and elastases, produce phospholipase A2, and release endotoxin that stimulate uterine contractions and cause preterm birth (Goldenberg et al, 2000, 2008; Romero et al, 2006; Slattery and Morrison, 2002).

The innate immune system and trophoblasts during pregnancy recognize bacterial and viral infections using TLRs. Placental transcripts for TLRs 1 to 10 have been detected in human placental tissue, and placental choriocarcinoma cell lines reportedly express TLR-2, TLR-4, and TLR-9 (Abrahams and Mor, 2005). Studies have demonstrated functionality for TLR-2, TLR-3, and TLR-4 in first- and third-trimester placental tissue (Patni et al, 2007). Decidual expression in humans has demonstrated functional receptors in term decidua of TLR-1, TLR-2, TLR-4, and TLR-6 (Canavan and Simhan, 2007). Our recent studies using mice have shown that extremely small

doses of the TLR-4 ligand lipopolysaccharide can cause preterm birth or fetal demise in pregnant IL-10–deficient mice by activating and promoting infiltration of uterine NK cells into the placenta and inducing apoptosis by secretion of TNF-α (Murphy et al, 2005, 2009). Similarly, activation of TLR-3 or TLR-9 has been shown to induce spontaneous abortion or preterm birth in IL-10–deficient pregnant mice that is attributed to immune infiltration and proinflammatory cascade in the placenta (Thaxton et al, 2009).

Decidual hemorrhage leading to vaginal bleeding increases the risk for preterm birth and PPROM. Increased occult decidual hemorrhage, hemosiderin deposition, and retrochorionic hematoma formation is seen between 22 and 32 weeks' gestation as a result of PPROM and preterm birth after preterm labor. The development of PPROM in the setting of abruption could be caused by high decidual concentration of tissue factors, which eventually generate thrombin. Thrombin activation as measured by serum thrombin-antithrombin III complex levels are elevated on preterm birth. Thrombin binds to decidual protease-activated receptors (PAR1 and PAR2), induces the production of IL-8 in decidua, attracts neutrophils, and promotes degradation of the fetal membrane MMPs that can result in PPROM (Lockwood et al, 2005; Salafia et al, 1995).

Polyhydramnios is also a high risk factor for preterm birth. It was shown recently that exposure of IL-10–deficient pregnant mice to polychlorinated biphenyls, an environmental toxicant, can lead to preterm birth with IUGR. The IUGR was due to increased amniotic fluid volume (polyhydramnios) and placental insufficiency caused by poor spiral artery remodeling associated with reduced expression of water channel aquaporin-1 in the placenta (Tewari et al, 2009). Increasing evidence also suggests impaired vascular activity because of an increase in antiangiogenic factors such as sFlt-1 and decreased VEGF in PPROM and preterm birth (Kim et al, 2003).

INTRAUTERINE GROWTH RESTRICTION

IUGR is used to designate a fetus that has not reached its growth potential; it can be caused by fetal, placental, or maternal factors. Disparities between fetal nutritional or respiratory demands and placental supply can result in impaired fetal growth. Chromosomal abnormalities (aneuploidy, partial deletions, gene mutation particularly on the gene for insulin-like growth factors), congenital abnormalities, multiple gestation, and infections can also result in IUGR. Preterm birth, preeclampsia, and abruption because of placental ischemia can result in IUGR. Reduced placental weight with identifiable placental histologic abnormalities (e.g, impaired development or obstruction in uteroplacental vasculature, chronic abruption, chronic infections, maternal floor infarction, thrombosis in uteroplacental vasculature or fetoplacental vasculature) are common findings in IUGR. In addition, a single umbilical artery, velamentous umbilical cord insertion, bilobate placenta, circumvallate placenta, and placental hemangioma are some of the other structural anomalies seen in the placenta. Maternal factors such as nutritional deficiency; severe anemia; pulmonary disease leading to maternal hypoxemia; smoking; exposure to toxins such as warfarin, anticonvulsants, folic acid antagonists, and caffeine; and pregnancies conceived through assisted reproductive techniques have a higher prevalence of IUGR. IUGR results in the birth of an infant who is SGA. Mortality and morbidity are increased in SGA infants compared with those who are appropriate for gestational age. SGA infants at birth have many clinical problems that include impaired thermoregulation; difficulty in cardiopulmonary transition with perinatal asphyxia, pulmonary hypertension, hypoglycemia, polycythemia and hyperviscosity; impaired cellular immune function; and increased risk for perinatal mortality. SGA infants in their childhood and adolescence are at higher risk for impaired physical growth and neurodevelopment. Adolescents born SGA at term were reported to have learning difficulties with attention deficits. Cognitive performance is generally lower in SGA infants at the ages of 1 to 6 years compared with those whoe are appropriate for gestational age. Adults who were SGA infants could be at higher risk for ischemic heart diseases and essential hypertension (Figueras et al, 2007; Kaijser et al, 2008; Lapillonne et al, 1997; Norman and Bonamy, 2005; O'Keefe et al, 2003; Spence et al, 2007).

FETAL MEMBRANES AND THEIR PATHOLOGY

The fetal tissue–derived membrane structure surrounds the fetus and forms the amniotic cavity. This membrane, which lacks both vascular and nerve cells, is composed of an inner layer adjacent to the amniotic fluid and is called the *amnion*. The outer layer that is attached to the decidua is called the *chorion*. Amnion is composed of inner epithelial cells, and the mesenchymal cell layer is composed of fibroblast and an outer spongy layer. Intact, healthy fetal membranes are required for normal pregnancy outcome. Chorion is composed of an outer reticular cell layer composed of fibroblasts and macrophages and an inner cytotrophoblast layer. The elasticity and strength of these membranes are maintained by extracellular matrix proteins such as collagens, fibronectin, laminins, and the activity of MMP-2 and MMP-9 and their inhibitors until the initiation of parturition when the membranes are susceptible to rupture. During parturition, when contractions begin or membranes rupture, MMP activity in the amnion and chorion increases with a concurrent fall in tissue inhibitors of metalloproteinases. This change is followed by apoptosis in the amnion epithelial and chorion trophoblast layers of fetal membrane. Interestingly, some evidence suggests that fetal membranes have antimicrobial activity and are known to express TLR-2 and TLR-4, which are pattern recognition receptors and help in initiating a protective host response to infection.

The histopathology of amnion and chorion includes infections, amniotic fluid contaminants, and fetal diseases. In addition to the membranes, whose infection can lead to chorioamnionitis, another vulnerable portal for infection to occur is the placental intervillous space and fetal villi that provide hematogenous access. Hematogenous sources of infection are typically associated with inflammation of villi (villitis) and intervillous space (intervillositis). Viral pathogens (cytomegalovirus, HIV, herpes simplex virus)

commonly produce hematogenous infection of the placenta in addition to bacteria, spirochetes, fungi, and protozoa (Gersell, 1993; Goldenberg et al, 2000; Lahra and Jeffery, 2004).

UMBILICAL CORD

The connecting cord from the developing embryo or fetus to the placenta is the umbilical cord, or funiculus umbilicalis. During prenatal development in humans, the normal umbilical cord contains two umbilical arteries and one umbilical vein buried within Wharton's jelly. The umbilical vein supplies the fetus with oxygenated blood from the placenta while the arteries return the deoxygenated, nutrient-depleted blood to the placenta. In the fetus, the umbilical vein branches into the ductus venosus and another branch that joins the hepatic portal vein. Shortly after parturition, physiologic processes cause the Wharton's jelly to swell with the collapse of blood vessels, resulting in a natural halting of the flow of blood. Within the infant, the umbilical vein and ductus venosus close and degenerate into remnants known as the *round ligament of the liver* and the *ligamentum venosum*, while the umbilical arteries degenerate into what is known as *medial umbilical ligaments*.

Abnormalities associated with the umbilical cord can affect both the mother and the child. Pathology of umbilical cord is generally grouped as congenital remnants, infections, meconium, and masses. Abnormalities that have clinical significance are nuchal cord, single umbilical artery, umbilical cord prolapse, umbilical cord knot, umbilical cord entanglement, vasa previa, and velamentous cord insertion. Common intrauterine infections can result in the umbilical cord being invaded by fetal cells and bacteria infiltrated from the decidua to amniotic fluid, or they can elicit fetal inflammatory response. Umbilical cord inflammation, known as *funisitis* or *vasculitis*, poses a higher risk for development of neurologic compromise in the fetus. Funisitis is predictive of a lower median Bayley psychomotor developmental index in infants. Meconium pigment at high concentrations can damage the umbilical cord by triggering apoptosis of smooth muscle cells. Vascular necrosis caused by meconium is associated with oligohydramnios, low Apgar scores, and significant neurodevelopmental delay. Interruption of normal blood flow in the cord can cause prolonged hypoxia in utero. Clamping of the umbilical cord within minutes of birth is hospital-based obstetric practice. A Cochrane review studying the effects of the timing of umbilical cord clamping in hospitals showed that infants whose cord clamping occurred later than 60 seconds after birth had a significantly higher risk of neonatal jaundice requiring phototherapy. However, randomized, controlled studies have shown that delayed cord clamping in preterm infants reduces the incidence of intraventricular hemorrhage and late-onset sepsis. Furthermore, premature clamping can increase the risk of ischemia and hypovolemic shock, which can lead to fetal complications (McDonald and Middletone, 2008; Mercer et al, 2006).

CHAPTER 6

Abnormalities of Fetal Growth

Rebecca Simmons

Fetal growth and size at birth are critical in determining mortality and morbidity, both immediately after birth and in later life. Normal fetal growth is determined by a number of factors, including genetic potential, the ability of the mother to provide sufficient nutrients, the ability of the placenta to transfer nutrients, and intrauterine hormones and growth factors. The pattern of normal fetal growth involves rapid increases in fetal weight, length, and head circumference during the last half of gestation. During the last trimester, the human fetus accumulates significant amounts of lipid. The birthweight for gestational measurements among populations has been shown to increase over time; therefore, standards for normal fetal growth require periodic reevaluation for clinical relevance. These increases in birthweight for gestational age over time are attributed to improvements in living conditions and maternal nutrition and changes in obstetric management. Variations in fetal growth have been identified in diverse populations and are associated with geographic locations (sea level versus high altitude), populations (white, African American, Latino), maternal constitutional factors, parity, maternal nutrition, fetal gender, and multiple gestations. In this chapter, we discuss these factors in greater detail and critically review the long-term effects of abnormal fetal growth.

DEFINITIONS

Most approaches for defining fetal growth use gestational age-based norms. The duration of pregnancy has become an integral component of prenatal growth assessment, and all currently prevailing definitions of fetal growth are specific for gestational age. Assessing the gestational age accurately, however, can be challenging. Any error in dating will lead to misclassification of the infant, which can have significant clinical implications. In many instances, the method of gestational age determination has contributed to variations in the gestational age–specific reference growth curves. For example, some nomograms are based on approximating the gestational age to the nearest week, whereas others use the completed weeks. The birthweight charts are also affected by other variables that may limit their reliability. Many of these variables, such as fetal gender, race, parity, birth order, parental size, and altitude, contribute to the normal biologic variations in human fetal growth. There is continuing controversy regarding whether the reference growth charts should be customized by multiple variables or developed from the whole population. The customized approach predicts the optimal growth in an individual pregnancy and therefore specifically defines suboptimal growth for that pregnancy. However, it has been argued that such an approach can lead to a profusion of standards and might not contribute to improving the outcome of infants who are small for gestational age (SGA). In recognition of the utility of a national standard, a population-based reference chart for fetal growth has been developed from all the singleton births (more than 3 million) in the United States in 1991 (Alexander, 1996). More recently, a similar national population-based fetal growth chart, which is also sex specific, has been developed in Canada (Kramer et al, 2001). There is insufficient evidence about whether one approach is superior to the other in improving the perinatal outcome.

There is no universal agreement on the classification of an SGA infant. Various definitions appear in the medical literature, making comparisons between studies difficult. In addition, investigators have shown that the prevalence of fetal growth restriction varies according to the fetal growth curve used (Alexander et al, 1996). The most common definition of SGA refers to a weight less than the 10th percentile for gestational age or birthweight less than 2 standard deviations (SDs) from the mean. Some investigators also use measurements less than the 3rd percentile to define SGA. However, these definitions do not make a distinction among infants who are constitutionally small, growth restricted and small, and not small but growth restricted relative to their potential. As an example, as many as 70% of fetuses with a weight less than the 10th percentile for gestational age at birth are small simply because of constitutional factors such as female sex or maternal ethnicity, parity, or body mass index; they are not at high risk of perinatal mortality or morbidity. In contrast, true fetal growth restriction is associated with numerous perinatal morbidities. This has clinical relevance to perinatologists and neonatologists, because many of the tiniest premature neonates in the neonatal intensive care units are probably growth restricted. McIntire et al (1999) reported a threshold of increased adverse outcomes in infants born with measurements less than the 3rd percentile and suggested that this level of restriction represents a clinically relevant measurement. Other researchers have found higher rates of neonatal complications when the 15th percentile of birthweight is used as a cutoff level (Seeds and Peng, 1998).

There is an important distinction in identifying the fetus with intrauterine growth restriction (IUGR), and the fetus that is constitutionally small (i.e., SGA). IUGR is a condition in which a fetus is unable to achieve its genetically determined potential size and represents a deviation and a reduction in the expected fetal growth pattern. IUGR complicates approximately 5% to 8% of all pregnancies and 38% to 80% of all neonates with low birthweight (LBW). This discrepancy underscores the fact that no uniform definition of IUGR exists. Even when a normal intrauterine growth pattern is established for a population, somewhat arbitrary criteria are used to define growth restriction.

PATTERNS OF ALTERED GROWTH

Neonates with intrauterine growth retardation can be classified as demonstrating either symmetrical or asymmetrical growth. Infants with symmetric IUGR have reduced weight, length, and head circumference at birth. Weight (and then length) of infants with asymmetric growth retardation is affected, with a relatively normal or "head-sparing" growth pattern. Factors intrinsic to the fetus in general cause symmetrical growth restriction, whereas asymmetric IUGR is often associated with maternal medical conditions such as preeclampsia, chronic hypertension, and uterine anomalies. Asymmetric patterns generally develop during the third trimester, a period of rapid fetal growth. However, now that fetal surveillance is more common, asymmetric growth restriction is often diagnosed in the second trimester. Furthermore, many extremely premature neonates (<750 g) probably have IUGR.

Factors that are well recognized to limit the growth of both the fetal brain and body include chromosomal anomalies (e.g., trisomies), congenital infections (toxoplasmosis, rubella, cytomegalovirus, herpes simplex, malaria, HIV, and parvovirus), dwarf syndromes, and some inborn errors of metabolism. Cardiac and renal structural anomalies are common fetal conditions associated with SGA. These conditions retard fetal growth primarily by impaired cell proliferation. Recognized causes of IUGR are listed in Table 6-1.

Etiologies of Fetal Growth Restriction

The epidemiology of fetal growth restriction varies internationally (Keirse, 2000). In developed countries, the most frequently identified cause of growth restriction is smoking, whereas in developing countries, maternal nutritional factors (prepregnancy weight, maternal stature) and infections (malaria) are the leading identified causes (Krampl, 2000; Robinson et al, 2000). In addition, in developing countries there is a direct correlation between the incidence of LBW (<2500 g) and IUGR. In developing countries, the high incidence of infants with LBW is almost exclusively caused by the incidence of IUGR. Data from developed countries show the opposite, with rates of LBW being explained almost exclusively by prematurity rates. In the United States, the cause of IUGR is identified in approximately 40% of cases, with the remaining cases labeled as *idiopathic*.

Numerous factors have been identified as influencing size at birth. In a simplified manner, these factors can be grouped as fetal, placental, or maternal in origin. These factors will be discussed in detail in the following sections.

TABLE 6-1 Causes of Intrauterine Growth Restriction

Genetic	Inheritance, chromosomal abnormalities, fetal gender
Maternal constitutional effects	Low maternal pre-pregnancy weight, low pregnancy weight gain, ethnicity, socioeconomic status, history of intrauterine growth restriction
Nutrition	Low pre-pregnancy weight (body mass index), low pregnancy weight gain, malnutrition (macronutrients, micronutrients), maternal anemia
Infections	TORCH infections (toxoplasmosis, rubella, cytomegalovirus, syphilis)
Decreased O_2-carrying capacity	High altitude, maternal congenital heart disease, hemoglobinopathies, chronic anemia, maternal asthma
Uterine and placental anatomy	Abnormal uterine anatomy, uterine fibroid, vascular abnormalities (single umbilical artery, velamentous umbilical cord insertion, twin-twin transfusion), placenta previa, placental abruption
Uterine and placental function	Maternal vasculitis (system lupus erythematosus), decreased uteroplacental perfusion, maternal illness (preeclampsia, chronic hypertension, diabetes, renal disease)
Toxins	Tobacco, ethanol, lead, arsenic

Fetal Causes of Growth Restriction

Fetal factors affecting growth include gender, familial genetic inheritance, chromosomal abnormalities, and dysmorphic syndromes. In one large, population-based study, the frequency of IUGR among infants with congenital malformations was 22%. The majority of the infants affected had chromosomal abnormalities. Other studies have similarly found that fetal growth restriction is more common among infants with malformations. Fetal gender also influences size, with male infants showing greater intrauterine growth than female infants (Glinianaia et al, 2000; Skjaerven et al, 2000; Thomas et al, 2000).

Placental Causes of Growth Restriction

In mammals, the major determinant of intrauterine growth is the placental supply of nutrients to the fetus (Fowden et al, 2006). In many species, fetal weight near term is positively correlated to placental weight, as a proxy measure of the surface area for maternal-fetal transport of nutrients. Fetal weight near term is positively correlated to placental weight, and the nutrient transfer capacity of the placenta depends on its size, morphology, blood flow, and transporter abundance (Fowden et al, 2006). In addition, placental synthesis and metabolism of key nutrients and hormones influences the rate of fetal growth (Fowden and Forhead, 2004). Changes in any of these placental factors can, therefore, affect intrauterine growth; however, the fetus is not just a passive recipient of nutrients from the placenta. The fetal genome exerts a significant acquisitive drive for maternal nutrients through adaptations in the placenta, particularly when the potential for fetal and placental growth is compromised.

Placental maturation at the end of pregnancy is associated with an increase in substrate transfer, a slowing (but not cessation) of placental growth, and a plateau in fetal growth near term (Fox, 1997). Abnormalities of placental growth, senescence, and infarction have been shown to affect fetal growth. The placentas from pregnancies complicated by poor fetal growth have a higher incidence of vascular damage and abnormalities (Pardi et al, 1997). Fetal size and placental growth are directly related, and placentas from pregnancies yielding growth-restricted infants demonstrate a higher incidence of smallness and abnormality than do those from

pregnancies with appropriately grown infants. The difference in size is seen even in a comparison of placentas associated with growth-restricted infants and those associated with appropriate for gestational age (AGA) infants of the same birthweight (Heinonen et al, 2001). Placental growth in the second trimester correlates with placental weight and function and, thus, with weight at birth (Godfrey et al, 1996). Clinical conditions associated with reduced placental size (and subsequent reduced fetal weight) include maternal vascular disease, uterine anomalies (uterine fibroids, abnormal uterine anatomy), placental infarctions, unusual cord insertions, and abnormalities of placentation.

Multiple gestations are associated with greater risk for fetal growth restriction. The higher risk stems from crowding and from abnormalities with placentation, vascular communications, and umbilical cord insertions. Divergence in fetal growth appears from approximately 30 to 32 weeks in twin gestation compared with singleton pregnancies (Alexander et al, 1996; Glinianaia et al, 2000; Skjaerven et al, 2000). Others have identified differences in fetal growth between twins and singletons as occurring earlier in gestation, at approximately 21 weeks' gestation (Devoe and Ware, 1995). Larger effects on fetal growth are seen with increasing number of fetal multiples. Abnormalities in placentation are also more common with multiple gestations (Benirschke, 1995). Monochorionic twins can share placental vascular communication (twin-twin transfusion), leading to fetal growth restriction during gestation. Fetal competition for placental transfer of nutrients raises the incidence of growth restriction and discordance in growth between fetuses. The rate of birthweights less than the 5th percentile is higher in monochorionic twins. Placental growth is restricted in utero because of limitation in space, leading to a higher incidence of placenta previa in multiple-gestation pregnancies. In addition, abnormalities in cord insertions (marginal and velamentous cord insertions) and occurrence of a single umbilical artery are more frequently found in multiple gestations. The higher incidence of growth restriction in multiple-gestation pregnancies is strongly associated with monochorionic gestations, the presence of vascular anastomoses, and discordant fetal growth (Hollier et al, 1999; Sonntag et al, 1996; Victoria et al, 2001). Placentas of smaller fetuses with discordant growth are significantly smaller than those of their larger twin counterparts (Victoria et al, 2001).

Investigators have shown an effect of altitude on fetal growth, with infants born at high altitudes having lower birthweights (Galan et al, 2001). Differences in fetal growth are detected from approximately 25 weeks' gestation with pregnancies at 4000 m. In these high-altitude pregnancies, the abdominal circumference is most affected (Krampl et al, 2000). At tremendously high altitudes, the incidence of LGA infant births is markedly reduced. In the United States (and at less severe altitudes), infants born at higher altitudes are lighter at birth, but those differences are not pronounced. Interestingly, investigators have shown that adaptation to high altitude during pregnancy is also possible. Tibetan infants have higher birthweights than infants of more recent immigrants of ethnic Chinese living at the same high-altitude (2700 to 4700 m) region of Tibet (Moore et al, 2001). Tibetan infants also have less IUGR than do infants born to more recent immigrants to the area.

Maternal Causes of Growth Restriction

Maternal health conditions associated with chronic decreases in uteroplacental blood flow (maternal vascular diseases, preeclampsia, hypertension, maternal smoking) are associated with poor fetal growth and nutrition. Preeclampsia has been shown to be associated with fetal growth restriction (Ødegård et al, 2000; Spinillo et al, 1994; Xiong et al, 1999). Investigators have shown that the extent of growth restriction correlates with the severity and the onset during pregnancy of the preeclampsia. Ødegård et al (2000) showed that fetuses exposed to preeclampsia from early in pregnancy had the most serious growth restriction, and more than half of these infants were born SGA. Chronic maternal diseases (cardiac, renal) may decrease the normal uteroplacental blood flow to the fetus and thus may also be associated with poor fetal growth (Spinillo et al, 1994).

Maternal constitutional factors have a significant effect on fetal growth. Maternal weight (pre-pregnancy), maternal stature, and maternal weight gain during pregnancy are directly associated with maternal nutrition and correlate with fetal growth (Clausson et al, 1998; Doctor et al, 2001; Goldenberg et al, 1997; Mongelli and Gardosi, 2000). Numerous studies show that these findings are often confounded by highly associated cultural and socioeconomic factors. The woman with a previous SGA infant has a higher risk of a subsequent small infant (Robinson et al, 2000). Investigators have shown a higher incidence of SGA infants to be associated with lower levels of maternal education (Clausson et al, 1998). Parity of the mother also affects fetal size; nulliparous women having a higher incidence of SGA infants (Cnattingius et al, 1998). A large population-based study in Sweden found that women who were older than 30 years, were nulliparous, or had hypertensive disease were at increased risk of preterm and term growth-restricted infants.

Studies have shown differential fetal growth for women of diverse ethnicities, with Latina and white women having higher rates of LGA infants, and African American women having a higher incidence of SGA infants (Alexander et al, 1999; Collins and David, 2009; Fuentes-Afflick et al, 1998). These gender and ethnic differences in birthweight become pronounced after 30 weeks' gestation (Thomas et al, 2000). Investigators in California have shown that U.S.-born black women have higher rates of prematurity and LBW infants than do foreign-born black women. Other researchers have found that even among women with low risk of LBW infants (married, age 20 to 34 years, 13 or more years of education, adequate prenatal care, and absence of maternal health risk factors and tobacco or alcohol use), the risk of delivering an SGA infant is still higher for African American women than for white women (Alexander et al, 1999; Collins and David, 2009). It is unclear whether these differences in fetal growth are caused by inherent differences or by differential exposure to environmental factors.

Maternal nutrition and supply of nutrients to the fetus affect fetal growth significantly, primarily in developing countries (Doctor et al, 2001; Godfrey et al, 1996; Neggers et al, 1997; Robinson et al, 2000; Zeitlin et al, 2001). Although numerous factors interact with and affect fetal

development, maternal malnutrition is assumed to be a major cause of IUGR in developing countries. Furthermore, pre-pregnancy weight may be a potential marker for intergenerational effects on infant weight in developing countries. A woman's birthweight has been shown to correlate with her infant's weight as well as the placental weight during pregnancy. In the United States, Strauss and Dietz (1999) report that low maternal weight gain in the second and third trimesters is associated with a twofold risk of IUGR, whereas poor maternal weight gain in the first trimester has no such effect on fetal growth (Strauss and Dietz, 1999). These investigators also showed that older women (older than 35 years) and smokers were at increased risk of IUGR associated with lower weight gains in late pregnancy.

Teen pregnancy represents a special condition in which fetal weight is highly influenced by maternal nutrition. Teen mothers (younger than 15 years) have been shown to have a higher risk for delivering a growth-restricted infant (Ghidini, 1996). Teen pregnancies are complicated by the additional nutritional needs of a pregnant mother, who is still actively growing, as well as by socioeconomic status of pregnant teens in developed countries (Scholl and Hediger, 1995). Maternal nutrition and maternal weight gain are adversely affected by inadequate or poorly balanced intake in conditions such as alcoholism, drug abuse, and poverty.

The effects of micronutrients on pregnancy outcomes and fetal growth have been less well studied. Maternal intake of certain micronutrients has also been found to affect fetal growth. Zinc deficiency has been associated with fetal growth restriction and other abnormalities, such as infertility and spontaneous abortion (Jameson, 1993; Shah and Sachdev, 2001). In addition, dietary intake of vitamin C during early pregnancy has been shown to be associated with an increase in birthweight (Mathews et al, 1999). Others have shown strong associations between maternal intake of folate and iron and infant and placental weights (Godfrey et al, 1996). In developing countries, the effects of nutritional deficiencies during pregnancy are more prevalent and easier to detect. Rao et al (2001) have estimated that one third of infants in India are born weighing less than 2500 g, mainly because of maternal malnutrition. These investigators have shown significant associations between infant birthweight and maternal intake of milk, leafy greens, fruits, and folate during pregnancy.

Although toxins such as cigarette smoke and alcohol have a direct effect on placental function, they may also affect fetal growth through an associated compromise in maternal nutrition. Other environmental toxins (lead, arsenic, mercury) are associated with IUGR and are believed to affect fetal growth by entering the food chain and depleting body stores of iron, vitamin C, and possibly other nutrients (Iyengar and Nair, 2000; Srivastava et al, 2001).

Numerous studies have shown associations between birthweight and maternal intake of macronutrients and micronutrients, but the effects of nutritional supplements used during pregnancy on fetal growth are equivocal (de Onis et al, 1998; Jackson and Robinson, 2001; Rush, 2001; Say et al, 2003). This finding is underscored by the results of a recent, large, double-blind, randomized controlled trial including 1426 pregnancies in rural Burkina Faso (Roberfroid et al, 2008). Pregnant women were randomly assigned to receive either iron and folic acid or the UNICEF-WHO-UNU* international multiple micronutrient preparation (UNIMMAP) daily until 3 months after delivery, with the UNIMMAP thereafter in both groups. Birthweight was increased by 52 g, and length was increased by 3.6 mm. Unexpectedly, the risk of perinatal death was marginally significantly increased in the UNIMMAP group (odds ratio, 1.78; 95% confidence interval, 0.95 to 3.32; $p = 0.07$).

Maternal socioeconomic status and ethnicity have also been identified as risk factors for IUGR and poor health outcomes in infants. Numerous investigators have shown a significant effect of socioeconomic status on birth outcomes, including fetal growth restriction, in both developing and developed countries (Wilcox et al, 1995). In the United States, low levels of maternal and paternal education, certain maternal and paternal occupations, and low family income are associated with lower birthweights in children of African American and white women (Parker et al, 1994). In a large population-based study in Sweden, investigators have shown a higher incidence of fetal growth restriction in association with low maternal education (Clausson et al, 1998). Researchers have also shown that rates of compromised birth outcome are higher among African American women than among Mexican American and non-Hispanic white women (Collins and Butler, 1997; Frisbie et al, 1997; Thomas et al, 2000). Some of these studies also show that the risk of IUGR is higher in women without medical insurance. In the United States, the incidence of IUGR is significantly higher among African American women than among white women; this higher incidence is seen even among African American women with higher socioeconomic status (Alexander et al, 1999).

In a study in Arizona, the incidence of IUGR was found to be lower in Mexican American women than in white women (Balcazar, 1994). Other researchers have shown that Mexican-born immigrants in California have better perinatal outcomes (including birthweight) than African Americans and U.S.-born women of Mexican descent (Fuentes-Afflick et al, 1998). The reasons for this apparent paradox are unclear, but one postulate is the tendency of recent immigrants to maintain the favorable nutritional and behavioral characteristics of their country of origin (Guendelman and English, 1995). These studies support the speculation that the differences in fetal growth between groups do not reflect inherent differences in fetal growth, but rather stem from inequalities in nutrition, health care, and other environmental factors (Keirse, 2000; Kramer et al, 2000).

Smoking

Cigarette smoking is consistently found to adversely affect intrauterine growth in all studies in which this factor is considered. In developed countries, cigarette smoking is the single most important cause of poor fetal growth (Kramer et al, 2000). The incidence of IUGR in smokers

*United Nations Children's Fund, World Health Organization, United Nations University.

is estimated to be threefold to 4.5-fold higher than in nonsmokers (Nordentoft et al, 1996). Cigarette smoking has a significant effect on abdominal circumference and fetal weight, but not on head circumference (Bernstein et al, 2000). Lieberman et al (1994) reported that cigarette smoking also appears to have a dose-dependent effect on the incidence of IUGR, with this effect being seen especially with heavy smoking and smoking during the third trimester. These investigators have shown that if women stop smoking during the third trimester, their infants' birthweights are indistinguishable from those of infants born to the normal population. Other researchers have shown that even a reduction in smoking is associated with improved fetal growth (Li et al, 1993; Walsh et al, 2001). Numerous potential causes of the effects of smoking on fetal growth have been suggested, including direct effects of nicotine on placental vasoconstriction, decreased uterine blood flow, higher levels of fetal carboxyhemoglobin, fetal hypoxia, adverse maternal nutritional intake, and altered maternal and placental metabolism (Andres and Day, 2000; Pastrakuljic et al, 1999).

SHORT-TERM OUTCOMES

IUGR alters many physiologic and metabolic functions in the fetus and neonate that result in a number of morbidities. A large cohort study of 37,377 pregnancies found a fivefold to sixfold greater risk of perinatal death for both preterm and term fetuses that had IUGR (Cnattingius et al, 1998; Lackman et al, 2001; Mongelli and Gardosi, 2000). Predictive factors for perinatal mortality in preterm fetuses with IUGR reveals that of all antenatal factors examined, only oligohydramnios and abnormal umbilical artery Dopplers with absent or reversed diastolic flow were predictive of perinatal mortality (Scifres et al, 2009). Although the growth-restricted fetus may show symmetric or asymmetric growth at birth, it is unclear whether the proportionality of the fetus with IUGR truly affects outcomes or is related to the timing or the severity of the insult. Lin et al (1991) found that symmetric IUGR resulted in higher levels of prematurity and higher rates of neonatal morbidity. In contrast, Villar et al (1990) have shown that infants with asymmetric IUGR have higher morbidity rates at birth. They found that infants with low ponderal index measurements (which they defined as Weight ÷ Length^3) had a higher risk of low Apgar scores, long hospitalization, hypoglycemia, and asphyxia at birth than infants with symmetric IUGR. There is evidence to suggest that infants with asymmetric IUGR show better gains in weight and length in the postnatal period than symmetrically restricted infants (May et al, 2001). Other investigators propose that IUGR represents a continuum, with symmetric IUGR occurring as the severity of growth retardation increases. Data also suggest that the more severe the growth restriction, the worse the neonatal outcomes, including risk of stillbirth, fetal distress, neonatal hypoglycemia, hypocalcemia, polycythemia, low Apgar scores, and mortality (Kramer et al, 1990; Spinillo et al, 1995).

Fetal growth restriction is associated with intrauterine demise. Almost 40% of term stillbirths and 63% of preterm stillbirths are SGA (Mongelli and Gardosi, 2000). Both short-term and long-term effects of abnormalities in SGA fetuses have been described. Perinatal mortality for intrauterine SGA infants is higher overall than that for appropriately grown term and preterm infants (Clausson et al, 1998). The risk of perinatal death is estimated to be fivefold to sixfold greater for both preterm and term fetuses with IUGR (Lackman et al, 2001). Overall, intrauterine death, perinatal asphyxia, and congenital anomalies are the main contributing factors to the higher mortality rate in SGA infants. The effects of acute fetal hypoxia may be superimposed on chronic fetal hypoxia, and placental insufficiency may be an important etiologic factor in these outcomes. Investigators have described higher incidences of low Apgar scores, umbilical artery acidosis, need for intubation at delivery, seizures on the first day of life, and sepsis in SGA infants (McIntire et al, 1999). The incidence of adverse perinatal effects correlates with the severity of the growth restriction, the highest rates of respiratory distress syndrome, metabolic abnormalities, and sepsis being found in the most severely growth-restricted infants (Spinillo et al, 1995). As previously described, Villar et al (1990) reported that infants with asymmetric IUGR and low ponderal index measurements had a higher risk of low Apgar scores, hypoglycemia, asphyxia, and long hospitalization.

Preterm infants with growth abnormalities have a much higher risk of adverse outcomes. Preterm SGA infants have a higher incidence of a number of complications, including sepsis, severe intraventricular hemorrhage, respiratory distress syndrome, necrotizing enterocolitis, and death, than do normally grown preterm infants (Gortner et al, 1999; McIntire et al, 1999; Simchen et al, 2000). In addition, SGA infants have a higher incidence of chronic lung disease at corrected gestational ages of 28 days and 36 weeks.

Neonatal hypoglycemia and hypothermia occur more frequently in growth-restricted infants (Doctor et al, 2001). These metabolic abnormalities presumably occur from decreased glycogen stores, inadequate lipid stores, and impaired gluconeogenesis in the growth-restricted neonate. Growth-restricted neonates have inadequate fuel stores and are at increased risk for hypoglycemia during fasting, and these risks are increased in preterm SGA infants. Infants with IUGR also have a higher incidence of hypocalcemia, with the incidence correlating strongly with the severity of growth restriction (Spinillo et al, 1995).

Developmental Outcomes: Early Childhood

Neurologic outcomes, including intellectual and neurologic function, are affected by growth restriction. Overall, neurologic morbidity is higher for SGA infants than for AGA infants. Without identified perinatal events, SGA infants have a higher incidence of long-term neurologic or developmental handicaps. Investigators have found the incidence of cerebral palsy to be greater in IUGR infants than in a population with normal fetal growth (Blair and Stanley, 1990; Spinillo et al, 1995; Uvebrant and Hagberg, 1992). SGA infants born at term appear to have double or triple the risk for cerebral palsy, between 1 to 2 per 1000 live births and 2 to 6 per 1000 live births (Goldenberg et al, 1998). The rate of cerebral palsy is also higher in preterm growth-restricted infants than in preterm infants with appropriate fetal growth (Gray et al, 2001). At 7 years

of age, children whose birth was associated with hypoxia-related factors had a higher risk for adverse neurologic outcomes. Infants with symmetric IUGR, or perhaps more severe restriction, were at higher risk than infants with asymmetric IUGR. Other researchers have shown higher rates of learning deficits, lower intelligence quotient scores, and increased behavioral problems in children with a history of fetal growth restriction, even at 9 to 11 years of age (Low et al, 1992).

LONG-TERM CONSEQUENCES: THE DEVELOPMENTAL ORIGINS OF ADULT DISEASE

Programming

The period from conception to birth is a time of rapid growth, cellular replication and differentiation, and functional maturation of organ systems. These processes are highly sensitive to alterations in the intrauterine milieu. The term *programming* describes the mechanisms whereby a stimulus or insult at a critical period of development has lasting or lifelong effects. The "thrifty phenotype" hypothesis proposes that the fetus adapts to an adverse intrauterine milieu by optimizing the use of a reduced nutrient supply to ensure survival; but because this adaptation favors the development of certain organs over that of others, it leads to persistent alterations in the growth and function of developing tissues (Hales and Barker, 1992). In addition, although the adaptations may aid in survival of the fetus, they become a liability in situations of nutritional abundance.

Epidemiology

It has been recognized for nearly 70 years that the early environment in which a child grows and develops can have long-term effects on subsequent health and survival (Kermack, 1934). The landmark cohort study of 300,000 men by Ravelli et al (1976) showed that men who were exposed in utero to the effects of the Dutch famine of 1944 and 1945 during the first half of gestation had significantly higher obesity rates at the age of 19 years. Subsequent studies demonstrated relationships among LBW, the later development of cardiovascular disease (Barker et al, 1989), and impaired glucose tolerance (Fall et al, 1995) in men in England. Men who were smallest at birth (2500 g) were nearly sevenfold more likely to have impaired glucose tolerance or type 2 diabetes than those who were largest at birth. Barker et al (1993) also found a similar relationship between lower birthweight and higher systolic blood pressure and triglyceride levels.

Valdez et al (1994) observed a similar association between birthweight and subsequent glucose intolerance, hypertension, and hyperlipidemia in a study of young adult Mexican American and non-Hispanic white men and women participants in the San Antonio Heart Study. Normotensive individuals without diabetes whose birthweights were in the lowest tertile had significantly higher rates of insulin resistance, obesity, and hypertension than subjects whose birthweights were normal. In the Pima Indians, a population with extraordinarily high rates of type 2 diabetes, McCance et al (1994) found that the development of diabetes in the offspring was related to both extremes of birthweight. In their study, the prevalence of diabetes in subjects 20 to 39 years old was 30% for those weighing less than 2500 g at birth, 17% for those weighing 2500 to 4499 g, and 32% for those weighing 4500 g or more. The risk of developing type 2 diabetes was nearly fourfold higher for those whose birthweight was less than 2500 g. Other studies of populations in the United States (Curhan et al, 1996), Sweden (Lithell et al, 1996; McKeigue et al, 1998), France (Jaquet et al, 2000; Leger et al, 1997), Norway (Egeland et al, 2000), and Finland (Forsen et al, 2000) have all demonstrated a significant correlation between LBW and the later development of adult diseases.

Studies controlling for the confounding factors of socioeconomic status and lifestyle have further strengthened the association between LBW and a higher risk of coronary heart disease, stroke, and type 2 diabetes. In 1976, the Nurses' Health Study was initiated, and a large cohort of American women born from 1921 to 1946 established. The association between LBW and increased risks of coronary heart disease, stroke, and type 2 diabetes remained strong even after adjustment for lifestyle factors such as smoking, physical activity, occupation, income, dietary habits, and childhood socioeconomic status (Rich-Edwards et al, 1999).

Role of Catch-up Growth

Many studies have suggested that the associations between birth size with later disease can be modified by body mass index (BMI) in childhood. The highest risk for the development of type 2 diabetes is among adults who were born small and become overweight during childhood (Eriksson et al, 2000). Insulin resistance is most prominent in Indian children who were SGA at birth, but had a high fat mass at 8 years of age (Bavdekar et al, 1999). Similar findings were reported in 10-year-old children in the United Kingdom (Whincup et al, 1997). In a Finnish cohort, adult hypertension was associated with both lower birthweight and accelerated growth in the first 7 years of life. In contrast, in two preliminary studies from the United Kingdom, catch-up growth in the first 6 months of life was not clearly related to blood pressure in young adulthood, although birthweight was (McCarthy et al, 2001).

Interpreting the findings of these studies is complicated by the vague definitions of *catch-up growth*. The term, which can encompass either the first 6 to 12 months only or as much as the first 2 years after birth, usually refers to realignment of genetic growth potential after IUGR. This definition allows for fetal growth retardation at any birthweight; large fetuses can be growth retarded in relation to their genetic potential. However, postnatal factors can obviously affect infant growth in the first few months of life. For example, breastfeeding appears to protect against obesity later in childhood, but breastfed infants usually exhibit higher body mass during the first year of life than formula-fed infants. Although it is likely that accelerated growth confers an additional risk to the growth-retarded fetus, these conflicting results demonstrate the need for additional, carefully designed studies to determine how childhood growth rates affect the later development of cardiovascular disease and type 2 diabetes.

Size at Birth, Insulin Secretion, and Insulin Action

The mechanisms underlying the association between size at birth and impaired glucose tolerance or type 2 diabetes are unclear. A number of studies in children and adults have shown that nondiabetic or prediabetic (abnormal glucose tolerance) subjects with LBW are insulin resistant and thus are predisposed to development of type 2 diabetes (Bavdekar et al, 1999; Clausen et al, 1997; Flanagan et al, 2000; Hoffman et al, 1997; Leger et al, 1997; Li et al, 2001; Lithell et al, 1996; McKeigue et al, 1998; Phillips et al, 1994; Yajnik et al, 1995). IUGR is known to alter the fetal development of adipose tissue, which is closely linked to the development of insulin resistance (Lapillonne et al, 1997; Widdowson et al, 1979). In a well-designed case-control study of 25-year-old adults, Jaquet et al (2000) demonstrated that individuals who were born SGA at 37 weeks' gestation or later had a significantly higher percentage of body fat (15%). Insulin sensitivity, after adjustment for BMI or total fat mass, was markedly impaired in these SGA subjects. There were no significant differences between the SGA and control groups regarding parental history of type 2 diabetes, cardiovascular disease, hypertension, or dyslipidemia. Of importance when generalizing the findings to other populations, the causes of IUGR in these subjects were gestational hypertension (50%), smoking (30%), maternal short stature (7%), congenital anomalies (7%), and unknown (6%).

The adverse effect of IUGR on glucose homeostasis was originally thought to be mediated through programming of the fetal endocrine pancreas. Growth-retarded fetuses and newborns have been shown to have a reduced population of pancreatic β cells (Van Assche et al, 1977). LBW has been associated with reduced insulin response after glucose ingestion in young men without diabetes; however, a number of other studies have found no effect of LBW on insulin secretion in humans (Clausen et al, 1997; Flanagan et al, 2000; Lithell et al, 1996). However, none of these earlier studies adjusted for the corresponding insulin sensitivity, which has a profound effect on insulin secretion. Jensen et al (2002) measured insulin secretion and insulin sensitivity in a well-matched population of 19-year-old, glucose-tolerant white men whose birthweights were either less than the 10th percentile (i.e., SGA) or between the 50th and 75th percentiles (controls). To eliminate the major confounding factors, such as "diabetes genes," the researchers ensured that none of the participants had a family history of diabetes, hypertension, or ischemic heart disease. They found no differences between the groups in regard to current weight, BMI, body composition, and lipid profile. When data were controlled for insulin sensitivity, insulin secretion was found to be lower by 30%. However, insulin sensitivity was normal in the SGA subjects. These investigators hypothesized that defects in insulin secretion precede defects in insulin action, and that SGA individuals demonstrate insulin resistance once they accumulate body fat.

Epidemiologic Challenges

The data described in the preceding section suggest that LBW is associated with glucose intolerance, type 2 diabetes, and cardiovascular disease. However, the question remains whether these associations reflect fetal nutrition or other factors that contribute to birthweight and the observed glucose intolerance. Because of the retrospective nature of the cohort identification, many confounding variables were not always recorded, such as lifestyle, socioeconomic status, education, maternal age, parental build, birth order, obstetric complications, smoking, and maternal health. Maternal nutritional status, either directly in the form of diet histories, or indirectly in the form of BMI, height, and pregnancy weight gain, were usually not recorded. Instead, birth anthropometric measures were used as proxies for presumed undernutrition in pregnancy.

Size at Birth Cannot Be Used as a Proxy for Fetal Growth

Birthweight is determined by the sum of multiple known and unknown factors, including gestational age, maternal age, birth order, genetics, maternal pre-pregnancy BMI, and pregnancy weight gain, plus multiple environmental factors, such as smoking, drug use, infection, and maternal hypertension. Some of these determinants may be related to susceptibility to adult disease, and others may not. Conversely, some prenatal determinants of adult outcomes may not be related to fetal growth. A good example of how size at birth may potentially be a proxy for an underlying causal pathway is the hypothesis that essential hypertension in the adult is caused by a congenital nephron deficit (Brenner and Chertow, 1993). This study shows that kidney volume is smaller in adults who were thinner at birth, after adjustment for current body size. In contrast, maternal cigarette smoking is a good example of a prenatal exposure that restricts fetal growth, but to date no association has been found between cigarette smoking and adverse long-term outcome in offspring.

Genetics versus Environment

Several epidemiologic and metabolic studies of twins and first-degree relatives of patients with type 2 diabetes have demonstrated an important genetic component of diabetes (Vaag et al, 1995). The association between LBW and risk of type 2 diabetes in some studies could theoretically be explained by a genetically determined reduced fetal growth rate. In other words, the genotype responsible for type 2 diabetes may itself restrict fetal growth. This possibility forms the basis for the fetal insulin hypothesis, which suggests that genetically determined insulin resistance could result in insulin-mediated low growth rate in utero as well as insulin resistance in childhood and adulthood (Hattersley et al, 1999). Insulin is one of the major growth factors in fetal life, and monogenic disorders that affect the fetus's insulin secretion or insulin resistance also affect fetal growth (Elsas et al, 1985; Froguel et al, 1993; Hattersley et al, 1998; Stoffers et al, 1997). Mutations in the gene encoding glucokinase have been identified that result in LBW and maturity-onset diabetes of the young. Such mutations are rare, and no analogous common allelic variation has been discovered, but it is likely that some variations exist that, once identified, will help to explain a proportion of the cases of diabetes in LBW subjects.

There is obviously a close relationship between genes and the environment. Maternal gene expression can alter the fetal environment, and the maternal intrauterine environment also affects fetal gene expression. An adverse intrauterine milieu is likely to have profound long-term effects on the developing organism that might not be reflected in birthweight.

Cellular Mechanisms

Fetal malnutrition has two main causes: poor maternal nutrition and placental insufficiency. In the extensive literature about the fetal origins hypothesis, these two concepts have not been discerned clearly. Such a distinction is necessary, because maternal nutrition has probably been adequate in the majority of populations in which the hypothesis has been tested. Only extreme maternal undernutrition, such as occurred in the Dutch famine, reduces the birthweight to an extent that could be expected to raise the risk of adult disease (Lumey et al, 1995). To a lesser extent but equally important is the LBW in populations with low resources, resulting in maternal undernutrition. Overall, in most populations it is reasonable that placental insufficiency has been a main cause of LBW. The oxygen and nutrients that support fetal growth and development rely on the entire nutrient supply line, beginning with maternal consumption and body size, but extending to uterine perfusion, placental function, and fetal metabolism. Interruptions of the supply line at any point could result in programming of the fetus for the future risk of adult diseases.

The intrauterine environment influences development of the fetus by modifying gene expression in both pluripotential cells and terminally differentiated, poorly replicating cells. The long-range effects on the offspring (into adulthood) are determined by which cells are undergoing differentiation, proliferation, or functional maturation at the time of the disturbance in maternal fuel economy. The fetus also adapts to an inadequate supply of substrates (e.g., glucose, amino acids, fatty acids, and oxygen) through metabolic changes, redistribution of blood flow, and changes in the production of fetal and placental hormones that control fetal growth.

The fetus's immediate metabolic response to placental insufficiency is catabolism, consuming its own substrates to provide energy. A more prolonged reduction in availability of substrates leads to slowed growth, which enhances the fetus's ability to survive by reducing the use of substrates and lowering the metabolic rate. Slowed growth in late gestation leads to disproportionate organ size, because the organs and tissues that are growing rapidly at the time are affected the most. For example, placental insufficiency in late gestation can lead to reduced growth of the kidney, which is developing rapidly at that time. Reduced replication of kidney cells can permanently reduce cell numbers, because there seems to be no capacity for renal cell division to catch up after birth.

Substrate availability has profound effects on fetal hormones and on the hormonal and metabolic interactions among the fetus, placenta, and mother. These effects are most apparent in the fetus of the mother with diabetes. Higher maternal concentrations of glucose and amino acids stimulate the fetal pancreas to secrete exaggerated amounts of insulin and stimulate the fetal liver to produce higher levels of insulin-like growth factors. Fetal hyperinsulinism stimulates the growth of adipose tissue and other insulin-responsive tissues in the fetus, often leading to macrosomia. However, many offspring of mothers with diabetes with fetal hyperinsulinism are not overgrown by usual standards, and many with later obesity and glucose intolerance were not macrosomic at birth (Pettitt et al, 1987; Silverman et al, 1995). These observations suggest that birthweight is not a good indication of intrauterine nutrition.

MACROSOMIA

Excessive fetal growth (macrosomia, being large for gestational age) is found in 9% to 13% of all deliveries and can lead to significant complications in the perinatal period (Gregory et al, 1998; Wollschlaeger et al, 1999). Maternal factors associated with macrosomia during pregnancy include increasing parity, higher maternal age, and maternal height. In addition, the previous delivery of an infant with macrosomia, prolonged pregnancy, maternal glucose intolerance, high pre-pregnancy weight or obesity, and large pregnancy weight gain have all been found to raise the risk of delivering an infant with macrosomia (Mocanu et al, 2000).

Maternal complications of macrosomia include morbidities related to labor and delivery. Prolonged labor, arrest of labor, and higher rates of cesarean section and instrumentation during labor have been reported. In addition, the risks of maternal lacerations and trauma, delayed placental detachment, and postpartum hemorrhage are higher for the woman delivering an infant with macrosomia (Lipscomb et al, 1995; Perlow et al, 1996). Complications of labor are more pronounced in primiparous women than in multiparous women (Mocanu et al, 2000). The neonatal complications of macrosomia include traumatic events such as shoulder dystocia, brachial nerve palsy, birth trauma, and associated perinatal asphyxia. Other complications for the neonate are elevated insulin levels and metabolic derangements, such as hypoglycemia and hypocalcemia (Wollschlaeger et al, 1999). In a large population-based study in the United States, macrosomia (defined as birthweight greater than 4000 g) was detected in 13% of births. Of these, shoulder dystocia was noted in 11% (Gregory et al, 1998).

Macrosomia is often not detected during pregnancy and labor. The clinical estimation of fetal size is difficult and has significant false-positive and false-negative rates. Ultrasonography estimates of fetal weight are not always accurate, and there are a wide range of sensitivity estimates for the ultrasound detection of macrosomia. In addition, there is controversy regarding how to define macrosomia and which ultrasound measurement is most sensitive in predicting macrosomia. Smith et al (1997) demonstrated a linear relation between abdominal circumference and birthweight. They showed that the equations commonly used for estimated fetal weight have a median error rate of 7%, with greater errors seen with larger infants. Using receiver operating characteristics curves to measure the diagnostic accuracy of ultrasound,

O'Reilly-Green and Divon (1997) reported sensitivity and specificity rates of 85% and 72%, respectively, for estimation of birthweight exceeding 4000 g. In their study, the positive predictive value (i.e., a positive test result represents a truly macrosomic infant) was approximately 49%. Chauhan et al (2000) found lower sensitivity for the use of ultrasound measurement of abdominal and head circumference and femur length (72% sensitivity), similar to the sensitivity of using clinical measurements alone (73%). Other investigators have shown that clinical estimation of fetal weight (43% sensitivity) has higher sensitivity and specificity than ultrasound evaluation in predicting macrosomia (Gonen et al, 1996). In a retrospective study, Jazayeri et al (1999) showed that ultrasound measurement of abdominal circumference of greater than 35 cm predicts macrosomia in 93% of cases and is superior to measurements of biparietal diameter or the femur. Other researchers have reported that an abdominal circumference of more than 37 cm is a better predictor (Al-Inany et al, 2001; Gilby et al, 2000).

Numerous investigators have also questioned whether antenatal diagnosis improves birth outcomes in macrosomic infants. Investigators indicate the low rates of specificity of antenatal tests resulting in high rates of false-positive results (Bryant et al, 1998, O'Reilly-Green and Divon, 1997). Antenatal identification of macrosomia or possible macrosomia can lead to a higher rate of cesarean section performed for infants with normal birthweights (Gonen et al, 2000; Mocanu et al, 2000; Parry et al, 2000). Macrosomia is a risk factor for shoulder dystocia, but the majority of cases of shoulder dystocia and birth trauma occur in infants with macrosomia (Gonen et al, 1996). A retrospective study of infants weighing more than 4200 g at birth showed a cesarean section rate of 52% in infants predicted antenatally to have macrosomia, compared with 30% in infants without such an antenatal prediction. The antenatal prediction of fetal macrosomia is also associated with a higher incidence of failed induction of labor and no reduction in the rate of shoulder dystocia (Zamorski and Biggs, 2001). Using retrospective data from a 12-year period, Bryant et al (1998) estimated that a policy of routine cesarean section for all infants with estimated fetal weight greater than 4500 g would require between 155 and 588 cesarean sections to prevent a single case of permanent brachial nerve palsy.

SUMMARY

This chapter has described many identified biologic and genetic factors associated with fetal growth and with abnormalities of fetal growth. Physicians are limited in the ability to identify a causative agent in every case. Modification of fetal growth is possible and occurs from diverse influences such as socioeconomic status, maternal nutrition, and maternal constitutional factors. Abnormal fetal growth influences acute perinatal outcomes and health during infancy, childhood, and adulthood. In schools of public health, students are taught to search "up river" for solutions to health problems. Solutions for ill health in adulthood may reside in the identification of methods to improve the health of the fetus.

CHAPTER 7

Multiple Gestations and Assisted Reproductive Technology

Kerri Marquard and Kelle Moley

EPIDEMIOLOGY OF MULTIPLES

Since the birth of the first in vitro fertilization (IVF) baby in 1978, the numbers of IVF clinics, ovarian stimulation cycles, and live births from assisted reproductive technology (ART) have all steadily increased. Between 1998 and 2003, total births in the United States increased by 4%, while ART births grew by 67% (Dickey, 2007). The growing use of ART, in addition to delayed childbearing until age-related fertility issues become apparent, has contributed greatly to multiple birth rates. In 2006 ART infants accounted for 1% of all U.S. births, but represented 17% of twins and 38% of triplets or greater (Centers for Disease Control and Prevention et al, 2008; Sunderam et al, 2009). Three percent of all U.S. births are multiples, yet in 2003 ART multiple live birth rates from fresh nondonor, donor oocyte, and frozen embryo transfer cycles were 34%, 40%, and 25%, respectively (Centers for Disease Control and Prevention et al, 2008).

The assisted conception and spontaneous rates associated with twins, triplets, and higher-order multiples (HOMs; i.e., four or more fetuses) are as follows. In 2003, 62.7%, 16.3%, and 21% of twins were conceived naturally, from ART, and from non-ART ovulation induction, respectively. For triplets in the same year, 17.7% were natural conceptions, 45.4% were from ART, and 36.9% were from non-ART ovulation induction. HOM rates from spontaneous conception, ART, and non-ART ovulation induction were 8%, 30%, and 62.4%, respectively (Dickey, 2007). Given the maternal, perinatal, and neonatal complications associated with multiples, the goal of infertility treatment is one healthy child. Multifetal pregnancies drastically affect individuals, families, and the public health system. Of particular importance in both maternal and fetal outcomes are fetal number and placentation.

DIAGNOSING ZYGOSITY AND CHORIONICITY

Determining zygosity and chorionicity is important medically, genetically, and psychosocially for the individual and family. More immediately, the chorion-amnion arrangement is crucial to antepartum management in cases of one fetal demise or selective reduction, and because of potential associated problems such as twin-twin transfusion syndrome (TTTS), growth discordance, intrauterine growth restriction (IUGR), congenital anomalies, and cord accidents. Diagnosing zygosity is possible using ultrasound markers including the number of placental sites, thickness of dividing membrane, the lambda sign, and fetal gender in addition to postpartum placental examination, physical similarity questionnaires, blood type, and DNA analysis (Hall, 2003; Ohm Kyvik and Derom, 2006; Scardo et al, 1995) At 10 to 14 weeks' gestation, ultrasound criteria correctly diagnosed chorionicity in 99.3% of cases as confirmed by postpartum placental examination and gender (Carroll et al, 2002). Assessment of zygosity and chorionicity in 237 same-sex twins with physical likeness questionnaires, DNA analysis, and placental inspection accurately diagnosed 96% of twin pairs (Forget-Dubois et al, 2003).

ZYGOSITY AND CHORIONICITY

Zygosity and placentation affect fetal morbidity and mortality in multifetal pregnancies. Dizygotic twins (DZTs), which comprise 67% of spontaneous twins, arise from the fertilization of two separate eggs by different sperm (Gibbs et al, 2008), and with few exceptions they lead to a dichorionic diamniotic arrangement in which the placenta can be separate or fused. A rare case of dizygotic monochorionic (MC) diamniotic (DA) twins has been reported (Souter et al, 2003). The overall DZT rate varies from 4 to 50 per 1000 worldwide: 1.3% in Japan, 7.1% to 11% in the United States, 8.1% in India, 8.8% in England and Wales, and 49% in Nigeria (Table 7-1) (MacGillivray, 1986). Risk factors for DZT include advancing maternal age, increased parity, female relatives with DZT, taller height, and larger body mass index (Hoekstra et al, 2008; MacGillivray, 1986).

The true incidence of monozygotic twins (MZTs) is difficult to ascertain because of its rarity, inaccuracies in diagnosis, and lack of confirmatory studies at birth, but spontaneous MZT rates are estimated to occur in 0.3% to 0.5% of all pregnancies and in 30% of all twins (Bulmer, 1970; MacGillivray, 1986). Unlike DZT, it is unclear whether MZT is related to genetics or environment (Bortolus et al, 1999; Hoekstra et al, 2008), although familial components may play a role (Hamamy et al, 2004). Chorionicity in monozygotic gestations is determined by the

TABLE 7-1 Twinning Rates per 1000 Births by Zygosity

Country	Monozygotic	Dizygotic	Total
Nigeria	5.0	49	54
United States			
African American	4.7	11.1	15.8
Caucasian	4.2	7.1	11.3
England and Wales	3.5	8.8	12.3
India	3.3	8.1	11.4
Japan	3.0	1.3	4.3

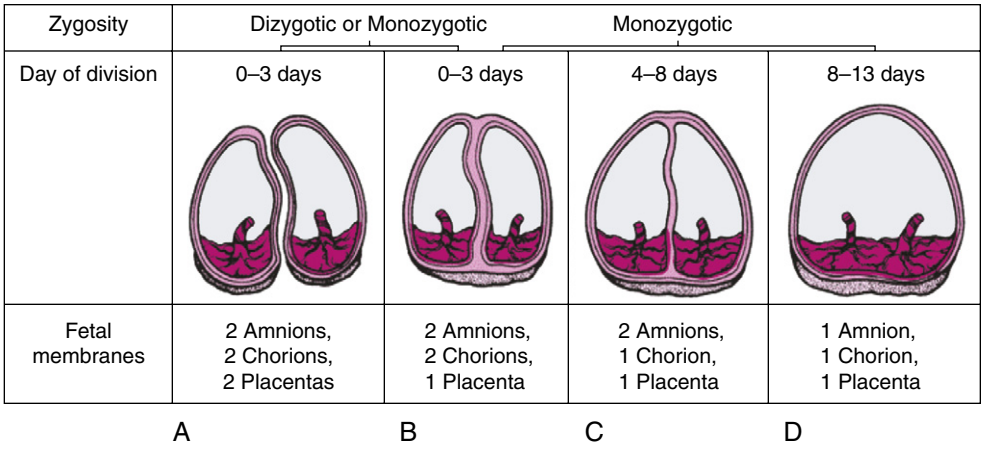

FIGURE 7-1 Placentation and membranes based on timing of embryonic division. A, Two amnions, two chorions, and separate placentas from the division of either a dizygotic or monozygotic embryo within 3 days of fertilization. **B,** Two amnions, two chorions, and one fused placenta from the division of either a dizygotic or monozygotic embryo within 3 days of fertilization. **C,** Two amnions, one chorion, and one placenta from monozygotic embryonic cleavage, days 4 to 8 after fertilization. **D,** One amnion, one chorion, and one placenta from a monozygotic embryo splitting, days 8 to 13 after fertilization. *(Modified from Gibbs R, Karlan B, Haney A, et al:* Danforth's obstetrics & gynecology, *ed 10, Philadelphia, 2008, Lippincott, Williams & Wilkins.)*

timing of the embryonic division (Figures 7-1 and 7-2) (Benirschke and Kim, 1973; Hall, 2003). In 18% to 36% of MZTs, the zygote divides within 72 hours of fertilization resulting in dichorionic (DC) DA gestation (the placenta can be separate or fused); 60% to 75% split between days 4 and 8, leading to an MC-DA unit, and 1% to 2% separate between days 8 and 13, leading to an MC monoamniotic (MA) pregnancy. Embryonic division after day 13 results in conjoined twins with an MC/MA placenta (Cunningham et al, 2005; Gibbs et al, 2008; Hall, 2003).

Although the majority of ART MZTs are MC/DA, any of the three MZ placental arrangements can transpire after ART, implying that the timing and mechanism of embryonic splitting are variable (Aston et al, 2008; Knopman et al, 2009). Monozygotic DCDA twins can occur after inner cell mass (ICM) splitting and atypical hatching in a blastocyst embryo (Meintjes et al, 2001; Van Langendonckt et al, 2000). In addition, MA twinning may be increased after IVF (Alikani et al, 2003) and zona pellucida (ZP) manipulation (Slotnick and Ortega, 1996). Contributing factors to MZT in ART include ICM damage and other ZP abnormalities (Hall, 2003).

INCREASE IN MONOZYGOTIC TWINS WITH ASSISTED REPRODUCTIVE TECHNOLOGY

The first reported association between ART and MZT (Yovich et al, 1984) preceded numerous accounts of similar findings. The majority (>90%) of ART twins are dizygotic (Gibbs et al, 2008) secondary to transferring multiple embryos; however, the rate of MZTs per pregnancy after fertility treatment is higher (0.9% to 4.9%) (Alikani et al, 2003; Blickstein et al, 2003; Elizur et al, 2004; Knopman et al, 2009; Papaniklaou et al, 2009; Schachter et al, 2001; Sharara and Abdo, 2010; Sills et al, 2000; Vitthala et al, 2009; Wenstrom et al, 1993) versus the general population (0.3% to 0.5%) (Bulmer, 1970; MacGillivray, 1986). Several theories to explain the mechanism responsible for elevated MZTs with ART have been proposed.

AGE

Maternal age affects fertility and reproductive outcomes. Spontaneous dizygotic twinning increases with advancing maternal age (Bortolus et al, 1999; Bulmer, 1970; MacGillivray, 1986), but the connection between age and MZTs is controversial. Some studies reported trends toward elevated MZT rates in older women (Abusheikha et al, 2000; Alikani et al, 2003; Bulmer, 1970), whereas others found no association with increasing maternal age and MZT (Bortolus et al, 1999; Skiadas et al, 2008), and one study found that the MZT risk doubles in women younger than 35 years (Knopman et al, 2009). Overall, the correlation between age and MZT in ART remains unclear.

ZONA PELLUCIDA MANIPULATION

The ZP, an acellular protein surrounding the ovum, provides a species-specific sperm barrier and decreases polyploidy by inhibiting penetration by multiple sperm (Speroff and Fritz, 2005). Components of both ART and non-ART procedures are capable of modifying this barrier. Stimulation protocol, elevated follicle-stimulating hormone or estradiol levels, and prolonged culture conditions can change ZP thickness (Loret et al, 1997). In addition, ZP manipulations performed during IVF all potentially affect MZT risk.

Manipulation of the ZP in IVF occurs via both intracytoplasmic sperm injection (ICSI) and AH (assisted hatching). The injection of one sperm into a mature oocyte (i.e., ICSI) is most commonly performed for male factor infertility. AH is achieved with an artificial breach in the ZP by laser, chemical, or mechanical methods and is indicated in patients with a poor prognosis (Practice Committee of Society for Assisted Reproductive Technology and Practice Committee of American Society for Reproductive Medicine, 2008c). Some studies indicate no association with ICSI or AH and MZT (Behr et al, 2000; Elizur et al, 2004; Knopman et al, 2009; Meldrum et al, 1998; Milki et al, 2003; Sills et al, 2000), whereas others imply that

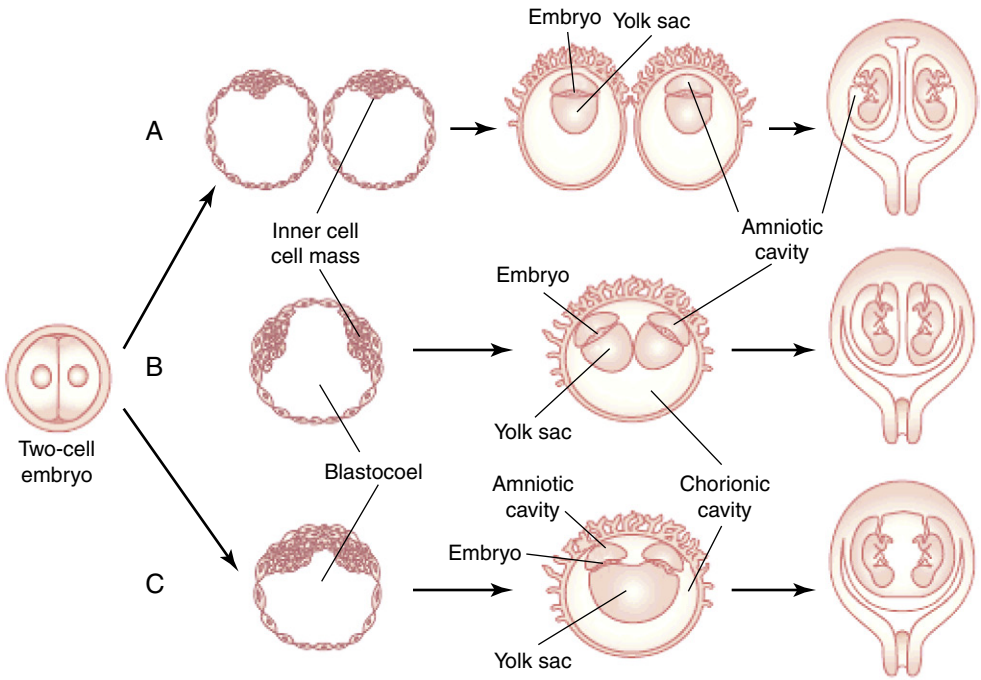

FIGURE 7-2 Types of monozygotic placentation. A, Dichorionic diamniotic pregnancy. **B,** Monochorionic diamniotic pregnancy. **C,** Monochorionic monoamniotic pregnancy. *(Adapted from Hall JG: Twinning,* Lancet *362:735-743, 2003; and Benirschke K, Kim CK: Multiple pregnancy,* N Engl J Med *288:1276-1284, 1973.)*

ZP manipulation increases the risk of MZT (Alikani et al, 1994; Saito et al, 2000; Schieve et al, 2000; Skiadas et al, 2008; Vitthala et al, 2009), particularly if multiple embryos undergo hatching before transfer (Alikani et al, 2003; Schieve et al, 2000). The results of a Cochrane review on the risk of multiples with AH and ICSI reported increased multiples with both ICSI and AH, and elevated MZT with AH versus no manipulation (0.8%) (Das et al, 2009). Alterations in ZP thickness or abnormal ICM splitting or embryo hatching in both animal (Cohen, 1991; Malter and Cohen, 1989) and human embryos may explain this increase in MZT after ZP manipulation (Alikani et al, 1994; Cohen, 1991; Malter and Cohen, 1989; Sheen et al, 2001).

BLASTOCYST TRANSFER

After oocyte retrieval and insemination, embryos undergo intrauterine transfer at either the cleavage stage (day 2 to 3 after retrieval) or the blastocyst stage (day 5 to 6 after retrieval). Blastocyst-stage embryo transfer produces higher pregnancy rates (29.4% vs 36%) (Blake et al, 2007) and may lower overall multiple rates (Frattarelli et al, 2003), but evidence supports the increased incidence of MZTs (Behr et al, 2000; Chang et al, 2009; Jain et al, 2004; Knopman et al, 2009; Peramo et al, 1999; Practice Committee of American Society for Reproductive Medicine and Practice Committee of Society for Assisted Reproductive Technology, 2008a; Sheiner et al, 2001; Skiadas et al, 2008; Wright et al, 2004) compared with cleavage-stage embryos. One institution initially noted increased MZT after blastocyst transfer (5.6% vs 2%; Milki et al, 2003), but a follow-up study 3 years later demonstrated similar MZT rates between blastocyst and day 3 embryos (2.3% vs 1.8%), indicating that changes in culture media and an experienced embryology team may affect the rate of MZTs (Moayeri et al, 2007).

Culture media or prolonged culture may influence MZTs with blastocyst transfer in both human and animal models. Elevated glucose levels in extended culture and subsequent glucose-induced apoptotic remodeling of the ICM (Cassuto et al, 2003; Menezo and Sakkas, 2002), and ICM splitting in extended culture in murine and human embryos are both explanations for the phenomenon of MZTs in blastocysts (Chida, 1990; Hsu and Gonda, 1980; Payne et al, 2007). Whether MZT rates are elevated with blastocyst transfer (Behr et al, 2000; Chang et al, 2009; Jain et al, 2004; Knopman et al, 2009; Peramo et al, 1999; Practice Committee of American Society for Reproductive Medicine and Practice Committee of Society for Assisted Reproductive Technology, 2008a; Sheiner et al, 2001; Skiadas et al, 2008; Wright et al, 2004), or similar to cleavage-stage transfer (Frattarelli et al, 2003; Papanikolaou et al, 2006, 2010; Sharara and Abdo, 2010), the explicit role of culture media remains to be determined. Another environmental factor that may affect MZTs is temperature variation in frozen-thawed embryo cycles. Although minute evidence links frozen embryo transfers and temperature fluctuations to MZTs (Belaisch-Allart et al, 1995; Faraj et al, 2008; Toledo, 2005), most studies show no difference between fresh and frozen-thawed embryos and multiple rates (Blickstein et al, 2003) or MZT rates (Alikani et al, 2003; Knopman et al, 2009; Sills et al, 2000a, 2000b).

OVARIAN STIMULATION

Human studies of ovarian stimulation with clomiphene citrate and gonadotropins reveal a higher rate (1.2%) of MZTs compared with the expected rates in the general

population (Derom et al, 1987). MZT incidences of 1.5% after ovulation induction with gonadotropins, 0.72% after IVF, and 0.87% with IVF ICSI-AH suggests that gonadotropins elevate MZTs regardless of ZP manipulation (Schachter et al, 2001). Ovulation induction medications may cause uneven hardening of the ZP and atypical blastocyst hatching thereby increasing the chance of MZTs (Derom et al, 1987).

FETAL COMPLICATIONS ASSOCIATED WITH MULTIPLES

Singleton pregnancies after assisted conception have increased complications, including preterm delivery (<37 weeks' gestation), low birthweight (LBW) (Helmerhorst et al, 2004; Schieve et al, 2007), prolonged hospital stay (Schieve et al, 2007), cesarean deliveries, neonatal intensive care unit (NICU) admission, and mortality compared with spontaneous singletons (Helmerhorst et al, 2004). Some risk persists in an IVF singleton pregnancy, even after spontaneous reduction from two to three initial heartbeats to one heartbeat (Luke et al, 2009). Although singleton IVF births are associated with morbidity and mortality, assisted-conception multiple gestations comprise the majority of adverse maternal, perinatal, and neonatal outcomes.

Multiple pregnancies account for a small percentage of overall live births, but are responsible for a disproportionate amount of morbidity and mortality, largely because of intrauterine growth restriction and prematurity (Garite et al, 2004), including 13% of all preterm deliveries, 21% of all LBW infants, and 25% of all very LBW infants (Robinson et al, 2001). Compared with a singleton pregnancy, fetal and maternal complications are elevated in twins, and pregnancies with three fetuses or more have even greater morbidity and mortality rates (Table 7-2) (ACOG Practice Bulletin #56, 2004; Albrecht and Tomich, 1996; Elliott and Radin, 1992; Ettner et al, 1997; Grether et al, 1993; Kiely et al, 1992; Luke, 1994; Luke and Keith, 1992; Luke et al, 1996; Martin et al, 2003; Mauldin and Newman, 1998; McCormick et al, 1992; Newman et al, 1989; Seoud et al, 1992). Higher fetal number correlates with increased risk of growth restriction, earlier delivery, LBW, neonatal intensive care unit admission, length of stay, risk of major handicap and cerebral palsy, and death in first year of life (ACOG Practice Bulletin #56, 2004; Gardner et al, 1995; Garite et al, 2004).

The average gestational ages for twin, triplet, and quadruplet deliveries are 35.3, 32.2, and 29.9 weeks, respectively (ACOG Practice Bulletin #56, 2004), corresponding to NICU admission rates fivefold higher in twins and 17-fold higher in triplets and HOMs (Ross et al, 1999). Twins have an increased risk of intrauterine fetal demise (fourfold), intraventricular hemorrhage, sepsis, necrotizing enterocolitis, respiratory distress syndrome and neonatal death (sixfold) versus singletons, and surviving infants of preterm multifetal pregnancies have higher rates of developmental handicap (Gardner et al, 1995). A review of 100 triplet gestations (88 with assisted conception) revealed that 78% experienced preterm labor (PTL), 14% delivered before 28 weeks, 5% had congenital anomalies, and 9.7% died in the perinatal period (Devine et al, 2001).

TABLE 7-2 Morbidity and Mortality by Fetal Number

Characteristic	Twins	Triplets	Quadruplets
Average birthweight	2347 g	1687 g	1309 g
Average gestational age at delivery	35.3 wk	32.2 wk	29.9 wk
Percentage with growth restriction	14-25	50-60	50-60
Percentage requiring admission to neonatal intensive care unit	25	75	100
Average length of stay in neonatal intensive care unit	18 days	30 days	58 days
Percentage with major handicap	-	20	50
Risk of cerebral palsy	4 times more than singletons	17 times more than singletons	-
Risk of death by age 1 year	7 times higher than singletons	20 times higher than singletons	-

From ACOG Practice Bulletin #56: Multiple gestation: complicated twin, triplet, and high-order multifetal pregnancy, *Obstet Gynecol* 104:869-883, 2004.

Similar to ART singleton versus spontaneous singleton outcomes, ART multiples may have higher morbidity compared with spontaneous multiples. Assisted-conception twins are at increased risk for LBW (Luke et al, 2009), preterm delivery (Luke et al, 2009; Nassar et al, 2003), cesarean delivery (Helmerhorst et al, 2004; Nassar et al, 2003), NICU admission (Helmerhorst et al, 2004; Nassar et al, 2003; Pinborg et al, 2004), longer length of stay, respiratory distress syndrome (Nassar et al, 2003), and birthweight discordance (Pinborg et al, 2004) versus spontaneously conceived twins. Oftentimes with IVF, because of multiple embryos transferred or MZ splitting, there are multiple heartbeats on an initial ultrasound examination that ultimately spontaneously reduce; however, these pregnancies are still at risk for an adverse outcome. In twin IVF cycles with two initial heartbeats on early ultrasound versus three heartbeats that spontaneously reduced to two heartbeats, pregnancies with three heartbeats on an early examination had increased rates of preterm delivery (35%) and LBW (47%) (Luke et al, 2009).

In contrast, other studies suggest comparable outcomes in assisted conception and spontaneous multiples. Rates of pregnancy-induced hypertension, gestational diabetes mellitus (GDM), preterm premature rupture of membranes (PPROM), placenta previa, placental abruption (Nassar et al, 2003), congenital malformations (Nassar et al, 2003; Pinborg et al, 2004), and mortality (Pinborg et al, 2004) were similar in IVF twins versus spontaneous twins. Similarly, morbidity and mortality in ART triplets versus spontaneous triplets were comparable regarding the rates of PPROM, PTL, pregnancy-induced hypertension, GDM, gestational age at delivery, birthweight, and NICU admissions (Fitzsimmons et al, 1998).

Besides fetal number, another important factor in pregnancy outcome is placental arrangement. MC multiples

TABLE 7-3 Incidence of Twin Pregnancy Zygosity and Chorionicity With Corresponding Complications

Type of Twinning	Incidence (%)	Complication (%)		
		IUGR	Delivery <37 Weeks' Gestation	Perinatal Mortality
Dizygotic	67-70	25	40	10-12
Monozygotic	30-33	40	50	15-18
Diamniotic-dichorionic	18-36	30	40	18-20
Diamniotic-monochorionic	60-75	50	60	30-40
Monoamniotic-monochorionic	1-2	40	60-70	30-70

IUGR, Intrauterine growth restriction.

experience higher rates of morbidity and mortality, largely because of placental factors (Table 7-3) (Cunningham et al, 2005; Gaziano et al, 2000; Hack et al, 2008; Manning, 1995). When Dube et al (2002) studied different chorionicity–zygosity groups (monozygotic monochorionic [MZMC], di zygotic dichorionic [DZDC], and monozygotic dichorionic [MZDC]) they found smaller birthweight, and IUGR, congenital anomalies, and perinatal death in the MZMC versus DZDC twins, whereas MZDC and DZDC risks were similar, implying that poor outcomes are related more to chorionicity than zygosity. Negative outcomes such as cerebral palsy, mental retardation, and death, measured at 1 year of life in MC twins, are elevated (10%) compared with DC twins (3.7%), the majority of which are caused by complications from TTTS (Minakami et al, 1999).

Both placental asymmetry and abnormal vascular anastomosis affect fetal morbidity and mortality. IUGR and growth discordance afflict both DC and MC pregnancies, but MC twins are more likely to have cord abnormalities, unequal placental distribution, and TTTS (Cleary-Goldman and D'Alton, 2008). TTTS, ranging in severity from oligohydramnios to hydrops and fetal death (Cleary-Goldman and D'Alton, 2008; Gaziano et al, 2000) occurs in 15% to 32% of MC pregnancies (Hack et al, 2008; Minakami et al, 1999). Mortality rates vary from 22% to 100% (Bajoria et al, 1995; Cleary-Goldman and D'Alton, 2008; Hack et al, 2008), and surviving infants are at risk for long-standing adverse neurologic outcomes (Cleary-Goldman and D'Alton, 2008).

MC-MA twins occur in 1 in 10,000 pregnancies, but they suffer the highest risk of perinatal morbidity and mortality (Cordero et al, 2006). Similar to other MC twins, MC-MA twins are susceptible to TTTS, growth discordance, IUGR, preterm delivery, and congenital anomalies, but they also face the unique complication of cord entanglement. These factors historically account for perinatal mortality rates of 30% to 70%; however, lower morbidity and mortality rates (8% to 23%) reported in recent articles (Allen et al, 2001; Cordero et al, 2006; Heyborne et al, 2005; Rodis et al, 1997; Roque et al, 2003) may be attributed to increased prenatal diagnosis and fetal surveillance (Allen et al, 2001; Heyborne et al, 2005; Rodis et al, 1997).

MATERNAL COMPLICATIONS

Approximately 80% of multiples experience antepartum complications versus 25% of singletons (Norwitz et al, 2005), and hospitalization for hypertensive disorders, PTL, PPROM, placental abruption, and postpartum hemorrhage are elevated sixfold (ACOG Practice Bulletin #56, 2004). Mothers with two or more fetuses are at increased risk for myocardial infarction, left ventricular heart failure, pulmonary edema, GDM, operative vaginal or cesarean delivery, hysterectomy, blood transfusion, longer hospital stay, and the three major causes of maternal mortality: post partum hemorrhage, venous thromboembolism, and hypertensive disorders (Walker et al, 2004).

Stratified by fetal number, plurality correlates with maternal morbidity where quadruplets and other HOMs experience significantly increased maternal morbidity versus twins and triplets (Wen et al, 2004). Hypertensive disorders occur in 12% to 20% of twins, triplets, and quadruplets compared with 6.5% of singletons, HELLP syndrome increases with higher numbers of fetuses (Day et al, 2005), and twins with preeclampsia experience more complications than singletons with preeclampsia (Sibai et al, 2000). Results of a triplet cohort showed that 96% had maternal complications, 96% required antenatal hospitalization, one in four were diagnosed with preeclampsia, and 44% encountered postpartum complications (Devine et al, 2001).

PSYCHOSOCIAL FACTORS

As fetal number in an assisted conception pregnancy increases, parents report decreased quality of life, increased social stigma, increased difficulty meeting material family needs (Ellison et al, 2005; Roca de Bes et al, 2009), increased depression (Ellison et al, 2005; Olivennes et al, 2005; Sheard et al, 2007), decreased marital satisfaction (Roca de Bes et al, 2009), increased fatigue (Sheard et al, 2007) and stress (Golombok et al, 2007; Olivennes et al, 2005; Sheard et al, 2007). Part of this challenge lies in the fact that there are 168 hours in 1 week, but adequately caring for 6-month-old triplets and household activities requires 197.5 hours per week (Bryan, 2003). Multiple fetuses themselves face an increased risk of long-term disabilities that contribute to increased parental fatigue and depression, and overall siblings of multiples are more at risk for behavioral issues (Bryan, 2003).

Psychosocial consequences between naturally conceived multiples versus IVF multiples might differ. On the one hand, parents of IVF multiples can experience significantly more stress, increased child difficulty (Cook et al, 1998; Glazebrook et al, 2004), and increased dysfunctional parent-child interactions (Glazebrook et al, 2004) compared with spontaneous multiples. On the other hand, both ART and non-ART twin conceptions are more stressful for parents, creating higher levels of anxiety and depression compared with singletons (Vilska

et al, 2009). Regardless of conception mode, multiples potentially have negative psychosocial effects on parents and families.

COST

Multiple gestations economically influence both the family and society. Preterm delivery, LBW, and postdischarge hospitalization are increased in multiple fetuses, all of which have a role in short- and long-term cost (Cuevas et al, 2005). Annually, neonatal health care consumes $10.2 billion in the Unites States, 57% of which comes from preterm infants (<37 weeks' gestation) who comprise less than 10% of live births (St. John et al, 2000). According to gestational age, the mean initial hospital charge for infants born between 26 and 28 weeks' gestation is approximately $240,000 compared with approximately $4800 for a term infant. By birthweight, infants weighing less than 1250 g cost approximately $250,000 compared with infants weighing more than 2500 g, who cost $5800 (Cuevas et al, 2005).

ART multiples and their associated comorbidities have a significant role in health care expenditures. In the United Kingdom, IVF-induced multiples account for 27% of pregnancies yearly, but represent 54% of expenditures (Ledger et al, 2006); this is due largely to IVF triplets and twins, which are remarkably more costly than IVF singletons from both neonatal and maternal standpoints. Estimated maternal cost ratios for IVF singleton:twin and singleton:triplet are approximately 1:1.94 and 1:3.96, respectively, and neonatal cost ratios for IVF singleton:twin and singleton:triplet are 1:16 and 1:109, respectively (Ledger et al, 2006). The cost for IVF triplets from diagnosis through 1 year of life is tenfold (Ledger et al, 2006), and IVF twin cost up to 6 weeks postpartum is fivefold versus IVF singletons (Lukassen et al, 2004). ART singletons are more costly than spontaneous singletons, possibly because of increased rates of LBW (Chambers et al, 2007) or the underlying infertility contributing to these outcomes (Koivurova et al, 2004). An Australian study comparing IVF singletons, twins, and HOMs to control counterparts revealed no significant cost differences between ART twins and non-ART twins or between ART HOMs and non-ART HOMs, but combined neonatal-maternal cost was 57% higher for ART births than for non-ART births (Chambers et al, 2007).

Because of the extreme economic cost of multiples, one proposed mechanism to reduce multifetal pregnancies is single embryo transfer (SET). Elective SET in first-cycle IVF patients costs less than double embryo transfer (DET) (Fiddelers et al, 2006; Gerris et al, 2004), and although SET produced lower live birth rates than DET in an unselected population (20.8% versus 39.6%) (Fiddelers et al, 2006), when stratified to less than 38 years age, SET and DET generate similar live birth rates (Gerris et al, 2004).

DECREASING THE RISK OF MULTIPLES

ART procedures and the rate of multiple pregnancies are rising concordantly. Although ART triplets and the incidence of HOMs has declined since 1996, ART twin rates are unchanged.[2] Primary forms of preventing multiples include canceling ovulation induction cycles or converting to IVF, and in IVF cycles limiting the number of embryos transferred. Worldwide differences exist in medical practice and laws regarding restrictions on the number of embryos transferred.

The American Society for Reproductive Medicine (ASRM) and the Society for Assisted Reproductive Technology established transfer guidelines to assist in determining the appropriate embryo number in an attempt to decrease multiples. Recommended limits are based on age, prognosis, and embryo stage and further differentiate between a favorable patient (first IVF cycle, good quality embryos, number of embryos for potential cryopreservation, successful past IVF cycles) and less favorable conditions. To date there are no embryo transfer guidelines for frozen embryo cycles. Transfer recommendations by the ASRM are not legally binding, and they are subject to interpretation or adjustment based on clinical experience and unique patient instances (Practice Committee of Society for Assisted Reproductive Technology and Practice Committee of American Society for Reproductive Medicine, 2008b). Reduction of the number of embryos transferred and the incidence of triplets or greater in women aged 37 years or less from 1996 to 2003 may be attributed to a change in the 1998-1999 ASRM guidelines (Stern et al, 2007).

The most important factor involved in creating multiple fetuses is the number of embryos transferred. Given the emotional, physical, and financial burden of ART and the concern that only one embryo might lower pregnancy rates, multiples fetuses were previously accepted as a known risk in an effort to ensure a pregnancy. More recently, however, practitioners across the globe are stressing the impact of multiples and are encouraging SET (Gerris, 2005).

A Swedish study in women aged less than 36 years undergoing their first or second IVF cycle with two or more good-quality embryos were randomized to DET or SET followed by frozen-thawed embryo transfer if unsuccessful. Live birth rates were lower in the SET-alone versus the DET group, but SET followed by frozen-thawed embryo transfer resulted in a 38.8% live birth rate and a 0.8% multiple rate, compared with a 42.9% live birth rate and a 33.1% multiple rate in the DET group, showing that with SET pregnancy rates were acceptable and multiple pregnancy rates were significantly lower (Thurin et al, 2004). Women aged 36 to 39 years may also be candidates for SET, because similar live birth rates between SET and DET and significantly higher cumulative multiple rates occur in the DET (16.6%) versus SET (1.7%) groups (Veleva et al, 2006). Superb cryopreservation technique with frozen embryo transfer after SET in the appropriate patient lowers multiple fetus rates (Gerris, 2005) and leads to comparable cumulative LBR compared with DET (Veleva et al, 2009).

Consideration of multiples from non-ART ovulation induction by controlled ovarian hyperstimulation also merits discussion. Twenty-two percent of twins, 40% of triplets, and 71% of HOMs in 2004 were a result of non-ART ovulation induction (Dickey, 2009). During gonadotropin stimulation, follicular growth is supervised via ultrasound examination, and estradiol levels are monitored in an attempt to minimize overstimulation. Ovulation

induction risk factors for multiples have revealed that HOMs are positively correlated with gonadotropin dose and stimulation length, estradiol levels greater than 1000 pg/mL, and seven or more follicles measuring 10 mm or greater, whereas negative predictors were age less than 32 years, lower body mass index, and a higher number of prior treatment cycles (Dickey, 2009). Techniques to reduce the chance of multiple fetuses include minimizing gonadotropin dose, canceling the cycle by discontinuing medications for excess follicles or high estradiol levels, or converting to IVF (Dickey, 2009; Nakhuda and Sauer, 2005); however, the specific criteria warranting cycle cancelation are not uniform between centers (Practice Committee of the American Society for Reproductive Medicine, 2006).

MULTIFETAL PREGNANCY REDUCTION

As the rates of ART procedures, multiple fetuses, and prematurity-related sequelae have increased, so has the use of selective reduction. Primary prevention of multiple fetuses by limiting the number of embryos transferred or canceling an overstimulated ovulation induction cycle is optimal; however, in reality multifetal pregnancies continue to occur. Multifetal pregnancy reduction (MFPR) provides another option to enhance overall survival and decrease the risk of fetal or neonatal morbidity and mortality by decreasing pregnancy loss rates and prematurity (Evans and Britt, 2005). First developed in the 1980s, selective termination of one or more fetuses is performed to reduce the final fetal number. The majority of patients reduce to twins, followed by singletons; few reduce to triplets (Stone et al, 2008). A discussion of the ethical, medical, and psychosocial factors involved in MFPR are important counseling points for any patient undergoing ovulation induction (Committee on Ethics, 2007).

Improvements in MFPR techniques have enhanced success rates such that quadruplet or triplets reduced to twins have equal outcomes compared with natural twins (Evans and Britt, 2005; Evans et al, 2001). Success rates correlate with both beginning and ending fetal number (Evans et al, 2001). The average loss rate in one series of 1000 MFPR cases was 4.7% (Stone et al, 2008). Loss rates are higher after reducing to a singleton versus reducing to twins, but twins overall have higher morbidity than do singletons (Evans and Britt, 2005, 2008; Evans et al, 2001; Stone et al, 2008). Reduction of twins to singletons may be considered given a lower loss rate after reduction versus continuing with twins (Evans et al, 2004). Benefits after MFPR are apparent in preterm delivery rates, because half of twins and almost 90% of singletons are delivered full term, and 95% were delivered after 24 weeks' gestation in one series (Stone et al, 2008). Although beneficial in certain cases, MFPR is not without medical and psychological risk. It might not be an option for some women; therefore primary prevention should be the focus for reducing the risk of multiple fetuses.

SUMMARY

Over the last 30 years, advances in ART have helped countless infertile couples achieve a pregnancy. The percentage of ART live births will likely continue on an upward trend because of increased accessibility of ART and delayed childbearing. These factors in addition to ART techniques will continue to contribute to multiple gestation rates. Multiple gestations are associated with increased maternal, fetal, and neonatal complications that generate a medical, psychological, and economic burden to families and society. Efforts to decrease multifetal pregnancies and prematurity-related sequelae include prevention-based practice policies and further knowledge regarding the mechanisms involved with MZT and ART.

CHAPTER 8

Nonimmune Hydrops

Scott A. Lorch and Thomas J. Mollen

An infant with hydrops has an abnormal accumulation of excess fluid. The condition varies from mild, generalized edema to massive edema, with effusions in multiple body cavities and with peripheral edema so severe that the extremities are fixed in extension. Fetuses with severe hydrops may die in utero; if delivered alive, they may die in the neonatal period from the severity of their underlying disease or from severe cardiorespiratory failure.

The first description of hydrops in a newborn, in a twin gestation, may have appeared in 1609 (Liley, 2009). Ballantyne (1892) suggested that the finding of hydrops was an outcome for many different causes, in contrast to the belief at that time that hydrops was a single entity. Potter (1943) first distinguished between hydrops secondary to erythroblastosis fetalis and nonimmune hydrops, by describing a group of infants with generalized body edema who did not have hepatosplenomegaly or abnormal erythropoiesis. Potter's description of more than 100 cases of hydrops included two sets of twins in which one had hydrops and the other did not, thus presenting the first description of twin-twin transfusion syndrome. With the nearly universal use of anti-D globulin and refinement of the schedule and doses for its administration, the occurrence of immune-mediated hydrops has steadily declined, such that later studies found that immune-mediated causes accounted for only 6% to 10% of all cases of hydrops (Heinonen et al, 2000; Machin, 1989). The reported incidence of nonimmune hydrops in the general population has been highly variable, ranging from 6 per 1000 pregnancies in a high-risk referral clinic in the United Kingdom between 1993 and 1999 (Sohan et al, 2001) to 1 in 4000 pregnancies (Norton, 1994); other published rates are 6 per 1000 pregnancies (Santolaya et al, 1992), 1.3 per 1000 pregnancies (Wafelman et al, 1999), and 1 per 1700 pregnancies (Heinonen et al, 2000). However, all the published studies come from single institutions, with the at-risk populations ranging from that of a high-risk pregnancy clinic to infants in a neonatal intensive care unit. No study has monitored all pregnant women in one geographic area to calculate the true population incidence of nonimmune hydrops, especially monitoring infants who died in utero. Geography also affects the incidence; several causes of nonimmune hydrops, such as α-thalassemia, are more common in certain areas of the world. Finally, the incidence of nonimmune hydrops may be rising because of the more routine use of ultrasound investigation in the late first trimester of pregnancy (Iskaros et al, 1997).

ETIOLOGY

Nonimmune hydrops has been associated with a wide range of conditions (Table 8-1). In many of these conditions, edema formation results from one of the following possible processes:

- Elevated central venous pressure, in which the cardiac output is less than the rate of venous return
- Anemia, resulting in high-output cardiac failure
- Decreased lymphatic flow
- Capillary leak

The actual pathophysiology of hydrops for many of the conditions in Table 8-1, however, is still not understood.

The most common causes of nonimmune hydrops are chromosomal, cardiovascular, hematologic, thoracic, infectious, and related to twinning (Abrams et al, 2007; Bellini et al, 2009; Wilkins, 1999). As with reported incidence rates, the relative contribution of these causes varies by study. The studies that focus on early fetal presentation of hydrops (postconceptional age of less than 24 weeks' gestation) have found that chromosomal abnormalities, such as Turner syndrome and trisomies 13, 18, and 21, are the causes of 32% to 78% of all cases of hydrops (Boyd et al, 1992; Heinonen et al, 2000; Iskaros et al, 1997; McCoy et al, 1995; Sohan et al, 2001). For infants whose hydrops becomes evident after 24 weeks' gestation, cardiovascular and thoracic causes are most prevalent, with rates ranging between 30% and 50% (Machin, 1989; McCoy et al, 1995; Shan et al, 2001). Studies from Asia have noted a higher percentage of cases from hematologic causes, probably because of the higher rates of α-thalassemia in the population (Lin et al, 1991; Nakayama et al, 1999).

The percentage of infants with "idiopathic" hydrops, or hydrops of unknown etiology, varies from 5.2% to 50%, depending on the ability of the clinicians to complete their diagnostic evaluation and the inclusion of fetal deaths in the analysis (Bellini et al, 2009; Heinonen et al, 2000; Iskaros et al, 1997; Machin, 1989; McCoy et al, 1995; Nakayama et al, 1999; Santolaya et al, 1992; Sohan et al, 2001; Wafelman et al, 1999; Wy et al, 1999). Yaegashi et al (1998) used enzyme-linked immunosorbent assay and polymerase chain reaction techniques to improve the detection of parvovirus infection. In both their own institution, and in eight other series of patients, these investigators found evidence of parvovirus infection in 15% to 19% of all infants previously diagnosed with idiopathic hydrops. It is likely that, as there is increased understanding of and testing for many of the conditions listed in Table 8-1, the number of infants diagnosed with idiopathic, nonimmune hydrops will continue to decline.

PATHOPHYSIOLOGY

NORMAL FLUID HOMEOSTASIS

Abnormal body fluid homeostasis is the underlying cause of edema, whether local or generalized. To understand the pathogenesis of hydrops, the clinician must consider the forces underlying normal fluid homeostasis. The regulation of net fluid movement across a capillary membrane depends on the Starling forces, which were first described by E.H. Starling in 1896 (Starling, 1896). Flow between intravascular and interstitial fluid compartments is

TABLE 8-1 Conditions Associated With Hydrops Fetalis

Condition Type	Specific Conditions
Hemolytic anemias	Alloimmune, Rh, Kell, α-Chain hemoglobinopathies (homozygous α-thalassemia) Red blood cell enzyme deficiencies (glucose phosphate isomerase deficiency, glucose-6-phosphate dehydrogenase)
Other anemias	Fetomaternal hemorrhage Twin-twin transfusion Diamond-Blackfan
Cardiac conditions	Premature closure of foramen ovale Ebstein anomaly Hypoplastic left or right heart Subaortic stenosis with fibroelastosis Cardiomyopathy, myocardial fibroelastosis Atrioventricular canal Myocarditis Right atrial hemangioma Intracardiac hamartoma or fibroma Tuberous sclerosis with cardiac rhabdomyoma
Cardiac arrhythmias	Supraventricular tachycardia Atrial flutter Congenital heart block
Vascular malformations	Hemangioma of the liver Any large arteriovenous malformation Klippel-Trenaunay syndrome Idiopathic infantile arterial calcification
Vascular accidents	Thrombosis of umbilical vein or inferior vena cava Recipient in twin-twin transfusion
Infections	Cytomegalovirus, congenital hepatitis, human parvovirus, enterovirus, other viruses Toxoplasmosis, Chagas disease Coxsackie virus Syphilis Leptospirosis
Lymphatic abnormalities	Lymphangiectasia Cystic hygroma Noonan syndrome Multiple pterygium syndrome Congenital chylothorax
Nervous system lesions	Absence of corpus callosum Encephalocele Cerebral arteriovenous malformation Intracranial hemorrhage (massive) Holoprosencephaly Fetal akinesia sequence
Pulmonary conditions	Cystic adenomatoid malformation of the lung Mediastinal teratoma Diaphragmatic hernia Lung sequestration syndrome Lymphangiectasia
Renal conditions	Urinary ascites Congenital nephrosis Renal vein thrombosis Invasive processes and storage disorders Tuberous sclerosis Gaucher disease Mucopolysaccharidosis Mucolipidosis
Chromosome abnormalities	Trisomy 13, trisomy 18, trisomy 21 Turner syndrome XX/XY
Bone diseases	Osteogenesis imperfecta Achondroplasia Asphyxiating thoracic dystrophy
Gastrointestinal conditions	Bowel obstruction with perforation and meconium peritonitis Small bowel volvulus Other intestinal obstructions Prune-belly syndrome
Tumors	Neuroblastoma Choriocarcinoma Sacrococcygeal teratoma Hemangioma or other hepatic tumors Congenital leukemia Cardiac tumors Renal tumors
Maternal or placental conditions	Maternal diabetes Maternal therapy with indomethacin Multiple gestation with parasitic fetus Chorioangioma of placenta, chorionic vessels, or umbilical vessels Toxemia Systemic lupus erythematosus
Miscellaneous	Neu-Laxova syndrome Myotonic dystrophy
Idiopathic	

determined by the balance among (1) capillary hydrostatic pressure, (2) serum colloid oncotic pressure, (3) interstitial hydrostatic pressure or tissue turgor pressure, and (4) interstitial osmotic pressure, which depends on lymphatic flow. The Starling equation defines the relationship among these forces and their net effect on net fluid movement, or filtration, across a semipermeable membrane (such as the capillary membrane) as:

$$\text{Filtration} = K[(P_c - P_t) - R(O_p - O_t)]$$

where K = capillary filtration coefficient, representing the extent of permeability of a membrane to water and thus describing capillary integrity; P_c = capillary hydrostatic pressure; P_t = interstitial hydrostatic pressure or tissue turgor pressure; R = reflection coefficient for a solute, representing the extent of permeability of the capillary wall to that solute; O_p = plasma oncotic pressure as determined by plasma proteins and other solutes; and O_t = interstitial osmotic pressure (Figure 8-1).

Although an abnormality of any of the components of this equation may, in theory, result in the accumulation of edema fluid, the fetal-placental unit presents a unique physiologic condition that effectively eliminates two of the factors, assuming unimpeded fetal-placental flow and an appropriately functioning maternal-placental interface. Because approximately 40% of fetal cardiac output is allocated to the placenta, there is rapid transport of water

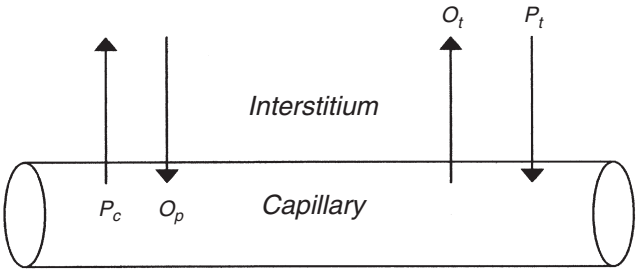

FIGURE 8-1 Starling forces and net effect on fluid homeostasis. *Arrows* represent net effect of movement of fluid across the capillary membrane for each factor under normal conditions. P_c, Capillary hydrostatic pressure; P_t, interstitial hydrostatic pressure or tissue turgor pressure; O_p, plasma oncotic pressure as determined by plasma proteins and other solutes; O_t, interstitial osmotic pressure.

between the fetus and mother. Any condition resulting in elevated fetal capillary hydrostatic pressure or low plasma colloid oncotic pressure would likely cause the net flow of water from fetal villi in the placenta to the maternal blood stream, where it can be effectively eliminated. This elimination of fluid would counteract the accumulation of interstitial fluid by the fetus. Although the placenta of a fetus with hydrops is also edematous, these changes are believed to occur with, and not before, fetal fluid accumulation.

DERANGEMENTS IN FLUID HOMEOSTASIS

Diamond et al (1932) suggested three possible mechanisms that might be relevant in infants with hydrops: anemia, low colloid osmotic pressure with hypoproteinemia, and congestive heart failure with hypervolemia. Others have reviewed these potential mechanisms (Phibbs et al, 1974), which remain among the central hypotheses addressed by investigators in this area. The causes of hydrops appear to be multifactorial, with mechanisms that produce elevated central venous pressure (CVP), capillary leakage, and impaired lymphatic drainage all contributing to its development.

Infants with alloimmune hydrops (and several of the nonimmune hydrops conditions as well) have significant anemia. It has been proposed that anemia leads to congestive heart failure with increased hydrostatic pressure in the capillaries, causing vascular damage that results in edema. However, the hematocrit values of infants with and without hydrops overlap significantly, suggesting that anemia alone is not the complete explanation. A rapidly lowered hemoglobin concentration results in greater cardiac output to maintain adequate oxygen delivery. This output results in higher oxygen demands by the myocardium, which may be difficult to meet because of the anemia. The hypoxic myocardium can become less contractile and less compliant, with ventricular stiffness causing increased afterload to the atria. High-output congestive heart failure may then exist, resulting in elevated CVP. Raised CVP leads to increased capillary filtration pressures and impairment of lymphatic return (Weiner, 1993). In addition, reduced compliance of a right ventricle may result in flow reversal in the inferior vena cava, which may in turn cause end-organ damage to the liver, with consequent hypoalbuminemia and portal hypertension enhancing formation of both edema and ascites. Hydrops has been produced in fetal lambs (Blair et al, 1994) in which the hemoglobin content was lowered in 12 fetuses through exchange transfusion using cell-free plasma; six became hydropic. Anemia developed more rapidly with a higher CVP in fetuses with hydrops than in the fetuses without hydrops. In the most severely anemic fetuses, it is probable that decreased oxygen transport causes tissue hypoxia, which in turn increases capillary permeability to both water and protein. These changes in capillary permeability also likely contribute to the development of hydrops.

Infants who have erythroblastosis and hydrops seem to demonstrate a correlation between serum albumin concentration and the severity of hydrops (Phibbs et al, 1974). Initial therapy after birth, however, tends to rapidly raise the serum albumin value toward normal, and with diuresis the albumin concentrations normalize. This finding suggests that hypoalbuminemia may be the result of dilution rather than the cause of hydrops.

To elucidate the role of isolated hypoproteinemia in the genesis of hydrops, Moise et al (1991) have induced hypoproteinemia in sets of twin fetal lambs. One twin from each set underwent serum protein reduction through repeated removal of plasma and replacement with normal saline; the other twin served as the control. Over 3 days, plasma protein concentrations were reduced by an average of 41%, with a 44% reduction in colloid osmotic pressure, in experimental subjects. No fetuses became edematous, and total body water content values were similar in experimental and control animals. Thus hypoproteinemia alone was insufficient to cause hydrops fetalis over the course of the study. Transcapillary filtration probably increased with hypoproteinemia, but was compensated by lymphatic return. Human fetuses with hypoproteinemia as a result of nephrotic syndrome or analbuminemia rarely experience hydrops, further supporting the hypothesis that hypoproteinemia alone is not sufficient to cause hydrops. Hypoproteinemia may, however, lower the threshold for edema formation in the presence of impaired lymphatic return or increased intravascular hydrostatic pressures.

The most commonly diagnosed causes of nonimmune hydrops that appears in fetuses older than 24 weeks' gestation are cardiac disorders. Any state in which cardiac output is lower than the rate of venous return results in an elevated CVP. Increased CVP raises capillary filtration pressures and, if high enough, restricts lymphatic return. Both of these mechanisms may then contribute to interstitial accumulation of fluid. Structural cardiac causes of elevated CVP include right-sided obstructive lesions and valvular regurgitation. The most common and easily reversible cause of nonimmune hydrops is supraventricular tachycardia (SVT). In general, cardiac output rises with heart rate. At the increasingly high rates seen in SVT, however, cardiac output plateaus and then diminishes. The heart rates observed with SVT are often associated with decreased cardiac output. Impaired cardiac output results in elevated CVP, which can give rise to edema through mechanisms discussed previously (Gest et al, 1990). Myocardial hypoxia (most often caused by severe anemia) and myocarditis (usually infectious) reduce both the contractility and compliance of the myocardium and can also cause an increase in CVP.

A fourth factor that contributes to hydrops is decreased lymph flow. If the rate of fluid filtration from plasma

to tissues exceeds the rate of lymph return to the central venous system, then edema and effusions may form. A structural impediment or increased CVP that opposes lymphatic return to the heart can impair lymph flow. To determine the effects of alterations in CVP on lymphatic return, Gest et al (1992) applied an opposing hydrostatic pressure to the thoracic duct in fetal lambs; they inserted catheters into the thoracic ducts of 10 fetuses. Varying the height of the catheter altered the thoracic duct outflow pressure. Thoracic duct flow was nearly constant over the physiologic range of CVP, but sharply decreased at elevated pressures; therefore lymphatic flow may be reduced or essentially blocked in pathologic states associated with elevated CVP.

PRENATAL DIAGNOSIS

The initial presentation of fetal hydrops varies by report. Watson and Campbell (1986) found that two thirds of prenatally diagnosed cases were discovered on routine ultrasonographic examinations, and one third was referred for evaluation because of suspected polyhydramnios. Graves and Baskett (1984) reported that hydrops was more commonly discovered after referral for polyhydramnios, fetus large for dates, fetal tachycardia, or pregnancy-induced hypertension. Despite the underlying cause of hydrops or the clinical presentation, the prenatal diagnosis is made via the ultrasonographic finding of excess fluid in the form of ascites, pleural or pericardial effusions, skin edema, placental edema, or polyhydramnios. Several definitions for ultrasonographic diagnosis based on quantity and distribution of excess fluid have been proposed. One widely accepted set of criteria consists of the presence of excess fluid in any two of the previously listed compartments. Because this definition is based on the presence of excess fluid alone, the degree of severity is generally subjective.

Swain et al (1999) outlined a multidisciplinary approach to the evaluation and management of the mother and fetus with hydrops. Table 8-2 provides recommendations for the investigation of fetal hydrops. Patient history should focus on ethnic background, familial history of consanguinity, genetic or congenital anomalies, and complications of pregnancy, including recent maternal illness and environmental exposures. Maternal disorders such as diabetes, systemic lupus erythematosus, myotonic dystrophy, and any type of liver disease should also be noted. Initial laboratory investigation includes blood typing and a Coombs' test to rule out immune-mediated hydrops. Other blood tests are a screening for hemoglobinopathies, a Kleihauer-Betke test to eliminate fetal-maternal hemorrhage, and testing for the TORCH diseases (i.e., toxoplasmosis, other infections, rubella, cytomegalovirus infection, and herpes simplex), including syphilis and parvovirus B19.

Further evaluation is directed at identifying possible causes (Forouzan, 1997). Rapid evaluation is necessary to determine whether fetal intervention is possible and to estimate the prognosis for the fetus. Many conditions, such as arrhythmias, twin-twin transfusion, large vascular masses, and congenital diaphragmatic hernias and other chest-occupying lesions, are discovered during the initial ultrasonographic evaluation (Coleman et al, 2002). Middle cerebral artery peak systolic velocity measurement can aid in detecting the presence of fetal anemia (Hernandez-Andrale et al, 2004). If the initial ultrasonic examination is not helpful in identifying a cause, it may be helpful to repeat it at a later date to reassess fetal anatomy, monitor progression of the hydrops, and evaluate well-being of the fetus.

Fetal echocardiography should also be performed to evaluate for cardiac malformations and arrhythmia. Amniotic fluid can be obtained for fetal DNA analysis, cultures, and lecithin-to-sphingomyelin ratio to assess lung maturity. Fetal blood sampling allows for other tests, such as a complete blood cell count, routine chemical analyses, DNA analysis, bacterial and viral cultures, metabolic studies, and serum immunoglobulin measurements.

TABLE 8-2 Antenatal Investigation of Fetal Hydrops

Area	Testing
Maternal	History, including: Age, parity, gestation Medical and family histories Recent illnesses or exposures Medications Complete blood count and indices Blood typing and indirect Coombs antibody screening Hemoglobin electrophoresis Kleihauer-Betke stain of peripheral blood Syphilis, TORCH, and parvovirus B19 titers Anti-Ro and anti-La, systemic lupus erythematosus preparation Oral glucose tolerance test Glucose-6-phosphate dehydrogenase, pyruvate kinase deficiency screening
Fetal	Serial ultrasound evaluations Middle cerebral artery peak systolic velocity Limb length, fetal movement Echocardiography
Amniocentesis	Karyotype Alpha-fetoprotein Viral cultures; polymerase chain reaction analysis for toxoplasmosis, parvovirus 19 Establishment of culture for appropriate metabolic or DNA testing Lecithin-to-sphingomyelin ratio to assess lung maturity
Fetal blood sampling	Genetic testing Complete blood count Hemoglobin analysis Immunoglobulin M test; specific cultures Albumin and total protein measurements Measurement of umbilical venous pressure Metabolic testing

PRENATAL MANAGEMENT

The goals of antenatal evaluation of fetal hydrops depend on the underlying cause. In diagnoses in which therapy is futile, the goal is to avoid unnecessary invasive testing and cesarean section. The prognosis should be discussed frankly with the parents, who should be given the option of terminating the pregnancy. If the underlying cause is

amenable to fetal therapy, the risks and benefits of such therapy, as well as the warning that diagnostic error is possible, should be discussed with the family.

SVT is one of the most common known causes of nonimmune hydrops, and it is the most amenable to treatment (Huhta, 2004; Newburger and Keane, 1979). Usually the mother is given antiarrhythmic agents, and the fetus is monitored closely for resolution of the SVT. Digoxin is most commonly administered, although other antiarrhythmics have been used, such as sotolol or flecainide, because transplacental transfer of digoxin may be impaired in the setting of hydrops. In extreme circumstances, such as fetal tachyarrhythmia refractory to maternal treatment, direct fetal administration of antiarrhythmic agents via percutaneous umbilical blood sampling or intramuscular injection, although untested and highly risky, has met with some success.

If anemia is the cause of hydrops, transfusions of packed red blood cells may be administered to the fetus. Often a single transfusion reverses the edema, although serial transfusions may be necessary. Parvovirus B19 (Anand et al, 1987) and fetal-maternal hemorrhage are examples of diagnoses that are amenable to this therapy. Other diagnoses involving anemias that are refractory to transfusions, such as α-thalassemia, may require neonatal stem cell transplantation. Transfusions should be given, with the use of ultrasonographic guidance, into the intraperitoneal space or umbilical vein. Blood instilled into the abdominal cavity is taken up by lymphatics, but elevated CVPs present in hydropic fetuses may impair this uptake. If uptake of intraperitoneal blood is incomplete, treatment for the hydrops is less successful; degeneration of the remaining hemoglobin may create a substantial bilirubin load, necessitating phototherapy or exchange transfusion after the infant is delivered.

Surgery continues to evolve as a promising therapy for select cases of fetal hydrops (Azizkhan and Crombleholme, 2008; Kitano et al, 1999). Fetal lung lesions such as congenital cystic adenomatoid malformation (CCAM) and pulmonary sequestration can, in the most extreme cases, result in mediastinal shift, pulmonary hypoplasia, cardiovascular compromise, and hydrops. A recent review of 36 fetuses with CCAM found higher rates of hydrops in infants whose mass-to-thorax ratio was greater than 0.56, in whom the lesion had a cystic predominance, or in whom the hemidiaphram was everted (Vu et al, 2007). Adzick et al (1998) reported on the outcome of 175 cases of fetal lung masses, including 134 cases of CCAM and 41 of extralobar pulmonary sequestration. The 76 fetuses with CCAM lesions without associated hydrops were all managed expectantly (maternal transport to a high-risk center, planned delivery near term, and resection in the newborn period). CCAMs frequently involute and may disappear before delivery; therefore there were no deaths in the nonhydropic group of fetuses in this study. Twenty-five fetuses with hydrops were managed expectantly, and all 25 died before or after preterm labor at 25 to 26 weeks' gestation. These results highlight the fact that fetuses with lung lesions leading to hydrops have high mortality rates. Thirteen fetuses with CCAM and associated hydrops underwent open fetal resection or lobectomy. Eight survived and were reported as healthy at 1 to 7 years of follow-up. Maternal morbidities related to fetal intervention ranged from uterine wound infection with dehiscence to mild postoperative interstitial pulmonary edema, which was treated with diuretics.

High morbidity and mortality rates in severe twin-twin transfusion with associated hydrops led to multiple international trials of laser photocoagulation of interfetal vascular connections. Although the trials met with varying results, metanalysis involving the three major trials demonstrates improvement in perinatal and neonatal outcomes. However, the current level of evidence is limited in the reported effect on neurodevelopmental outcomes in survivors. A 2008 Cochrane review recommends considering treatment with laser coagulation at all stages of twin-twin transfusion (Roberts et al, 2008).

Fetal intervention has met with some success in other diagnoses with associated hydrops. Thoracoamniotic shunts for large unicystic lesions and pleuroamniotic shunts for hydrothorax have reportedly enhanced survival in extreme cases. Similarly, in cases of massive urinary ascites, urinary diversion via peritoneal shunts has been reported, but with a poor long-term prognosis (Crombleholme et al, 1990).

However, as with other invasive interventions, there are potential risks with fetal surgery. A review of the reproductive outcomes of future pregnancies after a pregnancy complicated by maternal-fetal surgery found a complication rate of 35%: 12% affected by uterine dehiscience, 6% with uterine rupture, 3% requiring hysterectomy; and 9% with hemorrhage requiring transfusion (Wilson et al, 2004). These longer-term complications suggest that the potential benefit of fetal surgical intervention must be balanced by the potential complications of the procedure experienced by the mother.

In cases in which the cause can be corrected by appropriate care at the time of delivery, such as elimination of a chorioangioma, and in cases in which no cause can be ascertained, close observation for fetal demise is the focus of prenatal management. Many cases of nonimmune hydrops manifest in the third trimester as preterm labor. It is difficult to decide whether to attempt tocolysis and delay delivery so as to allow the potentially beneficial administration of steroids before birth or to deliver the fetus immediately. If tocolysis is possible, expectant management should include usual biophysical testing, although fetal decompensation may be difficult to measure. Abnormal fetal heart tracings, oligohydramnios, decreased fetal movement, and poor fetal tone are all ominous signs. There is no indication to prolong pregnancy beyond attainment of a mature lung profile unless available evidence indicates improvement or resolution of the hydrops.

NEONATAL EVALUATION

Table 8-3 summarizes the diagnostic evaluations recommended for newborn infants with nonimmune hydrops of unknown cause.

INTENSIVE CARE OF THE INFANT WITH HYDROPS FETALIS

After successful resuscitation, including intubation, administration of surfactant, and placement of umbilical catheters, the clinical management can address both the cause and the complications of hydrops. Morbidity and

TABLE 8-3 Diagnostic Evaluation of Newborns With Nonimmune Hydrops

System	Type of Evaluation
Cardiovascular	Echocardiogram, electrocardiogram
Pulmonary	Chest radiograph, pleural fluid examination
Hematologic	Complete blood cell count, differential platelet count, blood type and Coombs' test, blood smear for morphologic analysis
Gastrointestinal	Abdominal radiograph, abdominal ultrasonography, liver function tests, peritoneal fluid examination, total protein and albumin levels
Renal	Urinalysis, blood urea nitrogen and creatinine measurements
Genetic	Chromosomal analysis, skeletal radiographs, genetic consultation
Congenital infections	Viral cultures or serologic testing, including TORCH agents and parvovirus
Pathologic	Complete autopsy, placental examination

TORCH, Toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex.

mortality may result from the hydropic state, the underlying conditions giving rise to hydrops, or both. A fetus with hydrops that is delivered prematurely is subject to the additional complications of prematurity. If there is massive ascites or pleural effusions, initial resuscitation may require thoracentesis or peritoneal tap. Because of pulmonary edema, infants with hydrops are susceptible to pulmonary hemorrhage and require high levels of positive end-expiratory pressure.

RESPIRATORY MANAGEMENT

Virtually all infants with hydrops require mechanical ventilation because of pleural and peritoneal effusions, pulmonary hypoplasia, surfactant deficiency, pulmonary edema, poor chest wall compliance caused by edema, or persistent pulmonary hypertension of the newborn. The presence of persistent pleural effusions may necessitate the placement of chest tubes. Ascites may also compress the diaphragm and impair lung expansion. Breath sounds, chest movement, blood gas levels, and radiographs must all be monitored frequently, so that ventilator support can be reduced in response to improvements in lung compliance and water clearance. Pneumothoraces and pulmonary interstitial emphysema remain potential complications as long as ventilator support is continued. Infants who need a prolonged course of ventilation, particularly those born prematurely, may develop bronchopulmonary dysplasia. Chronic lung disease results in a longer and more complicated hospital course and contributes to the late mortality of hydrops.

FLUID AND ELECTROLYTE MANAGEMENT

A primary goal of fluid management is resolution of the hydrops itself. Maintenance fluids should be restricted, with volume boluses given only in response to clear signs of inadequate intravascular volume. The hydropic newborn has an excess of free extracellular water and sodium. Fluids given during resuscitation further increase the amount of water and sodium that must be removed during the immediate neonatal period. Initial maintenance fluids should contain minimal sodium. Serum and urine sodium levels, urine volume, and daily weights should be monitored carefully to guide administration of fluids and electrolytes. Urinary sodium levels may help differentiate between hyponatremia caused by hemodilution and urinary losses.

CARDIOVASCULAR MANAGEMENT

Shock may be a prominent feature of patients with hydrops. Hydropic infants may have hypovolemia as a result of capillary leakage, poor vascular tone, and impaired myocardial contractility from hypoxia or infection, impaired venous return caused by shifting or compression of mediastinal structures, or pericardial effusion. Adequate intravascular volume must be maintained, and correctable causes of impaired venous return should be addressed. Peripheral perfusion, heart rate, blood pressure, and acid-base status should be monitored carefully.

CLINICAL COURSE AND OUTCOME

Despite improvements in diagnosis and management, mortality from nonimmune hydrops remains high. Reported survival rates for all fetuses diagnosed antenatally with hydrops range from 12% to 24% (Heinonen et al, 2000; McCoy et al, 1995; Negishi et al, 1997). Higher survival rates have been reported in infants born alive, but the highest rates are still only 40% to 50% (Wy et al, 1999). Improved ultrasonography techniques and earlier testing may actually lead to lower survival rates as hydrops is diagnosed in more first-trimester infants. These infants are more likely to have chromosomal abnormalities that are incompatible with survival, but were previously not included in populations of hydropic fetuses. The best predictor of survival is the cause of the hydrops and the gestational age of the child at delivery. Highest survival rates are seen in infants with parvovirus infection, chylothorax, or SVT. The lowest survival rates are for hydrops from chromosomal cause, although the figures may be biased because a significant number of the pregnancies in such cases are terminated (Heinonen et al, 2000; Sohan et al, 2001). A recent review of 598 patients with nonimmune hydrops found other risk factors for increased mortality including younger gestational age, lower 5-minute Apgar score, and the need for increased respiratory support (Abrams et al, 2007). A smaller study from Taiwan also found that lower albumin levels were associated with a higher mortality rate (Huang et al, 2007).

Interventions to improve outcomes in hydrops are limited by the rarity of the disease. Carlton et al (1989) reported on a group of 36 infants with nonimmune hydrops and noted that 90% of the infants who died within 24 hours had pleural effusions, compared with only 50% of those who survived. More than one third of the infants in this study required thoracentesis in the delivery room to aid in lung expansion. All the infants who lived more than 24 hours were treated with mechanical ventilation and

received supplemental oxygen; they needed ventilation for an average of 11 days (range, 2 to 48 days). Most hydropic infants lose a minimum of 15% of their birthweight, and some lose as much as 30%. Ordinarily, diuresis begins on the second or third day after birth and continues for a period of 2 to 4 days. Once the edema has resolved, the infants have normal levels of circulating protein and eventually recover from their apparent capillary leak syndrome. No specific management strategies during the neonatal period, such as the use of high-frequency oscillatory ventilation, have been shown to improve outcome, although the published studies are powered to detect small survival differences (Wy et al, 1999).

For infants who survive the immediate neonatal period, long-term outcomes appear to be excellent. Nonimmune hydrops by itself does not seem to lead to residual developmental delay. A small study from Japan found that 13 of 19 surviving infants with nonimmune hydrops had normal development at 1 to 8 years (Nakayama et al, 1999). The six infants with mild or severe delays in this study had other morbidities, such as extreme prematurity, structural cardiac lesions, or chromosomal anomalies. Thus long-term morbidities from nonimmune hydrops appear to result from the underlying cause of the hydrops, gestational age at delivery, and complications arising immediately after delivery.

PART III

Maternal Health Affecting Neonatal Outcome

CHAPTER 9

Endocrine Disorders in Pregnancy

Gladys A. Ramos and Thomas R. Moore

DIABETES IN PREGNANCY

Currently, 17 million people in the United States have a form of diagnosed diabetes. Alarmingly, the data for 2003 to 2006 indicate that approximately 10.2% (11.5 million) of women older than 20 years have diabetes. Data indicate that new cases of type 2 diabetes mellitus are occurring at an increasing rate among American Indian, African American, Hispanic, and Latino children and adolescents (http://diabetes.niddk.nih.gov/dm). Continued immigration among populations with high rates of type 2 diabetes mellitus and the effects of changes in diet (increases in number of calories and fat content) and lifestyle (sedentary) portend marked rises in the percentage of patients with preexisting diabetes who will become pregnant in the future. There is also an epidemic of childhood obesity currently under way in the United States, with approximately 23 million (30%) children and youth who are overweight. This trend will have a profound effect on obstetrics and pediatric practice in the future. Expanded efforts to reach the populations at risk are necessary if a significant increase in maternal and neonatal morbidity is to be avoided (Persson and Hanson, 1998).

Depending on the population surveyed, abnormalities of glucose regulation occur in 3% to 8% of pregnant women. Although more than 80% of this glucose intolerance arises only during pregnancy (gestational diabetes) and involves relatively modest episodes of hyperglycemia, the attendant fetal and newborn morbidity is disproportionate. Compared with weight-matched controls, infants of diabetic mothers (IDMs) have double the risk of serious birth injury, triple the likelihood of cesarean section, and quadruple the incidence of admission to a newborn intensive care unit. Studies indicate that the magnitude of risk of these maloccurrences is proportional to the level of maternal hyperglycemia. Therefore, to some extent, the excessive fetal and neonatal morbidity of diabetes in pregnancy is preventable or at least reducible through meticulous prenatal and intrapartum care.

MATERNAL-FETAL METABOLISM IN NORMAL PREGNANCY AND DIABETIC PREGNANCY

Normal Maternal Glucose Regulation

With each meal, a complex combination of maternal hormonal actions, including the secretion of pancreatic insulin, glucagon, somatomedins, and adrenal catecholamines, ensures an ample but not excessive supply of glucose to the mother and fetus during pregnancy. The key effects of pregnancy on maternal metabolic regulation are as follows:

- Because the fetus continues to draw glucose from the maternal bloodstream across the placenta, even during periods of fasting, the tendency toward maternal hypoglycemia between meals becomes increasingly marked as pregnancy progresses and fetal glucose demand grows.
- Placental steroid and peptide hormone production (estrogens, progesterone, and chorionic somatomammotropin) rises linearly throughout the second and third trimesters, resulting in a progressively increasing tissue resistance to maternal insulin action.
- Progressive maternal insulin resistance requires a significant augmentation in pancreatic insulin production (more than twofold nonpregnant levels) during feeding to maintain euglycemia. Twenty-four–hour mean insulin levels are 30% higher in the third trimester than in the nonpregnant state.
- If pancreatic insulin output is not adequately augmented, maternal hyperglycemia and then fetal hyperglycemia result. The severity of hyperglycemia and its timing depend on the relative inadequacy of insulin production.

Fetal Effects of Maternal Hyperglycemia

Congenital Anomalies

A major threat to IDMs is the possibility of a life-threatening structural anomaly. In the normoglycemic pregnancy, the risk of a major birth defect is 1% to 2%. Among women with pregestational diabetes, the risk of a fetal structural anomaly is fourfold to eightfold higher. In a recent cohort study of 2359 pregnancies in women with pregestational diabetes, the rate of anomalies was more than doubled. Major congenital anomalies occurred in 4.6% overall with 4.8% for type 1 diabetes mellitus and 4.3% for type 2 diabetes mellitus. This is a significant increase over the expected rate of birth defects in the general population (approximately 1.5%). Neural tube defects in IDM were increased 4.2-fold (Figure 9-1), and congenital heart disease by 3.4-fold. Prenatal diagnosis of these anomalies was accomplished in 65% of neonates (Macintosh et al, 2006). The typical defects and their frequency of occurrence,

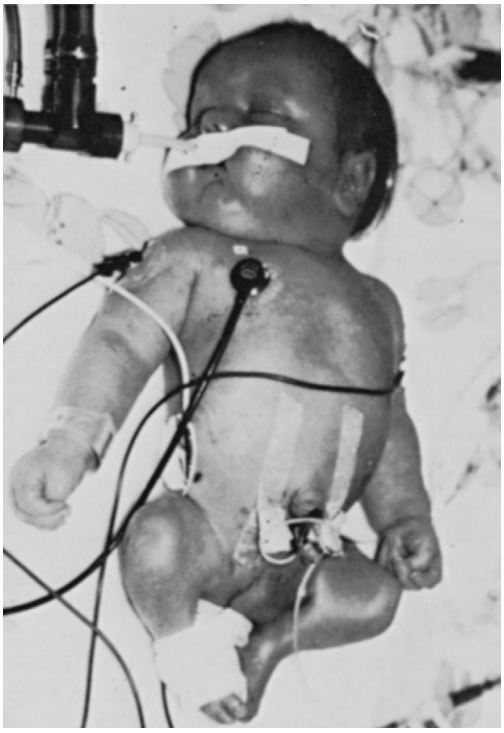

FIGURE 9-1 Newborn with caudal regression syndrome, macrosomia, and respiratory distress. The mother had type 1 diabetes and a glycosylated hemoglobin concentration of 13.5% when first seen for prenatal care at 12 weeks' gestation. *(From Creasy RK, Resnik R, editors:* Maternal-fetal medicine: principles and practice, *ed 2, Philadelphia, 1989, WB Saunders.)*

TABLE 9-1 Congenital Malformations in Infants of Mothers With Insulin-Dependent Diabetes

Anomaly	Appropriate Risk Ratio	Risk (%)
All cardiac defects	18×	8.5
All central nervous system anomalies	16×	5.3
Anencephaly	13×	–
Spina bifida	20×	–
All congenital anomalies	8×	18.4

Becerra JE, Khoury MJ, Cordero JF, et al: Diabetes mellitus during pregnancy and the risks for specific birth defects: a population based case-control study, *Pediatrics* 85:1, 1990.

noted in a prospective study of infants with major malformations, are listed in Table 9-1. The majority of lesions involve the central nervous and cardiovascular systems, although other series have reported an excess of genitourinary and limb defects (Cousins, 1991).

There is no increase in birth defects among offspring of diabetic fathers, nondiabetic women, or women in whom gestational diabetes develops after the first trimester. These findings suggest that glycemic control during embryogenesis is a critical factor in the genesis of diabetes-associated birth defects. In a study by Miller et al (1981), the frequency of congenital anomalies was proportional to the maternal glycohemoglobin (HbA_{1c}) value in the first trimester (rate of anomalies 3.4% with HbA_{1c} <8.5%, and 22.4% with HbA_{1c} >8.5%). Lucas et al (1989) reported a similar experience with 105 diabetic patients, finding an overall malformation rate of 13.3%. A recent study conducted in the United Kingdom from 1991 to 2000 in patients with type 1 diabetes mellitus found similar results (Temple et al, 2002). Adverse outcome was significantly higher in the poor control group (HbA_{1c} ≥7.5) than in the fair control group (HbA_{1c} <7.5), with a ninefold increase in the congenital malformation rate (relative risk, 9.2; 1.1 to 79.9) (Temple et al, 2002). For a woman with an HbA_{1c} value of less than 7.1%, the risk of delivering a malformed infant was equivalent or slightly less than that for the normoglycemic population. However, the anomaly rate rose progressively with increasing HbA_{1c}, 14% with an HbA_{1c} value of 7.2% to 9.1%, 23% with an HbA_{1c} value of 9.2% to 11.1%, and 25% with an HbA_{1c} value of greater than 11.2%.

Pathogenesis

The specific mechanisms by which hyperglycemia disturbs embryonic development are incompletely elucidated, but reduced levels of arachidonic acid and *myo*-inositol and accumulation of sorbitol and trace metals in the embryo have been demonstrated in animal models (Pinter et al, 1986). Fetal hyperglycemia may promote excessive formation of oxygen radicals in the mitochondria of susceptible tissues, leading to the formation of hydroperoxides, which inhibit prostacyclin. The resulting overabundance of thromboxanes and other prostaglandins may then disrupt vascularization of developing tissues. In support of this theory, the addition of prostaglandin inhibitors to mouse embryos in culture medium prevents glucose-induced embryopathy. Furthermore, the addition of dietary antioxidants in the form of high doses of vitamins C and E decreased fetal dysmorphogenesis to nondiabetic levels in rat pregnancy and rat embryo culture (Cederberg and Eriksson, 2005; El-Bassiouni et al, 2005).

Prevention

Because the critical period for teratogenesis is the first 3 to 6 weeks after conception, normal glycemic control must be instituted before pregnancy to prevent these birth defects. Several clinical trials of meticulous preconception glycemic control in women with diabetes have resulted in malformation rates equivalent to those in the general population (Fuhrmann et al, 1983). A recent metaanalysis of these trials demonstrated that the pooled risk of malformations was lower in women with preconception care compared with those without preconception counseling (Ray et al, 2001). The threshold level of glycemic control, as evidenced by the HbA_{1c} value, necessary to normalize a patient's risk of congenital anomalies appears to be a near-normal value. Thus any elevation of the HbA_{1c} above normal increases the risk of teratogenesis proportionately.

Macrosomia

Fetal overgrowth is a major problem in pregnancies complicated by diabetes, leading to unnecessary cesarean sections and potentially avoidable birth injuries. A 1992 study of birthweights in the previous 20 years indicated that 21% of infants with birthweights of 4540 g or greater were born to mothers who were glucose intolerant, a rate clearly disproportionate to the only 2% to 5% of gravidas with some form of diabetes (Shelley-Jones et al, 1992). Thus the

problem of abnormal fetal growth in diabetic pregnancy remains an important clinical challenge.

Macrosomia is defined variously as birthweight above the 90th percentile for gestational age or birthweight greater than 4000 g; it occurs in 15% to 45% of diabetic pregnancies. Excessive fetal size contributes to a greater frequency of intrapartum injury (shoulder dystocia, brachial plexus palsy, and asphyxia). Macrosomia is also a major factor in the higher rate of cesarean delivery among diabetic women. Because the risk of macrosomia is fairly constant for all classes of diabetes, it is likely that first-trimester metabolic control has less of an effect on fetal growth than does glycemic regulation in the second and third trimesters.

Growth Dynamics

IDMs with macrosomia follow a unique pattern of in utero growth compared with fetuses in euglycemic pregnancies. During the first and second trimesters, differences in size between fetuses born to diabetic and nondiabetic mothers are usually undetectable with ultrasound measurements. After 24 weeks, however, the growth velocity of the IDM fetus' abdominal circumference typically begins to rise above normal (Ogata et al, 1980). Reece et al (1990) demonstrated that the IDM fetus has normal head growth, despite marked degrees of hyperglycemia. Landon et al (1989) have reported that although head growth and femur growth of IDM fetuses were similar to those of normal fetuses, abdominal circumference growth significantly exceeded that of controls beginning at 32 weeks' gestation (abdominal circumference growth in IDM fetuses is 1.36 cm/week, versus 0.901 cm/week in normal subjects).

Morphometric studies of the IDM newborn indicate that the greater growth of the abdominal circumference is caused by deposits of fat in the abdominal and interscapular areas. This central depositing of fat is a key characteristic of diabetic macrosomia and underlies the pathology associated with vaginal delivery in these pregnancies. Acker et al (1986) showed that although the incidence of shoulder dystocia is 3% among infants weighing more than 4000 g, the incidence in infants from diabetic pregnancies who weigh more than 4000 g is 16%. Finally, despite our emphasis on birthweight, this alone may not be a sensitive measure of fetal growth. Catalano et al (2003) conducted body composition studies on infants born to mothers with diabetes and found that even when appropriate for gestational age, these infants have increased fat mass and percent body fat compared with a normoglycemic control group.

Childhood Effects

Higher growth velocity, begun in fetal life during a pregnancy complicated by diabetes, may extend into childhood and adult life. Silverman et al (1995) reported follow-up of IDMs through age 8 years in which half the infants weighed more than the 90th percentile for gestational age at birth. By age 8 years, approximately half of the IDMs weighed more than the heaviest 10% of the nondiabetic children. The asymmetry index was 30% higher in diabetic offspring than in the controls by age 8 years. These investigators also showed that offspring with diabetes have permanent derangement of glucose-insulin kinetics, resulting in a higher incidence of impaired glucose tolerance. In addition, Dabelea et al (2000) also reported that the mean adolescent body mass index was 2.6 kg/m^2 greater in sibling offspring of diabetic pregnancies compared with the index siblings born when the mother previously had normal glucose tolerance.

Pathophysiology

The pathophysiology of excessive fetal growth is complex and reflects the delivery of an abnormal nutrient mixture to the fetoplacental unit, regulated by an abnormal confluence of growth factors. Pedersen (1952) hypothesized that maternal hyperglycemia stimulates fetal hyperinsulinemia, which in turn mediates acceleration of fuel utilization and growth. The features of the abnormal growth in diabetic pregnancy include excessive adipose deposition, visceral organ hypertrophy, and acceleration of body mass accretion (Ogata et al, 1980).

Data from the Diabetes in Early Pregnancy project suggest that maternal metabolic control is a critical factor leading to fetal macrosomia (Jovanovic-Peterson et al, 1991). In this study, in which meticulous glycemic care was maintained in early pregnancy and beyond, fetal weight did not correlate significantly with fasting glucose levels. During the second and third trimesters, however, postprandial blood glucose levels were strongly predictive of both birthweight and the overall percentage of macrosomic infants. With postprandial glucose values averaging 120 mg/dL, approximately 20% of infants had macrosomia; a 30% rise in postprandial levels to 160 mg/dL resulted in a predicted percentage of macrosomia of 35%. In contrast, Persson et al (1996) showed that fasting glucose concentrations account for 12% of the variance in birthweight and correlated best with estimates of neonatal fat. Similarly, Uvena-Celebrezze et al (2002) found that the strongest correlation was between fasting glucose and neonatal adiposity rather than postprandial measures.

The Pedersen hypothesis (Pedersen, 1977) presumes that abnormal fuel milieu in the maternal bloodstream is reflected contemporaneously in the fetal compartment: *Maternal hyperglycemia = Fetal hyperglycemia*. Studies by Hollingsworth and Cousins (1981) have confirmed much of Pedersen's hypothesis and note the following features of normal pregnancy:

- Maternal fasting blood glucose levels decline from approximately 85 mg/dL to 75 mg/dL. Mean blood glucose also declines.
- At night, maternal glucose levels drop markedly as the fetus continues to draw glucose stores from the maternal circulation.
- Postprandial peaks in maternal blood glucose rarely exceed 120 mg/dL at 2 hours or 130 mg/dL at 1 hour.

In addition, in diabetic pregnancies:

- If maternal glucose levels surge excessively after a meal, the consequent fetal hyperglycemia is accompanied by fetal pancreatic beta-cell hyperplasia and hyperinsulinemia.
- Fetal hyperinsulinemia, lasting only episodically for 1 to 2 hours, has detrimental consequences for fetal growth and well-being, in that it (1) promotes storage of excess nutrients, resulting in macrosomia, and (2) drives catabolism of the oversupply of fuel, using energy and depleting fetal oxygen stores.

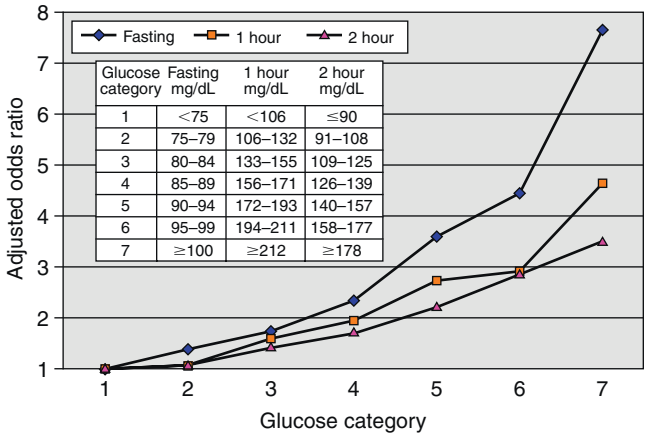

FIGURE 9-2 Adjusted odds ratios for cord C-peptide levels at >90th percentile at different glucose categories based on a 2-hour oral glucose challenge test. (*Adapted from HAPO Study Cooperative Research Group, Metzger BE, Lowe LB, et al: Hyperglycemia and adverse pregnancy outcomes*, N Engl J Med *358:1991-2002, 2008*.)

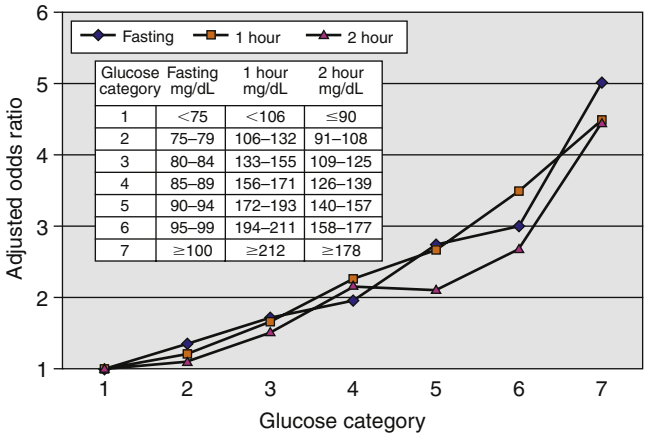

FIGURE 9-3 Adjusted odds ratios for macrosomia at >90th percentile at different glucose categories based on a 2-hour oral glucose challenge test. (*Adapted from HAPO Study Cooperative Research Group, Metzger BE, Lowe LB, et al: Hyperglycemia and adverse pregnancy outcomes*, N Engl J Med *358:1991-2002, 2008*.)

- Episodic fetal hypoxia stimulated by episodic maternal hyperglycemia leads to an outpouring of adrenal catecholamines, which in turn causes hypertension, cardiac remodeling, and cardiac hypertrophy.

The Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study provided additional evidence in support of the Pedersen hypothesis. In this well-designed, multicenter prospective trial, women underwent a 75-g oral glucose challenge test between 28 and 32 weeks' gestation. Providers were blinded to test results if the fasting value was 105 mg/dL or less and the 2-hour plasma glucose level was 200 mg/dL or less. The women did not receive any therapeutic intervention. The study found a continuous association between maternal glucose values, cord C-peptide levels (Figure 9-2) and birthweight above the 90th percentile (Figure 9-3) (HAPO Study Cooperative Research Group et al, 2008). A followup analysis of the same cohort evaluating neonatal anthropometric measurements, found a link between maternal hyperglycemia, cord C-peptide levels and neonatal adiposity (HAPO Study Cooperative Research Group et al, 2009). This study suggested that maternal hyperglycemia results in neonatal adiposity that is mediated by fetal insulin production (C-peptide level >90th percentile) (HAPO Study Cooperative Research Group et al, 2009).

Prevention of Macrosomia

Because macrosomic fetuses are at an increased risk for immediate complications related to birth injury and for potential long-term consequences such as late childhood obesity and insulin resistance, measures for prevention of macrosomia have been recommended. As described previously, fetal hyperinsulinemia, which acts as a fetal growth factor, occurs in response to fetal hyperglycemia, which in turn reflects the maternal hyperglycemic condition. Therefore, measures that promote consistent maternal euglycemia may prevent macrosomia. Several prospective trials have shown that strict maternal glycemic control using insulin and dietary therapy and fastidious blood glucose monitoring can reduce the incidence of macrosomia (Coustan and Lewis, 1978; Langer et al, 1994; Thompson et al, 1990). Langer et al (1994) compared the outcomes of diabetic pregnancies managed conventionally (four blood glucose measurements per day) or intensely (seven blood glucose measurements per day). Fasting blood glucose values were maintained between 60 and 90 mg/dL and 2-hour postprandial values at less than 120 mg/dL. Outcomes were compared to nondiabetic control pregnancies. The rate of infants born weighing more than 4000 g was 14% in the conventionally managed group, 7% in the intensely managed group, and 8% in nondiabetic controls. Similarly, the rate of shoulder dystocia was 1.4% in the conventionally managed group, 0.4% in the intensely managed group, and 0.5% in the control group. Thus, like the reduction of congenital anomalies in mothers with diabetes by means of first-trimester euglycemia, strict glycemic control in the second and third trimesters may reduce the fetal macrosomia rate to near baseline.

Fetal Hypoxic Stress

As noted previously, episodic maternal hyperglycemia promotes a fetal catabolic state in which oxygen depletion occurs. Several fetal metabolic adaptive responses to this episodic hypoxia occur. For example, the drop in fetal oxygen tension causes stimulation of erythropoietin, red cell hyperplasia, and elevation in fetal hematocrit. Polycythemia can lead to poor circulation and postnatal hyperbilirubinemia. Profound episodic hyperglycemia in the third trimester causing severe fetal hypoxic stress has been theorized as the cause of sudden intrauterine fetal demise in poorly controlled diabetes.

CLASSIFYING AND DIAGNOSING DIABETES IN PREGNANCY

The classification system for diabetes in pregnancy recommended by White has been replaced by a scheme based on the pathophysiology of hyperglycemia and developed by the National Diabetes Data Group (NDDG) in 1979 (Hare and White, 1980). The two types are summarized

in Table 9-2. This nomenclature is useful because it categorizes patients according to the underlying pathogenesis of their diabetes—insulin-deficient (type 1) and insulin-resistant (type 2 and gestational). One must remember that the diagnosis of gestational diabetes applies to any woman who is found to have hyperglycemia during pregnancy. A certain percentage of such women actually have type 2 diabetes, but the diagnosis cannot be confirmed until postpartum testing.

Pregestational Diabetes

Patients with type 1 diabetes mellitus typically exhibit hyperglycemia, ketosis, and dehydration in childhood or adolescence. Often the diagnosis is made during a hospital admission for diabetic ketoacidosis and coma. Rarely is the diagnosis of type 1 diabetes mellitus made during pregnancy. Conversely, it is not unusual for women with a tentative diagnosis of gestational diabetes to be found to have overt, type 2 diabetes mellitus after delivery. The American Diabetic Association has outlined three criteria for diagnosing type 2 diabetes mellitus in nonpregnant subjects. They include the finding of a casual plasma glucose of 200 mg/dL or greater, a fasting plasma glucose of 126 mg/dL or greater, or a 2-hour glucose value of 200 mg/dL or greater on a 75-g, 2-hour glucose tolerance test (GTT). Diagnostic criteria are listed in Box 9-1.

Gestational Diabetes

Gestational diabetes mellitus (GDM) is defined as glucose intolerance that begins or is first recognized during pregnancy (American Diabetes Association, 2002). Almost uniformly, GDM arises from significant maternal insulin resistance, a state similar to type 2 diabetes mellitus. In many cases, GDM is simply preclinical type 2 diabetes mellitus unmasked by the hormonal stress imposed by the pregnancy. Although GDM complicates no more than 5% to 6% of pregnancies in the United States, the prevalence of GDM in specific populations varies from 1% to 14% (American Diabetes Association, 2002). Clinical recognition of GDM is important because therapy—including medical nutrition therapy, insulin when necessary, and antepartum fetal surveillance—can reduce the well-described perinatal morbidity and mortality associated with GDM.

Traditionally, universal screening for GDM has been recommended (Metzger, 1991). However, the Fourth International Workshop-Conference on Gestational Diabetes and the American College of Obstetricians and Gynecologists have now indicated that either a risk-factor approach or universal screening can be considered (American College of Obstetricians and Gynecologists, 2001; Metzger and Coustan, 1998). This recommendation is based on the findings of Sermer et al (1994), who reported the results of screening Canadian women at 26 weeks' gestation with the 100-g, 3-hour GTT. They identified several risk factors as significantly increasing the likelihood of GDM, among which were maternal age of 35 years or more, body mass index higher than 22 kg/m^2, and Asian or other ethnicity than white. Women with one or no risk factors had a 0.9% risk of GDM, whereas the risk for those with two to five factors was 4% to 7%. By limiting screening for GDM to patients with more than one risk factor, these investigators were able to reduce testing by 34% while retaining a sensitivity rate of approximately 80%, with a false-positive result rate of 13%. Therefore in patients meeting all criteria listed in Table 9-3 and Box 9-2, it may be cost effective to avoid screening. Currently a multicenter trial is underway by National Institute of Child Health and Human Development Maternal Fetal Medicine Unit Network in which women with GDM will be randomized to standard therapy versus no therapy (Landon et al, 2009). This randomized study will address whether identification and treatment of GDM decrease perinatal morbidity.

Notwithstanding these findings, multiple studies from more heterogeneous U.S. populations have demonstrated

TABLE 9-2 Classification of Diabetes Mellitus

Type	Old Nomenclature	Clinical Features
Type 1	Juvenile-onset diabetes	Insulin-deficient, ketosis-prone; virtually all patients with type 1 diabetes mellitus are insulin dependent
Type 2	Adult-onset diabetes	Insulin-resistant, not ketosis-prone; few patients with type 2 diabetes mellitus are truly insulin dependent
Gestational	—	Occurs during and resolves after pregnancy; insulin-resistant; not ketosis-prone

BOX 9-1 Criteria for the Diagnosis of Type 2 Diabetes Mellitus

- Symptoms of diabetes (polyuria, polydipsia, and unexplained weight loss) and a casual plasma glucose level >200 mg/dL (11.1 mmol/L). *Casual* is defined as any time of day without regard to time of last meal, or
- Fasting glucose level >126 mg/dL (7.0 mmol/L). *Fasting* is defined as no caloric intake for at least 8 hours, or
- Two-hour plasma glucose >200 mg/dL (11.1 mmol/L) during a 75-g oral glucose challenge test.

Adapted from the American Diabetes Assoication: Clinical practice recommendations: Standards of medical care for diabetes, 2007, *Diabetes Care* 30:s4-s41, 2007.

TABLE 9-3 Oral Glucose Tolerance Test for Gestational Diabetes

	Venous Plasma Glucose Level*			
	100-g Glucose Load		75-g Glucose Load	
	mg/dL	mmol/L	mg/dL	mmol/L
Fasting value	95	5.3	95	5.3
1-hr value	180	10.0	180	10.0
2-hr value	155	8.6	155	8.6
3-hr value	140	7.8	—	—

*Test prerequisites: 1-hr, 50-g glucose challenge result >135 mg/dL; overnight fast of 8 to 14 hours; carbohydrate loading for 3 days, including >150 g carbohydrate; seated and not smoking during the test; two or more values must be met or exceeded; either a 2-hr (75-g glucose) or 3-hr (100-g glucose) test can be performed.

BOX 9-2 Criteria for Low Risk of Gestational Diabetes*

- Age <25 years
- Normal prepregnancy body weight
- No first-degree relatives with diabetes
- Not a member of an ethnic group at high risk for GDM
- No history of GDM in prior pregnancy
- No history of adverse pregnancy outcome

Data from Metzger BE, Coustan DR: Summary and Recommendations of the Fourth International Workshop-Conference on Gestational Diabetes Mellitus. The Organizing Committee, *Diabetes Care* 21(Suppl 2):B161-B167, 1998.
GDM, Gestational diabetes mellitus.
*Screening for GDM may be omitted only if all criteria are met.

BOX 9-3 Indications for the First-Trimester 50-g Glucose Challenge

- Maternal age >25 years
- Previous infant >4 kg
- Previous unexplained fetal demise
- Previous pregnancy with gestational diabetes
- Strong immediate family history of type 2 or gestational diabetes mellitus
- Maternal obesity (>90 kg)
- Fasting glucose level >140 mg/dL (7.8 mmol/L) or random glucose reading >200 mg/dL (11.1 mmol/L)

the inadequacy of risk factor based screening of patients for GDM. Lavin et al (1981) noted that if only those with risk factors were screened, the percentage of GDM cases detected was similar to the detection rate in those without risk factors (1.4%). A later study (Weeks et al, 1995), which assessed the effect of screening only patients with risk factors, reported that selective screening would have failed to detect 43% of cases of GDM. Moreover, 28% of the women with undiagnosed GDM would have required insulin and had a several-fold higher risk of cesarean section because of macrosomia.

Universal screening should be performed in women in ethnic groups at a higher risk for glucose intolerance during pregnancy, namely those of Hispanic, African, Native American, South or East Asian, Pacific Islands, or Indigenous Australian ancestry. For simplicity of administration, universal screening, with the possible exception of the lowest risk category, is probably best. The universal screening method for GDM has been shown to result in earlier diagnosis and improved pregnancy outcomes, including lower rates of macrosomia and a decrease in neonatal admissions to neonatal intensive care units (Griffin et al, 2000).

The timing of screening for GDM is important. Because maternal insulin resistance rises progressively during pregnancy, screening too early can miss some patients who will become glucose intolerant later. Screening too late in the third trimester can limit the time during which metabolic interventions can take place. Thus, risk factors for GDM should be assessed at the initial prenatal visit. Factors that should lead to a first-trimester glucose challenge test are listed in Box 9-3. In the remaining patients, screening should be performed with the use of 50 g of glucose at 26 to 28 weeks' gestation.

Various threshold levels for the 50-g glucose challenge are in use, including 140 mg/dL, 135 mg/dL, and 130 mg/dL. The sensitivity of the GDM testing regimen depends on the threshold value used. The most commonly used threshold, 140 mg/dL, detects only 80% of patients with GDM and results in requiring a 3-hour oral GTT in approximately 10% to 15% of patients. Using a challenge threshold of 135 mg/dL improves sensitivity to more than 90% but increases the number of 3-hour oral GTTs by 42% (Ray et al, 1996). Thus, the clinician encountering a newborn with multiple stigmata of an IDM, yet whose mother had a negative diabetes screening test result, should realize that this result during pregnancy does not rule out GDM. This is also why every patient who delivered an infant with macrosomia in a prior pregnancy should be screened early in all subsequent pregnancies.

Definitive diagnosis of gestational diabetes is made with a GTT. Either 100 g of glucose and 3 hours of testing, or 75 g of glucose and 2 hours of testing can be used. The diagnostic criteria are shown in Box 9-1. Two or more values must be met or exceeded for the diagnosis of GDM to be made. A GTT should be performed after overnight fasting and with modest carbohydrate loading before the test.

PERINATAL COMPLICATIONS OF DIABETES DURING PREGNANCY

Fetal Morbidity and Mortality

Perinatal Mortality

Perinatal mortality in diabetic pregnancy has decreased 30-fold since the discovery of insulin in 1922 and the advent of intensive obstetric and infant care in the 1970s (Figure 9-4). Improved techniques for maintaining maternal euglycemia have led to later timing of delivery and have reduced the incidence of iatrogenic respiratory distress syndrome (RDS).

Nevertheless, the currently reported perinatal mortality rates among women with diabetes remain approximately twice those observed in nondiabetic women (Table 9-4). Congenital malformations, RDS, and extreme prematurity account for most perinatal deaths in contemporary diabetic pregnancy. Figure 9-5 shows the different rates of RDS in diabetic and euglycemic pregnancies. In the past decade, fewer intrauterine deaths have been reported, probably reflecting more careful fetal monitoring. Nevertheless, intrapartum asphyxia and fetal demise remain persistent problems.

Birth Injury

Birth injury, including shoulder dystocia (Keller et al, 1991) and brachial plexus trauma, is more common among IDMs, and macrosomic fetuses are at the highest risk (Mimouni et al, 1992). Shoulder dystocia, defined as difficulty in delivering the fetal body after expulsion of the fetal head, is an obstetric emergency that places the fetus and mother at great risk. Shoulder dystocia occurs in 0.3% to 0.5% of vaginal deliveries among normal pregnant women; the incidence is twofold to fourfold higher in women with diabetes, probably because the hyperglycemia in a diabetic pregnancy causes the fetal shoulder and abdominal widths

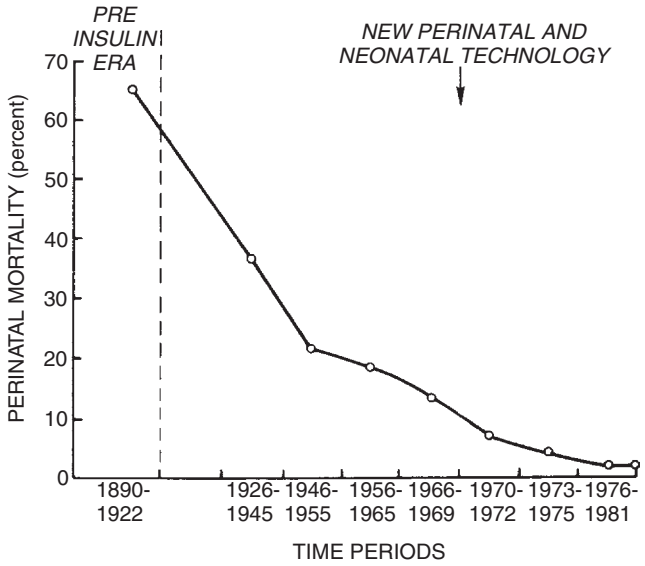

FIGURE 9-4 Perinatal mortality rate (percentage) among infants of diabetic mothers from 1890 to 1981. *(From Creasy RK, Resnik R, editors:* Maternal-fetal medicine: principles and practice, *ed 2, Philadelphia, 1989, WB Saunders. to become massive (Nesbitt et al, 1998). This relationship was investigated by Athukorala et al, (2007), who found a strong association with fasting hyperglycemia such that with each 1-mmol increase in the fasting value in the oral glucose-tolerance test there was an increasing relative risk (RR) of 2.09 (95% confidence interval [CI], 1.03 to 4.25) for shoulder dystocia. Although half of shoulder dystocias occur in infants of normal birthweight (2500 to 4000 g), the incidence of shoulder dystocia is 10-fold higher (5% to 7%) among infants weighing 4000 g or more and rises to 31% for infants whose mothers have diabetes (Gilbert et al, 1999; see also Chapter 15 for a discussion of complicated deliveries and Chapter 64 for a discussion of the neurologic consequences of birth injury.)

Neonatal Morbidity and Mortality

For a complete discussion of neonatal morbidity and mortality, see Chapter 94.

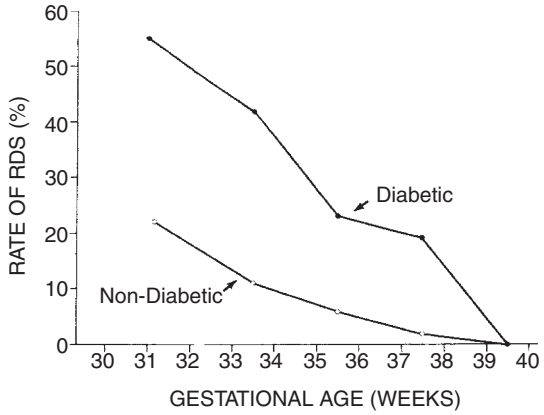

FIGURE 9-5 Rate of respiratory distress syndrome (RDS) versus gestational age. Improved management of maternal glycemic control permits delaying delivery until after 38 weeks' gestation, when the risk of RDS approaches that in nondiabetic pregnancy. *(From Moore TR: A comparison of amniotic fluid fetal pulmonary phospholipids in normal and diabetic pregnancy,* Am J Obstet Gynecol *186:641-650, 2002.)*

Polycythemia and Hyperviscosity

Polycythemia (defined as central venous hemoglobin concentration >20 g/dL or hematocrit >65%) is not uncommon in IDMs and is apparently related to glycemic control. Widness et al (1990) demonstrated that hyperglycemia is a powerful stimulus to fetal erythropoietin production, probably mediated by decreased fetal oxygen tension. Neonatal polycythemia may promote vascular sludging, ischemia, and infarction of vital tissues, including the kidneys and central nervous system.

Neonatal Hypoglycemia

Approximately 15% to 25% of neonates delivered from women with diabetes during gestation will develop hypoglycemia during the immediate newborn period (Alam et al, 2006). This complication is usually much milder and less common in the infant of a woman whose insulin-dependent diabetes is well controlled throughout the entire pregnancy and who exhibits euglycemia during labor and delivery. Unrecognized postnatal hypoglycemia can lead to neonatal seizures, coma, and brain damage; therefore, it is imperative that the nurseries receiving IDMs have a protocol for frequent monitoring of the infant's blood glucose level until metabolic stability is ensured.

Hyperbilirubinemia

The risk of hyperbilirubinemia is higher in IDMs than in normal infants. There are multiple causes of hyperbilirubinemia in IDMs, but prematurity and polycythemia are the primary contributing factors. Increased destruction of red blood cells contributes to the risks of jaundice and kernicterus. This complication is usually managed using phototherapy, but exchange transfusions may be necessary for marked bilirubin elevations.

Hypertrophic and Congestive Cardiomyopathy

In some infants with macrosomia of mothers with poorly controlled diabetes, a thickened myocardium and significant septal hypertrophy have been described (Gutgesell et al, 1976). Although the prevalence of myocardial

hypertrophy in IDMs may exceed 30% at birth, almost all cases have resolved by 1 year of age (Mace et al, 1979).

Hypertrophic cardiac dysfunction in a newborn IDM often leads to respiratory distress, which may be mistaken for hyaline membrane disease. IDMs with cardiomegaly may have either congestive or hypertrophic cardiomyopathy. Echocardiograms show a hypercontractile, thickened myocardium, often with septal hypertrophy disproportionate to the ventricular free walls. The ventricular chambers are often smaller than normal, and there may be anterior systolic motion of the mitral valve, producing left ventricular outflow tract obstruction.

The pathogenesis of hypertrophic cardiomyopathy in IDMs is unclear, although it is recognized to be associated with poor maternal metabolic control. There is evidence that the fetal myocardium is particularly sensitive to insulin during gestation, and Susa et al (1979) reported a doubling of cardiac mass in hyperinsulinemic fetal rhesus monkeys. The myocardium is known to be richly endowed with insulin receptors. Recently maternal insulin-like growth factor-1 (IGF-1), which is elevated in suboptimally controlled diabetic pregnancies, has been shown to be significantly elevated among neonates with asymmetrical septal hypertrophy. Because IGF-1 does not cross the placenta, it can exert its action through binding to the IGF-1 receptor on the placenta (Hayati et al, 2007). Halse et al (2005) noted that B-type natriuretic peptide, a marker for congestive cardiac failure, is elevated in neonates whose mothers had poor glycemic control during the third trimester.

IDMs can also have congestive cardiomyopathy without hypertrophy. Echocardiography shows the myocardium to be overstretched and poorly contractile (Jaeggi et al, 2001). This condition is often rapidly reversible with correction of neonatal hypoglycemia, hypocalcemia, and polycythemia; it responds to digoxin, diuretics, or both. In contrast, treatment of hypertrophic cardiomyopathy with an inotropic or diuretic agent tends to further decrease the size of the ventricular chambers and leads to obstruction of blood flow. Prenatal echocardiogram can identify septal hypertrophy and other structural abnormalities, but routine fetal echocardiogram in diabetics has not been proved to be cost-effective or to improve outcomes (Bernard et al, 2009).

Respiratory Distress Syndrome

Since the 1970s, improved maternal management and better protocols for timing of delivery have resulted in a dramatic decline in the incidence of RDS from 31% to 3%. Nevertheless, respiratory dysfunction in the newborn IDM continues to be a common complication of diabetic pregnancy; it may be because of surfactant deficiency or another form of pulmonary distress. Surfactant production occurs late in diabetic pregnancies. Studies of fetal lung ion transport in the diabetic rat by Pinter et al (1991) demonstrated decreased fluid clearance and a lack of thinning of the lung's connective tissue in diabetic rats compared with controls. In humans, Kjos et al (1990) noted respiratory distress in 18 of 526 infants delivered after diabetic gestations (3.4%). Surfactant-deficient airway disease accounted for fewer than one third of cases, with transient tachypnea, hypertrophic cardiomyopathy, and pneumonia responsible for the majority.

As a result, the near-term infant of a mother with poorly controlled diabetes is more likely to have neonatal RDS than the infant of a mother without diabetes at the same gestational age. This circumstance further compounds the diabetic infant's metabolic and cardiovascular difficulties after birth. The fetus without diabetes achieves pulmonary maturity at a mean gestational age of 34 to 35 weeks. By 37 weeks' gestation, more than 99% of normal newborn infants have mature lung profiles as assessed by phospholipid assays. In a diabetic pregnancy, however, it is unwise to assume that the risk of respiratory distress has passed until after 38.5 weeks' gestation (Moore, 2002). Any delivery contemplated before 38.5 weeks' gestation for other than the most urgent fetal and maternal indications should be preceded by documentation of pulmonary maturity through amniocentesis.

OBSTETRIC COMPLICATIONS

Pregnancy complicated by diabetes is subject to a number of obstetric disorders, including ketoacidosis, preeclampsia, polyhydramnios, and abnormal labor, at higher rates than in nondiabetic pregnancy.

Preeclampsia

Preeclampsia is an unpredictable multisystem disorder in which maternal neurologic, renal, and cardiovascular status can decline precipitously, which can threaten fetal health through placental ischemia and abruptio placentae. Preeclampsia is more common among women with diabetes, occurring two to three times more frequently in women with pregestational diabetes than in nondiabetic women (Moore et al, 1985; Sibai et al, 2000). However, the risk of developing preeclampsia is proportional to the duration of diabetes before pregnancy and the existence of nephropathy and hypertension; preeclampsia develops in more than one third of women who have had diabetes for more than 20 years. Patients with type 2 diabetes mellitus without complications have a risk profile similar to that of patients without diabetes, but the risk of hypertensive complications is 50% higher in women with evidence of renal or retinal vasculopathy than in those with no hypertension. The rate of fetal death is higher in women with diabetes and preeclampsia. In the patient with diabetes and chronic hypertension, preeclampsia may be difficult to distinguish from near-term blood pressure elevations. The onset is typically insidious and not confidently recognized until it is severe. Renal function assessment (creatinine, blood urea nitrogen, uric acid, and 24-hour urine collection) should be performed each trimester in women with evidence of pregestational diabetes and vascular disease.

When a patient with diabetes experiences preeclampsia, she should be evaluated for delivery. If signs of severe disease are present (e.g., blood pressure >160 mm Hg systolic and 110 mm Hg diastolic, neurologic symptoms, or significant renal dysfunction), delivery should be performed promptly. In mild cases, the patient may be observed if the fetal lungs are immature. Preeclampsia after 38 weeks' gestation, however, is appropriate grounds for initiating delivery.

Polyhydramnios

Polyhydramnios is defined as excess amniotic fluid. The precise clinical definition varies, encompassing the recording of more than 2000 mL of amniotic fluid at delivery and various measures of amniotic fluid pocket depths as observed on ultrasonography. In practice, polyhydramnios is usually diagnosed when any single vertical pocket of amniotic fluid is deeper than 8 cm (equivalent to the 97th percentile) or when the sum of four pockets, one from each quadrant of the uterus (amniotic fluid index), exceeds approximately 24 cm (95th percentile; Moore and Cayle, 1990). The principal cause of hydramnios in diabetic pregnancies is usually poor glycemic control, although fetal gastrointestinal anomalies (e.g., esophageal atresia) need to be excluded. A rapid increase in fundal height should prompt a thorough ultrasound examination by a skilled examiner. The main clinical problems associated with hydramnios are fetal malposition and preterm labor.

Management of the patient with hydramnios is predominantly symptomatic, focused on improving glycemic control and preventing premature labor. Enhanced patient awareness of contractions and the signs and subtle sensations of preterm labor is essential.

MANAGEMENT

Preconception Management

Preconception counseling and a detailed medical risk assessment are recommended for all women with overt diabetes as well as for those with a history of gestational diabetes in a previous pregnancy. The significant effects on the maternal and neonatal complications of diabetic pregnancy cannot be realized until meticulous preconception metabolic control is achieved in all women contemplating pregnancy.

The important elements to be considered in preconception counseling of patients with diabetes are the patient's level of glycemic control; current status of the patient's retinal and renal health; and any medications being taken, especially antihypertensive or thyroid medications. A realistic assessment of the patient's risk of complications during pregnancy, including worsening of renal or ophthalmologic function, should be provided.

Preconception management should lead to a comprehensive program of glucose control. The major goals of the prepregnancy metabolic program are as follows:

- Establishing a regimen of frequent, regular monitoring of capillary blood glucose levels
- Adopting an insulin dosing regimen that results in a smooth interprandial glucose profile (fasting blood glucose value 90 to 99 mg/dL, 1-hour postprandial glucose level of less than 140 mg/dL or 2-hour postprandial glucose level less than 120 mg/dL, no reactions between meals or at night)
- Bringing HbA_{1c} level into the normal range
- Developing family, financial, and personal resources to assist the patient if pregnancy complications require that she lose work time or assume total bed rest

This preconception care has been shown to decrease congenital anomalies and to result in fewer hospitalizations, fewer infants requiring intravenous glucose after delivery, and a substantial reduction in total costs (Herman et al, 1999).

Prenatal Metabolic Management

The goals of glycemic monitoring, dietary regulation, and insulin therapy in diabetic pregnancy are to prevent the postnatal sequelae of diabetes in the newborn—macrosomia, shoulder dystocia, and postnatal metabolic instability. These measures must be instituted early and aggressively if they are to be effective.

Principles of Dietary Therapy

Because women with diabetes have inadequate insulin action after feeding, the goal of dietary therapy is to avoid single, large meals and foods with a large proportion of simple carbohydrates. Three major meals and three snacks are prescribed. The use of nonglycemic foods that release calories into the gut slowly also improves metabolic control.

Nutritional therapy should be supervised by a trained professional who performs formal dietary assessment and counseling at several points during the pregnancy. The dietary prescription should provide adequate quantity and distribution of calories and nutrients to meet the needs of the pregnancy and support achieving the plasma glucose targets that have been established. For obese women (body mass index >30 kg/m^2), a 30% to 33% restriction in caloric intake (to 25 kcal per kilogram of actual weight per day or less) has been shown to reduce hyperglycemia and plasma triglycerides with no increase in ketonuria. Moderate restriction of dietary carbohydrate intake to 35% to 40% of calories has been shown to reduce maternal glucose levels and improve maternal and fetal outcomes (Major et al, 1998). In a nonrandomized study, subjects with low carbohydrate intake (<42% of calories) had lower requirements for insulin for glucose control and significantly lower rates of macrosomia and cesarean deliveries for cephalopelvic disproportion and macrosomia. Recently, a randomized trial was performed in which 958 women with gestational diabetes were randomized to usual prenatal care or treatment (Landon, 2009). Women randomized to treatment underwent nutritional counseling, diet therapy, and insulin if indicated. Among those who underwent treatment there was lower mean birthweight, neonatal fat mass, rates of large for gestational age and macrosomic (>4000 g) infants. There was also a trend toward lower cord C-peptide levels in the treatment group. Maternal outcomes were significant for lower rates of cesarean delivery, preeclampsia, and shoulder dystocia (Landon et al, 2009).

Principles of Glucose Monitoring

The availability of chemical test strips for capillary blood glucose measurements has revolutionized the management of diabetes, and their use should now be considered the standard of care for pregnancy monitoring. The discipline of measuring and recording blood glucose levels before and after meals may have the effect of improving glycemic control (Goldberg et al, 1986).

Controversy exists as to whether the target glucose levels to be maintained during diabetic pregnancy should be

designed to limit macrosomia or to closely mimic nondiabetic pregnancy profiles. The Fifth International Workshop Conference on Gestational Diabetes (Metzger et al, 2007) recommended the following: fasting plasma glucose less than 90 to 99 mg/dL (5.0 to 5.5 mmol/L) and 1-hour postprandial plasma glucose less than 140 mg/dL (7.8 mmol/L), or 2-hour postprandial plasma glucose less than 120 to 127 mg/dL (6.7 to 7.1 mmol/L).

The glycemic control profiles from Cousins et al (1980) were derived from highly controlled studies in which volunteer subjects were fed test meals with specific caloric content on a rigid schedule. Parretti et al (2001) profiled normal pregnant women twice monthly, preprandially, and postprandially during the third trimester. Testing was conducted with capillary glucose meters, and the women followed an ad libitum diet. The data demonstrate that fasting and premeal plasma glucose levels are usually less than 80 mg/dL and often less than 70 mg/dL. Peak postprandial plasma glucose values rarely exceed 110 mg/dL. Yogev et al (2004) used a sensor that monitored interstitial fluid glucose levels to obtain continuous glucose information from pregnant women without diabetes and found similar results to those of Parretti et al (2001). The range of normal glucose levels in nondiabetic pregnancy is summarized in Table 9-5.

Postprandial values must be assessed because they have the strongest correlation with fetal growth (Jovanovic-Peterson et al, 1991). The Diabetes in Early Pregnancy Study found that postprandial glucose levels were strongly predictive of both birthweight and the overall percentage of macrosomic infants. With postprandial glucose values averaging 120 mg/dL, approximately 20% of infants were macrosomic; a 30% rise in postprandial levels to 160 mg/dL resulted in a predicted percentage of macrosomia of 35%.

Similar results were reported by de Veciana et al (1995). Compared with the group who performed preprandial glucose monitoring, the group performing postprandial glucose monitoring demonstrated a greater mean change in the HbA_{1c} value (3.0% vs. 0.6%; $p < 0.001$), lower birthweights (3469 g vs. 3848 g; $p = 0.01$), and lower rates of both neonatal hypoglycemia (3% vs. 21%, $p = 0.05$) and macrosomia (12% vs. 42%; $p = 0.01$).

A typical schedule involves performing blood glucose checks upon rising in the morning, 1 or 2 hours after breakfast, before and after lunch, before and after dinner, and before bedtime. The goal of physiologic glycemic control in pregnancy, however, is not met by simply avoiding hypoglycemia. The data summarized here regarding fetal macrosomia and postnatal morbidity emphasize the key role of excessive postprandial excursions in blood glucose values. Therefore, close attention must be paid to preprandial and postprandial glycemic profiles.

Principles of Insulin Therapy

No available insulin delivery method approaches the precise secretion of the hormone from the human pancreas. The therapeutic goal of exogenous insulin therapy during pregnancy is to achieve diurnal glucose excursions similar to those of nondiabetic pregnant women. Normal pregnant women maintain postprandial blood glucose excursions within a relatively narrow range (70 to 120 mg/dL). As pregnancy progresses, the fasting and between-meal blood glucose levels drop progressively lower as a result of the continual uptake of glucose from the maternal circulation by the growing fetus. Any insulin regimen for pregnant women must be designed to avoid excessive unopposed insulin action during the fasting state.

Insulin type and dosage frequency should be individualized. Use of regular insulin before each major meal helps to limit postprandial hyperglycemia. To provide basal insulin levels between feedings, a longer-acting preparation is necessary, such as isoprotane insulin (NPH) or insulin zinc (Lente). Typical subcutaneous insulin dosing regimens are two thirds of total insulin in the morning, of which two thirds as intermediate-acting and one third as regular insulin. The remaining third of the total insulin dose is given in the evening, with 50% as short-acting insulin before dinner and 50% as intermediate-acting given at bedtime.

The use of an insulin pump for type 1 diabetes mellitus during pregnancy has become more widespread (Gabbe et al, 2000). An advantage of this approach is the more physiologic insulin release pattern that can be achieved with the pump.

Ultrasonography has also been used to direct insulin management (Rossi et al, 2000). Kjos et al (2001) showed that serial normal fetal abdominal circumference measurements can be used to avoid insulin therapy without increasing neonatal morbidity.

Oral Hypoglycemic Therapy

Historically, insulin has been the mainstay of therapy for gestational diabetes because of early reports that oral hypoglycemic drugs are a potential cause of fetal anomalies and neonatal hypoglycemia. Sulfonylurea compounds are contraindicated during pregnancy because of a high level of transplacental penetration and clinical reports of prolonged and severe neonatal hypoglycemia (Zucker and Simon, 1968). An increased rate of congenital malformations, particularly ear anomalies, has been reported from a small case-control study (Piacquadio et al, 1991).

TABLE 9-5 Ambulatory Glucose Values in Pregnant Women With Normal Glucose Tolerance

Study	No. of Subjects	Fasting (mg/dL)	Postprandial Level at 60 min (mg/dL)	Postprandial Peak (mg/dL)
Parretti et al, 2001	51	69 (57-81)	108 (96-120)	—
Yogev et al, 2004	57	75 (51-99)	105 (79-131)	110 (68-142)*

Adapted from Metzger BE, Buchanan TA, Coustan DR, et al: Summary and recommendations of the Fifth International Workshop-Conference on Gestational Diabetes Mellitus, *Diabetes Care* 30:S251-S260, 2007.
*The time of the peak postprandial glucose concentration was 70 minutes (range, 44 to 96 minutes).

However, when Towner et al (1995) evaluated the frequency of birth defects in patients who took oral hypoglycemic agents during the periconception period, they noted that first-trimester HbA_{1c} level and duration of diabetes were strongly associated with fetal congenital anomalies, but that use of oral hypoglycemic medications was not.

Glyburide, a second-generation sulfonylurea, has been shown to cross the placenta minimally in laboratory studies (Elliott et al, 1994) and in a large clinical trial. The prospective, randomized trial conducted by Langer et al (2000) compared glyburide and insulin in 404 women with gestational diabetes and showed equivalently excellent maternal glycemic control and perinatal outcomes.

Beyond this single, encouraging study, experience with glyburide during pregnancy is limited (Coetzee and Jackson, 1985; Lim et al, 1997). Chmait et al (2004), reporting experience with 69 patients with gestational diabetes who were given glyburide, found a failure rate of 19% (>10% glucose values above target). Glyburide failure rate was higher in women receiving a diagnosis earlier in pregnancy (20 vs. 27 weeks' gestation; $p < 0.003$) and whose average fasting glucose in the week before starting glyburide was higher (126 vs. 101 mg/dL).

Following the publication of the randomized control trial, several retrospective series have been published comprising 504 glyburide-treated patients, summarized recently by Moore (2007). Jacobson et al (2005) performed a retrospective cohort comparison of glyburide and insulin treatment of gestational diabetes. The insulin group ($n = 268$) consisted of those diagnosed in 1999 through 2000 and the glyburide group ($n = 236$) was diagnosed in 2001 through 2002. Glyburide dosing was begun with 2.5 mg in the morning and increased by 2.5 to 5.0 mg weekly. If the dose exceeded 10 mg daily, twice daily dosing was considered. If glycemic goals were not met on a maximum daily dose of 20 mg, treatment was changed to insulin. There were no statistically significant differences in gestational age at delivery, mode of delivery, birthweight, large for gestational age (LGA), or percent macrosomia. The rate of preeclampsia doubled in the glyburide group (12% vs 6%; $p = 0.02$). Women in the glyburide group also had significantly lower posttreatment fasting and postprandial blood glucose levels. The glyburide group was also superior in achieving target glycemic levels (86% vs. 63%; $p < 0.001$). The failure rate (transfer to insulin) was 12%. The study size, however, was insufficient to detect less than a doubling of the rate of macrosomia/LGA and a 44% increase in neonatal hypoglycemia.

Conway et al (2004) reported a retrospective cohort of 75 glyburide-treated patients with GDM. Good glycemic control was achieved by 84% of the subjects with glyburide, and treatment for 16% was switched to insulin. The rate of fetal macrosomia was similar between women successfully treated with glyburide and those who received insulin (11.1% vs. 8.3%; $p = 1.0$), and mean birthweight was also similar. Of note, a nonsignificantly higher proportion of infants in the glyburide group required intravenous glucose infusions because of hypoglycemia (25.0% vs. 12.7%; $p = 0.37$). Currently there is a growing acceptance of glyburide use as a primary therapy for GDM (Coustan, 2007).

OTHER AGENTS

Metformin is frequently used in patients with polycystic ovary syndrome and type 2 diabetes mellitus to improve insulin resistance and fertility (Legro et al, 2007). Metformin therapy has been demonstrated to improve the success of ovulation induction (Vandermolen et al, 2001) and may reduce first-trimester pregnancy loss in women with polycystic ovary syndrome (Jakubowicz et al, 2002). However, the effects of continuing metformin treatment during pregnancy are currently being studied. Older studies evaluating the efficacy and safety of the treatment of pregestational and gestational diabetics with metformin raised concerns regarding a higher perinatal mortality, a higher rate of preeclampsia, and failure of therapy (Coetzee and Jackson 1979; Hellmuth et al, 2000). However, the metformin-treated women were older, more obese, and treated later in pregnancy.

A more recent cohort study of metformin in pregnancy by Hughes and Rowan (2006) included 93 women with metformin treatment (only 32 continued until delivery) and 121 controls. There was no difference in perinatal outcomes between the groups. Glueck et al (2002) compared women without diabetes but with polycystic ovary syndrome who conceived while taking metformin and continued the agent through delivery ($n = 28$) to matched women without metformin therapy ($n = 39$). Gestational diabetes developed in 31% of women who did not take metformin versus 3% of those who did (odds ratio, 0.115; 95% CI, 0.014 to 0.938).

Recently a large randomized controlled trial was performed comparing metformin to insulin for the treatment of gestational diabetes (Rowan et al, 2008). This study was powered to detect a 33% increase in composite outcome (neonatal hypoglycemia, respiratory distress, need for phototherapy, birth trauma, 5-minute American Pediatric Gross Assessment Record score of less than 7, or prematurity) in neonates born to mothers treated with metformin. Seven hundred fifty-one women with gestational diabetes between 20 and 30 weeks' gestation were randomized to metformin or insulin. Of these, 363 women were assigned to metformin and 370 were assigned to insulin. Forty-six percent of women receiving metformin required the addition of insulin to obtain adequate glycemic control. There were no differences in the rate of the primary composite outcome. There was a lower rate of severe neonatal hypoglycemia in the metformin-treated group and no differences in neonatal anthropometric measurements. There was, however, a higher rate of prematurity in the metformin-treated group (12.1%) versus the insulin group (7.6%). A follow-up study is currently under way to assess the offspring of these women at 2 years of age.

Prenatal Obstetric Management

The overall strategy for managing a diabetic pregnancy in the third trimester involves two goals: (1) preventing stillbirth and asphyxia and (2) monitoring growth of the fetus to select the proper time and route of delivery to minimize maternal and infant morbidity. The first goal is accomplished by testing fetal well-being at frequent intervals, and the second through ultrasonographic monitoring of fetal size.

Periodic Biophysical Testing of the Fetus

A variety of biophysical tests of the fetus are available to the clinician, including fetal heart rate testing, fetal movement assessment, ultrasound biophysical scoring, and fetal umbilical Doppler studies. Most of these tests, if applied properly, can be used with confidence to provide assurance of fetal well-being while awaiting fetal maturity; they are summarized in Table 9-6.

Testing should be initiated early enough to avoid significant risk of stillbirth, but not so early that the risk of a false-positive result is high. In patients with poor glycemic control or significant hypertension, testing should begin as early as 28 weeks' gestation. In lower-risk patients, most centers begin formal fetal testing by 34 to 36 weeks' gestation. Counting of fetal movements is performed in all pregnancies from 28 weeks' gestation onward.

Assessing Fetal Growth

Monitoring of fetal growth continues to be a challenging and highly inexact process. Although the current tools, consisting of serial plotting of fetal growth parameters, are superior to earlier clinical estimations, accuracy is still ±15%. Single and multiple longitudinal assessments of fetal size have been attempted.

Calculation of Estimated Fetal Weight

Several polynomial formulas using combinations of head, abdominal, and limb measurements have been proposed to predict the weight of the macrosomic fetus from ultrasonography parameters (Ferrero et al, 1994; Tongsong et al, 1994). Unfortunately, in such formulas, small errors in individual measurements of the head, abdomen, and femur are typically multiplied together. In the obese fetus, the inaccuracies are further magnified. Bernstein and Catalano (1992) observed that a significant correlation exists between the degree of error in the ultrasonographically estimated fetal weight and the percentage of body fat on the fetus ($r = 0.28$; $p < 0.05$). Perhaps this problem explains why no single formula has proved to be adequate in identifying the macrosomic fetus (Tamura et al, 1985).

Shamley and Landon (1994) reviewed the relative accuracy of the various available formulas. Approximately 75% of the fetal weight predictions were within 10% of actual birthweight, with sensitivity for detecting macrosomia varying greatly (11% to 76%). In another study, McLaren et al (1995) found that 65% of weight estimates based on a simple abdominal circumference and femur length formula were within 10% of actual weight. A similar accuracy was achieved with more complex models (53% to 66% of estimates within the range).

The formula developed by Shepard et al (1982), which uses biparietal diameter and abdominal circumference, is readily available in textbooks and is used most commonly in current ultrasonographic equipment software. The formula has accuracy levels similar to the statistics quoted previously.

Serial Estimated Fetal Weight Assessments

Because prediction of fetal weight from a single set of measurements is inaccurate, serial estimates showing the trend of ultrasonographic parameters (typically made every 1.5 to 3 weeks) might theoretically offer a better estimate of actual weight percentile. A comparison of the efficacy of serial estimated fetal weight calculations to a single measurement, however, did not show better predictive accuracy. Larsen et al (1995) reported that predictions based on the average of repeated weight estimates, on linear extrapolation from two estimates, or on extrapolation by a second-order equation fitted to four estimates were no better than the prediction from the last estimate before delivery. Similar findings (that a single estimate is as accurate as multiple assessments) were reported by Hedriana and Moore (1994).

TABLE 9-6 Tests of Fetal Well-Being

Test	Frequency	Reassuring Result	Comment
Counting of fetal movements	Every night from 28 weeks' gestation	Ten movements in <60 min	Performed in all patients
Nonstress test	Twice weekly	Two heart rate accelerations in 20 min	Begin at: 28-34 wk in patients with insulin-dependent diabetes, 36 wk in patients with diet-controlled gestational diabetes
Contraction stress test	Weekly	No heart rate decelerations in response to ≤3 contractions in 10 min	Same as for nonstress test
Ultrasound biophysical profile	Weekly	Score of 8 in 30 min	The following findings are given 2 points each: 3 movements 1 flexion 30 sec breathing 2 cm amniotic fluid

Choosing the Timing and Route of Delivery

Timing of delivery should be selected to minimize maternal and neonatal morbidity and mortality. Delaying delivery to as near as possible to the due date helps to maximize cervical ripeness and improve the chances of spontaneous labor and vaginal delivery. Yet the risks of fetal macrosomia, birth injury, and fetal death rise as the due date approaches (Rasmussen et al, 1992). Although earlier delivery at 37 weeks' gestation might reduce the risk of shoulder dystocia, the higher rates of failed labor inductions and poor neonatal pulmonary status at this time must be considered. Therefore an optimal time for delivery of most diabetic pregnancies is between 39.0 and 40 weeks' gestation.

Delivery of a diabetic patient before 39 weeks' gestation without documentation of fetal lung maturity should be performed only for compelling maternal or fetal reasons. Fetal lung maturity should be verified in such cases from the presence of more than 3% phosphatidyl glycerol or the equivalent in amniotic fluid as ascertained from an amniocentesis

specimen. After 39 weeks' gestation, the obstetrician can await spontaneous labor if the fetus is not macrosomic and results of biophysical testing are reassuring. In patients with gestational diabetes and superb glycemic control, continued fetal testing and expectant management can be considered until 41 weeks' gestation (Lurie et al, 1992).

Given the previous data, the decision to attempt vaginal delivery or perform a cesarean section is inevitably based on limited data. The patient's obstetric history from previous pregnancies, the best estimation of fetal weight, the fetal adipose profile (abdomen larger than head), and results of clinical pelvimetry should all be considered. A policy of elective cesarean section for suspected fetal macrosomia (ultrasonographically estimated fetal weight of greater than 4500 g) would require 443 cesarean deliveries to avoid one permanent brachial plexus injury (Rouse et al, 1996). Most large series of diabetic pregnancies report a cesarean section rate of 30% to 50%. The best means by which this rate can be lowered is early and strict glycemic control in pregnancy. Conducting a long labor induction in the patient with a large fetus and marginal pelvis may increase rather than decrease morbidity and costs.

Intrapartum Glycemic Management

Maintenance of intrapartum metabolic homeostasis is essential to avoid fetal hypoxemia and promote a smooth postnatal transition. Strict maternal euglycemia during labor does not guarantee newborn euglycemia in infants with macrosomia and long-established islet cell hypertrophy. Nevertheless, the use of a combined insulin and glucose infusion during labor to maintain maternal blood glucose in a narrow range (80 to 110 mg/dL) during labor is a common and reasonable practice. Typical infusion rates are 5% dextrose in lactated Ringer's solution at 100 mL/hr and regular insulin at 0.5 to 1.0 U/hr. Capillary blood glucose levels are monitored hourly in such patients.

For patients with diet-controlled gestational diabetes in labor, avoiding dextrose in all intravenous fluids normally maintains excellent blood glucose control. After 1 to 2 hours, no further assessments of capillary blood glucose are typically necessary.

Neonatal Management

Neonatal Transitional Management

One of the metabolic problems common to IDMs is hypoglycemia, which is related to the level of maternal glycemic control over the 6 to 12 weeks before birth. Neonatal hypoglycemia is most likely to occur between 1 and 5 hours after birth, as the rich supply of maternal glucose stops with ligation of the umbilical cord and the infant's levels of circulating insulin remain elevated. These infants therefore require close monitoring of blood glucose concentration during the first hours after birth. IDMs also appear to have disorders of catecholamine and glucagon metabolism as well as diminished capability to mount normal compensatory responses to hypoglycemia.

In the past, IDMs were treated with glucagon; however, this treatment frequently results in high blood glucose levels that trigger insulin secretion and repeated cycles of hypoglycemia and hyperglycemia. Current recommendations, therefore, consist of early oral feeding, when possible, with infusion of intravenous glucose.

Ordinarily, blood glucose levels can be controlled satisfactorily with an intravenous infusion of 10% glucose. If greater amounts of glucose are required, bolus administration of 2 mL/kg of 10% glucose is recommended. Close monitoring to correct hypoglycemia while avoiding hyperglycemia and consequent stimulation of insulin secretion is important.

Breastfeeding

Most authorities prefer to maintain strict monitoring of newborn IDM glucose levels for at least 4 to 6 hours, which frequently necessitates admission to a newborn special care unit. IDMs who are delivered atraumatically and are well oxygenated, however, can be kept with their mothers while undergoing close glycemic monitoring for the first 1 to 2 hours of life. This approach permits early breastfeeding, which may reduce the need for intravenous glucose therapy.

Summary

Intensive management of women with glucose intolerance during pregnancy has resulted in markedly improved pregnancy outcomes. Despite these advances, care of the IDM continues to require vigilance and meticulous monitoring with a full understanding of the quality of the glycemic milieu in which the infant developed.

DISORDERS OF THE THYROID

INCIDENCE

Thyroid disorders, in general, are more common in women than in men and represent a common endocrine abnormality during pregnancy. Both hyperthyroidism and hypothyroidism in the mother put the infant at risk and require careful management by the perinatal-neonatal team. Table 9-7 presents an overview of the approach to infants who are thought to be at risk for abnormal thyroid function because of maternal thyroid abnormalities. The most frequently described problem is the syndrome of postpartum thyroiditis, which has been reported to complicate as many as 5% of all pregnancies. The diagnosis of thyroid disease in pregnancy is complicated by the natural changes that occur in immunologic status of the mother and fetus and that variously affect the assessment of any of the autoimmune thyroid disorders.

MATERNAL-FETAL THYROID FUNCTION IN PREGNANCY

Maternal Thyroid Function

Several pregnancy-related physiologic conditions affect maternal thyroid function, and the appropriate interpretation of thyroid function test results during pregnancy must take these normal physiologic factors into account. One important modification that occurs during pregnancy is the estrogen-dependent increase in thyroid-binding globulin. This results in an increase in total thyroxine and total triiodothyronine levels throughout pregnancy. The

TABLE 9-7 Approaches for Infants Judged to be at Risk for Abnormal Thyroid Function

Possible Thyroid Abnormality	Cord Blood Analyses	Assessment at Birth	Assessment at 2-7 Days of Life
Congenital hyperthyroidism because mother has any of the following: Graves' disease with hyperthyroidism and may have been treated with PTU, methimazole, ^{131}I, iodides, or surgery; history of Graves' disease; history of Hashimoto's disease	T_4, TSH, TSAb	Physical examination for intrauterine growth restriction, goiter, exophthalmos, tachycardia, bradycardia, size of anterior fontanel, synostosis, congenital anomalies; determination of gestational age by dates, ultrasonography during pregnancy, or Dubovitz examination; neurologic examination; determination of bone age (knee); for selected cases: electrocardiogram, auditory and visual evoked potentials, motor conduction, velocity tests, skull radiographs	T_4, TSH, TSAb (if available) determinations: If results normal, give no treatment; observe and repeat T_4, T_3, TSH determinations at 7-10 days*; if results indicate hypothyroidism, repeat T_4, TSH; if results are abnormal, begin treatment at 7-10 days†; if results indicate hyperthyroidism, begin treatment with PTU (8 mg/kg) and propranolol
Congenital or early childhood hypothyroidism because mother has any of the following: Graves disease with excessive PTU therapy; Hashimoto's disease; acute (subacute) thyroiditis; familial genetic defect in thyroxine synthesis; treatment with iodides or lithium for nonthyroidal illness; exposure to ^{131}I while pregnant	T_4, TSH, ThyAb	Same as for hyperthyroidism	T_4, TSH, ThyAb determinations: If results indicate hypothyroidism, perform ultrasound scan to define presence, size, location of thyroid tissue; if hypothyroidism confirmed, begin treatment with levothyroxine sodium (Synthroid), 0.05 mg/day

levels of unbound (free) thyroxine (FT_4) and free triiodothyronine (FT_3), as well as levels of thyroid-stimulating hormone (TSH), in general remain unchanged. However, human chorionic gonadotropin, a second factor in pregnancy that may modify thyroid function, has a stimulatory effect on the thyroid and may transiently effect the FT_4, FT_3, and TSH levels in the first trimester and early in the second trimester. This stimulatory affect of human chorionic gonadotropin rarely causes aberrations of the thyroid function parameters into the thyrotoxic range (American College of Obstetricians and Gynecologists, 2001).

Fetal Thyroid Function

The fetal thyroid actively concentrates iodide after 10 weeks' gestation, releases thyroxine (T_4) after 12 weeks' gestation, and becomes responsive to pituitary TSH at 20 weeks' gestation. Although maternal TSH does not cross the placenta, maternal thyroid hormones and thyrotropin-releasing hormone are transferred to the fetus throughout gestation. Early studies found that cord blood thyroid function testing of neonates with congenital thyroid agenesis revealed hormone levels that were 30% of normal (Vulsma et al, 1989), suggesting a maternal source. Recent studies show that by 4 weeks after conception, small amounts of T_4 and triiodothyronine (T_3) from the maternal origin are found in the fetal compartment, with T_4 levels increasing throughout gestation. Free T_4 levels reach concentrations of biologic significance in the adult by midgestation. Studies using rat models have demonstrated that this thyroid hormone is important for corticogenesis early in the pregnancy (Morreale de Escobar et al, 2004). Transplacental transfer of thyroid-stimulating immunoglobulin (TSI) may occur, causing fetal thyrotoxicosis. Other substances that may be transferred from the maternal compartment to the fetal compartment and affect fetal thyroid function are iodine, a radioactive isotope of iodine, propylthiouracil (PTU), and methimazole. The fetal effects of these agents are reviewed later.

Hyperthyroidism

Hyperthyroidism occurs in approximately 0.2% of pregnancies and results in a significant increase in the prevalence of both low-birthweight delivery and a trend toward higher neonatal mortality. The most common cause of thyrotoxicosis (85% of cases) in women of child-bearing age is Graves' disease; other causes are acute (or subacute) thyroiditis (transient), Hashimoto's disease, hydatidiform mole, choriocarcinoma, toxic nodular goiter, and toxic adenoma. Graves' disease has a peak incidence during the reproductive years, but patients with the disorder may actually have remissions during pregnancy, followed by postpartum exacerbations. The unique feature of these pregnancies is that the fetus may also be affected, regardless of the mother's concurrent medical condition. Thyroid function is difficult to evaluate in the fetus, and the status of the fetus may not correlate with that of the mother.

Diagnosis

The differential diagnosis of thyrotoxicosis becomes more difficult during pregnancy because normal pregnant women may have a variety of hyperdynamic signs and symptoms—intolerance to heat, nervousness, irritability, emotional lability, increased perspiration, tachycardia, and anxiety. Laboratory data are also difficult to evaluate

because total serum thyroxin values are normally elevated during pregnancy as a result of estrogen-induced increases in thyroxine-binding globulin. Therefore if thyroxine-binding globulin is increased, then T_3 resin uptake may be in the euthyroid to slightly increased range in a patient who has true hyperthyroidism. Hollingsworth (1989) has reviewed the assessment of thyroid function tests in nonpregnant and pregnant women, along with the differential diagnosis of hyperthyroidism during pregnancy.

Pathogenesis of Graves' Disease

The pathogenesis of Graves' disease is not completely understood, but it probably represents an overlapping spectrum of disorders that are characterized by the production of polyclonal antibodies. It has been appreciated since the 1960s (Sunshine et al, 1965) that abnormal TSIs, which appear to be immunoglobulin G, are present in pregnant women with Graves' disease and cross the placenta easily to cause neonatal hyperthyroidism in some infants (McKenzie and Zakarija, 1978). The clinical spectrum of Graves' disease in utero is broad and may result in stillbirth or preterm delivery. Some affected infants have widespread evidence of autoimmune disease, including thrombocytopenic purpura and generalized hypertrophy of the lymphatic tissues. Thyroid storm can occur shortly after birth, or the infant may have disease that is transient in nature, lasting from 1 to 5 months. Infants born to mothers who have been treated with thioamides may appear normal at birth, but demonstrate signs of thyrotoxicosis at 7 to 10 days of age, when the effect of thioamide suppression of thyroxine synthesis is no longer present. The measurement of thyroid-stimulating antibodies is useful in predicting whether the fetus will be affected.

Management of the Mother

Because radioactive iodine therapy is contraindicated during pregnancy, treatment of the pregnant woman with thyrotoxicosis involves a choice between antithyroid drugs and surgery. The therapeutic goal is to achieve a euthyroid, or perhaps slightly hyperthyroid, state in the mother while preventing hypothyroidism and hyperthyroidism in the fetus. Either PTU or methimazole can be used to treat thyrotoxicosis during pregnancy. Because methimazole therapy can be associated with aplasia cutis in the offspring of treated women, and because PTU crosses the placenta more slowly than methimazole, PTU has become the drug of choice for use during pregnancy. Ordinarily, thyrotoxicosis can be controlled with doses of 300 mg per day. Once the disorder is under control, however, it is important to keep the dose as low as possible, preferably less than 100 mg daily, because this drug crosses the placenta and blocks fetal thyroid function, possibly producing hypothyroidism in the fetus.

In women with cardiovascular effects, the use of beta-blockers may be appropriate to achieve rapid control of thyrotoxicosis. Because administration of propranolol to pregnant women has been associated with intrauterine growth restriction and impaired responses of the fetus to anoxic stress as well as postnatal bradycardia and hypoglycemia, the doses must be closely controlled. Iodides have also been used, particularly in combination with beta-blocking agents, to control thyrotoxicosis. Long-term iodide therapy presents a risk to the fetus. Because of the inhibition of the incorporation of iodide into thyroglobulin, a large, obstructive goiter can develop in the fetus. Surgery during pregnancy is best reserved for cases in which the mother is hypersensitive to antithyroid drugs, compliance with medication is poor, or drugs are ineffective in controlling the disease.

Effects on the Newborn

Approximately 1% of infants born to mothers with some level of thyrotoxicosis have thyrotoxicosis (Figure 9-6). Assessment of fetal risk in utero includes measurement of TSIs, with the expectation that if the titers are high, there is a higher risk of thyrotoxicosis. Additional assessment of the fetus should pay particular attention to elevated resting

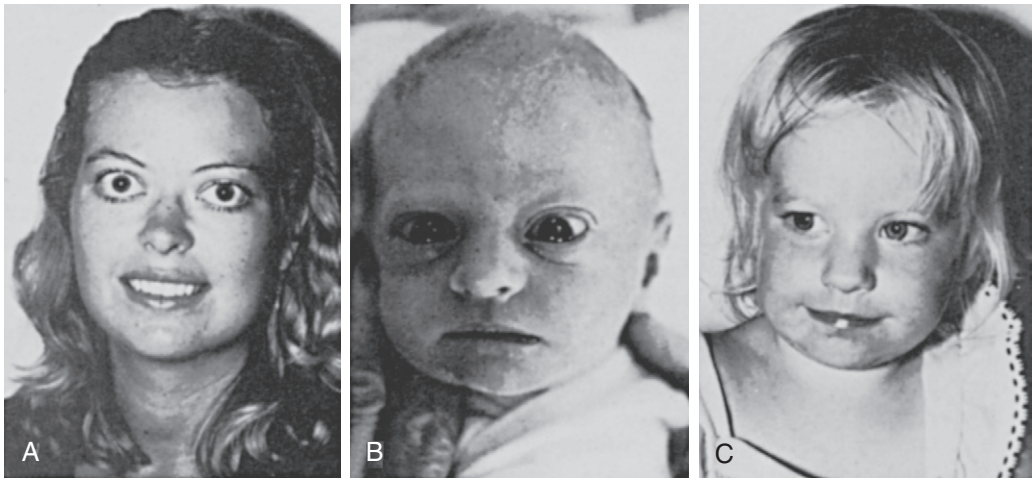

FIGURE 9-6 **A,** Hypothyroid 21-year-old mother who experienced Graves' disease at age 7 years and was treated by subtotal thyroidectomy. She was given maintenance therapy with daily levothyroxine sodium (Synthroid; 0.15 mg) throughout pregnancy. **B,** Her infant girl was born at term with severe Graves' disease, goiter, and exophthalmos that persisted for 6 months. **C,** The child was healthy at 20 months old. *(From Creasy RK, Resnik R, editors:* Maternal-fetal medicine: principles and practice, *ed 2, Philadelphia, 1989, WB Saunders.)*

heart rate and poor fetal growth. Daneman and Howard (1980) reported on the outcome of nine infants with neonatal thyrotoxicosis and noted normal growth, but a high incidence of craniosynostosis and intellectual impairment. It may be necessary to treat the asymptomatic mother with thioamides and propranolol (and thyroid replacement) during pregnancy to treat the infant and prevent serious neonatal morbidity and long-term problems.

Mothers with thyrotoxicosis who are taking normal doses of thioamide can safely breastfeed their infants, although thioamide appears in breast milk in low amounts. Currently there does not appear to be any long-term adverse outcome for infants whose mothers have received PTU during pregnancy.

HYPOTHYROIDISM

Hypothyroidism complicates about 1 to 3 per 1000 pregnancies. The leading cause of hypothyroidism in pregnancy is Hashimoto's thyroiditis, which is a chronic autoimmune thyroiditis characterized by painless inflammation and enlargement of the thyroid gland (Casey and Leveno, 2006). Other causes of primary hypothyroidism include iodine deficiency, thyroidectomy, or ablative radioiodine therapy for hyperthyroidism. Secondary causes of hypothyrodism include Sheehan's syndrome caused by obstetric hemorrhage leading to pituitary ischemia, necrosis and abnormalities in all pituitary hormones, lymphocytic hypophysitis, and hypophysectomy (Casey and Leveno, 2006). Women with over hypothyroidism are at increased risk of pregnancy complications, such as a higher rate of miscarriage, preeclampsia, placental abruption, growth restriction, and stillbirth (Casey and Leveno, 2006).

Diagnosis

The finding of a goiter may be associated with cases of Hashimoto's thyroiditis or iodine deficiency. The signs and symptoms of hypothyroidism are usually insidious and easily confused with those of normal pregnancy including fatigue, cold intolerance, cramping, constipation, weight gain, hair loss, insomnia, and mental slowness. The serum TSH level is an accurate and widely clinically available test to diagnose hypothyroidism. If the serum TSH is elevated, a free T_4 level should be obtained. In the classic definition of hypothyroidism, the serum TSH is elevated and the free T_4 is low. Other forms of hypothyroidism have also been described, including subclinical hypothyroidism, which is defined as an elevated TSH with a normal free T_4, or hypothyroxinemia defined as a normal TSH but a low free T_4; these have no clinical significance to the mother, but may be associated with neonatal effects discussed later in the neonatal neurologic development section.

Management of the Mother

Levothyroxine is the treatment of choice. Adults with hypothyroidism require approximately 1.7 μg/kg of body weight and should be initiated on full replacement (www.thyroidguidelines.org). The goal of therapy is normalization of the TSH level; therefore the TSH is checked at 4- to 6-week increments, and the dose of levothyroxine is adjusted by 25- to 50-μg increments.

Neonatal Neurologic Development

In humans, early epidemiologic data from iodine-deficient areas of Switzerland suggested a link between mental retardation in the children of women with abnormal thyroid function (Gyamfi et al, 2009). Studies performed by Haddow et al (1999) found that in women with overt, untreated hypothyroidism, the intelligence quotient (IQ) points of children aged 7 to 9 years (using the Wechsler Intelligence Scale IQ test) were 7 points lower in cases than in controls ($p = 0.005$). The percentage of children with IQ scores less than 85 was higher in the cases than in controls (19% versus 5%; $p = 0.007$; Haddow et al, 1999).

It has been demonstrated that early transplacental passage of thyroid hormone is important for normal neurodevelopment of the fetus. T_3 is made from the conversion of maternal T_4. If maternal T_4 levels are low, fetal T_3 in the brain will be low even if the maternal and fetal serum T_3 are normal (Morreale de Escobar et al, 2004). Studies involving rats—which, like humans, are dependent on maternal thyroid hormone early in development—have demonstrated that thyroid hormone receptor is present in the brain before neural tube closure, suggesting a biologic role (Morreale de Escobar et al, 2004). Furthermore in humans, thyroid hormone concentrations in the cerebral cortex at 20 weeks' gestation are comparable to those found in adults (Morreale de Escobar et al, 2004). Lavado-Autric et al (2003) have demonstrated that in iodine-deficient rat pups, there is aberrant neuronal migration, blurring of the cytoarchitecture, and abnormal morphology in the somatosensory cortex and hippocampus. Early in human development there is expression of nuclear thyroid receptors, which are already occupied by T_3, suggesting that normal maternal T_4 levels are necessary for normal cortical development (Morreale de Escobar et al, 2004).

Given the increased risk of adverse perinatal and neurodevelopmental outcomes, all women with overt hypothyroidism should be treated in pregnancy. However, controversy still exists as to whether subclinical hypothyroidism (defined as an elevated TSH level, but normal free T_4) or hypothyroxinemia (defined as a normal TSH level, but a low free T_4) warrant treatment in pregnancy. In 1969, Man and Jones were the first to evaluate offspring of mothers with hypothyroxinemia and found that they had lower IQ scores than normal controls or of those born to mothers with adequately treated hypothyroidism (Gyamfi et al, 2009). Studies performed by Pop et al (1999) in the iodine-deficient areas of the Netherlands have shown that free T_4 levels below the 10th percentile at 12 weeks' gestation were associated with lower scores on the Dutch version of the Bayley Scale of Infant Development at 10 months old. The study included women with a low free T_4 (hypothyroxinemia) and excluded women with elevated TSH. A follow-up study on these same infants, tested in both motor and mental scores at 1 and 2 years of age, found significantly lower scores in infants born to mothers with low free T_4 levels (Pop et al, 2003). Casey et al (2005) performed a study on

Parkland Hospital patients with subclinical hypothyroidism defined as a TSH at 97.5th percentile or higher and a normal free T_4 level. Approximately 2.3% of women screened (404 women) were identified as having subclinical hypothyroidism; compared with normal controls, they had a higher incidence of placental abruption (RR, 3.0; 95% CI, 1.1 to 8.2) and preterm birth before 34 weeks' gestation (RR, 1.8; 95% CI, 1.1 to 2.9) (Casey et al, 2005). The authors concluded that the reduction in IQ in children born to women with subclinical hypothyroidism may be caused by prematurity. Based on the available animal and clinical data, the American Association of Clinical Endocrinologists, the American Thyroid Association, and the Endocrine Society recommend universal screening for all pregnant women. However, the American College of Obstetricians and Gynecologist (2001) recommend that screening should be performed only in women who have risk factors, such as pregestational diabetes, or who are symptomatic. Universal screening is not recommended by the American College of Obstetricians and Gynecologist, given that decision and cost effectiveness studies on the effects of such a strategy are currently lacking. Furthermore, data are lacking regarding therapy dosing, efficacy, or whether medication should be stopped after pregnancy in otherwise asymptomatic women with subclinical hypothyroidism and hypothyroxinemia. A multicenter randomized trial is currently underway to examine whether screening and treatment of hypothyroxinemia or subclinical hypothyroidism have a long-term effect on neurodevelopment of offspring (http://clinicaltrials.gov; study identifier number NCT00388297).

CHAPTER 10

Maternal Medical Disorders of Fetal Significance: Seizure Disorders, Isoimmunization, Cancer, and Mental Health Disorders

Thomas F. Kelly and Thomas R. Moore

A significant spectrum of maternal medical disorders may complicate pregnancy. Some of these disorders, although readily manageable in nonpregnant patients, can be lethal to pregnant women. As a result, two questions arise for the specialist caring for a pregnant woman with a medical complication. First, is the condition affected by the patient's normal adaptations to pregnancy? Second, how does the medical problem affect the woman and her fetus? Although many medical conditions during pregnancy can be managed much like they would be in a nonpregnant woman, there are usually nuances in care during gestation to which the obstetrician must be attuned and that will potentially affect the fetus and neonate.

During pregnancy, any potential medical therapy should be considered carefully to minimize fetal risk. For example, thalidomide and diethylstilbestrol were prescribed in the past for morning sickness and recurrent miscarriages, respectively, on the basis of the reasonable hypotheses that maternal sedation would decrease nausea and increased estrogens would support the placenta and reduce the likelihood of first-trimester loss. Unfortunately, the use of both of these agents led to significant and tragic congenital anomalies in the offspring. In view of the profusion of new drugs available today, the importance of assessing the expected risk-to-benefit ratio for each medication prescribed to a pregnant woman is increasingly important. An example is phenytoin treatment for maternal seizures. If there is a less teratogenic alternative that is effective, it should be prescribed; however, for most women taking phenytoin, other agents are unable to control their seizures, and the risks to the fetus must be accepted.

The altered pharmacokinetics of many drugs during pregnancy must be considered, because the dosing of familiar medications may have to be adjusted if toxicity is to be avoided. Classic examples are thyroid hormone replacement (a higher level of thyroid-binding globulin in pregnancy increases total thyroxin, but leaves the serum free thyroxin value unchanged) and aminoglycoside antibiotic therapy (increased glomerular filtration in pregnancy results in lower serum drug levels).

This chapter discusses four maternal conditions that can influence fetal growth, development, and outcome: seizure disorders, red blood cell isoimmunization, cancer, and mental disorders. The basics of management, the potential effects of pregnancy on the condition, and the effects of the condition on the mother and fetus are considered.

MATERNAL SEIZURE DISORDERS

Epilepsy is the most common major neurologic disorder in pregnancy. Approximately 18 million women are affected worldwide, and 40% of those are of childbearing age. The estimated prevalence in pregnancy is 0.2% to 0.7% (Chen et al, 2009). The pattern of maternal seizures ranges from complex partial to generalized tonic clonic (grand mal) and generalized absence (petit mal) seizures. Physiologically, seizures arise from paroxysmal episodes of abnormal brain electrical discharges; when associated with motor activity, they are termed *convulsive*.

The effect of pregnancy on the frequency and severity of the seizure disorder has been difficult to ascertain because of limited prospective data. The International Registry of Antiepileptic Drugs and Pregnancy (EURAP) recently reported on more than 1800 patients whose seizure frequency and treatment were recorded. Fifty-eight percent of patients had no seizures during their pregnancy. When using first-trimester seizure activity as a reference, 64% had no change in frequency in the second and third trimester, 6% improved, and 12% deteriorated (EURAP Study Group, 2006). The only exception was that tonic-clonic seizures occurred more frequently in women using oxcarbazepine monotherapy; this has been confirmed by an Australian registry in which seizures occurred in 50% of pregnant women with epilepsy who were receiving therapy. However, in a subset that had no seizures for 12 months before pregnancy, there was a 50% to 70% reduced frequency during gestation (Vajda et al, 2008). In patients in whom higher numbers of seizures occur during gestation, decreased plasma concentrations of antiepileptic medications have been hypothesized as causative. The fall in plasma drug levels during pregnancy may be due in part to increased protein binding, reduced absorption, and increased drug clearance. The adequacy of prepregnancy seizure control can influence a patient's course during gestation. Patients whose seizures were poorly controlled tended to have more frequent seizures during pregnancy, whereas patient who had no seizures for 2 years before pregnancy had only a 10% chance of experiencing seizures during gestation. These latter patients may be candidates for stopping therapy or considering monotherapy if they have previously required multiple antiepileptic drugs (Schmidt et al, 1983; Walker et al, 2009).

PERINATAL RISK

For reasons that are not clear, women with seizures have more obstetric complications during pregnancy and a higher rate of poor perinatal outcomes. Rates of preeclampsia, preterm delivery, small-for-gestational-age infants, congenital malformations, cerebral palsy, and perinatal mortality have all been reported as higher in women with an antecedent seizure disorder (Lin et al, 2009; Nelson and Ellenberg, 1982). Pregnancy outcome is also greatly influenced by the mother's socioeconomic status and age as well as by the prenatal care received.

Earlier publications suggested an increased risk of congenital malformations in children of mothers with epilepsy even without prenatal use of antiepileptic drugs (Bjerkedal, 1982). More recent data appear to refute this, and the malformation risk apparently correlates with the number of medications used. A study comparing patients with epilepsy to matched controls revealed that women receiving no medication had no increased rate of congenital malformations; however, monotherapy was associated with and increased risk of embryopathy (odds ratio of 2.8). Furthermore the frequency was even higher with use of two or more drugs (odds ratio of 4.2) (Homes et al, 2001). Recent updates from five international registries have reported malformation rates ranging from 3.7% to 8.0% (with monotherapy) and 6% to 9.8% (with polytherapy) (Meador et al, 2008). Specific malformations include a fivefold rise in the rate of orofacial clefts (Friis et al, 1986), an increase in the rate of congenital heart disease, particularly with trimethadione (Friis and Hauge, 1985), and a 3.8% incidence of neural tube defects in fetuses exposed to valproic acid (Samrén et al, 1997). Facial abnormalities (e.g., midface hypoplasia) are not specific to any particular antiepileptic drug; they have been seen with phenytoin, carbamazepine, and trimethadione. Some antiepileptic medications can adversely affect postnatal cognitive development. Although conclusive data are lacking, there may be an increased adverse effect, particularly with valproate (Meador et al, 2008; Tomson and Battino, 2009).

FETAL HYDANTOIN SYNDROME

The classic features of the fetal hydantoin syndrome are facial clefting, a broad nasal ridge, hypertelorism, epicanthal folds, distal phalangeal hypoplasia, and growth and mental deficiencies; however, these effects also result from the use of other antiseizure medications (Table 10-1). The postulated cause of this syndrome is the teratogenic action of a common epoxide intermediate of these medications. The hydantoin syndrome was found to develop in fetuses with inadequate epoxide hydrolase activity (Buehler et al, 1990). This enzymatic deficiency appears to be recessively inherited. It appears that preconception folic acid supplementation can reduce the risk of major congenital malformations in women taking antiepileptic medication (Harden et al, 2009).

MANAGEMENT

Management of the pregnant patient with epilepsy is based on keeping her free of seizures. Theoretically, this goal reduces maternal physical risk and lowers the incidence of fetal complications. Preconception counseling is preferable and should entail (1) adjusting medication doses into the therapeutic range, (2) attempting to limit the patient to one drug if possible, and (3) choosing an agent with the least risk of teratogenesis. Frank discussion of the various risks of each agent should be conducted, particularly the risks associated with valproic acid and trimethadione. Usually if the patient's disease is adequately controlled with one agent, it rarely needs to be changed, because the risks of increasing seizure activity are believed to outweigh the potential for reducing congenital malformations.

Patients taking antiepileptic medications should also take folic acid supplements (800 to 1000 μg) before conception, because inhibition of folate absorption has been proposed as a teratogenic mechanism, particularly with phenytoin. During gestation, the anticonvulsant levels should be checked monthly, and the dose should be adjusted accordingly, particularly with the use of lamotrigine, carbamazepine, and phenytoin (Harden et al, 2009). Although the evidence is less clear with other agents such as phenobarbital, valproate, primidone, and ethosuximide, serial level assessment should not be discouraged. Medications should not be changed unless they prove ineffective at the optimal serum level. If a patient reports greater seizure activity, the serum drug level should be checked immediately. A common reason for increased seizures is that the patient is not taking her medication, usually because she fears its teratogenicity.

Mothers taking phenytoin, phenobarbital, or primidone may have a higher incidence of neonatal coagulopathy as a result of vitamin K–dependent clotting factor deficiency. Although maternal vitamin K supplementation in the third trimester may be reasonable, there is insufficient evidence to determine whether it will reduce neonatal hemorrhagic complications (Harden et al, 2009).

RED BLOOD CELL ISOIMMUNIZATION

Hydrops fetalis, a condition associated with abnormal fluid collections in various body cavities of the fetus, was first described in 1892. The causes are many but can be divided into two categories: immune causes and nonimmune causes. In immune-mediated hydrops, circulating immunoglobulins lead to the destruction of fetal red blood cells and hemolytic anemia. Landsteiner and Weiner first elucidated the Rhesus factor (Rh) in 1940. Levine et al, showed pathogenesis of erythroblastosis to be due to maternal isoimmunization in 1941. Rh immune globulin was developed in the middle 1960s. Prophylaxis protocols using Rh immune globulin significantly reduced the incidence of D isoimmunization, increasing the relative frequency of alloimmunization against atypical red blood cell antigens such as E, Duffy, and Kell (Figure 10-1). The pathophysiology of immune-mediated fetal hemolytic disease is similar, regardless of the blood group antigen involved; therefore this discussion focuses on the Rh system.

GENETICS

The Rh blood group actually represents a number of antigens, designated D, Cc, and Ee. The genes for these antigens, located on the short arm of chromosome 1, are

inherited in a set of three from each parent. The presence of D determines whether the individual is Rh positive, and the absence of D (there is no recessive allele, so "d" does not exist) yields the Rh-negative type. Rarely, a patient exhibits a Du variant and should be considered D positive. The combinations of these various antigens occur with different frequencies. For example, prevalence of Cde (41%) is higher than that of CDE (0.08%) (Lewis et al, 1971). Although the Rh phenotype is the result of D status, the various genotype combinations help to predict the zygosity of an individual. Approximately 45% of Rh-positive individuals are homozygous and therefore will always produce an Rh-positive offspring; 55% are heterozygous and may have an Rh-negative child if paired with an Rh-negative partner.

TABLE 10-1 Clinical Features of the Fetal Hydantoin Syndrome

Craniofacial abnormalities	Broad nasal ridge Wide fontanel Low-set hairline Broad alveolar ridge Metopic ridging Short neck Ocular hypertelorism Microcephaly Cleft lip with or without palate Abnormal or low-set ears Epicanthal folds Ptosis of eyelids Coloboma Coarse scalp hair
Limb abnormalities	Smallness or absence of nails Hypoplasia of distal phalanges Altered palmar crease Digital thumb Dislocated hip

Data from Briggs GC, Freeman RK, Yaffe SJ: *Drugs in pregnancy and lactation*, ed 7, Baltimore, 2005, Lippincott Williams & Wilkins.

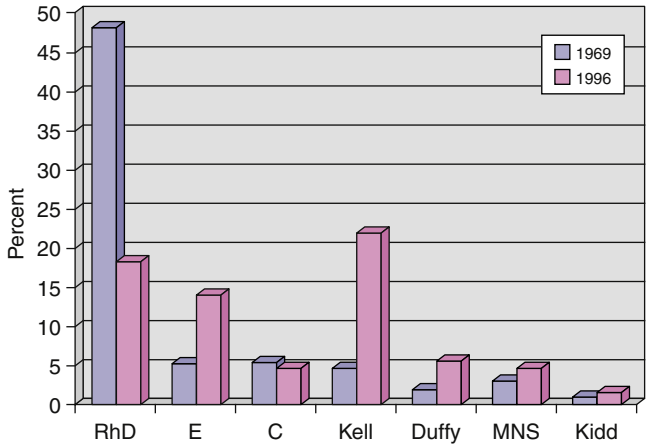

FIGURE 10-1 Differences in incidence of maternal red cell antibodies over time. (*Adapted from Queenan JG, Smith BD, Haber JM, et al: Irregular antibodies in the obstetric patient*, Obstet Gynecol *34:767-770, 1969; and Geifman-Holtzman O, Wojtowycz M, Kosmas E, et al: Female alloimmunization with antibodies known to cause hemolytic disease*, Obstet Gynecol *89:272-275, 1997.*)

There are no sex differences in the frequency of Rh negativity; however, racial variations are striking. Rh negativity is common in the Basque population (30% to 35%), but rare in Chinese, Japanese, and North American Indian populations (1% to 2%). The average incidence in white populations is approximately 15%. North American blacks have a higher incidence (8%) than African blacks (4%).

PATHOGENESIS

Before modern blood banking, Rh-negative patients became immunized from the transfusion of Rh-positive blood. In the case of atypical red blood cell antigens (e.g., Duffy, Kidd), blood transfusion is still a significant cause of isoimmunization. Currently, fetal transplacental hemorrhage is the primary cause of Rh isoimmunization. Rh immune globulin prophylaxis protocols have reduced but not eliminated this problem. Transplacental hemorrhage of fetal cells into the maternal circulation is surprisingly common, with 75% of women showing evidence of this event at some time during gestation (Bowman et al, 1986). Using sensitive Kleihauer-Betke testing, 0.01 mL or more fetal cells are found in 3%, 12% and 46% of women in the first, second and third trimesters, respectively. The amount of fetal blood is usually small, but approximately 1% of women have 5 mL. In 0.25% of women, 30 mL or more of fetal cells are noted after delivery. Obstetric events increase the chance of transplacental hemorrhage (Box 10-1). As little as 0.3 mL of Rh-positive blood produces immunization, and the risk is dose dependent. ABO blood group incompatibility between fetus and mother affords some protection, reducing the risk from 16% to 2%.

The primary maternal immune response is slow and can take as long as 6 months to develop. The first appearance of immunoglobulin (Ig) M class anti-D antibodies is weak; they do not cross the placenta, but are soon followed by smaller IgG antibodies that are capable of traversing the placental barrier. Therefore the initial event causing sensitization rarely results in fetal hemolysis. A second transplacental hemorrhage leads to the more rapid and abundant amnestic IgG response that, in the presence of fetal D-positive cells, can cause significant hemolysis and fetal anemia.

The severity of hemolytic disease is related to the maternal antibody titer, the affinity for the red blood

BOX 10-1 Obstetric Events Associated With Increased Risk of Fetal-Maternal Hemorrhage

- Unexplained vaginal bleeding
- Abruptio placentae
- External breech version
- Amniocentesis
- Chorionic villus sampling, placental biopsy
- Umbilical cord sampling
- Manual removal of the placenta
- Abdominal trauma
- Ectopic pregnancy

cell membrane, and the ability of the fetus to compensate for the red blood cell destruction. Table 10-2 summarizes the severity levels of fetal and neonatal disease and their incidence. Most cases are mild and result in normal outcomes; the cord blood is strongly Coombs positive, but the infants do not exhibit significant anemia or hyperbilirubinemia. Moderate disease results from the red blood cell destruction and the greater production of indirect bilirubin. Although the mother is able to clear this product for the fetus in utero, the neonate is deficient in the liver glucuronyl transferase enzyme, leading to the buildup of this water-insoluble molecule. Albumin carries the indirect bilirubin, but if the binding capacity is exceeded, diffusion of the bilirubin into the fatty tissues occurs. Neural tissue is high in lipid content. Ultimate destruction of neurons can occur, resulting in kernicterus. Treatment depends on the recognition of the hyperbilirubinemia and usually entails phototherapy and possible exchange transfusion in the nursery (see Chapter 79).

Severe disease occurs when the fetus is unable to produce sufficient red blood cells to compensate for the increased destruction of these cells. Extramedullary hematopoiesis, which is prominent in the liver, ultimately leads to enlargement, hepatocellular damage, and portal hypertension. This process is believed to be the etiology of placental edema and ascites. Albumin production diminishes because of hepatocellular damage and results in anasarca, giving rise to hydrops fetalis. The theory that hydrops is due to fetal heart failure no longer holds, as a result of observations that these infants are neither hypervolemic nor in failure. The relationship between fetal anemia and hydrops is variable, but most hydropic fetuses have hemoglobin levels less than 4 g/dL or have a hemoglobin concentration deficit greater than 7 g/dL (Nicolaides et al, 1988).

MANAGEMENT

Management of the sensitized patient, for both Rh and atypical red blood cell antigens, requires an understanding of the mechanism of disease and the skill and experience to predict its severity. Although management schemes follow some basic guidelines, successful management requires access to a blood bank with expertise in antibody typing and individuals skilled in prenatal diagnostic procedures (e.g., cordocentesis). Referral to experienced high-risk centers for the management of this problem is common in the United States.

MONITORING

At their first prenatal visit, all pregnant patients should undergo a blood type and antibody screen (indirect Coombs' test), which identifies the Rh-negative woman and screens for the presence of anti-D antibody and other immunoglobulins that are associated with atypical red blood cell antigens and capable of causing fetal hemolytic disease (Table 10-3). Any positive result on antibody screening should be evaluated aggressively to identify the antibody and quantify its amount by titer. A consultation with a blood bank pathologist may be necessary for atypical antibodies.

The amount of the anti-D antibody present according to indirect antibody titer is important. For a titer that is less than 16 and remains at that level throughout the pregnancy, most centers consider the fetus to be at negligible risk of hydrops or stillbirth. Each blood bank sets different standards for this critical titer, which depend on the assay used. At a titer of 16, the risk is 10%; at 128, it is 75%. For a woman with a previously affected fetus, no titer is predictive; therefore management based on its result may underestimate the severity of fetal disease.

Once the patient has been identified as isoimmunized, obtaining her obstetric history is important. All of her prior pregnancies and their outcomes must be documented to attempt to elucidate the timing and cause of the sensitization and to assess the risk in the current pregnancy. In general, the condition is worse with each pregnancy. In a first sensitized pregnancy, the risk of hydrops is approximately 10%. More than 90% of patients who have delivered one hydropic baby will deliver another one subsequently.

Paternal blood typing and Rh genotyping should be performed to calculate the fetal risk of Rh positivity. Given

TABLE 10-2 Classification of the Severity of Hemolytic Disease

Severity	Description	Incidence (%)
Mild	Indirect bilirubin result, 16-20 mg/dL No anemia No treatment needed	45-50
Moderate	Fetal hydrops does not develop Moderate anemia Severe jaundice with risk of kernicterus unless treated after birth	25-30
Severe	Fetal hydrops develops in utero Before 34 weeks' gestation After 34 weeks' gestation	20-25 10-12 10-12

TABLE 10-3 Examples of Atypical Red Blood Cell Antigens Associated With Fetal Hemolytic Disease

Blood Group System	Antigen	Severity of Hemolytic Disease
Kell	K	Mild to severe
Duffy	Fya	Mild to severe
Kidd	JKa	Mild to severe
	JKb	Mild to severe
MNSs	M	Mild to severe
	N	Mild
	S	Mild to severe
	s	Mild to severe
	U	Mild to severe
P	PP	Mild to severe
Public antigens	Yta	Moderate to severe

the high percentage of heterozygosity in Rh-positive individuals, assays utilizing free DNA in the maternal circulation are used to determine a potentially D+ fetus. Accuracy with this technique can approach 97% (Geifman-Holtzman et al, 2006). For atypical blood group immunization, a history of prior obstetric outcomes plus transfusions (a significant cause of such antibodies) and determination of the father's antigen status are of similar importance. For example, a woman with an anti-Kell antibody titer of 128 would be at moderate risk of hydrops, unless the father of the baby were found to be Kell negative. No invasive procedures for isoimmunization should be performed until the father's antibody status is established, unless the fetus's paternity is in question or the partner is unavailable.

Ultrasonographic screening to identify the prehydropic fetus is notoriously unreliable, in that significantly anemic fetuses may not be grossly hydropic. However, clues that have been proposed to suggest impending hydrops are polyhydramnios, skin thickening, early ascites (particularly around the fetal bladder), and placental thickening. Ultrasonographic measurements of the liver and spleen have been suggested as aids in predicting anemia in nonhydropic fetuses, but lack sensitivity and specificity (Bahado-Singh et al, 1998; Vintzileos et al, 1986).

Antibody titers should be followed monthly to predict which fetus is at risk (in the absence of a history of a prior infant with hydrops). If the indirect antibody titer value is less than 16, the development of hydrops is unlikely. Most centers consider the critical value to be 16, because above this level, one cannot ensure the absence of hydrops. When a patient's antibody titer value is equal to or greater than 16, more invasive testing is needed. Such testing is usually accomplished with amniocentesis and, less commonly, through direct fetal blood sampling.

Amniocentesis is the standard screening technique for fetal anemia, because amniotic fluid contains hemolytic products excreted from the fetal kidneys and lungs, including bilirubin. The unconjugated form of bilirubin is secreted across the respiratory tree and therefore into the amniotic fluid. The supernatant is analyzed with a spectrophotometer, and the bilirubin peak corresponding to the level of absorbance (or optical density [OD]) of these hemoglobin products (450 nm) is quantified. The magnitude of the peak is calculated after subtracting the mean baseline value surrounding the peak. The difference from baseline to peak is the ΔOD_{450} value.

The amount of the increase in the ΔOD_{450} value correlates reasonably well with severity of hemolysis. In 1961, Liley developed a graph that has been used to predict the severity of fetal hemolytic disease using the ΔOD_{450} value. The graph is divided into three zones. Zone I represents the lowest risk and indicates an unaffected fetus, whereas zone III strongly suggests a severely affected fetus, in which fetal hydrops and death can ensue if disease is not treated within the next 7 to 10 days. The Liley curve is authoritative in the third trimester, but its reliability before 26 weeks' gestation has been questioned (Queenan et al, 1993). At less than 20 weeks' gestation, the ΔOD_{450} value must be greater than 0.15 or less than 0.09 to be predictive of severe or mild disease, respectively, with a "gray zone" between the two values that is nonpredictive (Ananth and Queenan, 1989). Thus, the clinician must integrate clinical history and ultrasonography clues for possible impending hydrops or consider fetal blood sampling in a fetus at risk between 18 and 25 weeks' gestation.

Amniocytes can be obtained during the amniocentesis procedure. Through polymerase chain reaction analysis, fetal D antigen typing can be obtained as early as 14 weeks' gestation (Dildy et al, 1996). This process allows the identification of the fetus that is not at risk for hemolytic disease caused by maternal antibody isoimmunization. Isoimmunization with atypical red blood cell antigens other than D can be detected similarly, reducing the amount of unnecessary invasive procedures on an otherwise unaffected fetus.

A recent advance in ultrasound technology has dramatically altered the assessment of the potentially affected fetus. Doppler blood flow measurements in the umbilical vein (Iskarios et al, 1998) and in the middle cerebral artery have shown to be altered in anemia, with the latter revealing an elevated peak systolic velocity. Using a developed reference range with a cutoff of 1.5 multiples of the median, Mari (2000), was able to predict which nonhydropic fetuses had moderate or severe anemia (Figure 10-2). A prospective multicenter trial compared the use of middle cerebral artery Doppler against the "gold standard" amniotic fluid ΔOD_{450}. One hundred sixty-five fetuses were studied, and almost half were found to have severe fetal anemia at cordocentesis. Middle cerebral artery Doppler was noted to have a sensitivity of 88%, a specificity of 85%, and an accuracy of 85%. Doppler outperformed ΔOD_{450} analysis using the Liley curve, with a 9% improvement in the accuracy. Furthermore, it has been suggested that 50% of invasive procedures could have been averted with the use of Doppler (Oepkes et al, 2006). Direct ultrasound-guided fetal umbilical blood sampling provides valuable

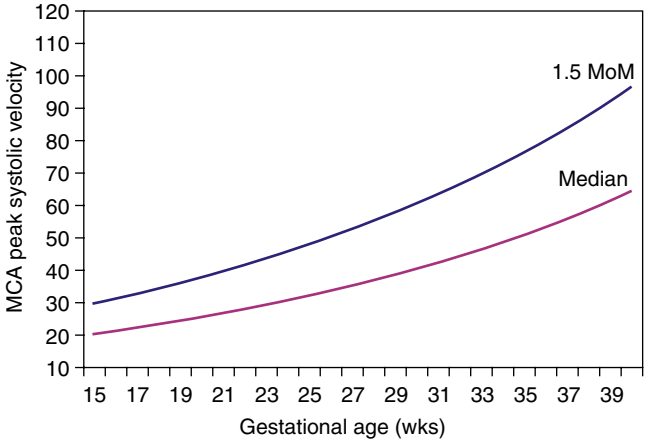

FIGURE 10-2 Peak velocity of systolic blood flow in the middle cerebral artery (MCA) with advancing gestation. The *bottom curve* indicates the median peak systolic velocity in the middle cerebral artery, and the *top line* indicates 1.5 multiples of the median (MoM; the threshold for significant fetal anemia). (*Adapted from Mari G, Hanif F: Fetal Doppler: umbilical artery, middle cerebral artery, and venous system*, Semin Perinatol *32:254, 2008.*)

data for the fetus at risk, particularly after 18 weeks' gestation. Cordocentesis is used most often when the risk determined from history, indirect antibody titer values, Liley curve comparisons, or ultrasonographic clues are significant. Cordocentesis also provides vascular access if fetal transfusion becomes necessary. Although most obstetricians are skilled in amniocentesis, cordocentesis is usually performed in tertiary centers by perinatologists. The latter procedure carries a higher risk of fetal loss and morbidity, and it is associated with a more significant chance of worsening maternal sensitization (Bowman and Pollock, 1994).

THERAPY

Fetal transfusion therapy is the mainstay of treatment for the severely affected but premature fetus. In most centers, for pregnancies beyond 33 weeks' gestation with suspected fetal anemia, administration of steroids and delivery are preferable to an invasive procedure with significant morbidity and mortality. Intraperitoneal transfusions, the primary therapy in the past, are still a useful treatment. O-negative, tightly packed, irradiated blood is infused percutaneously into the fetal peritoneal cavity via an amniocentesis needle with real-time ultrasound guidance. Approximately 10 mL is transfused for each week of gestation beyond 20 weeks. Red blood cell absorption occurs promptly through the subdiaphragmatic lymphatics, although it may be erratic in the hydropic fetus. Overall survival rates with fetuses requiring transfusion approaches 89% (Van Kamp et al, 2005). However, hydrops was associated with a decreased survival rate of 78% (Van Kamp et al, 2001), with severely hydropic fetuses having a survival rate of 55%. Problems associated with intraperitoneal transfusions include injury to vascular or intraabdominal organs and the inability to obtain fetal blood type and blood count. This procedure should be avoided if possible in the hydropic fetus, because the resulting higher abdominal pressure can precipitate venous compression and lead to circulatory collapse.

Direct intravascular transfusions are currently the first line of treatment. The advantages of this procedure include assessing the severity of fetal anemia and documenting the fetal blood type. Ultimate success does not appear to be affected by the presence of hydrops (Ney et al, 1991). The overall success rate is approximately 85%. Limitations are usually related to the procedure. The most accessible site usually requires an anterior placenta, in which the cord root can be visualized; posterior placentation makes the technique more difficult. In addition, risks include bleeding from the cord puncture site, fetal exsanguination, cord hematoma, rupture of membranes, and chorioamnionitis.

Additional transfusions are required every 2 to 3 weeks to compensate for the falling hematocrit associated with fetal growth, the finite life of the transfused red blood cells, and ongoing hemolysis of the existing fetal erythrocytes. Ultimately the entire fetal blood supply is replaced with Rh-negative blood by successive transfusions. A major neonatal side effect is bone marrow depression, which may require postnatal transfusions for 1 to 3 months (De Boer et al, 2008).

As the pregnancy proceeds through the third trimester, frequent fetal testing is performed either with nonstress tests and amniotic fluid index or with biophysical profiles. Delivery is planned for 3 to 6 weeks before term, usually after demonstration of a mature fetal lung profile. Preterm delivery may be indicated in a severely affected fetus, regardless of lung profile, if the risk of transfusion is deemed to exceed the morbidity of a delivery of a near-term yet premature baby.

CANCER

PRINCIPLES

Cancer complicating pregnancy is rare, with an estimated frequency of 1 case per 1000 live births. The trend of delaying childbearing to later maternal age may have influenced this rate. The sites or types of cancer in pregnancy, in descending order of frequency, are cervical, breast, ovarian, lymphoma, melanoma, brain, and leukemia (Table 10-4) (Haas et al, 1984; Jacob and Stringer, 1990). Finding a malignancy during gestation poses a unique set of issues that must be addressed with care. Will the pregnancy accelerate the malignant process? Are the accepted therapies appropriate for the mother, and are they safe for the unborn fetus? Will delay of therapy adversely affect the mother? Should the pregnancy be terminated, or should the child be delivered prematurely to maximize treatment of the mother with no resultant risk to the child?

Few conditions in pregnancy require as meticulous a multidisciplinary approach as cancer. Oncologists who are unaccustomed to interacting with a pregnant woman commonly wish to have the child delivered before giving definitive cancer therapy, for fear of the teratogenic risks to the fetus. Therefore input regarding the situation must be acquired not only from an oncologist but also from the obstetrician, perinatologist, pediatrician, neonatologist, and dysmorphologist. The patient and her family must be involved in decision making, being given information not only about the risks of the disease and its potential therapies, but also about the limitations of current knowledge about cancer in pregnancy and the uncertainties of outcomes.

TABLE 10-4 Cancers that Can Complicate Pregnancy

Site/Type	Incidence (per number of gestations)
Cervix	1:2000 to 1:10,000
Breast	1:3000 to 1:10,000
Melanoma	1:1000 to 1:10,000
Ovary	1:10,000 to 1:100,000
Colorectal	1:13,000
Leukemia	1:75,000 to 1:100,000
Lymphoma	1:1000 to 1:6000

Data from Pentheroudakis G, Pavlidis N, Castiglione M: Cancer, fertility and pregnancy: ESMO clinical recommendations for diagnosis, treatment and followup, *Ann Oncol* 20(Suppl 4):S178-S181, 2009.

SURGERY

Patients can undergo indicated surgery during pregnancy safely. The risk of fetal loss does not seem to rise with uncomplicated anesthesia and surgery. However, if there are any complications from either the anesthesia or the operation, the risk of fetal and maternal mortality increases. For example, fetal loss is rarely related temporally to maternal appendectomy, but is common when the mother's appendix has ruptured. The most comprehensive series of pregnant patients undergoing surgery was collected in Sweden (Mazze and Kallen, 1989). Although these researchers found a slight increase in the rates of low birthweight and neonatal death by 7 days of life, the rates of stillbirth and congenital malformation were similar to the outcomes expected without surgery. Anesthetic agents are not believed to be teratogenic.

A few management guidelines help to optimize outcome for the pregnant patient undergoing surgery. If general anesthesia is used, the maternal airway must be protected to avoid aspiration. Gastrointestinal motility is reduced during pregnancy, and the stomach may contain significant residual contents after many hours without eating. A left lateral decubitus position on the operating table is preferred to maximize uteroplacental blood flow. If the fetus is viable, monitoring of the fetal heart rate should be performed to assist the anesthesia team in optimizing fetal status. Preoperative counseling with the patient is important to allow the surgical team to make appropriate choices in regard to any interventions for fetal distress.

CHEMOTHERAPY

Administering agents that impair cell division in pregnancy is a concern for both the mother and the care team. Often the patient is more concerned about this issue than about the underlying cancer. Cytotoxic chemotherapy should be avoided in the first trimester because of the high incidence of spontaneous abortion and the potential teratogenic effects on the fetus (Table 10-5). For a few agents with confirmed teratogenic effects (e.g., methotrexate, amethopterin, chlorambucil), chemotherapy must be avoided during organogenesis. The use of folic acid antagonists in first-trimester cancer treatment raises the specific problem of possible induction of neural tube defects, because these lesions are known to be folate sensitive.

The literature regarding most other chemotherapeutic agents is limited, consisting of a few collected series; therefore these agents should be used cautiously, with their potential harm to the fetus balanced against their benefit to the maternal condition. Little is also known regarding the long-term outcomes of fetuses exposed to chemotherapeutic agents in utero. The National Cancer Institute in Bethesda, Maryland, maintains a registry in the hopes of determining the delayed effects. A small series of fetuses exposed to chemotherapeutic agents for acute leukemia revealed normal mental development with follow-up between 4 and 22 years (Aviles and Niz, 1988).

The risk of teratogenicity does not appear to be higher with combination chemotherapy than with single-agent therapy (Doll et al, 1989). Studies performed thus far involve small numbers of patients, with power insufficient to show a statistic difference, but there seems not to be a trend. Low birthweight is found in approximately 40% of babies whose mothers received cytotoxic drugs during pregnancy (Nicholson, 1968). Theoretical consequences, such as bone marrow suppression, immune suppression, and anemia, could occur in the fetus. As a result, the timing of chemotherapy should account for the anticipated date of delivery. Data regarding safety for breastfeeding the neonate of a mother receiving cancer chemotherapy are limited. For this reason, the majority of agents are contraindicated in nursing mothers.

TABLE 10-5 Common Chemotherapy Agents and Uses

Class or Drug	Risk Category	Common Uses
Alkylating Agents		
Busulfan	Dm	Leukemias
Chlorambucil	Dm	Lymphomas, leukemias
Cyclophosphamide	Dm	Breast, ovary, lymphomas, leukemias
Melphalan	Dm	Ovary, leukemia, myeloma
Procarbazine	Dm	Lymphomas
Antimetabolites		
5-Fluorouracil	D*	Breast, gastrointestinal
6-Mercaptopurine	Dm	Leukemias
Methotrexate	Xm	Trophoblastic disease, lymphomas, leukemias, breast
6-Thioguanine	Dm	Leukemias
Antibiotics		
Bleomycin	Dm	Cervix, lymphomas
Daunorubicin	Dm	Leukemias
Doxorubicin	Dm	Leukemias, lymphomas, breast
Other Agents		
All-*trans*-retinoic acid	X	Leukemias
L-Asparaginase	Cm	Leukemias
Cisplatin	Dm	Ovary, cervix, sarcoma
Hydroxyurea	D	Leukemias
Prednisone	C*	Lymphomas, leukemias, breast
Tamoxifen	Dm	Breast, uterus
Paclitaxel	Dm	Breast, ovarian
Vinblastine	Dm	Breast, lymphomas, choriocarcinoma
Vincristine	Dm	Leukemias, lymphomas

RADIATION THERAPY

The deleterious effects of irradiation on the fetus have been both theorized and actual. Fortunately, the amount of concern about the former far exceeds the incidence of the latter. Irradiation promotes genetic damage and thus the potential for congenital malformations. The risk depends on both dose and time (Table 10-6). A dose of less than 5 rad is believed to be of little consequence (Brent et al, 1989). If radiation exposure occurs before implantation, the adverse outcomes are usually a small increase in miscarriage.

The major concern is high-dose radiation (>10 rad) received during the period of organogenesis (embryonic weeks 1 to 10). The central nervous system is the most radiation-sensitive organ, and the complications most often observed are microcephaly and mental retardation. Cataracts and retinal degeneration are also seen. After organogenesis is complete, there is still a risk of central nervous system abnormalities. However, the sequelae most often seen are skin changes and anemia. Because of the highly variable yet potentially grave consequences of irradiation greater than 10 rad, patients should be counseled accordingly, and termination of pregnancy should be offered as an alternative if exposure has occurred in the previable period (Orr and Shingleton, 1983).

There are several other considerations for a pregnant woman undergoing radiation therapy. First, the dose used in estimating risk should be the amount that the fetus actually receives. For example, axillary or neck irradiation for lymphoma involves a lower direct fetal exposure than direct pelvic irradiation for cervical cancer. The latter treatment, if given in the second trimester, will likely cause fetal demise. Second, the magnitude of radiation scatter to the pelvis must be considered. External shielding does not prevent internal reflection of the ion beam. Third, the advancing size of the uterus actually increases the amount of radiation exposure of the fetus, because of the closer proximity of the nonpelvic irradiation. Therefore an 8-week-old fetus may actually receive a smaller radiation dose from supraclavicular irradiation than a 30-week-old fetus. Fourth, will the fetus concentrate the radiation, and therefore increase its dose? This is exemplified by the use of radioactive iodine (^{131}I) for maternal thyroid conditions. The actual rad dose is markedly higher in the fetus, because the fetal thyroid concentrates the iodine.

Diagnostic tests such as radiography may also be associated with radiation exposure for the fetus (Table 10-7). The doses involved are usually much smaller than those used for cancer therapy. Nonetheless, the practitioner should limit the amount of radiographic testing if at all possible. Inadvertent imaging of a patient who is not known to be pregnant continues to occur despite sensitive pregnancy tests, thus creating significant concerns. Indicated radiographs should never be withheld because of pregnancy, but lead shielding of the patient's abdomen and careful selection of the type of study should be performed to minimize the pelvic dose. Usually the amount of fetal exposure is much less than 5 rad, with no significantly greater risk of malformations. There does appear to be a slightly higher incidence of childhood cancer if the fetus is exposed to doses on the order of 10 mGy (Doll and Wakeford, 1997).

CERVICAL CANCER

Cervical cancer is the most common malignancy found in pregnancy. The incidence is approximately 1 in 2500 gestations. A Papanicolaou test smear should be performed for all patients at their first prenatal visit. However, approximately 30% of cervical cancers can be associated with negative cytologic smear results. Although the evaluation for

an abnormal Papanicolaou test result should not be altered because of pregnancy, many physicians are reluctant for fear of cervical hemorrhage. Cervical biopsy remains the mainstay of diagnosis. The greater vascularity of the cervix during pregnancy predisposes bleeding. An experienced colposcopist may be able to defer actual biopsy in cases of possible visual findings of a noninvasive process. However, if cancerous invasion is suspected or if the physician is uncertain of the visual findings, biopsy is necessary. If microinvasive disease is confirmed by biopsy, cone biopsy is required to rule out frankly invasive disease. This procedure is undertaken with caution during pregnancy, because of the associated high rate of bleeding complications and miscarriage. Cervical conization may raise the risk of incompetence or preterm labor. The assistance of a gynecologic oncologist is preferred, given these unique sets of potential consequences. A shallow cone biopsy will reduce the risk of subsequent cervical weakness.

The therapy for invasive cervical cancer is based on the stage of disease and the gestational age of the fetus. Therapy can involve external beam radiation, internal radiotherapy (brachytherapy), or surgery (Table 10-8). In most cases, delay of definitive therapy by 4 to 14 weeks may be acceptable. Pregnancy does not seem to accelerate the growth of the tumor. However, patient counseling is important. In the extremely previable gestation, the likelihood of achieving a safe gestational age for the fetus without worsening the stage or spread of the cancer in the mother must be balanced against parental desires based on ethical or religious beliefs. Conversely, it might be reasonable to delay definitive therapy until a time when delivery would not likely result in a long-term disability because of extreme prematurity.

BREAST CANCER

Breast cancer is the most common malignancy of women, with approximately 1 in 8 women affected in their lifetimes (Goldman and O'Hair, 2009). The incidence of breast cancer in pregnancy is estimated to be 10 to 30 per 100,000 pregnancies (Isaacs, 1995). Pregnancy does not seem to influence the actual course of the disease; however, there appears to be a higher risk of delay in diagnosis and a trend toward more advanced stages at diagnosis in pregnant women than in nonpregnant controls.

The diagnostic procedures for breast cancer should not be altered during pregnancy. Any suspicious mass should undergo biopsy. Mammography, although discouraged for routine screening in pregnancy, can be used safely if indicated. The amount of radiation is negligible—approximately 0.01 cGy (Liberman et al, 1994). Mammography imaging may be hampered by physiologic changes because of pregnancy, and ultrasound examination may be a useful alternative. Metastatic evaluation may be hampered somewhat because of a reluctance to use bone and liver scans during pregnancy. Magnetic resonance imaging can be used safely in the second and third trimesters.

Surgical therapy for breast cancer should not be delayed because of pregnancy. The risks of mastectomy and axillary node dissection appear to be low (Isaacs, 1995). Radiation therapy is usually not recommended during pregnancy because of the risk of beam scatter to the pregnant uterus. If the pregnancy is to continue and the patient has evidence of tumor invasion in the lymph nodes, adjuvant chemotherapy is often given. The timing of delivery should account for the following factors:

- When would the fetus have a reasonable chance for survival with a low risk of severe permanent morbidity?
- Can the number of cycles of chemotherapy be minimized with an earlier delivery? In addition, avoiding delivery just before or just after administration of chemotherapy is important to reduce the risk of immunosuppression and infection.
- How long can radiotherapy be delayed without increasing the risk of metastatic spread of the tumor?

Approximately 10% of women treated for breast cancer become pregnant, the majority within 5 years of diagnosis. Data from small series suggest that pregnancy does not influence the rate of recurrences or of distal metastasis (Dow et al, 1994). However, women should be encouraged to delay childbearing for at least 2 to 3 years, which is the time of the highest rate of recurrence. Breastfeeding may be possible in women who have undergone conservative breast cancer surgery.

TABLE 10-8 Treatment Options for Cervical Cancer in Pregnancy

Gestational Age (weeks)	Stage I to IIa	Stage IIb to IIIb
<20	4500 cGy Wide pelvic irradiation If no spontaneous abortion: modified radical hysterectomy If spontaneous abortion: brachytherapy or radical hysterectomy with lymphadenectomy	5000 cGy Wide pelvic irradiation If no spontaneous abortion: type II radical hysterectomy If spontaneous abortion: brachytherapy or cesarean section at fetal viability Subsequent wide pelvic radiation (±5000 cGy) and brachytherapy (±5000 cGy)
>20	Cesarean section at fetal viability Subsequent wide pelvic radiation (5000 cGy) and brachytherapy (5000 cGy) or cesarean radical hysterectomy with lymphadenectomy	Cesarean section at fetal viability Subsequent wide pelvic radiation (±5000 cGy) and brachytherapy (±5000 cGy)

Data from Berman ML, Di Saia PJ, Brewster WR: Pelvic malignancies, gestational trophoblastic neoplasia and nonpelvic malignancies. In Creasy RK, Resnik R, editors: *Maternal-fetal medicine*, ed 4, Philadelphia, 1999, WB Saunders.

OVARIAN CANCER

Most ovarian cancer occurs in women older than 35 years. Delayed childbearing has been more widely accepted, exemplified by British birth rates doubling in women older than 30 years and tripling in women older than 40 years since 1975 (Palmer et al, 2009), in addition to a twofold increased birth rate among U.S. women older than 40 years since 1981 (Martin et al, 2009). It would not be surprising for the rate of ovarian and other cancers during pregnancy to increase. However, the current estimate of actual ovarian malignancies in pregnancy is low and estimated to range from 1 in 10,000 to 1 in 50,000 deliveries (Jacob and Stringer, 1990; Palmer et al, 2009). Whereas most ovarian cancers are epithelial in origin, borderline epithelial and germ cell tumors (dysgerminomas and malignant teratomas) are more common in pregnancy.

The widespread use of ultrasonography, particularly in the first two trimesters, has been helpful in identifying adnexal masses. Fortunately, most are benign functional cysts. Actual malignancy is rare and is estimated at 5% of the ovarian masses found. The risk is higher in nonpregnant females, approaching 15% to 20%. Surgery for a suspected ovarian mass occurs in approximately 1 per 1000 pregnancies. Most procedures are performed not for suspected malignancy, but because of concern about torsion and rupture. The incidence of adnexal torsion ranges from 1% to 50%, and there appears to be a trend with increasing rates in masses greater than 6 cm (Yen et al, 2009). The maximal times of risk of these events are at the end of the first trimester, when the uterus elevates beyond the true pelvis, and at the time of delivery. The characterization of an ovarian process can be aided by ultrasonography or magnetic resonance imaging, but these modalities are not definitive. Ultrasound scoring systems that use size and character poorly predict malignancy, but have a better negative predictive value (Lerner et al, 1994). Although an ovarian cyst, particularly if it is simple in nature, is likely not malignant, the patient must be cautioned that histologic diagnosis is more definitive. Indications for surgical exploration include a complex mass, a persistent simple cyst 8 cm or larger, or one that is symptomatic (Leiserowitz, 2006). The optimal time for laparotomy is in the second trimester. At that time, there is minimal interference from the gravid uterus and less of a risk of fetal loss, and the theoretical concerns of teratogenic exposure to anesthetic agents are avoided. Some patients opt for more conservative management; they should be counseled that they have a 40% chance of needing urgent intervention with either surgery or percutaneous drainage (Platek, 1995).

If a malignancy is confirmed at the time of laparotomy, treatment and staging are no different than for a nonpregnant woman. Frozen-section diagnosis, peritoneal washings, omentectomy, and subdiaphragmatic biopsy are performed. Depending on the cell type and the stage, treatment can range from removal of the affected adnexa to complete hysterectomy and bilateral oophorectomy. Chemotherapy may be given during pregnancy if necessary. Fortunately, most epithelial ovarian cancers found in pregnant women are usually of a lower stage, with 59% of reported cases being stage I (Palmer et al, 2009).

SURVIVORS OF CHILDHOOD CANCER

Given the improvements of therapy for childhood cancer, a large number of these individuals have survived into adulthood. Some are unable to conceive because of high-dose radiation or cytotoxic chemotherapy. The risk of decreased fertility for patients exposed to pelvic radiation therapy may as high as 32% (Geogeseu et al, 2008). Those who remain fertile may have concerns regarding whether their treatment increases the risk of adverse pregnancy outcomes. Although data are limited, female cancer survivors treated with radiation therapy appear to have increased risks of premature delivery, low birthweight, and miscarriage. There is no evidence that female partners of male cancer survivors treated with radiation have these excess risks (Reulen et al, 2009).

MENTAL DISORDERS

Pregnancy can be a stressful process. At times, it may induce a psychotic event. Women experiencing a mental disorder during pregnancy who have no history of a mood disorder usually exhibit a milder constellation of symptoms. Serious disorders such as mania and schizophrenia that are antecedent to pregnancy may not be so benign. In women with all types of mental illness, and in previously nonaffected women, the postpartum state is a time of greater maternal risk. Ten percent to 15% of new mothers experience a depressive disorder (Weissman and Olfson, 1995). Furthermore, there appears to be an increased perinatal risk with mental disorders and pregnancy (Table 10-9). Women with preexisting mental illness have a higher recurrence risk in the puerperium. Patients with suspected mental illness should be assessed for substance abuse and thyroid dysfunction. A multidisciplinary approach is advantageous. If the patient's mental competency is an issue, the caregiver should obtain legal assistance to be able to make medical decisions for the patient.

DEPRESSION

Depression ranks as the fourth leading cause of disability worldwide, and recognized prevalence appears to be increasing (Dossett, 2008). A study by Dietz et al (2007) suggests that the prevalence of depression during pregnancy or postpartum, as defined by onset within 3 to 6 months after delivery, to be approximately 10%.

The predisposing risk factors for depression include early childhood loss, physical or sexual abuse, socioeconomic deprivation, genetic predisposition, and lifestyle stress caused by multiple roles (McGrath et al, 1990). These factors can exaggerate or prolong symptoms and, if not addressed, can lengthen the duration of depression. The obstetrician must be aware that life events such as miscarriage, infertility, and complicated pregnancy in patients with risk factors are likely to precipitate depression; therefore there is a low threshold for diagnosis and treatment of mood alterations in such patients.

TABLE 10-9 Impact of Psychiatric Illness on Pregnancy Outcome

		Impact on Outcome		
Illness	**Teratogenic Effects**	**Obstetric**	**Neonatal**	**Treatment Options**
Anxiety disorders	N/A	Increased incidence of forceps deliveries, prolonged labor, precipitate labor, fetal distress, preterm delivery, and spontaneous abortion	Decreased developmental scores and inadaptability; slowed mental development at 2 years of age	Benzodiazepines Antidepressants Psychotherapy
Major depression	N/A	Increased incidence of low birthweight, decreased fetal growth, and postnatal complication	Increased newborn cortisol and catecholamine levels, infant crying, rates of admission to neonatal intensive care units	Antidepressants Psychotherapy ECT
Bipolar disorder	N/A	Increased incidence of low birthweight, decreased fetal growth, and postnatal complication	Increased newborn cortisol and catecholamine levels, infant crying, rates of admission to neonatal intensive care units	Lithium Anticonvulsants Antipsychotics ECT
Schizophrenia	Congenital malformations, especially cardiovascular	Increased incidence of preterm delivery, low birthweight, small for gestational age, placental abnormalities and placental hemorrhage	Increased rates of postnatal death	Antipsychotics

From ACOG Practice Bulletin: Clinical management guidelines for obstetrician-gynecologists number 92, April 2008 (replaces practice bulletin number 87, November 2007): use of psychiatric medications during pregnancy and lactation, *Obstet Gynecol* 111:1001-1020, 2008.
ECT, Electroconvulsive therapy.

Alternatively, perinatal loss experienced by a woman without predisposing risk factors will probably lead to a grief reaction or adjustment disorder, which may be misdiagnosed as depression.

Chronic medical conditions that are associated with a high prevalence of depression and may occur in women of childbearing age include renal failure, cancer, AIDS, and chronic fatigue or pain. Antihypertensives, hormones, anticonvulsants, steroids, chemotherapeutics, and antibiotics can cause depression. Alcoholism and substance abuse may manifest as depression. Underlying personality disorders complicate the diagnosis of depression by confusing the clinical situation, in addition to contributing to the secondary effect of many physicians' avoidance of patients suffering from such disorders.

Therapeutic interventions for depression include psychotherapy and medication. Electroconvulsive therapy has been shown to be an effective and relatively safe treatment in refractory cases (Rabheru, 2001). However, there remains controversy and some degree of concern because of published series and case reports suggesting a risk of fetal cardiac arrhythmias, vaginal bleeding, and premature uterine contractions (Bhatia et al, 1999); therefore it should be reserved for refractory cases and performed in a setting with immediate access to obstetric care (Pinette et al, 2007; Richards, 2007). Treatment of depression is effective in approximately 70% of cases. Supportive treatment alone is rarely effective in major depressive episodes. Most antidepressant medications currently prescribed during pregnancy are selective serotonin reuptake inhibitors (SSRIs). SSRIs have an advantage over the tricyclic antidepressants by not causing orthostatic hypotension. Unfortunately, and although limited series suggest that the SSRIs are relatively safe, little is known about long-term consequences for children exposed to SSRIs in utero (Altshuler et al, 1996; Chambers et al, 1996; Karasu et al, 2000). Fluoxetine is the best-studied SSRI in terms of safety. Alternatively, paroxetine has been associated with an increased risk of congenital heart defects (Kallen et al, 2007). Although data remain inconsistent, they suggest avoiding paroxetine as a first-line agent. However, if a certain agent is controlling the patient's symptoms, it would seem reasonable not to change medications for the sake of these concerns.

A recent issue has been raised regarding the use of SSRIs and persistent pulmonary hypertension of the newborn; however, the incidence remains low at approximately 10 in 1000 fetuses exposed after 20 weeks' gestation (Chambers et al, 2006). Currently, there is no consensus regarding the use of SSRIs during breastfeeding. Fluoxetine has an active metabolite with a long half-life and is found in higher concentrations in infants (Eberhard-Gran et al, 2006). Short-term neonatal effects have been reported, including increased crying, decreased sleep, and irritability, particularly with fluoxetine and citalopram. Reasonable guidelines regarding the use of SSRIs and other psychotropic medications are listed in Table 10-10. The long-term side effects are currently listed as "unknown" (Briggs et al, 2005; Dodd et al, 2000). The theoretical concerns are that such drugs may affect the developing central nervous system of the newborn and that abnormalities may not be readily apparent in the short term. Therefore SSRIs should be prescribed for a nursing mother only if the benefit clearly exceeds the risk, and after the patient has been counseled regarding the potential yet currently ill-defined risks. Given current medical knowledge, bottle feeding should be offered as an acceptable alternative if antidepressants must be used.

TABLE 10-10 Summary of Current Knowledge of Drug Excretion into Breast Milk, Drug Concentrations in Infant Serum, Adverse Effects in the Child, and Breastfeeding Recommendations for Different Psychotropic Drugs

Class or Drug	Drug Transfer into Breast Milk	Infant Plasma Concentrations	Adverse Effects in the Child	Breastfeeding Recommendations
SSRIs	Low transfer	Low plasma concentrations	Case reports of adverse effects in infants exposed to fluoxetine and citalopram	Compatible with breastfeeding; however, fluoxetine and citalopram may not be drugs of first choice
TCAs	Low transfer	Low plasma concentrations (except doxepin)	No suspected immediate adverse effects observed (except doxepin)	Compatible with breastfeeding; however, doxepin should be avoided
Other antidepressants	Limited data	Limited data	Limited data	None able to be made
Benzodiazepines	Low transfer	High plasma concentrations with longer acting drugs with active metabolites	Case reports of CNS depression reported for diazepam	Sporadic use of short-acting benzodiazepines unlikely to cause adverse effects
Lithium	Low transfer	Dose received by the infant is high	Limited data; some reports of toxicity in the infant	Limited data; however, breastfeeding should be avoided
Carbamazepine, sodium valproate	Low transfer	Low plasma concentrations	Some case reports of various adverse effects in the infant	Generally more compatible with breastfeeding than lithium
Lamotrigine	High transfer	High plasma concentrations	Limited data	None able to be made
Novel antipsychotics	Moderate transfer	Variable plasma concentrations	Limited data	None able to be made

CNS, Central nervous system; *SSRI*, selective serotonin reuptake inhibitor; *TCA*, tricyclic antidepressants.

POSTPARTUM PSYCHOSIS

A severe disorder, postpartum psychosis is fortunately rare, occurring in 1 to 4 per 1000 births (Weissman and Olfson, 1995). This condition is more worrisome than postpartum depression, because of the patient's inability to discern reality from the periods of delirium. Patients at risk for postpartum psychosis may have underlying depression, mania, or schizophrenia. Other risks are younger age and family history. The recurrence rate is approximately 25%. The peak onset of symptoms is between 10 and 14 days after delivery. Recognition of this disorder is extremely important to the protection of the patient and her family.

SCHIZOPHRENIA

The prevalence of schizophrenia is approximately 1% in the general population (Myers et al, 1984); it is associated with delusions, hallucinations, and incoherence. Morbidity due to this mental illness is higher than that due to any other. There appears to be a genetic component to the etiology; schizophrenia develops in approximately 10% of offspring of an affected person. Concordance of schizophrenia in identical twins reaches 65%. There is some speculation and controversy as to whether low birthweight (Smith et al, 2001) and obstetric complications (Kendell et al, 2000) are associated with a higher rate of schizophrenia.

Because the peak age of incidence is approximately 20 years and women are affected more often than men, it is unrealistic to assume that obstetricians will never encounter patients with schizophrenia. There appear to be higher rates of cesarean section and surgical vaginal delivery in affected patients (Bennedsen et al, 2001b). Children of women with schizophrenia may have a higher rate of sudden infant death syndrome and congenital malformations (Bennedsen et al, 2001a). However, it is difficult to ascertain whether these risks are independent of other factors such as smoking, poor socioeconomic status, and use of certain medications.

Treatment is achieved primarily through the use of psychotropic medication. The potential for teratogenesis appears low with the older-generation medications in the phenothiazine class, but most data for this issue were derived from the use of lower doses given to patients with hyperemesis gravidarum. Antipsychotic medication does cross the placenta. Current recommendations include avoiding use in the first trimester if possible, the use of lower doses or higher-potency alternatives, and cessation of medication 5 to 10 days before delivery (Herz et al, 2000). The use of most antipsychotics in breastfeeding is associated with an unknown risk (Briggs et al, 2005).

Lithium, used primarily in mania, is associated with a higher rate of Ebstein anomaly. Although the incidence of this consequence is low, either discontinuing the medication in the first trimester or continuing its use with careful counseling is a viable alternative. Fetal echocardiography should be performed in women who have used lithium in early pregnancy.

CHAPTER 11

Hypertensive Complications of Pregnancy

Andrew D. Hull and Thomas R. Moore

Hypertension is the most common medical problem in pregnancy, affecting 10% to 15% of all pregnant women. As the third most common cause of maternal mortality after thromboembolic disease and hemorrhage, hypertension accounts for almost 16% of maternal deaths in the United States (Berg et al, 2003). Complications arising from hypertensive disorders have profound effects on the fetus and neonate and thus are a major source of perinatal mortality and morbidity. Preeclampsia is also the primary cause of iatrogenic prematurity.

CLASSIFICATION OF HYPERTENSIVE DISORDERS OF PREGNANCY

Any discussion of hypertension and pregnancy must begin with a set of definitions. Although many classifications are in use worldwide, perhaps one of the more useful comes from the Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy (2000) (Table 11-1). Although this classification scheme appears to be somewhat pedantic, it is of paramount importance because pregnancy outcome varies according to the type of hypertension involved. For practical purposes, hypertension in pregnancy can be divided into the following categories: chronic hypertension, gestational hypertension, and preeclampsia.

Hypertension is defined as a systolic blood pressure of 140 mm Hg or higher or a diastolic pressure of 90 mm Hg or higher, measured on two separate occasions. Korotkoff phase V (disappearance of sound) is used rather than Korotkoff phase IV (muffling of sound) to define *diastolic pressure*, because Korotkoff IV is poorly reproducible in pregnancy. The term *severe hypertension* identifies a population at significantly increased risk for stroke and cardiac decompensation, and it is defined as a systolic blood pressure of 160 mm Hg or a diastolic pressure of 110 mm Hg or higher.

CHRONIC HYPERTENSION

Up to 5% of pregnant women have chronic hypertension, which is diagnosed when hypertension is present before pregnancy or recorded before 20 weeks' gestation. However, when hypertension is first noted in a patient after 20 weeks' gestation, it may be difficult to distinguish chronic hypertension from pregnancy-induced hypertension or preeclampsia. In such cases, the precise diagnosis might not be made until after delivery. Hypertension that is first diagnosed during the second half of pregnancy and persists more than 12 weeks postpartum is diagnosed as chronic hypertension.

Chronic hypertension has an adverse effect on pregnancy outcome. Women with the disorder are at higher risk for preterm delivery and placental abruption, and their fetuses are at risk for intrauterine growth restriction (IUGR) and demise (Ferrer et al, 2000). Superimposed preeclampsia complicates up to 50% of pregnancies in women with preexisting severe chronic hypertension (Sibai and Anderson, 1986), and it occurs before 34 weeks' gestation in 50% of cases (Chappell et al, 2008). The adverse effects on fetal and maternal perinatal outcomes are directly related to the severity of the preexisting hypertension. When chronic hypertension is secondary to maternal renal disease, the risks of poor outcome are further increased, with as much as a tenfold rise in fetal loss rate (Jungers et al, 1997). Women with untreated severe chronic hypertension are at increased risk for cardiovascular complications during pregnancy, including stroke (Brown and Whitworth, 1999).

The majority of cases of chronic hypertension seen in pregnancy are idiopathic (essential hypertension), but causes of secondary hypertension should always be sought because pregnancy outcome is worse in women with secondary hypertension. Renal disease (e.g., chronic renal failure, glomerulonephritis, renal artery stenosis), cardiovascular causes (coarctation of the aorta, Takayasu arteritis), and, rarely, Cushing disease, Conn syndrome, and pheochromocytoma should be excluded through physical examination, history, and more detailed testing if needed.

All patients with chronic hypertension should be evaluated periodically with serum urea, creatinine, and electrolyte measurements, urinalysis, and 24-hour urine collection for protein and creatinine clearance determinations. Typically this assessment should be performed in each trimester and more frequently if the patient's condition deteriorates.

ANTIHYPERTENSIVE TREATMENT OF CHRONIC HYPERTENSION IN PREGNANCY

Except in cases of severe hypertension, randomized trials have shown that antihypertensive treatment of chronic hypertension in pregnancy does not improve fetal outcome (Sibai and Anderson, 1986). Rates of preterm delivery, abruption, IUGR, and perinatal death are similar in treated and untreated women. Therefore treatment is usually reserved for patients whose hypertension places them at a significant risk of stroke (systolic blood pressure of 180 mm Hg or higher or diastolic pressure of 110 mm Hg or higher). Patients with less severe hypertension who were taking medications before conception might be able to discontinue therapy with close surveillance. The risk of superimposed preeclampsia is not changed by antihypertensive therapy, so its development should be tracked carefully.

TABLE 11-1 Classification of Hypertensive Disorders of Pregnancy*

Category	Definition
Chronic hypertension	Hypertension present before pregnancy or diagnosed before 20 weeks' gestation, or diagnosed for the first time during pregnancy that persists postpartum
Gestational hypertension	Transient if blood pressure returns to normal by 12 weeks after delivery, and preeclampsia was not diagnosed before delivery Chronic if blood pressure does not resolve by 12 weeks after delivery
Preeclampsia-eclampsia	Usually occurs after 20 weeks' gestation Hypertension accompanied by proteinuria in a woman normotensive before 20 weeks' gestation Strongly suspected if nonproteinuric hypertension is accompanied by systemic symptoms such as headache, visual disturbance, abdominal pain, or laboratory abnormalities such as low platelet count and elevated liver enzyme values (HELLP syndrome)
Preeclampsia superimposed on chronic hypertension	Preeclampsia occurring in a chronically hypertensive woman

Adapted from the Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy, *Am J Obstet Gynecol* 183:S1-S22, 2000.
HELLP, Hemolysis, elevated liver enzymes, and low platelets.
**Hypertension* is defined as a systolic blood pressure ≥140 mm Hg systolic or diastolic blood pressure ≥90 mm Hg.

TABLE 11-2 Drugs Commonly Used to Treat Chronic Hypertension in Pregnancy and Their Modes of Action

Drug	Mode of Action
Methyldopa	Centrally acting antihypertensive
Labetalol	Mixed alpha- and beta-adrenergic blocker
Nifedipine	Calcium channel blocker
Hydralazine	Peripheral vasodilator
Prazosin	Alpha-blocker

The choice of antihypertensive agent for use in pregnancy is governed by a desire to adjust blood pressure without having ill effects on the fetus. Because excessive lowering of maternal blood pressure below 140 mm Hg systolic or 90 mm Hg diastolic (140/90 mm Hg) can compromise uterine perfusion, with consequent slowing of fetal growth, fetal hypoxia, or both, the therapeutic goal is to maintain maternal pressures at 140 to 155 systolic and 90 to 105 diastolic. The drugs most commonly used in pregnancy are listed in Table 11-2.

Methyldopa, a centrally acting antihypertensive agent, formerly was the most widely used drug in this setting. Many obstetricians remain faithful to the use of this agent because of extensive clinical and research experience demonstrating its safety for both mother and fetus during pregnancy (Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy, 2000). This agent does not impair uteroplacental perfusion and has a wide therapeutic margin before side effects are seen. However, methyldopa has the disadvantage of a rather slow onset of action with prolonged time to therapeutic effect (days), and compliance with methyldopa therapy may be impeded by side effects such as sedation in some patients.

Labetalol is a mixed $alpha_1$-adrenergic and $beta_1$- and $beta_2$-adrenergic blocking agent, and it is the most frequently used alternative to methyldopa. Some pure beta-blockers have been associated with a significant increase in the risk of IUGR (e.g., atenolol), and the mixed adrenergic blockade produced by labetalol is thought to mitigate this unwanted effect (Pickles et al, 1989). Labetalol is also used intravenously to manage severe hypertension accompanying preeclampsia.

Calcium channel blockers (e.g., nifedipine) are used mainly as second-line drugs, usually in long-acting, extended-release forms. Calcium channel blockers appear to be as effective as methyldopa and labetalol with minimal fetal side effects (Levin et al, 1994).

Hydralazine, a potent peripheral vasodilator, is frequently used intravenously to treat acute hypertensive emergencies in pregnancy (blood pressure of >160/110 mm Hg). Its role as an oral agent in the management of chronic hypertension is limited to a second- or third-line choice. Long-term use of hydralazine may be associated with a lupuslike syndrome in some patients.

Prazosin, an alpha-adrenergic blocker, has been used as a second- or third-line drug in pregnant women whose hypertension is difficult to control or is severe with an early onset. This agent appears to be similar in efficacy to nifedipine in such a setting (Hall et al, 2000).

Although diuretics are used extensively in adults with hypertension, there appears to be little role for them in the treatment of chronic hypertension in pregnancy. Diuretics have been alleged to reduce or prevent the normal plasma volume expansion seen in pregnancy (Sibai et al, 1984), an effect that theoretically might impede fetal growth, although the evidence for this is mixed. Most authorities restrict the use of diuretics in pregnant patients to those with cardiac dysfunction or pulmonary edema.

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers should not be used during pregnancy. In the second and third trimesters, these agents are associated with malformation of the fetal calvarium, fetal renal failure, oligohydramnios, pulmonary hypoplasia, and fetal and neonatal death (Buttar, 1997). Angiotensin-converting enzyme inhibitors appear to be safe when taken in the first trimester (Steffensen et al, 1998), but a patient who conceives while taking an angiotensin receptor blocker or angiotensin-converting enzyme inhibitor should be switched to a safer alternative as soon as possible. Similar precautions apply to the use of angiotensin receptor blockers in pregnancy.

ANTENATAL FETAL SURVEILLANCE IN CHRONIC HYPERTENSION

As the third trimester progresses, patients with chronic hypertension are at an increasing risk of slowing of fetal growth and superimposed preeclampsia. Antenatal surveillance

in women with chronic hypertension should include careful screening for signs and symptoms of superimposed preeclampsia, which constitutes the greatest perinatal risk. Fetal growth should be followed with serial ultrasonography evaluations (every 3 to 6 weeks). All patients should perform fetal movement counts from 28 weeks' gestation onward, and cases with suspected fetal growth impairment should be followed with twice-weekly non-stress tests with amniotic fluid index or weekly ultrasound biophysical profile. Although the optimum interval for these tests is controversial (every 3 to 7 days), and their role is unproven in the absence of fetal IUGR or other evidence of fetal compromise, most centers begin regular fetal biophysical testing at 32 to 34 weeks' gestation and continue until delivery.

If fetal growth tapers below expectations (typically sonographic estimated fetal weight [EFW] falls below the tenth percentile or abdominal circumference much smaller percentile than head), more intensive fetal surveillance is indicated. In cases with IUGR, serial sonography should be performed at 10- to 21-day intervals with attention paid to amniotic fluid volume, careful profiling of each biometric parameter, and cerebral and umbilical Doppler waveforms. Typical indications for delivery in the setting of IUGR and hypertension include no growth of the head and abdomen over a 10-day interval, severe oligohydramnios, biophysical score of less than 6, or reversal of end-diastolic velocity on the umbilical Doppler waveform. However, individualization of management in these cases is important.

Women with renal impairment and chronic hypertension have a markedly higher risk of poor perinatal outcome than normotensive women and women with hypertension without renal impairment. In addition, moderate or severe renal disease (serum creatinine level ≥1.4 mg/dL) may accelerate the loss of renal function during pregnancy (Cunningham, 1990; Hou, 1999). The incidence of impaired fetal growth is directly related to the degree of renal impairment, and women undergoing dialysis are at particular risk for fetal growth failure, preterm delivery, and fetal death, even with optimal management. Those who start dialysis during pregnancy are at the greatest risk, with only a 50% chance of a surviving infant (Hou, 1999).

GESTATIONAL HYPERTENSION

The diagnosis of gestational hypertension can be made with confidence only after delivery; it is defined as hypertension occurring in the second half of pregnancy in the absence of any other signs or symptoms of preeclampsia. Because a woman with apparent gestational hypertension at 36 weeks' gestation can rapidly evolve into preeclampsia at 39 weeks' gestation, the diagnosis of gestational hypertension should always evoke caution and vigilance. Only if the patient's blood pressure returns to normal postpartum without development of signs of preeclampsia during the pregnancy should the final diagnosis of gestational hypertension be applied. During pregnancy, gestational hypertension is indistinguishable from preeclampsia in evolution. Therefore all patients with gestational hypertension should be regarded as being at risk for progression to preeclampsia.

The earlier gestational hypertension is evident, the greater the risk of preeclampsia. When the diagnosis is made before 30 weeks' gestation, more than one third will develop preeclampsia, whereas the risk is less than 10% when the diagnosis is made after 38 weeks' gestation. Decisions to treat patients with gestational hypertension with antihypertensive agents must be carefully considered, given the risk of concurrent preeclampsia and the lack of evidence supporting improved fetal outcome. Gestational hypertension tends to recur in subsequent pregnancies and predisposes women to hypertension in the future (Marin et al, 2000).

PREECLAMPSIA-ECLAMPSIA

Preeclampsia is one of the most enigmatic diseases affecting humans. Apparently unique to humans, preeclampsia has proved difficult to simulate in animal experiments. Despite years of intensive research, the underlying causes of the disease are only recently becoming clearer. It is evident that the clinical manifestations of preeclampsia arise from vascular endothelial dysfunction that ultimately may involve the central nervous, renal, hepatic, and cardiovascular systems. In its full-blown form, preeclampsia can produce a profound coagulopathy and liver, respiratory, or cardiac failure.

The classic symptom triad of hypertension, proteinuria, and edema defines preeclampsia. Most classifications of preeclampsia no longer include edema, because this common finding affects approximately 80% of pregnant women near term. Preeclampsia is divided into mild and severe forms (Box 11-1). This distinction is important, because in the presence of severe disease at any gestational age, the only appropriate treatment option is delivery, whereas expectant management may be acceptable in a woman who has mild disease and is remote from term.

Although the precise etiology of preeclampsia remains uncertain, numerous factors are associated with elevated the risk (Table 11-3). Up to 10% of primigravid patients have mild preeclampsia, and approximately 1% have severe disease.

PREECLAMPSIA

Etiology

The most widely accepted theory for the pathophysiology of preeclampsia is based on a model of impaired placental implantation that results in placental hypoperfusion and hypoxia. The placenta then releases substances into the maternal circulation that adversely affect endothelial function, leading to the clinical syndrome of widespread vascular dysfunction, which is recognized as the syndrome of preeclampsia (Myers and Baker, 2002). Individual responses to the process of progressive vascular dysfunction vary in severity and timing in a manner that seems to have genetic, familial, and immunologic components. For example, preeclampsia occurring in a first-degree relative confers a fourfold increase in risk of the disease in siblings and children (Chesley and Cooper, 1986). Women born to mothers with preeclampsia have a higher risk. There is some evidence that the presence of certain genotypes, such as factor V Leiden and thrombophilia (de Vries et al, 1997), or metabolic defects such as hyperhomocystinemia secondary to methylenetetrahydrofolate reductase deficiency (Kupferminc et al, 1999), predispose women to

BOX 11-1 Features of Mild and Severe Preeclampsia

MILD

- Systolic blood pressure ≥140 mm Hg or diastolic pressure of 90 mm Hg
- Proteinuria ≥300 mg/24 hr

SEVERE*

- Systolic blood pressure ≥160 mm Hg or diastolic pressure of 100 mm Hg
- Proteinuria ≥5 g/24 hr
- Elevated serum creatinine value
- Eclampsia
- Pulmonary edema
- Oliguria <500 mL/hr
- HELLP syndrome
- Intrauterine growth restriction
- Symptoms suggestive of end-organ involvement: headache, visual disturbance, epigastric or right upper quadrant pain

Modified from ACOG practice bulletin: Diagnosis and management of preeclampsia and eclampsia. Number 33, January 2002. American College of Obstetricians and Gynecologists, Int *J Gynaecol Obstet* 77:67-75, 2002.
HELLP, Hemolysis, elevated liver enzymes, and low platelets.
*Any single feature in the severe definition satisfies criteria for the diagnosis of severe preeclampsia.

preeclampsia, although a true candidate gene is yet to be established and probably never will be. Population studies have suggested that women exposed to the antigenic effects of sperm before conception have a lower rate of preeclampsia than do women who conceive with lesser degrees of exposure, although the evidence is inconclusive (Koelman et al, 2000).

The endothelial dysfunction that characterizes preeclampsia (Roberts, 1999) manifests as greater vascular reactivity to circulating vasoconstrictors such as angiotensin, reduced production of endogenous vasodilators such as prostacyclin and nitric oxide (Ashworth et al, 1997), increased vascular permeability, and an increased tendency toward platelet consumption and coagulopathy. The end result is hypertension, proteinuria secondary to glomerular injury, edema, and a tendency toward extravascular fluid overload with intravascular hemoconcentration.

Predictors

Perhaps one of the most important contributions that prenatal care makes to maternal and fetal outcomes is the detection of preeclampsia and the prevention of eclampsia (Backe and Nakling, 1993; Karbhari et al, 1972). A wide variety of biochemical and physical tests has been proposed as screening tools for the early detection of preeclampsia (Dekker and Sibai, 1991). Most physical tests have been discredited, and even the most widely used biochemical tests have poor predictive values. Uric acid levels are elevated in many cases of preeclampsia, but the sensitivity of the measurement is low (Lim et al, 1998). Early detection of proteinuria is possible with the use of more sensitive tests, such as gel electrophoresis (Winkler et al, 1988), rather than conventional urinalysis, but such tests do not lend themselves to routine use. Clinicians should be aware of the limitations of routine urine testing for detection of proteinuria, with standard dipstick testing being notoriously inaccurate (Bell et al, 1999).

TABLE 11-3 Risk Factors for Development of Preeclampsia

Factor	Relative Risk
Primigravida	3
Age >40 years	3
African American race	1.5
Family history	5
Chronic hypertension	10
Chronic renal disease	20
Antiphospholipid syndrome	10
Insulin-dependent diabetes mellitus	2
Multiple gestation	4

Doppler ultrasonographic assessment of the vascular dynamics in the uterine arteries during the second trimester has been proposed as a valuable screening tool in populations in which obstetric ultrasonography is routine (Kurdi, 1998). Up to 40% of women who develop preeclampsia have abnormal waveforms, and this finding was reported to be associated with a sixfold rise in the risk of preeclampsia (Papageorghiou et al, 2002). Other researchers have obtained less impressive results (Goffinet et al, 2001).

Recently the role of angiogenic factors in the pathophysiology of preeclampsia has been explored. Vascular endothelial growth factor (VEGF) and placental growth factor bind to Flt-1 and sFlt-1 receptors and have a critical role in angiogenesis and placental development. The interactions among FLt-1, VEGF, and placental growth factor promote angiogenesis and placental vasculogenesis, whereas those among sFLT-1, VEGF, and placental growth factor lead to the inactivation of those proteins and disordered angiogenesis and endothelial dysfunction. sFlt-1 levels have been found to be elevated in women with preeclampsia, and such elevated levels of sFlt-1 precede the features of clinical preeclampsia. Recent reviews of the state of the art in this area (Wang et al, 2009; Widmer et al, 2007) concluded that sFlt-1 and placental growth factor levels were significantly different after 25 weeks' gestation between women destined to develop preeclampsia and those with a normal pregnancy course. Measurements of these factors earlier in pregnancy do not appear to have the same predictive value. There is no doubt that angiogenic factors are intimately involved in the pathophysiology of preeclampsia, but alterations in their levels do not seem to be the cause of the disease. Several large studies are ongoing to further explore the role of these factors and their potential use in the prediction of disease. On balance, no effective screening test to predict preeclampsia currently exists, and clinicians are faced with the necessity of diagnosing the disease early and managing it as adroitly as possible.

Prevention

If an accurate predictor of preeclampsia could be identified, the next logical step would be the application of a preventive or ameliorative treatment. Unfortunately attempts to identify an effective treatment have proved equally

difficult. Given the recognized association between vascular endothelial dysfunction and preeclampsia (in particular, vasoconstriction and excessive clotting in the maternal placental arteries), prostaglandin inhibitors have been viewed as a likely candidate for prophylaxis or treatment. Numerous trials (Duley et al, 2001) have been conducted with low-dose aspirin, based on the idea that the ability of aspirin to irreversibly inhibit production of the vasoconstrictive prostaglandin thromboxane would promote greater activity of prostacyclin, a vasodilatory prostaglandin. This ability of aspirin would help to maintain patency in the maternal placental vascular bed and limit or prevent the evolution of preeclampsia. Unfortunately, although a modest reduction in the frequency of preeclampsia (approximately 15%) was documented, no improvement in key measures of perinatal outcome was demonstrable in a metaanalysis of the results of available studies (Duley et al, 2001).

Calcium supplementation was briefly in vogue as a preventive treatment in the 1990s, on the basis of the known vasodilatory effect of calcium and impressive results in earlier, small studies (Atallah et al, 2000); however, its worth was not supported in a metaanalysis (Atallah et al, 2000). Similarly, it has been suggested that antioxidants may have a role in preeclampsia prevention, but the only available trial to date showed mixed results, with improvements in biochemical indices in women receiving vitamins C and E, although perinatal outcomes were not different in treated and untreated groups (Chappell et al, 1999). Of concern was the finding that women in whom preeclampsia developed despite vitamin therapy had markedly worsened preeclampsia than controls in whom the disease developed. Therefore, at present, an ideal preventive measure for preeclampsia does not exist.

Antepartum Management

Given the current inability to predict or prevent preeclampsia, clinicians are left to address established disease and to try to prevent maternal and fetal morbidity. The division of established preeclampsia into mild and more severe forms is of great worth in determining management and minimizing morbidity (see Box 11-1). Mild disease is generally managed conservatively (bed rest and frequent fetal and maternal biophysical assessments) until term is reached or there is evidence of maternal or fetal compromise. The appearance of severe preeclampsia mandates delivery in all but highly selected cases regardless of gestational age.

Patients with a diagnosis of mild preeclampsia should be evaluated for signs of maternal or fetal compromise, which would make their disease severe. Evaluation should include a 24-hour urine collection to evaluate for proteinuria; full blood count and platelet measurements; determination of serum uric acid, blood urea nitrogen, and creatinine levels; and evaluation of liver transaminases. Fetal size should be estimated with ultrasonography; the presence of IUGR (less than the tenth percentile) is a sign of severe preeclampsia. Patients with mild disease at 37 weeks' gestation or more should be delivered, because prolonging pregnancy has no material benefit and increases the risks of maternal and fetal morbidity. Patients at earlier gestational stages should be closely monitored with sequential clinical and laboratory evaluations. Such monitoring often begins in the hospital and may be continued in an outpatient or home setting with appropriate supervision. If the clinical picture deteriorates or term is reached, the baby should be delivered. There is no evidence that antihypertensive therapy influences progression of preeclampsia, and its use may actually be dangerous by masking worsening hypertension. Fetal well-being should be evaluated until delivery by means of kick counts and regular non-stress tests or modified biophysical profiles.

TABLE 11-4 Drugs for Acute Treatment of Hypertension in Severe Preeclampsia

Drug	Dosage
Hydralazine	1-2 mg test dose 5-10 mg IV followed by 5-10 mg every 20 min as required, to a total of 30 mg
Labetalol	10-20 mg IV followed by 20-80 mg every 10 min to a total of 300 mg
Nifedipine	10 mg PO every 10-30 min up to three doses

IV, Intravenous; *PO*, by mouth.

Patients with severe disease should be delivered. The only exception to this approach is the diagnosis of severe preeclampsia, in a patient remote from term (<28 weeks' gestation), on the basis of proteinuria and transiently (unsustained) severe hypertension alone. Such patients may be managed conservatively under close supervision while antenatal corticosteroids are administered without adversely affecting maternal or fetal outcome (Sibai et al, 1990). There is no reason for conservative management in any other circumstance. The patient with severe preeclampsia at less than 24 weeks' gestation should be offered termination of the pregnancy; all others should be delivered by the most expedient means. Cesarean section should be reserved for obstetric indications.

Severe hypertension requires treatment with fast-acting antihypertensive agents if stroke and placental abruption are to be avoided. Intravenous hydralazine is well established as a first-line drug for this purpose, although there is a growing experience with other agents, including intravenous labetalol and oral nifedipine (Duley and Henderson-Smart, 2000a) (Table 11-4). The aim of treatment is to lower blood pressure into the mild preeclampsia range (140/90 mm Hg) to reduce the risk of stroke and other maternal cardiovascular complications. There is evidence to support the use of parenteral magnesium sulfate to prevent eclampsia in all cases of severe disease (Duley et al, 2003).

Severe preeclampsia can manifest as classic disease with severe proteinuric hypertension, or it can cause atypical findings such as pulmonary edema or severe central nervous system symptoms, including blindness. More commonly, patients show evidence of microangiopathy leading to the hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome. The full-blown clinical syndrome of HELLP carries a significant maternal risk. Earlier reports suggested that the disease carries a grave prognosis (Weinstein, 1982). This suggestion remains true for florid clinical cases, but most patients now have "laboratory" HELLP and never experience major clinical features

of the syndrome because delivery is initiated before their condition deteriorates to that point.

Preeclampsia and Fetal Risk

Because the only recourse in severe preeclampsia is delivery, the disease has a corresponding effect on prematurity and its attendant complications. IUGR is not uncommon in severe preeclampsia, and there may be evidence of progressive deterioration in fetal well-being with worsening disease. Infants delivered at less than 34 weeks' gestation will benefit from antenatal steroid therapy—even as little as 8 hours of therapy before delivery may have benefit. Many patients are able to deliver vaginally, but fetal compromise may preclude aggressive induction and mandate delivery by cesarean section. The incidence of respiratory distress syndrome is lower in infants of mothers with preeclampsia who are delivered preterm than in those of age-matched controls without antenatal steroid exposure (Yoon et al, 1980). Nonetheless, the morbidity of such infants is greater because of hypoxemic insults received in utero. Infants born to mothers with preeclampsia may also have thrombocytopenia or neutropenia, which further complicates their newborn course (Fraser and Tudehope, 1996).

Intrapartum Management

All women in labor with a diagnosis of preeclampsia should receive magnesium sulfate as seizure prophylaxis (Box 11-2). Although the absolute risk of seizure is low (1 in 2000 to 3000), the occurrence of seizures is unpredictable, and the efficacy of magnesium sulfate and margin of safety has been validated in multiple randomized trials (Duley et al, 2003). The mechanism of action of $MgSO_4$ in the prevention of seizures is still unresolved, with various theories being advanced, including peripheral neuromuscular blockade, membrane stabilization, N-methyl D-aspartate (NMDA) receptor blocking activity, cerebral vasodilation, and calcium channel blocking action (Belfort et al, 2006).

Blood pressure should be maintained in the mild preeclampsia range using intravenous antihypertensive agents (labetalol, hydralazine). Epidural anesthesia is indicated for pain control and to aid in blood pressure management. Vaginal delivery should be possible in most cases. Delivery by cesarean section should be reserved for obstetric indications. Careful attention to fluid balance should be maintained. After delivery, the preeclamptic process should begin to resolve rapidly.

ECLAMPSIA

Eclampsia is the occurrence of generalized tonic-clonic seizures in association with preeclampsia. It affects approximately 1 in 2500 deliveries in the United States and may be much more common in developing countries, affecting as many as 1% of parturients. Up to 10% of maternal deaths are due to eclampsia (Duley, 1992).

BOX 11-2 Magnesium Sulfate Therapy for Prevention of Eclampsia

- Bolus 4-6 g IV over 20 min
- Continuous infusion 1-2 g/hr
- Follow up levels every 6-8 hours to target 4-6 mEq/L
- Continue infusion 24 hours after delivery or 24 hours after seizure if seizure occurs despite magnesium therapy

Most cases of eclampsia occur within 24 hours of delivery. Almost 50% of seizures occur before the patient's admission to the labor and delivery department, approximately 30% are intrapartum, and the remainder are postpartum. There is a considerable drop in the risk of eclampsia by 48 hours postpartum, with seizures occurring in less than 3% of women beyond that time. Most patients have antecedent features that are suggestive of preeclampsia, although in some cases eclampsia may occur without warning. If eclampsia is left untreated, repetitive seizures become more frequent and of longer duration, and ultimately status eclampticus develops. Maternal and fetal mortality may be as high as 50% in severe cases, especially if the seizures occur while the patient is far from medical care.

Randomized controlled trials have demonstrated the clear superiority of magnesium sulfate for the treatment of eclampsia over all other anticonvulsants (Duley and Gulmezoglu, 2002; Duley and Henderson-Smart, 2002b, 2002c). Intravenous magnesium sulfate is given as a 4-g bolus over 5 minutes followed by a maintenance infusion of 1 to 2 g/hr for 24 hours after delivery. Subsequent seizures can be treated with further bolus injections. In refractory cases, second-line treatment with other anticonvulsants may be required, or the patient may have to be paralyzed and their lungs ventilated.

Delivery after an eclamptic seizure should take place in a controlled, careful manner. There is little to be added by performing an emergency cesarean section (Coppage and Polzin, 2002). The patient's condition should be stabilized first. Vaginal delivery is possible in most cases, although cesarean delivery may be indicated if the status of the cervix is unfavorable or if fetal compromise is ongoing despite control of seizures and maternal stabilization. Infants born to mothers after eclampsia require careful observation after birth.

CHAPTER 12

Perinatal Substance Abuse

Linda D. Wallen and Christine A. Gleason

Substance abuse during pregnancy has been recognized as a problem for more than a century. Psychotropic substances, both legal (alcohol, cigarettes, and prescription drugs such as opioids and benzodiazepines) and illegal (opioids, amphetamines, cocaine, and marijuana), can cause obstetric, fetal, and neonatal complications. These complications include poor intrauterine growth, prematurity, abruptio placenta, fetal distress, spontaneous abortion, stillbirth, fetal (and maternal) cerebral infarctions and other vascular accidents, malformations, and neonatal neurobehavioral dysfunction. Although substance abuse occurs in all socioeconomic classes, illegal drug abuse is more frequently associated with unhealthy lifestyles, poor access to prenatal care, untreated health problems, poverty, stress, and psychological disorders. Because of these socioeconomic confounders as well as the confounders of polysubstance exposure and the influence of various postnatal environmental factors, it is often difficult to determine the effects of maternal use of one specific drug on the fetus and newborn. This chapter addresses the epidemiology of perinatal substance use and abuse; the effects of specific drugs on the fetus and newborn; maternal issues and their effects on the newborn; identification of pregnancies and babies at risk; neonatal management; and long-term effects and follow-up. The discussion will focus on abused substances that are known or suggested to be associated with significant perinatal and neonatal morbidity: alcohol, tobacco, nicotine, opioids, cocaine, marijuana, and methamphetamine.

EPIDEMIOLOGY OF PERINATAL SUBSTANCE EXPOSURE

PREVALENCE

Prevalence rates for perinatal substance exposure have been determined by using a number of different definitions, survey methods, and drug use detection procedures (Lester et al, 2004). One of the most comprehensive geographically based prevalence studies on substance use and abuse by pregnant women was undertaken in California in the early 1990s by the Perinatal Substance Exposure Study Group (Vega et al, 1993). In that study, urine was collected at the time of delivery from more than 30,000 pregnant women. The prevalence rates for illicit drug use were 3.5% (overall), 8.8% (tobacco), and 7.2% (alcohol). The authors concluded that if these results could be extrapolated to the United States at large, an estimated 450,000 infants per year (11% of 4 million live births) would be exposed to alcohol, illicit drugs, or both in the days before delivery.

Rates of perinatal substance exposure have not changed substantially over the past 20 years, although there is wide geographic variation. The U.S. Department of Health and Human Services Pregnancy Risk Assessment Monitoring System is designed to monitor maternal behaviors and experiences among women who deliver live-born infants. Data collected during 2000 to 2003 from 19 states revealed that during the last 3 months of pregnancy, tobacco use ranged from 4.9% to 27.5%, and alcohol use ranged from 2% to 8.7%. Data from a 2005-2006 National Survey on Drug Use and Health revealed that of pregnant women aged 15 to 44, 4% reported using illicit drugs, 16.5% reported using tobacco, and 12% reported using alcohol sometime within the past month (Substance Abuse and Mental Health Services Administration, 2007). These rates are significantly lower than the rates reported by women aged 15 to 44 years who were not pregnant (10% reported using illicit drugs, 29.5% reported using tobacco, and 53% reported using alcohol within the past month), confirming that the prevalence of substance use among pregnant women remains less than among nonpregnant women.

The Maternal Lifestyle Study was developed in the early 1990s by the National Institute of Child Health and Human Development (NICHD) and National Institute on Drug Abuse (NIDA) to follow pregnant women known to be using opioids or cocaine and to follow their offspring. The study followed 11,800 pregnant women who received prenatal care during 1993 to 1995 at four teaching hospital sites. Women were followed from initial presentation throughout their offspring's childhood, with a planned evaluation at 8 to 11 years. Meconium analyses were used to confirm maternal substance use; there was 66% agreement between meconium analyses and positive maternal reports. The prevalence of cocaine and opioid exposure was 10.7%; 98% of cocaine users also used other drugs; and only 2% of women used cocaine alone (Shankaran et al, 2007).

EPIDEMIOLOGY OF SPECIFIC SUBSTANCES

Nicotine—in the form of cigarettes, smokeless tobacco, and nicotine replacement patches—remains the substance used most often during pregnancy. Although cigarette smoking in the United States has decreased significantly over the last 20 years, 26% of reproductive-aged women still smoke, and 15% to 20% of women smoke during their pregnancies (Andres and Dar, 2000). Women who smoke during pregnancy are more likely to use opioids, alcohol, cocaine, amphetamines, and marijuana during pregnancy than women who do not smoke (Vega et al, 1993). Cigarette smoking has been associated with numerous perinatal complications, often in a dose-dependent fashion. Smoking has been shown to raise the risk of spontaneous abortion, stillbirth, fetal growth retardation, prematurity, perinatal mortality, and sudden infant death syndrome (Andres and Day, 2000; Kallen, 2001; Lambers and Clark, 1996; Tuthill et al, 1999). Cigarette smoking represents

the most influential and most common factor adversely affecting perinatal outcomes. In a 2008, Rogers "estimated that if all the women in the United States stopped smoking, there would be an 11% reduction in stillbirths and 5% reduction in neonatal deaths."

Before 1970, the detrimental effects of alcohol abuse during pregnancy were believed to be related only to drunkenness, such as an increased risk for accidents. There was a widely held belief that the placenta formed a protective barrier between alcohol and the fetus. This belief repudiated by studies in the United States (Jones and Smith, 1973) and France (Lemoine et al, 1967) describing fetal alcohol syndrome. These studies led to the 1989 U.S. federal law requiring that warning labels be placed on all alcoholic beverage containers regarding alcohol-related birth defects. Despite this extensive public health campaign designed to inform and warn women about the dangers of alcohol consumption during pregnancy, approximately 10% of pregnant women still report using alcohol (Centers for Disease Control and Prevention, 2009). A smaller percentage of these women are alcoholics, but their infants are at significantly higher risk for fetal alcohol syndrome or alcohol-related neurobehavioral disorders compared with the infants of nonalcoholic pregnant women who use alcohol.

Opium derivatives have been used as analgesics for centuries and remain the most effective analgesics available. Opioids of clinical interest are morphine, heroin, methadone, meperidine, oxycodone, and codeine. Perinatal problems associated with opium were first reported in the late 1800s. Since the 1950s, heroin use, particularly among women, has been endemic in most major American cities. Compared with cocaine, marijuana, alcohol, and tobacco abuse, opioid addiction during pregnancy is rare (Shankaran et al, 2007). The prevalence of opioid use among pregnant women is reported to range from 1% to 2% (Vega et al, 1993; Yawn et al, 1994) to as much as 21% in a highly selected group of women (Behnke and Eyler, 1993; Nair et al, 1994; Ostrea et al, 1992b). One multicenter study found that the prevalence of opioid use varied by center and ranged from 1.6% to 4.5% at the different sites (Lester et al, 2001). In addition, these centers reported higher rates of opioid use by mothers of low-birthweight and very low-birthweight infants. Rates for heroin use are higher in metropolitan areas and cities and are more concentrated in northeastern and west coast cities. Opioid abuse is more common in groups of lower socioeconomic status, and women using opioids during pregnancy are more likely to use other drugs (Bauer, 1999; Brown et al, 1998; van Baar and de Graaff, 1994). Investigators have also reported that 93% of women identified as using opioids and cocaine during pregnancy had also used a combination of alcohol, nicotine, or marijuana (Bauer, 1999). Of the opioid drugs known to be abused during pregnancy, heroin and methadone have been studied the most extensively. Heroin can be ingested through smoking or by the intranasal or intravenous route. Reports from European countries suggest a trend away from intravenous injection of opioids (Hartnoll, 1994). The use of noninjectable heroin may reduce the risk of transmission of human immunodeficiency virus (HIV); however, its wider use ensures the emergence of new groups of heroin users for whom the risk of intravenous use is a major deterrent.

The euphoria-producing effect of cocaine was exploited extensively in the United States in the late nineteenth and early twentieth centuries, when the agent was an active ingredient in a number of widely used over-the-counter elixirs and tonics. Cocaine use markedly decreased after the Harrison Narcotic Act of 1914 and the supervening Comprehensive Drug Abuse Prevention and Control Act of 1970, which classified cocaine as a schedule II drug (i.e., one of "high abuse potential with restricted medical use," similar to opioids, barbiturates, and amphetamines). Cocaine's reputation as a glamour drug, the widely held misconception that cocaine is not addictive, and the development and marketing of crack, a cheap version of cocaine, were major factors in the resurgence of drug use. Growing concern regarding the effects of maternal cocaine use on pregnancy outcomes was one of the reasons that the U.S. Congress passed the 1986 Narcotics Penalties and Enforcement Act, which imposed severe penalties on any person convicted of either possessing or distributing effects; however, this law did not appreciably alter the fact that cocaine and other stimulants had become the drugs of choice for women in the United States. In the 1990s, studies based on urine toxicology screening reported a prevalence of cocaine use among pregnant women of 5% in New York City, 1.1% in a geographic sample in California, and less than 0.5% in private hospitals in Denver, Colorado (Burke and Roth, 1993). Prevalence increases to 18% when both self-reporting and urine testing are used, and the highest prevalence rates are reported from studies using meconium testing.

Amphetamines have surpassed cocaine as the primary illicit drugs used by pregnant women in many areas of California and other states. Methamphetamine (or "crystal") has been the primary form abused, because it can be produced locally and fairly cheaply. Greater restrictions on the importing of cocaine have also contributed to resurgence in amphetamine use. Amphetamines have always been popular among adolescents, especially females, and accordingly women of child-bearing age are at high risk for perinatal abuse. A California study of drug-exposed infants in the social welfare system documented a higher prevalence of amphetamine use among white pregnant women than in women of other ethnicities (Sagatun-Edwards et al, 1995). The Infant Development, Environment, and Lifestyle (IDEAL) study chose four major U.S. cities with known methamphetamine abusing populations and reported methamphetamine use in 5.2% of pregnant women. As in previous reports, these women frequently used other substances: 25% used tobacco, 22.8% used alcohol, 6% used marijuana, and 1.3% used barbiturates (Arria et al, 2006).

According to the 2003 National Survey on Drug Use and Health, marijuana is the most widely used illegal drug used in the United States, with approximately 14.6 million people reporting that they use the drug. In a 1986 study, the most frequent age of marijuana use for women included the childbearing ages, with 50% of 18- to 35-year-old women reporting that they used marijuana at least once and 8% reporting that they used marijuana a minimum of 10 of the past 30 days (Clayton et al,

1986). The 2002-2006 National Household Survey on Drug Abuse included information on drug use in the last 30 days from over 94,000 women aged 18 to 44 years, of whom 5017 were pregnant. Marijuana use was reported in 7.3% of nonpregnant women and 2.8% of pregnant women with moderate to heavy use (more than five times per month) in 1.8% of pregnant women compared with 3.7% in nonpregnant women. Marijuana use declined over the course of pregnancy, from 4.5% in the first trimester to 1.5% in the third trimester (Muhuri and Gfroerer, 2009).

HEALTH POLICY

In the 1980s, with rising cocaine use and the emergence of crack cocaine, national attention turned to drug use during pregnancy, with a general public outcry being the result. Children born to crack addicts were widely believed to be irrevocably damaged and public opinion was that mothers should be punished. As the foster care system became overwhelmed and as evidence to the contrary has emerged, public opinion regarding prenatal drug use has shifted more toward maternal treatment and prevention rather than punishment. As Lester et al (2004) stated, the initial overreaction of the public "in which drug-exposed children were characterized as irrevocably and irreversibly damaged" has shifted "to a perhaps equally premature excessive 'sigh of relief' that drugs such as cocaine do not have lasting effects, especially if children are raised in appropriate environments." This statement has led to a change in the public discourse regarding health policy interventions for substance use and abuse during pregnancy.

The focus of current policy is to provide appropriate medical care for substance-using pregnant women, including medical management of their chemical dependency and programs to decrease substance use during pregnancy. However, there remains the important step of recognizing that "the idea that illegal drugs are more harmful to the unborn fetus than legal drugs is incorrect" (Thompson et al, 2009). Future research and intervention need to include programs to educate women of childbearing age of the significant effects of both legal and illegal substance use on the early-gestation fetus, starting even before pregnancy may be recognized.

PERINATAL EFFECTS OF SPECIFIC DRUGS (Table 12-1)

ETHANOL (ALCOHOL)

Pharmacology and Biologic Actions

Alcohol is a mood-altering substance that enhances the effects of the inhibitory neurotransmitter gamma-aminobutyric acid and lessens the effect of the excitatory neurotransmitter glutamate, thus acting as a central nervous system (CNS) depressant or sedative. Alcoholic beverages come in many forms, and for centuries they have been consumed for diverse reasons: celebrations, relaxation, religious ceremonies, and medicinal purposes (alcohol is an excellent sedative and tocolytic agent). The alcohol contained in alcoholic beverages is ethanol. Ethanol is absorbed in the digestive tract and into the body fat and bloodstream. Ethanol is metabolized to acetaldehyde by alcohol dehydrogenase (ADH), primarily in the liver. ADH is then metabolized to acetate by aldehyde dehydrogenase (ALDH) and eventually eliminated as water and CO_2. Although acetaldehyde is short-lived, it can cause significant tissue damage, which is particularly evident in the liver, where most alcohol metabolism takes place. Pregnant women have slower rates of alcohol clearance, likely related to hormonal alterations in the activity of the alcohol-metabolizing enzymes; this leads to slower clearance of alcohol compared with nonpregnant women consuming the same amount of alcohol (Shankaran et al, 2007).

Complications of Pregnancy

Heavy drinking carries a higher risk of cardiovascular and hepatic complications in women compared with men, and the alcohol-associated mortality rate is also considerably higher (Smith and Weisner, 2000). These factors alone can clearly complicate a woman's pregnancy. In addition, nutritional deficiencies and poor diet can affect general health and dentition, which can negatively affect a pregnancy. Alcoholism is a chronic disease that is often progressive and can be fatal. Pregnant alcoholics often have related medical disorders such as cirrhosis, pancreatitis, and alcohol-related neurologic problems. These disorders can affect the health and well-being of their fetus.

TABLE 12-1 Enhanced Risk for Various Events or Processes after Substance Use during Pregnancy*

Event or Process	Ethanol	Cigarettes	Marijuana	Opiates	Cocaine	Amphetamines
Malformations	+	–	–	–	–	–
Abortion/stillbirth	+	+	?	+	+	+
Intrauterine growth restriction	+	+	–	+	+	+
Prematurity	–	+	?	+	+	+
Withdrawal	?	+	+/–	+	–	–
Central nervous system sequelae	+	?	+	?	+	?
Sudden infant death syndrome	+	+	?	+	?	?
Foster care	+	–	–	+	+	+

+, Causes event or process; –, does not cause event or process; ?, not known whether agent causes event or process.
*Although risk is increased, the risk ratio ranges for many from 1 to 2 for these associations.

Alcohol affects prostaglandin levels, increasing levels of its precursors in human placental tissue and thus affecting fetal development and parturition. In fact, researchers have used this knowledge to test the effect of aspirin, which inhibits alcohol-induced increases in prostaglandin levels, on reducing alcohol-induced fetal malformations in a mouse model (Randall, 2001). Specific obstetric complications of heavy drinking may relate to alterations in prostaglandin levels, including an increased risk for spontaneous abortion, abruptio placenta, and alcohol-related birth defects such as fetal alcohol syndrome.

Fetal Alcohol Syndrome

Fetal alcohol syndrome (FAS) was first described by Lemoine (1967), a Belgian pediatrician who observed a common pattern of birth anomalies in children born to alcoholic mothers in France. This description was followed by a landmark article by Jones and Smith (1973) reporting similar features in several children born to alcoholic mothers in the United States.

It is unclear how much alcohol exposure is necessary to cause fetal teratogenicity, and even high consumption levels do not always result in the birth of a child with FAS (Abel and Hannigan, 1995). However, a woman with a previous affected child is at increased risk for having a child with FAS if she consumes alcohol during a subsequent pregnancy. The adverse effects of alcohol on the fetus are related to gestational age at exposure, the amount of alcohol consumed, and the pattern of consumption (e.g., binge drinking), maternal peak blood alcohol concentrations, maternal alcohol metabolism, and the individual susceptibility of the fetus. Studies show that maternal peak blood alcohol levels are affected by maternal nutrition, age, body size, and genetic disposition (Eckardt et al, 1998; Maier and West, 2001). In addition, various risk factors increase susceptibility to FAS, including advanced maternal age and confounding factors such as nonwhite race, poverty, and socioeconomic status (Abel, 1995; Bagheri et al, 1998; May and Gossage, 2001). In the United States, the incidence of FAS is tenfold higher for African Americans living in poverty than for white middle-class women (Abel, 1995). Despite the differences in incidence of FAS worldwide, reports consistently indicate poverty or socioeconomic status as major determinants of FAS (Abel, 1995; May et al, 2000).

Features of FAS include characteristic facial dysmorphology (short palpebral fissures, midface hypoplasia, broad flat nasal bridge, flat philtrum, and thin upper lip; Figure 12-1), prenatal and postnatal growth deficiency, and variable CNS abnormalities. Skeletal anomalies, abnormal hand creases, and ophthalmologic, renal, and cardiac anomalies have been described in children with FAS, but less frequently than the facial dysmorphology and CNS abnormalities that include structural brain defects (e.g., dysgenesis of the corpus callosum and cerebellar hypoplasia), cognitive abnormalities, delayed brain development, and signs of neurologic impairment, including lifelong behavioral and psychosocial dysfunction. In 1996, the Institute of Medicine further defined the criteria for the diagnosis of FAS and proposed a new term—alcohol-related neurodevelopmental disorder (ARND).

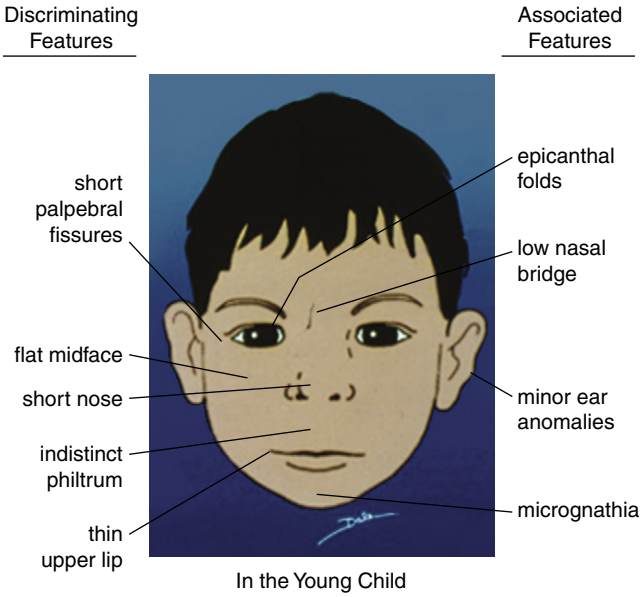

FIGURE 12-1 Facies in fetal alcohol syndrome. *(From Streissguth AP, Little RE: Alcohol, pregnancy, and the fetal alcohol syndrome, ed 2, unit 5 of* Alcohol use and its medical consequences: a comprehensive slide teaching program for biomedical education. *Developed by Project Cash of the Dartmouth Medical School. Reproduced with permission from Milner-Fenwick, Inc., Timonium, Michigan, 1994.)*

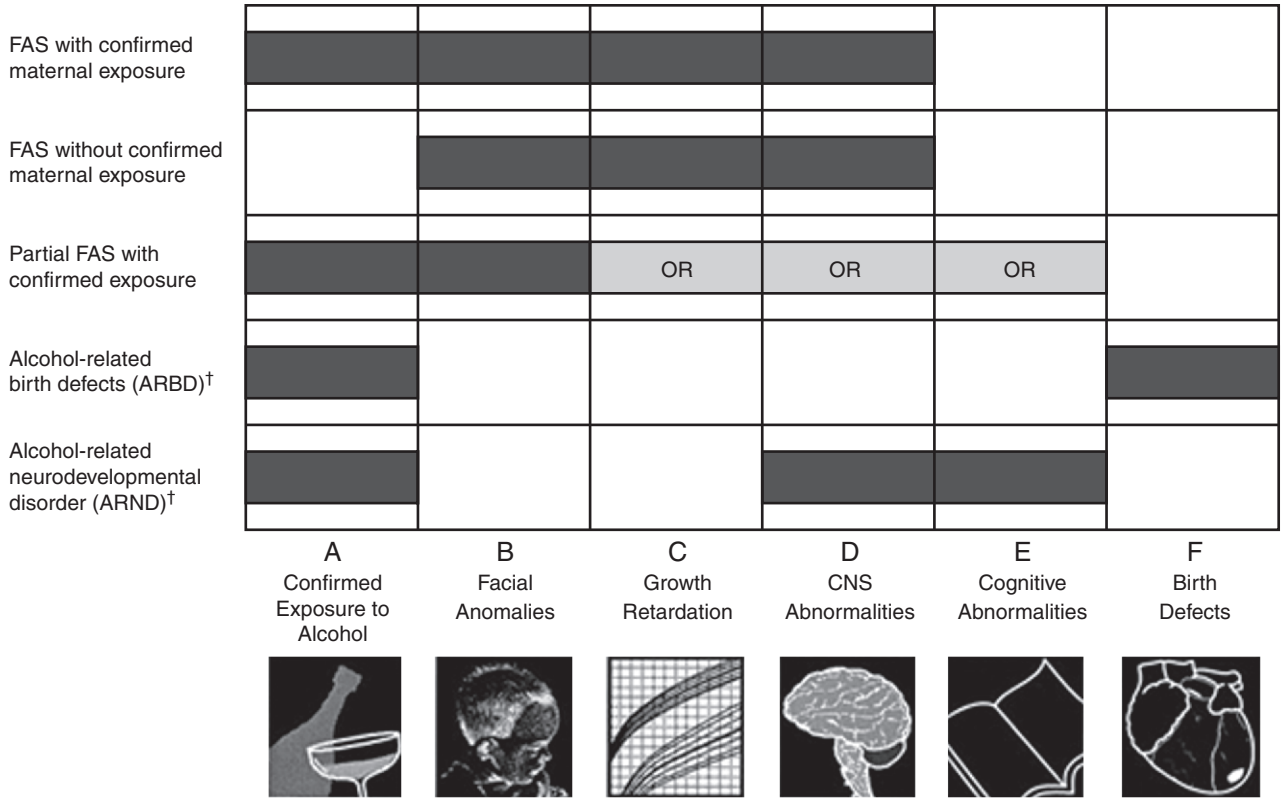
This term includes structural CNS and cognitive abnormalities in children with confirmed fetal exposure to alcohol. Unlike FAS, a diagnosis of ARND does not require the presence of facial or other physical abnormalities. In 2000, the American Academy of Pediatrics Committee on Substance Abuse published these new definitions with an explanatory drawing (Figure 12-2).

The incidence of FAS in the United States has been estimated to vary from 1.95 to 5 cases per 1000 live births (Abel, 1995; American Academy of Pediatrics Committee on Substance Abuse and Committee on Children with Disabilities, 2000; Bertrand et al, 2005; Sampson et al, 1997). FAS is recognized more frequently in the United States than in other countries and is most common (4.3%) among women who report heavy drinking (Abel, 1995). Accurate incidence and prevalence rates of FAS are difficult to obtain because of wide variations in methodologies used for estimation of rates, and because the clinical diagnosis is often missed in the neonatal period. In fact, most cases (up to 89%) are not diagnosed until after a child is age 6 (Centers for Disease Control and Prevention [CDC], 1997).

FAS is diagnosed from the history and physical findings. No laboratory tests are available for clinical use to quantify the extent of alcohol exposure during fetal life. There are also no clinical methods for validating maternal self-reporting of alcohol use, quantifying the level of fetal exposure, or predicting future disability after fetal exposure (Jones and Chambers, 1999). Koren et al (2002) have proposed meconium fatty acid ethyl ester levels as a potential biologic marker for fetal alcohol exposure. Whether this finding is shown to correlate with childhood outcomes remains to be studied. Investigators have shown that pediatricians fail to recognize FAS in the newborn and do not always inquire about alcohol exposure during pregnancy



*Adapted from *Fetal Alcohol Syndrome; Diagnosis, Epidemiology, Prevention, and Treatment*. 1996;4–5. Letter designations in the figure indicate the following:

A. Confirmed maternal alcohol exposure indicates a pattern of excessive intake characterized by substantial, regular intake or heavy episodic drinking. Evidence of this pattern may include frequent episodes of intoxication, development of tolerance or withdrawal, social problems related to drinking, legal problems related to drinking, engaging in physically hazardous beavior while drinking, or alcohol-related medical problems such as hepatic disease.

B. Evidence of a characteristic pattern of facial anomalies that includes features such as short palpebral fissures and abnormalities in the premaxillary zone (e.g., flat upper lip, flattened philtrum, and flat midface).

C. Evidence of growth retardation, including at least one of the following:
- low birthweight for gestational age
- decelerating weight over time not caused by nutrition
- disproportional low weight to height

D. Evidence of CNS neurodevelopmental abnormalities, including at least one of the following:
- decreased cranial size at birth
- structural brain abnormalities (e.g., microcephaly, partial or complete agenesis of the corpus callosum, cerebellar hypoplasia)
- neurological hard or soft signs (as age appropriate), such as impaired fine motor skills, neurosensory hearing loss, poor tandem gait, poor eye-hand coordination

E. Evidence of a complex pattern of behavior or cognitive abnormalities that are inconsistent with developmental level and cannot be explained by familial background or environment alone, such as learning difficulties; deficits in school performance; poor impulse control; problems in social perception; deficits in higher level receptive and expressive language; poor capacity for abstraction or metacognition; specific deficits in mathematical skills; or problems in memory, attention, or judgment

F. Birth defects associated with alcohol exposure include:

Cardiac	Atrial septal defects	Aberrant great vessels
	Ventricular septal defects	Tetralogy of Fallot
Skeletal	Hypoplastic nails	Clinodactyly
	Shortened fifth digits	Pectus excavatum and carinatum
	Radioulnar synostosis	Klippel-Feil syndrome
	Flexion contractures	Hemivertebrae
	Camptodactyly	Scoliosis
Renal	Aplastic, dysplastic, hypoplastic kidneys	Ureteral duplications
	Horseshoe kidneys	Hydronephrosis
Ocular	Strabismus	Refractive problems
	Retinal vascular anomalies	Secondary to small globes
Auditory	Conductive hearing loss	Neurosensory hearing loss
Other	Virtually every malformation has been described in some patient with FAS. The etiologic specificity of most of these anomalies to alcohol teratogenesis remains uncertain.	

†Alcohol-related effects indicate clinical conditions in which there is a history of maternal alcohol exposure, and where clinical or animal research has linked maternal alcohol ingestion to an observed outcome. There are two categories, alcohol-related neurodevelopmental disorder and alcohol-related birth defects, which may co-occur. If both diagnoses are present, then both diagnoses should be rendered.

FIGURE 12-2 Diagnostic classification of fetal alcohol syndrome and alcohol-related effects. *(From the American Academy of Pediatrics Committee on Substance Abuse and Committee on Children with Disabilities: Fetal alcohol syndrome and alcohol-related neurodevelopmental disorders*, Pediatrics *106:359. Reproduced with permission from the American Academy of Pediatrics, 2000.)*

(Stoler and Holmes, 1999). One promising screening tool is the use of averaged cranial ultrasound images to examine the size and shape of the corpus callosum, which is typically dysgenic in FAS (Bookstein et al, 2005). Guidelines to aid in the earlier recognition and referral of infants and children with FAS and fetal alcohol spectrum disorder have been published recently (Bertrand et al, 2005; Hoyme et al, 2005). FAS is not a problem just for neonatologists. Adolescents who were exposed prenatally to alcohol have a different approach to alcohol than their nonexposed peers, with an increased risk for earlier use and subsequent alcohol abuse (Baer et al, 2003). One study in rodents suggests that fetal ethanol exposure increases ethanol intake later in life by making it smell and taste better (Youngentob and Glendinning, 2009). Children with FAS continue to have serious disabilities into adulthood (Streissguth et al, 1991; Streissguth, 1993). Although the facial features and growth restriction are no longer as distinctive as during childhood, mental retardation continues to have a significant effect. Adults with FAS have behavior, socialization, and communication dysfunction, and on average they function at the second- or third-grade level. A significant number of FAS patients do not achieve fully independent living. Earlier recognition and intervention for children with FAS and its variants may help to minimize eventual adulthood disabilities and help to prepare adolescents and young adults with the disorder for independent living (Bertrand et al, 2005).

Fetal Growth

Intrauterine growth restriction (IUGR) is one of the most consistent findings of prenatal exposure to alcohol (Hannigan and Armant, 2000). Growth deficit begins in utero and continues throughout childhood (American Academy of Pediatrics Committee on Substance Abuse and Committee on Children with Disabilities, 2000). The facial features and the growth restriction become less noticeable during adolescence and puberty (Streissguth et al, 1991; Streissguth, 1993).

CIGARETTE SMOKING AND NICOTINE

Pharmacology and Biologic Actions

Cigarette smoke contains a complex mixture of approximately 4000 compounds, including nicotine and carbon monoxide, which can adversely affect the fetus (Lester et al, 2004). In rodents, nicotine releases chemicals in the reward center of the brain, which likely triggers the euphoria that smokers experience. Nicotine activates nicotinic acetylcholine receptors, and these receptors remain depressed for a longer time after their activation stops, which likely accounts for compulsive smoking (Cohen, 2007). Nicotine crosses the placenta and concentrates in fetal blood and amniotic fluid, where its levels significantly exceed maternal blood concentrations (Haustein, 1999). The serum concentration of cotinine, the primary metabolite of nicotine, is used to quantitate the level of smoking and fetal exposure. Cotinine has a half-life of 15 to 20 hours, and because its serum levels are tenfold higher than those of nicotine, this substance may represent a better marker for intrauterine exposure (Lambers and Clark, 1996).

Complications of Pregnancy

Although the exact mechanism of the adverse effects of smoking on pregnancy is unknown, cigarettes contain numerous potentially toxic compounds that affect fetal health in a number of ways. Nicotine and its metabolites can act as vasoconstrictors, and a study in pregnant rhesus monkeys demonstrated a nicotine-associated decrease in uterine blood flow (Suzuki et al, 1980), which might provide a partial explanation for the association between maternal cigarette smoking and low birthweight. Theories regarding mechanisms for the adverse effects of smoking on fetal health include direct vasoconstrictive effects of nicotine on uteroplacental blood flow, the induction of fetal hypoxia from carbon monoxide production, direct toxic effects and indirect effects of altered maternal nutritional intake, and altered maternal and placental metabolism (Andres and Day, 2000; Pastrakuljic et al, 1999). When pregnant women smoke cigarettes, the resulting increased levels of carbon monoxide cross the placenta and form carboxyhemoglobin in the fetus, with resulting hypoxemia (Lambers and Clark, 1996). Supporting this theory, serum erythropoietin levels are higher in tobacco smoke–exposed infants at delivery, a finding that is presumed to reflect fetal hypoxia (Beratis et al, 1999; Jazayeri et al, 1998). In addition to the fetal hypoxia theory, there have recently been studies demonstrating that nicotine may act as a developmental neurotoxin targeting nicotinic acetylcholine receptors (Lester et al, 2004; Levin and Slotkin, 1998) and may disturb protein metabolism during gestation, leading to decreased serum amino acids in umbilical cord blood (Jauniaux et al, 2001).

Maternal smoking has also been show to affect the length of gestation in a dose-dependent manner, with a higher risk of preterm delivery (Jaakkola et al, 2001; Savitz et al, 2001) and a twofold increase in the incidence of placental abruption (Ananth et al, 1996). Perinatal mortality is increased in pregnant smokers, likely reflecting the increases in rates of prematurity, placental abruption, and placenta previa in women who smoke. Mothers who smoke during pregnancy commonly continue to smoke during their infants' childhood. Asthma and recurrent otitis media are more common in infants who are exposed to passive smoking (Ey et al, 1995; Martinez et al, 1995).

Fetal Growth

The effect of smoking on fetal growth is significant and dose dependent (Kyrklund-Blomberg et al, 1998; Nordentoft et al, 1996). Studies have shown lower birthweights associated with levels of nicotine exposure, with a 1-g reduction in birthweight observed for every microgram per milliliter increase in maternal serum cotinine level (Eskenazi et al, 1995; Perkins et al, 1997). Investigators have shown a dose-dependent relationship between the amount of smoking and the extent of fetal growth restriction and birthweight reduction (Horta et al, 1997; Jaakkola et al, 2001; Savitz et al, 2001; Sprauve et al, 1999).

Both reducing and ceasing cigarette smoking during pregnancy have been shown to be beneficial and to lead to improved fetal growth. Lieberman et al (1994) have shown that if pregnant women stop smoking during the third trimester, their infants' weights are indistinguishable from those of a nonsmoking population. Other investigators report that even a modest reduction in smoking is associated with improved fetal growth (Li et al, 1993; Walsh et al, 2001).

MARIJUANA

Pharmacology and Biologic Actions

Marijuana, the dried material from the hemp plant *Cannabis sativa*, is most often smoked but can be ingested with food. Its most active ingredient is delta-9-tetrahydrocannabinol (THC), which binds to cannabinoid receptors in the brain and modifies the release of several neurotransmitters. Its primary biologic effects include euphoria; relaxation; increased heart rate, blood pressure, and appetite; and impaired coordination, decision-making, short-term memory, concentration, and learning. Although controversial, there is increasing evidence that regular marijuana use can cause respiratory difficulties, cognitive impairments, withdrawal, and dependence (Khalsa et al, 2002). THC crosses the placenta and collects in the amniotic fluid.

Complications of Pregnancy

Marijuana use during pregnancy is inconsistently reported to have effects on birth outcomes. The inconsistency likely stems from the fact that marijuana is often used in combination with other substances, thus potentiating the risks for prematurity and low birthweight. Day et al (1991) reported a higher incidence of meconium-stained amniotic fluid and other pregnancy and delivery complications after maternal marijuana use, but subsequent studies have not replicated this finding. The IDEAL study did not find any relation between marijuana use and altered fetal growth parameters (Smith et al, 2006). Frequent use of marijuana was associated with a small decrement in birthweight in a study that did not control for other illicit drug use (Schempf, 2007).

OPIOIDS (INCLUDING PRESCRIPTION PAIN KILLERS)

Pharmacology and Biologic Actions

Opioids are either drugs derived from the opium poppy or synthesized compounds that have similar biologic actions. The prototype opioid is morphine, and all opioids relate to it. For example, heroin (diacetylmorphine) exerts its effects by being metabolized to morphine, as does codeine, which is methylated morphine. Other opioids, such as methadone and oxycodone, are structurally unlike morphine but share its pharmacologic properties, because they stimulate similar opioid receptors. Specific opioid receptors (μ, δ, κ) have been identified in the nervous system and bowel that are activated by endogenous opioids, such as the naturally occurring endorphins and enkephalins (Vaccarino and Kastin, 2000). As modulators of the sympathoadrenal system, endogenous opioids are important during periods of diverse forms of stress. Activation of these receptors by the endogenous opioids has physiologic effects, including analgesia, drowsiness, respiratory depression, decreased gastrointestinal motility, nausea, vomiting, and alterations in the endocrine and autonomic nervous systems. Activation of these same endogenous opioid receptors by exogenous opioid drugs has similar clinical effects, producing euphoria, sleepiness, and decreased sensitivity to pain, as well as adverse effects such as constipation and nephrotic syndrome (ACOG, 2005).

The use of opioid drugs can result in the development of tolerance, physiologic dependence, and addiction. Tolerance leads to a shortened duration of the action of opioids and a decrease in the intensity of the drug action, followed by the need for a higher dose to obtain the same clinical effect. Tolerance is believed to result from continued occupancy of the opioid receptor. Continuous administration of opioids, therefore, leads to the more rapid onset of tolerance (Anand and Arnold, 1994; Suresh and Anand, 2001). With physiologic dependence, there is a need for further drug administration to prevent withdrawal symptoms (agitation, dysphoria, temperature instability). Addiction is a more severe form of dependence that involves a complex pattern of drug-seeking behavior (Christensen, 2008).

Complications of Pregnancy

Obstetric complications associated with maternal use of opioids include a higher incidence of spontaneous abortion, premature delivery, preterm labor, abruptio placentae, chorioamnionitis, impaired fetal growth, and fetal distress. In women who use opioids during pregnancy, the incidence of preterm labor and premature delivery ranges from 25% to 41% (Chiriboga, 1993; Lam et al, 1992; Little et al, 1990). Maternal opioid use is also associated with higher rates of meconium-stained amniotic fluid, lower American Pediatric Gross Assessment Record (Apgar) scores, longer duration of membrane rupture (Gillogley et al, 1990), and increased incidence of syphilis and HIV infection at birth (Bauer, 1999). The rates of maternal complications of pregnancy are further increased when drug use is added to infection with HIV. Women infected with HIV who also use opioids, particularly methadone, have higher rates of miscarriage, preterm deliveries, and small-for-gestational-age infants, and more vaginal and urinary tract infections than women with HIV who do not use drugs (Mauri et al, 1995).

The etiology of these opioid-associated pregnancy complications is multifactorial. Maternal lifestyle, malnutrition, infections, and polydrug effects are likely to result in poor perinatal outcomes, including poor intrauterine growth and prematurity. Because the drug supply is often episodic, the pregnant addict is subject to episodes of withdrawal and overdose, thereby subjecting the fetus to intermittent episodes of hypoxia in utero, hindering growth and raising the risk of spontaneous abortion, stillbirth, fetal distress, and prematurity. Infants born to mothers who are addicted to opioids are more

likely to be of low birthweight, to be premature, and to suffer from infection and perinatal asphyxia (Christensen, 2008).

Fetal Growth

Initial reports from studies addressing the effects of maternal opioid use on the fetus suggested that infants exposed to opioids in utero have a higher incidence of IUGR (Lam et al, 1992) and smaller head circumference (Bauer, 1999; Boer et al, 1994). Hulse et al (1997) reported an association with heroin abuse and increased prematurity, low birthweight, and reduced fetal growth. However, more recent work controlling for confounding factors has not demonstrated a significant relationship between opioid use and prematurity, low birthweight, or IUGR (Minozzi et al, 2008; Sharpe and Kuschel, 2004).

COCAINE

Pharmacology and Biologic Actions

Cocaine is a highly psychoactive stimulant with a long history of abuse. A naturally occurring anesthetic of the tropane family of alkaloids, cocaine is obtained from the *Erythroxylon coca* plant, which is indigenous to the mountain slopes of Central and South America. The coca leaf has been chewed or made into a stimulant tea by the natives of these areas to decrease fatigue and hunger. The pharmacologic actions of cocaine include inhibition of postsynaptic reuptake of norepinephrine, dopamine, and serotonin neurotransmitters by sympathetic nerve terminals, thus allowing higher concentrations of these neurotransmitters. In adults, cocaine binds strongly to neuronal dopamine reuptake transporters, thereby increasing postsynaptic dopamine at the mesolimbic and mesocortical levels and producing the addictive cycle of euphoria and dysphoria (Malanga and Kosofsky, 1999). Tryptophan uptake is similarly inhibited, altering serotonin pathways with resultant effects on sleep.

Cocaine use leads to a sense of well-being, increased energy, increased sexual achievement, and an intense euphoria or "high." The sympathomimetic action can have potentially devastating physiologic effects on the cardiovascular system. In adults, cocaine has been associated with cerebral hemorrhage, cardiac arrest, cardiac arrhythmias, myocardial infarction, intestinal ischemia, and seizures. Chronic use is associated with anorexia, nutritional problems, and paranoid psychosis and can ultimately result in neurotransmitter depletion and a "crash," characterized by lethargy, depression, anxiety, severe insomnia, hyperphagia, and cocaine craving.

Two forms of cocaine are commonly used—cocaine hydrochloride and cocaine base, which are either extracted by organic solvents or precipitated as "crack" through the use of ammonia and baking soda). Cocaine hydrochloride is a water-soluble white powder that is used orally, intranasally ("snorting"), or intravenously ("running"). Intravenous users are more likely to have a history of heroin abuse and often use the drug in combination with heroin (known as *speedballing*). Cocaine hydrochloride decomposes on heating and is, therefore, cocaine converted to the free base for inhalation. "Freebasing" involves extracting cocaine from aqueous solution into an organic solvent such as ether. Crack, the most widely available form of freebase, is almost pure cocaine; when smoked, it readily enters the bloodstream to produce levels similar to those occurring with intravenous use. Crack cocaine is popular in urban minority communities, where it may be smoked in combination with PCP (known as *spacebasing*). Crack smoking appears to be particularly reinforcing and is associated with compulsive use, binges, and acceleration of the addictive process.

Cocaine and some of its metabolites readily cross the placenta and achieve pharmacologic levels in the fetus (Schenker et al, 1993). Amniotic fluid may serve as a reservoir for cocaine, and its metabolites and prolong exposure to vasoactive compounds. The extent to which cocaine or its metabolites are responsible for aberrant fetal growth, neurodevelopmental sequelae in exposed infants, and the range of congenital malformations reported in the literature may be less than suggested by uncontrolled case reports early in the cocaine-epidemic era. The confounding effects of increased use of multiple drugs, tobacco, alcohol, nutritional deficits, and decreased use of prenatal care among cocaine users make interpretation of the causal relationships between gestational cocaine exposure and intrauterine growth and subsequent neurobehavioral development difficult (Chiriboga, 1993). These identified confounders might serve to explain the reported effects attributed to cocaine in clinical series (Dempsey et al, 1996), although significant effects on the fetus and newborn have been reported in more recent studies that controlled for many confounders (Bada et al, 2002; Shankaran et al, 2007).

Complications of Pregnancy

Adverse perinatal outcomes associated with cocaine use are believed to be largely because of the vasoconstrictive effects of cocaine on uterine blood supply (Woods et al, 1987). An increase in maternal mean arterial blood pressure, a decrease in uterine blood flow, and a transient rise in fetal systemic blood pressure after an intravenous cocaine infusion have been described in fetal sheep along with significant fetal hypoxemia associated with changes in uterine blood flow (Moore et al, 1986; Woods et al, 1987). Maternal hypertension and intermittent fetal hypoxia contribute to the higher risks for abruptio placentae and IUGR seen in cocaine-exposed infants.

To date, no well-defined cocaine-associated syndrome has been identified, and the teratogenic potential of cocaine remains controversial. Earlier reports had suggested that cocaine-exposed infants had a higher rate of limb reduction anomalies, heart defects, ocular anomalies, intestinal atresia or infarction, and other vascular disruption sequences. However, the preponderance of more recent data from multiple studies has failed to demonstrate higher rates of other congenital anomalies among cocaine-exposed infants (Behnke et al, 2001). Any association between fetal cocaine exposure and malformations is likely to be confounded by higher rates of maternal tobacco, marijuana, or alcohol use among the cocaine-exposed groups.

Women who use cocaine during pregnancy are at higher risk for stillbirths, spontaneous abortions, abruptio placentae, IUGR, anemia and malnutrition, and maternal death from intracerebral hemorrhage. Cocaine directly stimulates uterine contractions because of its alpha-adrenergic, prostaglandin, or dopaminergic effects, with resulting greater risk for fetal distress and premature deliveries. Abruptio placentae appears to be related to cocaine only when the drug is used shortly before delivery (Ostrea et al, 1992b). Pregnant women who use cocaine are also at high risk for premature labor, low-birthweight infants, premature rupture of the membranes, and perinatal infections. Cocaine use significantly increases the odds ratio for prematurity, low birthweight, premature rupture of membranes, and IUGR (Bada et al, 2002, 2005; Shankaran et al, 2007) as well as perinatal infections.

Overall, because of the higher risks of premature delivery, the frequency of respiratory distress syndrome is greater in cocaine-exposed infants. Cocaine-exposed infants less frequently require surfactant administration and intubation for respiratory distress syndrome; however, the risks of bronchopulmonary dysplasia are similar in infants who have and those who have not been exposed to cocaine during gestation (Hand et al, 2001).

Fetal Growth

Infants exposed to cocaine in utero have lower birthweight, smaller birth length, and smaller head circumference (Bada et al, 2002, 2005; Behnke et al, 2001). Cocaine is hypothesized to reduce fetal growth via vasoconstriction of uteroplacental vessels with consequent decreased fetal substrate and oxygen delivery (Schempf, 2007). Several studies have shown a dose-response effect of cocaine exposure on fetal growth. In the Maternal Lifestyle Study, cocaine-exposed infants were 1 week younger in gestational age, and after controlling for confounders, cocaine exposure was associated with decrements in birthweight (151 g), length (0.71 cm), and head circumference (0.43 cm) at 40 weeks' gestation (Shankaran et al, 2007). After adjusting for the effects of birthweight, gestational age, sex, maternal height, maternal weight gain, and other drug use, newborns with a high exposure to cocaine, as measured by radioimmunoassay of cocaine metabolites in maternal hair, had a disproportionately smaller head circumference even for their birthweight, resulting in "head wasting" (Bateman and Chiriboga, 2000).

AMPHETAMINES

Pharmacology and Biologic Actions

Amphetamine (methylphenethylamine) was synthesized in 1887 and introduced in the United States in 1931. The *N*-methylated form, methamphetamine (or "crystal"), is increasingly abused because it readily dissolves in water for injection and it sublimates (converts directly from a solid to gas) when smoked (known as *ice*). The amphetamine isomers have similar clinical effects and can be distinguished only in the laboratory. Amphetamines were initially marketed for the treatment of obesity and narcolepsy and continue to be used for the treatment of attention deficit disorders in children. Amphetamines are classified as schedule II drugs, like cocaine and narcotics. Amphetamines are taken orally, inhaled, or injected. The clinical effects and toxicity of these agents are often indistinguishable from those of cocaine. The primary difference is in the duration of action. The psychotropic effects of cocaine are of a short duration—5 to 45 minutes. The effects of amphetamines may last from 2 to 12 hours. Methamphetamine exposure has direct and indirect effects on the fetus, with increases in maternal blood pressure and restrictions in delivering nutrients and oxygen to the fetus (Smith et al, 2003). The clinical effects of amphetamines resemble those of cocaine. Like cocaine, amphetamines are sympathomimetics, and they potentiate the actions of norepinephrine, dopamine, and serotonin. In contrast to cocaine, amphetamines appear to exert their CNS effects primarily by enhancing the release of neurotransmitters from presynaptic neurons. Amphetamines can block reuptake of released neurotransmitters; they can also exert a weaker direct stimulatory action on postsynaptic catecholamine receptors.

Complications of Pregnancy

The medical and obstetric complications of amphetamine use are similar to those described for cocaine use. Amphetamine toxicity has been described as more intense and prolonged than cocaine toxicity. Visual, auditory, and tactile hallucinations are common, and microvascular damage has been seen in the brains of chronic users. Amphetamine withdrawal is characterized by prolonged periods of hypersomnia, depression, and intense, often violent paranoid psychosis. Obstetric complications include a higher incidence of stillbirth. Methamphetamine use is also associated with an increased incidence of premature delivery and placental abruption. Methamphetamine users who stop using earlier in gestation have rebound weight gain, suggesting that the anorexic effects are limited to continuous use (Smith et al, 2003). Like the pregnancies of cocaine users, the pregnancies of amphetamine users are characterized by poor prenatal care, sexually transmitted diseases, and cardiovascular problems including abruptio placentae and postpartum hemorrhage. The risk of cerebrovascular accidents is lower in pregnant amphetamine users than in pregnant cocaine users, but the mechanism for this difference is not understood.

Perinatal problems associated with maternal amphetamine use include prematurity and IUGR (Smith et al, 2006). Fetal growth restriction, leading to smaller head circumference and lower birthweight, can result from the vasoconstrictive effects of norepinephrine or other vasoactive amines or from diminished maternal nutrient delivery as a consequence of the anorectic effect of amphetamine. Systemic effects from altered norepinephrine metabolism explain the transient bradycardia and tachycardia reported in exposed infants. Studies have failed to show consistent patterns of malformations in amphetamine-exposed infants, although several studies report cleft lip and cleft palate in association with amphetamine and methamphetamine exposure during early gestation (Plessinger, 1998).

Fetal Growth

The IDEAL study followed 84 methamphetamine-exposed and 1534 unexposed infants (confirmed by screening for meconium). Both groups included alcohol, tobacco, and marijuana use, but excluded opioids, PCP, and LSD (Arria et al, 2006; Smith et al, 2003, 2006). Cocaine and methamphetamine use occurred together in 13% of the methamphetamine users, and tobacco, alcohol, and marijuana use were also more frequent in the methamphetamine users. Methamphetamine-exposed infants were 3.5-fold more likely to be small for gestational age (less than the tenth percentile; 18% incidence). Methamphetamine contributed significantly to low birthweight, even after correcting for confounders such as low socioeconomic status, gestational age, and tobacco exposure.

TABLE 12-2 Risk Indicators for Gestational Substance Exposure

Maternal	No prenatal care Precipitous labor Placental abruption Repeated spontaneous abortions Hypertensive episodes Severe mood swings Previous unexplained fetal demise Myocardial infarction or stroke
Newborn	Jittery with normal blood glucose level Marked irritability Unexplained seizures or apneic spells Unexplained IUGR NEC in an otherwise healthy term infant Neurobehavioral abnormalities Signs of neonatal abstinence syndrome

IUGR, Intrauterine growth restriction; *NEC*, necrotizing enterocolitis.

IDENTIFYING PREGNANCIES AND BABIES AT RISK

PREGNANCIES

Identification of perinatal substance abuse to intervene and protect the health and well-being of both mother and child has been a goal of practitioners for decades, ever since the scope of the problem became known—particularly for alcohol. Urine toxicology testing was initially believed to be the best approach, and the universal approach was used in many busy labor and delivery units, particularly in urban centers. In 1994, an American College of Obstetricians and Gynecologists (ACOG) Technical Bulletin concluded that urine toxicology testing had limited ability to detect substance abuse and therefore recommended against universal toxicology screening and for alternative screening methods. In 2003, the U.S. Congress passed the Keeping Children and Family Safe Act. This law requires each state (as a condition of receiving federal funds under the Child Abuse Prevention and Treatment Act) to develop policies and procedures designed "to address the needs of infants born and identified as being affected by illegal substance abuse or withdrawal symptoms resulting from prenatal drug exposure." This law included a requirement that health care providers notify child protective services regarding prenatal substance exposure, but differed from the providers' legal responsibility to report suspected child abuse or neglect because the former "shall not be construed to be child abuse" and "shall not require prosecution of the mother" (Washington State Department of Health, 2009). Each state was expected to develop their own guidelines for identification of at-risk pregnancies. A 2004 ACOG Committee Opinion stated that best practices included universal screening questions followed by brief interventions or referrals. A number of screening tools have been developed including tolerance, annoyed, cut down, eye-opener (T-ACE), tolerance, worried, eye-opener, amnesia, K/cut down (TWEAK), and parents, partner, past, pregnancy (assess for substance abuse, domestic violence) (4 *P*'s Plus) (Chang, 2001; Chasnoff et al, 2005; Sokol et al, 1989). Identification of at-risk pregnancies concentrated on the maxim "if you don't ask, they won't tell." In 2008, ACOG issued a committee opinion entitled *At-Risk Drinking and Illicit Drug Use: Ethical Issues in Obstetric and Gynecologic Practice*, which reaffirmed the 2004 ACOG statement. The opinion stated that "as a result of intensive research in addiction over the past decade, evidence-based recommendations have been consolidated into a protocol for universal screening questions, brief intervention and referral to treatment." This approach—in particular, the use of standard screening questionnaires—was strongly recommended for obstetricians. Therefore a history of drug and alcohol use should be routinely included in the initial contact with every pregnant patient. To be effective, the history taking must be nonjudgmental and must occur in the context of other lifestyle questions. When a positive history of use is obtained, intervention should begin immediately. The person taking the history should be prepared to offer preliminary counseling on risk reduction and concrete referrals for treatment programs, although access to drug programs is often restricted, inadequate, or delayed.

Although the screening questionnaire approach works well for women who seek prenatal care, it is not useful for the significantly higher percentage of substance-using pregnant women who do not seek or actively avoid prenatal care. For these women, it is more helpful to identify maternal risk indicators for perinatal substance abuse at the time of delivery. Use of one of the screening questionnaires in addition to drug testing increases the likelihood of identifying at-risk pregnancies and neonates, allowing for earlier referral for treatment or specialized interventions. Several of these maternal risk indicators for perinatal substance abuse were identified in the 2004 ACOG statement (Table 12-2) (American College of Obstetricians and Gynecologists, 2004).

BABIES

It is important for practitioners to know the difference between a substance-exposed newborn and a substance-affected newborn. The Washington State Department of Health defines them as follows:

- Substance exposed:
  - Tests positive for substances at birth or
  - Mother tests positive for substances at time of delivery or
  - Is identified by medical practitioner as having been prenatally exposed to substances

- Substance affected:
  - Has withdrawal symptoms resulting from prenatal substance exposure or
  - Demonstrates physical and behavioral signs that can be attributed to prenatal exposure to substances and is identified by a medical practitioner as affected

For the identification of either of these groups of infants, assessment of both maternal and newborn risk indicators (see Table 12-2) is essential. If risk indicators suggest perinatal substance abuse, then consideration should be given to newborn drug testing. For urine testing, there is a poor correlation between maternal and newborn tests. The earliest newborn urine will contain the highest concentration of substances, but the first urination may be missed and urine output in the first day is often scant. However, some drug metabolites such as cocaine are present for 4 to 5 days, and marijuana metabolites may persist for weeks. The disadvantages of newborn urine drug testing are that it primarily reflects substance exposure during the preceding 1 to 3 days, and alcohol is nearly impossible to detect. Meconium drug testing (at term) reflects substance exposure during the second half of gestation, has a high sensitivity for opioids and cocaine, and can assess for more drugs than urine testing. The cost is similar to newborn urine testing, but it generally takes longer to obtain results. Other newborn drug tests include hair—which is costly and has a high sensitivity for cocaine, amphetamines, and opioids but not for marijuana—and umbilical cord segments, which is an evolving technology that is not widely available (Kuschel, 2007).

PREGNANCY MANAGEMENT

Ideally, perinatal substance use or abuse should be identified by universal screening procedures during prenatal visits; this gives the practitioner an opportunity to intervene, with the goal being prevention of significant obstetric and neonatal complications related to substance abuse. Screening procedures and counseling should include the following topics:

Antepartum
- Initial screening for hepatitis, HIV, and tuberculosis (if not part of routine prenatal care) and ongoing screening for sexually transmitted infections
- Referring to methadone treatment program, if appropriate
- Discussing possible drug effects on the fetus and newborn
- Discussing contraception and prevention of sexually transmitted disease
- Discussing breastfeeding issues related to alcohol and drug use

Intrapartum
- Effects of recent drug use on labor and fetal well-being
- Pain management (women in methadone or alternative opioid treatment programs will be less responsive to opioid pain medications)
- Intrapartum prophylaxis for HIV, herpes simplex virus infections
- Need for social services involvement

Postpartum
- Breastfeeding issues (related to both drug use and infection)
- Contraception and pregnancy prevention including tubal ligation
- Support for continuation in, or initiation of, a drug treatment program
- Child Protective Services notification

MATERNAL METHADONE MAINTENANCE

The potential benefits of maternal methadone maintenance are numerous (Kandall and Doberczak, 1999; Ward et al, 1999) and include the prevention of opioid withdrawal symptoms in the mother, better medical and prenatal care, improved health and growth of the fetus, and maintenance of opioid levels in the mother to decrease both the use of illicit drugs and the potential for perinatal infections. Methadone maintenance programs associated with comprehensive medical and psychosocial services for the pregnant woman are of additional benefit. Methadone maintenance has been shown to be associated with higher birthweight in some but not all studies (Brown et al, 1998; Kandall and Doberczak, 1999). Detoxification of a pregnant heroin user is infrequently attempted, because maternal drug withdrawal is believed to be associated with subsequent fetal withdrawal, fetal asphyxia, and spontaneous abortions (Barr and Jones, 1994). Dashe et al (1998) reported on a small study of opioid-using pregnant women undergoing safe maternal detoxification. Close to 60% of the women completed detoxification, but almost 30% resumed opioid use. McCarthy et al (1999) showed that women who reduced their methadone dose during pregnancy had infants with higher birthweights than a control group who continued on the same or increased methadone dose throughout pregnancy. In the United States, most pregnant, narcotic-addicted women are treated with daily methadone rather than a program of detoxification. Some authorities, however, have urged the reappraisal and reevaluation of the benefits of methadone maintenance in pregnancy (Brown et al, 1998; Hulse and O'Neil, 2001), and there are recent studies comparing methadone with buprenorphine in pregnancy (Jones et al, 2008; Minozzi et al, 2008).

In the Netherlands, women enrolled in a methadone program had higher rates of prenatal care, which were associated with higher birthweights and reduced prematurity in the offspring (Soepatmi, 1994). When women in a methadone maintenance program were enrolled in an enhanced prenatal care program, their infants' birthweights were significantly larger than those in the control group of women receiving regular methadone maintenance during pregnancy (Chang et al, 1992). Others have shown that higher methadone doses are associated with improved head circumference and increased gestational age at delivery (Hagopian et al, 1996). Using a metaanalysis design, Hulse et al (1997) found that low infant birthweight was associated with heroin use and that birthweights were improved with methadone treatment during pregnancy. These favorable outcomes are believed to be to the result of a stable intrauterine environment uncomplicated by periods of intoxication and withdrawal, as well as less stress and better nutrition in the mother.

Several investigators have found that neonatal withdrawal symptoms, birthweight, length of pregnancy, and the number of days infants require treatment for abstinence do not correlate with maternal methadone dosage (Brown

et al, 1998; Finnegan, 1991; Madden et al, 1977; Rosen and Pippenger, 1976). In contrast, others have reported a correlation between the severity of neonatal withdrawal and maternal methadone dose (Dryden et al, 2009; Harper et al, 1977; Maas et al, 1990; Malpas et al, 1995). Studying maternal and neonatal serum levels of methadone does not help clarify this dilemma. Investigators have found no correlation between neonatal serum levels of methadone and the maternal methadone dose at delivery, the maternal serum levels, or the severity of withdrawal symptoms in the neonates (Harper et al, 1977; Mack et al, 1991). Other researchers have reported that neonatal signs of withdrawal correlate with the rate of decline of the neonatal plasma level during the first few days of life (Doberczak et al, 1993).

There are no definitive guidelines for methadone doses during pregnancy, and there is continuing controversy over the most appropriate dose of methadone maintenance during pregnancy. The divergent findings noted previously have been used to argue either for weaning a pregnant woman to a low methadone maintenance dose or for attempting complete maternal detoxification during pregnancy. Some authorities believe in maintaining high methadone doses to keep the mother from "chipping" with additional street drugs, which would put her at risk for greater complications of pregnancy and for a higher risk of infections transmitted by intravenous use of drugs (HIV, hepatitis) or sexually transmitted disease. High-dose methadone maintenance ranges between 60 and 150 mg/day. Despite reports of the safe detoxification of pregnant women, there are still concerns that the fetus is placed at risk during maternal detoxification. The medical management of pregnant women who are addicted to opioids remains controversial (Christensen, 2008).

There is a growing body of literature promoting breastfeeding for infants of mothers in methadone maintenance programs as both beneficial and safe. Studies have shown that breastfed infants tend to have less need for pharmacotherapy for neonatal abstinence syndrome, despite low and unpredictable levels of methadone in breast milk and in infant serum. Maternal serum levels, breast milk levels, and infant serum levels do not correlate with maternal methadone dose (Jansson et al, 2008).

Buprenorphine (Suboxone, Subutex)

Buprenorphine is an alternative opioid substitute that was first introduced in France in 1996. It is increasingly being used with or instead of methadone for the treatment of opioid addiction, because it has fewer autonomic side effects than methadone as well as improved compliance and treatment efficacy. Recent trials have compared methadone with buprenorphine treatment during pregnancy and found no difference in the neonatal outcome or incidence of withdrawal symptoms (Jones et al, 2008; Minozzi et al, 2008).

Human Immunodeficiency Virus and Other Viral Infections

Nationwide, intravenous drug abusers are the second largest risk group for HIV infection. Drug abusers also may be the primary source of infection for non–drug-using heterosexuals and children (Chamberland and Dondero, 1987). Seventy-five percent of cases of acquired immunodeficiency syndrome (AIDS) in children are perinatally acquired. The seropositivity rate varies across the country; the rate among female intravenous drug users in New York City and northern New Jersey is estimated at 50% to 70%, compared with 5% to 20% in California. Heroin and cocaine addicts often resort to prostitution to support their habits, and amphetamine and methamphetamine users often inject drugs several times daily. Alcohol decreases sexual inhibition, impairs judgment, and increases the incidence of unsafe sexual activity. Every infant born to a substance abuser should be evaluated for HIV infection, and universal precautions should be observed. The American Academy of Pediatrics Committee on Infectious Diseases (2009) recommends rapid HIV testing of any mother whose HIV status is not known, with appropriate consent as required by local law.

Intravenous drug use places the woman at risk for multiple infectious complications, including cellulitis, thrombophlebitis, hepatitis, endocarditis, syphilis, gonorrhea, and AIDS. In a prospective study undertaken in Canada, a 5-year incidence of HIV seroconversion was 13.4%; the rate of conversion associated with injection of heroin or cocaine was 40% higher in women than in men (Spittal et al, 2002). Opioid abusers are also less likely to receive prenatal care or to obtain late prenatal care (Bauer, 1999). Heroin-addicted mothers are often poorly nourished, and iron-deficiency anemia is more common in pregnant opioid users than in nonusers. Bauer (1999) found that maternal hepatitis infections were fivefold higher in opioid-using women than in a control group of nonusers.

Hepatitis C virus (HCV) is another chronic infectious condition that is spread by parenteral exposure to infected blood and can be perinatally acquired by the newborn. The most common risk factors for acquiring infection are injection drug use, having multiple sexual partners, or having received blood products before 1992. The 2009 American Academy of Pediatrics Red Book (American Academy of Pediatrics Committee on Infectious Diseases, 2009) states that "seroprevalence [of hepatitis C] among pregnant women in the United States has been estimated at 1% to 2%," and the risk of perinatal transmission averages 5% to 6% from women who are HCV-RNA positive at the time of delivery. Maternal coinfection with HIV has been associated with increased risk of perinatal transmission of HCV. Antibodies to HCV and HCV RNA have been detected in colostrum, but the risk of HCV transmission is similar in breastfed and bottle-fed infants, so breastfeeding is currently allowed.

NEONATAL MANAGEMENT AFTER GESTATIONAL SUBSTANCE ABUSE

GENERAL

Although at higher risk for medical complications, the majority of infants of drug-using women do not require intensive neonatal care; however, symptomatic infants often need more nursing care. Physical examination on admission should document a gestational age assessment, birthweight, head circumference, and length. Infants

should be examined carefully for evidence of malformations, dysmorphic facial features, or both. Studies such as electroencephalography and brain imaging may add diagnostic or prognostic information when physical or neurologic abnormalities are not clearly consistent with drug exposure, but these procedures are not indicated for most drug-exposed infants. If indicated by neonatal or maternal risk indicators, toxicology testing should be performed on neonatal urine, meconium, or both as soon as possible after birth. Infants whose mothers were not screened for HIV should undergo screening for perinatal HIV exposure and other infections such as hepatitis and syphilis, as clinically indicated. In some states, rapid testing of the newborn for HIV is "required by law if the mother refuses to be tested," so that appropriate treatment of the infant can be started before 12 hours of age. Rapid screening detects only HIV-1, the most common serotype of HIV in the United States, but it can miss HIV-2, so measurement of HIV antibodies should also be performed (American Academy of Pediatrics Committee on Infectious Diseases, 2009).

Cocaine-exposed infants weighing more than 1500 g have longer hospital stays and increased need for therapies, procedures, intravenous fluid, and formula feeding. These infants also undergo more investigations for sepsis, more neonatal intensive care unit (NICU) admissions, and more social and family problems delaying discharge (Bada et al, 2002). In the Maternal Lifestyle Study, cocaine-exposed infants had a higher frequency of infection (odds ratio [OR], 3.1; 99% confidence interval [CI], 1.8 to 5.4) and neurologic signs and symptoms (adjusted OR, 1.7; 99% CI, 1.0 to 2.1). Neurologic signs were highest in the infants exposed to opioids and cocaine, but remained significantly increased in infants exposed to cocaine alone. Smoking also increased the risk for neurologic signs and symptoms (Shankaran et al, 2007). The association between cocaine exposure and fetal hypoxic ischemic episodes creates special concerns. Maternal cocaine use exposes infants to a higher than expected risk of problems with postasphyxial syndrome, and organ dysfunction from hypoxic-ischemic injury should be investigated and treated. Feedings in premature infants with cocaine exposure should be started cautiously, because premature infants exposed to cocaine may be at increased risk for necrotizing enterocolitis. In addition, after controlling for gender, gestational age, birthweight, maternal parity, ethnicity, and polydrug use, heavy cocaine use during pregnancy was associated with a slightly higher risk of subependymal hemorrhage (Shankaran et al, 2007).

Using the NICU Network Neurobehavioral Scale (NNNS), subtle differences in behavior were detected in drug-exposed infants (Lester et al, 2002; Smith et al, 2008). Cocaine-exposed infants showed lower arousal, and with heavy cocaine use they showed lower regulation and higher excitability than did unexposed infants (Lester et al, 2002). There were no stress or abstinence signs associated with cocaine exposure. Marijuana use was associated with more stress and abstinence signs and higher excitability scores (Lester et al, 2002). Low birthweight was also significantly correlated with poorer regulation and higher excitability. Methamphetamine exposure was also associated with increased stress signs, especially in first-trimester use. Heavy methamphetamine use was related to lethargy, lower arousal, and increased physiologic stress (Smith et al, 2008). Neonatal neurologic abnormalities similar to a mild withdrawal syndrome, consisting of hypertonicity, irritability, and jitteriness, have been reported after in utero marijuana exposure, but without documented evidence of long-term sequelae (Cornelius et al, 1995). Finally, gestational nicotine exposure definitely altered the newborn neurobehavioral scores and has also been reported to elevate neonatal abstinence scores (Godding et al, 2004; Law et al, 2003).

In the Maternal Lifestyle Study, only 100 women were identified as isolated users of opioids, and a similar number used cocaine and opioids. Transient but dramatic neurobehavioral signs are present in the first week of life as symptoms of opioid withdrawal (increased irritability, jitteriness, poor feeding, sweating, sneezing; Shankaran et al, 2007). See the discussion under Neonatal Abstinence Syndrome.

BREASTFEEDING AND DRUG EXPOSURE

Breastfeeding has the benefit of improved bonding, but the risks of HIV and continued drug exposure may outweigh this benefit. Women who wish to breastfeed despite these potential risks should undergo drug monitoring and sequential HIV antibody testing. Close observation of mother-infant interactions should be documented in the infant's chart. Parenting and childcare skills should be stressed as part of the discharge education for the mother. All physician interactions with the family should be documented in detail.

Most illicit drugs of abuse that are of low molecular weight and lipophilic, are readily excreted in breast milk, but have varying degrees of bioavailability (Howard and Lawrence, 1998). Cocaine has been detected in breast milk and Chasnoff et al described a two-week-old breastfed infant who had clinical signs of cocaine intoxification. Both the baby's urine and the mother's milk contained cocaine (Chasnoff et al, 1987). A widely-referenced report of cocaine seizures in a breastfed infant actually resulted from topical coacine applied to sore nipples, not from cocaine-laced breast milk (Chaney et al, 1988). Because of the potential risk of toxicity, breastfeeding is generally discouraged in women who are known abusers of these drugs and who are not willing to engage in substance abuse treatment and monitoring. Breastfeeding may be supported for women who are engaged in substance abuse treatment and who have received good prenatal care with a confirmed period of sobriety prior to delivery. Breastfeeding by women using methadone is recommended. Concentrations of methadone in human milk are low, and there are other significant advantages for the mother and infant (Jansson et al, 2008).

Alcohol use while breastfeeding is not listed as a contraindication by the American Academy of Pediatrics, but excessive maternal alcohol intake during breastfeeding can be deleterious for the infant and should be avoided. Smoking in the postnatal period and during breastfeeding also has deleterious effects on the newborn. Smoking is associated with measurable levels of nicotine and cotinine in maternal breast milk.

NEONATAL ABSTINENCE SYNDROME

Clinical Findings

Classic neonatal withdrawal or abstinence syndrome consists of a wide variety of CNS signs of irritability, gastrointestinal and feeding problems (diarrhea, hyperphagia or poor feeding), autonomic signs of dysfunction (fever, sweating, sneezing), and respiratory symptoms (Tables 12-3 and 12-4). These symptoms are most often related to gestational opioid exposure, but are relatively nonspecific, with the differential diagnosis including infection, meningitis, hypocalcemia, hyponatremia, intracranial hemorrhage, seizures, and stroke. The signs of neonatal serotonin syndrome (or selective serotonin reuptake inhibitor withdrawal) may also mimic the signs of neonatal opioid abstinence syndrome (Boucher et al, 2008; Moses-Kolko et al, 2005). The timing of withdrawal signs from specific drug exposures can often be anticipated; for example, heroin withdrawal usually occurs within 24 hours of birth, whereas methadone withdrawal symptoms typically begin later, at approximately 48 to 72 hours after birth. The incidence of neonatal abstinence syndrome (NAS) in infants of women using heroin or methadone is high, with wide ranges reported between 16% and 90% (Agarwal et al, 1999; Boer et al, 1994; Maas et al, 1990; van Baar et al, 1994), and between 30% and 91% of infants with signs of NAS receive pharmacologic treatment for NAS with inpatient stays averaging 3 weeks (Dryden et al, 2009; Kuschel, 2007). Premature infants generally have milder signs of withdrawal and often show alternating periods of hyperactivity and lethargy, with tremors seen less commonly. The mortality rate for these infants is less than 1% (Boer et al, 1994). Death is rarely associated with withdrawal alone, but usually occurs as a consequence of prematurity, infection, and severe perinatal asphyxia.

A number of evaluation tools are used to assess the severity of opioid withdrawal after birth. The neonatal abstinence score is a scale based on nursing observations of the severity of signs of withdrawal (Finnegan et al, 1975) and is the most widely used scale. The Lipsitz score was developed at the same time and is simpler to use, with a score greater than 4 indicating withdrawal. Green and Suffet (1981) introduced the Neonatal Narcotic Withdrawal Index as a rapid physician-based evaluation for neonatal signs of withdrawal. The use of these scoring systems allows more objective quantification of the severity of the infant's withdrawal and the response to treatment. These scoring systems have shown good interobserver reliability and can improve clinicians' ability to treat the withdrawing infant appropriately (Anand and Arnold, 1994; Franck and Vilardi, 1995).

The goal of medical management of opioid withdrawal is to avoid serious symptoms of NAS, such as seizures, and to maintain the infant's comfort while enabling the infant to feed, sleep, and gain weight in an appropriate manner. There are a number of reported threshold scores for initiating pharmacologic treatment (Finnegan NAS scores between 7 and 12) (Kuschel, 2007), but none of these choices have been examined in a scientific manner. The decision to begin treatment or to wean treatment should be influenced by the absolute score and other factors, such as the infant's age, comorbidities, other conditions leading to abnormal behavior, and a daily evaluation of the abnormal clinical elements observed in the scoring system (Kuschel, 2007). Standard medical practice is to combine both developmental and behavioral methods with pharmacologic interventions as necessary to control symptoms and signs of narcotic abstinence.

TABLE 12-3 Clinical Signs of Neonatal Withdrawal Syndrome (Narcotic Abstinence Syndrome)

Central nervous system dysfunction	Excoriation (from frantic movement) Hyperactive reflexes Increased muscle tone Irritability, excessive crying, high-pitched cry Jitteriness, tremulousness Myoclonic jerks Seizures Sleep disturbance
Autonomic dysfunction	Excessive sweating Frequent yawning Hyperthermia
Respiratory symptoms	Nasal stuffiness, sneezing Tachypnea
Gastrointestinal and feeding disturbances	Inadequate oral intake Diarrhea (loose, watery, frequent stools) Excessive sucking Hyperphagia Regurgitation

These signs were abstracted from Finnegan L, Connaughton J, Kron R: Neonatal abstinence syndrome: assessment and management, *Addict Dis* 2:141-158, 1975.

TABLE 12-4 Neonatal Neurobehavioral Symptoms after Fetal Drug Exposure

Drug	Onset (days)	Peak (days)	Duration	Relative Severity	Likely NICU Admission	Symptoms
Alcohol	0-1	1-2	1-2 days	Mild	No	?
Amphetamine	0-3	—	2-8 wk	Mild	No	Neuro
Cocaine	0-3	1-4	? mo	Mild	No	Neuro
Heroin	0-3	3-7	2-4 wk	Mild to severe	Yes	Neuro, Resp, GI
Methadone	3-7	10-21	2-6 wk	Mild to severe	Yes	Neuro, Resp, GI
SSRI	0-3	1-3	2-10 days	Mild to moderate	No	Neuro, Resp, GI
Tobacco	0-1	1-2	2-3 days	Mild	No	Neuro

GI, Gastrointestinal symptoms including poor weight gain; *Neuro*, neurobehavioral symptoms; *NICU*, neonatal intensive care unit; *Resp*, respiratory symptoms; *SSRI*, selective serotonin reuptake inhibitor.

Treatment

Treatment for opioid withdrawal should always begin with supportive, nonpharmacologic measures such as soothing including swaddling, rocking, decreased environmental stimulation, avoiding unnecessary handling and irritation, and progressing to pharmacologic management only when medically necessary. Between 30% and 91% of infants exhibiting signs of NAS will receive pharmacologic treatment (Kuschel, 2007). The mainstay of treatment for opioid withdrawal is the use of opioids, either alone or in combination with other medications (American Academy of Pediatrics Committee on Drugs, 1998; Osborn et al, 2002, 2005). Medication is titrated for each infant according to the severity of the signs of withdrawal and abstinence scoring.

A recent survey in the United States showed that opioids are the most common medication used for narcotic withdrawal, and phenobarbital is frequently used or added for polydrug exposure (Sarkar and Donn, 2006). A metaanalysis of seven studies found that opioid treatment reduced the time to regain birthweight and the duration of supportive care compared with supportive care alone; however, the length of hospital stay was increased (Osborn et al, 2005). Phenobarbital was also shown to be superior to diazepam for treating NAS, but small, randomized, controlled trials comparing morphine to phenobarbital for treatment of NAS suggested that opioids are superior at decreasing treatment duration and lowering NAS scores (Ebner et al, 2007; Jackson et al, 2004; Osborn et al, 2002).

Morphine is the opioid most often used in treating NAS. The only study comparing an oral preparation of morphine to dilute tincture of opium (DTO), a concentrated morphine solution that also contains alcohol, recommends oral morphine to avoid problems with dilution of highly concentrated DTO and the unwanted effects of the alcoholic extracts with various alkaloids (Langenfeld et al, 2005). A standard starting dose of morphine is 0.04 to 0.05 mg/kg given orally every 3 to 4 hours. This dose can be increased in increments of 0.05 to 0.1 mg until the symptoms are controlled. The usual dose for infants experiencing withdrawal at birth ranges from 0.08 to 0.2 mg every 3 to 4 hours (American Academy of Pediatrics Committee on Drugs, 1998; Anand and Arnold, 1994; Burgos and Burke, 2009; Levy and Sino, 1993). Higher doses may be needed to control significant physiologic signs of withdrawal such as diarrhea, pyrexia, hypertension, and significant hypertonicity.

Although preparations of oral morphine are most commonly used in recent studies, methadone has also been reported as an option for treatment of NAS (Burgos and Burke, 2009; Kuschel, 2007). There is one retrospective report of methadone use for neonatal abstinence syndrome (Lainwala et al, 2005) and more extensive experience with methadone in the treatment of opioid withdrawal in older infants and children (Tobias, 2000; Tobias et al, 1990). Methadone has a long duration of action and can be administered by either the oral or the parenteral routes. The initial recommended methadone dose is 0.05 to 0.1 mg/kg followed by 0.025 to 0.05 mg/kg every 4 to 12 hours until abstinence scores are controlled. The total daily dose given to control symptoms is then divided into two doses and given every 12 hours. Tobias et al (1990) showed that methadone could be given every 12 to 24 hours because of its longer half-life. There were no advantages to methadone over morphine in neonatal abstinence (Lainwala et al, 2005). In addition, sublingual buprenorphine has been reported as a treatment for NAS (Kraft et al, 2008).

Phenobarbital has been used for signs of acute opioid withdrawal. Phenobarbital does not, however, reduce significant physiologic signs of withdrawal, such as diarrhea and seizures. At higher doses, phenobarbital has also been shown to impair infant sucking and cause excessive sedation. The doses of phenobarbital used are 5 to 20 mg/kg in the first 24 hours, followed by 2 to 4 mg/kg every 12 hours; the therapeutic blood level of phenobarbital for control of opioid withdrawal signs is not known. Combining oral morphine solution (i.e., DTO) and phenobarbital treatment was found to shorten duration of hospitalization and lessen the severity of withdrawal symptoms, compared with morphine treatment alone (Coyle et al, 2002, 2005). Compared with those treated with morphine alone, infants treated with morphine and phenobarbital were more interactive, had smoother movements, were easier to handle, and were less stressed. Dual treatment resulted in improved neurobehavioral organization during the first 3 weeks of life, which may indicate a more rapid recovery from opioid withdrawal (Coyle et al, 2005). In these studies, however, the infants were discharged home on phenobarbital therapy, from which they were slowly weaned throughout infancy. Some of these infants received phenobarbital for prolonged times.

Clonidine, an α_2-adrenergic receptor antagonist, is used treating opioid withdrawal symptoms in older children and adults. A recent randomized, controlled trial showed that adding clonidine to opioid treatment (i.e., DTO) significantly reduced the median length of therapy with opioids and the number of infants requiring high dose opioids, and it eliminated infants who met their definition of treatment failure (Agthe et al, 2009). During hospitalization, there were no significant adverse events (i.e., hypertension, hypotension, bradycardia, desaturations) related to clonidine use. A German group has also retrospectively reported their experience using clonidine and chloral hydrate for NAS compared to a larger group treated with morphine and phenobarbital; they also reported decreased duration of treatment, decreased length of stay, and reduction of symptoms in the clonidine group (Esmaeili et al, 2010). Before clonidine is used widely, a larger trial is indicated to investigate appropriate dosing regimens and to determine long-term safety.

Once medications have been titrated to a level that controls the severity of opioid withdrawal and lowers the NAS scores, then tapering of the dosage should be started. A common method is to decrease the opioid dose by 10% to 20% of the highest dose, with continued surveillance of NAS scores to assure the infant tolerates the decrease. It is not unusual to note increased signs of opioid withdrawal during the medication tapering. The goal of weaning is to allow the infant to acclimate to a new and lower dose of medication while ensuring that he or she is comfortable and consolable and is able to sleep, eat, and gain weight appropriately. Objective measurements using established withdrawal scoring systems should be used to determine

the rate and efficacy of medication tapering. Most often opioid medications are weaned every 24 to 48 hours as long as NAS scores remain low and the infant's clinical condition is unchanged (Burgos and Burke, 2009; Coyle et al, 2002; Jackson et al, 2004). Whether narcotics can safely be weaned more rapidly in infants has not been studied. One small study reported good results using oral morphine on an as-needed basis for elevated individual withdrawal scores, rather than providing regular doses of morphine every 3 to 4 hours (Ebner et al, 2007). No specific protocols for weaning phenobarbital or clonidine have been reported.

The average length of hospital stay for infants with NAS who are treated with medications varies from 8 to 78 days, with a stay of 21 to 30 days being common (Coyle et al, 2002; Ebner et al, 2007; Jackson et al, 2004; Kuschel, 2007). Investigation of outpatient management of detoxification may result in a shorter hospital stay, but with a more prolonged duration of neonatal treatment (Kuschel, 2007).

LONG-TERM EFFECTS OF PERINATAL SUBSTANCE ABUSE

SUDDEN INFANT DEATH SYNDROME IN DRUG-EXPOSED INFANTS

The incidence of sudden infant death syndrome (SIDS) is greater in drug-exposed infants, although the increase appears less significant for cocaine-exposed infants (Chasnoff et al, 1989b; Kandall et al, 1993) than for methadone-exposed or heroin-exposed infants (Bauchner and Zuckerman, 1990). A metaanalysis of 10 studies demonstrated a 4.1 OR for SIDS among cocaine-exposed infants (Fares et al, 1997) compared with infants not exposed to perinatal drugs. However, after data were controlled for concurrent use of other drugs, the increased risk for SIDS could not be attributed to intrauterine cocaine alone, but was believed to be caused by exposure to other illicit drugs and smoking.

There is a significant relationship between exposure to tobacco smoke and SIDS. A higher risk for SIDS is reported in infants exposed to maternal smoking with either antenatal or postnatal exposure (Blair et al, 1996; Mitchell et al, 1993; Schoendorf and Kiely, 1992). Additional evidence supporting a causal role includes a dose-response relationship (Rogers, 2008). With recent substantial decreases in SIDS risk (after "back to sleep"), maternal smoking is calculated to account for an increasing proportion of SIDS risk. Mitchell and Millerad (2006) suggest that one third of all SIDS deaths might be prevented by eliminating in utero exposure to maternal smoking. Despite the increased risks of SIDS among drug- and tobacco-exposed infants, home apnea monitoring is not indicated in the absence of other risk factors.

POSTNATAL GROWTH AND MEDICAL PROBLEMS

There are no documented long-term effects of substance exposure on postnatal growth. In the Maternal Lifestyle Study, cocaine-exposed infants were lighter than non–cocaine-exposed infants at birth, but there were no differences in weight between ages 1 and 6 years. For height, cocaine-exposed infants were shorter at birth through 2 years, but the difference disappeared by age 3, and cocaine-exposed infants had a smaller head circumference from birth to 1 year old, but this difference subsequently disappeared (Shankaran et al, 2007). A previous systematic review concluded that there is no consistent effect of cocaine exposure on physical growth in children younger than 6 years (Frank et al, 2001). Opioid-exposed infants also show no difficulties with postnatal growth through 3 years (Hunt et al, 2008). Infants with IUGR at birth remained significantly lighter (by 2.1 kg) and shorter (by 1.8 cm) at 6 years, and they continued to have a smaller head circumference (by 0.9 cm). There was no interaction between cocaine exposure and IUGR status (Shankaran et al, 2007).

There were also no differences in medical diagnoses, blood pressure, hospitalizations, or overall health status associated with opioid exposure (Shankaran et al, 2007). The effect of cocaine on subsequent blood pressure is unclear. IUGR status at birth was significantly associated with hypertension after correcting for in utero drug exposures, maternal race, and child's body mass index.

NEUROBEHAVIORAL ABNORMALITIES

Detailed studies have identified both neurologic soft signs and a higher risk of cognitive, behavioral, and psychiatric problems linked to gestational substance exposure. However, significant confounding factors make it difficult to attribute specific deficits directly to substance exposures. No major neurologic deficits in motor development are found after in utero exposure to cocaine (Shankaran et al, 2007) or opioids (Hunt et al, 2008). Infants exposed to cocaine were reported to have lower motor skills at 1-month testing, but they displayed significant improvements over time. Both higher and lower levels of tobacco use were related to poor motor performance (Shankaran et al, 2007).

Subtle neurobehavioral abnormalities have been reported in older studies and more recently using the NNNS to evaluate infants in the month after birth. Cocaine-exposed infants manifest a range of neurobehavioral abnormalities that were initially described as drug withdrawal, but are more likely caused by acute intoxication (Dempsey et al, 1996). Signs are present at birth and wane as cocaine and the metabolite, benzoylecgonine, are cleared from plasma. The infants are hypertonic, irritable, and tremulous (Chiriboga, 1993), and they may have abnormal crying, sleep, and feeding patterns. Tachycardia, tachypnea, and apnea have been noted in two blinded, controlled studies, with significant elevations in cardiac output, stroke volume, mean arterial blood pressure, and cerebral artery flow velocity resolving by day 2, which is consistent with an intoxicant effect of cocaine (van de Bor et al, 1990a, 1990b) Cocaine-exposed infants may have abnormal electroencephalograms or clinical seizures, perhaps the result of toxicity from the metabolite, benzoylecgonine (Konkol et al, 1994); however, neonatal seizures attributable directly to maternal use of cocaine are rare (Legido et al, 1992).

A number of studies suggest that exposure to exogenous opioids during fetal development may produce lifelong alterations in the developing brain. Infants who have been exposed to opioids in utero have a higher risk for fetal growth retardation and smaller head circumference than those who have not (Bauer, 1999). In addition, significant developmental and learning deficits have been described in both methadone-exposed and heroin-exposed children (Soepatmi, 1994; van Baar and de Graaff, 1994; van Baar et al, 1994), and Bunikowski et al (1998) have reported a higher incidence of abnormalities in intellectual performance, developmental retardation, and neurologic abnormalities in a group of opioid-exposed infants compared with a control group of infants. However, the treated infants in the study had an unusually high incidence of seizures during withdrawal treatment with phenobarbital alone, as well as a higher incidence of prematurity than the control infants. These important considerations temper the findings of that study.

Early neurobehavioral changes have been associated with maternal methamphetamine use; heavy use was associated with lower arousal, increased lethargy, and increased CNS stress (Smith et al, 2008). However, a detailed analysis in a subgroup of the same population found that these same abnormalities on the NNNS were associated with maternal depression and that prenatal methamphetamine exposure was not associated with additional neurodevelopmental differences (Paz et al, 2009).

Persisting behavioral, neurologic, and rearing problems are reported in children exposed to both cocaine and opioids (Chasnoff et al, 1989; Hunt et al, 2008). No significant differences in mean developmental scores were noted in a group of children exposed to cocaine plus polydrugs compared to a group without drug exposure (Chasnoff et al, 1992). Other investigators reported no differences between infants who have and those who have not been exposed to cocaine in mean cognitive, psychomotor, or language quotients at age 36 months (Kilbride et al, 2000). A recent report following a cohort of opioid exposed infants documented lower Bayley mental development index (MDI) scores at 18 months old, lower Stanford Binet Intelligence Scale scores at 3 years, and decreased scores on the Vineland Social Maturity Scale and Reynell Language Scale at 3 years (Hunt et al, 2008). However, a similar evaluation at 3 years showed no mental, motor, or behavioral deficits after controlling for birthweight and environmental risk factors (Messinger et al, 2004).

The neurodevelopmental problems among children exposed to cocaine may occur either from a direct teratogenic drug effect during gestation or from the effects of the social environment in which the developing infant is reared. Singer et al (2002) reported that cocaine-exposed infants are twice as likely to have significant cognitive but not motor delays at 2 years, and they demonstrated a downward trend in mean developmental scores by 2 years, which is consistent with a deleterious effect of the environment, parental stimulation, socioeconomic status, or possibly other, indirect effects of drugs on the developing CNS. Other studies have not consistently demonstrated this association (Frank et al, 2001). In contrast, the Maternal Lifestyle Study, after controlling for covariates, found no differences in Bayley scores between cocaine-exposed, opioid-exposed, and control infants for the first 3 years of life (Shankaran et al, 2007), although subtle effects on cognitive subscales were reported at 3 years (Messinger et al, 2004).

Other investigators have shown normal development for opioid-exposed infants during the first 2 years of life after data have been controlled for socioeconomic status and birthweight (Bauer, 1999). Using regression analysis, researchers have shown that the amount of prenatal care obtained by the mother and the postnatal home environment were more predictive of the infant's future intellectual performance. Conversely, the amount of maternal opioid use during pregnancy was not found to be predictive. Ornoy et al (2001) have shown that children exposed to heroin but adopted at an early age performed better on intelligence testing than did opioid-exposed infants who were raised in the homes of their biologic parents. The same investigators found a higher rate of attention deficit disorders in children exposed to opioids regardless of home environment, with the highest incidence in children who were raised in the homes of their biologic parents. Numerous studies point also to the importance of the home environment in optimizing child development. Variable outcomes of these studies may depend on the amount and type of drug use, or on other covariates such as nutritional status, poverty, psychosocial problems, and parental educational level.

With the lack of major neurologic deficits, recent studies have focused on neurologic soft signs, nonfocal signs with no localized findings that are more often associated with cognitive deficits, and increased prevalence of attention deficit hyperactivity disorder and behavior problems. Neurologic soft signs including speech, balance, coordination, and tone were markedly stable over a 1-year period in 6- to 9-year-olds. Soft signs are a marker for increased risk of cognitive and psychiatric problems. In the Maternal Lifestyle Study, 23.5% of children exposed to cocaine had more than two soft neurologic signs, similar to rates in the comparison group. Soft signs were more common in infants born weighing less than 1500 g. Both cocaine and alcohol use significantly increased the incidence of soft signs in exposed infants weighing less than 1500 g, and this effect persisted after controlling for other substances used, birthweight, sex, and race (Shankaran et al, 2007).

Childhood behavior problems were more common in infants with heavy cocaine exposure than in those with no or some cocaine exposure. Prenatal tobacco and alcohol exposure were also significantly associated with behavioral problems until 7 years, with a significant dose-response relationship (Shankaran et al, 2007). Evaluation at 7 years demonstrated behavior problems in cocaine- and substance-exposed infants that suggested direct effects resulting in neurobehavioral dysregulation, which was tracked through serial assessments beginning at an early age. This work on a model of early abnormalities predictive of later behavioral problems may allow for early identification and possible prevention of later behavioral problems (Lester et al, 2009).

Follow-up studies have been reported at 9 to 15 years. Cognitive outcomes at 10 years were not abnormal in opioid-exposed children (Shankaran et al, 2007). Cocaine-exposed children were more likely to

be referred for special education services in school than unexposed children, with an estimated additional cost to the United States of $25,248,384 per year (Shankaran et al, 2007). Prenatal marijuana exposure is reported to be associated with deficiencies in executive function in 9 to 12 year olds (Fried and Smith, 2001; Fried et al, 1998), and recent reports have found that prenatal marijuana exposure has a significant effect on school-age intellectual performance (Goldschmidt et al, 2004, 2008; Richardson et al, 2002).

In methamphetamine-exposed infants, neurodevelopmental abnormalities have been described to persist as late as 14 years (Cernerud et al, 1996). Intellectual capacity does not appear to be diminished among exposed infants. These children are described as exhibiting disturbed behavior, including hyperactivity, aggressiveness, and sleep disturbances. Eriksson et al (2000) reported that neurobehavioral abnormalities appear to be associated with the extent and duration of fetal exposure and with the severity of head growth restriction. In this study, children with the most severe problems were those born to mothers who abused amphetamines throughout pregnancy and were reared in homes with an addicted parent. Alterations in growth have been reported after prenatal exposure, with striking gender differences (Cernerud et al, 1996). Drug-exposed boys in Sweden were taller and heavier, and girls were smaller and lighter, than national standards. This finding suggests that fetal amphetamine exposure affects the onset of puberty and amphetamines may interfere with neurodevelopment of the adenohypophysis. Children of amphetamine abusers appear to be at high risk for social problems, including abandonment, abuse, and neglect. In two Swedish studies, only 22% of 10-year-old children who had been exposed to amphetamine in utero remained in the care of their biologic mothers, whereas 70% were in foster care (Cernerud et al, 1996; Eriksson and Zetterstrom, 1994).

Considering all the data, it is still difficult to create a coherent picture and provide a prognosis for a newborn after gestational substance exposure. A recent report of volumetric magnetic resonance imaging in thirty five 12-year-old children exposed to cocaine in utero found smaller total parenchymal volumes, lower cortical gray matter volumes, and smaller head circumferences with prenatal substance exposure. The decreases were statistically significant only for prenatal cigarette exposure and for infants exposed to all substances studied (cocaine, tobacco, marijuana and alcohol) (Rivkin et al, 2008). As in other studies, exposure to multiple substances clearly has detrimental effects on the developing brain.

SUMMARY

The magnitude of observed perinatal outcomes after illicit maternal substance use pales in comparison to the established health and developmental risks associated with tobacco and alcohol exposure (Schempf, 2007). The greatest impact of illicit substance use may be the increased postnatal risks of neglect, maltreatment, and disruptions in the home environment. Health policy must be directed at reducing all these complex factors associated with perinatal substance abuse.

PART IV

Labor and Delivery

CHAPTER 13

Antepartum Fetal Assessment

Christian M. Pettker and Katherine H. Campbell

A primary objective of obstetric care is the assessment and prevention of adverse fetal and neonatal outcomes. Maternal care is an integral step toward this goal. Optimization of the maternal state, through careful monitoring and treatment of chronic conditions such as diabetes or hypertension or acute states like preeclampsia or preterm labor, is one important facet of care to achieve desirable perinatal outcomes. Monitoring and management of the fetus, although a more obvious step toward this goal, are somewhat less straightforward. Fetal assessment demands a view into the intrauterine environment, which is somewhat inaccessible. Our ability to gain access to this space to gauge the needs and health of the fetus has improved dramatically with the developments in technology, as well as the increased understanding of fetal physiology over the past 50 years. As a result, perinatal morbidity and mortality have decreased substantially (Figure 13-1).

In general, antepartum fetal assessment encompasses the screening and diagnosis of fetal disorders and fetuses that are at risk. Selecting appropriate patients at risk for adverse perinatal events can enhance the prediction of these events, although some tests may be appropriate even for a low-risk population. The assessment may allow for certain therapeutic options—often, timely delivery—to prevent fetal harm. The overall goal of these efforts is to reduce perinatal mortality, although the reduction of morbidities such as cerebral palsy or preventable birth injury is intertwined with this objective. In antenatal assessment in the third trimester, the prediction and detection of fetal acidemia and hypoxemia form a central principle underlying these efforts.

It is important to make the distinction between antepartum and intrapartum fetal assessment. The latter is specifically related to monitoring the fetus during labor. The nature of labor affords certain advantages (e.g., dilation allows blood samples from the fetus) and restrictions (the lack of fluid after rupture of membranes creates difficulties for ultrasound examination) that do not occur in the antenatal period. As a result, this chapter focuses only on events and assessment preceding labor.

GENERAL PRINCIPLES

PRINCIPLES OF TESTING

Many of the tests used for antepartum fetal assessment are screening tests that will lead to further testing allowing for diagnosis and decision-making; therefore it is important to note the principles guiding such tests. The outcome, principally perinatal morbidity and mortality, is a significant burden to both the individual and the overall health care system. The primary tools for assessment, ultrasound examination, and fetal heart rate monitoring, are generally easy, safe, and acceptable to patients. Screening has the potential to allow important and timely interventions, such as antenatal steroid administration or delivery. The predominant difficulty with fetal testing comes in the unproven utility of testing to improve outcomes. Furthermore, some tests, such as the nonstress test (NST), have high false-positive rates; therefore, when used as a diagnostic test (e.g., to decide on delivery), they can lead to the overuse of interventions. The specificity and sensitivity of the tests vary and the critical step to enhancing test performance is patient selection. The utility of fetal surveillance involves the judicious application of the tests in patients with specific risk profiles.

FETAL PHYSIOLOGY AND BEHAVIOR

The first trimester (≤14 weeks' gestation) is mainly a time of system development and organogenesis. The hyperplastic enlargement during the first 11 weeks produces standard rates of growth, with deviation being rare. At the completion of the first trimester, the major organ systems have developed, allowing the opportunity during the second trimester to assess for anomalies in development. The second and third trimesters involve maturation of these systems. Because antenatal fetal assessment is primarily concerned with the prediction or detection of fetal hypoxemia and acidemia, the integration of the neurologic and cardiovascular systems, particularly as reflections of fetal acid-base status, is the cornerstone of this assessment. We are thus able to monitor the manifestations of hypoxemia and acidemia as shown by neurologic and cardiovascular changes.

TECHNOLOGY

The technology underpinning fetal assessment is ultrasound. Fetal heart rate monitoring during the antepartum period depends on a Doppler cardiogram; movements of the fetal heart, in particular the sounds of the valves, are detected by this monitor. The time between the beats is translated into a heart rate, which is then graphically represented on a chart over time. This process produces the

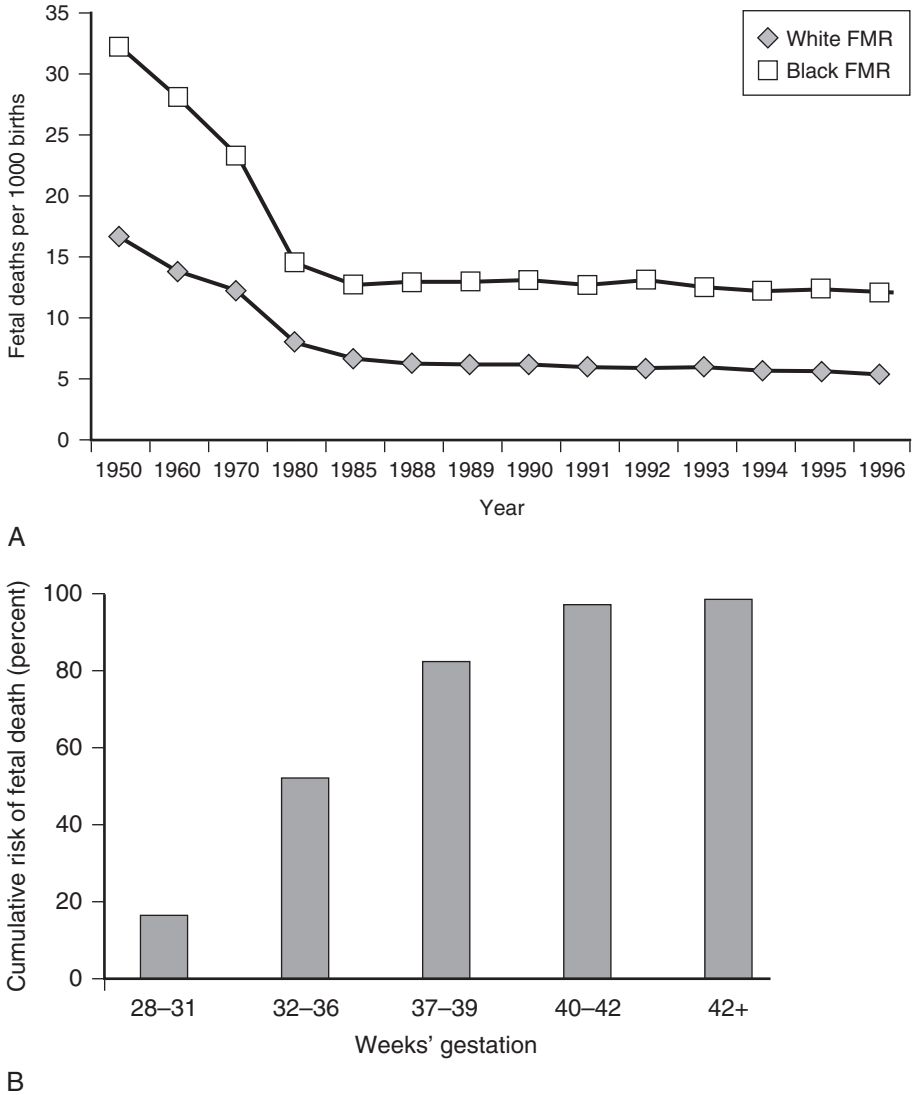

FIGURE 13-1 Fetal mortality rate (FMR) in the United States, 1959 to 1996. *(Adapted from McIlwaine GM, Dunn FH, Howat RC, et al: A routine system for monitoring perinatal deaths in Scotland,* Br J Obstet Gynaecol *92:9-13, 1985.)*

fetal heart rate monitoring strip that becomes the NST or contraction stress test (CST).

Contemporary ultrasound technology involves a wide array of features, including B-mode (basic imaging), M-mode (mapping the movement of structures over time), pulsed Doppler (demonstrating flow velocity in a particular area, such as a vessel), color Doppler (showing intensity and direction of flow through shades of red and blue), and power Doppler (a more sensitive form of colorized Doppler).

INDICATIONS AND TIMING

Most fetal testing protocols involve a stepwise approach, and the first step is the selection of the appropriate patient. Suggested assessments for low-risk pregnancies include one ultrasound examination for dating and one for the basic anatomic survey. Prenatal risk assessments for chromosomal disorders, such as first-trimester risk assessment with maternal serum analysis and fetal nuchal translucency assessment or the second-trimester maternal quadruple serum screen, are additional options. Whereas up to 30% of perinatal morbidity may occur in low-risk patients, routine fetal testing beyond that described previously in a low-risk pregnancy is an ineffective use of resources.

High-risk pregnancies are those at greater peril for perinatal morbidity and mortality. These pregnancies often have more justification for targeted or detailed anatomic ultrasound examinations and for regular assessment of fetal growth or heart rate assessment. Common conditions requiring increased fetal surveillance are shown in Box 13-1.

Pregnancy dating should be confirmed at the earliest possible moment, and fetal anatomic screening is best accomplished in the second trimester, specifically at 18 to 20 weeks' gestation, when visualization of the anatomic features is adequate. However, standards for the timing of antepartum fetal assessment to survey for fetal compromise do not exist. Certainly assessment with NST or biophysical profiles would have little utility before viability (approximately 24 weeks' gestation). Guidelines for initiating fetal testing for specific indications are largely based on the risk of fetal loss at a particular gestational age.

BOX 13-1 Typical Indications for Antepartum Fetal Assessment: High-Risk Pregnancies

FETAL

- Abnormal fetal testing, fetal distress
- Anatomic anomaly
- Decreased fetal movement
- Heart block
- Intraamniotic infection
- Intrauterine growth restriction
- Multiple gestation
- Oligohydramnios

MATERNAL-FETAL

- Abruptio placenta
- Anemia, fetal (e.g., parvovirus, Rh alloimmunization, NAIT)
- Abnormal serum screening (low PAPP-A, high MSAFP)
- Placenta previa, vasa previa
- Postterm or postdates premature rupture of fetal membranes
- Threatened preterm delivery

MATERNAL

- Advanced maternal age
- Cardiac disease (severe)
- Cholestasis of pregnancy
- Diabetes, gestational
- Diabetes, pregestational
- Hemoglobinopathies
- HIV (receiving medication)
- Hypertension, chronic
- Hypertension, gestational
- History of IUFD
- Obesity
- Preeclampsia
- Pulmonary disease (severe)
- Renal disease
- Seizure disorder
- Substance abuse
- Systemic lupus erythematosis
- Thyroid disease
- Thrombophilia or thromboembolic disease

IUFD, Intrauterine fetal demise; *MSAFP,* maternal serum alpha-fetoprotein; *NAIT,* neonatal alloimmune thrombocytopenia; *PAPP-A,* pregnancy associated plasma protein

FETAL ASSESSMENT IN LOW RISK PREGNANCIES

ULTRASOUND: PREGNANCY DATING

The *estimated date of delivery* is defined at the beginning of pregnancy based on the best available information, including menstrual history, ultrasound data, and assisted reproduction technology. The median duration of a singleton pregnancy is 280 days (40 weeks) from the first day of the last menstrual period or 266 days (38 weeks) from the time of ovulation. *Term* is defined as 37 to 42 weeks' (259 to 294 days) gestation. Given that the preterm and postterm periods are associated with increased risks to the fetus and newborn, pregnancy dating provides an approximate expectation for the completion of the pregnancy and serves as a basis for the efficient and appropriate use of fetal surveillance, testing, and treatment. Accurate pregnancy dating by ultrasound has been associated with reduced diagnoses of growth restriction (Waldenstrom et al, 1992), reduced use of tocolysis for preterm labor (LeFevre et al, 1993), and a reduced need to intervene in postterm pregnancies (Neilson, 2000).

In a spontaneous pregnancy in a woman with regular cycles and normal menstrual periods, the last menstrual period is often an accurate way of dating a pregnancy. Menstrual dating is less accurate in women who are taking oral contraceptives, were recently pregnant, or have irregular periods or intermenstrual bleeding. In these cases, and others in whom there is uncertainty, ultrasound dating in the first trimester is accurate and effective. A fetal pole may be seen beginning at 5 weeks' gestation, and the fetal heartbeat should be visualized at 6 to 8 weeks' gestation. In the first trimester, measurement of the crown-rump length is accurate to within 3 to 5 days; therefore this measurement should take priority in dating a pregnancy when the timing of the last menstrual period suggests a gestational age outside this range of variation (Drumm et al, 1976; Robinson and Fleming, 1975). A first-trimester ultrasound examination is indicated to confirm an intrauterine pregnancy (i.e., exclude ectopic pregnancy), confirm fetal viability, document fetal number, estimate gestational age, and evaluate the maternal pelvis and ovaries.

In the second trimester, ultrasound dating is less accurate, but can nonetheless be helpful. Measurement of the biparietal diameter (BPD) of the fetal head, the most accurate parameter, can be accurate to within 7 to 10 days (Campbell et al, 1985; Waldenstrom et al, 1990). The BPD is also a parameter of choice because it is less affected by chromosomal anomalies, in particular Down syndrome (Cuckle and Wald, 1987). Usually in the second or third trimesters, several biometric measurements—such as cerebellar distance, femur and humerus length, and abdominal circumference—are recorded and a computerized algorithm can generate an estimated gestational age.

ULTRASOUND: SECOND AND THIRD TRIMESTERS

Perinatal ultrasound examination in the second and third trimesters can be classified broadly into three types: the basic or standard examination, the specialized (detailed) examination, and the limited examination. The standard examination (level I) includes the determination of fetal number, fetal viability, fetal position, gestational age, placental location, amniotic fluid volume, the presence or absence of a maternal pelvic mass, and the presence of gross fetal malformations (American College of Obstetricians and Gynecologists, 2009). Most pregnancies can be evaluated adequately by this basic examination. If the patient's history, physical examination, or basic ultrasound examination suggest the presence of a fetal malformation, a specialized examination (level II) should be performed by a sonographer who is skilled in fetal evaluation. During a detailed ultrasound, which is best performed at 18 to 20 weeks' gestation, fetal structures are examined in detail to identify and characterize any fetal malformation. In addition to identifying structural abnormalities, a specialized ultrasound examination can identify sonographic markers of fetal aneuploidy. In some situations, a limited

examination may be appropriate to answer a specific clinical question (such as fetal viability, amniotic fluid volume, fetal presentation, placental location, or cervical length) or to provide sonographic guidance for an invasive procedure (such as amniocentesis).

Current debate centers on who should undergo sonographic examination and what type of evaluation these patients should have. Advocates of routine sonography cite several advantages of universal ultrasound evaluation, including more accurate dating of pregnancy and earlier and more accurate diagnosis of multiple gestation, structural malformations, and fetal aneuploidy (discussed later in ultrasound section). Opponents of routine sonographic examination argue that it is an expensive screening test ($100 to $250 for a standard examination) and that the cost is not justified by published research, which suggests that routine ultrasound examinations do not significantly change perinatal outcome (Crane et al, 1994; Ewigman et al, 1993; LeFevre et al, 1993)

Second-trimester ultrasound examination is indicated in patients with uncertain dating, uterine size larger or smaller than expected for the estimated gestational age, a medical disorder that can affect fetal growth and development (e.g., diabetes, hypertension, collagen vascular disorder), a family history of an inherited genetic abnormality, or a suspected fetal malformation or growth disturbance (American College of Obstetricians and Gynecologists, 2009). In the United States, most patients undergo a standard examination at 18 to 20 weeks' gestation to screen for structural defects. An understanding of normal fetal physiology is critical to the diagnosis of fetal structural anomalies. For example, extraabdominal herniation of the midgut into the umbilical cord occurs normally in the fetus at 8 to 12 weeks' gestation and can be misdiagnosed as an abdominal wall defect. Placental location should be documented with the bladder empty, because overdistention of the maternal bladder or a lower uterine contraction can give a false impression of placenta previa. If placenta previa is identified at 18 to 22 weeks' gestation, serial ultrasound examinations should be performed to follow placental location. Only 5% of placenta previa identified in the second trimester will persist to term (Zelop et al, 1994). The umbilical cord should also be imaged, and the number of vessels, placental insertion, and insertion into the fetus should be noted.

The indications for third-trimester ultrasound examination are similar to that for second-trimester ultrasound. Fetal anatomy survey examinations and estimates of fetal weight become less accurate as gestational age increases, especially in obese women or in pregnancies complicated by oligohydramnios. However, fetal biometry and an anatomic survey should still be performed, because certain fetal anomalies, such as achondroplasia, will become evident for the first time later in gestation.

FETAL MOVEMENT COUNTING

Fetal movement (quickening) is typically perceived by the mother at 16 to 22 weeks' gestation. Fetal hypoxemia is typically associated with a reduction in fetal activity; the fetus is essentially conserving energy and oxygen for vital activities. A typical procedure for fetal movement counting consists of having the patient record the interval taken to feel 10 fetal movements, usually after a meal when the fetus is more active. If 10 movements are not detected in 1 hour, further testing is often recommended. The data supporting fetal movement counting are mixed. A large international cluster randomized trial involving more than 68,000 patients demonstrated no benefit (Grant et al, 1989), and a Cochrane analysis found insufficient evidence to support this technique to prevent stillbirth (Mangesi and Hofmeyr, 2007). Fetal movement counting represents a low-technology screening test that can be applied easily to all pregnancies. Although its effectiveness in improving perinatal outcomes is debatable, it can be used as a cost-effective first line strategy

FETAL ASSESSMENT IN HIGH-RISK PREGNANCIES

CARDIOTOCOGRAPHY

Cardiotocography is the visual representation of fetal heart rate and uterine contractions. Fetal heart rate has been recognized as an important indicator of fetal status since the nineteenth century, with Lejumeau Kergaradec of Switzerland being credited with the first accounts of direct fetal auscultation and the uterine soufflé in 1821. Fetal heart rate monitoring is based on the principle that the fetal neurologic system, through its afferent and efferent networks, serves as a key mediator to demonstrate fetal well-being. Oxygenation, acidemia, and other vital functions are monitored by peripheral chemoreceptors and baroreceptors, which provide input on fetal status through afferent neurologic networks to the central nervous system (CNS). This information is processed by the CNS, and signals are conducted through efferent networks to produce peripheral changes, particularly to the heart via direct parasympathetic vagal neurons, direct sympathetic signals, or indirect sympathetic stimulation of catecholamine release. In this way, fetal cardiac activity can be seen as a surrogate for fetal oxygenation and acid-base status.

For many years, assessment of the fetal heart rate was limited to the fetoscope, a direct stethoscope attributed to Adolphe Pinard in 1876. In 1957, Orvan Hess and Ed Hon at Yale University introduced electronic fetal heart rate monitoring as a window into the status of the fetus (Hon and Hess, 1957). This technology relied on direct monitoring through a scalp electrode; only years later would Doppler technology allow cardiac signals to be detected noninvasively. Fetal heart rate monitoring became a tool for fetal assessment as it was recognized that certain fetal heart rate patterns were associated with fetal compromise and poor fetal outcomes.

The basic elements of a fetal heart rate strip are baseline, variability, accelerations, and decelerations. A baseline of 110 to 160 beats per minute is normal. Variability is determined by the irregular fluctuations in amplitude and frequency in the baseline, and variability of fewer than 6 beats per minute is often abnormal. Accelerations are classified as visually apparent abrupt increases that peak at 15 beats per minute or more above the baseline that last 15 seconds or longer. Fetal movements often coincide with fetal heart rate (FHR) accelerations. Finally decelerations,

TABLE 13-1 Interpretation of Antepartum Cardiotocography

Term	Characteristic	Description
Baseline	Definition	Mean fetal heart rate, rounded to increments of 5 beats/min (e.g. 140, 145); need baseline duration of ≥2 min during a 10-min segment, between periodic or episodic changes, to determine baseline
	Bradycardia	<110 beats per minute for >10 min
	Tachycardia	>160 beats per minute for >10 min
Variability	Definition	Fluctuations of the baseline heart rate; measured from peak to trough
	Absent	Undetectable
	Minimal	Undetectable to ≤5 beats/min
	Moderate	6-25 beats/min
	Marked	>25 beats/min
Acceleration	Definition	Abrupt increase ≥15 beats/min lasting ≥15 s
	Prolonged	≥2 min and <10 min (≥10 min is a baseline change)
Deceleration	Definition	Decreases in the fetal heart rate
	Variable	Abrupt decrease onset to nadir <30 s; decrease ≥15 beats/min lasting ≥5 s to <2 min
	Early	Gradual decrease onset to nadir ≥30 s with contraction
	Late	Gradual decrease onset to nadir ≥30 s; nadir of deceleration occurring after peak of contraction
	Prolonged	Decrease ≥15 beats/min lasting ≥2 min, but <10 min (≥10 min is a baseline change)
	Recurrent	Occur with ≥50% of uterine contractions in any 20-min window
	Intermittent	Occur with <50% of uterine contractions in any 20-min window
Contractions	Considerations	Frequency, duration, intensity, and relaxation
	Normal	≤5 contractions per 10 minutes averaged over a 30-min window
	Tachysystole	>5 contractions per 10 minutes averaged over a 30-min window; should always be qualified as to the presence or absence of associated FHR decelerations

often classified as early, variable, or late, are decreases in the fetal heart rate that have specific pathologic and physiologic associations. Although primarily focused on intrapartum monitoring, the 2008 National Institute of Child Health and Human Development workshop report on fetal monitoring provides an excellent summary of the nomenclature and interpretation involved (Table 13-1) (Macones et al, 2008).

NONSTRESS TEST

A normal result of an NST is defined as a 20-minute fetal heart rate tracing that contains two heart rate accelerations lasting 15 seconds or longer that peak 15 beats or more above the baseline. Often this is called a *reactive NST* (Figure 13-2). Modifications are made in reference to gestational age. NSTs for fetuses at less than 32 weeks' gestation are often considered reactive if the acceleration is 10 beats per minute or more above the baseline and lasts for at least 10 seconds. Furthermore, to account for the periodicity of 20- to 30-minute sleep cycles in the fetus, an NST that is not reactive over the first 20 minutes may be continued an additional 20 to 40 minutes. A nonreactive NST or an NST with specific abnormalities (e.g., high or low baseline, decelerations) should be followed by a biophysical profile (BPP). It is important to note that some abnormal states, such as a fetal CNS abnormality or maternal drug ingestion, may contribute to a nonreactive NST. In these cases, ultrasound examination may provide appropriate information to determine the diagnosis or required management.

Falsely reassuring NSTs occur at a rate of 3 to 5 per 1000 tests, although this does not account for a baseline rate of unpreventable fetal deaths (Freeman et al, 1982b). The difficulty with the NST really lies in its lack of specificity for fetal death or compromise; the false-positive rate may be as high as 50% (Freeman et al, 1982b).

The rather modest false-negative rate is likely because of the NST being a measurement of short-term hypoxemia. Indeed, longer-term fetal status can be measured through amniotic fluid assessment, because the amniotic fluid is correlated with fetal urinary output, which is a surrogate for renal perfusion. When combined with an assessment of amniotic fluid level, the false-negative rate of the NST is reduced to 0.8 per 1000, although a 60% false-positive rate remains (Miller et al, 1996). Indeed, when combined with the NST and amniotic fluid assessment—sometimes known as the *modified biophysical profile*—reduces the risk of fetal death to negligible levels in high-risk populations (Clark et al, 1989). For these reasons, the NST combined with amniotic fluid assessment is a modality of choice for monitoring the high-risk pregnancy.

CONTRACTION STRESS TEST

The CST assesses the fetal heart rate response in the presence of contractions. This test improves on the specificity and sensitivity of the NST by assessing the fetal response to stress. In fact, the CST preceded the NST, although the NST became more favorable because of fewer contraindications, ease of administration, and reduced time and supervision necessary. Compared with the NST, there is a much lower incidence of falsely reassuring tests (0.4 per 1000), representing an eightfold reduction in the risk of fetal loss in one study (Freeman et al, 1982a).

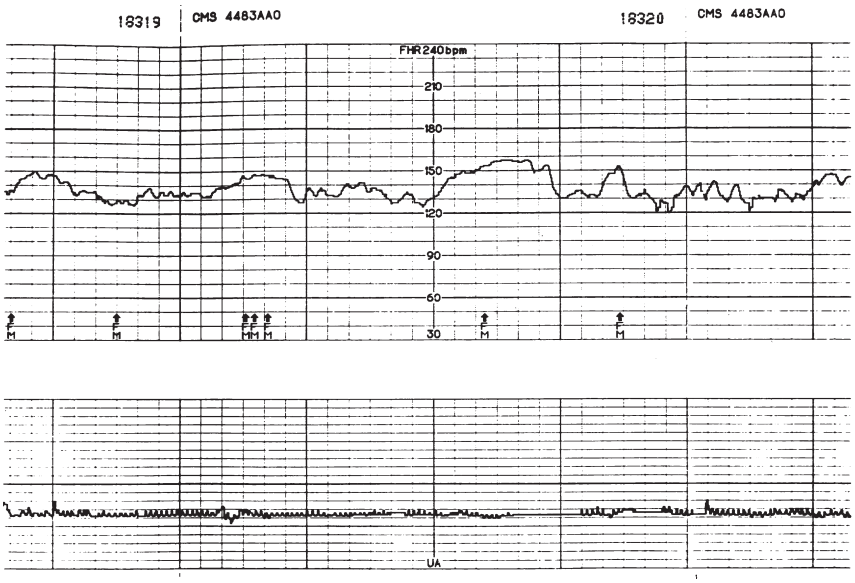

FIGURE 13-2 A reassuring nonstress test. Note two fetal heart rate accelerations exceeding 15 beats/min and lasting at least 15 seconds during the monitoring period.

FIGURE 13-3 A contraction stress test. The fetal heart rate is plotted above the uterine contraction signal. Note the late deceleration after a contraction; this is a positive, or abnormal, test result.

Contractions are stimulated by the administration of intravenous oxytocin or through maternal nipple stimulation. Of course, the CST is contraindicated in patients in whom contractions should not be provoked, such as threatened preterm delivery or preterm premature rupture of membranes, prior classical cesarean delivery, or placenta previa. A minimum of three contractions over a 10-minute period of continuous fetal heart rate assessment are necessary for a satisfactory test interpretation. An unsatisfactory test should be followed by continued testing with a modification of the mode of contraction stimulation. A negative (i.e., normal) test result demonstrates no late decelerations, whereas a positive test result shows late decelerations after 50% or more of contractions (Figure 13-3). A positive test result requires immediate further testing or evaluation, if not delivery. An equivocal test demonstrates late decelerations with less than 50% of contractions and requires further testing or monitoring. A test that encompasses a hyperstimulatory contraction pattern (e.g., five contractions within 10 minutes or contractions lasting longer than 90 seconds) is also considered equivocal and requires further testing.

ULTRASOUND

Although routine sonography for low-risk pregnant women is controversial, few would disagree that the benefits far outweigh the costs for high-risk patients. Given the higher risk for fetal complications such as anatomic anomalies or growth disturbances, a specialized examination is performed between 18 and 20 weeks' gestation in most high-risk pregnancies.

Additional ultrasound modalities are also available, including fetal echocardiography, three-dimensional (3D) sonography, and Doppler. Cardiac anomalies are the most common major congenital defects encountered in the antepartum period. A four-chamber view of the heart at the time of fetal anatomy survey at 18 to 20 weeks' gestation will detect only 30% of congenital cardiac anomalies, although the detection rate can be increased to approximately 60% to 70% if the outflow tracts are adequately visualized (Kirk et al, 1994), but this still leaves 30% to 40% of all congenital cardiac anomalies undiagnosed. For this reason, fetal echocardiography should be performed by a skilled and experienced sonologist at 20 to 22 weeks' gestation in all pregnancies at high-risk of a fetal cardiac

anomaly; this includes pregnancies complicated by pregestational diabetes mellitus, a personal or family history of congenital cardiac disease regardless of the nature of the lesion or whether it has been repaired), maternal drug exposure (e.g., lithium and paroxitene) (Bérard et al, 2007), and pregnancies conceived by in vitro fertilization, but not if the pregnancy was conceived using clomiphene citrate or ovarian stimulation or intrauterine insemination alone (Olson et al, 2005).

Compared with standard two-dimensional (2D) ultrasound, 3D ultrasound (or four-dimensional if fetal movements are included) allows for visualization of fetal structures in all three dimensions concurrently for the improved characterization of complex fetal structural anomalies and for storage of scanned images with 3D reconstruction at a later date or remote location (telemedicine). Unlike 2D ultrasound, 3D images are greatly influenced by fetal movements and are subject to more interference from structures such as fetal limbs, umbilical cord, and placental tissue. Because of movement interference, visualization of the fetal heart with 3D ultrasound is suboptimal.

In addition to rapid acquisition of images that can be later reconstructed and manipulated, 3D ultrasound has other potential advantages:

- Surface rendering mode can provide clearer images of many soft tissue structures. Such images can improve the diagnosis of certain fetal malformations, especially craniofacial anomalies (cleft lip and palate, micrognathia, ear anomaly, facial dysmorphism, club foot, finger and toe anomalies), intracranial lesions, spinal anomalies, ventral wall defects, and fetal tumors.
- 3D ultrasound may be useful in early pregnancy by providing more accurate measurements of the gestational sac, yolk sac, and crown-rump length. It may also allow for a more accurate midsagittal view of the fetus for measuring nuchal translucency.
- 3D ultrasound can also be used to measure tissue volume. Preliminary data suggest that the assessment of cervical volume may predict the risk of cervical insufficiency (Rovas et al, 2005), and measurement of placental volume in the first trimester may predict fetuses at risk of intrauterine growth restriction (IUGR) (Schuchter et al, 2001).

Despite these advantages and the fact that 3D ultrasound has been available since the early 1990s, it has yet to live up to its promises. Although 3D ultrasound is unlikely to replace standard 2D imaging in the near future, it is a valuable complementary modality in obstetric imaging. As the technology improves, it is likely that perinatal ultrasound will evolve to resemble computed tomography and magnetic resonance imaging.

GROWTH ASSESSMENT

Normal fetal growth is a critical component of a healthy pregnancy and the subsequent long-term health of the child. A systematic method of examination of the gravid abdomen was first described by Leopold and Sporlin (1894). Although abdominal examination has several limitations, particularly in the setting of maternal obesity, multiple pregnancy, uterine fibroids, or polyhydramnios, it is safe, free, and well tolerated and may add valuable information to assist in antepartum management. Palpation is divided into four separate Leopold maneuvers. Each maneuver is designed to identify specific fetal landmarks or to reveal a specific relationship between the fetus and mother. For example, the first maneuver involves measuring fundal height. The uterus can be palpated above the pelvic brim at approximately 12 weeks' gestation. Thereafter, fundal height should increase by approximately 1 cm per week, reaching the level of the umbilicus at 20 to 22 weeks' gestation. Between 20 and 32 weeks' gestation, the fundal height (in centimeters, from the superior edge of the pubic symphysis) is approximately equal to the gestational age (in weeks) in healthy women of average weight with an appropriately grown fetus. However, there is a wide range of normal fundal height measurements. One study has shown a 6-cm difference between the 10th and 90th percentiles at each week of gestation after 20 weeks (Belizan et al, 1978). Moreover, fundal height is maximal at approximately 36 weeks' gestation, at which time the fetus drops into the pelvis in preparation for labor and the fundal height decreases. For these reasons, reliance on fundal height measurements alone will fail to identify more than 50% of fetuses with IUGR (Gardosi and Francis, 1999). Serial fundal height measurements by an experienced obstetric care provider are more accurate than a single measurement, and they will lead to an improved diagnosis of fetal growth restriction with reported sensitivities as high as 86% (Belizan et al, 1978).

If the clinical examination is not consistent with the stated gestational age, an ultrasound examination is indicated to confirm gestational age and to establish a more objective measure of fetal growth. Ultrasound examination may also identify an alternative explanation for the discrepancy, such as multiple pregnancy, polyhydramnios, oligohydramnios, fetal demise, or uterine fibroids.

For many years, obstetric sonography has used fetal biometry to define fetal size by weight estimation, although this approach has a number of key limitations. For example, regression equations used to create weight estimation formulas are derived primarily from cross-sectional data that rely on infants delivering within an arbitrary period of time after the ultrasound examination, and they assume that body proportions (i.e., fat, muscle, bone) are the same for all fetuses. Moreover, growth curves for healthy infants from 24 to 37 weeks' gestation rely on data collected from pregnancies delivered preterm, which should not be regarded as normal pregnancies and are likely to be complicated by some element of uteroplacental insufficiency regardless of whether the delivery was spontaneous or iatrogenic. Despite these limitations, if the gestational age is well validated, the prevailing data suggest that prenatal ultrasound can be used to verify an alteration in fetal growth in 80% of cases and exclude abnormal growth in 90% of cases (Sabbagha, 1987).

Sonographic estimates of fetal weight are commonly derived from mathematical formulas that use a combination of fetal measurements, especially the BPD, abdominal circumference (AC), and femur length (Hadlock et al, 1984). Whereas the BPD may be the most accurate indicator of gestational age in the second or third trimesters, fetuses gain weight in their abdomen, making the AC the

single most important measurement for fetal size. The AC is thus given more weight in these formulas. Unfortunately the AC is also the most difficult measurement to acquire, and a small difference in the AC measurement will result in a large difference in the estimated fetal weight (EFW). The accuracy of the EFW depends on a number of variables, including gestational age (in absolute terms, EFW is more accurate in preterm or IUGR fetuses than in term or macrosomic fetuses), operator experience, maternal body habitus, and amniotic fluid volume (measurements are more difficult to acquire if the amniotic fluid volume is low). Although objective, sonographic EFW estimations are not particularly accurate and have an error of 15% 20%, even in experienced hands (Anderson et al, 2007). Indeed, a sonographic EFW at term is no more accurate than a clinical estimate of fetal weight by an experienced obstetric care provider or the mother's estimate of fetal weight if she has delivered before (Chauhan et al, 1992). Sonographic estimates of fetal weight must therefore be evaluated within the context of the clinical situation and balanced against the clinical estimate of fetal weight. Serial sonographic evaluations of fetal weight are more useful than a single measurement in diagnosing abnormal fetal growth. The ideal interval to evaluate fetal growth is every 3 to 4 weeks, with a minimum 10- to 14-day interval necessary to see significant differences. Because of the inherent error in fetal biometric measurements, more frequent ultrasound determinations of EFW may be misleading. Similarly, the use of population-specific growth curves, if available, will improve the ability of the obstetric care provider to identify abnormal fetal growth. For example, growth curves derived from a population that lives at high altitude, where the fetus is exposed to lower oxygen tension, will be different from those derived from a population at sea level. Abnormal fetal growth can be classified as insufficient (i.e., IUGR) or excessive (fetal macrosomia).

The definition of IUGR has been a long-standing challenge for modern obstetrics. Distinguishing the healthy, constitutionally small-for-gestational-age fetus, defined as an EFW below the 10th percentile for a given week of gestation, from the nutritionally deprived, truly growth-restricted fetus has been particularly difficult. Fetuses with an EFW less than the 10th percentile are not necessarily pathologically growth restricted. Conversely, an EFW greater than the 10th percentile does not mean that an individual fetus has achieved its growth potential, and such fetuses may still be at risk of perinatal mortality and morbidity. As such, IUGR is best defined as either an EFW of less than the 5th percentile for gestational age in a well-dated pregnancy or an EFW of less than the 10th percentile for gestational age in a well-dated pregnancy with evidence of fetal compromise, such as oligohydramnios or abnormal umbilical artery Doppler velocimetry.

Fetal growth restriction has traditionally been classified into asymmetric or symmetric IUGR. Asymmetric IUGR is characterized by normal head growth, but suboptimal body growth, and is seen most commonly in the third trimester. It is thought to result from a late pathologic event, such as chronic placental abruption leading to uteroplacental insufficiency, in an otherwise uncomplicated pregnancy and healthy fetus. In cases of symmetric IUGR, both the fetal head size and body weight are reduced, indicating a global insult that likely occurred early in gestation. Symmetric IUGR may reflect an inherent fetal abnormality (e.g., fetal chromosomal anomaly, inherited metabolic disorder, early congenital infection) or long-standing severe placental insufficiency caused by an underlying maternal disease (e.g., hypertension, pregestational diabetes mellitus, collagen vascular disorder). In practice, the distinction between asymmetric and symmetric IUGR is not particularly useful.

Early and accurate diagnosis of IUGR coupled with appropriate intervention will lead to an improvement in perinatal outcome. If IUGR is suggested clinically and by ultrasound examination, thorough evaluations of the mother and fetus are indicated. Referral to a maternal-fetal medicine specialist should be considered. Every effort should be made to identify the cause of IUGR and to modify or eliminate contributing factors. Up to 20% of cases of severe IUGR are associated with fetal chromosome abnormalities or congenital malformations, 25% to 30% are related to maternal conditions characterized by vascular disease, and a smaller proportion are the result of abnormal placentation. However, in a substantial number of cases (50% or more in some studies), the cause of the IUGR will remain uncertain even after a thorough investigation (Resnik, 2002). Fetal macrosomia is defined as an EFW (not birthweight) of 4500 g or greater, measured either clinically or by ultrasound, and is independent of gestational age, diabetic status, or actual birthweight (American College of Obstetricians and Gynecologists, 2000). Fetal macrosomia refers to a single cutoff EFW; this should be distinguished from the large-for-gestational age fetus, which is one in whom the EFW is greater than the 90th percentile for gestational age. By definition, 10% of all fetuses are large for gestational age at any given gestational age. Fetal macrosomia is associated with an increased risk of cesarean delivery, operative vaginal delivery, and birth injury to both the mother (including vaginal, perineal, and rectal trauma) and the fetus (orthopedic and neurologic injury) (American College of Obstetricians and Gynecologists, 2000, 2001; Kjos and Buchanan, 1999; Magee et al, 1993; O'Sullivan et al, 1973; Widness et al, 1985). Shoulder dystocia with resultant brachial plexus injury (Erb's palsy) are a serious consequence of fetal macrosomia and are further increased in the setting of diabetes, because of the increased diameters in the upper thorax and neck of fetuses of mothers with diabetes.

Fetal macrosomia can be determined clinically, by abdominal palpation using the Leopold's maneuvers, or by ultrasound examination; these two techniques appear to be equally accurate (Watson et al, 1988). However, EFW measurements are less accurate in large (macrosomic) fetuses than in normally grown fetuses, and factors such as low amniotic fluid volume, advancing gestational age, maternal obesity, and the position of the fetus can compound these inaccuracies. Clinical examination has been shown to underestimate the birthweight by 0.5 kg or more in almost 80% of fetuses with macrosomia (Niswander et al, 1970). For these reasons, the prediction of fetal macrosomia is not particularly accurate, with a false-positive rate of 35% and a false-negative rate of 10% (Niswander et al, 1970; Watson et al, 1988). A number of alternative sonographic measurements have therefore been proposed

in an attempt to better identify the macrosomic fetus, including fetal AC alone, umbilical cord circumference, cheek-to-cheek diameter, and upper arm circumference; however, these measurements remain investigational and should not be used clinically.

Despite the inaccuracy in the prediction of fetal macrosomia, an EFW should be documented either by clinical estimation or ultrasound examination in all women at high risk at approximately 38 weeks' gestation. Suspected fetal macrosomia is not an indication for induction of labor, because induction does not improve maternal or fetal outcomes (American College of Obstetricians and Gynecologists, 2000). However, if the EFW is excessive, an elective cesarean delivery should be considered to prevent fetal and maternal birth trauma. Although controversy remains as to the precise EFW at which an elective cesarean delivery should be recommended, a suspected birthweight in excess of 4500 g in women with diabetes or 5000 g in women without diabetes is a reasonable threshold (American College of Obstetricians and Gynecologists, 2000, 2001, 2002).

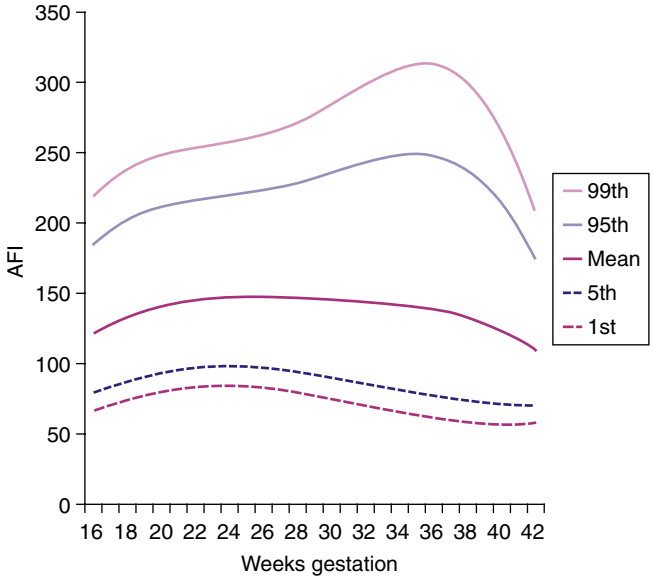

FIGURE 13-4 Amniotic fluid index (AFI; in mm) plotted against gestational age. The lines represent percentiles.

AMNIOTIC FLUID ASSESSMENT

Amniotic fluid plays a key role in the health and development of a growing fetus. Once considered an afterthought during the ultrasound examination of the fetus, evaluation of the amniotic fluid is now considered an integral part of ultrasound evaluation for fetal well-being. Amniotic fluid serves a number of important functions for the developing embryo and fetus. It provides cushioning against physical trauma; creates an environment free of restriction and or distortion, allowing for normal growth and development of the fetus; provides a thermally stable environment; allows the respiratory, gastrointestinal, and musculoskeletal tracts to develop normally; and helps to prevent infection (Hill et al, 1984).

The chorioamnion acts as a porous membrane early in pregnancy, allowing the passage of water and solutes across the membrane; there is little contribution from the small embryo. As the pregnancy progresses into the late first trimester, the diffusion of fluid across the fetal skin occurs, increasing the volume of amniotic fluid. In the second half of the pregnancy, the main sources of amniotic fluid come from fetal kidneys and lungs. The primary sources for removal of fluid are from fetal swallowing and absorption into fetal blood perfusing the surface of the placenta. As more fluid is produced than is resorbed by the fetal-placental unit, the volume of amniotic fluid increases throughout the first 32 weeks of pregnancy (Figure 13-4). The volume peaks at approximately 32 to 33 weeks' gestation, and at this gestational age equal amounts of fluid are produced and resorbed. After term, the amniotic fluid declines at a rate of 8% per week (Brace and Wolf, 1989).

Because amniotic fluid plays a critical role in the normal development of a fetus, the assessment of amniotic volume is an essential component of the ultrasound evaluation for fetal well-being. Subjective estimates of the amniotic fluid volume have been validated, but two ultrasound measurements—amniotic fluid index (AFI) and maximum vertical pocket—have been developed to quickly and accurately assess the quantity of amniotic fluid surrounding the fetus.

The AFI is a semiquantitative method for assessing the amniotic fluid volume with ultrasound. The gravid uterus is divided into four quadrants using the umbilicus, linea nigra, and external landmarks (Rutherford et al, 1987). The deepest amniotic fluid pocket is measured in each quadrant with the ultrasound transducer perpendicular to the floor. The four measurements are added together and the sum is regarded as the AFI. Pockets filled with umbilical cord or fetal extremities should not be used for generating the AFI (Hill, 1997). Researchers and clinicians have used a variety of measurements to define abnormalities in amniotic fluid volume. However, the normal range of the AFI most commonly used in clinical practice is 5 to 20 cm of fluid. Pregnancies with AFIs less than 5 cm can be described as having oligohydramnios, and pregnancies with measurements greater than 20 cm can be described as having polyhydramnios.

The maximal vertical pocket is another semiquantitative method for assessing the fluid volume. The technique involves scanning the gravid uterus for the single deepest pocket of amniotic fluid that is free of umbilical cord and fetal parts and with the transducer perpendicular to the floor, measuring the pocket of fluid (Manning et al, 1981b). Currently this method is used mostly in multiple gestation pregnancies in which the AFI is not technically feasible. Oligohydramnios can be defined as a single measurement less than 2 cm. Polyhydramnios can be defined as a single measurement greater than 10 cm.

BIOPHYSICAL PROFILE

An NST alone might not be sufficient to confirm fetal well-being; in such cases, a biophysical profile (BPP) may be performed. The BPP refers to a sonographic scoring system performed over a 30- to 40-minute period designed to assess fetal well-being. The BPP was initially described for testing postterm fetuses, but has since been validated for use in both term and preterm fetuses (Manning et al,

1981a, 1985, 1987; Vintzileos et al, 1983, 1987a, 1987b). Notably, BPP is not validated for use in active labor. The five variables described in the original BPP were: gross fetal body movements, fetal tone (i.e., flexion and extension of limbs), amniotic fluid volume, fetal breathing movements, and NST (summarized in Table 13-2) (Manning, 1989). More recently, however, BPP is interpreted without the NST.

The individual variables of the BPP become apparent in healthy fetuses in a predictable sequence: fetal tone appears at 7.5 to 8.5 weeks, fetal movement at 9 weeks, fetal breathing at 20 to 22 weeks, and FHR reactivity at 24 to 28 weeks' gestation. Similarly, in the setting of antepartum hypoxia, these characteristics typically disappear in the reverse order in which they appeared (i.e., FHR reactivity is lost first followed by fetal breathing, fetal movements, and finally fetal tone) (Vintzileos et al, 1987a). The amniotic fluid volume, which is composed almost entirely of fetal urine in the second and third trimesters, is not influenced by acute fetal hypoxia or acute fetal central nervous system dysfunction. Rather, oligohydramnios (decreased amniotic fluid volume) in the latter half of pregnancy and in the absence of ruptured membranes is a reflection of chronic uteroplacental insufficiency, increased renal artery resistance leading to diminished urine output, or both (Oz et al, 2002); it predisposes to umbilical cord compression, thus leading to intermittent fetal hypoxemia, meconium passage, or meconium aspiration. Adverse pregnancy outcome (including nonreassuring FHR tracing, low Apgar score, and neonatal intensive care unit admission) is more common when oligohydramnios is present (Bochner et al, 1987; Morris et al, 2003; Oz et al, 2002; Tongsong and Srisomboon, 1993). Serial (weekly) screening of high-risk pregnancies for oligohydramnios is important, because amniotic fluid can become drastically reduced within 24 to 48 hours (Clement et al, 1987).

Although each of the five features of the BPP are scored equally (2 points if the variable is present or normal, and 0 points if absent or abnormal, for a total of 10 points), they are not equally predictive of adverse pregnancy outcome. For example, amniotic fluid volume is the variable that correlates most strongly with adverse pregnancy events. The recommended management based on the BPP is summarized in Table 13-3 (Manning, 1989). A score of 8 to 10 out of 10 is regarded as reassuring; a score of 4 to 6 is suspicious and requires reevaluation, and a score of 0 to 2 suggests nonreassuring fetal testing—previously referred to as *fetal distress* (Manning et al, 1981a, 1981b). Evidence of nonreassuring fetal testing or oligohydramnios in the setting of otherwise reassuring fetal testing should prompt evaluation for immediate delivery (Vintzileos et al, 1987a, 1987b).

TABLE 13-2 Fetal Biophysical Profile

Element	Criterion (2 points for each element satisfied)
Breathing	≥1 episode of breathing movements lasting 30 seconds
Movement	≥3 discrete body or limb movements
Tone	≥1 episode of active extension and flexion of limbs or trunk
Amniotic fluid	≥1 pocket of amniotic fluid measuring ≥2 cm in two perpendicular planes
Nonstress test	≥2 fetal heart rate accelerations lasting ≥15 seconds over 20 minutes

DOPPLER

Doppler velocimetry shows the direction and characteristics of blood flow, and it can be used to examine the maternal, uteroplacental, or fetal circulations. Because of placental capacitance, the umbilical artery is one of the few arteries that normally has forward diastolic flow, and it is one of the most frequently targeted vessels during

TABLE 13-3 Interpretation and Management of Biophysical Profile

Score	Comment	Perinatal Morbidity or Mortality Within 1 week (no intervention)	Management
10/10	Normal	<1/1000	No intervention
8/8	Normal	—	No intervention
8/10 (abnormal NST)	Normal	—	No intervention
8/10 (abnormal amniotic fluid)	Suspect chronic fetal compromise, renal anomaly, or rupture of membranes	89/1000	Rule out renal abnormality or rupture of membranes; consider delivery or prolonged observation if dictated by gestational age
6/8 (other)	Equivocal, possible asphyxia	Variable	If fetus is mature, deliver; if immature, repeat test within 4-6 hours
6/8 (abnormal amniotic fluid)	Suspect asphyxia	89/1000	Repeat 4-6 hours; consider delivery
4/8	Suspect asphyxia	91/1000	If ≥36 weeks' gestation or documented pulmonary maturity, deliver immediately; if not, repeat within 4-6 hours
2/8	High suspicion of asphyxia	125/1000	Immediate delivery
0/8	High suspicion of asphyxia	600/1000	Immediate delivery

NST, Nonstress test.

pregnancy. Umbilical artery Doppler velocimetry measurements reflect resistance to blood flow from the fetus to the placenta. Factors that affect placental resistance include gestational age, placental location, pregnancy complications (placental abruption, preeclampsia), and underlying maternal disease (chronic hypertension).

Doppler velocimetry of umbilical artery blood flow provides an indirect measure of placental function and fetal status (Giles et al, 1985). Decreased diastolic flow with a resultant increase in systolic-to-diastolic ratio suggests increased placental vascular resistance and fetal compromise. Severely abnormal umbilical artery Doppler velocimetry (defined as absent or reversed diastolic flow) is an especially ominous observation and is associated with poor perinatal outcome, particularly in the setting of IUGR (Ducey et al, 1987; McCallum et al, 1978; Rochelson et al, 1987; Trudinger et al, 1991; Wenstrom et al, 1991; Zelop et al, 1996). The overall mortality rate for fetuses with absent or reversed flow may be near 30% (Karsdorp et al, 1994). It should be noted that abnormal Doppler studies are often seen in cases of anatomic anomalies or chromosomal abnormalities, which should be noted when managing a case.

The role of ductus venosus and middle cerebral artery (MCA) Doppler in the management of IUGR pregnancies is not well defined. As such, urgent delivery should be considered in IUGR pregnancies when the results of umbilical artery Doppler studies are severely abnormal regardless of gestational age. However, it is unclear how to interpret these findings in the setting of a normally grown fetus. For these reasons, umbilical artery Doppler velocimetry should not be performed routinely on low-risk women. Appropriate indications include IUGR, cord malformations, unexplained oligohydramnios, suspected or established preeclampsia, and possibly fetal cardiac anomalies. Umbilical artery Doppler velocimetry has not been shown to be useful in the evaluation of a variety of high-risk pregnancies, including diabetic and postterm pregnancies, primarily because of its high false-positive rate (Baschat, 2004; Farmakides et al, 1988; Landon et al, 1989; Stokes et al, 1991).

As such, in the absence of IUGR, obstetric management decisions are not usually made on the basis of Doppler velocimetry studies alone. Nonetheless, new applications for Doppler technology are currently under investigation. A recent application that has proved extremely useful is the noninvasive evaluation of fetal anemia resulting from isoimmunization. When a fetus develops severe anemia, cardiac output increases and there is a decline in blood viscosity, resulting in an increase in MCA blood flow, which can be demonstrated by measuring the peak velocity using MCA Doppler velocimetry (Mari et al, 1995). This demonstration can help the perinatologist to better counsel such patients about the need for cordocentesis and fetal blood transfusion. Doppler studies of other vessels—including the uterine artery, fetal aorta, ductus venosus, and fetal carotid arteries—have contributed considerably to our knowledge of maternal-fetal physiology, but as yet have resulted in few clinical applications.

SUMMARY

There are a variety of testing modalities available to the obstetrician for assessing fetal well-being in the antepartum period, each with specific applications, advantages, and disadvantages. As such, it is difficult to apply generalized protocols to the assessment of the fetus. A stepwise approach entails applying the appropriate tests for low-risk patients and identifying those patients, from the results of those tests or from historical factors, for whom further testing is needed. Although many tests, including NST, fetal weight assessment, and uterine artery Doppler, may be somewhat nonspecific and may have misleading false-positive rates, combining those tests with others increases the specificity. Test results that raise concerns require further investigation or active management.

CHAPTER 14

Prematurity: Causes and Prevention

Tonse N.K. Raju and Caroline Signore

BURDEN OF PRETERM BIRTH

Despite major advances in perinatal medicine, preterm births (PTBs) in the United States have been increasing over the past two decades, reaching a high of 12.8% of live births in 2006 (Martin et al, 2009). This rate amounts to one PTB occurring at each minute of every day, throughout the year. From the perspective of a societal health care burden, these data are sobering, because infants born even 1 or 2 weeks before full term suffer higher rates of morbidity and mortality throughout life. Thus even a minimal increase in the PTB rate has a major effect on the societal burden of disease. Conversely, even a modest reduction in the PTB rate can have a major positive effect on the societal health care burden. In this chapter we focus on the etiology, prediction, and prevention of PTB.

DEFINITIONS

The World Health Organization defines *preterm birth* as a birth occurring either before 37 completed weeks of gestation or on or before the 259th day, counting from the first day of the last menstrual period. Only completed weeks of gestation are reported; therefore an infant born 6 days after completing 35 weeks of gestation is noted as 35 weeks, not rounded up to 36 weeks. However, one can precisely denote the exact gestational age by using a superscript for the number of days after the completion of the gestational week. Thus, the infant in the example can be noted as being born at $35^{6/7}$ weeks' gestation.

PTBs can be categorized into three major gestational age strata: those occurring at <32 weeks' (on or before 224 days) gestation, usually referred to as *very preterm births;* those occurring between $32^{0/7}$ and $33^{6/7}$ weeks' (between 225 and 238 days) gestation (a group with no specific name, but can be termed *moderate preterm births*); and those occurring between $34^{0/7}$ and $36^{6/7}$ weeks' (239 to 259 days) gestation, referred to as *late preterm births* (Figure 14-1). It is worth noting that the phrase *near term* is no longer used to refer to the third group, because the phrase falsely conveys a message that such "borderline" preterm infants are almost as mature as term infants (Raju et al, 2006).

EPIDEMIOLOGY

In the United States, the PTB rate increased from 10.6% in 1990 to 12.8% in 2006—a 21% increase (Goldenberg et al, 2008; Martin et al, 2009). This increase was part of a general trend in the distribution of gestational age at delivery, which showed a dramatic, leftward shift by 1 week, such that the peak modal week (the gestational week at which most deliveries occurred) shifted from 40 weeks in 1992 to 39 weeks in 2002 (Davidoff et al, 2006). Whereas this shift has decreased births at 41 weeks' gestation or later, it has also led to an increase in the number of all PTBs.

Preliminary data in the United States for 2007 showed that among the total number of live births, 2.04% were very preterm, 1.59% were moderate preterm, and 9.03% were late preterm (Hamilton et al, 2009). Thus, of all the PTBs the late PTB stratum was the largest at 71%, the very PTB stratum was intermediate at 16.1%, and the moderate PTB stratum was the smallest at 12.6%.

The U.S. 2007 preliminary data also suggest a slight decline in the total PTB rate to 12.7%, from 12.8% in 2006. The 2007 decline was predominantly among late PTB, from 9.1% in 2006 to 9.0% in 2007 (Hamilton et al, 2009). However, trends over longer periods need to be examined to confirm these preliminary findings and to judge whether the PTB rates in the United States have leveled or begun to decline.

ETIOLOGY AND RISK FACTORS

Individual PTBs can be categorized into two major groups: (1) spontaneous PTB (accounting for up to 60% of all PTBs), which occur after the spontaneous onset of preterm labor, and in some cases, after spontaneous preterm rupture of the fetal membranes before the onset of labor; and (2) indicated PTB (accounting for about 40% of PTBs), which arise from interventions by the health care team to reduce poor outcomes in the presence of specific medical, surgical, or obstetric conditions and indications in the mother or fetus.

SPONTANEOUS PRETERM BIRTHS

In most spontaneous PTBs, the precise cause for the onset of labor remains unknown; however, a variety of risk factors have been identified (Behrman and Butler, 2007) (Table 14-1).

BEHAVIORAL AND PSYCHOLOGICAL CONTRIBUTORS

Behavioral and psychological contributors, especially when occurring in constellation, tend to increase the risk for PTB. Some of these factors include excessive consumption of alcohol, smoking, use of cocaine, unfavorable diet, prolonged and stressful physical labor during pregnancy, shorter interval between pregnancies, and a variety of psychosocial stressors (Goldenberg et al, 2008).

Sociodemographic and Community Contributors

Increased risk for PTB has been associated with extremes of maternal age (<17 or >35 years), unmarried status, poverty, adverse neighborhood conditions, and lower educational attainment. The causal pathways for the

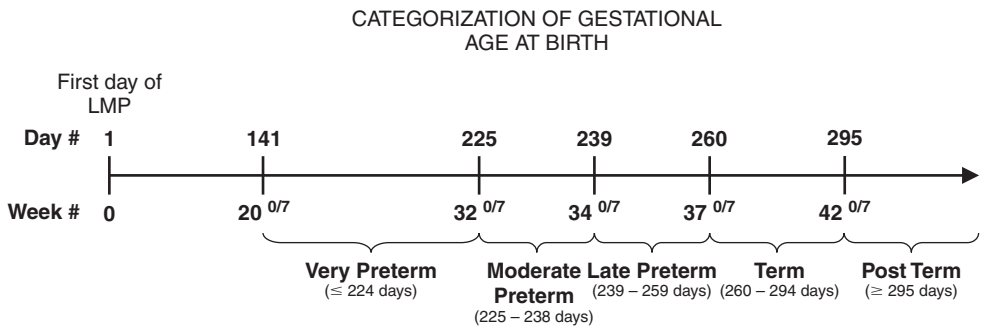

FIGURE 14-1 Categorization of gestational age at birth.

TABLE 14-1 Risk Factors for Preterm Birth*

Category	Specific Variable	Effect Size and Comments
Behavioral and psychological contributors	Tobacco and alcohol	Inconsistent effect; these variables may be confounders with lower socioeconomic status
	Other drugs	Cocaine users experience a twofold increase in PTB; other drugs (e.g., marijuana) have inconsistent effects
	Nutrition	Low prepregnancy weight and lower weight gain increase PTB risk; these factors may be confounders with other medical conditions
	Physical activity, employment	Inconsistent effect of employment per se; but long work hours and stress have been associated with increased risk of PTBs
	Douching	Frequent and prolonged vaginal douching during pregnancy can alter vaginal flora and enhance the risk for PTB
	Stress (chronic, acute, life events)	Emotional stress, living conditions, major stressful life events, discrimination, and racism, and other forms of stress experiences may act through diverse mechanistic pathways, affect many body functions, such as the HPA, immune defense mechanisms, and autonomic nervous system, leading to PTB
Sociodemographic contributors	Maternal age	U-shaped relationship with maternal age and PTB rate, with increased risk in women <17 and >35 years; in black women, risk seems to increase by age 30
	Marital status	Although unmarried mothers have higher rates of PTB, the protective effects of marital status on the PTB rate may vary across different ethnic groups
	Race and ethnicity	Non-Hispanic black women have high rates of PTB; the causes are likely to multifactorial
	Socioeconomic conditions	Disparities in PTB rates by SES (high rates with low SES) are well documented, although the etiologic pathways for such effects are unclear
	Community and neighborhood	Adverse neighborhood conditions influence health outcomes, including PTB rates, through direct and indirect pathways
Medical and pregnancy conditions	Maternal medical illnesses and conditions	Indicated PTBs may occur with chronic hypertension, hypertensive disorders of pregnancy, systemic lupus, hyperthyroidism, pregestational diabetes mellitus, cardiac disease, asthma, renal disorders, and gestational diabetes mellitus
	Underweight and low weight gain	Low prepregnancy weight and lower-than-average increase in weight during pregnancy have been documented with higher rates of PTB
	Fetal conditions	In vitro fertilization, assisted reproductive technology, multifetal pregnancy, congenital anomalies, umbilical cord accidents
	Pregnancy conditions	Placenta previa, first-trimester vaginal bleeding, abruption of the placenta, uterine malformations
	Infections	Maternal-fetal infections, bacterial vaginosis
	Other	Interpregnancy interval of less than 6 months is estimated to increase PTB rate by 30% to 60%; family history of PTB is associated with higher rates of PTB; it is unclear if the effect is caused by genetic factors, environmental factors, or a combination of both
Environmental toxins	Lead, air pollution	Exposures linked to higher PTB rates include lead, tobacco smoke, air pollution (sulfur dioxide, particulates, carbon monoxide), and arsenic in drinking water; however, interactions between such exposures and confounding factors such as SES, race, and ethnicity need to be studied
Gene-environment interactions		Genetic susceptibility and gene environmental interactions is a rapidly evolving field; according to some experts, epigenetic mechanisms are the final common pathway to explain diverse sociodemographic, racial, and ethnic factors and their effects on PTB rates

HPA, Hypthalamopituitary axis; *PTB*, preterm birth; *SES*, socioeconomic status.
*For a comprehensive discussion of various factors noted in this table, please see Behrman RE, Butler AS: *Preterm birth, causes, consequences, and prevention*, Washington, DC, 2007, The National Academies Press.

association between adverse sociodemographic and community contributors are complex and poorly understood. It should be noted, however, that these factors are interrelated and often coexist with other medical or obstetric conditions.

Racial Disparity

African American women are consistently found to have higher PTB rates than women of other racial and ethnic groups (16% to 18% versus 5% to 9%; Goldenberg et al, 2008). Black women are also more likely to experience preterm premature rupture of membranes (PPROM) and very PTB. The reason for this persistent racial disparity is unknown.

Previous Preterm Birth

The prior history of a PTB is consistently identified as one of the strongest predictors of preterm delivery, elevating the risk to more than twofold the background rate (Mercer et al, 1999). Risk is further elevated if there is a history of multiple PTBs, consecutive previous PTBs, and births at earlier gestational ages (Spong, 2007).

Short Cervix

Among asymptomatic women, cervical length less than 25 mm at 24 weeks' gestation, as measured by transvaginal ultrasound, in singleton pregnancy is associated with a sixfold increase in the risk of delivery before 35 weeks' gestation (Iams et al, 1996). Among women in suspected preterm labor, a cervical length of less than 15 mm may discriminate between women who are likely to deliver preterm and those whose pregnancies will continue (Tsoi et al, 2003).

Genetic Factors

The risk of PTB is increased in women with a positive family history of PTB. Single nucleotide polymorphisms in a number of maternal and fetal candidate genes involved in inflammatory pathways have been associated with PPROM and PTB (Varner and Esplin, 2005). Studies using genomic and proteomic approaches to further investigate molecular risk factors for PTB are in progress.

Infections

Overt or subclinical intrauterine infection, which might lead to rupture of the membranes before onset of labor, has been hypothesized to etiologically contribute to onset of labor, especially among very PTBs. The most common route of intrauterine infection is ascension of vaginal bacteria. Bacterial vaginosis (BV) is a common vaginal infection characterized by a shift in vaginal flora toward anaerobic species, accompanied by an abnormally high pH. Risk of PTB is increased up to twofold in women with BV (Hillier et al, 1995; Meis et al, 1995). Periodontal disease has also been linked to PTB (Jeffcoat et al, 2001); however, the biologic pathway is not well understood.

Multifetal Gestation

Twin and higher-order pregnancies account for 3% of all births. Multiple pregnancies are at increased risk of preterm delivery, with approximately 40% of twins delivered spontaneously before 37 weeks' gestation. Uterine overdistention is believed to be the major etiologic factor in these births. An additional 20% of twins will develop maternal or fetal complications leading to indicated PTB. The mean gestational age at delivery is 35 weeks' gestation for twins, 32 weeks' gestation for triplets, and 29 weeks' gestation for quadruplets (Elliott, 2005; Martin et al, 2003).

Infertility Treatment

The use of assisted reproductive technology (ART), in which gametes are manipulated outside the body, is steadily increasing. In 2006, 41,000 American women delivered after successful infertility treatment with ART, accounting for approximately 1% of all live births (Sunderam et al, 2009). The use of ART is strongly associated with multifetal pregnancies, dramatically increasing the risk for PTBs. However, even singleton pregnancies following ART have a twofold higher risk for PTB (Jackson et al, 2004), suggesting a complex relationship between a history of infertility, ART, and reproductive outcomes. Medical treatment of infertility (i.e., ovulation induction) is also associated with multiple gestation and PTB. In 2003, 21% of twin, 37% of triplet, and 62% of quadruplet and higher-order multiple births were attributable to non-ART ovulation induction (Dickey, 2007).

Maternal Body Habitus: Underweight and Obesity

Low prepregnancy body mass index (<18.9 kg/m^2) is associated with a 1.5- to 2.5-fold increase in the risk of PTB and has previously been a target of PTB prevention efforts (Goldenberg et al, 1998; Siega-Riz et al, 1996). Currently there is an epidemic of overweight and obesity in all U.S. populations. Maternal obesity is not associated with an increased risk of spontaneous PTB (Hendler et al, 2005). However, maternal obesity is a risk factor for a variety of pregnancy complications, including congenital anomalies, preeclampsia, and macrosomia, which may result in the need for indicated PTB (Aly et al, 2010).

Fetal Fibronectin

Fetal fibronectin (FFN) is a glycoprotein involved in the adherence of the fetal membranes to the uterine wall. The presence of FFN in the cervicovaginal secretions has been considered a risk factor for PTB and has been evaluated for its predictor value of preterm delivery in large cohort studies. A positive test result for FFN at 22 to 24 weeks' gestation in asymptomatic women is significantly associated with PTB (Goldenberg et al, 1998); however, because of its low positive predictive value, it is not a reliable universal screening tool in low-risk women. The most useful aspect of FFN assessment is its high negative predictive value: among women with signs and symptoms of preterm

labor and a negative FFN, 99% will not deliver over the next 7 days (Lu et al, 2001).

INDICATED PRETERM BIRTHS

Medical and Pregnancy Conditions

Well-recognized medical and pregnancy-related conditions are noted in Table 14-1. Many of these conditions are also encountered to a greater extent among women in lower socioeconomic strata and among those living under adverse conditions.

Maternal and fetal conditions that can lead to indicated preterm deliveries include diabetes; hypertension; preeclampsia or eclampsia; maternal cardiovascular and pulmonary disorders; multifetal gestations; uterine structural disorders; polyhydramnios or oligohydramnios; placenta previa, abruption, and other uterine hemorrhagic events; chorioamnionitis and fetal infection; fetal distress; and congenital anomalies.

Causes for Increasing Preterm Birth

The precise reasons for increasing rates of PTB are unclear. The contribution of many factors is noted in Table 14-2 (Behrman and Butler, 2007; Raju, 2006; Raju et al, 2006).

Etiologic Pathways

Preterm labor and delivery arise from abnormal activation of parturition. No single mechanism describes all cases of PTB; rather, preterm parturition can be viewed as an obstetric syndrome with multiple etiologies, a long preclinical phase, frequent fetal involvement, and genetic factors that modify risk. Contributing pathologic processes may include intrauterine inflammation or infection, uterine ischemia, uterine over distension, abnormal allograft reaction, allergy, cervical insufficiency, and hormonal dysregulation (Romero et al, 2006).

TABLE 14-2 Possible Causes for Increasing Preterm Birth*

Variable	Comments
Increasing maternal age at first pregnancy	Number of pregnant women 35-39 years nearly doubled between 1993 and 2003
Increasing infertility treatment and multifetal gestations	Number of women seeking infertility treatment increased twofold between 1996 and 2002
Change in practice parameters or guidelines	Improved surveillance and increased medical interventions to prevent still births
Increasing cesarean section rates and decreasing VBAC	—
Increasing maternal overweight and obesity	Errors in estimating gestational age of macrosomic fetus
Inaccuracy in estimating gestational age	Lack of early ultrasound examination
Iatrogenic or nonmedical reasons	Maternal request for early delivery or other logistical considerations of the patient, family or health care team

VBAC, Vaginal birth after cesarean.
*For a review, please see Goldenberg et al (2008), Raju (2006), and Reddy et al (2007, 2009).

Allostatic Load

Recent studies of the pathophysiology of and biologic responses to stress have uncovered a series of causal pathways for adverse outcomes caused by stresses at multiple levels and from different sources. The biologic responses to stressors have been collectively called *allostatic load*, a summary measure of major perturbations in the autonomic, endocrine, and immune systems. Allostatic load has been linked to accelerated aging, worsened immunologic tolerance, ineffective defense systems, and increased cardiovascular morbidity. Abnormal allostatic load during the entire life span of a woman can potentially modulate her biologic systems and worsen perinatal outcomes (Groer and Burns, 2009; Herring and Gawlik, 2007; Latendresse, 2009; Lu and Halfon, 2003; McEwen, 2006; Shannon et al, 2007). Studies are under way to understand the complex relationship between the effects of sociodemographic and biologic stressors on organ systems and their influence on perinatal outcomes.

PREVENTION OF PRETERM BIRTH

Despite intense research efforts, few widely effective strategies for preventing PTB have been identified. Because of the multifactorial nature of preterm labor and birth, it is unlikely that any single intervention could serve to prevent all cases of prematurity. In the United States, efforts have focused on addressing specific risk factors to prevent PTB (i.e., secondary prevention), such as treatment of infection, and interventions to mitigate the morbidity and mortality of PTB (i.e., tertiary prevention), such as administration of tocolytic drugs to women in preterm labor (Iams et al, 2008). A better understanding of the complex mechanisms leading to preterm labor and birth is needed to advance development of interventions to prevent PTB. In this section, a number of strategies—both encouraging and disappointing in terms of effectiveness—are described.

Progesterone

Progesterone is thought to have antiinflammatory effects and to be a smooth muscle relaxant that inhibits uterine contractions. Administration of progesterone has shown the most promise as an effective intervention for preventing PTB in women with certain risk factors for PTB. In a recent metaanalysis of 11 trials, progesterone significantly decreased PTB of singleton gestations less than 34 weeks in women with a prior spontaneous preterm birth (SPTB) by 85%, with a number needed to treat of seven (Dodd et al, 2005). However, progesterone does not prevent PTB in women carrying twins (Rouse et al, 2007) or triplets (Caritis et al, 2009). Petrini et al, (2005) estimated that if all eligible women with a history of prior SPTB were treated with progesterone, then 10,000 PTBs per year could be prevented. Progesterone treatment does not appear to pose a developmental risk to the fetus or infant. In a follow-up study of children exposed to 7-alpha hydroxyprogesterone caproate versus placebo in utero, there were

no differences in growth or neurodevelopmental measures between groups at age 4 years (Northen et al, 2007).

Cerclage

Cervical cerclage is a purse-string suture of the cervix intended to mechanically prevent cervical dilation. A number of investigators have evaluated the use of cerclage to prevent PTB in women with shortened cervical length, and they have not demonstrated a significant effect (Berghella et al, 2004; To et al, 2004). A more recent trial indicated a significant beneficial effect (adjusted odds ratio, 0.23; 95% confidence interval, 0.08 to 0.66) of cerclage in women with a history of previous SPTB and cervical length less than 15 mm (Berghella et al, 2008; Owen et al, 2009).

Limited Embryo Transfer

Preterm delivery of multifetal pregnancies arising from ART can be prevented in many cases by limiting the number of embryos transferred to the uterus. The proportion of in vitro fertilization cycles in which three or more fresh embryos were transferred declined significantly in the United States between 1996 and 2002 (92% to 54%; $p < 0.001$); however, the proportion of single-embryo transfer cycles remained small (2.5% in 2002) (Reynolds and Schieve, 2006). Recent practice guidelines from the American Society for Reproductive Medicine call for wider consideration of single-embryo transfer in many clinical situations (American Society for Reproductive Medicine, 2008).

Multifetal Pregnancy Reduction

Reduction of multifetal pregnancy, or the selective termination of one or more fetuses in a high-order pregnancy, has been proposed as a means to reduce the risk of prematurity and other pregnancy complications. Although effective at preventing some very PTBs, the procedure carries an approximately 1% risk of loss of the entire pregnancy (Stone et al, 2002) and can create profound ethical dilemmas (American College of Obstetricians and Gynecologists, 2007).

Treatment of Vaginal Infections

Despite consistent associations between lower genital tract infection and PTB, multiple randomized trials have failed to demonstrate a benefit of screening and antibiotic treatment for vaginitis or genital tract colonization on the PTB rates (Carey et al, 2000; Iams et al, 2008; Klebanoff et al, 2001; McDonald et al, 2007).

Treatment of Periodontal Disease

PTB has been associated with maternal periodontal disease in a number of studies, and early clinical trials suggested that treatment of periodontitis reduces the risk of PTB (Jeffcoat et al, 2003; Lopez et al, 2002). On the other hand, a recent multicenter clinical trial in the United States found that, whereas periodontal disease improved in pregnant women randomized to treatment, there were no differences in rates of PTB, low birthweight, or fetal growth restriction in the treatment group compared with controls (Michalowicz et al, 2006).

Tocolytics: Acute and Maintenance

Preterm labor (PTL), is defined as the onset before 37 weeks' gestation of regular uterine contractions that result in cervical change. Although numerous pharmacologic and nonpharmacologic treatments have been aimed at arresting PTL and preventing PTB, none have been shown to prolong pregnancy for more than 2 to 7 days (Iams et al, 2008). Nevertheless, tocolytic drugs are often used to allow for the administration of steroids and maternal transfer to a facility capable of caring for a preterm neonate. Drugs commonly used to treat PTL are summarized in Table 14-3. Maintenance tocolysis after an acute episode of PTL has not been shown to prevent PTB (Dodd et al, 2006; Gaunekar and Crowther, 2004; Nanda et al, 2002).

MANAGEMENT OF PRETERM PREMATURE RUPTURE OF MEMBRANES

Preterm premature rupture of membranes (PPROM) is defined as the prelabor rupture of membranes before 37 weeks' gestation. The period between initial leakage of

TABLE 14-3 Drugs Commonly Used to Treat Preterm Labor*

Agent	Class, Mechanism	Maternal Side Effects	Fetal and Neonatal Effects
Magnesium sulfate	Decreases intracellular calcium, inhibits contractile response	Flushing, lethargy, nausea, muscle weakness	Lethargy, decreased tone, respiratory depression
Terbutaline	β-Mimetic	Tachycardia, hyperglycemia, myocardial ischemia, pulmonary edema	Tachycardia, hyperinsulinemia, hyperglycemia
Nifedipine	Calcium channel blocker	Hypotension, flushing	None reported
Indomethacin	NSAID, prostaglandin synthase inhibitor	Gastrointestinal upset	Decreased renal function, oligohydramnios, closure of the ductus arteriosus
Atosiban (not available in the United States)	Oxytocin inhibitor	Hypersensitivity, injection site reaction	Increased risk of fetal or infant death if administered before 28 wk

NSAID, Nonsteroidal antiinflammatory drug.
*For a review, see American College of Obstetricians and Gynecologists (2007), Dodd et al (2006), Gaunekar and Crowther (2004), Nanda et al (2002), Simhan and Caritis (2007), and Stone et al (2002).

fluid and the onset of labor and delivery is known as the *latency period*. Without treatment, the latency period after PPROM is usually less than 1 week, with an inverse relationship between the gestational age at rupture and length of the latency period. In a large multicenter trial, a 7-day course of broad-spectrum antibiotics was shown to prolong the latency period for up to 3 weeks in women who had experienced PPROM at 24 to 32 weeks' gestation. In addition, antepartum antibiotic treatment decreased the incidence of chorioamnionitis and major morbidity (respiratory distress syndrome, early sepsis, severe intra ventricular hemorrhage, or severe necrotizing enterocolitis) in the infants (Mercer et al, 1997).

SUMMARY

PTBs are occurring at epidemic proportions in the United States. With more than 4.3 million live births each year, a prematurity rate of 12.5% results in more than 537,000 PTBs annually. As described in other chapters, preterm infants are at greater risk for mortality, and short- and long-term morbidities compared with term infants. A recent study from Norway on the adult-age outcomes of preterm infants reported that even mild prematurity was associated with significantly elevated risk for long-term adverse medical, behavioral, psychological, and vocational outcomes (Moster et al, 2008). In addition to the families' burden of illness, death, and disability, society bears a large burden of health care costs related to PTBs. The collective economic burden from prematurity was more than $26 billion in 2005 (Behrman and Butler, 2007). Given the complex nature of the risk factors and causal pathways for PTBs, and the difficulties in diagnosing, preventing, and treating them, there have been renewed calls in support of multidisciplinary research to address the problems of PTBs. The Institute of Medicine of the National Academies of Science issued a major publication providing specific recommendations and guidelines for research, surveillance, and education on this topic (Behrman and Butler, 2007). The U.S. Senate approved the PREEMIE Act on August 1, 2006. This bill called for efforts to reduce preterm labor and delivery and the risk of pregnancy-related deaths and complications, and to reduce infant mortality caused by prematurity. The U.S. House of Representatives passed the bill unanimously on December 9, 2006, and the president signed it into law on December 22, 2006 (March of Dimes Foundation, 2006). The March of Dimes Foundation initiated the *Prematurity Campaign*, designed to educate and inform health care professionals, industry, government agencies, and the general public about prematurity-related issues. These and other efforts have begun recently and will take time to yield positive results. Their collective effect on reducing the burden of PTBs needs to be monitored on a long-term basis.

CHAPTER 15

Complicated Deliveries: Overview

Sarah A. Waller, Sameer Gopalani, and Thomas J. Benedetti

Historically, child birth was often regarded as a perilous undertaking. However, over the past century in the United States, perinatal and maternal mortality have dramatically fallen with advances in modern obstetric care, such as widespread use of antibiotics, easy access to expedient cesarean delivery, and better understanding of the proper use of instruments such as forceps and vacuum extraction (Ali and Norwitz, 2009). Indeed, adverse outcomes are generally uncommon in modern obstetrics, and unlike in the past, most labor and delivery concludes with a healthy mother and neonate. Nevertheless, complicated deliveries still exist, and knowledge of their conduct and sequelae is still required for the administration of proper maternal and infant care.

In this chapter we will first address the complicated vaginal delivery, with particular attention to neonatal outcomes. We will then discuss cesarean delivery and vaginal birth after a prior cesarean delivery (VBAC) and what neonatal implications these may have. Before discussing complicated labor and its neonatal effects, it is important to have a brief understanding of the conduct of normal labor and delivery. A comprehensive discussion of labor and delivery is beyond the scope of this chapter, and the interested reader is directed *Williams Obstetrics*, ed 23, chapter on normal labor.

The first stage of labor begins with the onset of regular uterine contractions with concomitant cervical dilation and effacement, and it ends with complete cervical dilation. The first stage is further subdivided into a latent phase, the length of which is variable and can last for several hours, and an active phase, which usually begins when the cervix is dilated 3 to 4 cm and is marked by further rapid, progressive cervical dilation and effacement. Often the diagnosis of the transition from latent to active phase labor is retrospective, because the time of onset of active labor is variable by patient. The second stage begins with complete cervical dilation and terminates with the expulsion of the fetus from the birth canal. The third stage of labor concludes with the delivery of the placenta.

Disorders of the conduct of labor are of either protraction, in which cervical dilation or fetal descent occurs but is at a rate much less than expected, or arrest. Both disorders are addressed by operative delivery if they are unresponsive to active medical management; this can be performed abdominally through cesarean section or vaginally by obstetric forceps or vacuum extraction if the cervix is fully dilated and specific criteria are fulfilled (see later discussion on operative vaginal delivery). All these modalities can have neonatal and maternal effects, and the choice of instrument or mode of delivery must always be selected taking these potential morbidities into account.

CESAREAN SECTION

Neonatal mortality within 7 days of birth was 17.8 per 1000 live births in 1950; it is currently 3.8 per 1000 (Ali and Norwitz, 2009). Certainly much of the improvement in neonatal survival stems from advances in neonatal intensive care and resuscitative techniques. Along with improved technology available to the pediatricians, however, is the fact that the last 50 years have also seen a dramatic increase in the universal access to safe cesarean section, which affords quick and timely fetal delivery. However, a cause-and-effect relationship between cesarean delivery and improved neonatal outcome has never been demonstrated, and recent evidence suggests that some current obstetric cesarean delivery practices may actually cause harm (Bates, 2009). Currently almost one mother in three is giving birth by cesarean section, a record level for the United States. Recommendations from the U.S. Department of Health and Human Services Healthy People 2010 recommend a cesarean section rate of less than 15% for a first pregnancy and 63% for previous cesarean sections. In addition, there are wide variations in cesarean delivery rates among hospitals in a given state or region, suggesting that factors other than pregnancy risk factors may be responsible for the current cesarean delivery rate. This rise in cesarean delivery has been associated with a parallel drop in the vaginal operative delivery rate to less than 10%. These two trends have increased the cost of childbirth in the United States and are now threatening many state budgets, because almost 50% of obstetric care cost is paid with public funds (i.e., Medicaid). In response as the result of a budget crisis, the state of Washington reduced hospital payment for uncomplicated cesarean delivery (DRG 371: Cesarean section) by reimbursing only the equivalent of a complicated vaginal birth (DRG 372: Normal delivery with problems), a projected savings of $2 million per year. Many states are actively working to safely reduce the rate of cesarean delivery. Projects are under way to reduce elective delivery before 39 weeks' gestation, safely promote VBAC and limit the occurrence of higher-order multiple gestations.

Cesarean section is usually performed through either a Pfannenstiel or vertical skin incision. The uterine incision is often made transversely in the lower uterine segment, because it minimizes intraoperative blood loss and future risk of rupture during subsequent labor, compared with a vertical or classical incision. The risk of rupture in future labor is thought to be 0.5% to 1.0% for a low transverse incision, compared to 4% to 9% for a classical incision (Feingold et al, 1988).

Cesarean delivery is also performed for disorders of protraction or arrest in the first stage of labor when conservative measures fail to augment delivery, such as oxytocin or amniotomy, or in the second stage when assisted or operative vaginal delivery is deemed unfeasible or unsafe.

Accepted obstetric indications for operative delivery are as follows:

1. Fetal malpresentation (e.g., shoulder or breech)
2. Placenta previa
3. Prior classical uterine incision

4. Fetal status not reassuring, remote from vaginal delivery
5. Higher-order multiple gestation (triplet or greater)
6. Fetal contraindications to labor (alloimmune thrombocytopenia, neural tube defect)
7. Maternal contraindication to labor (e.g., history of rectal or perineal fistulas from inflammatory bowel disease, large lower-uterine segment, cervical leiomyoma preventing vaginal delivery)
8. Maternal choice after counseling regarding risks versus benefits

COMPLICATED VAGINAL DELIVERY: OBSTETRIC FORCEPS AND VACUUM EXTRACTION

DESCRIPTION OF THE OBSTETRIC FORCEPS

Obstetric forceps have been used to facilitate vaginal deliveries since 1500 BC. Most commonly, the invention is credited to Peter Chamberlen and his brother of England. Designed originally as a means of extracting fetuses from women who were at high risk of dying during childbirth, forceps now are an alternative to cesarean delivery in women with a protracted second stage of labor. Originally, many of these instruments were furnished with hooks and other accessories of destruction, and they were intended to save the mother but not the fetus. Over the last 500 years, the modern instruments in current use have been through hundreds of modifications, safer techniques have been established, and the overriding goal now includes delivering an intact, living baby and a healthy mother (Meniru, 1996; O'Grady et al, 2002).

Current obstetric forceps were first devised for practical use in the sixteenth and seventeenth centuries and were perfected over the past 300 years into the models in current use. Although there are many variations on the standard blueprint depending on the indication for its use, all obstetric forceps have a similar design.

Forceps are made of stainless steel and consist of two blades (each approximately 37.5 cm long, crossing each other), a lock at the site of crossing, and a handle, whereby the instrument is grasped by the obstetrician. The long blades are parallel, divergent, or convergent, depending on the type of instrument; the lower 8 cm comprises the shank, which is the part between the blade proper and the handle, giving a length for the forceps that is sufficient to be locked easily outside the vagina. The four most common types of lock are the sliding lock, which can articulate anywhere along the shanks of the blade (Kielland and Barton's forceps); the English, which is fixed, a double slot lock; the French, which is a screw lock; and the German, which is a combination of the English and French. The part of the forceps that grasps the fetal head is the blade; this is further divided into the heel, which is the part closest to the lock, and the toe, which is the most distal part of the blade. The blade can be either fenestrated—meaning the body of the blade is hollow—or solid to prevent fetal head compression. A further modification is pseudofenestration, in which a solid blade has a ridged edge, combining the advantages of easier applicability and less fetal trauma that a solid blade affords with the ease of traction of a fenestrated blade. Obstetric forceps also possess a rounded cephalic curve, which accommodates the fetal vertex, and a pelvic curve that mirrors the maternal pelvic curve (Figure 15-1).

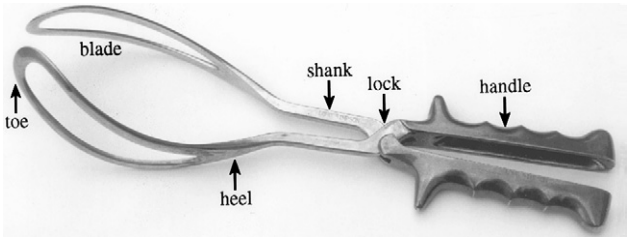

FIGURE 15-1 Simpson forceps: a standard obstetric forceps with features common to all such instruments.

TABLE 15-1 Types of Obstetric Forceps in Most Common Use

Type	Anatomic Modification	General Use
Classic		
Tucker-McClane	Solid blade	Nonmolded vertex
Simpson	Parallel shanks	Molded vertex or significant caput
Elliot	Convergent shanks	Nonmolded vertex
Laufe	Pseudofenestrated blade; divergent shanks	For preterm infants or EFW <2500 g
Rotational		
Kielland	English lock; absent pelvic curve	For rotation of fetal vertex ≥45 degrees
Breech		
Piper	Long handles with no pelvic curvature	For after-coming head in breech vaginal delivery

EFW, Estimated fetal weight

There are more than 60 different types of obstetric forceps described in the literature, but most of are not used currently. The forceps used most commonly today are described in Table 15-1 , along with their indications for use and the variations in anatomy, which distinguish one from the other.

INDICATIONS FOR USE OF OBSTETRIC FORCEPS

To an individual without obstetric training, the use of forceps can be a dangerous and difficult undertaking, fraught with potential trauma for both the mother and fetus. It is true that the use of this instrument, if not performed carefully or appropriately, can have serious consequences. Nevertheless, with properly trained hands, and a proper appreciation of its use, forceps can be lifesaving for both mother and fetus.

The criteria for the safe application of obstetric forceps are as follows:

1. The cervix must be fully dilated.
2. The position of the fetal vertex must be known. Forceps should not be applied when the fetal presentation is in doubt.

3. The fetal vertex must be engaged within the maternal pelvis. Often in difficult or challenging labors, significant caput can lead to the false impression that fetal station is lower than it actually is. For this reason, the obstetrician must be confident that the actual biparietal diameter has passed the pelvic inlet and that the leading part of the fetal skull is beyond the level of the ischial spines. In addition, when the presentation is occiput posterior, the leading point of the fetal skull may appear to be lower in the pelvis although the biparietal diameter has not yet passed through the pelvic inlet; this can also lead to an erroneous conclusion about fetal station.
4. When the forceps are properly applied, the sagittal suture must be exactly midway between the blades, and the lambdoidal sutures should be equidistant (usually one fingerbreadth) from the edge of the blade.

If these conditions are not met, application of the forceps should be reconsidered. Furthermore, in 1988 the American College of Obstetricians and Gynecologists (ACOG) revised its classification of the type of forceps delivery, according to the station of the fetal vertex before forceps application (Ali and Norwitz, 2009), which is as follows:

1. Outlet forceps—the fetal vertex is visible at the labia without manually separating them, and the fetal skull has reached the pelvic floor
2. Low forceps—the leading point of the fetal skull is greater than 2 cm beyond the ischial spines
3. Mid forceps—the fetal head is engaged and is beyond the level of the ischial spines; the forceps should be applied only if cesarean delivery is not quickly or imminently possible, and the fetus is in distress; or there should be a high likelihood that the forceps operation will be successful
4. High forceps—the vertex is not engaged (i.e., not at the level of the ischial spines or beyond); under these circumstances, the forceps must never be applied.

The forceps are further divided into whether they are rotational (sagittal suture is ≥45 degrees from the midline) or nonrotational (sagittal suture <45 degrees from the midline).

The indications for use of the obstetric forceps are:

1. Maternal exhaustion or inability to push (endotracheal intubation with sedation or paralysis; neuromuscular disease)
2. Fetal heart tracing not reassuring or fetal distress
3. Maternal contraindications to pushing (cardiopulmonary disease, cerebrovascular aneurysm)
4. After-coming head in a vaginal breech delivery
5. Facilitate difficult extraction of the fetal vertex during cesarean delivery

FORCEPS AND POTENTIAL NEONATAL MORBIDITY

As stated previously, forceps were used for hundreds of years without regard to fetal survival and were primarily needed to facilitate or terminate difficult labors for maternal benefit. Today, with the widespread availability of cesarean delivery, considerations turn to providing the best neonatal outcome possible; therefore the difficult forceps deliveries of the past have been abandoned. Nevertheless, forceps still play a crucial role in modern obstetrics, and if judiciously used can provide a safer alternative to cesarean delivery for both mother and baby.

The difficulty in interpreting the obstetric literature, in regard to neonatal morbidity incurred by forceps, is that the classification for type of forceps was revised by the ACOG in 1988; therefore prior studies do not use the same clinical criteria used currently to select appropriate candidates for forceps use. Furthermore, residency training in operative vaginal delivery has dramatically decreased over the past 30 years, potentially increasing fetal risk (Benedetto et al, 2007). Consequently, for proper interpretation of adverse outcomes, one must look to studies performed after the ACOG revised the classifications.

The incidence of operative vaginal delivery in the United States is approximately 5% (1 in 20 deliveries), ranging from 1% to 23% with a 99% success rate (Menacker and Martin, 2008). The prevalence of forceps use varies widely by region (highest in the South), and recent estimates show that it accounts for approximately 25% (1:4 ratio with vacuum extractions) of all operative vaginal deliveries (Benedetto et al, 2006). National statistics show that of the 1,268,502 deliveries in 12 states (31% of U.S. deliveries) in 2005, 1% were forceps assisted and 3.7% were vacuum assisted, for a estimated total national operative vaginal delivery rate of 4.7% (Menacker and Martin, 2008). Unfortunately, the prevalence of low, outlet, and mid-forceps (the application of forceps when the head is engaged but the leading point of the skull is more than +2 cm station) deliveries nationally is not known, nor is the rate of rotational and nonrotational forceps use. Neonatal outcome by type of forceps application is also not generally known and is hindered by the fact that even with the universal ACOG classification scheme, the determination of fetal station and type of forceps can be subjective and dependent on the experience and examining skill of the obstetrician. Moreover the indication for forceps use varies widely by clinical situation, and the neonatal morbidity that can result from a "difficult pull" in a patient with a transverse arrest with marked fetal asynclitism may be different from the quick delivery of a 2600-g fetus whose mother is unable to push, even if both deliveries are by low-forceps.

Nevertheless, what large studies show that long-term and short-term neonatal morbidity from outlet or low-forceps delivery is uncommon? In 2009, Prapas et al (2009) noted that the rate of vacuum- versus forceps-assisted deliveries had increased and that different maternal and neonatal outcomes have been proposed. The aim of their study was to compare the short-term maternal and neonatal outcomes between vacuum and forceps delivery. They conducted a medical record review of live born singleton, vacuum- and forceps-assisted deliveries. Of 7098 deliveries, 374 were instrument assisted, 324 were conducted by vacuum (86.7%), and 50 were assisted by forceps (13.3%). The incidence of third-degree lacerations and periurethral hematomas was similar between vacuum and forceps (3.4% vs. 2% and 0.3% vs. 0%, respectively), whereas perineal hematomas were more common in forceps compared

with vacuum application (2% vs. 0.3%, respectively), albeit not significantly. The rate of neonates with Apgar scores ≤6 at 1 min was significantly higher after forceps compared with vacuum delivery (18% vs. 5.2%, respectively; $p = 0.0003$). The rate of neonatal trauma and respiratory distress syndrome did not differ significantly between the two groups. The conclusion was that both modes of instrumental vaginal delivery are safe in regard to maternal morbidity and neonatal trauma (Prapas et al, 2009).

Alternatively, Benedetto et al, (2007) found that in healthy women with antenatally normal singleton pregnancies at term, instrument-assisted deliveries are associated with the highest rate of short-term maternal and neonatal complications. Of the 332 women who underwent an operative vaginal delivery, 201 met study criteria and were analyzed, with 54% forceps-assisted deliveries. Maternal complications were mostly associated with forceps-assisted and vacuum-assisted instrumental deliveries (odds ratio [OR], 6.9; 95% confidence interval [CI], 2.9 to 16.4; and OR, 3.0; 95% CI, 1.1 to 8.8, respectively, versus spontaneous deliveries). Neonatal complications were also mostly correlated with forceps-assisted and vacuum-assisted instrumental deliveries (OR, 3.5; 95% CI, 1.9 to 6.7; and OR, 3.8; 95% CI, 2.0 to 7.4, respectively, versus spontaneous deliveries) (Table 15-2) (Bendetto et al, 2007).

There are few randomized prospective trials specifically addressing the issue of neonatal morbidity arising from forceps operations, yet those that exist suggest no significantly increased risk from operative vaginal delivery when compared with spontaneous birth. Yancey et al (1991) randomized 364 full-term women at +2 station to elective outlet forceps delivery or unassisted birth. Women with suspected fetal macrosomia or chorioamnionitis were excluded. Neonates were examined at birth and 72 hours of age, and cranial ultrasound examinations were performed by neonatologists 24 to 72 hours after birth. The spontaneous and forceps-assisted births had no statistically significant differences in the incidence of scalp abrasions, facial bruising, cephalhematoma, subconjunctival hemorrhage, or abnormal cranial sonograms (Herbst and Källén, 2008).

Several retrospective, population-based studies have further examined the issue of potential adverse neonatal sequelae arising from forceps procedures. Robertson et al (1991) reclassified forceps operations in accordance with the 1988 revised ACOG guidelines and examined neonatal outcomes by type of forceps operation, matched to cesarean section with a second stage of at least 30 minutes, from a similar station. They found that mid-forceps operations compared with a cesarean section from a comparable station resulted in greater neonatal resuscitation requirements, lower umbilical artery pH, and *birth trauma*, defined as nerve injuries or fractures. There was no increased risk of trauma from low forceps procedures compared with cesarean delivery, although the prevalence of arterial cord pH less than 7.10 was increased (Keith et al, 1988). It must be noted, however, that this study was not randomized and that an abdominal delivery group is not necessarily an appropriate control for operative vaginal delivery. Nevertheless, this large population-based study (from a database of 20,831) emphasizes the relative safety of outlet and low-forceps procedures, casting some doubt as to the safety of mid-forceps operations.

The role of mid-forceps delivery in modern obstetrics, specifically in regard to rotation of 45 degrees or greater, has incited much controversy. The difficulty lies in the fact that no randomized trials exist comparing mid-forceps operations and other modes of delivery, and it is unlikely that any will be done in the near future given that training in this type of delivery has declined among obstetric residents in the United States (Kozak and Weeks, 2002; Learman, 1998).

Hankins et al reported a case-control study of 113 rotational forceps of 90 degrees or greater matched to 167 controls with rotation 45 degrees or less. They found no significant differences in major injuries, defined as skull fracture, brachial plexus, facial or sixth nerve palsy, and subdural hemorrhage. There were also no differences in the prevalence of cephalhematoma, clavicular fracture, or superficial laceration. All deliveries were performed with Kielland forceps by resident staff members, with attending supervision as required. The prevalence of nerve injury in these forceps-assisted operations ranged from 2% to 3%; there were no skull fractures (Lipitz et al, 1989).

The available literature supports the fact that neonatal morbidity from outlet or low forceps is exceedingly low, and comparable to spontaneous vaginal delivery. This finding comes from prospective data and large, population-based investigations. The evidence concerning neonatal safety from more advanced forceps operations (mid-forceps and rotations) shows that there is some degree of increased morbidity from these procedures, although whether this arises from the operative vaginal delivery itself or from difficult labor is not currently possible to discern (Meniru, 1996; O'Grady et al, 2002). In well-trained hands, the benefit of appropriately selected candidates for mid-forceps or rotational forceps may be justifiable, although the number of physicians in the United States who are facile and comfortable with attempting these procedures is steadily declining.

TABLE 15-2 Risk of Intracranial Injury According to Type of Delivery

Mode of Delivery	Incidence of Intracranial Injury
Vacuum	1 in 860
Forceps	1 in 664
Combined vacuum and forceps	1 in 256
Cesarean, in labor	1 in 907
Cesarean, not in labor	1 in 2750
Spontaneous vaginal delivery	1 in 1900

VACUUM DELIVERY: INDICATIONS, USES, AND COMPARISON WITH FORCEPS PROCEDURES

Operative vaginal delivery for the indications listed previously can also be performed by the vacuum extractor. Vacuum extraction was first described in 1705 by Dr. James

Yonge, an English surgeon, several decades before the invention of the obstetric forceps. However, it did not gain widespread use until the 1950s, when it was popularized in a series of studies by the Swedish obstetrician Dr. Tage Malmström. By the 1970s, the vacuum extractor had almost completely replaced forceps for assisted vaginal deliveries in most northern European countries, but its popularity in many English-speaking countries, including the United States and the United Kingdom, was limited. By 1992, however, the number of vacuum-assisted deliveries surpassed the number of forceps-assisted deliveries in the United States, and by the year 2000 approximately 66% of operative vaginal deliveries were by vacuum (Ali and Norwitz, 2009; Hillier and Johanson, 1994).

The situations that indicate the use of the vacuum and the requirements that must be fulfilled for its correct use are identical to those for the obstetric forceps. The device consists of a metal or plastic cup (flexible or semirigid) that is applied to the fetal vertex. Care is taken in its application to ensure that an adequate seal has been created, and that no maternal soft tissue is trapped between the suction device and the fetus. Traction is then applied to the fetal head in the line of the birth canal in an effort to assist delivery. It is also cautioned that rocking movements or torque to the cup are not used. The premature infant is a relative contraindication to vacuum application. It is generally advised that no more than three detachments occur before attempts at vacuum extraction are abandoned (Ali and Norwitz, 2009).

In a laboratory experiment, Duchon et al (1988) compared the maximum force at suggested vacuum pressures (550-600 mm Hg) prior to detachments for different types of vacuum devices. They found that the average force of traction exerted before detachments ranged from 18 to 20 kg (Benedetto et al, 2007). This result is interesting to bear in mind when one considers the older data of Wylie who estimated the average tractive force required for delivery of infants weighing 15.95 kg for a primigravida and 11.33 kg for a multipara (Feingold et al, 1988) (Figure 15-2).

The original vacuum device developed in the 1950s by the Swedish obstetrician Dr. Tage Malmström was a disc-shaped stainless steel cup attached to a metal chain for traction. Because of technical problems and lack of experience with this instrument, vacuum devices did not gain popularity in the United States until the introduction of the disposable cups in the 1980s. There are two main types of disposable cups, which can be made of plastic, polyethylene, or silicone. The soft cup is a pliable, funnel- or bell-shaped cup, which is the most common type used in the United States. The rigid cup is a firm mushroom-shaped cup (M cup) similar to the original metal disc-shaped cup and is available in three sizes.

FIGURE 15-2 A soft, bell-shaped vacuum extractor (*top*) and a rigid, mushroom-shaped vacuum extractor (*bottom*). (*Courtesy Cooper Surgical.*)

A metaanalysis of 1375 women in nine trials comparing soft and rigid vacuum extractor cups demonstrated that soft cups were more likely to fail to achieve a vaginal delivery, because of more frequent detachments (OR, 1.65; 95% CI, 1.19 to 2.29), but were associated with fewer scalp injuries (OR, 0.45; 95% CI, 0.15 to 0.60) and no increased risk of maternal perineal injury (Benedetto et al, 2007; Hillier and Johanson, 1994). For example, the risk of scalp laceration with the rigid Kiwi OmniCup (Clinical Innovations, Murray, Utah) was reported to be 14.1% compared with 4.5% using a standard vacuum device ($p = 0.006$). These and other authors concluded that handheld soft bell cups should be considered for more straightforward occiput-anterior deliveries, and that rigid M cups should be reserved for more complicated deliveries, such as those involving larger infants, significant caput succedaneum (scalp edema), occiput-posterior presentation, or asynclitism.

The vacuum extractor is widely used in the United States, but is not free of preventing neonatal injury. Other than superficial scalp lacerations or abrasions, which usually heal without incident, as well as local soft tissue swelling or bruising, the use of the vacuum has been associated with cephalhematoma and subgaleal hemorrhages.

Cephalhematoma occurs when the force created by the vacuum results in the rupture of diploic or emissary vessels between the periosteum and outer table of the skull; this fills the potential space that exists between the two with blood. Although cephalhematomas are often cosmetically alarming, they are limited to traveling along one cranial bone, because the firm periosteal attachments limit further extravasation of blood across suture lines. Thus large amounts of blood cannot usually collect in this space, and serious neonatal compromise from this bleeding is rare. In a randomized trial of continuous and intermittent vacuum application, Bofill examined factors associated with increasing the risk of cephalhematoma; they found that only asynclitism and traction time were independently related to this complication (Hartley and Hitti, 2005). There was a clear relationship between increasing time of vacuum application (up to 6 minutes) and cephalhematoma. Interestingly, Hartley and Hitti did not find a significant independent association of neonatal injury with continuous versus intermittent vacuum, or with decreasing gestational age or increasing birthweight. Furthermore, the number of detachments was not correlated with cephalhematoma. These results were further corroborated by Teng who conducted a prospective observational study of 134 vacuum extractions and found that only increasing total duration of vacuum application was associated with neonatal injury (Feingold et al, 1988). Metaanalysis of randomized trials comparing vacuum to forceps extractions showed that vacuums are more likely to fail to deliver the baby and lead to increased rates of cephalhematoma and retinal hemorrhage (Figure 15-3) (Vacca, 2007).

Subgaleal hemorrhage poses much more of a potential risk for the neonate; it occurs when emissary veins above

the skull and periosteum rupture, with blood dissecting through the loose tissue underlying the cranial aponeurosis, unimpeded by suture lines. A tremendous amount of blood, potentially the entire neonatal blood volume (approximately 250 mL) can fill this space, and thus can significantly compromise the neonate's condition (Hillier and Johanson, 1994). Much of the literature about this rare complication of vacuum extraction was published in the 1970s and early 1980s, with few recent studies to detail associated risk factors. Plauche, in his classic paper on vacuum related neonatal injury, identified only 18 cases of subgaleal hematomas among 14,276 cases of vacuum-assisted births, in contrast to a mean incidence of cephalhematoma of 6% (Keith et al, 1988). These morbidity estimates are derived from data that are approximately 30 to 40 years old; nevertheless, Teng noted an incidence of cephalhematoma of 8%, and 0.7% for subgaleal hemorrhage in their more recent investigation, which agrees well with Plauche's estimates (Herbst and Källén, 2008).

A recent study from Australian investigators evaluated 37 cases of subgaleal hemorrhage at a single tertiary care center accrued over a period of 23 years, with an estimated prevalence of 1.54/10,000 total births. The finding was that this complication occurred most often in primigravidae, and that a large proportion of these infants (89.1% compared with 9.8% of the general control population) had an attempted vacuum extraction (Figure 15-4) (Hillier and Johanson, 1994; Kozak and Weeks, 2002).

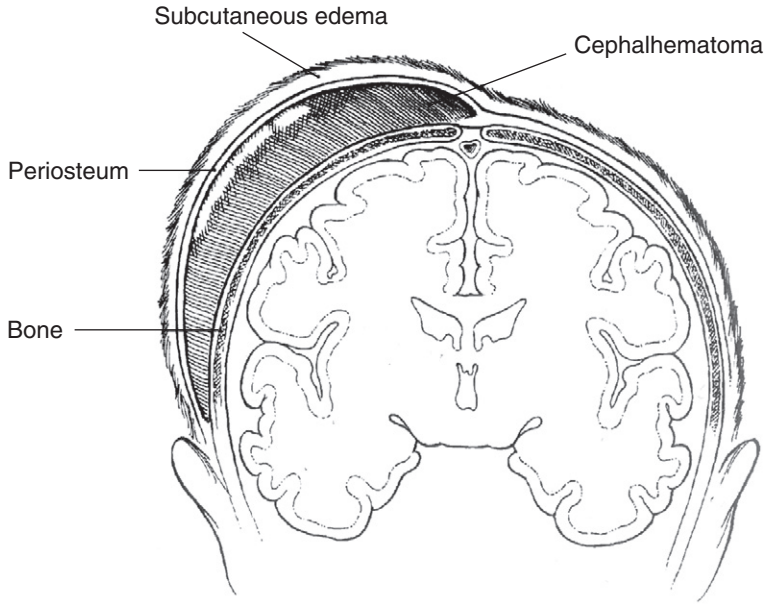

FIGURE 15-3 A cephalhematoma is a hemorrhage that occurs under the periosteum of the skull and is thus confined to a defined space with limited capacity for expansion. (*Adapted from Gilstrap LC, Cunningham FG, Hankins GDV, et al:* Operative obstetrics, *ed 2, Stamford, Conn, 2002, Appleton and Lange.*)

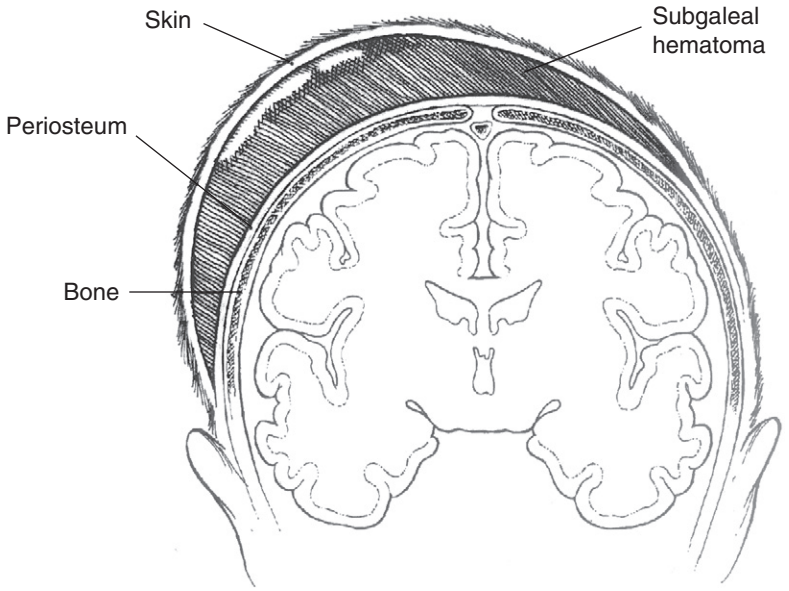

FIGURE 15-4 A subgaleal hematoma spreads along subcutaneous soft tissue planes and has no immediate barrier to expansion, creating the potential for significant neonatal hemodynamic compromise. (*Adapted from Gilstrap LC, Cunningham FG, Hankins GDV, et al:* Operative obstetrics, *ed 2, Stamford, Conn, 2002, Appleton and Lange.*)

It must be kept in mind that the overall neonatal morbidity of the vacuum extractor is low, as ascertained from the large population-based study by Towner showed that the risk of intracranial injury is only 1 in 664 (Learman, 1998). Yet as outlined previously, there are definite neonatal risks associated with the use of vacuum extraction. The U.S. Food and Drug Administration has suggested that infants delivered with the vacuum have close monitoring for subgaleal or subaponeurotic hematoma, and that a high index of suspicion be maintained for this rare complication.

It must be emphasized that the overall risk of adverse events attributable to the vacuum is extremely low, because the U.S. Food and Drug Administration estimated five serious complications per year of recent use during a time period when 228,354 vacuum deliveries were performed. However, it is likely that sequelae related to vacuum extraction often go underreported (Menacker and Martin, 2008).

The choice of which instrument to use, forceps or vacuum, is usually determined by the obstetric care provider depending on the skill level and experience with either method. There have been several randomized trials exploring this issue (Menacker and Martin, 2008, Meniru, 1996; O'Grady et al, 2002; Prapas et al, 2009). The Cochrane Library has pooled the results from 10 randomized trials comparing neonatal morbidity and successful vaginal delivery between these two devices (Roberts et al, 2002). This analysis found that the vacuum was more likely than forceps to fail (OR, 1.69; 95% CI, 1.31 to 2.19), and was associated with a greater likelihood of Apgar scores less than 7 at 5 minutes (OR, 1.67; 95% CI, 0.99 to 2.81), cephalhematoma (OR, 2.38; 95% CI, 1.68 to 3.37), and retinal hemorrhage (OR, 1.99; 95% CI, 1.35 to 2.98). However the overall serious complication rate was low, and there was no difference in long-term morbidity between groups (Johnson and Menon, 2003).

The greatest danger in the use of either vacuum or forceps comes in the combination of both instruments together. Towner showed that the use of one instrument after the other had failed and carried a neonatal intracranial injury risk of 1 per 256, significantly greater than that of either modality alone (Learman, 1998). This finding was further supported by the work of Gardella et al, (2001), who matched 11,223 women (a third of whom had combined instruments, vacuum alone, or forceps alone, respectively) to an equivalent number of spontaneous vaginal deliveries. These investigators found no statistically significant difference in intracranial hemorrhage when a single instrument was compared to spontaneous vaginal delivery; however, the combined use of both instruments markedly increased the risk of intracranial hemorrhage, seizures, and low 5-minute Apgar scores (Ron-El et al, 1981). The overall risk of nerve and scalp injury was greater when single-instrument delivery was compared with spontaneous delivery, but the overall incidence of each complication is rare.

The vacuum extractor is an acceptable instrument if used judiciously and in the proper circumstances, carrying an overall minimal risk of serious neonatal complications. Its safety is comparable to the obstetric forceps, although it has a higher incidence of cephalhematoma, but a lower potential for facial nerve injury. The chance of failure is greater with the vacuum, which could then potentially tempt the health care provider to subsequently use the forceps. The use of both forceps and vacuum after one instrument has failed carries a higher risk of adverse outcomes, and it should be undertaken only with an understanding of the higher likelihood of neonatal morbidity.

SHOULDER DYSTOCIA

Shoulder dystocia is arguably the most dreaded complication in obstetrics. The problem posed by this entity is that although it is highly anticipated, it is unpredictable and can appear despite the most cautious measures taken to prevent it. *Shoulder dystocia* is defined as the delivery of the fetal head with an impaction of the fetal shoulder girdle or trunk against the pubic symphysis, making subsequent delivery either difficult or impossible without performing auxiliary delivery maneuvers. In some cases the posterior shoulder may be lodged behind the sacral promontory—a bilateral shoulder dystocia.

Once shoulder dystocia occurs, a series of maneuvers—which have never been tested in a prospective fashion, because of the sporadic and unpredictable nature of this complication—are used to resolve it. The first step is usually the McRoberts maneuver, which consists of hyperflexing the maternal thighs onto the abdomen. This maneuver flattens the pubic symphysis and sacral promontory and facilitates delivery of both the anterior and posterior shoulders. If unsuccessful, this maneuver is usually followed by suprapubic pressure to remove the anterior shoulder from its impacted state behind the pubic symphysis. If these two maneuvers fail, either rotational maneuvers or extraction of the posterior fetal arm are usually tried. The Woods-Screw maneuver, or the Rubin's rotational maneuver, is used in an attempt to rotate the infant's shoulders in an effort to relieve the impaction of the shoulder against the pubic bone. Alternatively, delivery of the posterior arm can be accomplished by inserting the operator's hand into the vagina and grasping the posterior fetal wrist and guiding it across the fetal chest and through the vaginal introitus. It is often necessary to perform an episiotomy to have sufficient room in the vagina to accomplish this maneuver. An alternative maneuver to fetal manipulation is the all-fours position, or Gaskin maneuver. With this maneuver, the mother is moved from the lithotomy position to a hands and knees position. Next the posterior fetal shoulder, which is now at the 12 o'clock position, is delivered with gentle downward traction. If the dystocia continues unresolved, the Zavanelli maneuver or cephalic replacement can be performed. After the fetal head is rotated from occiput transverse to occiput anterior, it is flexed and pushed back in the birth canal, and the child was delivered by emergent cesarean section. McRoberts maneuver, suprapubic pressure, or both will relieve greater than 50% of instances. Cephalic replacement should be necessary in rare cases. Recent data have focused on enhanced practitioner training for shoulder dystocia by means of simulation. It is estimated that almost 50% of currently practicing obstetric birth attendants have never successfully performed maneuvers other than the McRoberts maneuver and suprapubic pressure. Draycott et al (2008) have published data showing that the annual compulsory training of all attending obstetric physicians

in Southmead Hospital in the United Kingdom reduced the incidence of fetal injury and brachial plexus injury within 3 years of introduction. These data await confirmation in the United States or other countries.

The prevalence of shoulder dystocia varies depending on the population studied and the presence of various risk factors known to predispose women to this obstetric emergency. Estimates range from 0.2% to 1% in a low-risk population to 20% in higher-risk groups (Ali and Norwitz, 2009; Benedetto et al, 2007; Feingold et al, 1988; Hartley and Hittii, 2005; Herbst and Källén, 2008). Maternal obesity, fetal macrosomia, history of prior shoulder dystocia, and maternal diabetes mellitus are the most common associated variables, but are not of sufficient prognostic power to be clinically useful in predicting should dystocia (Ali and Norwitz, 2009; Benedetto et al, 2007; Herbst and Källén, 2008).

Because shoulder dystocia has the potential to cause significant neonatal morbidity and mortality, efforts have been made to predict its occurrence; unfortunately, no clinical guidelines have been clinically tested or proved. Ultrasound examination is commonly used in patients with suspected fetal macrosomia or diabetes to detect large birthweight in infants who might be more likely to suffer shoulder dystocia. Third-trimester sonographic examination has an accuracy of 10% to 15% in the prediction of fetal weight, and is thus not highly reliable (Feingold et al, 1988; Hillier and Johanson, 1994; Keith et al, 1988). In addition, if ultrasound examination were completely reliable, the fetal weight cut-off that would prompt an elective cesarean section has not been determined.

Lipscomb evaluated the deliveries of 227 mother-infant pairs at their institution with birthweights greater than 4500 g and found a shoulder dystocia rate of 18.5%; therefore the majority of those delivering vaginally did so without any adverse event occurring (Hartley and Hitti, 2005). In those with a shoulder dystocia, 51.7% infants had a neurologic injury, but at 2 months, all the infants had a normal neurologic examination. Therefore the occurrence of brachial plexus injury at birth does not necessarily guarantee permanent neurologic morbidity.

This conclusion has been reinforced by several other studies. Gherman et al (2006) reviewed 285 cases of shoulder dystocia and found that 77 (24.9%) suffered fatal injury, most commonly of the brachial plexus (16.8%) or clavicular (9.5%) and humeral (4.2%) fractures. Almost half of the shoulder dystocias resolved with use of the McRoberts maneuver alone; the rest required Woods' maneuver, posterior arm extraction, or the Zavanelli maneuver. The requirement of additional fetal manipulative procedures increased the risk of humeral fracture only and not clavicular or brachial plexus injury. The incidence of permanent musculoskeletal injury was only 1.4% (Kozak and Weeks, 2002).

A prospective investigation evaluated the natural history of recovery following a birth-related brachial plexus injury of infants referred to a tertiary care, multidisciplinary neurological center. Enrollment required identification of injury in the newborn period, initial evaluation at the center between 1 and 2 months of age, and lack of antigravity movement in the shoulder or elbow persisting until 2 weeks of age. In this group of children subject to ascertainment bias (as those injuries resolving before 2 weeks of age would not have been included in the results), complete neurologic recovery was documented in 66%, and only 14% had persistent, severe weakness (Learman, 1998). In the best systematic review of brachial plexus injury to date, the risk of permanent brachial plexus impairment, if recognizable at birth, was 15% to 20% (Pondaag et al, 2004). Rouse et al (1996) elaborated further on these concepts in their decision analysis, which showed that if one chose to perform an elective cesarean section for all women without diabetes and with sonographically predicted macrosomia (estimated fetal weight >4000 g), 2345 cesarean sections would need to be performed to prevent one permanent brachial plexus injury. If the 4500-g cut-off were selected, 50% more cesarean deliveries would be needed to prevent one permanent brachial plexus injury. In the mother with diabetes, if one chose a cut-off of 4500 g or greater, 443 cesareans would need to be done to prevent one permanent injury (Keith et al, 1988)—a tradeoff that most practitioners now believe is acceptable. The conclusions from this decision analysis have been borne out by several other investigators who have established that the risk of nerve injury certainly increases with rising birthweight, but the large number of macrosomic infants who have a normal, spontaneous vaginal delivery without sequelae does not justify a policy of elective cesarean for macrosomia alone in a nondiabetic population (Lipitz et al, Loucopoulos and Jewewicz, 1982; Menacker and Martin, 2008; Meniru, 1996; O'Grady et al, 2002; Pondaag et al, 2004; Roberts et al, 2002).

Therefore at present there is no universally accepted method to prevent shoulder dystocia. Studies have shown that operative vaginal delivery, especially vacuum delivery, of a fetus suspected to have macrosomia either clinically or sonographically could increase the risk of shoulder dystocia (Ron-El et al, 1981). It seems wise to avoid difficult forceps or vacuum delivery if a patient is thought to have an infant weighing more than 4000 g, especially if she has diabetes or a past history of shoulder dystocia. In addition, the ACOG states that "for pregnant women with diabetes who are suspected of carrying macrosomic fetuses, a planned cesarean delivery may be a reasonable course of action, depending on the incidence of shoulder dystocia, the accuracy of predicting macrosomia, and the cesarean delivery rate within a specific population" (Ali and Norwitz, 2009; Benedetto et al, 2007).

The documentation of the events surrounding shoulder dystocia are important, as is the discussion of current status and future status of an infant delivered with a birth injury after shoulder dystocia. Both obstetric and pediatric providers should debrief the shoulder dystocia event immediately after the delivery. In the case of fetal injury, it is optimal for both obstetric and pediatric providers to discuss the delivery events and subsequent newborn treatment plans with the mother before discharge.

VAGINAL BREECH DELIVERY

Three percent to 4% of all infants at term will be in the breech presentation at the time of delivery. There are three main types of breech presentations. The footling breech has one (single footling) or both (double footling) lower extremities presenting. The frank breech has both thighs flexed, but legs extended. The complete breech has both thighs and legs flexed. The vaginal delivery of a singleton

footling breech carries attendant risks of cord prolapse and head entrapment, and the consensus among obstetricians is that this presentation should be delivered operatively (unless the fetus is a second twin, see later discussion on Twin Delivery). The frank breech with buttocks presenting has a lower risk of these adverse events occurring, and thus could potentially deliver vaginally. The complete breech presentation will convert to frank or footling during labor, and the appropriate management scheme for delivery depends on which leading fetal part will descend.

The mechanics of vaginal breech delivery are as follows. The frame of reference for the presenting part is the sacrum (i.e., sacrum anterior, posterior, or transverse). In the absence of urgent fetal indications, the singleton breech is allowed to deliver passively with maternal expulsive efforts until the infant has been delivered past the umbilicus. At this point the legs are gently reduced, and the trunk and body are gently rotated to bring the sacrum anteriorly. With the appearance of the scapula below the maternal symphysis, the arms are then delivered by gently sweeping them across the chest. Every effort is then made to keep the neck from extending during the delivery of the aftercoming head; this is accomplished during delivery of the body by an assistant exerting suprapubic pressure on the fetal head to keep it flexed. Once the body has delivered, the delivery of the head is accomplished by either the Mariceau-Smellie-Veit maneuver, in which one hand extends along the posterior neck and occiput and applies pressure to prevent hyperextension, while the other hand gently applies downward traction against the maxilla to flex the head forward as the head is delivered, or with Piper forceps directly applied to the fetal vertex.

The feasibility of vaginal breech delivery and its safety have been the subject of much debate throughout the past half century. With the advent of safe, expedient cesarean delivery in the United States, many obstetricians have favored the operative approach as the method of choice for management of the breech presentation at term. The literature to support this point of view has produced conflicting conclusions, and its interpretation is consequently difficult. There has been an extensive body of literature over the past half century examining this issue. Unfortunately, there are only two randomized trials that have explored the question of which delivery route is best for the term singleton frank breech fetus (Ali and Norwitz, 2009; Benedetto et al, 2007), but there are several large retrospective series describing neonatal outcomes with the vaginal approach, most of which suggest that vaginal delivery in carefully selected patients carries a low risk of long-term neonatal morbidity and mortality. Diro et al (1999) evaluated 1021 term singleton breech deliveries occurring at their institution over a 4-year period. Infants with a clinically adequate pelvis and frank breech presentation less than 3750 g were allowed a trial of labor. They found an overall cesarean rate of 85.6%; however, for women allowed to deliver vaginally, the success rate, defined as vaginal delivery, was 50% (19 of 38 patients) for nulliparous women and 75.8% (116 of 153 patients) for multiparous women. The length of neonatal intensive care unit (NICU) stay was higher for the group delivered vaginally (17.4% vs. 12.1%; $p = 0.036$), but major morbidities between operative and vaginal delivery were not significantly different (Feingold et al, 1988). Long-term outcome was not evaluated. Of note, the women in this cohort had pelvic dimensions evaluated clinically, and not by x-ray or computed tomography pelvimetry, as has been performed in other studies.

Norwegian investigators examined their similar policy of vaginal breech delivery and evaluated maternal and neonatal outcomes in a large cohort of women (Fang and Zelop, 2006). Patients were allowed a trial of vaginal delivery if they had adequate x-ray pelvimetry, and they were excluded if they had an estimated fetal weight greater than 4500 g or a footling presentation. Each vaginal breech was matched to a term vaginal vertex birth; each cesarean delivery was matched to the appropriate vertex control; 1212 breech deliveries were evaluated, 639 (52.7%) of which were vaginal, 172 (11.4%) were intrapartum cesarean section, and 138 (11.4%) were planned cesarean section. Once major or lethal anomalies and fetal disorders not related to delivery were excluded, there were no perinatal deaths attributable to mode of delivery. When births planned vaginally were compared with operative deliveries, there was an increased risk of 1-minute Apgar score less than 7 and traumatic morbidity in the vaginal group, but no significant differences in NICU admissions, 5-minute Apgar scores, or normal neonatal course. The conclusion reached was that short-term morbidity was worse in the group delivered vaginally, but long-term outcome was similar between groups. It must be remembered, however, that this study was not randomized, and the infants selected for vaginal delivery versus cesarean section were intrinsically different. In addition, all deliveries occurred in a tertiary care institution.

The truly interesting point raised by these investigators is that, aside from the issue of cesarean versus trial of labor, singleton breech infants regardless of mode of delivery have an increased risk of morbidity compared with their vertex counterparts. Breech infants had higher incidences of NICU admissions, eventful courses, hip dislocation, and traumatic morbidity (soft tissue trauma, fracture, facial nerve paralysis, and brachial plexus palsy). Thus both the obstetrician and pediatrician must be aware that the infant in breech presentation requires careful attention upon birth for the presence of these potential factors.

Christian evaluated their policy of offering a trial of vaginal breech delivery to women with an estimated fetal weight between 2000 and 4000 g and having computed tomographic pelvimetry documenting adequate pelvic dimensions (Herbst and Källén, 2008). Of 122 women evaluated, 85 were judged appropriate by these standards for vaginal delivery, of which 81.2% had a successful vaginal delivery. The only indices of neonatal outcome evaluated were the Apgar score, which was not different between groups, and neonatal cord pH, which was lower in a statistically but not clinically significant manner in the vaginal delivery group.

The largest difficulty in interpreting the large number of retrospective studies examining the issue of vaginal breech delivery in the obstetric literature is that even the best designed reports have relatively small numbers of patients, and the possibility of a type II or beta error is high. In addition, the groups being compared (planned cesarean section and vaginal delivery) are different because the patients are not randomized (Herbst and Källén, 2008; Hillier

and Johanson, 1994). Often the women chosen to have a cesarean section tend to have factors that would place their neonates at higher risk than those allowed a trial of labor. A metaanalysis evaluating seven cohort studies and two randomized trials compared 1825 trial of labor patients to 1231 elective cesarean patients and found a statistically significant, but clinically questionable, increased risk with vaginal breech delivery of 1.10% (Keith et al, 1988).

There is a paucity of randomized trials to specifically address the role of the vaginal breech delivery in modern obstetrics. Collea et al randomized 208 women with a singleton frank breech presentation at term to vaginal delivery or cesarean section; they found a low overall risk of permanent birth injury or neonatal morbidity in the vaginal delivery group, although the incidence of neonatal morbidity was higher in the vaginal delivery group (Ali and Norwitz, 2009). Of note, a majority of conditions listed as morbidities (hyperbilirubinemia, meconium aspiration, mild brachial plexus injury) had resolved by hospital discharge. In addition, decreased neonatal morbidity with cesarean section was offset by a striking increase in higher maternal risk in the operative group. It must be remembered that this study was published in 1979, and standards of maternal and neonatal care have changed dramatically since then. Until 2001, no additional randomized investigations were available to settle the long raging debate of the optimal mode of delivery for term singleton breech.

This controversy has recently been clarified by a large, multicenter, multinational trial that randomized 2088 women at 121 centers in 26 countries to planned vaginal birth or planned elective cesarean section (Benedetto et al, 2007). Criteria for enrollment were frank or complete term singleton breech with no evidence of fetal macrosomia. The investigation was halted when preliminary results showed that there was significantly increased neonatal mortality and severe morbidity in the vaginal breech arm compared with the cesarean arm (5.0% vs. 1.6%). This conclusion was not altered by the experience of the delivering obstetrician or maternal demographic factors such as parity and race. Maternal morbidity between both groups was comparable. The difference in outcome was even more striking in countries, such as the United States, with a low national perinatal mortality rate (5.7% vs. 0.4%).

Criticisms of this study are that patients enrolled did not have computed tomography pelvimetry performed, which in some institutions is standard practice before considering a vaginal breech delivery. Furthermore, subjects did not have continuous fetal monitoring, but rather intermittent fetal auscultation every 15 minutes. In addition, the capability of various centers to perform emergent cesarean sections differs markedly, and this could have potentially affected the neonatal morbidity and mortality rate. Nevertheless, it is unlikely that another large study will ever be performed to examine this issue again, and the ultimate results are difficult to dispute given the excellent study design and adequate sample size. Indeed the ACOG recently issued a statement that "planned vaginal delivery of a term singleton breech may no longer be appropriate … patients with a persistent breech presentation at term in a singleton gestation should undergo a planned cesarean delivery" (Kozak and Weeks, 2002). As will be discussed later in Multifetal Delivery, this statement does not apply to the vaginal delivery of a nonvertex second twin.

The delivery of the vaginal breech is also an emotional issue; physicians trained in the art of the vaginal breech delivery maintain that for an appropriately selected candidate, vaginal breech delivery has acceptable neonatal risk and has the advantage of sparing the mother significant operative morbidity. Proponents of cesarean delivery further state that the level of resident training in the art of the singleton vaginal breech delivery has markedly diminished, with most graduating senior residents having performed few such births. Nonetheless, many practitioners will be required to assist in vaginal birth of a breech infant in unplanned situations. The acquisition of skills necessary to competently perform this procedure may need to be learned and practiced with simulation-based training, because the opportunities for training in most residency programs are few.

MULTIFETAL DELIVERY

With the advent of in vitro fertilization and the sophisticated assisted reproductive technologies (ARTs), the incidence of multifetal pregnancies has dramatically increased, particularly higher-order multiples. The incidence of twin gestations in patients undergoing in vitro fertilization is currently more than 30%, and it is 1% to 3% in higher-order multiples. As a result, the frequency of twin gestation in the United States has increased 65% since 1980; twins now account for 3% of births. Of these, 80% are dizygotic and 20% are monozygotic. This 3% of births accounts for 17% of preterm births and approximately 25% of infants of low birthweight and very low birthweight. The perinatal mortality rate of twins is sevenfold that of singletons, of which a small fraction is due to problems during labor and at delivery. The mode of delivery for twins is well delineated by several studies, and the issues surrounding the choice of vaginal birth versus cesarean is outlined in the following sections (Smith et al, 2005).

TWIN DELIVERY

Vertex-Vertex

It is almost universally accepted that the appropriate method of delivery is vaginal if both twins are vertex. The first infant is delivered like a singleton infant. The second infant is delivered in a similar fashion, but care must be taken not to rupture membranes before the head is well engaged, because this may increase the risk of cord accident. Of note, the delivery of the second twin does not necessarily occur immediately after the first.

Vertex-Nonvertex

The first twin is usually delivered vaginally. The options for delivery of the second twin are as follows: cesarean section, breech extraction, or attempts at external cephalic version and vertex delivery of the second twin if successful. The subject of the optimal delivery choice for the second twin has been the subject of much controversy. Many obstetricians claim that cesarean section is the safest approach

to the nonvertex twin, whereas others claim that vaginal delivery affords equivalent neonatal outcome, sparing the mother from an unnecessary surgical procedure (Usta et al, 2005). Fortunately there is a large body of evidence in the literature addressing these issues.

If the vaginal approach is chosen, once the first twin is delivered the obstetrician inserts a hand into the uterine cavity and, under sonographic guidance if necessary, finds the feet of the second twin. Once the feet are firmly grasped, they are brought down into the vagina, and the membranes are then ruptured. Traction is applied to the fetus along the pelvic curve; once the body has been delivered through the introitus, delivery of the arms, shoulders, and aftercoming head proceed in a fashion similar to that of a singleton breech.

In 2003, Hogle et al performed a metaanalysis to determine whether a policy of planned cesarean or planned vaginal birth is preferable for twins. They found only four studies with a total of 1932 infants met their inclusion criteria. There were no significant differences in maternal morbidity, perinatal or neonatal mortality, or neonatal morbidity between the two groups. They did find significantly fewer low 5-minute Apgar scores in the planned cesarean group, principally because of a reduction among breech first twins. They concluded that, if twin A is vertex, "there is no evidence to support planned cesarean section for twins." In contrast, Smith et al (2005) published a retrospective cohort study of 8073 twin births after 36 weeks of gestation in Scotland between 1985 and 2001. There was a death of either twin in two of 1472 (0.14%) deliveries by planned cesarean and in 34 of 6601 (0.52%) deliveries by other means ($p = 0.05$; OR for planned cesarean, 0.26; 95% CI, 0.03 to 1.03). They concluded that planned cesarean may reduce the risk of perinatal deaths of twins at term by 75% despite the lack of statistical significance in outcomes between the two groups. The data also suffer from the fact that 30 of the 36 deaths were in second twins, and there were no data regarding fetal presentation (Smith et al, 2004).

There are several large cohort studies examining the issue of feasibility and safety of total breech extraction of the nonvertex second twin. These studies have almost unanimously reached the similar conclusion that the neonatal outcome for nonvertex second twins delivered vaginally is similar to the vertex first twin, but is not statistically different from those second twins delivered by cesarean section, regardless of birthweight or gestational age (Ali and Norwitz, 2009; Benedetto et al, 2007; Feingold et al, 1988; Hartley et al, 2005; Herbst and Källén, 2008; Hillier and Johanson, 1994; Keith et al, 1988). Hartley et al (2005) conducted a retrospective analysis of birth certificates and fetal and infant death certificates for 5138 twin pairs selected from those born in Washington State from 1989 to 2001. They concluded that if prompt vaginal delivery of twin B does not occur, the benefits of vaginal delivery for twin A might not outweigh the risks of distress and low Apgar scores in twin B and vaginal plus cesarean delivery for the mother (Hartley and Hitti, 2005).

Although there are several retrospective studies evaluating the outcome of vaginally born nonvertex second twins, there is only one randomized trial (Hillier and Johanson, 1994). Rabinovici et al (1987) allocated 60 women with vertex-nonvertex twins to either operative or vaginal delivery. Maternal morbidity and hospital stay were increased in the surgical group, but there were no differences in neonatal outcome. In addition, Acker et al (1982) retrospectively reviewed 150 nonvertex second twins of all birthweights, 74 delivered by cesarean and 76 by breech extraction, and they found no mortality in either group and a 3.9% incidence of low Apgar scores in the breech extraction group, which was no different from that in the cesarean group. Chervenak et al (1986) reviewed 76 breech extractions for second twins, found no morbidity or mortality in the 60% weighing more than 1500 g, and concluded "for birthweights >1500 gm, routine cesarean for vertex/nonvertex twins may not be necessary."

The available body of evidence supports attempts at vaginal delivery of the nonvertex second twin. Of course the responsible obstetrician must choose a management plan most compatible with his or her experience and training. For those not versed in the techniques of successful vaginal breech extraction, cesarean delivery might be a more prudent plan. As in the case of the singleton vaginal breech, simulation training may play a role in the acquisition and maintenance of skills for safe vaginal breech birth.

In addition to abdominal delivery and total breech extraction, there is the option of external cephalic version (i.e., attempting to turn a nonvertex fetus to vertex by abdominal manipulation). Studies have shown that this option is associated with a higher failure rate at successful vaginal delivery and other complications (such as cord accidents and malpresentations not amenable to vaginal delivery) when compared with primary breech extraction or cesarean section (Hillier and Johanson, 1994; Learman, 1998).

Nonvertex-Nonvertex

Because of to the theoretical risk of interlocking twins, as well as the recent data showing the greater morbidity for the singleton vaginal breech (see the preceding discussion), cesarean section is the recommended choice for delivery of the nonvertex-nonvertex presentation.

Monochorionic, Monoamniotic Twins

Monochorionic, monoamniotic twins share a single intraamniotic space, and thus have a higher risk of cord and extremity entanglement during the course of delivery. It is commonly accepted that the optimal mode of delivery is a planned cesarean section before labor ensues.

HIGHER-ORDER MULTIPLE GESTATIONS

Most perinatologists would suggest cesarean delivery for triplets and higher-order multiples (Lipitz et al, 1989). Although this practice is common, the data mandating operative delivery are far from conclusive.

A Dutch study compared the outcomes of triplets delivered vaginally and abdominally at two institutions (Learman, 1998). One hospital favored cesarean section, whereas at another trial of labor was offered to all appropriate candidates. The success of vaginal delivery was relatively high (34 of 39 women [87%]). There was a higher incidence of neonatal mortality and postdelivery depression (as estimated by Apgar score) in the hospital favoring operative

delivery compared with the vaginal delivery group. The biases inherent in this study are obvious, although the reported findings have been corroborated by several other reports from single institutions that offer trial of vaginal delivery to triplet gestations (Menacker and Martin, 2008; Meniru, 1996; O'Grady et al, 2002). Vintzileos et al (2005) attempted to estimate the risks of stillbirth and neonatal and infant deaths in triplets, according to mode of delivery; they used the "matched multiple birth" data file that was composed of triple births that were delivered in the United States during 1995 through 1998 and found that 95% of all triplets were delivered by cesarean delivery. Vaginal delivery (all vaginal) was associated with an increased risk for stillbirth (relative risk, 5.70; 95% CI, 3.83 to 8.49) and neonatal (relative risk, 2.83; 95% CI, 1.91 to 4.19) and infant (relative risk, 2.29; 95% CI, 1.61 to 3.25) deaths. They concluded that cesarean delivery of all three triplet fetuses is associated with the lowest neonatal and infant mortality rate and that vaginal delivery among triplet gestations should be avoided (Vintzileos et al, 2005). Most of the data on triplet births consists of small cohort studies and not randomized trials, and the possibility of type II or beta errors exists in the interpretation of many of these studies (Feingold et al, 1988; Keith et al, 1988). Thus delivery of triplet gestations vaginally while not an unreasonable approach has nearly disappeared from the practice of modern obstetrics in favor of routine cesarean delivery. Currently quadruplets and other higher-order multiples are usually delivered by cesarean section (Ron-El et al, 1981).

VAGINAL BIRTH AFTER CESAREAN: NEONATAL ISSUES

Cesarean section accounts nationally for one quarter of all deliveries (Ali and Norwitz, 2009). Surgery carries the maternal risks of increased blood loss, prolonged hospital stay, and longer recovery period compared with vaginal delivery. During the 1980s to 1990s, efforts were made to encourage women to attempt vaginal birth after a prior cesarean delivery, because success rates vary from 60% to 80% for vaginal delivery, dependent on the indications for the prior cesarean delivery (Benedetto et al, 2007). Whereas VBAC rates remain relatively high in the United Kingdom at 33% (range, 6% to 64%), the rates are decreasing rapidly in the United States from a high rate of 28.3% in 1996 to less than 10 per 1000 deliveries in 2006 (Caughey, 2009; Fang and Zelop, 2006). This decrease occurred primarily because VBAC can result in uterine dehiscence, in which the prior scar asymptomatically separates or, more seriously, uterine rupture occurs. This decrease has significantly affected the United States cesarean section rate of 31.1% (Caughey, 2009; Fang and Zelop, 2006). A full discussion of VBAC, studies supporting its safety, and controversies surrounding its feasibility is beyond the scope of this chapter, and the interested reader is urged to consult *Williams Obstetrics*, ed 23, for further details. This discussion instead focuses on neonatal risks from VBAC, particularly from its most dreaded complication, uterine rupture.

Studies have uniformly shown a risk of uterine rupture with VBAC on the order of 0.5% to 1% (Benedetto et al, 2007; Caughey, 2009; Feingold et al, 1988). A recent large, retrospective study evaluated 20,095 women with a history of prior cesarean delivery and found that rupture risk was 0.16% if the woman elected a repeated, elective operative delivery; 0.52% if VBAC occurred as a result of spontaneous labor; 0.77% if labor was induced without prostaglandins; and 2.5% if labor was induced with prostaglandins (Feingold et al, 1988). Thus VBAC carries the lowest risk if labor is spontaneous and not augmented.

There are few large, well-designed studies specifically evaluating neonatal rather than maternal outcomes in VBAC. Most recently, Kamath et al (2009) performed a retrospective cohort study of 672 women with one prior cesarean section undergoing trial of labor. They found that infants born by cesarean delivery had higher rates of admission to the NICU (9.3% compared with 4.9%) and higher rates of oxygen supplementation for delivery room resuscitation (41.5% compared with 23.2).

Yap retrospectively evaluated 38,027 deliveries occurring at a single tertiary care institution and found 21 cases of uterine rupture; 17 occurred after a history of a prior cesarean delivery (Herbst and Källén, 2008). The two neonatal deaths that occurred were a result of prematurity (23-week-old fetus) and multiple congenital anomalies; all live born infants were discharged from the hospital without neurologic sequelae. Thus the ultimate neonatal outcome despite uterine rupture was favorable. However, all deliveries occurred in a tertiary care institution with readily available obstetric anesthesiologists, neonatologists, and obstetricians. Most deliveries after diagnosis of rupture occurred within 26 minutes.

A third group of investigators retrospectively identified 99 cases of uterine rupture occurring over a period including 159,456 births (Hillier and Johanson, 1994). Thirteen of these ruptures occurred before the onset of labor. There were six neonatal deaths, but four of these occurred in women with uterine rupture at admission, and thus were never given a trial of labor. There were five cases of perinatal asphyxia, but once again it is not detailed whether these occurred in women allowed a trial of labor or in those who had ruptured on presentation to the hospital. Moreover, many of these women had an undocumented prior scar, which in some institutions would warrant an elective repeated cesarean section. The aforementioned recent study evaluating 20,095 women with a prior cesarean delivery and their subsequent risk of rupture found a neonatal mortality of 5.5% (Feingold et al, 1988). However, because this was a population based study, it was not specified whether these deliveries occurred in tertiary care institutions with the capability of performing emergent operative rescue procedures in the event of uterine rupture.

Finally Fang et al (2006) reviewed all of the literature to date in regard to adverse neonatal outcomes and found that the combined rates of intrapartum stillbirth and neonatal death were not statistically different between trial of labor and those who elected for repeated cesarean section. Thus the true neonatal risk of VBAC, especially in the event of uterine rupture, cannot be precisely estimated at the current time. There are no studies adequately evaluating long-term outcomes of surviving infants after uterine rupture (Fang and Zelop, 2006).

It appears that the risk of uterine rupture after a prior cesarean delivery is low, but this risk increases when labor is augmented with oxytocin or prostaglandins. It is appropriate to offer women VBAC, but they must be counseled carefully about the potential risk of uterine rupture. Careful documentation of the informed consent and labor management must be completed. Moreover, VBAC should ideally occur in a tertiary care institution or in facilities capable of rapidly performing an emergent cesarean section, because this improves the likelihood of minimizing adverse neonatal sequelae.

CORD ACCIDENTS

The term *cord accident* usually refers to adverse events affecting the fetus that occur as a result of a problem with the umbilical cord. This heterogeneous term encompasses umbilical cord prolapse, in which the cord delivers through the cervix and compression by a fetal part results in a significantly increased risk of asphyxia; it also includes such entities as cord entanglements or "true knots," which can lead to fetal compromise.

The incidence of such events is not clearly known, because the diagnosis is often one of exclusion. One large population-based study compared 709 cases of cord prolapse occurring among 313,000 deliveries to matched controls and found that low birthweight, male sex, multiple gestations, breech presentation, and congenital anomalies all increased the risk of umbilical cord prolapse (Ali and Norwitz, 2009). Not surprisingly, cord prolapse was associated with a high mortality rate (10%) that was reduced if cesarean rather than vaginal delivery was performed.

The standard of care in cases of cord prolapse is to proceed immediately with cesarean section as quickly as possible while an assistant elevates the presenting fetal part with a vaginal hand to prevent compression of the umbilical cord. It is also of paramount importance to have appropriate pediatric support available at the time of delivery, because the newborn is likely to be depressed and require resuscitation.

Cord accident, or in utero compromise, secondary to entanglement of the umbilical cord as a clinical entity is difficult to understand. Often in cases of in utero fetal demise (IUFD), a diagnosis or cause of fetal death is never found. It is tempting to attribute the demise to an event that compromises umbilical blood flow to the developing pregnancy. The literature on this subject is scarce. Hershkovitz et al (2001) identified 841 cases of true knots from a population of 69,139 deliveries (for a prevalence of 1.2%) and in a case-controlled study found that grand multiparity (>10 deliveries), chronic hypertension, history of genetic amniocentesis, male gender, and umbilical cord prolapse were all independently associated with true knots of the umbilical cord. The presence of a true knot was associated with both in utero fetal demise and greater likelihood of cesarean delivery (Figure 15-5) (Benedetto et al, 1994).

FIGURE 15-5 *(See also Color Plate 2.)* A 28-year-old woman was admitted to the labor and delivery department with an intrauterine demise. Examination of the fetus shows the cord wrapped tightly around the torso, leg, and ankle, suggesting cord accident as a cause of death. No other pathologic abnormalities were found on autopsy. (*Courtesy Thomas R. Easterling.*)

CHAPTER 16

Obstetric Analgesia and Anesthesia

Mark D. Rollins and Mark A. Rosen

This chapter introduces some of the scientific background and clinical techniques used in providing obstetric analgesia and anesthesia. These practices provide substantial benefit to the patient in labor and are essential for operative delivery. Although the effects of obstetric analgesia and anesthesia on the fetus and neonate are typically benign, there is potential for significant neonatal effects.

HISTORY OF OBSTETRIC ANESTHESIA

Modern obstetric anesthesia began in Edinburgh, Scotland, on January 19, 1847, when the professor of obstetrics James Young Simpson used diethyl ether to facilitate child delivery by anesthetizing a woman with a contracted pelvis. Morton's historic demonstration of the anesthetic properties of ether at the Massachusetts General Hospital in Boston had occurred only 3 months earlier. Fanny Longfellow, wife of Henry Wadsworth Longfellow, was the first American to receive anesthesia for childbirth, publicly proclaiming in 1847, "This is certainly the greatest blessing of this age" (Longfellow and Wagenknecht, 1956).

Although anesthesia for surgery was rapidly and widely accepted, most of Simpson's contemporaries in the United States, France, and England were critical of using anesthesia in obstetrics, presenting both medical and religious arguments in outspoken opposition. However, the public outcry in support of labor analgesia was vehement. In 1853, the negative reaction from Thomas Wolsley, editor of *The Lancet*, after John Snow administered ether for Queen Victoria's eighth child was so strong that court physicians denied anesthesia had been used. The great debate was largely settled 4 years later when Victoria delivered her ninth and last child, and the use of a royal anesthetic was acknowledged. Although many physicians had remained opposed, public opinion had changed and women were requesting labor analgesia from their doctors.

During the second half of the twentieth century, anesthesiologists made significant advances in techniques and improved safety for delivering labor analgesia. Hingson and Edwards (1943) developed the continuous caudal catheter that preceded development of the epidural catheter. Apgar (1953) initially proposed a simple neonatal scoring system as a guide for evaluating the effects of obstetric anesthesia and later as a guide for neonatal resuscitation. Other early pioneers in the emerging specialty of obstetric anesthesia were Gertie Marx (Marx and Orkin, 1958), John Bonica (1967), and Sol Shnider et al (1963). These pioneers helped to characterize the normal changes in maternal physiology related to pregnancy, confirm the safety and efficacy of obstetric analgesia, determine the effects of these techniques on uterine blood flow and placental transfer of anesthetic agents, and evaluate the effects of these techniques and agents on newborn well-being.

ANATOMY OF LABOR PAIN

Contraction of the uterus, dilatation of the cervix, and distention of the perineum cause pain during labor and delivery. Somatic and visceral afferent sensory fibers from the uterus and cervix travel with sympathetic nerve fibers to the spinal cord (Figure 16-1). These fibers pass through the paracervical tissue and course with the hypogastric nerves and the sympathetic chain to enter the spinal cord at T10 to L1. During the first stage of labor (cervical dilation), the majority of painful stimuli are the result of afferent nerve impulses from the lower uterine segment and cervix, as well as contributions from the uterine body causing visceral pain (poorly localized, diffuse, and usually described as "a dull but intense aching"). These nerve cell bodies are located in the dorsal root ganglia of levels T10 to L1. During the second stage of labor (pushing and expulsion), afferents innervating the vagina and perineum cause somatic pain (well localized and described as "sharp"). These somatic impulses travel primarily via the pudendal nerve to dorsal root ganglia of levels S2 to S4. Pain during this stage is caused by distention and tissue ischemia of the vagina, perineum, and pelvic floor muscles, associated with descent of the fetus into the pelvis and delivery. Neuraxial analgesic techniques that block levels T10 to L1 during the first stage of labor must be extended to include S2 to S4 for efficacy during the second stage of labor.

Labor pain can have significant physiologic effects on the mother, fetus, and the course of labor. Pain stimulates the sympathetic nervous system, elevates plasma catecholamine levels, creates reflex maternal tachycardia and hypertension, and reduces uterine blood flow. In addition, changes in uterine activity can occur with the rapid decrease in plasma epinephrine concentrations associated with onset of neuraxial analgesia. Oscillations in epinephrine can result in a range of uterine effects from a transient period of uterine hyperstimulation (Clarke et al, 1994) to a transient period of uterine quiescence, or conversion of dysfunctional uterine activity patterns associated with poorly progressive cervical dilation to more regular patterns associated with normal cervical dilation (Leighton et al, 1999).

CHANGES IN MATERNAL PHYSIOLOGY AND THE IMPLICATIONS

During pregnancy, labor, and delivery, women undergo fundamental changes in anatomy and physiology. These alterations are caused by changing hormonal activity, biochemical shifts associated with increasing metabolic demands of a growing fetus, placenta, and uterus, and mechanical displacement by an enlarging uterus (Cheek and Gutsche, 2002; Parer et al, 2002).

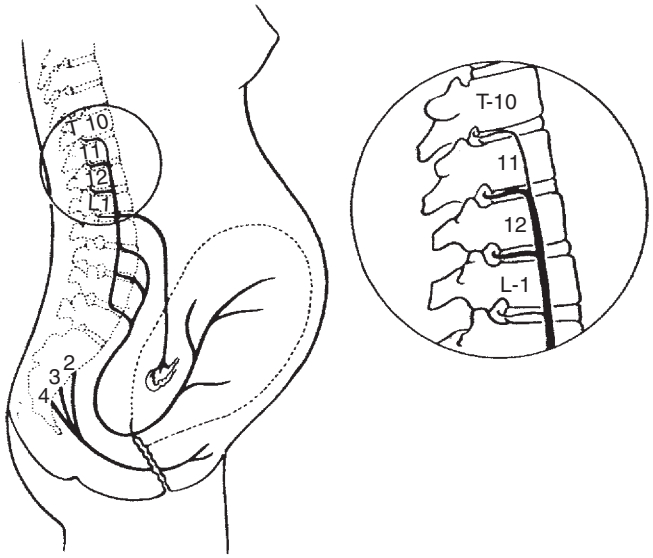

FIGURE 16-1 Parturition pain pathways. Nerves that accompany sympathetic fibers and enter the neuraxis at the *T10*, *T11*, *T12*, and *L1* spinal levels carry afferent pain impulses from the cervix and uterus. Pain pathways from the perineum travel to *S2*, *S3*, and *S4* via the pudendal nerve. (*From Bonica JJ:* Principles and practice of obstetric analgesia and anesthesia, *Philadelphia*, *1967*, *F.A. Davis Co.*)

MATERNAL CIRCULATORY SYSTEM

Hypotension can occur when a pregnant woman is in the supine position because of compression of the vena cava by the gravid uterus. Significant aortoiliac artery compression occurs in 15% to 20% of parturients and vena caval compression is universal, often as early as 13 to 16 weeks' gestation. Vena caval compression contributes to lower extremity venous stasis and can cause ankle edema and varices despite increased collateral circulation. Venous compression by the gravid uterus diverts some blood returning from the lower extremities through the internal vertebral venous plexus, the azygos, and the epidural veins. This increases the likelihood of entering an epidural vein with spinal or epidural anesthetic techniques. Anesthetic interventions that diminish sympathetic tone can further exacerbate the effects of vena caval compression induced by supine positioning, potentially causing profound hypotension. Therefore supine positioning is avoided during anesthetic administration in the second and third trimesters. Significant lateral tilt is used in all operative deliveries and frequently during labor analgesia to help preserve uterine blood flow and fetal circulation.

Cardiac output increases during pregnancy, reaching an output 50% greater than the prepregnant state by the third trimester. During labor, maternal cardiac output increases during the first and second stages, reaching an additional 40% above prelabor values in the second stage (Robson et al, 1987). Each uterine contraction results in the autotransfusion of 300 to 500 mL of blood back into the maternal central circulation. The greatest increase in cardiac output occurs immediately after delivery, when values can increase as much as 75% above predelivery levels. This abrupt increase in cardiac output is secondary to the loss of aortocaval compression, autotransfusion from the contracted uterus, and decreased venous pressure in the lower extremities (Kjeldsen, 1979).

Physiologic (dilutional) anemia of pregnancy occurs as a result of a greater increase in plasma volume (45%) than in red blood cell volume (20%) at term. Average blood loss at delivery—Approximately 500 mL for vaginal delivery and 1000 mL for cesarean section—is well tolerated because of this expanded blood volume and autotransfusion (normally in excess of 500 mL) from the contracted uterus after delivery (Cheek and Gutsche, 2002).

MATERNAL AIRWAY AND RESPIRATORY SYSTEMS

During pregnancy, the maternal airway has significantly increased mucosal edema and tissue friability throughout the pharynx, larynx, and trachea. These changes make laryngoscopy and intubation more challenging. In addition, the presence of comorbidities such as preeclampsia, upper respiratory tract infections, and the active pushing and increased venous pressure during the second stage further exacerbate airway tissue edema (Munnur et al, 2005).

At term, minute ventilation is increased approximately 50%, oxygen consumption is increased by more than 20%, and functional residual capacity is decreased by 20%. The combination of these changes (increased oxygen consumption and decreased oxygen reserve) results in a state promoting rapid desaturation during periods of apnea. The changes in both airway and respiratory physiology during pregnancy make ventilation and intubation more difficult and increase the potential for complications.

MATERNAL GASTROINTESTINAL SYSTEM

The gravid uterus displaces the stomach cephalad and anterior and the pylorus cephalad and posterior. These changes reposition the intraabdominal portion of the esophagus into the thorax and result in decreased competence of the esophageal sphincter. Higher progesterone and estrogen levels further reduce esophageal sphincter tone. Gastric pressure is increased by the gravid uterus and by the lithotomy position used during vaginal delivery. Maternal gastric reflux symptoms increase with the gestational age of the pregnancy and ultimately affect the majority of parturients (Marrero et al, 1992).

Beyond midgestation, women are at increased risk for pulmonary aspiration of acidic gastric contents; this is caused by decreased tone and competence of the lower esophageal sphincter as well as delayed gastric emptying with onset of labor or administration of opioids. This risk has important implications for induction of general anesthesia and airway management by the anesthesiologist, and it is discussed in detail under General Anesthesia.

UTERINE AND FETAL CIRCULATION

Uterine weight and blood flow increase throughout gestation from approximately 100 mL/min before pregnancy to approximately 700 mL/min (10% of cardiac output) at term gestation, with 50% to 80% of the uterine blood flow perfusing the intervillous space (placenta) and 20% to 50% supporting the myometrium. Uterine vasculature has limited autoregulation and remains (essentially) maximally dilated under normal conditions during pregnancy.

Maternal uterine blood flow decreases as a result of either decreased uterine arterial perfusion pressure or increased arterial resistance. Decreased perfusion pressure can result from systemic hypotension secondary to hypovolemia, aortocaval compression, or significant decreases in vascular resistance from the initiation of neuraxial anesthesia or induction of general anesthesia. Uterine perfusion pressure can also decrease from increased uterine venous pressure associated with vena caval compression (e.g., supine position), uterine contractions (particularly uterine hypertonus by oxytocin hyperstimulation), or significant increase in intra-abdominal pressure (pushing during second stage or seizure activity). Stress-induced endogenous catecholamines and exogenous vasopressors can increase uterine artery resistance and decrease uterine blood flow. Despite these potential effects, phenylephrine (alpha-adrenergic) is useful for treating maternal hypotension secondary to neuraxial anesthesia, and it has been demonstrated to result in less fetal acidosis and base deficit compared to treatment with ephedrine (primarily beta-adrenergic) in many clinical trials (Lee et al, 2002a; Ngan Kee et al, 2009; Smiley, 2009).

ANALGESIC OPTIONS FOR LABOR AND VAGINAL DELIVERY

The pain of labor is highly variable and described by many women as severe. Factors influencing the patient's perception of labor pain include duration of labor, maternal pelvic anatomy in relation to fetal size, use of oxytocin, parity, participation in childbirth preparation classes, fear and anxiety about childbirth, attitudes about and experience of pain, and coping mechanisms. Labor analgesia prevents autonomic reflex effects that can be deleterious for certain high-risk patients and their fetuses (e.g., patients with severe preeclampsia, valvular heart disease, myasthenia gravis). The American College of Obstetricians and the American Society of Anesthesiologists issued a joint statement indicating that a maternal request for pain relief is sufficient justification for administration of analgesics during labor (American College of Obstetricians and Gynecologists, 2002). Although older observational studies associate increased cesarean delivery rates with early administration of epidural analgesia, more recent randomized studies found no difference in the rate of cesarean delivery or instrument-assisted vaginal delivery between women in whom analgesia was initiated early in labor versus later (Eltzschig et al, 2003; Wong et al, 2005). Consequently the American Society of Anesthesiology stated in its 2007 Practice Guidelines, "Neuraxial analgesia should not be withheld on the basis of achieving an arbitrary cervical dilation, and should be offered on an individualized basis. Patients may be reassured that the use of neuraxial analgesia does not increase the incidence of cesarean delivery" (American Society of Anesthesiologists Task Force on Obstetric Anesthesia, 2007).

The choice of analgesic method resides primarily with the patient. The medical condition of the parturient, stage of labor, urgency of delivery, condition of the fetus, and availability of qualified personnel are also factors. Many different techniques are available to alleviate labor and delivery pain. *Analgesia* refers to pain relief without loss of consciousness; *regional analgesia* denotes partial sensory blockade in a specific area of the body, with or without partial motor blockade. *Regional anesthesia* is the loss of sensation, motor function, and reflex activity in a limited area of the body. *General anesthesia* results in the loss of consciousness and the goals for providing general anesthesia typically include hypnosis, amnesia, analgesia, and skeletal muscle relaxation.

BOX 16-1 Techniques for Labor Analgesia

- Nonpharmacologic analgesia
- Systemic medications
  - Opioid analgesics
  - Sedatives and anxiolytics
  - Dissociative analgesics
- Inhalation analgesia
- Regional analgesia
  - Epidural
  - Spinal
  - Combined spinal-epidural
  - Paracervical block
  - Pudendal block

Techniques for labor analgesia must be safe for mother and fetus and individualized to satisfy the analgesic requirement and desires of the parturient; they also must accommodate the changing nature of labor pain and the evolving, varied course of labor and delivery (e.g., spontaneous vaginal delivery, instrumentally assisted vaginal delivery, and cesarean delivery). The current approaches to pain relief are outlined in Box 16-1.

NONPHARMACOLOGIC ANALGESIA

There is a variety of nonpharmacologic techniques for labor analgesia. These techniques include hypnosis, the breathing techniques described by Lamaze, acupuncture, acupressure, the LeBoyer technique (LeBoyer, 1975), transcutaneous nerve stimulation, massage, hydrotherapy, vertical positioning, presence of a support person, intradermal water injections, and biofeedback. A metaanalysis reviewing the effectiveness of a support individual (e.g., doula, family member) noted that parturients with a support individual used fewer pharmacologic analgesia methods, had a decreased length of labor, and had a lower incidence of operative deliveries (Hodnett et al, 2007). In a 2006 retrospective national survey of women's childbearing experiences, although neuraxial methods of pain relief were rated as the most helpful and effective, nonpharmacologic methods of tub immersion and massage were rated more or equally helpful in relieving pain compared with the use of opioids (Declercq et al, 2006). Although many nonpharmacologic techniques seem to reduce labor pain perception, most studies lack the rigorous scientific methodology for the useful comparison of these techniques to pharmacologic methods.

SYSTEMIC MEDICATIONS

Systemic medications for labor and delivery are widely used, but are administered with limitations on both dose and timing because they readily cross the placenta and are

associated with a risk of neonatal respiratory depression in a dose-dependent fashion. Although the use of systemic opioid analgesics is common (e.g., fentanyl, meperidine, morphine, nalbuphine, butorphanol), the use of sedatives and anxiolytics (e.g., barbiturates, phenothiazine derivatives and benzodiazepines), and dissociative agents (e.g., ketamine, scopolamine) is rare.

Opioid Analgesics

Opioids are the most frequently used systemic analgesic, but for many patients opioids do not provide adequate analgesia during labor and delivery (Bricker and Lavender, 2002; Olofsson et al, 1996). Opioids are inexpensive, easy to administer, and do not require a trained anesthesia provider. However, they have a high rate of maternal side effects (sedation, respiratory depression, dysphoria, nausea, pruritus), can decrease fetal heart rate variability and fetal movements, and carry a potential risk of neonatal respiratory depression and changes in neurobehavior. Systemic administration of opioids at doses that are safe for mother and newborn provides some analgesia, but it is not a substitute for the analgesia provided by regional techniques. Systemic opioids are recommended for administration in the smallest doses possible with minimization of repeated dosing to reduce the accumulation of drug and metabolites in the fetus. Systemic opioids are most useful for patients with minimal pain, precipitous labor, or contraindications to neuraxial blockade, such as a coagulopathy.

The opioid analgesics act by binding to opiate receptors located throughout the central nervous system. Although this is the main site of action, opioid receptors have also been identified in other peripheral tissues. Four main types of receptor have been identified: mu (μ), kappa (κ), delta (δ), and sigma (σ). The analgesic effects, side effects, and pharmacodynamic characteristics depend on the receptor affinity of each individual opioid. These receptors are also responsible for the associated respiratory depression, sedation, and dysphoria and may affect thermoregulation. Binding of opiate agonist agents (e.g., meperidine, morphine, and fentanyl) and subsequent receptor activation alters neural transmission of pain by inhibiting the presynaptic and postsynaptic release of neurotransmitters. The opioid antagonists (e.g., naloxone, naltrexone) are competitive antagonists and bind with high affinity to the μ receptor more so than the κ or δ opioid receptors. These drugs do not produce analgesia and are capable of displacing other agonist drugs from the receptor and reversing their effects. A third class of agents interacts with the receptors and results in both agonist and antagonist activity depending on the receptor type. These drugs, with high receptor affinity, are capable of analgesic effect (e.g., pentazocine, nalbuphine, and butorphanol).

Opioids differ in pharmacokinetics, pharmacodynamics, method of elimination, and the presence of active metabolites, but all readily cross the placental barrier through passive diffusion. In order for systemic opioids to effectively alleviate labor pain, larger doses would be necessary. This dosing would risk excessive maternal sedation, maternal respiratory depression, loss of protective airway reflexes, newborn respiratory depression, and impairment of both early breastfeeding and neurobehavior. Consequently, large doses of opioids are avoided, and the doses used routinely for labor analgesia typically do not have significant adverse effects on either the mother or neonate.

Meperidine remains the most widely used opioid worldwide. Maternal half-life of meperidine is 2 to 3 hours, with the half-life in the fetus and newborn being significantly greater and more variable at values between 13 and 23 hours (Kuhnert et al, 1979). In addition, meperidine is metabolized to an active metabolite (normeperidine) that can significantly accumulate after repeated doses. With increased dosing and shortened time interval between dose and delivery, there is greater neonatal risk of decreased Apgar scores, lowered oxygen saturation, prolonged time to sustained respiration, abnormal neurobehavior, and more difficulty initiating successful breastfeeding (Nissen et al, 1997).

Morphine was used more frequently in the past, but currently is rarely used. Like meperidine it has an active metabolite (morphine-6-glucuronide) and a prolonged duration of analgesia (3 to 4 hours). The half-life is longer in neonates compared with adults, and it produces significant maternal sedation.

Fentanyl is a synthetic opioid with a short duration of action (approximately 30 minutes), no active metabolites, and a ratio of fetal to maternal plasma concentrations of approximately 1:3. In small intravenous (IV) doses of 50 to 100 μg/hr there were no significant differences in Apgar scores, respiratory depression, or neurobehavior scoring compared with newborns of mothers who did not receive fentanyl (Rayburn et al, 1989a). In addition, a comparison of equianalgesic doses of IV fentanyl compared with IV meperidine (Rayburn et al, 1989b) demonstrated a decreased frequency of maternal nausea, vomiting, and prolonged sedation in the fentanyl group. In addition, neonates whose mothers received meperidine required naloxone more often compared with the fentanyl-exposed infants. There was no difference in the neuroadaptive testing scores of the two groups of infants.

Opioids can be given by intramuscular (IM) or IV administration. IM injection of opioids is technically easy but leads to uneven analgesia, the possibility of late respiratory depression, and profound neonatal effects if not properly timed (Shnider and Moya, 1960). IM administration is associated with a high incidence of neonatal depression 2 to 4 hours after injection in some of the less lipid soluble opioids. IV administration is the most widely used technique to give opioids to a woman in labor, with effects that are more predictable and doses more easily timed. However, achievement of a steady blood level of opiate sufficient to provide analgesia is difficult, with the parturient frequently suffering underdosage (rarely overdosage). In an effort to improve pain relief and maternal satisfaction, continuous IV infusion of short-acting opiates (e.g., alfentanil, remifentanil) or self-administration of IV opiates is increasingly used for systemic opioid delivery during labor.

Patient-controlled analgesia (PCA) has the implied advantage of allowing the patient to titrate her dose to the minimum required for analgesia with the lowest blood levels of opiates, resulting in considerably less placental transfer and fewer side effects with increased patient satisfaction (McIntosh and Rayburn, 1991). Remifentanil, an

ultra-short–acting opioid rapidly metabolized by nonspecific serum esterases, is significantly metabolized by the fetus with umbilical artery–to–vein ratios of approximately 0.3 (Kan et al, 1998). It can be used effectively for labor PCA, but it appears difficult to achieve satisfactory analgesia without significant potential of maternal respiratory depression (Olufolabi et al, 2000; Thurlow and Waterhouse, 2000; Volikas, 2001). In a prospective randomized controlled trial comparing the effectiveness of epidural analgesia to a remifentanil PCA with optimized settings, epidural analgesia was significantly more effective than PCA in regard to labor pain, but no differences were noted in neonatal outcome measures (Volmanen et al, 2008).

Although there are individual differences among opioids, all readily cross the placental barrier and exert neonatal effects in typical clinical doses, including decreased fetal heart rate variability and dose-related neonatal respiratory depression. All opioids can have maternal side effects, including nausea, vomiting, pruritus, and decreased gastrointestinal motility and stomach emptying.

Sedatives and Anxiolytics

Sedatives and anxiolytics are administered infrequently to pregnant patients because they increase risks of sedation and respiratory depression in both mother and newborn, especially when used with opioids. Sedatives and anxiolytics were used more frequently in the past to diminish the adverse motivational-affective component of labor pain. Examples of such drugs are barbiturates and benzodiazepines.

Diazepam and midazolam are benzodiazepines used as anxiolytic agents in obstetrics. They rapidly cross the placenta, yielding approximately equal maternal and fetal blood levels within minutes of IV administration (Cree et al, 1973). In addition, the neonate has a limited ability to excrete diazepam, so the drug and its active metabolite may persist in significant amounts in the neonate for up to 1 week (Scher et al, 1972). Diazepam can result in neonatal hypotonia, lethargy, and hypothermia when used in large maternal doses (30 mg) (Cohen et al, 1993). However, when it is used in small doses (2.5 to 10 mg IV), minimal sedation and hypotonia have been observed (McAllister, 1980). Midazolam has a shorter duration of activity, but rapidly crosses the placenta and is associated with neonatal hypotonia in larger doses. The use of benzodiazepines remains somewhat controversial, but these agents can reduce maternal anxiety and are useful for treating convulsions associated with local anesthetic toxicity or eclampsia. However, all benzodiazepines are amnestics, and therefore may not be appropriate in many childbirth situations, depending on the desires of the parturient.

Dissociative Analgesia

The IM or IV administration of low-dose ketamine (0.25 mg/kg) produces a state called *dissociative analgesia*, which is characterized by analgesia and unreliable amnesia without loss of consciousness or protective airway reflexes (Galloon, 1976). This state is accompanied by a dreaming phenomenon, which may be unpleasant but can be minimized by coadministration of benzodiazepines to improve amnesia. In divided doses totaling less than 1 mg/kg, ketamine provides adequate analgesia for vaginal delivery and episiotomy repair. Although these low doses are not associated with neonatal depression, higher doses are associated with decreased Apgar scores (Akamatsu et al, 1974). With larger doses, maternal airway protection cannot be guaranteed, increasing the risk of gastric content aspiration. Ketamine is best reserved for use as a supplement (in low doses) to other techniques or for situations in which (1) more reliable and safer agents or techniques are contraindicated or ineffective or (2) when rapid control is required because the mother's pain is compromising the fetus (e.g., mother is moving uncontrollably, unable to effectively push, and jeopardizing delivery while the fetal head is presenting during a prolonged fetal heart rate deceleration).

INHALATION ANALGESIA

The use of nitrous oxide is widespread in Canada, Australia, the United Kingdom and other parts of the world, but its use in the United States as a labor analgesic is uncommon. It is usually administered as a 50% mixture with oxygen. At a 50% concentration (without coadministration of opioids), nitrous oxide is insufficient to cause unconsciousness or loss of protective airway reflexes. Appropriate equipment and trained personnel are essential to ensure safety (i.e., limiting the nitrous oxide concentration, avoiding administration of a hypoxic mixture, avoiding coadministration of other agents). Nitrous oxide is a weak analgesic but can provide satisfactory pain relief for some parturients. It can be used during the first, second, or third stage of labor either alone or as a supplement for a regional block or local infiltration (Rosen, 1971). The use of 50% nitrous oxide in a supervised fashion is safe and rapid acting, causes minimal maternal cardiovascular or respiratory depression, and does not affect uterine contractility. The effects of nitrous oxide are rapidly reversed with discontinuation, and it does not cause neonatal depression regardless of duration of administration (Rosen, 2002a). Although the use of inhaled halogenated agents such as sevoflurane in low-inspired concentrations was found to be safe and effective at reducing labor pain in a small study (Yeo et al, 2007), barriers to routine use include the need for specialized vaporizers, scavenging systems, and the lack of larger studies.

NEURAXIAL (REGIONAL) ANALGESIA

Neuraxial analgesia, including epidural, spinal, and combined spinal-epidural (CSE) techniques, has become the most widely used method for labor analgesia in the United States (Bucklin et al, 2005). Neuraxial techniques typically involve epidural and spinal administration of local anesthetic agents, and often the co-administration of epidural and spinal opioid analgesics. Other adjuvant agents, such as clonidine and neostigmine, can decrease the dose of local anesthetics or opioids required for effective analgesia; however, they are not routinely used and do not appear to offer a significant advantage when compared to local anesthetics with or without opioids (Eisenach, 2009; Parker et al, 2007; Roelants, 2006).

Neuraxial Local Anesthetics

Local anesthetic agents consist of amine moieties linked by an intermediate chain containing an ester or amide. Local anesthetics reversibly block nerve impulse conduction via voltage-gated sodium channels. Their chemical structures are secondary or tertiary amines, which are weak bases, marketed as the hydrochloride salts to achieve aqueous solubility.

The ester-linked local anesthetics (e.g., chloroprocaine, procaine, tetracaine) are rapidly metabolized by plasma cholinesterase, decreasing the risk of maternal toxicity and placental drug transfer (O'Brien et al, 1979). Amide-linked local anesthetics (e.g., lidocaine, bupivacaine, ropivacaine) are degraded by P-450 enzymes in the liver. Local anesthetics differ in their onset, peak plasma concentration, potency and duration based on their lipid solubility, protein binding, site of injection, and concentration. Vascular absorption of local anesthetics limits the safe dose that can be administered. Elevated plasma concentrations produce neurologic toxicity (seizures) or cardiovascular toxicity (myocardial depression, ventricular arrhythmia). Bupivacaine and ropivacaine are the most commonly used local anesthetics for labor analgesia. Ropivacaine is a pure amide-linked *S*-isomer, unlike bupivacaine, which is a racemic mixture. Because the *R*-isomer of bupivacaine can bind strongly to cardiac sodium channels, ropivacaine can decrease the possibility of severe cardiac toxicity associated with accidental intravascular injection of large doses of bupivacaine. However, ropivacaine is less soluble than bupivacaine and may be slightly less potent. Regardless of differences, bupivacaine and ropivacaine are extremely safe when appropriately used for epidural or intrathecal administration. An accidental, large intravascular dose of any local anesthetic can result in significant maternal morbidity or mortality.

As with all drugs, placental transfer is determined by molecular size, lipid solubility, protein binding, and maternal drug concentration. Local anesthetics are weak bases with high lipid solubility and a low ionized fraction. However, the lower pH of the fetus has the potential to increase the fraction of ionized molecules, decrease lipid solubility, and result in ion trapping. Therefore in an acidotic fetus, higher concentrations of local anesthetic can accumulate (ion trapping). Increased concentrations of local anesthetics result in decreased neonatal neuromuscular tone similar to that seen with magnesium. If a direct intravascular or intrafetal injection of local anesthetics occurs, significant toxicity and depression can develop, signified by bradycardia, ventricular arrhythmia, and severe cardiac depression with acidosis.

Neuraxial Opioids

Although intraspinal (intrathecal) opiates were demonstrated in 1979 to be capable of producing profound analgesia in humans (Behar et al, 1979; Wang et al, 1979), the epidural injection of opioids as sole agents has proved to be of limited use for effective labor analgesia. In one study, high doses of epidural morphine (7.5 mg) provided satisfactory but not excellent analgesia for 6 hours in the first stage of labor, whereas 2 to 5 mg produced barely satisfactory analgesia in fewer than half the patients (Hughes et al, 1984). Besides the inadequate analgesia and the long onset time (approximately 1 hour), the side effect of pruritus was significant. In contrast, when lipid-soluble opioids (e.g., sufentanil, fentanyl) are administered in the epidural space as sole agents, analgesia is rapid and equivalent to that of systemic administration (Camann et al, 1992), but remains inferior to that of dilute concentrations of local anesthetics, and less effective for somatic pain associated with the second stage of labor. When lipid-soluble opioids are administered as an adjunctive agent with local anesthetics in the epidural space, they decrease the total local anesthetic dose required and lower the minimum local anesthetic concentration needed to achieve adequate labor analgesia (Buyse et al, 2007; Celleno and Capogna, 1988; Lyons et al, 1997). The most common maternal side effect of conventional doses of epidural fentanyl or sufentanil is pruritus. After maternal epidural administration, the lipid-soluble, poorly ionized opioid analgesics rapidly enter the fetal circulation. An epidural bolus injection of an opioid results in peak neonatal depression at 30 to 60 minutes (similar to an IV bolus dose). Although typical doses used for labor analgesia adversely affect the neonate, the potential for respiratory depression is a function of the amount and timing of drug administered.

Subarachnoid (i.e., spinal, intrathecal) injections of fentanyl, sufentanil, meperidine, and morphine as sole agents are more promising for effective maternal labor analgesia. Analgesic effects of spinal opioids are more potent than epidural or systemic administration, but are of limited duration (2 hours) and are less effective than dilute epidural solutions of local anesthetics for analgesia in the second stage (Honet et al, 1992; Leighton et al, 1989). Spinal opioid administration is often performed as part of a CSE technique (discussed in the following section), with fentanyl or sufentanil being the most commonly used agents. The intrathecal opioid is often combined with a small dose of local anesthetic (e.g., 2.5 mg bupivacaine), decreasing the dose of opioid needed and incidence of pruritus (Wong et al, 2000). Reports of fetal heart rate changes after intrathecal administration of fentanyl or sufentanil (Cohen et al, 1993) may be caused by rapid onset of analgesia and rapid decrease in circulating catecholamines, with epinephrine decreasing faster than norepinephrine, resulting in an unopposed oxytocic effect on the uterus. This effect would increase uterine tone and decrease uterine blood flow. This mechanism is speculative, but it is suggested by observed cases and case reports (Friedlander et al, 1997). Some prospective randomized studies have found no difference in incidence of fetal bradycardia between epidural administration of local anesthetics and intrathecal opioids administered with the CSE technique (Fogel et al, 1999; Nageotte et al, 1997). A systematic review of studies comparing intrathecal opioids to other methods of labor analgesia noted an increase in fetal bradycardia (odds ratio [OR], 1.8; 95% CI, 1.0 to 3.1) and increased maternal pruritus (RR, 29.6; 95% CI, 13.6 to 64.6), but the risk of cesarean section because of FHR abnormalities was similar (Mardirosoff et al, 2002).

NEURAXIAL TECHNIQUES FOR LABOR ANALGESIA

Neuraxial techniques represent the most effective form of labor analgesia, and they achieve the highest rates of maternal satisfaction (Declercq et al, 2006). The patient

remains awake and alert without sedative side effects, maternal catecholamine concentrations are reduced (Shnider et al, 1983), hyperventilation is avoided (Levinson et al, 1974), cooperation and capacity to participate actively during labor are facilitated, and predictable analgesia can be achieved, superior to the analgesia provided by all other techniques. Before initiating any neuraxial blockade, anesthesiologists assess the patient's gestational and health history, perform a focused physical examination, discuss the risks, benefits, and alternatives, and obtain consent. In otherwise healthy parturients, routine laboratory tests are not required (American Society of Anesthesiologists Task Force on Obstetric Anesthesia, 2007). Resuscitation equipment and drugs must be immediately available to manage serious complications secondary to initiation of epidural or spinal blocks (discussed under Contraindications and Complications of Neuraxial Techniques). During initiation of the neuraxial blockade, mother and fetus are closely monitored.

EPIDURAL ANALGESIA

Epidural labor analgesia is a catheter-based technique to provide continuous analgesia during labor. The technique involves insertion of a specialized needle and catheter (Figure 16-2) between vertebral spinous processes in the back, into the epidural space. Most commonly, the needle is inserted at a lumbar space between L1 and L4. The needle traverses the skin and subcutaneous tissues, supraspinous ligament, interspinous ligament, and the ligamentum flavum, and it is advanced into the epidural space (Figure 16-3). The tip of the needle does not penetrate the dura, which forms the boundary between the intrathecal or subarachnoid space and the epidural space. To locate the epidural space, a tactile technique called *loss of resistance* is used. The tactile resistance noted with pressure on the plunger of an air- or saline-filled syringe dramatically decreases as the tip of the needle is advanced through the ligamentum flavum (dense resistance) into the epidural space (no resistance), which has an average depth of approximately 5 cm from the skin. Once the needle is properly positioned, a catheter is inserted through the needle. The catheter remains in the epidural space and the needle is removed. The catheter is secured with adhesives and used for intermittent or continuous injections. Once the catheter is placed, analgesia is achieved by administration of local anesthetics, opioids, or both (see Neuraxial Local Anesthetics and Neuraxial Opioids, earlier) and maintained throughout the course of labor and delivery. The catheter can also be used for operative anesthesia (cesarean delivery) and postoperative analgesia, when necessary.

After an incremental local anesthetic bolus to initiate reliable analgesia, local anesthetics are typically infused continuously with similar or lower blood drug levels compared with repetitive, intermittent boluses of local anesthetics (Hicks et al, 1988; Rosenblatt et al, 1983). Most importantly, the possibility of disastrous complications is reduced with continuous infusions, such as total spinal anesthesia or massive intravascular injections with cardiovascular collapse secondary to large bolus doses of local anesthetics (D'Athis et al, 1988). If the catheter enters the subarachnoid space instead, the level of sensory and motor blockade increases slowly without the sudden onset of complete subarachnoid blockade that can occur with large bolus techniques (Li et al, 1985). Patient-controlled epidural anesthesia is a delivery technique allowing the patient to self-administer small boluses of epidural analgesics with or without a background infusion. Studies comparing patient-controlled epidural anesthesia with continuous infusion technique have found decreased local anesthetic requirements, less anesthesia provider intervention, equivalent or improved patient satisfaction, equivalent or decreased motor blockade, and no significant differences in effects on the fetus or neonate (Halpern, 2005; van der Vyver et al, 2002).

The choices for local anesthetics for epidural infusion include dilute solutions of bupivacaine, ropivacaine, lidocaine, or chloroprocaine (Lee et al, 2002b). The concentration and volume of the loading dose, which is administered before initiating the continuous infusion, and the volume and concentration of the infusion are highly variable. With higher concentrations of local anesthetics, the density of the motor blockade increases. With larger volumes, a greater dermatomal spread of analgesia is achieved. Most practitioners routinely use low concentrations of local

anesthetics and many coadminister an opioid with both the initial bolus and the infusion (e.g., 2 μg/mL fentanyl) for its synergistic effect. Dilute solutions of local anesthetics (0.0625% to 0.125% bupivacaine or ropivacaine) minimize the motor blockade and preserve the perception of pelvic pressure with descent of the fetus.

Effects on the Progress of Labor and Rate of Operative Delivery

The use of epidural analgesia has been associated with prolonged labor and increased rates of assisted delivery and cesarean section. Retrospective studies are difficult to interpret, because higher pain scores are predictive of increased labor duration (Wuitchik et al, 1989), and higher analgesic requirements are predictive of increased rates of cesarean section (Alexander et al, 2001). A Cochrane review of the effects of epidural analgesia, including CSE, compared with nonepidural analgesia or no analgesia during labor (Anim-Somuah et al, 2005) concluded that, although there was an increased risk of instrumental vaginal birth (RR, 1.38; 95% CI, 1.24 to 1.53; 17 trials including 6162 women), there was no evidence of a significant difference in the risk of caesarean delivery (RR, 1.07; 95% CI, 0.93 to 1.23; 20 trials including 6534 women). A recent meta-analysis summarized the results of studies addressing the timing of neuraxial analgesia in labor on operative deliveries in nulliparous women (Marucci et al, 2007). Cesarean delivery rates (OR, 1.00; 95% CI, 0.82 to 1.23) and instrumental vaginal delivery rates (OR, 1.00; 95% CI, 0.83 to 1.21) were similar in the early neuraxial analgesia and later control groups. Neonates of patients with early neuraxial analgesia had a higher umbilical artery pH and received less naloxone than did patients when using other methods. The timing and use of neuraxial labor analgesia have differing effects on the length of labor. Compared with opioids for labor analgesia, the use of epidural analgesia minimally lengthens the first stage in some women and shortens it in others, but overall appears to lengthen the second stage by approximately 15 minutes (Anim-Somuah et al, 2005; Ohel et al, 2006; Sharma et al, 2004; Wong et al, 2005).

SPINAL ANALGESIA

Spinal analgesia is typically administered near the time of anticipated delivery. A small dose of a local anesthetic, opioid, or both is injected into the subarachnoid space. This dose of local anesthetic is far lower than that used for spinal anesthesia for cesarean section, and it has minimal effects on motor nerve function. Compared with epidural analgesia, it has the benefits of a more rapid onset, a lower failure rate, and being technically easier and quicker to perform. It has the significant disadvantage of a finite effective duration (approximately 90 minutes), but can be extremely useful for certain circumstances such as forceps-assisted delivery for a woman without epidural analgesia.

COMBINED SPINAL-EPIDURAL ANALGESIA

One variation of the lumbar epidural technique is a CSE analgesic. After placement of the epidural needle, but before insertion of the epidural catheter, a longer spinal needle is passed through the indwelling epidural needle (see Figure 16-2), puncturing the dura, and a small dose of local anesthetic or opioid is administered. If opioid alone is administered and the epidural catheter is placed but no local anesthetic is given, some analgesia can be achieved without motor blockade or sympathectomy. This method can allow the patient to walk safely (i.e., a "walking epidural"), but the analgesia is limited in efficacy and duration (approximately 2 hours in the first stage) and is rarely effective for the second stage of labor.

If small doses of local anesthetics are administered through the spinal needle, segmental analgesia results more rapidly than with epidural administration of local anesthetics. Specifically, the onset of analgesia in the sacral root distribution is much more rapid with CSE compared with epidural alone. The epidural placement of the catheter allows continuation of the segmental analgesia initiated by the spinal technique. In a metaanalysis of 19 trials (2658 women) comparing CSE to epidural labor analgesia (Simmons et al, 2007), CSE had a faster onset of effective analgesia (especially in spread to sacral roots), was associated with more pruritus, and was associated with a clinically insignificant lower umbilical arterial pH. No differences were seen for maternal satisfaction, walking in labor, type of delivery, maternal hypotension, postdural puncture headache rate, or need for blood patch.

CONTRAINDICATIONS AND COMPLICATIONS OF NEURAXIAL TECHNIQUES

Certain conditions contraindicate neuraxial procedures; these include patient refusal, infection at the needle insertion site, significant coagulopathy, hypovolemic shock, increased intracranial pressure from mass lesion, and inadequate provider expertise. Other conditions such as systemic infection, neurologic disease, and mild coagulopathies should be evaluated on a case-by-case basis. Human immunodeficiency virus infection is not a contraindication to regional technique in the pregnant patient (Hughes et al, 1995).

Infrequent but occasionally life-threatening complications can result from administration of regional anesthesia. The most serious complications are from accidental IV or intrathecal injections of local anesthetics. A prospective study of 145,550 epidurals in the United Kingdom noted unintended intravascular injection rates of 1 in 5000 and high spinal rates of 1 in 16,000 (Jenkins, 2005). An unintended bolus of IV local anesthetic causes dose-dependent consequences ranging from minor side effects (e.g., tinnitus, perioral tingling, mild blood pressure, heart rate changes) to major complications (e.g., seizures, loss of consciousness, severe arrhythmias, cardiovascular collapse). The severity depends on the dose, type of local anesthetic, and preexisting condition of the parturient. Measures that minimize the likelihood of accidental intravascular injection include careful aspiration of the catheter before injection, test dosing, and incremental administration of therapeutic doses. If a local anesthetic overdose occurs, consider using a 20% IV lipid emulsion to bind the drug and decrease toxicity. Successful resuscitation and support of the mother will reestablish uterine blood flow; this will provide adequate fetal oxygenation and allow time for excretion of local anesthetic from the fetus. The neonate has an extremely limited ability to metabolize local anesthetics and may have prolonged convulsions if emergent delivery is required (Morishima and Adamsons, 1967; Ralston and Shnider, 1978).

A "high spinal" (or total spinal) can result from an unrecognized epidural catheter placed subdural, migration of the catheter during its use, or an overdose of local anesthetic in the epidural space (i.e., high epidural). Both high spinals and high epidurals can result in severe maternal hypotension, bradycardia, loss of consciousness, and blockade of the motor nerves to the respiratory muscles (Yentis and Dob, 2001).

Treatment of complications resulting from both intravascular injection and high spinal is directed at restoring maternal and fetal oxygenation, ventilation, and circulation. Intubation, vasopressors, fluids, and advanced cardiac life support algorithms are often required. In any situation of maternal cardiac arrest with unsuccessful resuscitation, the fetus should be delivered by cesarean section if the mother is not resuscitated within 4 minutes of the arrest. This guideline for emergent operative delivery increases the chances of survival for both the mother and neonate (American Heart Association, 2005; Katz et al, 1986).

In addition, a variety of less severe complications and side effects can occur with neuraxial blockade. The retrospective rates of inadequate epidural analgesia or inadequate CSE analgesia requiring catheter replacement were 7% and 3%, respectively, at a U.S. academic center (Pan et al, 2004). The rate of accidental dural puncture during epidural catheter placement is 1.5%, and approximately half of these will result in a severe headache (Choi et al, 2003), which are typically managed with analgesics or a blood patch if necessary. Hypotension (decrease in systolic blood pressure greater than 20%) secondary to sympathetic blockade is the most common complication of neuraxial blockade for labor analgesia, with rates between 10% and 24% (Brizgys et al, 1987; Simmons et al, 2007). Prophylactic measures include left uterine displacement and hydration. Although standards for timing, amount, and hydration fluid remain controversial, dehydration should be avoided (Hofmeyr et al, 2004; Kinsella et al, 2000; Ko et al, 2007). Treatment of hypotension consists of further uterine displacement, IV fluids, and vasopressor administration. Small boluses of either phenylephrine or ephedrine can be used to treat hypotension. Although ephedrine (primarily β-adrenergic) was historically used, phenylephrine (primarily α-adrenergic) is associated with less fetal acidosis (Lee et al, 2002a; Ngan Kee et al, 2009; Smiley, 2009). If treated promptly, maternal hypotension does not lead to fetal depression or neonatal morbidity.

A rise in core maternal body temperature is associated with labor epidural analgesia and may be influenced by several factors; these include duration, ambient temperature, administration of systemic opioids, and the presence of shivering. During the first 5 hours of epidural analgesia, there is no significant rise in body temperature (Mercier and Benhamou, 1997). In a retrospective study, temperature increases approximately 0.10° C per hour, and may reach 38° C in as many as 15% of parturients with a labor epidural compared with 1% without an epidural (Lieberman et al, 1997). Although Lieberman et al suggest a significant increase in the rate of newborn evaluation for sepsis (i.e., sepsis work-up [SWU]) with epidural analgesia, 67.3% of the noted SWUs were ordered in infants born to mothers without fever. Kaul et al (2001) found no association between epidural analgesia and SWU. However, patients who received epidural analgesia and their neonates had an increased body temperature at delivery, and approximately 6% of these women had temperatures equal to or exceeding 38° C. Although maternal temperature had no predictive value for the SWU, Kaul et al (2001) found other risk factors associated with the SWU, including low birthweight, gestational age, meconium, or respiratory distress requiring intubation at birth, hypothermia at birth, group-B β-hemolytic *streptococcus* colonization, and maternal preeclampsia or hypertension. Although the etiology of the maternal temperature rise remains uncertain, it need not affect the neonatal SWU. Epidural analgesia during labor does not increase the incidence of neonatal sepsis. Although it is suggested that the fever is associated with noninfectious inflammatory activation or altered thermoregulation, the fever is not associated with a change in white blood cell count or with an infectious process, and treatment is not necessary.

Other potential side effects from neuraxial blockade include pruritus, nausea, shivering, urinary retention, motor weakness, low back pain, and a prolonged block. More serious complications of meningitis, epidural hematoma, and nerve or spinal cord injury are extremely rare.

A retrospective Swedish study of severe neurologic complications from neuraxial blockade included 200,000 obstetric epidurals and 50,000 obstetric spinals. Rates of serious neurologic events (i.e., neuraxial hematoma or abscess, nerve or cord damage) were 1:29,000 for obstetric epidural and 1:25,000 for obstetric spinal anesthetic procedures (Moen et al, 2004).

PARACERVICAL BLOCK

A paracervical block is used to provide pain relief during the first stage of labor in up to 3% of patients (Bucklin et al, 2005). The technique consists of submucosal administration of local anesthetics immediately lateral and posterior to the uterocervical junction, which blocks transmission of pain impulses at the paracervical ganglion. Analgesia is not as profound as with epidural or spinal regional block, and the duration of analgesia is short (45 to 60 minutes), but the complications and side effects of epidural analgesia, such as hypotension, hypoventilation, and motor blockade, are avoided. Complications from systemic absorption or transfer of local anesthetic can occur. There is also the possibility of direct fetal trauma or injection. Paracervical block is associated with a 15% rate of fetal bradycardia based on a metaanalysis of studies (Rosen, 2002b). The mechanism of this phenomenon is unclear, and close fetal monitoring is warranted. The bradycardia may occur secondary to decreased uterine blood flow from the vasoconstrictor properties of local anesthetics, greater uterine activity, or transfer of the local anesthetic across the placenta to the fetus, causing direct toxic effects on the fetal heart. The bradycardia is usually limited to less than 15 minutes, and treatment is supportive, consisting of lateral positioning and administration of oxygen.

PUDENDAL BLOCK

The obstetrician performs a pudendal block with a transvaginal technique, guiding a sheathed needle to the vaginal mucosa and sacrospinous ligament just medial and posterior to the ischial spine. The technique primarily blocks sensation of the lower vagina and perineum, and it is typically placed just before vaginal delivery. Although the technique provides analgesia for vaginal delivery or uncomplicated instrumental delivery, the rate of failure is high. In many centers, this technique is used when epidural or spinal techniques are unavailable. Complications in addition to failure include systemic local anesthetic toxicity, ischiorectal or vaginal hematoma, and, rarely, fetal injection of local anesthetic.

ANESTHESIA FOR CESAREAN DELIVERY

In the United States, the vast majority of cesarean deliveries are performed with neuraxial anesthesia. It offers the advantages of less anesthetic exposure to the neonate, has the benefit of an awake mother at the delivery, allows for placement of neuraxial opioids to decrease postoperative pain, and avoids the risks of maternal aspiration and difficult airway associated with general anesthesia. However, the use of general anesthesia is sometimes required if regional anesthesia is contraindicated (e.g., coagulopathy, hemorrhage) or if a rapid onset is needed for emergent deliveries (e.g., fetal bradycardia, uterine rupture). Benefits of general anesthesia compared with regional anesthesia include a secure airway, controlled ventilation, rapid and dependable onset, and potential for less hemodynamic instability.

EPIDURAL ANESTHESIA

Epidural anesthesia is an excellent choice for surgical anesthesia when an indwelling, functioning epidural catheter had been placed for labor analgesia. Epidural anesthesia provides the ability to titrate the desired level of anesthesia and extend the block time, if needed for a prolonged procedure. Epidural anesthesia is also ideal for patients in a nonemergent delivery who would not tolerate the abrupt onset of a sympathectomy from spinal anesthesia, such as some patients with cardiac disease. The volume and concentration of local anesthetic agents used for surgical anesthesia are larger than those used for labor analgesia. However, the technique of catheter placement, test dosing, and potential complications are similar. A typical dose regimen of epidural anesthesia for cesarean delivery could include 2% lidocaine (20 mL). Typically the anesthesiologist attempts to provide a dense block from the T4 level to the sacrum. This technique might not completely alleviate the visceral pain and pressure sensation associated with peritoneal manipulation, and adjuvant drugs are occasionally necessary. IV ondansetron and metoclopramide are frequently given to decrease nausea and vomiting associated with the operative delivery and hemodynamic effects from the dense neuraxial blockade (Lussos et al, 1992; Pan and Moore, 2001). Epidural morphine (3 to 5 mg) is typically given near the end of the procedure to decrease postoperative pain for up to 24 hours (Cohen et al, 1991).

SPINAL ANESTHESIA

For the patient without an epidural catheter, spinal anesthesia is the most common regional anesthetic technique used for cesarean delivery. The block is technically easier than epidural blockade, more rapid in onset, and more reliable in providing surgical anesthesia from the midthoracic level to the sacrum (Riley et al, 1995). The risk of profound hypotension is higher with spinal anesthesia than with epidural anesthesia, because the onset of the sympathectomy is more rapid. However, this risk can be nearly eliminated by avoidance of aortocaval compression, prehydration, and appropriate use of vasopressors. Colloid is significantly more effective than crystalloid (Ko et al, 2007). Historically, ephedrine was recommended as the vasopressor of choice, but more recent data confirm that a phenylephrine infusion at the time of spinal placement is effective at preventing hypotension and is associated with less fetal acidosis compared to ephedrine (Ngan Kee et al, 2004, 2009). Data also suggest that spinal anesthesia can be used safely for patients with preeclampsia (Hood and Curry, 1999; Wallace et al, 1995). A typical spinal anesthetic could consist of bupivacaine (12.5 mg) with morphine (200 μg) added to decrease postoperative pain. A large variety of other combinations of local anesthetics and opioids

are used. A hyperbaric solution of local anesthetic is often used to facilitate anatomic and gravitational control of the block distribution. The medication will flow with the spinal curvature to a position near T4, and a head-down position can enhance the rostral spread of the block if needed. The duration of a single shot spinal anesthetic is variable, but normally provides adequate surgical anesthesia for greater than 90 minutes. In selected circumstances, the use of a CSE technique offers the advantage of a spinal anesthetic, with rapid onset of a dense block and the ability to administer additional local anesthetic through the epidural catheter if the procedure lasts for an extended time. A continuous spinal anesthetic technique with deliberate subdural catheter placement is a rarely used alternative, but is sometimes chosen in cases of accidental dural puncture during attempts to place an epidural catheter. This technique allows the advantage of a titratable, reliable, dense anesthetic, but carries the risks of high spinal if the intrathecal catheter is mistaken for an epidural catheter, or if the provider is unfamiliar with the technique. The rates of rare complications of meningitis or neurologic impairment from local anesthetic toxicity with the use of a spinal catheter may be somewhat higher than the other neuraxial techniques, but they remain unknown. Some data suggest that leaving the spinal catheter in place for 24 hours decreases the risk of postdural puncture headache (Ayad et al, 2003; Cohen et al, 1994).

LOCAL ANESTHESIA

Although cesarean delivery can be performed with local infiltration, it is accompanied with considerable discomfort to the woman and risks the possibility of local anesthetic overdose. Most obstetricians are not trained to perform the technique. However, local infiltration is useful in rare circumstances, such as acute fetal distress without an available anesthesia provider.

GENERAL ANESTHESIA

General anesthesia is used in obstetric practice for cesarean section typically when regional anesthesia is contraindicated or for emergencies, because of its rapid and predictable action. The major risks for maternal morbidity are pulmonary aspiration and failed intubation. Appropriate airway examination, preparation for unanticipated events, and familiarity with techniques and the algorithm for difficult intubation (American Society of Anesthesiologists Task Force on Management of the Difficult Airway, 2003) are critical for providing a safe general anesthetic.

After denitrogenation of the lungs (i.e., preoxygenation), general anesthesia is induced by rapid-sequence administration of an IV induction agent, followed by a rapidly acting muscle relaxant. The trachea is intubated with a cuffed endotracheal tube, and a surgical incision is made after confirmation of tracheal intubation and adequate ventilation. Anesthesia is maintained by administering a combination of inhaled nitrous oxide and a potent inhaled halogenated agent (e.g., isoflurane), as well as sedative-hypnotics, opioid analgesics, and additional muscle relaxants if needed. During typical general anesthesia for cesarean delivery, opioids and benzodiazepines are administered after the baby is delivered, to avoid placental transfer of these agents to the neonate. Before delivery of the baby, the primary anesthetic for the incision and delivery is the induction agent, because there is little time for uptake and distribution of the inhaled agents into the mother or fetus (Dwyer et al, 1995). If intubation attempts fail, the operative delivery may proceed if the anesthesiologist communicates that it is possible to reliably ventilate the mother's lungs with either facemask or laryngeal mask airway (American Society of Anesthesiologists Task Force on Management of the Difficult Airway, 2003).

Induction Agents

Anesthesiologists use a variety of agents to rapidly induce unconsciousness. Among the most common are thiopental, propofol, etomidate, and ketamine. Each agent represents a different biochemical class, and each has specific advantages and cardiovascular effects.

Sodium thiopental is a highly lipid-soluble, protein-bound barbiturate that can cause decreased cardiac output and hypotension and rapidly crosses the placenta. Historically, it was the most common induction agent for cesarean section under general anesthesia. In a study of healthy volunteers undergoing uncomplicated cesarean section, the mean umbilical artery (UA)–to–umbilical vein (UV) ratio of thiopental concentrations was 0.87 (Morgan et al, 1981). IV administration of an appropriate dose (4 to 6 mg/kg) renders the patient unconscious within a circulation time (30 seconds), peaks in the UV blood in 1 minute and in the UA blood in 2 to 3 minutes, and has no significant clinical effect on neonatal well-being. However, doses of 8 mg/kg can result in neonatal depression (Finster et al, 1972), and higher doses may require cardiorespiratory supportive techniques until the neonate can excrete the drug. This elimination may take up to 2 days (Fox et al, 1979). The lack of neonatal effects is unclear, but may be caused by first-pass metabolism by the neonatal liver, rapid redistribution into maternal vascular-rich tissue beds, additional dilution by the fetal circulation, and higher fetal brain water content.

Propofol is a diisopropylphenol that is available as a 1% aqueous solution in an oil-in-water emulsion containing soybean oil, glycerol, and egg lecithin. Like thiopental, propofol is rapid in onset and can cause significant hypotension with a similar UA:UV ratio of 0.7 (Dailland et al, 1989). Unlike thiopental, propofol is preservative free and must be drawn up only hours before use. Other differences are that propofol decreases the incidence of nausea and vomiting, and it is currently not a controlled substance. Propofol has not been demonstrated to be superior to thiopental in maternal or neonatal outcome. Propofol administration has no significant effect on neonatal behavior scores with induction doses of 2.5 mg/kg, but larger doses (9 mg/kg) are associated with newborn depression (Gregory et al, 1990).

Etomidate contains a carboxylated imidazole ring that provides water solubility in acidic solutions and lipid solubility at physiologic pH. Like thiopental, etomidate has a rapid onset of action because of its high lipid solubility, it rapidly crosses the placenta, and redistribution results in a relatively short duration of action. Unlike thiopental

and propofol, etomidate has minimal effects on the cardiovascular system, but it is painful on injection, can cause involuntary muscle tremors, has higher rates of nausea and vomiting, and can increase the risk of seizures in patients with decreased thresholds. At typical induction doses (0.3 mg/kg), etomidate administration can cause decreased neonatal cortisol production (<6 hours), but the clinical significance remains uncertain (Crozier et al, 1993).

Ketamine, a structural analogue to phencyclidine, is more lipid soluble and less protein bound than thiopental. It is an analgesic, hypnotic, and amnestic with minimal respiratory depressive effects. Ketamine is biotransformed in the liver to active metabolites, such as norketamine. In contrast to thiopental, sympathomimetic characteristics of ketamine increase arterial pressure, heart rate, and cardiac output through central stimulation of the sympathetic nervous system, making it an ideal choice for a patient in hemodynamic compromise. Doses that are higher than those appropriate for induction of general anesthesia (1 mg/kg) can increase uterine tone, reducing uterine arterial perfusion. No neonatal depression is noted with typical induction doses (Little et al, 1972). In low doses (0.25 mg/kg), ketamine has profound analgesic effects, unlike barbiturates, but has been associated with undesirable psychomimetic side effects (e.g., illusions, bad dreams), which can be lessened by coadministration of benzodiazepines.

Nitrous Oxide

Inhaled nitrous oxide is often used as part of maintenance for general anesthesia, because of its minimal effects on maternal hemodynamics and uterine tone. As a sole agent, it is insufficient to provide an appropriate level of anesthesia for an operative procedure. It rapidly crosses the placenta with increasing UV-to–maternal artery ratios of 0.37 in the first 2 to 9 minutes increasing to 0.61 at 9 to 14 minutes (Karasawa et al, 2003). The effects of nitrous oxide on the neonate are not significant. Additional information about nitrous oxide is found in the previous section under Inhalation Analgesia.

Inhaled Halogenated Anesthetics

Isoflurane, sevoflurane, desflurane, and halothane are all halogenated hydrocarbons that differ in chemical composition, physical properties, biotransformation, potencies, and rates of uptake and elimination. In clinical use, specialized vaporizers deliver these volatile liquid agents, so that the inhaled concentrations can be carefully titrated by anesthesiologists because of the relatively profound cardiovascular effects and potential for uterine muscle relaxation. These agents are important components of general anesthesia for cesarean section, but readily cross the placenta. Without the use of these agents, the incidence of maternal recall of intraoperative events is unacceptably high (Schultetus et al, 1986; Tunstall, 1979).

Placental transfer of inhalation agents is rapid because these are nonionized, highly lipid-soluble substances of low molecular weight. The concentrations of these agents in the fetus depend directly on the concentration and duration of anesthetic in the mother. Clinicians often confuse the use of general anesthesia and the terms *fetal distress* and *depressed neonate*. A depressed fetus will likely become a depressed neonate, and general anesthesia may be used because it is the most rapidly acting anesthetic to allow cesarean delivery. For a healthy fetus, the use of general anesthesia is not contraindicated. A Cochrane review of 16 studies comparing neuraxial blockade versus general anesthesia in otherwise uncomplicated cesarean deliveries found that "no significant difference was seen in terms of neonatal Apgar scores of six or less and of four or less at one and five minutes and need for neonatal resuscitation" (Afolabi et al, 2006). The authors concluded that there was no evidence to show that neuraxial anesthesia was superior to general anesthesia for neonatal outcome. Recent experimental animal studies have demonstrated neuronal apoptosis in the developing brain when a variety of agents are administered to induce and maintain general anesthesia (Istaphanous and Loepke, 2009; Loepke and Soriano, 2008). Implications for the fetus and neonate from brief anesthetic exposures are currently unknown because of a lack of human studies and difficulties extrapolating animal study methodology to humans.

The induction–delivery interval is not as important in neonatal outcome as the uterine incision–delivery interval, during which uterine blood flow may be compromised and fetal asphyxia may occur. A long induction–delivery time may result in a neonate who is lightly anesthetized but not asphyxiated. If excessive concentrations of anesthetic are given for inordinately long times, neonatal anesthesia, evidenced by flaccidity, cardiorespiratory depression, and decreased tone, can be anticipated (Moya, 1966). It cannot be overemphasized that if the neonatal depression is caused by transfer of anesthetic drugs, the infant is merely lightly anesthetized and should respond easily to basic treatment measures. Treatment should include and focus on effective ventilation; cardiopulmonary resuscitation is rarely necessary. Ventilation will allow elimination of the inhalation anesthetic by the infant's lungs. Rapid improvement of the infant should be expected. Otherwise, a search for other causes of depression is imperative. For these reasons, it is critical that clinicians experienced with neonatal ventilation are present at operative deliveries under general anesthesia in which the time from skin incision to delivery may be longer (i.e., known percreta, large fibroids), or maternal condition necessitates an atypical induction and maintenance of anesthesia (e.g., a patient with critical aortic stenosis undergoing an opioid-based induction). A discussion of the operative and anesthetic plan by the neonatologist, obstetrician, and anesthesiologist is crucial for optimizing the outcome of neonates in these situations.

Neuromuscular Blocking Agents

Succinylcholine remains the skeletal muscle relaxant of choice for obstetric anesthesia, because of its rapid onset and short duration of action. In doses of 1.5 mg/kg, appropriate intubating conditions are present within 45 seconds. Because it is highly ionized and poorly lipid soluble, only small amounts cross the placenta. Side effects include increased maternal potassium levels, myalgias, and succinylcholine is a known trigger agent for malignant hyperthermia in susceptible individuals. This depolarizing neuromuscular blocking agent is normally hydrolyzed

in maternal plasma by pseudocholinesterase and usually does not interfere with fetal neuromuscular activity. If the hydrolytic enzyme is present either in low concentrations (Shnider, 1965) or in a genetically determined atypical form (Baraka, 1975), prolonged maternal or neonatal respiratory depression secondary to muscular paralysis can occur.

Rocuronium is a rapid-acting, nondepolarizing neuromuscular blocker that is an acceptable alternative to succinylcholine. It provides adequate intubating conditions in approximately 90 seconds at doses of 0.6 mg/kg and in less than 60 seconds at doses of 1.2 mg/kg (Abouleish et al, 1994; Magorian et al, 1993). Unlike succinylcholine, it has a much longer duration of action, decreasing maternal safety in the event the anesthesiologist is unable to intubate or ventilate the patient. It has the benefit of not being a triggering agent of malignant hyperthermia or elevating serum potassium levels.

During the operation, nondepolarizing neuromuscular blocking agents can be titrated to improve operating conditions. Under normal circumstances, the poorly lipid-soluble, highly ionized, nondepolarizing neuromuscular blockers (i.e., rocuronium, vecuronium, *cis*-atracurium, pancuronium) do not cross the placenta in amounts significant enough to cause neonatal muscle weakness (Kivalo and Saaroski, 1972). This placental impermeability is only relative, however, and neonatal neuromuscular blockade can occur when large doses are given (Older and Harris, 1968).

The diagnosis of neonatal depression secondary to neuromuscular blockade can be made on the basis of the maternal history (e.g., prolonged administration of neuromuscular blockers, history of atypical pseudocholinesterase), the response of the mother to neuromuscular blocking drugs, and the physical examination of the newborn. The paralyzed neonate has normal cardiovascular function and good color, but lacks spontaneous ventilatory movements, has muscle flaccidity, and shows no reflex responses. The anesthesiologist can place a nerve stimulator on the neonate and demonstrate the classic signs of neuromuscular blockade (Ali and Savarese, 1976). Treatment consists of ventilatory support until the neonate excretes the drug, up to 48 hours. Reversal of nondepolarizing relaxants with cholinesterase inhibitors may be attempted (e.g., neostigmine, 0.06 mg/kg), but adequate ventilatory support is the mainstay of treatment. Concomitant administration of an anticholinergic (e.g., atropine, glycopyrrolate) is normally necessary to prevent severe bradycardia from muscarinic side effects of the increased acetylcholine.

SUMMARY

This chapter serves as a general overview of the changes in maternal physiology during pregnancy and briefly discusses options and techniques for both labor analgesia and anesthesia for operative delivery. Its purpose is to allow the pediatrician and neonatologist a better understanding of the decisions and concerns of the anesthesiologist and the implications of his or her interventions. To provide the best care for mother and child, excellent communication is required between the obstetrician, pediatrician, anesthesiologist, and nurse. Only by facilitating these lines of communication and obtaining input from each discipline can patient care and safety become optimized.

PART V

GENETICS

CHAPTER 17

IMPACT OF THE HUMAN GENOME PROJECT ON NEONATAL CARE

Jeffrey C. Murray

HISTORY OF THE HUMAN GENOME PROJECT

Within 50 years of the discovery of the structure of DNA by Watson and Crick, the Human Genome Project achieved a major milestone with its description of an almost complete sequence of the approximately 3 billion nucleotides (A,C,G,T) contained within the human haploid genome. This effort was the result of an early vision by a group of scientists that with advances in technology and sequence analysis this task could be achieved (Watson and Cook-Deegan, 1991). The central goal was to provide a reference sequence of the human genome that could serve as a framework on which to better understand disease pathogenesis. Eventually, it was hoped, this would lead to improved treatments and prevention.

There have been numerous spin-offs from the technology and analytic platforms developed. A wide range of other organisms have now had their genomes sequenced from pathogenic viruses to complex plants and animals. These sequences provide insights into disease pathogenesis that are infectious or immunologic and open new doors to therapies. Comparing DNA sequences across species to look for evolutionary conservation has also provided tremendous insights into the protein structure of genes and the regulatory elements that control the cell type, timing, and amount for the synthesis of any individual protein. The nature of how a gene is defined has been substantially altered by these insights, so that the gene is now recognized as a far more complex structure with elements dispersed sometimes 1 million nucleotides or more from the protein coding components classically thought of as "the gene" (Gerstein et al, 2007).

Understanding the genetic relationships between individuals of different ancestral origins has led to the current effort to describe genetic variation across the human species as an essential aspect of understanding predisposition to or resistance from disease. Because the identification that carriers of sickle cell trait had increased resistance to malaria, or the identification of genetic factors conferring persistence of lactose tolerance into adult life as a mechanism associated with the advantages of dairy farming (Bersaglieri et al, 2004), it has been evident that individual genetic variation is an important contributor to health and disease. The hemoglobin system has provided an evolving paradigm for our understanding of the molecular nature of genetic disease beginning in the 1940s (Neel, 1949; Pauling et al, 1949) and onward to serving as a model for gene therapy in the modern era. The conception of the genome project led to wide ranging concerns about ethical, legal, and social aspects and resulted in the development of the Ethical, Legal and Social Issues (ELSI) Project to investigate these areas and to anticipate future concerns and problems. Finally, as part of the social and legal component, the work has led to legislation in the United States and abroad that is designed to protect individuals from discrimination based on their genetic background.

The Human Genome Project has been an international effort from its beginnings and had critical predecessors in the human gene mapping (HGM) meetings that had an initial focus on identifying the chromosomal location of normal and disease causing genetic variants. The community established by the HGM meetings provided an infrastructure that enabled the more comprehensive sequence-based maps developed in the wake of the HGM meetings. One early outcome of these meetings and the recognized need to convert research findings to clinical utility was creation of *Mendelian Inheritance in Man* by Victor McKusicks, which has now evolved into *Online Mendelian Inheritance in Man* (www.ncbi.nlm.nih.gov/omim/)—a comprehensive catalogue of single-gene disorders that is an essential reference tool for learning about the genetic aspects of both rare and common disease.

The international effort continues with many individual countries now focusing on genome efforts that are specifically relevant to their own high-risk medical conditions (e.g., malaria, HIV, hemoglobinopathies). These early collaborative international efforts also created the framework for one of the greatest successes of the Human Genome Project—that is, information generated relevant to the human DNA sequence and its variation should be held in public trust and there should be open access to DNA sequence and its annotation. This spirit of open access has, in turn, led to a stronger community ethic for the sharing of scientific and medical data that may be a legacy that will exceed the value of the sequence itself.

There have been many technical and analytic advances that have enabled the sequence, and more recently its variation, to be understood and applied. Currently these advances extend to the characterization of hundreds of thousands of genetic variants on large populations of individuals. In the last few years this characterization has led to dramatic advances in the understanding of how common

genetic variation can contribute to human genetic disease. This chapter will provide some detail on the various aspects of the Human Genome Project that are of current relevance.

The interval of more than 50 years between the elucidation of DNA as the information-containing macromolecule and its structural description by Watson and Crick has also spanned the embedding of medical genetics as an important specialty in health care. This same time interval has seen the identification, treatment, and in some cases prevention of a wide range of disorders that have a strong genetic component (including Rh incompatibility and phenylketonuria) and a variety of other neonatal biochemical disorders and the hemoglobinopathies. Discussed in Chapters 3 and 27 are the details of the current state of our knowledge of these important advances in prenatal and neonatal screening. It now seems apparent that the past focus on adding one disease at a time to the armamentarium of those that can be studied and treated using genetic tools will soon give way to a comprehensive analysis available at the level of the individual genome. Much of the current effort in human genome work is devoted toward individualized medicine, in which physicians will have the ability to treat not just a disease but a specific person with a disease and to account for their genetic and environmental variation in response to therapy or risks associated with prevention. Motulsky (1957) recognized this pharmacogenetic (or pharmacogenomic when applied globally) approach in the early days of human genetic study as being essential to understanding the significant variation in response to therapeutic agents or toxins. Pharmacogenetics is already being applied clinically to identify patients at risk for toxic reactions to some chemotherapeutic agents as well as antiinfectious compounds. Individualization of diet and nutritional approaches is also on the immediate horizon, and it seems likely that over the next few years there will be in place high-throughput genotyping platforms that will provide comprehensive information to the pediatrician and neonatologist for providing direct alterations and care beginning in early infancy. These individualized genome-wide profiles are already available to early adopters and are creating new models for how physicians will anticipate health care needs and outcomes for their patients.

The history of the Human Genome Project, both its scientific and social basis, has been published widely in review articles and books. Its central conceit arose in the middle 1980s, when it became apparent that technology was advancing so that an undertaking could at least be considered (Watson and Cook-Deegan, 1991). By the early 1990s there were formal projects devoted to its implementation in academic settings (e.g., the U.S. Department of Energy, the National Institutes of Health [NIH] and the Medical Research Council in the United Kingdom) as well as several commercially based entities that had an interest in gene identification as a mechanism to developing therapeutic products. Besides the primary emphasis on DNA sequencing, preliminary steps that entailed the development of physical and genetic maps also proved critical to assembling the DNA sequence of humans into its linear order on each of the individual chromosomes. These steps were also necessary for the conversion of DNA sequence data into useful tools for gene identification and mutation discovery. The combination of academic and commercial interests led to a competition that in the end provided the stimulus to develop large-scale, high-throughput methodologies and the analysis tools that in 2001 enabled the project to reach one of its primary goals ahead of some of even the most aggressive predictions for when a complete human sequence might be in place (Lander et al, 2001; Venter et al, 2001). These successes and their resulting technologies and algorithmic advances were based on trials in less complex organisms (e.g., *Escherichia coli*, yeast, fruit fly) and were then quickly applied to model and experimental organisms and to identify the sequences of plants and animals of commercial and nutritional importance. At the time of this writing, there are 998 microorganisms (www.ncbi.nlm.nih.gov/genomes/lproks.cgi), as well as many higher organisms, whose sequences have been completed.

SCIENCE AND THE HUMAN GENOME

In the years since the description of the primary human sequence, a deeper understanding of the nature of the DNA sequence and its regulation has developed. Phenomena that are still relatively new in 2011 (e.g., copy number variants, micro-RNA, epigenetic regulation) are important aspects of how the human genome functions and interacts. There is doubtless much more to learn about our DNA sequence, but this chapter will review some current understandings. There are enormous numbers of highly conserved DNA sequences outside of traditional DNA-encoded protein sequences for which function is completely unknown. The next decades will be, in part, devoted to developing and understanding how these conserved sequences play a role in human health and disease. A few current features will be discussed, with many more evolving almost daily in the primary literature. The effects of these approaches have been reviewed recently for neonatology, and this chapter will expand on those themes (Cotten et al, 2006).

SINGLE NUCLEOTIDE POLYMORPHISMS

Single nucleotide polymorphisms (SNPs) are the workhorses of human genetic variation and indeed are only a more specific term and characterization of restriction fragment length polymorphisms (RFLPs), which were the original DNA variants studied in the human genome. The advent of the polymerase chain reaction eliminated the need for RFLP studies. SNPs are specific nucleotide sites in the human genome, where it is possible to have one of two different nucleotides, or polymorphisms, at that position on one of the DNA strands. For example, there might be either a T or a G at a specific site. These variant sites are common with up to 1% of the human DNA sequence being potentially variable between any two individuals, resulting in tens of millions of SNPs across the genome. Most variation is found across all human populations, although some variants appear to be highly population specific. These variants are usually normal, in the sense that they do not appear to be disease causing, although they may lie adjacent to DNA changes that do contribute to disease predisposition. Chip-based DNA sequence detection allows the assay of up to 1 million SNPs simultaneously on one individual at a cost of a few hundred dollars.

COPY NUMBER VARIANTS

A relatively recent discovery in human genetic variation has been the importance of copy number variants as contributors to human inherited disorders. Although both small and large deletion and duplication events of the human DNA sequence have been known since the 1970s, based on cytogenetic banding, only recently has the role that these play in disease been recognized widely. Early copy number variants ranged in length from one to five nucleotides and proved to be useful in characterizing common genetic variation used in family linkage studies. In parallel with these were variants of which the central element might be 15 to 50 nucleotides in length—so-called mini satellites, which were also used in family-based linkage studies. The new class of variation is thousands to occasionally hundreds of thousands (or millions) of base pairs in length. These variations may contain one or multiple genes that can exist in two, three, or more copies arrayed in tandem at particular chromosomal positions. When these tandem arrays of largely identical sequences align themselves during meiosis, there is occasionally a misalignment that can result in the deletion or duplication of one or more of the copies. This event in turn can create a range of the number of copies present from zero to many (Zhang et al, 2009). When functional genes are contained within the copied element or functional regulatory elements, the amount of gene product made may be increased or decreased from a reference level. Early examples in which copy number variants contributed to disease include the Di George syndrome 22q- deletion and deletions associated with spinal muscular atrophy and Charcot-Marie-Tooth disease. New microdeletion syndromes are now being characterized with great precision using array-based DNA analysis that is rapidly replacing the traditional karyotype as the first line of chromosomal analysis. The recognizable syndromes that are found recurrently, and with an identifiable phenotype such as 22q-, are complemented by rare deletion or duplication events that result in congenital anomalies, developmental delay, or both, and where their etiologic nature can be inferred from the normal structure of the parental chromosomes. Finally, in areas such as autism, it is clear that these microdeletion duplication events are a major explanation for the sometimes sporadic, as well as familiar nature, of these disorders. Their contribution to human genetic disease is now suggested to be in the vicinity of 10% of all variant-contributed disease, and thus they form an important class for investigation. Despite their clear importance, there remains to be resolved many technical and clinical issues related to their identification and meaning (Aki-Khan et al, 2009).

MITOCHONDRIAL DNA

Mitochondria are the energy-producing organelles present in thousands of copies within each cell. Each mitochondrion has its own genome, distinct from the nuclear genome and thought to arise from incorporation of bacterial DNA by a eukaryotic cell. Although the mitochondrial genome is approximately 16,500 bp in length (compared with the 3 billion bp of the nuclear genome), there is a wide range of disorders associated with variation in mitochondrial sequence. In addition, because mitochondria reside in the cytoplasm and are not found in sperm, they have a unique pattern of maternal-only inheritance, in which mothers pass their mitochondria to all of their offspring with their daughters in turn passing that on to subsequent generations and with no passing of mitochondrial DNA from males to their children.

GENE IDENTIFICATION

One of the primary benefits of the reference human DNA sequence is our ability to move quickly from finding the location of a gene on a chromosome to identifying the specifics of that gene and the disease-causing mutations. Gene discovery can provide immediate clinical benefit in the form of more accurate diagnoses and risk predictions and longer-term benefits when gene discovery leads to an understanding of gene function and physiology that can be converted into treatment and prevention. Gene mapping approaches to human gene identification have been in use since the late 1970s, and the first successes were the identification of single-gene disorders, sometimes termed *monogenic* or *Mendelian* because their inheritance patterns follow the traditional modes of autosomal dominant, autosomal recessive, and sex linked. Currently there are three primary methodologies under use for gene identification (Altshuler et al, 2008). The first involves linkage studies using large families with genetic disorders or many small families with the same disorder than can be studied and their data pooled. These linkage-based approaches can provide a relatively well-defined chromosomal location for single-gene conditions and has led to successful gene finding for cystic fibrosis, neurofibromatosis, and hundreds of additional, mostly rare, conditions. This approach can also be applied to common but genetically complex traits for which there are no simple inheritance pattens. This technique may require many hundreds of small families, and the resultant gene localization is imprecise. A second method for gene localization can make use of small chromosome rearrangements, such as balanced translocations or small deletions or duplications, that result in a phenotype for a known disorder. In these cases, the location of the chromosomal rearrangement immediately suggests that a gene at or near that rearrangement is etiologic and can be used to again directly search for evidence of a specific gene and mutation in that region. A third approach now in great favor is described next in some detail, and it is exerting a major influence on disease gene finding.

HAPMAP AND GENOME-WIDE ASSOCIATION

As noted previously, it is particularly challenging to find genes associated with complex traits that have multiple genetic and environmental contributors. This heterogeneity creates substantial difficulties in both finding and confirming that any particular gene plays a role in the disorder of interest. A new approach, enabled by advances in technology (i.e., DNA chips) and statistical analysis is proving to be remarkably successful. This approach takes the form of the genome-wide association (GWA) study in which a panel of genetic variants are densely arrayed on DNA chips and characterized in large case and control

populations (Manolio and Collins, 2009). GWA can also be applied successfully to case-parent approaches, as will be described in more detail.

The prerequisite to this comprehensive search for variation was the development of the human HapMap (http://hapmap.ncbi.nlm.nih.gov/). The HapMap project developed a comprehensive understanding of the relationship of SNPs across multiple human ancestral groups including Europe, Africa, and Asia (International HapMap Consortium, 2007). HapMap is an essential component of a GWA study because it provides a comprehensive reference listing of the relationships of SNPs and copy number variants to enable their careful characterization in case and control populations. By looking for evidence of DNA sequence variation or allelic variation in which one allele is found significantly overrepresented in a case compared with a control population, there is a strong suggestion that the etiologic gene and variant lies in the vicinity of the surrogate or marker gene allele. In the last 2 years this approach has greatly extended the gene discovery process. Because these common complex traits have a far greater population impact, they are the ones that hold the greatest promise for providing information about the common contributors to pediatric disease. As of this writing approximately 100 associations have been identified (Manolio et al, 2009), but to date the emphasis has largely been on adult complex disorders (e.g., type 2 diabetes, cardiovascular disease, mental health disorders such as schizophrenia), with only a handful applied to pediatric traits. Autism (Wang et al, 2009), asthma (Himes et al, 2009), and cleft lip or palate (Birnbaum et al, 2009) have had new loci identified with the hope that this will provide insights into their pathogenesis. One challenge of the GWA study is that at present, whereas it can identify one or more loci associated with the disease, implementation of a GWA requires expensive technology and large (usually numbering in the thousands), well-phenotyped case and control populations. Thousands of cases and controls must be available to have sufficient power to detect the small effects seen. A second caveat is that the loci found usually have low relative risks or odds ratios, so that the clinical effect of any one identified locus is very small (Hardy and Singleton, 2009). However, collections of loci can have a combined substantial impact, and even a low odds ratio may identify a new biologic pathway that could provide great insights into etiology and treatment (Hirschhorn, 2009). As analytic approaches improve and as costs drop, it seems likely that the GWA study will become a common approach to a wide range of neonatal disorders in which either genetic risks or pharmacogenetic variation important in drug choice and dosing will be unraveled.

Besides detecting disease-associated genetic risk factors, these studies also contribute to knowledge of the genetics of normal trait variation, such as height and skin color. Substantial advances in this area have also occurred with more than 50 genes found to have a role in factors such as height determination (Hirschhorn and Lettre, 2009). However, although identical twin studies tell us that height is almost entirely genetically determined across a broad range of environmental variation, the genetic findings to date explain only a small amount of the contributors to height. There is still much to learn in regard to normal trait variation and the ability to make predictions about a child's future physical traits or cognitive behavioral range. New approaches beyond GWA are still critically needed to find this large amount of unexplained genetic contributors (Manolio et al, 2009).

The final, and in some ways ultimate, strategy for identifying gene variation associated with disease will be to perform comprehensive genome-wide sequencing. In the last few years, completely new technologies have been applied to DNA sequencing, and the costs of DNA sequencing of a specific individual have dropped by four or five factors of 10 from the original cost of assembling the reference human genome. The reference genome was an amalgamation of many individuals and cost approximately $3 billion, or $1 per nucleotide of sequence. The goal is to eventually reduce this cost by $1000 per individual genome sequenced, which would place it well within the realm of current medical investigations, such as imaging, and well below the cost of many therapeutic approaches. At the time of this writing, several individuals have had their individual genome sequence reported (Wheeler et al, 2008). There is a newly initiated project under way to sequence the genome from approximately 1000 individuals around the world to provide a catalog of DNA sequence variation that can be used as a reference point for comparisons in the future for normal and disease trait variation studies.

The high-throughput sequencing projects have an initial focus on the sequencing of all exons or conserved elements in the genome that are known to be at higher risk for containing disease-causing mutations. Nonetheless, mutations can also reside in the intergenic regions and outside of regions of conservation. Eventually whole-genome sequencing will be required for a comprehensive view of contributors to human inherited disorders. This high-throughput sequencing approach, when performed in sufficient numbers of individuals, can identify disorders in which there are common variants contributing to the disease process as well as individually rare variants that also compose a portion of the disease risk panel. Cystic fibrosis provides an example of this model in that of the single mutation (the ΔF508) consisting of a three-nucleotide deletion, which explains approximately 70% of the allelic variants that result in cystic fibrosis. The remaining 30%, however, are divided across an additional 20 to 50 that are relatively common, and then more than 1000 others that may be rare or family specific. Therefore to identify all the mutations associated with cystic fibrosis risk, one would need to perform comprehensive DNA sequencing.

COMPARATIVE GENOMIC HYBRIDIZATION

Comparative genomic hybridization (CGH), or array-based hybridization, is another technical advance that is now providing, in many cases, a replacement for traditional karyotype-based chromosomal analysis. CGH has already had a substantial influence on prenatal and newborn testing for genetic disease and is discussed in more detail in Chapter 20. Although these array approaches cannot yet detect every form of chromosomal abnormality (e.g., balanced translocations are not detected), they are highly successful in detecting major structural whole chromosomal

aneuploidy such as Turner syndrome (45X) or trisomy 21, and they are also effective in identifying small deletions and duplications with a high degree of resolution. These approaches are increasingly becoming a first-line screen for chromosomal structural abnormalities, with the potential for replacing standard karyotypes almost entirely. The arrays also benefit from being able to use DNA directly, so that live cells are not required as they have been for traditional karyotypes. Thus material obtained from even a deceased infant or fetus can be used in the analysis. Because the amount of DNA required is also small, minimal DNA quantity further facilitates its technical application. There are a variety of competing approaches available for such CGH. The current generation of array-based tools use fragments of DNA that are far smaller than prior versions; therefore the resolution is in the range of thousands of nucleotides. This resolution provides detection of very small deletions or duplication events of potential etiologic importance and begins to approach the level of direct sequence comparison. At some point, direct genome sequencing may replace these tiled-array approaches for detection of deletions and duplications.

In parallel with this improvement in resolution has been the recognition that there is no comprehensive catalog of the normal range of variation for rare deletion and duplication events. When new deletions or duplications are identified for which there is not a strong prior track record for their clinical importance (as would be the case for 22q- for example), then the interpretation as to whether they are causal for disease can be challenging. This challenge can sometimes be aided by examining parental samples in which the presence of a de novo deletion or duplication event may be more strongly indicative of contributing to a disease etiology than when the event is also identified in one or more other family members. However, caution needs to be exercised when such deletion-duplications are found in other family members, because there can be a range of penetrance for such abnormalities as well as other co-contributors that might be necessary for the full disease phenotype to be expressed (van Bon et al, 2009). Therefore caution must be exercised in family counseling, and it is essential to have the most accurate and up-to-date information on the nature and role of such variants when using them in a clinical setting. Fortunately these catalogs of normal variation are becoming available (Shaikh et al, 2009). With these caveats, it is still clear that there is an enormous amount to learn about how these structural variants can contribute to disease of the neonate.

PHARMACOGENOMICS

Pharmacogenomics, although originally described in the 1950s as a result of genetic variation associated with commonly recognized enzymes such as G6PD (Motulsky, 1957), is now a highly active area for the clinical application of genome studies. The U.S. Food and Drug Administration has already identified more than a dozen genes for which characterization of allelic variation of those genes may be an important component of therapeutic decision making, including several that have a pediatric application. Perhaps one of the best understood is the role of thiopurine methyltransferase and its genetic variation associated with major adverse events associated with chemotherapeutic agents such as 6-mercaptopurine (Weinshiboum, 2006). It is now standard care to study pediatric patients preparing to begin chemotherapy for their risks associated with these allelic variants that affect thiopurine methyltransferase drug metabolism. These current pharmacogenetic variants are the beginnings of a much larger group of variants that will tie individual response to therapeutics and will eventually result in direct individualized medicine on an individual basis. In neonatology, many potentially toxic medications are used routinely; these include indomethacin or ibuprofen for treatment of patent ductus arteriosus, antibacterial and antifungal agents that have potential serious adverse consequences such as gentamicin, medications to treat pulmonary or systemic hypertension, antiarrhythmic agents, and others for which individual patient response may be based in part on enzyme allelic variation in those individuals.

By identifying individual risk beforehand, one can either adjust medication doses or choose alternative medications to minimize complications and maximize therapy. In some cases it may be that larger doses of medication will be required based on pharmacogenetic variation as well. It is in the area of this pharmacogenetic variation that perhaps the greatest advances will come in the application of the genome project to neonatal care in the next decade.

With the availability of large clinical trials, such as those overseen by the Neonatal Network and others, improved understanding of the role of genetic variation in drug response will almost certainly be obtained. Because the cost of studies of genetic variation are modest, and the consequences of using the wrong drug or the wrong dose potentially devastating, it will be critical for neonatologists and pediatricians to understand the evidence for which variants can contribute in a proven way to improved therapeutic approaches. Just as measuring drug levels has become a routine part of care in many settings, so will testing beforehand for genetics risk identification and dosage plans also become a part of neonatal care.

INDIVIDUALIZED GENETIC INFORMATION

One of the most dramatic recent advances has been the application of the SNP-based association technologies to commercial entities that are now providing direct consumer testing to interested parties. Currently there are multiple commercial organizations that, for a fee of between $100 and $1000, will extract DNA from a saliva sample and perform high throughout SNP analysis. The results are then provided to the individual with the whole array of GWA risks that have been published in peer-review journals. Although currently controversial (Ng et al, 2009), it seems likely that the use of these technologies will expand in the private or “recreational” setting, directly in the clinical care setting, and eventually into newborn screening. A challenge for clinicians is presented when families have obtained this information but have little context for its meaning, and anecdotal examples of its application to neonates in terms of risk are already arising. This example is yet another example of why clinicians need to remain current with the rapidly advancing genomic capabilities.

MICROBIOMES AND THE METAGENOME

As described previously, there have been approximately 1000 bacterial and viral genomes sequenced, as well as more complicated pathogenic eukaryotic species. These microbial and viral sequences can be used to establish the genetic framework of the many organisms that are found in or on an individual. Because the newborn infant is largely thought to be sterile at birth, but rapidly acquires its microbial flora through environmental exposures, an understanding of the relationships of these many microbial species and how they participate in maintaining health or contributing to disease will be critical to an understanding of neonatal health and disease. Humans have tens of thousands of microbial and viral species contained in or on their bodies in locations such as the gut, mouth, and skin (Turnbaugh et al, 2007). A few obvious disease states, such as necrotizing enterocolitis (Neu et al, 2008) or presumed sepsis, are already under active study for the role in which microbial communities might have a role in predisposition or disease prevention.

It would seem likely that probiotic therapy at sometime in the future might be targeted to provide a milieu that would optimize the microbial flora or the neonatal gut to prevent or limit disease and to assist in nutrition. Our understanding of the transmittal of microbiomes to the infant from maternal and environmental sources is still limited (Palmer et al, 2007), but the capacity of the Human Genome Project and its DNA sequencing capabilities allows identification of the organisms involved with a high degree of precision. It is already apparent that there are many organisms present in and on newborns that have been previously unknown to science, because the identification of species has been limited by the ability to characterize them initially through culture or antigen characterization. For organisms for which appropriate culture media have not been identified, their existence was not known until the development of the ability to perform direct genome sequencing of material collected from the stool, urine, or elsewhere (DiGiulio et al, 2008).

By bypassing the culture step and sequencing biologic samples with DNA sequenced directly, it is possible to establish the identification of new organisms that may be contributing directly to disease in ways that were not previously identifiable. This concept of the microbiome also suggests that in the future—whereas the core DNA sequence will need to be sequenced only once because it is relatively unchanging, except in the case of rare somatic events—the metagenome sequence is constantly evolving based on alterations in factors such as nutrition and antibiotic exposure. In the pediatric population, it may be that DNA sequences sampled from the metagenome will be performed repeatedly as a way of assaying responses to therapy or risks to disease.

EPIGENETICS

Epigenetic regulation or the modification of DNA sequences through environmental exposures, such as altered nutrition or drug exposure, is also an evolving part of the Human Genome Project's contributions to our understanding of how genes function and work (Devaskar and Raychaudhuri, 2007). Many of these epigenetic changes are thought to arise in utero. As a result, a new field of inquiry into the developmental origins of adult disease (Joss-Moore and Lane, 2009; Simmons, 2009) is now expanding to help better understand the consequences of how DNA can be modified and gene function altered, whereas the linear DNA sequence remains the same. Alterations of DNA can include methylation of individual nucleotides or acetylation or other modifications that take place in the histones that help to establish the chromosomal and chromatin-based structure of DNA sequences.

The developmental origins of disease hypothesis posits that in utero changes can be induced by altered exposure states such as malnutrition, and these exposure states can imprint on the DNA a modified form that is then transmitted cell to cell and established in the infant, with continuing effects on gene regulation into childhood and adulthood. For example, if this imprinting results in a more effective storage capacity for calories, then in adult life when calories are more readily accessible, adults may be predisposed to obesity and its consequences. Similarly, such changes might also regulate cell division and transfer and play a role in childhood leukemias. Because these effects may occur in utero and in the premature infant, it seems likely that in the future a better understanding of our nutritional and drug exposure to infants will be important, which could have direct consequences on the predisposition of neonates to later disease. Although there are some technologies in place to develop an understanding of epigenetic modifications and changes, their application in a clinical setting is still relatively modest.

GENE THERAPY

Although not a direct consequence of the Human Genome Project, the idea of gene therapy has developed in parallel with our understanding of the human genome. Early efforts to use direct gene replacement are continuing, and although many challenges still remain it seems likely that these forms of therapy will continue to expand and eventually be commonly applied in the pediatric setting. Enzyme replacement therapy for several biochemical disorders is now widely available and, for those disorders for which earlier treatment results in better outcomes, recognition of such disorders early in life becomes critical. In other settings direct gene replacement has begun to suggest it may be both safe and efficacious (Maguire et al, 2009), opening an important door to future therapies. In parallel with projects that examine gene replacement, there is also the development of a better understanding of how related phenomena such as micro RNAs or small interfering RNAs also function. These small interfering RNAs, for example, may prove to be highly effective therapeutic agents, and a wide range of pediatric disorders are now under study to determine whether these can be used in a therapeutic or preventive sense. The genome sequence is likely to contribute to an understanding of undiscovered elements that may have an important role in gene regulation that could be effective in therapeutic settings as well, and these advances are eagerly anticipated.

Finally, advances in stem cell research and its therapeutic potential have now been enabled by new legislation

that is affording the NIH an opportunity to make stem cell lines available to investigators for studies using NIH funding (Collins, 2009). More readily available stem cells will likely increase the pace of research into the use of these potentially powerful therapeutic agents.

ETHICAL ASPECTS OF HUMAN GENETICS

The ethical, legal, and social aspects of the Human Genome Project have been of at least equal importance to the technology developments that have provided the advances in basic science and translational science described elsewhere in this chapter. It was Watson's insight early on in the process of establishing the Human Genome Project to allot 3% to 5% of the NIH Genome Institute budget directly for ELSI Project activities. The goal was to anticipate the controversies that might develop and to address them proactively whenever possible. In addition, the ELSI Project has also been involved in a wide range of concerns about genetic discrimination. ELSI Project investigators and their colleagues worked hard to develop model legislation that could eliminate genetic discrimination in the job and for health insurance purposes.

The successful passage of the Genetic Information Nondiscrimination Act (Tan, 2009) in the summer of 2008 was a major milestone at the federal level in providing protection for all citizens from workplace and health insurance discrimination. While many states had already addressed these issues, this federal assurance provides a greater level of national protection that is likely to facilitate the ease with which individuals enroll in both clinical genetics studies and research-oriented studies. The second critical aspect of the ELSI Project is addressing the need to have common forms and formats for enrolling research subjects in what are now the highly complex and large genetic investigations required to perform GWA studies described elsewhere in this chapter. It was recognized early that obtaining informed consent for participation in a genetics study was a constantly moving target, because technologies often outstripped the ability of social scientists to be prepared for the scale and possibilities of what might come next. These issues have been dramatically highlighted in recent years during which the scale of genetic characterization is being performed on the SNP ChIP assays, and the recognition that even aggregate data might be able to result in individual identification (Homer et al, 2008) has dramatically altered the clinical and research landscape for genetics.

GWA studies in particular have been scrutinized in great depth, and the NIH has detailed guidelines in place for how consent documents should be worded and the information that must be provided to research subjects. Similar oversight is provided for external users of the GWA data, which, to the benefit of the research community, have been deposited in readily accessible databases after appropriate scientific and ethical review. Another area of influence of the genome project has been on forensic DNA analysis. Although such a discussion is beyond the scope of this chapter, the ability to identify family relationships or ancestral origins has now made DNA analysis a widely used legal investigative and as a commercial tool. It has had spectacular successes in freeing convicts whose DNA evidence has exonerated them from being a participant in major crimes. DNA analysis is also applied widely to assess paternity and to help suggest the ancestral origin of an individual when it might be unknown, as with adoptees or descendants of slaves.

SUMMARY

The advances in the genome project have now begun to be evident at the bedside. Individualized or personalized medicine already has applications in pharmacogenetic variation, and risk profiles can also be generated for common diseases. These risk profiles may one day assist in anticipatory guidance for common disorders such as asthma, diabetes, or preterm birth. The microbiome will also represent an opportunity to better identify disease etiology and to improve therapeutic specificity. As long as protections against discrimination continue to be aggressively implemented, detailed genetic information will greatly improve patient care.

CHAPTER 18

Prenatal Genetic Diagnosis

Diana W. Bianchi

As a result of the expanding number of prenatal diagnostic tests that are performed on pregnant women, clinicians know a lot about their patients long before they even touch them. To date, prenatal genetic diagnosis has focused broadly on detection of fetal structural abnormalities. Whereas in the past the major indication for prenatal diagnosis was advanced maternal age or a family history of a single-gene disorder, currently most pregnant women receive an invasive prenatal diagnosis because of abnormal screening results. This chapter discusses the common methods of prenatal genetic diagnosis, the information they convey, and the implications for the newborn.

NONINVASIVE TECHNIQUES

MATERNAL SERUM SCREENING

Maternal serum screening is part of routine obstetric care worldwide. It is used to identify a high-risk pregnancy in a low-risk population of pregnant women. First-trimester maternal serum screening consists of measuring pregnancy-associated plasma protein A and the free beta subunit of human chorionic gonadotropin (hCG). Second-trimester maternal serum screening consists of measurement of alpha-fetoprotein (AFP), hCG, unconjugated estriol (uE_3), and inhibin A—proteins that are made by the fetus or placenta.

Biochemical Screening for Neural Tube Defects

AFP is one of the major proteins in fetal serum. Its precise physiologic role is unknown. It can be detected as early as 4 weeks' gestation when it is synthesized by the yolk sac (Bergstrand, 1986). Subsequently, it is produced in the fetal liver and peaks in the fetal serum between 10 and 13 weeks' gestation. AFP is then excreted into the fetal urine or leaks into the amniotic fluid through the skin before keratinization at 20 weeks' gestation. It is also present in cerebrospinal fluid. AFP in maternal serum is exclusively fetal in origin (Crandall, 1981). Maternal serum AFP peaks at 32 weeks' gestation because of greater placental permeability for the protein (Ferguson-Smith, 1983). For interpretation of results, accurate gestational dating and knowledge of maternal race, weight, and presence or absence of diabetes are critical.

Brock and Sutcliffe (1972) observed that there were markedly increased levels of AFP in the amniotic fluid of fetuses with anencephaly and open neural tube defects. Subsequently, it was shown that elevated amniotic fluid AFP levels were associated with increased maternal serum AFP (Ferguson-Smith, 1983). The possibility of a screening test for open neural tube defects became apparent. In the initial collaborative efforts aimed at studying maternal serum AFP, results were expressed as multiples of the median (MoM) to allow comparisons between laboratories. It has become a convention to describe results greater than 2.5 MoM as abnormally high and less than 0.6 MoM as abnormally low. Both findings require further investigation.

If the AFP is elevated, the patient is offered an ultrasonographic examination to verify gestational age, determine fetal viability, and diagnose many of the structural abnormalities that can be associated with an elevated AFP. Although the AFP test was developed to screen for neural tube defects, abnormally high results are not specific for this condition (Box 18-1). If the ultrasonographic examination is unrevealing, the patient undergoes amniocentesis to assay the amniotic fluid for the presence of AFP and acetylcholinesterase, which are elevated in open spina bifida (Crandall et al, 1983). Although an elevated AFP is compatible with a normal diagnosis, a study of 277 infants with elevations of maternal serum AFP and normal levels of amniotic fluid AFP revealed a higher incidence of intrauterine growth restriction and non–neural tube anomalies (Burton and Dillard, 1986).

Aneuploidy Screening

Maternal serum AFP screening has also been used to detect chromosomally abnormal fetuses since the observation was made that a low AFP value was more likely in a fetus with trisomy 18 or 21 than in a normal fetus (Merkatz et al, 1984). Several prospective studies have demonstrated that expressing risk for Down syndrome as a combined function of maternal age and AFP value, and offering amniocentesis to all women with a risk of 1 in 270 or greater (the equivalent risk in a 35-year-old woman based on age alone), makes it possible to detect approximately one third of otherwise unexpected cases of Down syndrome in fetuses (Dimaio et al, 1987; Palomaki and Haddow, 1987). Low AFP values are probably caused by decreased hepatic production in the affected fetus. Although it would make sense to ascribe this phenomenon to the small size of the liver, one study found no association between fetal weight and low AFP values in chromosomally abnormal fetuses (Librach et al, 1988). The differential diagnosis of a decreased AFP level is shown in Box 18-2. Because a low AFP value detects only one third of fetuses with Down syndrome, a normal AFP value does not rule out trisomy 21.

Experience with using low maternal AFP levels as a screen for fetal chromosome abnormalities has led to the evaluation of many other proteins produced by both the fetus and placenta. Three of these—uE_3, hCG, and inhibin A—were incorporated into second-trimester maternal serum screening panels (Wenstrom et al, 1999). Measurements of all four can be combined to improve the sensitivity and specificity of Down syndrome detection. AFP, uE_3, and hCG are only weakly correlated with one another, and

BOX 18-1 Differential Diagnosis of Abnormally High Maternal Serum Alpha-Fetoprotein Levels

- Incorrect gestational dating
- Multiple pregnancies
- Threatened pregnancy loss
- Fetomaternal hemorrhage
- Anencephaly
- Open spina bifida
- Anterior abdominal wall defects
- Congenital nephrosis
- Acardia
- Lesions of the placenta and umbilical cord
- Turner syndrome
- Cystic hygroma
- Renal agenesis
- Polycystic kidney disease
- Epidermolysis bullosa
- Hereditary persistence (autosomal dominant trait)

BOX 18-2 Differential Diagnosis of Abnormally Low Maternal Serum Alpha-Fetoprotein Levels

- Incorrect gestational dating
- Trisomy 18
- Trisomy 21
- Intrauterine growth restriction

their values are all independent of maternal age (Norton, 1994). Elevations of hCG are the most specific markers for fetal trisomy 21 (Bogart et al, 1987; Rose and Mennuti, 1993), whereas estriol levels are approximately 25% less than normal. Pregnancies affected by fetal trisomy 18 also have reduced levels of uE_3 and hCG. Each measurement is compared with population-specific normal values (i.e., MoM), which are then converted to a likelihood ratio that is expressed as a numeric risk for Down syndrome. Women whose serum screening results indicate a fetal Down syndrome risk of greater than 1 in 270 are offered amniocentesis. Approximately 5% of all serum screen values are calculated to be false-positive results to achieve a sensitivity of detection of at least 70% for cases of Down syndrome.

In 1996 the National Health Technology Assessment Program in the United Kingdom launched a study comparing the performance of first-trimester to second-trimester screening—the Serum, Urine, and Ultrasound Screening Study (SURUSS) (Wald et al, 2003). In addition to the well-validated second-trimester markers, the first-trimester serum markers (pregnancy-associated plasma protein A and free beta hCG) and an ultrasound marker, nuchal translucency (NT), were measured. The results suggested that combining all measurements in an integrated panel improved the sensitivity of detection of trisomy 21 to 93% at a fixed false-positive rate of 5%; this was followed by the largest obstetric clinical trial ever performed in the United Sates and funded by the National Institutes of Health—the First and Second Trimester Evaluation of Risk (FASTER) study (Malone et al, 2005a). In this prospective study of 38,189 pregnant women, 117 had a fetus affected with Down syndrome. All study subjects were required to have a first-trimester NT measurement, as well as first- and second-trimester serum screening. The results of the study showed that first-trimester combined serum and sonographic screening was better than conventional second-trimester screening, and that the highest sensitivity was achieved by the integrated test that combined results from both trimesters. The excellent results achieved by both of these large-scale studies resulted in the American College of Obstetricians and Gynecologists recommendation that all pregnant women be offered screening for Down syndrome as part of their routine prenatal care (American College of Obstetricians and Gynecologists, 2007).

ULTRASONOGRAPHIC EXAMINATION OF THE FETUS

Ultrasonographic examination of the fetus is the best noninvasive method for gestational dating, definition of fetal anatomy, serial measurements of fetal growth, and evaluation of dynamic parameters such as cardiac contractility, fetal urine production, and fetal movement. In addition, it has been suggested that antenatal visualization of the fetus promotes maternal-infant bonding (Fletcher and Evans, 1983). The advent of antenatal ultrasonography has had a significant influence on the types of patients who are admitted to the neonatal intensive care unit.

First Trimester

With the advent of transvaginal scanning and improved imaging, coupled with advances in first-trimester biochemical screening, fetal ultrasonography during the first trimester has become routine. A major emphasis of first-trimester sonography is screening for aneuploidy, using the following markers: nuchal translucency measurement, absent nasal bone, cystic hygroma, and abnormal ductus venosus blood flow.

NUCHAL TRANSLUCENCY MEASUREMENT

Ultrasonographic visualization and quantification of the normal subcutaneous fluid-filled space at the back of the fetal neck is known as the *nuchal translucency measurement* (Said and Malone, 2008). This particular fluid-filled space is especially well seen in the first-trimester fetus (10 to 14 weeks' gestation; Figure 18-1). In normal fetuses, the maximal thickness of the subcutaneous translucency between the skin and soft tissue overlying the fetal spine increases as a function of crown-rump length. Normal standards have been established for each gestational week. An enlarged NT measurement is thought to be caused by abnormal or delayed development of the lymphatic system, fetal cardiovascular abnormalities, or defects in the intracellular matrix (Said and Malone, 2008). An increased NT thickness is associated with a higher risk of fetal trisomy 21 (Snijders et al, 1998), cardiac defects in chromosomally normal fetuses (Hyett et al, 1996), and anomalies such as diaphragmatic hernia, omphalocele, skeletal defects, Smith-Lemli-Opitz syndrome, and spinal

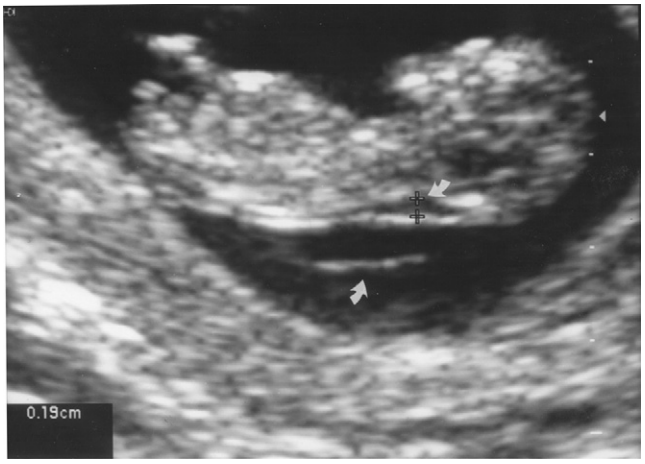

FIGURE 18-1 *(See also Color Plate 3.)* **Sagittal ultrasonographic image of a first-trimester fetus.** The nuchal translucency measurement is the distance between the two crosses. A measurement larger than normal standards for gestational age indicates that the fetus is at high risk for Down syndrome, congenital heart disease, or both. *(Courtesy Dr. Fergal Malone.)*

muscular atrophy (Sonek, 2007). In the largest prospective study (96,127 pregnant women) to examine the association of NT and aneuploidy, Snijders et al (1998) detected 82.2% of the cases of trisomy 21 at a false-positive rate of 8.3%. The implementation of large-scale, first-trimester sonographic screening protocols into clinical practice has emphasized the need for quality assessment, training, and standardized measurements. Assessment of the risk of fetal chromosomal abnormalities in the first trimester allows pregnant women the option of earlier (invasive) diagnostic testing. The disadvantage of this approach is that earlier diagnosis of aneuploidy may preferentially identify fetuses already destined for miscarriage.

CYSTIC HYGROMA

Cystic hygroma manifests sonographically in the first trimester as an enlarged echolucent space that extends along the entire fetal body (Said and Malone, 2008). What distinguished it from the NT is the presence of characteristic septations. Cystic hygroma in the first trimester is the single most powerful sonographic marker that is associated with aneuploidy (Malone et al, 2005b). In the FASTER trial there were 134 cases of cystic hygroma among 38,167 study subjects (incidence of 1 in 285). In the 134 cases, 67 were associated with chromosome abnormalities, (51%), 22 were associated with major structural anomalies (primarily skeletal and cardiac) (34%), and five were associated with fetal death (8%) (Malone et al, 2005b). Therefore pediatricians and neonatologists need to have a high level of suspicion for anomalies in live born infants with an in utero history of cystic hygroma.

ABSENT NASAL BONE

In the original description of his eponymous syndrome, Dr. Langdon Down noted that affected individuals had a small nose (Down, 1995). In one study, absence of the nasal bone in the fetal facial profile was noted in 43 of 59 (73%) fetuses with trisomy 21 and in 3 of 603 (0.5%) of chromosomally normal fetuses (Cicero et al, 2001). The prevalence of absence of the nasal bone is affected by ethnicity (most common in individuals of African ancestry), gestational age, and NT thickness. Using standardized imaging techniques, the nasal bone is absent in 70% of fetuses with trisomy 21, 55% of fetuses with trisomy 18, and 34% of fetuses with trisomy 13 (Cicero et al, 2004).

ABNORMAL DUCTUS VENOSUS BLOOD FLOW

The use of first-trimester Doppler assessment has identified abnormal blood flow velocity patterns across the ductus venosus (Said and Malone, 2008). Blood flows in the ductus during ventricular systole (the S wave) and diastole (the D wave) have characteristic forms with high velocity (Sonek, 2007). This velocity decreases during atrial contraction (the A wave), but in normal fetuses forward blood flow is maintained. When there is complete cessation or reversal of forward flow, the A wave is considered to be abnormal. Abnormal ductal flow is associated with chromosomal abnormalities, cardiac defects, and adverse pregnancy outcomes (Sonek, 2007).

Second Trimester

Within the context of prenatal genetic diagnosis, ultrasonography can be used to detect congenital anomalies. A malformation is present in 2% to 3% of live births (Nelson and Holmes, 1989). This risk is doubled in twins. Fetal structures that are normally filled with fluid are especially well visualized by ultrasonography. In approximately 10% of infants with anomalies, the central nervous system is involved (Hill et al, 1983). Ultrasonography is particularly useful in the diagnosis of anencephaly, microcephaly, encephalocele, and hydrocephalus. By 20 weeks' gestation, the fetal facial structures can be examined with this method for cyclopia, cleft lip, and micrognathia. Nuchal thickening is suggestive of Down syndrome, familial pterygium coli, and other chromosome abnormalities (Benacerraf et al, 1987; Chervenak et al, 1983). Fetal cardiovascular structures may be reliably examined at 20 weeks' gestation. The presence or absence of four cardiac chambers, the dynamic relationships between the cardiac valves and the locations of the vessels allow diagnoses such as hypoplastic left heart, double-outlet right ventricle, tricuspid atresia, tetralogy of Fallot, and Ebstein anomaly. Pericardial effusion and arrhythmias may be similarly observed.

Gastrointestinal anomalies occur in approximately 0.6% of live births, and one third of them are associated with chromosome abnormalities (Barss et al, 1985). The decrease in fetal swallowing seen in some cases of bowel obstruction (from atresia, stenosis, annular pancreas, or diaphragmatic hernia) may lead to polyhydramnios that results in a uterine size greater than expected for gestational dates. Although gastroschisis and omphalocele are readily diagnosed on ultrasonography, they may be confused with each other, and their differing prognoses may cause considerable parental anxiety (Griffiths and Gough, 1985). Gastroschisis usually occurs as an isolated anomaly; infants generally do well after surgical repair. The kidneys are identifiable by 14 weeks' gestation, but the presence of perirenal fat and large adrenal glands may obscure the

diagnosis of renal agenesis (Hill et al, 1983). Renal cysts, hydronephrosis, and obstructive uropathy are easily visualized. Oligohydramnios is indicative of poor renal function.

Multiple standard curves have been developed for fetal anthropometric measurements (Elejalde and Elejalde, 1986; Saul et al, 1988). These instruments are particularly helpful in diagnosing skeletal dysplasias and evaluating growth restriction. Fetal genitalia may be determined reliably in the second trimester. In addition, ultrasonographic examination is of benefit in the diagnosis and management of multiple pregnancies.

Although there have been no documented adverse outcomes related to ultrasound exposure during human pregnancy, the reported experimental biologic effects—altered immune response, cell death, change in cell membrane functions, formation of free radicals, and reduced cell reproductive potential—necessitate judicious use of this technology. Another concern is the appropriate pediatric follow-up for prenatally observed conditions with unclear clinical significance, such as minimal hydronephrosis and echogenic bowel.

SECOND TRIMESTER GENETIC SONOGRAM

The *genetic sonogram* is a term that is used to describe the use of a second-trimester sonographic examination to adjust the risk of fetal aneuploidy (Breathnach et al, 2007). The genetic sonogram relies on the identification of major structural anomalies in association with soft markers—that is, findings that are normal variants that often resolve in the third trimester. An example of a soft marker for trisomy 18 is the presence of choroid plexus cysts. Therefore the presence of choroid plexus cysts, with other soft markers such as echogenic bowel, single umbilical artery, or both, in association with an omphalocele or a neural tube defect, would strongly increase the suspicion of fetal trisomy 18.

NEW IMAGING MODALITIES

New fetal imaging modalites include three-dimentional ultrasound examination and magnetic resonance imaging (Lee and Simpson, 2007). Three-dimensional sonography improves detection of cleft palate, and magnetic resonance imaging improves assessment of fetal brain anomalies.

CELL-FREE NUCLEIC ACIDS IN MATERNAL BLOOD

Lo et al (1997) first described the circulation of large amounts of cell-free DNA in maternal plasma and serum samples. Since then, knowledge regarding the biology of fetal cell-free DNA and mRNA in the maternal circulation has greatly expanded (Maron and Bianchi, 2007). The placenta is the predominant source of the circulating nucleic acids. To date, two main clinical applications have transitioned from bench to bedside: fetal rhesus D genotyping (Bianchi et al, 2005) and fetal gender determination (Rijnders et al, 2001). Both have been routinely available in the United Kingdom and Europe for a number of years and are just beginning to be available in the United States (Hill et al, 2010). Fetal gender determination is particularly useful in guiding maternal steroid administration in patients at risk of congenital adrenal hyperplasia, as well as aiding further management of fetuses at risk for X-linked disorders. Extensive research is ongoing toward using circulating cell-free fetal nucleic acids for the noninvasive prenatal diagnosis of aneuploidy and in developing assays of normal fetal developmental gene expression at different gestational ages (Maron et al, 2007).

INVASIVE TECHNIQUES

AMNIOCENTESIS

Amniocentesis refers to the removal of up to 20 mL of amniotic fluid from the pregnant uterus. Contained within this fluid are cellular components (desquamated fetal epithelial and bladder cells) that serve as sources of chromosomes, DNA, or enzymes. Most of the cellular elements are nonviable; therefore amniocytes generally require tissue culture under specific conditions to provide enough material for diagnosis (Gosden, 1983). Herein lies one of the major disadvantages of the procedure, in that results are received late in the second trimester after fetal movement has been perceived by the pregnant woman. In contrast, the amniotic fluid itself may be assayed biochemically immediately after being removed for the presence of AFP, acetylcholinesterase, bilirubin, lecithin, sphingomyelin, or phosphatidylcholine.

The indications for genetic amniocentesis are (1) an abnormal maternal serum screen result indicating an increased risk of aneuploidy or neural tube defect, (2) maternal age of 35 years or older at the time of delivery, because there is an increased risk for fetal chromosome abnormalities, (3) a previous pregnancy that resulted in a fetus or an infant with chromosome abnormalities, (4) one parent with a balanced chromosome translocation, (5) a family history of a child with a neural tube defect, (6) a family history of a metabolic disorder for which the enzyme defect is known, (7) maternal history of an X-linked disorder, (8) a family history of a disorder for which DNA diagnosis is available, and (9) detection of a sonographic abnormality that is associated with aneuploidy.

Extensive clinical experience with amniocentesis has accrued over the past 30 years (Simpson et al, 1976; U.S. National Institutes of Health, 1976). Historically, institutions in the United States currently quoted a 1% to 2% incidence of minor complications, such as amniotic fluid leakage, uterine cramping, and vaginal spotting after the procedure. The incidence of more serious complications, such as chorioamnionitis and miscarriage, is 0.25% to 0.5% (Centers for Disease Control and Prevention, 1995). More recently, however, the rate of fetal loss after second-trimester amniocentesis was calculated using data from the FASTER trial (Eddleman et al, 2006). The spontaneous fetal loss rate at less than 24 weeks' gestation did not differ statistically significantly between those that did and did not undergo the procedure. The procedure-related loss rate after amniocentesis was 0.06%.

Because results of amniocentesis are received relatively late in the pregnancy, the Canadian early and Mid-Trimester Amniocentesis Trial focused on evaluation of the procedure when performed between 12 and 15 weeks' gestation. This study showed a higher fetal loss rate and a 1.3% risk of fetal clubfoot when amniocentesis was

performed between 11 and 13 weeks' gestation (Canadian Early and Mid-Trimester Amniocentesis Trial Group, 1998). The rate of clubfoot in the early amniocentesis group was tenfold the risk in the general population. The cause of clubfoot is thought to be a disruption of normal foot development secondary to transient oligohydramnios (Farrell et al, 1999). For these reasons, early amniocentesis is not generally recommended.

CHORIONIC VILLUS SAMPLING

The increased use of first-trimester biochemical and ultrasound screening has increased uptake of chorionic villus sampling as the diagnostic follow-up procedure of choice. Chorionic villus sampling (CVS) involves the aspiration of the chorion frondosum between 10 and 11 weeks' gestation (Figure 18-2). The fact that the procedure is performed early is advantageous, because most women at this point do not have external manifestations of pregnancy and have not yet perceived fetal movement. The chorionic villi are composed of syncytiotrophoblast and mesenchymal core cells that are actively growing and dividing. In contrast to the dying epithelial cells shed into the amniotic fluid, chorionic villus cells do not require prolonged culture to provide enough mitoses for a cytogenetic diagnosis. Karyotype results are generally available within 1 week of the procedure. Initially, direct preparations derived from syncytiotrophoblast were used for analysis, but the number of apparently mosaic abnormal results proved unacceptable. Cultured preparations derived from the cell of the mesenchymal core are more closely related in embryonic origin to the actual fetus (Bianchi et al, 1993). It is currently recommended that both direct and cultured preparations be used for cytogenetic analysis. Mosaicism, defined as the presence of two or more cell lines carrying different chromosomal constitutions, is a true biologic (not technical) problem in CVS. In several large studies, 0.8% to 1.7% of 1000 cases demonstrated a chromosome abnormality that was present in the villus but not in the fetus (Hogge et al, 1986; Ledbetter et al, 1992) This finding has led to the observation that postzygotic nondisjunction is more common than was previously suggested.

The indications for CVS are the same as those for amniocentesis, with two exceptions. First, neural tube defects cannot be diagnosed by this procedure, and AFP or other serum screening is not routinely offered at this early point in gestation. Second, evidence shows that the fetomaternal hemorrhage associated with placental biopsy results in elevated maternal serum AFP immediately after the procedure (Brambati et al, 1988).

CVS is performed transcervically or transabdominally. With the transcervical technique, the inherent risks of fetal and maternal infection appear to be greater, because it is impossible to sterilize the cervix. Under ultrasonographic guidance, a flexible catheter is passed through the endocervix and placed into the chorion frondosum. A small segment of placenta is then aspirated into sterile tissue culture medium, and the catheter is withdrawn (Jackson, 1985). In contrast, the transabdominal technique uses a needle to obtain villus material; sterilization of the skin surface is straightforward (Brambati et al, 1988). With either

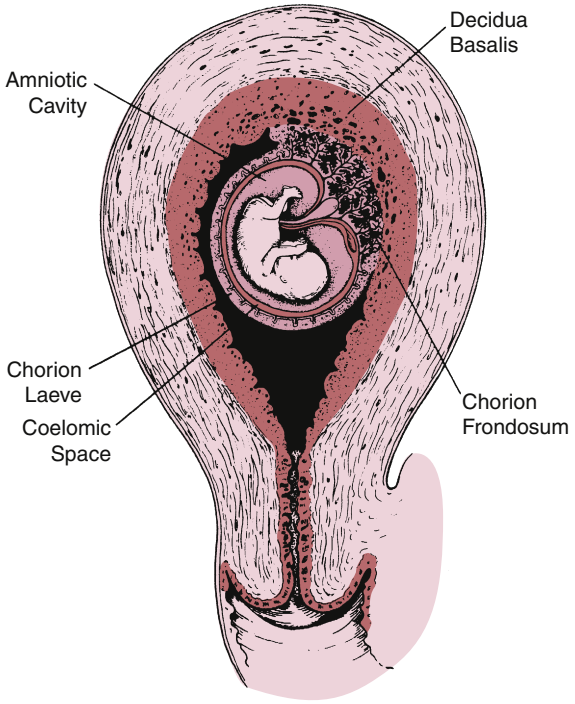

FIGURE 18-2 A pregnant uterus containing a fetus at approximately 9 weeks' gestation. The chorion frondosum, if sampled for biopsy, can provide fetal cells for chromosome, enzyme, or DNA analysis. *(From Jackson LG: First trimester diagnosis of fetal genetic disorders,* Hosp Pract (Off Ed) *20:40, 1985.)*

method, approximately 10 to 50 mg of tissue is obtained. Subsequently, the villi are dissected from maternal decidua and processed for tissue culture or DNA extraction.

The safety and accuracy of these techniques have been extensively monitored. A randomized National Institutes of Health clinical trial compared amniocentesis with CVS (Rhoads et al, 1989). The Centers for Disease Control and Prevention and the National Institutes of Health held a consensus conference to summarize worldwide experience. After adjustment for confounding factors such as gestational age, the risk of miscarriage after CVS was found to be on the order of 0.5% to 1.0% (Centers for Disease Control and Prevention, 1995).

The advantages and disadvantages of CVS are summarized in Box 18-3. For patients at high risk for single-gene disorders amenable to DNA diagnosis (e.g., cystic fibrosis, sickle cell anemia, Duchenne muscular dystrophy), CVS is probably the preferred prenatal diagnostic method. Alternatively, for patients with relatively low risk (e.g., a 35-year-old woman being tested for chromosome abnormalities), an amniocentesis may be more appropriate. There have been a few reports of serious maternal sepsis and transient bacteremia in association with transcervical CVS (Barela et al, 1986; Silverman et al, 1994).

The 1% incidence of mosaicism in villus samples may necessitate a further invasive technique, such as amniocentesis or cordocentesis, to confirm or refute diagnoses. However, the detection of mosaicism in a CVS sample may identify a fetus at risk for uniparental disomy. *Uniparental disomy* refers to the inheritance of both copies of a chromosome pair from a single parent. This inheritance occurs when a trisomic fetus undergoes rescue and loses

BOX 18-3 Advantages and Disadvantages of Chorionic Villus Sampling

ADVANTAGES

- Performed in first trimester; results available quickly
- Cells obtained are mitotically active
- Amount of tissue obtained is preferable for DNA analysis
- Placental mosaicism is detected

DISADVANTAGES

- Miscarriage rate slightly higher
- Increased fetomaternal hemorrhage after procedure
- Risk of serious maternal infection
- Risk of fetal limb and jaw malformations

BOX 18-4 Indications for Fetal Blood Sampling

- Thrombocytopenia
- Rapid third-trimester diagnosis of chromosome abnormalities*
- Immunodeficiency
- Congenital infection
- Acid-base abnormalities
- Metabolic disorders*
- Fetal blood type incompatibility*
- Hemoglobinopathy*

*Diagnosis can also be made by a DNA-based test performed on any nucleated fetal material, such as amniocytes.

the extra copy of the chromosome. One third of the time, the fetus will be left with two chromosomes that originated in a single parent. Uniparental disomy is an important mechanism in conditions such as Prader-Willi syndrome.

Initially, there was concern regarding the association between CVS and the risk of limb deficiencies in infants whose mothers underwent the procedure. The risk of limb malformations was first suggested by a number of studies describing an increased incidence of transverse limb anomalies and the hypoglossia-hypodactyly syndrome in infants whose mothers had undergone CVS (Burton et al, 1992; Firth et al, 1991; Firth et al, 1994; Hsieh et al, 1995). The overall rate of non–syndrome-related transverse limb deficiency from 65 centers performing CVS is 7.4 per 10,000 procedures (Centers for Disease Control and Prevention, 1995). This number is reasonably similar to that in population-based registries that monitor infants with all limb deficiencies, which give a rate of 5 to 6 per 10,000 live births (Centers for Disease Control and Prevention, 1995). Factors likely to influence the rate of limb malformations include gestational age (risk of limb deficiency is greatest at or before 9 weeks' gestation and decreased at or after 10 weeks' gestation), type of catheter used, and operator experience. The overall risk of limb deficiency appears to be on the order of 1 per 3000 procedures (Centers for Disease Control and Prevention, 1995). A higher incidence of hemangioma has also been suggested in infants born after CVS (Burton et al, 1995). The most important issue at present, however, is the fact that relatively few maternal-fetal medicine and obstetric clinics have personnel who are adequately trained to perform the procedure (Cleary-Goldman et al, 2006).

CORDOCENTESIS

Percutaneous umbilical blood sampling, or cordocentesis, was first described as a means of obtaining fetal immunoglobulin M (IgM) measurements in the prenatal diagnosis of congenital toxoplasmosis (Daffos et al, 1985). Under continuous ultrasonographic imaging, the insertion site of the umbilical cord into the placenta is identified. The umbilical vein is punctured with a 20-gauge needle, the sample is withdrawn, and the umbilical cord is observed for signs of hemorrhage. The technique has been used diagnostically in many clinical settings (Forestier et al, 1988) (Box 18-4). Regarding genetic diagnosis, the lymphocytes are a source of cells for a rapid karyotype; this is helpful in two situations: (1) when anomalies have been noted on ultrasonographic examination, but it is too late in gestation to perform an amniocentesis (antenatal diagnosis of trisomy 13 or 18 influences delivery room management), and (2) for confirmation of a fetal karyotype when amniocentesis or CVS has shown mosaicism (Gosden et al, 1988).

SUMMARY

There has been a major shift away from using maternal age as an indication for prenatal genetic diagnosis. Instead, the results of biochemical and sonographic screening tests, which are increasingly being performed in the first trimester, are used to guide the need for amniocentesis and CVS. Safety considerations and patient preferences have influenced the emphasis on noninvasive prenatal diagnosis. The results of large-scale clinical trials, such as the SURUSS and the FASTER study, have shown a high sensitivity and specificity for fetal Down syndrome detection using noninvasive techniques. Circulating cell-free fetal nucleic acids in maternal blood are already being used for noninvasive diagnosis of fetal gender and rhesus D genotype, and many potential opportunities exist to use this material for future clinical applications.

CHAPTER 19

Evaluation of the Dysmorphic Infant

Chad R. Haldeman-Englert, Sulagna C. Saitta, and Elaine H. Zackai

Genetic disorders have a major impact on public health, as indicated by several large epidemiologic studies (Table 19-1) (Hall et al, 1978; McCandless et al, 2004; Scriver et al, 1973). The latest data indicate that genetic factors contribute to more than two thirds of the conditions prompting admission to a children's hospital (McCandless et al, 2004). Early identification of the genetic nature of a given condition may then help to appropriately focus resources for providing better care to these individuals. It is therefore critical to implement a systematic approach to evaluating a dysmorphic or malformed infant. This chapter outlines such a general approach.

The clinical geneticist incorporates the following five essential tools in the evaluation of a child suspected of having a primary genetic disorder:

- History: prenatal, birth, and medical
- Pedigree analysis or family history
- Specialized clinical evaluation that includes a detailed dysmorphology examination
- Comprehensive literature search
- Focused genetic laboratory analyses (e.g., chromosomes, fluorescence in situ hybridization, DNA microarray, sequencing)

TABLE 19-1 Genetic Disorders in Pediatric Hospital Admissions

Genetic disorders	Montreal (1973)	Seattle (1978)	Cleveland (2004)
Chromosome, single gene (%)	7.3	4.5	11
Polygenic (%)	29	49	60
Nongenetic disorders (%)	64	47	29
Total number of admissions	12,801	4115	5747

Alcohol
Environmental agents
Infections (gestational age at exposure)

PRENATAL TESTING

Ultrasonography (gestational age performed)
Triple screen
Chorionic villus sampling, amniocentesis, and indications

HISTORY

PRENATAL

A complete gestational history should be generated, including results of prenatal testing such as maternal serum screening, ultrasonography, chorionic villus sampling (CVS), and amniocentesis (Box 19-1). The maternal age at conception should be documented, because the risk of chromosomal anomalies such as nondisjunction rises with maternal age. It is important to identify prenatal exposures to infection and medications, maternal habits such as alcohol and drug use, maternal chronic illnesses such as maternal diabetes, and pregnancy-related complications. An additional significant historical component involves the presence of abnormal levels of amniotic fluid. Oligohydramnios (decreased amniotic fluid volume) can be associated with either a fluid leak or a genitourinary abnormality, whereas polyhydramnios (excess amniotic fluid volume) can be seen in fetuses with neuromuscular disease or gastrointestinal malformations.

It is also important to identify exposure to environmental agents that might act as teratogens. Teratogens are environmental agents that may cause structural and functional diseases in an exposed fetus. Each teratogen may have a characteristic expression pattern, with a specific range of associated structural anomalies and dysmorphic features. Effects and the extent of the effects depend on the time of exposure, duration, and dosage as well as interactions with maternal and genetic susceptibility factors. In general, more severe effects are typically correlated with exposure early in the pregnancy and with more extensive (i.e., higher dose) exposure. The list of well-documented human teratogens is short and includes such substances as alcohol, thalidomide, warfarin, trimethadione, valproate, and hydantoin. If history of an exposure is documented, an effort should be made to identify the developmental time and level of exposure. This information is critical, because

TABLE 19-2 Dermatoglyphic Patterns Associated With Specific Dysmorphic Disorders

Dermatoglyphic Pattern	Associated Disorders
Excess arches	Trisomy 13, trisomy 18, Klinefelter syndrome (47,XXY), deletion 5p (cri du chat), fetal phenytoin exposure
Excess ulnar loops	Trisomy 21
Excess whorls	Smith-Lemli-Opitz syndrome, Turner syndrome (45,X), 18q deletion

BOX 19-2 Adjunct Studies in the Evaluation of the Dysmorphic Infant

- Investigation of internal malformation
- Assessment of neurologic function
- Identification of organ systems involved
- Ultrasonography magnetic resonance imaging
- Brain imaging
- Electroencephalography as indicated
- Electromyography as indicated
- Prognosis
- Treatment and intervention

the counseling and calculation of recurrence risk for a given malformation are vastly different if environmental exposures are involved.

BIRTH

Another important component of the gestational history is obtaining information on fetal activity, size, and position. Often the mother's subjective impressions can be further confirmed by examining obstetric records of the perinatal period. A history of hypotonia may be further supplemented by reports of poor fetal movements and breech presentation. Perinatal information including gestational age, fetal position at delivery, the length of labor, type of delivery, and any evidence of fetal distress, such as passage of meconium, are all relevant data (Table 19-2). Apgar scores, the need for resuscitation, birth parameters (weight, length, and head circumference), any malformations seen at birth, and all abnormal test results should be noted.

MEDICAL

A full review of the medical issues of the child should include the baby's general health, test results, identification of any chronic medical issues, and need for hospitalization. Evaluation of growth, review of systems, developmental assessment, and notation of unusual behaviors can also provide important clues to a diagnosis.

PEDIGREE ANALYSIS AND FAMILY HISTORY

A critical part of any genetic evaluation is to obtain the family history (Box 19-2); this is best accomplished by creating a three-generation pedigree, which is a schematic diagram depicting familial relationships using standard accepted symbols (Figure 19-1). This formal record can also be used to summarize positive responses elicited during the interview. Special attention should be paid to ethnic origins of both sides of the family, consanguinity, and any first-degree relatives with similar malformations to those of the patient being evaluated, also known as the *index case*, *proband*, or *propositus*. An extended family history should be used to identify relatives with congenital anomalies, developmental abnormalities, or physical differences. Often photographs can provide clear objective evidence of a descriptive history.

Reproductive histories, especially of the parents, should be elicited. Specifically, questions should be asked about infertility, miscarriages, and stillbirths. The occurrence of more than two first-trimester miscarriages increases the probability of finding a balanced translocation in one parent (Campana et al, 1986; Castle and Bernstein, 1988). A balanced translocation is a rearrangement of genetic material such that two chromosomes have an equal exchange without loss or gain of material. There are typically no associated clinical features with such a rearrangement. However, when chromosomes align to recombine for meiosis in the sperm or egg, this exchange produces a risk of unequal distribution and an unbalanced translocation in the resulting fetus. In this case, there would be aneuploidy for part of a chromosome. It has been estimated that 25% of stillbirths exhibit single or multiple malformations, and in at least half of these cases there is a genetic etiology for the malformations. Couples with two or more pregnancy losses should undergo routine chromosome analysis or karyotyping. When possible, such analysis should be performed on the stillborn fetus or on products of conception.

Obtaining a formal family history is helpful in discovering information that is often critical to making a diagnosis. Positive responses may help to discern a Mendelian pattern of inheritance for a given genetic disorder. For example, a disease affecting every generation, with both males and females involved, such as Marfan syndrome, would most likely be autosomal dominant. A pattern of X-linked recessive disease, such as hemophilia, would show affected males related through unaffected or minimally affected females; transmission in this pattern should not occur from father to son.

PHYSICAL EXAMINATION FOR DYSMORPHOLOGY

A congenital malformation can be described as a "morphologic defect of an organ, part of an organ, or larger region of the body resulting from an intrinsically abnormal developmental process" (Jones, 2006). The term *dysmorphology* was introduced by Dr. David Smith in the 1960s to describe the study of human congenital malformations (Aase, 1990). This study of "abnormal form" emphasizes a focus on structural errors in development with an attempt to identify the underlying genetic etiology and pathogenesis of the disorder.

In a landmark study, Feingold and Bossert (1974) examined more than 2000 children to define normal values for a number of physical features. These standards were devised as screening tools to objectively identify children with differences possibly attributable to a genetic disorder. Important measurements include head circumference, inner and outer canthal distances, interpupillary distances, ear length, ear placement, internipple distances, chest circumference, and hand and foot lengths. Other graphs and measurements using age-appropriate standards can be found in compendia such as the *Handbook of Physical Measurements* (Hall et al, 2007).

The assessment should begin with newborn growth parameters that can reflect the degree of any prenatal insult. Measurements such as height, weight (usually reflecting nutrition), and head circumference should be plotted on newborn graphs. Gestational age–appropriate graphs should be used for premature infants. It is often helpful to express values that are outside the normal range as 50th percentile for a different gestational age. For example, a full-term baby with microcephaly may have a head circumference of less than the 5th percentile for 38 weeks. This can be expressed as a measurement at the 50th percentile for 33 weeks, which imparts the degree of microcephaly more clearly.

A complete physical examination should include assessment of patient anatomy for features varying from usual or normal standards. This assessment can often provide clues to embryologic mechanisms. The data obtained should then be interpreted in regard to normal standards using comprehensive standard tables that are available for these purposes. Special attention to familial variants should be given.

The shape and size of the head and fontanels should be noted as well as the cranial sutures, with assessment for evidence of craniosynostosis or an underlying brain malformation. Any scalp defects should also be noted. The shape of the forehead, appearance of the eyebrows (noting synophrys), and the texture and distribution of hair should be noted. The spacing of the eyes, or canthal measurements (Figure 19-2), the interpupillary distances (Figure 19-3; see also Figure 19-2), palpebral fissure lengths (Figure 19-4), presence or absence of colobomata and epicanthal folds, and noting whether the palpebral fissures are turned upward or downward are components of the dysmorphology examination. Examination of the ears should include a search for preauricular and postauricular pits, tags, and assessment of the placement (Figure 19-5), length (Figure 19-6), and folding of the ear is important. Ear development occurs in a temporal frame similar to that of the kidneys, and external ear anomalies can be associated with renal anomalies. Evaluation of the nose should cover the shape of nasal tip, the alae nasi, presence of anteverted nares, the length of the columella, and patency of the choanae.

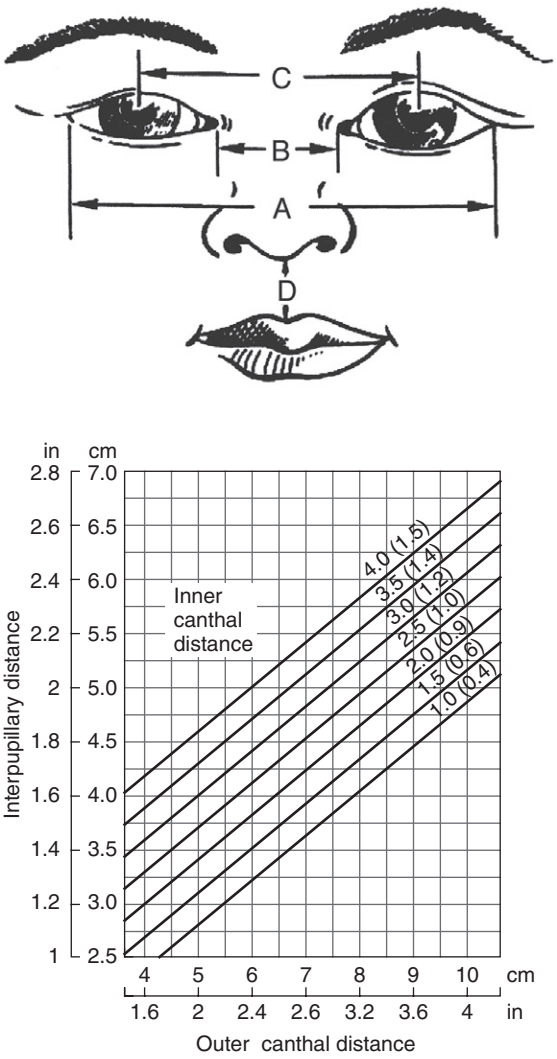

FIGURE 19-2 Various eye measurements are depicted (*top*). *A* indicates the outer canthal distance, *B* indicates the inner canthal distance, and *C* indicates the interpupillary distance (IPD), which is difficult to measure directly. The IPD can be determined using the graph at the *bottom* or with the Pryor formula: IPD = (A – B) 2 + B. (*From Feingold M, Bossert WH: Normal values for selected physical parameters: an aid to syndrome delineation*, Birth Defects *10:1-16, 1974.*)

The mouth and throat are examined for the presence of a cleft lip or palate; the shape of the palate and uvula are noted, and the presence of unusual features, such as tongue deformities, lip pits, frenula, and natal teeth, are recorded. A small retrognathic or receding chin, which can be a part of several syndromes or an isolated finding, should be noted. The neck is inspected for excess nuchal folds or skin and evidence of webbing. Any bony abnormalities in the neck should prompt an evaluation of the cervical vertebrae to confirm cervical and airway stability.

Evaluation of the chest and thorax involves lung auscultation and cardiac examination. Abnormal findings should prompt a consultation with a cardiologist and appropriate echocardiographic or invasive studies as needed. External measurements include determining the internipple distance and its ratio in regard to the chest circumference (Figure 19-7). The abdominal examination is focused on determining whether organomegaly is present, a finding typically associated with an inborn error of metabolism. The umbilicus should also be examined, with any hernias and the number of vessels present in the newborn cord being noted. A two-vessel cord, in which only a single artery is present, can be associated with renal anomalies. The genitourinary examination concentrates on determining whether anomalies such as hypospadias, chordee, cryptorchidism, microphallus, and ambiguous genitalia are present. These external anomalies may be associated with internal anomalies involving the upper urinary tract as

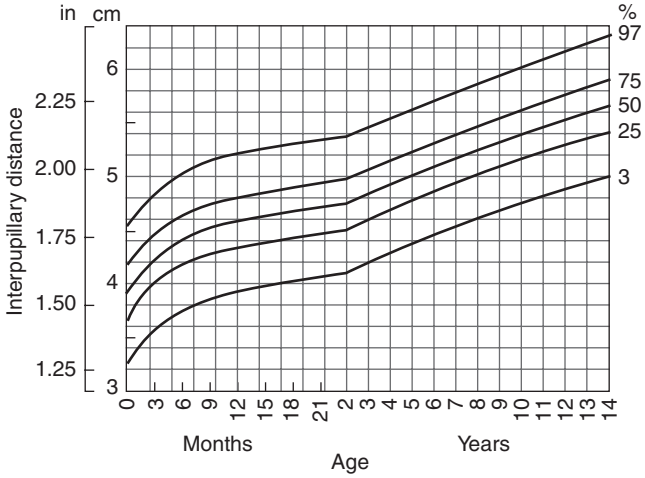

FIGURE 19-3 A nomogram for interpupillary distance at different ages for both sexes. (*From Feingold M, Bossert WH: Normal values for selected physical parameters: an aid to syndrome delineation*, Birth Defects *10:1-16, 1974.*)

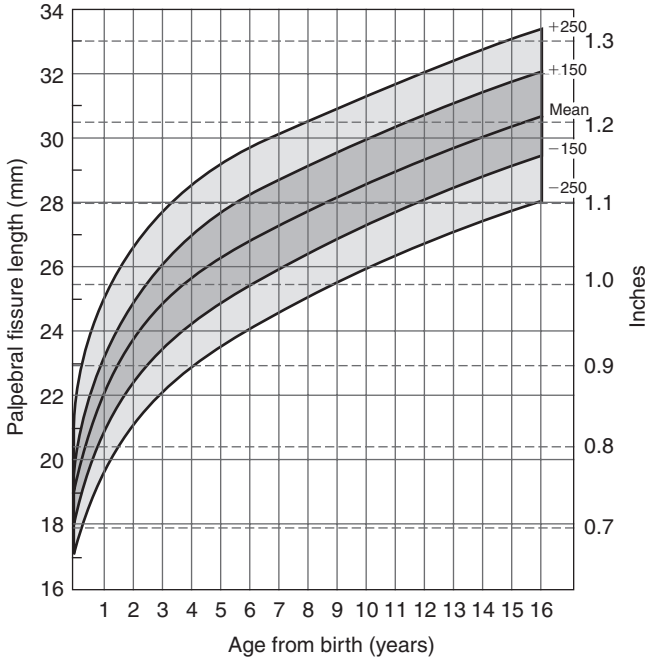

FIGURE 19-4 A graph of palpebral fissure length from birth to age 16 years for both sexes. (*From Hall JG, Allanson JE, Gripp KW, et al:* Handbook of physical measurements, *Oxford, 2007, Oxford University Press.*)

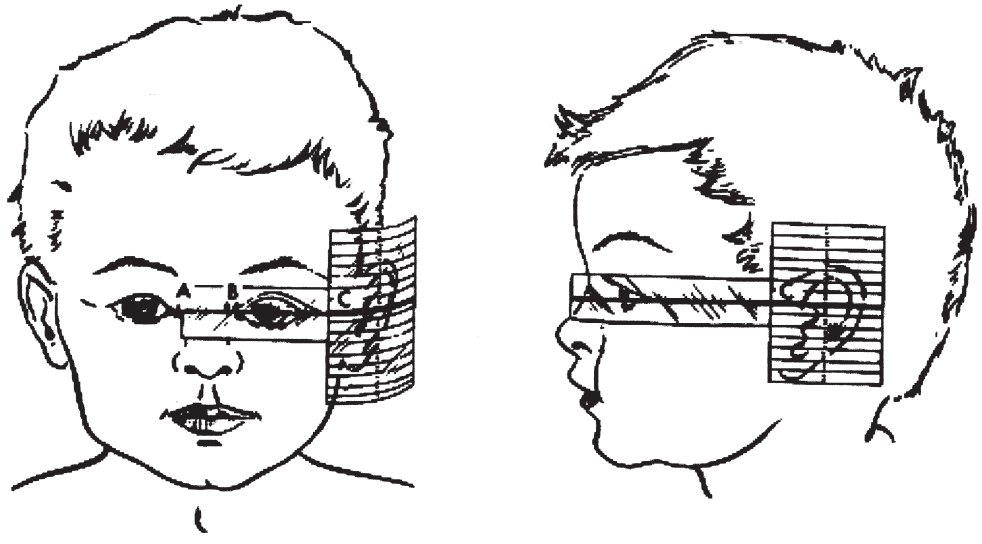

FIGURE 19-5 Ear placement. Using the medial canthi (*A* and *B*) as landmarks, one draws a central horizontal line and extends it to a point (*C*) on the side of the face. Ears attached below this line are considered low set.

well. The anus is examined for evidence of tags, its placement, and its patency.

The back should be assessed, especially for the shape of the spine and any associated defects, such as myelomeningocele. These defects prompt further radiologic evaluation to assess for potential functional limitations. In addition, a sacral dimple or hair tuft at the base of the spine should be noted, because either could signify developmental abnormalities in the underlying neural tissue.

Minor anomalies are often manifested in the extremities. Gross differences in the hands and feet include polydactyly (more than five digits), whether the extra digits are located in a preaxial or postaxial position should be noted, syndactyly (fusion of the digits), clinodactyly (incurving of the digits), and extremity length, which should be expressed as a percentile measured on age-appropriate graphs (Figures 19-8 and 19-9). Often these data can provide important clues to a unifying syndrome.

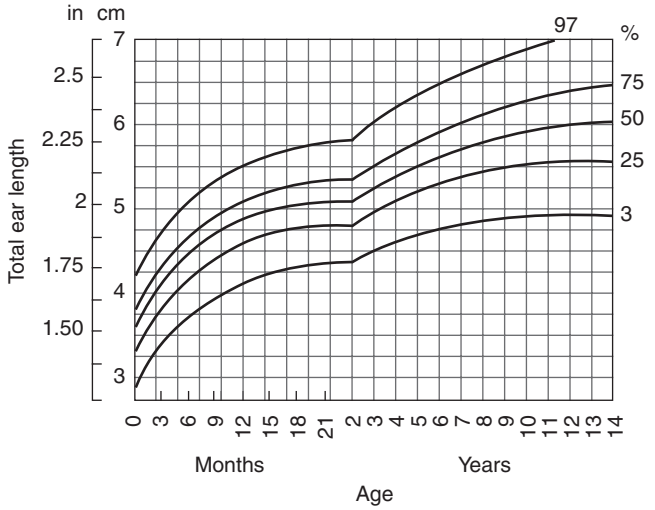

FIGURE 19-6 Graph showing various percentiles for ear length plotted against age. (*From Feingold M, Bossert WH: Normal values for selected physical parameters: an aid to syndrome delineation*, Birth Defects *10:1-16, 1974.*)

Dermal ridge patterns, or dermatoglyphics, are formed on the palms and soles early in embryonic life, and they vary considerably among individuals. This variation can be inherited and can be influenced by disturbances to the development of the peripheral limb buds. Environmental exposures and chromosomal aberrations can greatly affect the formation of these structures and are reflected by the dermatoglyphic pattern of an individual. Each of the distal phalanges has one of three basic dermal ridge patterns: arches, whorls, or loops (Figure 19-10). The predominance of a single pattern can be an associated feature of a genetic disorder. For example, the occurrence of arches on eight or more digits is a rare event, but is frequently encountered in children with trisomy 18 (Box 19-3).

Deltas, or triradii, form at the convergence of three sets of ridges on the palm. This junction is where the hypothenar, thenar, and distal palmar patterns converge. There are typically no triradii in the hypothenar area of the palm, but when patterning is present or is large, a distal triradius arises, which is found in only 4% of normal Caucasian individuals but in 85% of patients with trisomy 21 (Down syndrome). A single transverse palmar crease is found in 4% of controls, but in more than half of patients with trisomy 21 (Figure 19-11) and in even greater proportions in patients with other trisomies. The hallucal area of the foot, located at the base of the big toe, also has a dermal ridge pattern, usually a loop or whorl. A simple pattern or open field in this region is found in less than 1% of controls but in more than 50% of patients with Down syndrome (Figure 19-12). This unusual dermal pattern is also associated with hypoplasia of the hallucal pad and a wide space between the great and second toes in these patients.

An examination of the skin is also important, to look for phakomatoses or skin manifestations that herald the presence of an underlying disorder. Examples are café-au-lait spots (associated with neurofibromatosis type I) and ash leaf spots (associated with tuberous sclerosis and detected

with the use of a Wood's lamp). Irregular pigmentation, such as hypomelanosis of Ito, can be suggestive of chromosomal mosaicism, in which the different skin pigmentation patterns represent a different, mixed chromosomal composition. Hemangiomas and other skin diseases are also noteworthy.

Finally a careful neurologic examination with input from a specialist is often warranted in the child with multiple anomalies, because the neurologic status is often the most reliable prognostic indicator. Evaluation of tone, feeding, unusual movements, and the presence of seizure activity are critical pieces of diagnostic information.

ADJUNCT STUDIES

An exhaustive physical examination often reveals differences that require further evaluation for diagnostic, prognostic, and treatment purposes (Box 19-4). Poor feeding or cyanosis may lead to detection of internal organ malformations on echocardiogram or abdominal ultrasonography. Differences in head shape suggest the need for skull radiographs, three-dimensional computed tomography,

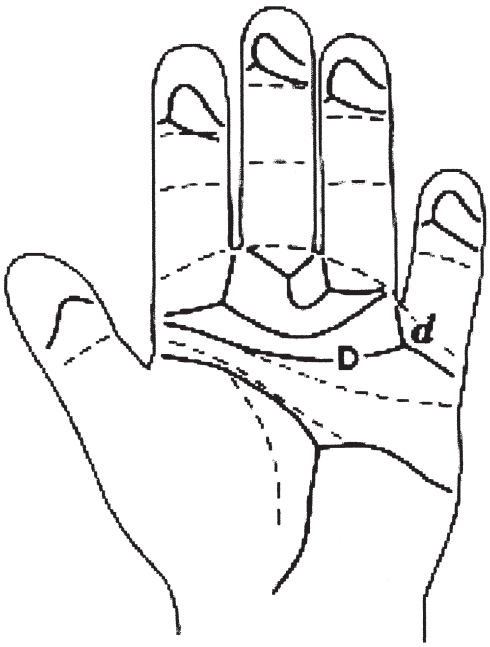

FIGURE 19-11 The patterns on the hand of a patient with Down syndrome depicting the palmar crease (*D*). (*From Holt SB:* The genetics of dermal ridges, *Springfield, Ill, 1968, Charles C Thomas.*)

or magnetic resonance imaging of the brain. A disproportionality of the limbs prompts a skeletal survey and bone age measurement.

It is prudent in children with anomalies involving multiple systems to obtain the input of relevant specialists. This step is often essential to medical decision making and the planning of interventions. Abnormal neurologic findings should prompt a consultation with a trained specialist and interpretation of studies such as head ultrasonography, brain magnetic resonance imaging, brainstem auditory evoked responses, and electroencephalogram for seizure activity. Muscle dysfunction might result in the ordering of electromyography, muscle ultrasound, or nerve conduction studies. Visual involvement requires a funduscopic examination by an experienced pediatric ophthalmologist, and sometimes studies of visual evoked responses or electroretinograms are needed to predict visual prognosis. Often there are well-characterized genetic disorders that have a specific pattern of abnormal findings in these highly specialized studies. Even when a unifying diagnosis is reached, there is often variation in the clinical phenotype, and determining the patient's prognosis on a system-by-system basis is typically the most appropriate and accurate way to proceed.

BOX 19-4 Processes Leading to Altered Form or Structure

DEFORMATION

Abnormal form resulting from mechanical forces

DISRUPTION

Morphologic defect caused by interference with a previously normal developmental process

DYSPLASIA

- Amniotic bands
- Localized: hemangioma
- Generalized (skeletal): achondroplasia

LITERATURE REVIEW

The occurrence of malformations can fit into one of several categories (Box 19-5). The next step toward reaching a diagnosis is to analyze the data generated from the evaluation and attempt to categorize the findings. A syndrome is a "collection of anomalies involving more than one developmental region or organ system," (Aase, 1990). The word itself means a "running together" or "pattern of multiple anomalies thought to be pathogenically related." Therefore a given congenital anomaly may be an isolated defect in an otherwise normal individual or part of a multiple malformation syndrome. Furthermore, the primary malformation itself can determine additional defects through an interrelated cascade of physical and functional processes; if ensuing malformations are related to one primary defect, factor, or event, a pathogenetic sequence has occurred. A classic example is the Pierre-Robin sequence or constellation, consisting of a small recessed jaw, midline U-shaped cleft palate, and relatively large and protruding tongue. The primary anomaly is the small jaw, which does not allow adequate room for the tongue and displaces it superiorly. The displaced tongue prevents closure of the palatine shelves, causing the cleft palate. The recurrence risk with this isolated occurrence is negligible. However,

Ethnic origin
Consanguinity

one should also remember that such sequences can also be part of a larger constellation of findings that does fit into a syndrome, as Pierre-Robin sequence can when it is part of velocardiofacial syndrome (caused by a deletion of chromosome 22q11) or Stickler syndrome (associated with mutations in the type II collagen gene). The recurrence risk for an affected individual passing on these particular syndromes to their children is 50%.

In addition, a cluster of several malformations that are not developmentally related can occur in a nonrandom fashion called an *association* that may appear without characteristic dysmorphic features. One such statistically nonrandom association of defects consists of vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, esophageal atresia, renal dysplasia, and limb anomalies (VACTERL). It should be noted that not all features need to be present and that the extent of involvement of each system is widely variable. Recently, the CHARGE syndrome (coloboma, heart disease, atresia choanae, retarded growth and development, genital anomalies, and ear anomalies/deafness) was considered an association until the *CHD7* gene was identified to cause approximately 60% of the cases (Lalani et al, 2006).

These associations often manifest as sporadic rather than familial occurrences. Because they are not clearly related by a common etiology or pathogenesis, they are not considered syndromes and do not technically constitute a diagnosis. Instead, they are a recognition of a statistically significant association of features. It is important to remember that many of these same anomalies can occur as features of chromosomal aneuploidy or other syndromes. Syndromic malformations tend to occur in more than one developmental field. A field defect or complex is a set of primary malformations in a developmental field that originates from a single or primary abnormality in embryonic development (see Box 19-5).

When generating a differential diagnosis of malformations that might occur together, the evaluator must also consider structures that may appear abnormally formed, but in fact are structures that underwent normal development and then received some insult that distorted their true form (Box 19-6). For example, a *deformation* describes the abnormal form, shape, or position of a part of the body that was caused by mechanical forces. Examples are clubfoot, hip dislocation, and craniofacial asymmetry; they can result from intrinsic (embryonic) or extrinsic (intrauterine) mechanical forces that alter the shape or position of an organ or part that had already undergone normal differentiation. Deformations are estimated to occur in 2% of births, and such factors as fetal crowding from the presence of multiple fetuses and uterine malformations, as well as oligohydramnios, and a face presentation during delivery can cause them.

Along similar lines, a *disruption* describes a "morphologic defect of an organ, part of an organ, or larger region of the body resulting from the extrinsic breakdown of, or an interference with, an originally normal developmental process," (Aase, 1990). The classic example of a disruption is entanglement of the fetus in amniotic bands. Amniotic bands are ribbons of amnion that have ruptured in utero and cause disruptions of normal developmental processes in the fetus, either through physical blockage or interruption of the blood supply or by entangling and tearing of developing structures. This effect is seen most often with digits and limbs, and remnants of the bands, or constriction marks, can frequently be seen at birth. If the fetus should swallow a band, a cleft palate might result; the etiology is a very different etiology from that of cleft palate occurring as a primary malformation. Recurrence risk counseling of the parent would be very different in these two scenarios.

Dysplasias occur when there is "an abnormal organization of cells into tissue(s) and its morphologic results," (Aase, 1990). Dysplasia tends to be tissue specific rather than organ specific (e.g., skeletal dysplasia) and can be localized or generalized.

In summary, structural or morphologic changes identified at birth can occur during intrauterine development as a result of malformations, deformations, disruptions, or dysplasia. However, approximately 90% of deformations undergo spontaneous correction. Malformations and disruptions often require surgical intervention when possible. Dysplasias are typically not correctable, and the affected individual experiences the clinical effects of the underlying cell or tissue abnormality for life (see Box 19-7). Examples of these entities are listed in Box 19-7.

After the history and physical evaluation are complete, a cross-reference of two or more anomalies is useful to generate a differential diagnosis. When the rest of the neonate's physical and history findings are added, the possibilities can often be narrowed down to a few entities that may be amenable to diagnostic testing. If multiple anomalies are present, it is usually best to start with the least common. As Aase (1990) has stated, "The best clues are the rarest. The physical features that will be the most

helpful on differential diagnosis are those infrequently seen either in isolation or as part of syndromes. Quite often, these are not the most obvious anomalies or even the ones that have the greatest significance for the patient's health." Cross-referencing is usually best accomplished by using published compendia of malformation syndromes. These compendia have been supplemented by databases that are accessible online (i.e., GeneReviews, *Online Mendelian Inheritance in Man*, and PubMed). The availability of such tools allows the cross-referenced features to be compared easily with those of other described syndromes that may include similar malformations. This systematic review produces a differential diagnosis for the constellation of features described and identifies references to pertinent literature.

The recognition of patterns of genetic entities involves the comparison of the proband with the examiner's personal experience of known cases and a search of the literature. Multiple anomalies may be causally related, occur together in a statistically associated basis, or occur together merely by chance. Diagnosis of a genetic disorder relies heavily on the ability of the clinician to suspect, detect, and correctly interpret physical and developmental findings and to recognize specific patterns. Accurate diagnosis of a syndrome in a child is important to the identification of major complications and their treatment if possible. It is also crucial for long-term management of patients and for parental counseling about recurrence in future offspring.

SPECIALIZED LABORATORY TESTS

In sorting through the array of possibilities listed, the geneticist uses one other important tool—the availability of highly specialized cytogenetic and molecular genetic testing, including:

- Karyotype
- Fluorescence in situ hybridization
- DNA microarray (see Chapter 20)
  - Comparative genomic hybridization
  - Single nucleotide polymorphism or oligonucleotide arrays
- Molecular analysis

The standard karyotype, or analysis of stretched and stained chromosome preparations usually taken from a peripheral blood sample, can often confirm a suggested diagnosis or explain a set of major malformations not classically encountered together. Further description of specific chromosomal abnormalities is addressed in Chapter 20; it is sufficient to note that multiple malformation syndromes can result from large visible chromosome rearrangements that lead to deletion or addition of material (aneuploidy). These rearrangements can involve an entire arm of a chromosome or can be submicroscopic, requiring further special testing. Such small deletions can often be detected by fluorescence in situ hybridization analysis, which is performed using a probe specific for the deleted region.

It has become the standard of care in several centers to offer more specialized molecular testing, such as a DNA microarray or individual gene sequencing, as an adjunct to or instead of karyotype analysis. In general, microarray-based methods are currently focused on detecting copy number changes (smaller deletions or duplications not detectable by a karyotype) and can be performed in a targeted or genome-wide fashion (Emanuel and Saitta, 2007). As more information is made available about the role of individual gene mutations in newborns with congenital malformations, testing for these mutations is becoming available in diagnostic laboratories. It can be useful to check with a geneticist or genetics counselor for the availability of gene mutation testing that may be clinically available or performed on a research basis. GeneTests is an internet database of laboratories worldwide that provides such services.

DIAGNOSIS

There are cases in which, after a detailed examination, exhaustive literature search, and genetic testing, no unifying diagnosis is evident. Aase (1990), a dysmorphologist, advises, "Don't panic! The absence of a diagnosis may be distressing to the diagnostician and the family, but it is much less dangerous than the possibility of assigning the wrong diagnosis with the risk of erroneous genetic and prognostic counseling and possibly hazardous treatment." Therefore, in cases in which there is no clear diagnosis, prognosis and treatment should be determined according to the organ systems involved and the extent of their impairment. In addition, when the infant has a severe, untreatable impairment or the patient's condition is critical, it may be prudent to offer and obtain consent for a full postmortem examination by an experienced pathologist. A skin sample, and sometimes blood, can be taken from the expired fetus for establishing a cell line or for extracting DNA for future testing. Information gained from such investigations may often become relevant for family members, including the parents, allowing one to provide accurate recurrence risk counseling and perhaps offer prenatal testing of a new pregnancy. Such information can often help to provide closure for the family as well.

When should a genetics evaluation be considered? The following clinical situations prompt a further genetic evaluation and counseling by a specialist:

- Multiple anatomic anomalies
- History of maternal exposure to teratogens
- Familial disorders
- Increased carrier frequency or ethnic risk
- Multiple pregnancy losses

As described previously, if a birth defect is identified in the presenting patient or proband, especially if the defect is associated with other anatomic anomalies, short stature, or developmental delays, the features of a specific genetic syndrome may be present. A known history of maternal exposure to a potential teratogen would also be an indication for consultation. Conditions appearing to be familial, a family history of hereditary disorders involving malformation of a major organ, or major physical differences such as unusual body proportions, short stature, or irregular skin pigmentation, would warrant genetic investigation. Mental retardation, blindness, hearing loss, or neurologic deterioration in multiple family members suggests a genetic etiology. Likewise, a strong family history of cancer or a defined ethnic risk such as Ashkenazi Jewish heritage and

its association with a higher carrier frequency for Tay-Sachs disease would be an indication for genetic evaluation. The occurrence of multiple pregnancy losses would also raise the suspicion of a genetically influenced cause and indicate the need for further investigation and counseling.

SUMMARY

Diseases with underlying genetic bases have significant effects on health care and its delivery. An appreciation of these entities, coupled with an organized, systematic evaluation, can help to define the nature of a given disorder and aid in the development of the optimal plan of treatment and care for the patient.

CHAPTER 20

Specific Chromosome Disorders in Newborns

Chad R. Haldeman-Englert, Sulagna C. Saitta, and Elaine H. Zackai

It has been estimated that 3% of newborns have a major structural anomaly that will affect their quality of life. Although most of these patients have a single malformation, 0.7% of infants have multiple major malformations. In an additional 2%, a major anomaly is discovered by the age of 5 years. Early identification of the genetic nature of a given condition can aid in treatment and help to identify resources for providing better health care to these individuals. This chapter will focus on genetic disorders and syndromes with underlying chromosomal abnormalities that typically manifest in the newborn period, in addition to the shift in genetic evaluation and diagnosis with the advent of newer array-based diagnostic techniques.

HUMAN KARYOTYPE

Chromosomes consist of tightly compacted DNA whose structure is maintained by association with histones and other proteins. When treated and stretched, chromosomes from dividing cells can be visualized under the light microscope as linear structures with two arms joined by a centromere. The short arm is designated *p* (petit) and the long arm is designated *q*. The ends of the p and q arms are known as *telomeres*. Human chromosomes were first visualized in 1956 (Lejeune and Turpin, 1960), and each pair shows a distinctive size, centromeric position, and staining or banding pattern after treatment with special dyes, allowing it to be identified and classified. Each chromosome is identified by a number, in general from largest to smallest, in standard international cytogenetic nomenclature. This presentation, or karyotype (Figure 20-1), normally consists of 46 chromosomes, with 22 pairs of autosomes and one set of sex chromosomes—two X chromosomes for females (46,XX), and an X and a Y for males (46,XY).

Karyotype analysis is performed in cells undergoing mitosis, or cell division, in which the chromosomes condense and can be stained and visualized. Thus, cells that can be stimulated to divide and grow in culture, such as peripheral blood lymphocytes, skin fibroblasts, and amniocytes, are typically used. Cells from bone marrow and chorionic villi are normally undergoing rapid cell division and can also be karyotyped successfully. Historically, several different staining methods have been described. However, G-banding (Giemsa staining) is the standard cytogenetic method used. This technique permits a resolution of at least 400 bands among all the chromosomes and can be adapted to allow for high-resolution analysis of up to 800 bands to analyze structural rearrangements as small as 5 to 10 million or megabase pairs (Mb).

Gamete formation, either spermatogenesis or oogenesis, is accomplished by a process known as *meiosis*. In the first part of meiosis (meiosis I), homologous chromosomes align as pairs and cross over, exchanging genetic material, also known as *recombination*. In this stage, reduction division, the recombined pairs separate and the typical diploid content (46 chromosomes) of the cell is reduced by half to a haploid complement of 23 chromosomes. In the next stage, meiosis II, the chromosomes separate, similar to mitosis (Nussbaum et al, 2007). The full diploid state of the cell will be restored at the time of fertilization.

An imbalance of genetic material, or aneuploidy, occurs from a net loss or gain of genetic material during sperm or egg formation or, less commonly, during the initial divisions of the embryo. This missing or extra genetic material can be small pieces or parts of chromosomes or an entire chromosome itself. The classic recognizable aneuploidy syndromes involve trisomy (three copies of a given chromosome) such as those of chromosomes 13, 18, and 21, or monosomy (only a single copy) of a complete chromosome, such as X. Trisomies in particular can occur from nondisjunction, a failure of normal chromosome separation. In such cases, a pair of homologues does not separate in meiosis; one daughter cell receives both homologs of that pair, and the other cell receives none. This event can occur in either part of gamete division, meiosis I or meiosis II. Most human meiotic nondisjunction arises during oocyte formation, specifically in maternal meiosis I. Nondisjunction of meiosis I is especially pronounced in trisomies of the acrocentric chromosomes (13, 14, 15, 21, and 22) and in XXX trisomy (MacDonald et al, 1994; Zaragoza et al, 1994). The occurrence of meiotic nondisjunction increases significantly with maternal age. Therefore prenatal karyotyping from amniocentesis or chorionic villus sampling is offered to women aged 35 years and older (Hook and Cross, 1982).

Nondisjunction can also occur in mitosis, with uneven division of genetic material during early embryonic cell division. This can result in two cell lines, one trisomic lineage that is potentially viable and one monosomic line. If this event occurs after the first postzygotic division, cells with a normal chromosome complement may also exist with cells containing an aneuploid complement as a mosaic chromosome constitution.

Partial aneuploidy may result from several mechanisms, such as rearrangements of material between nonhomologous chromosomes that can occur in the gametes of a balanced translocation carrier. The carrier parent who has no net loss or gain of genetic material is usually phenotypically normal; however, the offspring are at increased risk for an unbalanced rearrangement and its phenotypic consequences. Attention has also been focused on deletion syndromes caused by the loss of genetic material from several chromosomes (e.g., 1p-, 4p-, 5p-), with a resulting, often recognizable phenotype. Other microdeletions have been associated with segmental duplications, or large blocks of DNA that contain chromosome-specific repetitive

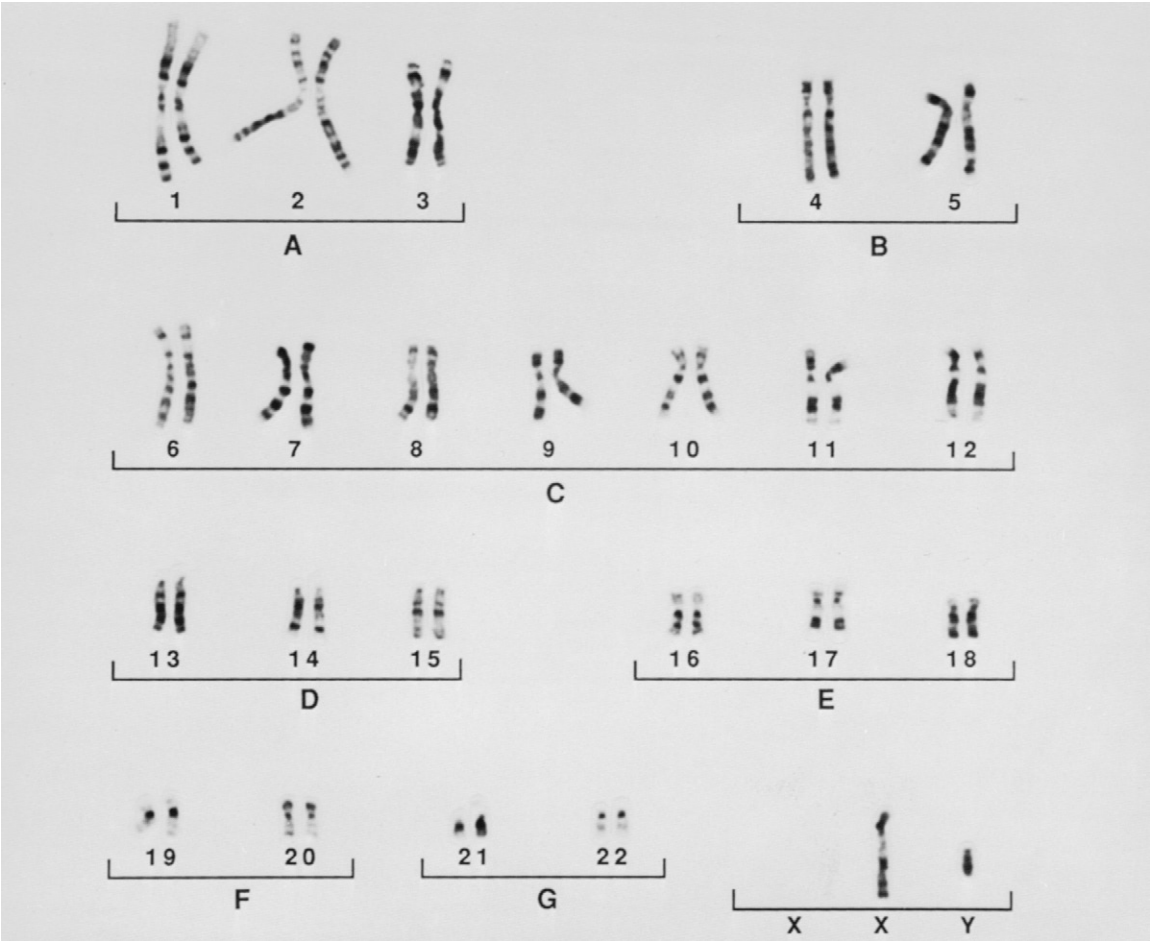

FIGURE 20-1 G-banded human male karyotype. The 46 chromosomes are arranged into 23 pairs, each with a specific banding pattern.

sequences (Emanuel and Saikh, 2001). It is thought that the repeats can mediate misalignment between two homologs and have been shown to be present in regions of the genome prone to instability, such as the pericentromeric regions of chromosomes 7q11, 15q11, 17q11, and 22q11, leading to the phenotypes seen in Williams-Beuren syndrome, Prader-Willi or Angelman syndrome, Charcot-Marie-Tooth disease or hereditary neuropathy with liability to pressure palsies, and DiGeorge or velocardiofacial syndrome, respectively (Emanuel and Saitta, 2007). The use of fluorescent in situ hybridization (FISH) and chromosome-specific subtelomeric FISH and the advent of DNA microarrays has allowed the identification of smaller chromosomal rearrangements that were largely unrecognized until recently. The use of high-resolution microarrays in infants with multiple congenital anomalies has in many cases led to the identification of a specific genotype, with clinical investigations then further defining the associated phenotype (Bejjani and Shaffer, 2008).

TRISOMIES

DOWN SYNDROME (TRISOMY 21)

Lejeune and Turpin (1960) demonstrated that trisomy of human chromosome 21 caused the constellation of findings recognized as Down syndrome (Figure 20-2). This chromosome disorder was the first to be described and is the most common viable autosomal trisomy, occurring in approximately 1 in 700 to 800 live births (Hook, 1992). The vast majority (>90%) occurs secondary to meiotic nondisjunction, and a pronounced maternal age effect is encountered. Approximately 3% to 5% of cases are caused by a translocation, that could be either de novo or passed from a balanced translocation-carrier parent, that becomes unbalanced and trisomic in the baby. Typically, the translocated chromosome 21 rearranges with another acrocentric chromosome, often chromosome 14, resulting in a Robertsonian translocation. Mitotic nondisjunction, or mosaic Down syndrome, has been demonstrated in approximately 3% of cases as well, with variable features ranging from normal to a typical Down syndrome phenotype.

Clinical Features

It is the more common occurrence of Down syndrome in babies of older mothers that led to the use of prenatal karyotyping for advanced maternal age (>35 years) at the time of conception, with samples typically obtained by amniocentesis after 15 weeks' gestation, or chorionic villus sampling at 10 to 12 weeks' gestation. Maternal serum analyte testing is used for prenatal screening purposes, with results showing low alpha-fetoprotein, low unconjugated estriol, and elevated total human chorionic gonadotropin.

FIGURE 20-2 Newborn with Down syndrome (trisomy 21) illustrating some of the characteristic facial features, including upward-slanting palpebral fissures and a flat facial profile.

Associated ultrasonographic findings for Down syndrome, including a cardiac defect, shortened long bones, underdeveloped fetal nasal bone, nuchal translucency or thickening, echogenic small bowel, and duodenal atresia ("double-bubble" sign), may be seen in 50% to 60% of fetuses. Most patients with Down syndrome, if not diagnosed prenatally, are usually recognized at birth because of the typical phenotypic features, which then prompt karyotype analysis.

The constellation of physical findings associated with Down syndrome consists of brachycephaly, presence of a third fontanel, upward-slanted palpebral fissures, epicanthal folds, Brushfield spots in the irises, flattened nasal root, small posteriorly rotated ears with over-folded superior helices, prominent tongue, short neck with excess nuchal skin, single palmar creases, brachydactyly, fifth-finger clinodactyly, exaggerated gap between the first and second toes, open field hallucal pattern, and hypotonia (see Figure 20-2). Often the physical features conform to an easily distinguishable phenotype, but in some cases, prematurity or ethnic variations can make a clinical diagnosis less straightforward. An immediate karyotype is indicated to confirm the diagnosis and as preparation for counseling the family.

Malformations involving many organ systems have been described in Down syndrome, and whether the diagnosis is known prenatally or determined in the newborn period, several clinical investigations are warranted when this diagnosis is suggested. The most common malformation is congenital heart disease (seen in approximately 50% of cases), which may require surgical intervention. Atrioventricular canal defects are often encountered (mean of 40%), although ventricular septal defects (VSDs), atrial septal defects (ASDs), tetralogy of Fallot, and patent ductus arteriosus (PDA) are all described in the disorder. An echocardiogram is indicated in all cases, and medical and surgical interventions of cardiac lesions are routine. Gastrointestinal malformations, especially duodenal atresia (2% to 5%), in addition to Hirschsprung disease and less frequently encountered conditions, such as esophageal atresias, fistulas, and webs throughout the tract, have been described. It is critical to carefully monitor the baby's feeding and bowel function before considering discharge from the nursery.

Although growth parameters can be in the range of 10% to 25% at birth, significantly decreased postnatal growth velocity is encountered in these patients. Separate growth curves have been devised for patients with Down syndrome (Fernandes et al, 2001), because growth retardation involving height, weight, and head circumference has been well documented. An initial ophthalmologic evaluation is also indicated in the first few months of life and then annually, because strabismus, cataracts, myopia, and glaucoma have been shown to be more common in children with Down syndrome. In addition, hearing loss of heterogenous origin is present in approximately half of patients, with middle ear disease contributing to this problem.

Spinal cord compression caused by atlantoaxial subluxation from ligamentous laxity and subsequent neurologic sequelae can be a complication of the disorder. Screening radiographs are typically performed at approximately 3 years of age. Physicians should be vigilant in evaluating the cervical spine, especially before administration of anesthesia and before an older child's participation in sports. Other associated disorders that merit screening are hypothyroidism in approximately 5% of patients, often with the presence of thyroid autoantibodies. Initial evaluation occurs with newborn screening programs, followed by additional thyroid-stimulating hormone and free thyroxine levels at 6 months, 12 months, and then yearly thereafter. Bone marrow dyscrasias, such as neonatal thrombocytopenia, and transient self-resolving myeloproliferative disorders, such as leukemoid reaction, have been observed in the first year of life. An elevated rate of leukemia with a relative risk of 10 to 18 times normal up to age 16 years has been described. Acute nonlymphoblastic leukemia is seen at higher rates in congenital or newborn cases, but the distribution becomes similar to that of non–Down syndrome patients after age 3 years. Survival of patients with Down syndrome is shorter after a diagnosis of acute lymphoblastic leukemia than in diploid patients (Epstein, 2001).

Patients with Down syndrome demonstrate a wide range of developmental abilities, with highly variable personalities and behavioral phenotypes as well (Pueschel et al, 1991). Central hypotonia with concomitant motor delay is most pronounced in the first 3 years of life, as are language delays. Therefore immediate and intensive early intervention and developmental therapy are critical for maximizing the developmental outcome. A wide range of intelligence has been described, with conflicting data on genetic and environmental modifiers of outcome (Epstein, 2001). Seizure disorders occur in 5% to 10% of patients, often manifesting in infancy.

The most common causes of death in patients with Down syndrome are related to congenital heart disease, to infection (e.g., pneumonia) that is thought to be associated with defects in T-cell maturation and function, and to malignancy (Fong and Brodeur, 1987). Once medical and surgical interventions for the correction of associated congenital malformations are complete and successful, the long-term survival rate is good. However, fewer than half of patients survive to 60 years, and fewer than 15% survive

past 68 years. Neurodegenerative disease with features of Alzheimer's disease is encountered in most patients who are older than 40 years, although frank dementia is not typical. Men with Down syndrome are almost always infertile, whereas small numbers of affected women have reproduced (Epstein, 2001).

In counseling the family of a newborn diagnosed with Down syndrome, it is important to include the organ systems affected in their baby and the severity of each malformation when defining a prognosis. Above all, the wide variability of the phenotype should be emphasized, with a care plan tailored to the needs of the individual patient.

Genetic Counseling

If a complete (full chromosome) or mosaic trisomy 21 is found, parental karyotypes are generally not analyzed, because the karyotypes are normal in virtually all cases. After having one child with Down syndrome, a mother's recurrence risk for another affected child is approximately 1% higher than her age-specific risk (Hook, 1992). This fact is especially significant in younger mothers, whose age-specific risks are low. If a de novo translocation resulting in Down syndrome is found, the recurrence risk is less than 1%. If the mother is found to carry a constitutional balanced Robertsonian translocation, the risk for another translocation Down syndrome fetus is approximately 15% at the gestational age when amniocentesis is offered, and 10% at birth. However, if the father is the translocation carrier, the recurrence risk is significantly smaller, approximately 1% to 2% (Epstein, 2001). Whereas newer array-based diagnostic techniques will identify the copy number change associated with the trisomy, structural rearrangements such as Robertsonian translocations are not readily detected. In this situation, a karyotype will provide information regarding the mechanism of the copy number change, which is needed for accurate recurrence risk counseling.

EDWARDS SYNDROME (TRISOMY 18)

Trisomy 18 is encountered in 1 in 6000 live births and is associated with a high rate of intrauterine demise. It is estimated that only 5% of conceptuses with trisomy 18 survive to birth and that 30% of fetuses diagnosed by second-trimester amniocentesis die before the end of the pregnancy (Hook, 1992). Findings on prenatal ultrasonography can raise suspicion for the disorder—growth retardation, oligohydramnios or polyhydramnios, heart defects, myelomeningocele, clenched fists, and limb anomalies. Maternal serum screening can show low values for alpha-fetoprotein, unconjugated estradiol, and total human chorionic gonadotropin, indicating the need for subsequent karyotype analysis and fetal ultrasonographic monitoring.

Clinical Features

Phenotypic features present at birth consist of intrauterine growth restriction (1500 to 2500 g at term), small narrow cranium with prominent occiput, open metopic suture, low-set posteriorly rotated ears, and micrognathia with small mouth. Characteristic clenched hands with overlapping digits, excess of arches on dermatoglyphic examination, hypoplastic nails, and "rocker-bottom" feet or prominent heels with convex soles (Figure 20-3) are also described. Additional malformations encountered in this syndrome are congenital heart disease (ASD, VSD, PDA, pulmonic stenosis, aortic coarctation), cleft palate, clubfoot deformity, renal malformations, brain anomalies, choanal atresia, eye malformations, vertebral anomalies, hypospadias, cryptorchidism, and limb defects, especially of the radial rays.

FIGURE 20-3 Newborn with trisomy 18, showing prominent occiput, characteristic facial appearance, and clenched hands.

The prognosis in this disorder is extremely poor, with more than 90% of babies succumbing in the first 6 months of life and only 5% alive at 1 year old. Death is caused by central apnea, infection, and congestive heart failure. The newborn period is characterized by poor feeding and growth, typically requiring tube feedings. A few patients have been described who have survived into childhood and beyond. Universal poor growth and profound mental retardation with developmental progress stopping at that of a 6-month-old infant (Baty et al, 1994) have been documented. Malignant tumors such as hepatoblastoma and Wilms' tumor have been described in some of the survivors. In the few patients in whom cardiac surgery was performed, outcome was not shown to be improved.

Genetic Counseling

The typical estimate of a recurrence risk for trisomy 18 in a future pregnancy is a 1% risk over the maternal age–specific risk for any viable autosomal trisomy (Hook, 1992). Trisomy occurring from a structural rearrangement, such as a translocation, warrants parental karyotype analysis before the recurrence risk can be assessed.

PATAU SYNDROME (TRISOMY 13)

It has been estimated that approximately 2% to 3% of fetuses with trisomy 13 survive to birth, with a frequency of 1 in 12,500 to 21,000 live births (Hook, 1992). As with

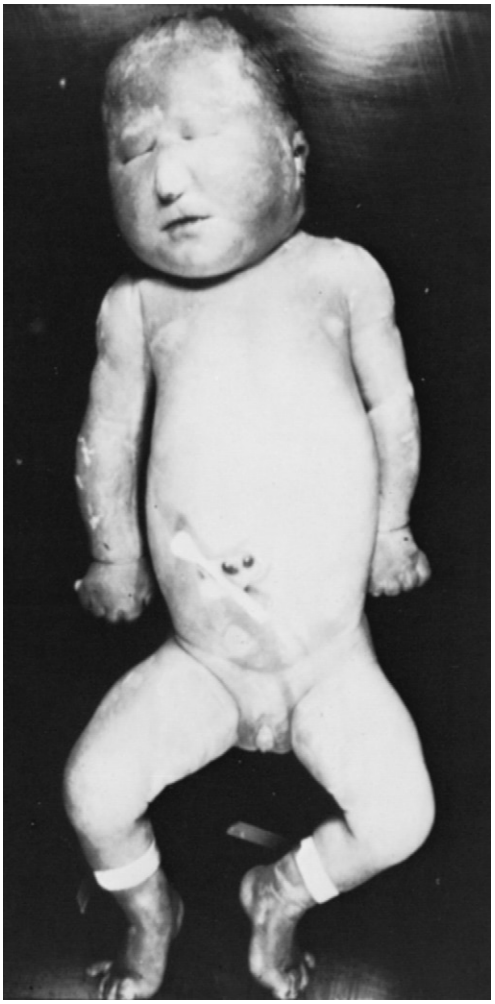

FIGURE 20-4 Stillborn with trisomy 13. The facial appearance is that of cebocephaly, which is associated with holoprosencephaly. There is an extra digit on the ulnar border of the right hand.

other trisomies, amniocentesis performed for advanced maternal age or indicated by fetal ultrasonographic findings may lead to a prenatal diagnosis of trisomy 13.

Clinical Features

Trisomy 13–associated malformations include congenital heart disease, cleft palate, holoprosencephaly, renal anomalies, and postaxial polydactyly (Figure 20-4). In addition, microcephaly, eye anomalies, and scalp defects can suggest the diagnosis. Brain malformations such as holoprosencephaly are found in more than half the patients, with concomitant seizure disorders. Microcephaly, split sutures, and open fontanels are encountered. A scalp defect (cutis aplasia) that can sometimes be mistakenly attributed to a fetal scalp monitor is specific to the disorder, being found in 50% of cases. Eye malformations, including iris colobomas and hamartomatous cartilage "islands," can be seen on funduscopic examination.

Congenital heart disease is present in approximately 80% of patients, usually VSD, ASD, PDA, or dextrocardia. Limb anomalies, such as postaxial polydactyly, single palmar creases, and hyperconvex narrow fingernails, are also seen. The fingers can be flexed or overlapped and can show camptodactyly. An increased frequency of nuclear projections in neutrophils, giving a drumstick appearance similar to that of Barr bodies, can also be found. This finding would be especially striking in males, in whom Barr bodies would not be expected.

As with trisomy 18, prognosis for the fetus with trisomy 13 is extremely poor, with 80% mortality in the neonatal period, and less than 5% of patients surviving to 6 months old. Mental retardation is profound, and many patients are blind and deaf as well. Feeding difficulties are typical.

Genetic Counseling

Recurrence risk data suggest that, as with trisomy 18, the chance that a woman will have a child with any trisomy after a pregnancy affected by trisomy 13 is rare. The estimated risk is 1% higher than the maternal age–related risk for the recurrence of any viable autosomal trisomy in a subsequent pregnancy.

TURNER SYNDROME (45,X)

In early embryogenesis, two active X chromosomes are required for normal development. Turner syndrome, a phenotype associated with loss of all or part of one copy of the X chromosome in a female conceptus, occurs in approximately 1 in 2500 female newborns. The 45,X karyotype or loss of one entire X chromosome accounts for approximately half of the cases. A variety of X chromosome anomalies—including deletions, isochromosomes, ring chromosomes, and translocations—account for the remainder of the causes. It is important to note that approximately 0.1% of fetuses with a 45,X complement survive to term; the vast majority (>99%) is spontaneously aborted. This fact underscores the requirement for both X chromosomes during embryonic development. Additional studies indicate that in approximately 80% of cases, it is the paternally derived X chromosome that is lost (Willard, 2001).

Clinical Features

There is wide phenotypic variability in patients with Turner syndrome. Features present at birth include short stature, webbed neck, craniofacial differences (epicanthal folds and high arched palate), hearing loss, shield chest, renal anomalies, lymphedema of the hands and feet with nail hypoplasia, and congenital heart disease. Typical cardiac defects are bicuspid aortic valve, coarctation of the aorta, valvular aortic stenosis, and mitral valve prolapse.

Growth issues, especially short stature, are the predominant concern in childhood and adolescence; the mean adult height of patients with Turner syndrome is 135 to 150 cm without treatment. Growth hormone therapy, which is routinely offered starting at approximately 4 to 5 years old, can lead to an average gain of 6 cm or more in final adult height (Willard, 2001). Primary ovarian failure caused by gonadal dysplasia (streak gonads) can result in delay of secondary sexual characteristics and primary amenorrhea. Cyclic hormonal therapy is initiated at the age of puberty to aid the development of secondary sex characteristics

and menses as well as to help bone mass. Infertility, related to gonadal dysplasia, is typical and has been successfully treated with assisted reproduction techniques and donor oocytes. It is important to evaluate for structural cardiovascular defects in the patient before pregnancy.

In terms of intellectual development, specific difficulties with spatial and perceptual thinking lead to a lower performance intelligence quotient; however, this syndrome is not characterized by mental retardation.

TRIPLOIDY (69,XXX OR 69,XXY)

As its name implies, triploidy is a karyotype containing three copies of each chromosome. Mechanisms that lead to this state include fertilization of the egg by two different sperm (dispermy) and complete failure of normal chromosome separation in maternal meiosis. The vast majority of triploid fetuses are spontaneously aborted, accounting for up to 15% of chromosomally abnormal pregnancy losses. Live births of affected fetuses are rare, and reports of survival beyond infancy are only anecdotal. Mosaicism with combinations of diploid and triploid cells (mixoploid) has also been documented. Malformations, including hydrocephalus, neural tube defects, ocular and auricular malformations, cardiac defects, and 3-4 syndactyly of the fingers, are associated findings. In addition, the placenta is often abnormal, typically large, and cystic.

DELETION SYNDROMES

In addition to the aneuploid conditions described previously, partial monosomy of a chromosome can lead to a recognizable pattern of malformations. Three known syndromes that are associated with the deletion or loss of genetic material from the short, or *p* arms of chromosomes 1, 4, and 5 are described. All these syndromes are associated with deletions that involve the loss of many genes located in a specific region.

CHROMOSOME 1p DELETION SYNDROME (1p-)

Monosomy for the distal short arm of chromosome 1, or deletion of 1p36, has been associated with a constellation of clinical findings. A characteristic facies consisting of frontal bossing, large anterior fontanel, flattened midface with deep set eyes, and developmental delay has been described (Figure 20-5). Orofacial clefting, hypotonia, seizures, deafness, and cardiomyopathy are also noted.

This deletion syndrome is estimated to occur in approximately 1 in 10,000 live births, and it is the most frequently occurring subtelomeric deletion. Greater recognition of the phenotype, the availability of a specific FISH test, and current widespread use of DNA microarrays will likely lead to improved diagnosis of this condition. The majority of deletions arise de novo in the patient, with approximately 3% being attributable to malsegregation of a balanced parental translocation. The size of the deletion varies, from submicroscopic (<5 Mb) to large, cytogenetically visible deletions greater than 30 Mb. A correlation between the size of the deletion and the severity of clinical features is suggested.

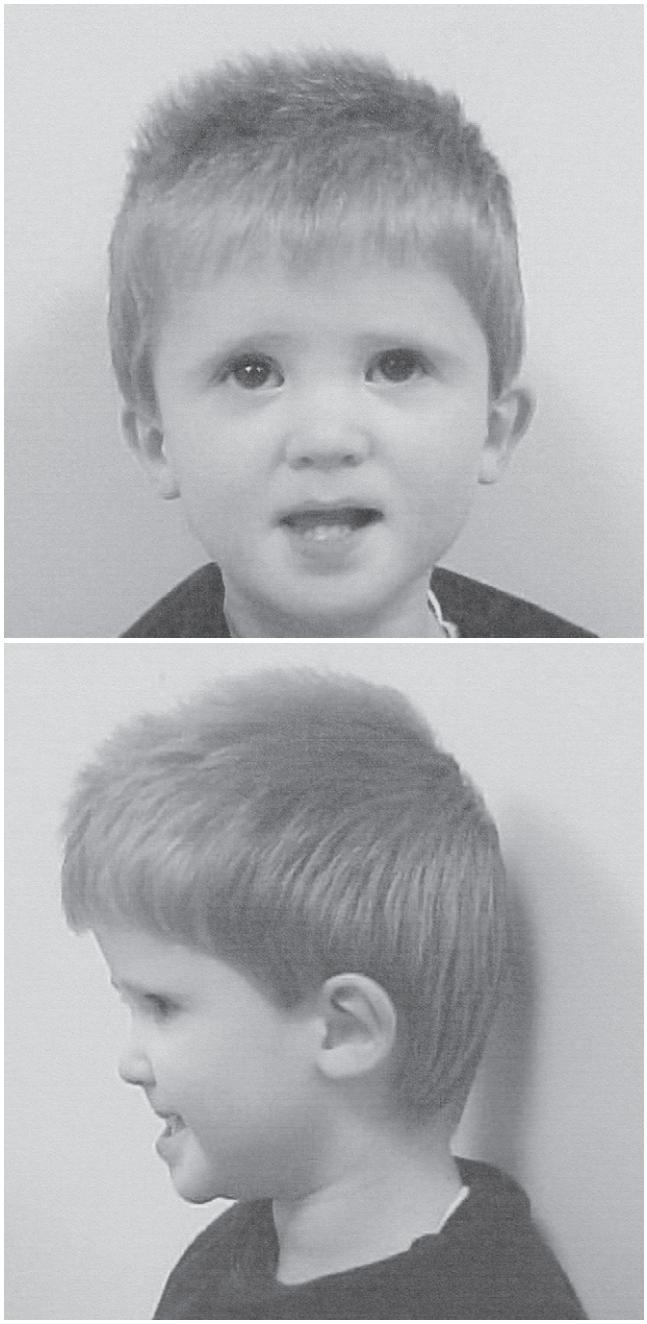

FIGURE 20-5 Child with deletion of chromosome 1p.

WOLF-HIRSCHHORN SYNDROME (4p-)

Distal deletions of the short arm of chromosome 4 are associated with a recognizable pattern of malformation. This syndrome is estimated to occur in 1 in 50,000 births and has features such as intrauterine growth restriction, microcephaly, midline structural defects such as cleft lip and cleft palate, cardiac septal defects, and hypospadias. The characteristic facial features are described as the Greek helmet facies, as evidenced by hypertelorism with epicanthi, a high forehead with a prominent glabella, and a beaked nose. Prominent, low-set ears are also seen. Hypotonia, failure to thrive, and developmental delay are common, with one third of infants dying in the first year of life.

Many patients have lived well into childhood and even into adulthood, although profound growth and mental retardation is typical and often accompanied by seizures.

Although most deletions are cytogenetically visible on karyotype analysis, small submicroscopic deletions have also been described. In cases in which the clinical features are suggestive but the karyotype is not revealing, further cytogenetic analysis using specific 4p telomere probes or a DNA microarray can be diagnostic. More than 80% of 4p deletions arise de novo in the patient, with minimal risk of recurrence. In the 10% to 15% of cases resulting from a translocation, analyzing parental samples is clinically indicated for appropriate recurrence risk counseling.

CRI DU CHAT SYNDROME (5p-)

Partial monosomy of chromosome 5p is seen in approximately 1 in 50,000 live births and is associated with a multiple congenital anomaly syndrome named for the unusual cry of the affected babies, described as similar to that of a cat, or *cri du chat*. The constellation of features associated with this disorder includes low birthweight, microcephaly, round face, hypertelorism or telecanthus, downward-slanting palpebral fissures, epicanthi, and broad nasal bridge. Hypotonia and cardiac defects are also seen, including ASD, VSD, and tetralogy of Fallot. Early issues include failure to thrive and pronounced developmental delay. The unusual cry usually resolves during infancy, and survival into adulthood is possible but is typically associated with severe mental retardation. Intensive therapy appears to provide some benefit, and more sensitive measures of cognition demonstrate clearly better receptive language skills than expressive language ability. Therefore children may understand more complex verbal language than their expressive skills might demonstrate (Cornish et al, 1999).

It is estimated that almost 100 genes are lost when the putative critical region from 5p15.2 to p15.33 is deleted (Shaffer et al, 2001; Zhang et al, 2005). Close to 90% of 5p deletions arise de novo in the affected child, incurring a minimal risk of recurrence (<1%). The remainder arise from malsegregation of a balanced translocation in a carrier parent, which would be associated with a 10% to 15% risk of recurrence of an unbalanced karyotype in a future live born infant. Parental chromosome analysis is indicated for proper recurrence risk counseling.

DNA MICROARRAYS

Recently, emphasis has been placed on characterizing variations of the genome that fall in the range between the single nucleotide and visible chromosomal changes—submicroscopic structural variants (less than 5 Mb) that cannot be seen by standard karyotype. An emerging technology rapidly gaining acceptance in various clinical settings involves the use of DNA microarrays (Bejjani and Shaffer, 2008; Miller et al, 2010). In general, microarray-based methods are focused on detecting copy number changes, and rearrangements such as balanced translocations or inversions are not detectable using this methodology. Microarray testing can be performed in either a targeted or genome-wide fashion. Two types of DNA microarray platforms are used currently: array comparative genomic hybridization, which can utilize bacterial artificial chromosomes containing large DNA segments as probes, or small oligonucleotides as DNA probes. Other approaches use single nucleotide polymorphism arrays that include probes based on known polymorphisms present in the human genome. Single nucleotide polymorphism–based arrays or dense oligonucleotide arrays have the advantage of detecting gains or losses of shorter stretches of the genome, because the probes for a given region can be densely arrayed, and the sensitivity for detecting alterations of that region is greatly enhanced.

With a single test, microarrays can detect genomic errors associated with disorders that are usually identified by cytogenetic analysis and multiple FISH studies. Whereas microarray analysis is proving robust and providing an exceptional level of resolution from a diagnostic perspective, the major difficulty with the current interpretation of the results lies in assigning causality and clinical significance to the multiple alterations that are detected in each individual. Toward this end, the availability of databases with information on normal variation in multiple ethnic populations and testing of unaffected parents remain standard approaches to discerning whether a copy number change is likely to cause disease.

SEGMENTAL DUPLICATIONS AND MICRODELETION SYNDROMES

A greater appreciation of the complexity of the human genome and its structure has now been afforded with the completion of the human genome sequence. This work has focused attention on regions of the genome that are prone to rearrangement. The presence of such unstable regions appears to have a significant role in the etiology of several genetic disorders (Emanuel and Shaikh, 2001; Emanuel and Saitta, 2007). These disorders result from inappropriate dosage of crucial genes in a given genomic segment via either structural mechanisms (deletion or duplication) or functional mechanisms (imprinting or uniparental disomy). It has also been demonstrated that many of these regions of genomic instability have a common element: the presence of large, chromosome-specific low copy repeats that most likely mediate misalignment and unequal crossover during recombination, leading to rearrangements such as a deletion and duplication (Figure 20-6). Many of these large repeat structures are localized to a single chromosome or within a single chromosomal band. Examples of such genomic disorders are hemophilia A (inversion of Xq28), Sotos syndrome (in which a number of patients have a deletion of 5q35), Smith-Magenis syndrome (deletion of 17p11.2), Charcot-Marie-Tooth disease (interstitial duplication on 17p12), and the reciprocal deletion of this same region of 17p12, leading to hereditary neuropathy with liability to pressure palsies and a small percentage of patients with neurofibromatosis type I (deletion involving 17q11.2).

In this section, we focus on several deletion syndromes that occur on chromosomes whose underlying genomic structure contains segmental duplications such as Williams-Beuren syndrome (involving chromosome 7q11.2), Prader-Willi syndrome or Angelman syndrome (involving an imprinted region of chromosome 15q11

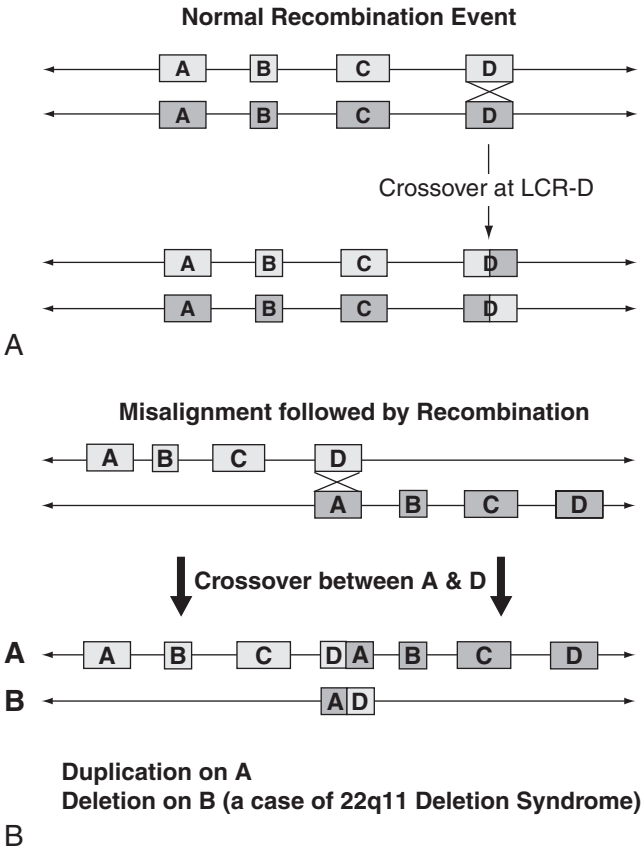

FIGURE 20-6 **A,** Alignment of low copy repeats (LCRs) before exchange. **B,** Misalignment of LCRs before exchange can result in rearrangement.

through 15q13), and DiGeorge or velocardiofacial syndrome (DGS/VCFS), the most commonly occurring microdeletion syndrome in humans, involving chromosome 22q11.2. It is important to note that in several of these microdeletion syndromes, there is the possibility that a reciprocal duplication of the exact same region may also occur (see Figure 20-6). Typically, the duplication syndromes cause fewer abnormalities and have wide phenotypic variability, but they are often characterized by developmental delays or behavioral abnormalities.

In addition, there are newly recognized microdeletion syndromes (e.g., 1q21.1, 3q29, 15q13.3, 16p11.2, and 17q21) that are rapidly being identified because of the increased use of DNA microarrays in the clinical and research settings. These regions are similarly flanked by segmental duplications, likely predisposing to their rearrangements. Many of the patients with these newly recognized rearrangements are not clinically diagnosed in the newborn period, because they may not have significant anatomic malformations or dysmorphic features that prompt a genetic evaluation; however, they can present during childhood with variable clinical findings. Typically there is developmental delay, often autistic spectrum disorder, or an intellectual disability. These syndromes are complicated because they have been reported in unaffected family members, which proves to be a challenge when ascribing causality to the rearrangement.

When an abnormality is identified by microarray analysis, the genes located in the affected region can be identified. It is then possible to decide what role, if any, the affected genes have in the observed phenotype. For example, deleted genes could be identified that may predispose a patient to cancer because of a germline loss of one copy of a tumor suppressor gene (Adams et al, 2009), resulting in careful surveillance for tumor formation. Therefore a new genetic paradigm is developing where patients are initially genotyped (genotype-first), followed by evaluation of the altered genes in a given region to determine their possible effect on the future phenotype.

WILLIAMS-BEUREN SYNDROME (7Q11.2 DELETION)

The estimated incidence of Williams-Beuren syndrome is 10,000 live births. The phenotype has a variable spectrum, but usually consists of distinctive facies, growth and developmental retardation, cardiovascular anomalies, and occasionally infantile hypercalcemia (Figure 20-7). Babies with Williams-Beuren syndrome usually show some degree of intrauterine growth restriction with mild microcephaly. Facial features include epicanthal folds with periorbital fullness of subcutaneous tissues, flat midface, anteverted nostrils, long philtrum, thick lips, large open mouth, and stellate irises that may not be discernible at birth. Most infants have a cardiovascular abnormality; supravalvular aortic stenosis (SVAS) is the most commonly associated defect, seen in more than 50% of cases. Pulmonary artery stenosis is also often encountered. It is interesting to note that isolated SVAS can also exist as a separate autosomal dominant trait and has been shown to occur from mutations of the elastin gene that is located within the deletion region on 7q11.2. Patients with Williams-Beuren syndrome are typically missing one copy of the elastin gene.

Hypercalcemia, which is manifested in approximately 10% of patients with this disorder, is severe and persists through infancy. Umbilical and inguinal hernias are also associated features. Issues in infancy include feeding and growth problems, with pronounced irritability and colicky behavior. Hoarse voice, strabismus, hypertension, and joint mobility restrictions may develop later in childhood. In terms of development, the typical mild to moderate mental retardation can be masked by advanced language skills, although gross motor and visual-motor integration skills are especially affected. Attention-deficit disorders are common, and a characteristic outgoing personality is often described in affected children.

Many of the classic features of Williams-Beuren syndrome are not clearly discernible in the newborn period, but the diagnosis should be suggested in any child with SVAS, hypercalcemia, and facial features consistent with the disorder. The diagnosis can be confirmed quickly by performing a DNA microarray or FISH using probes specific for the deleted region of chromosome 7q11.2. Because the condition is typically sporadic and most deletions arise de novo, the risk of recurrence in subsequent pregnancies is minimal. An affected adult, however, would pass on the condition in an autosomal dominant manner, with a 50% risk of the disorder in his or her child.

FIGURE 20-7 Williams syndrome. A, Neonate with a coarse face, periorbital fullness, wide mouth, and thick lips with decreased Cupid's bow. **B,** Neonate profile showing periorbital fullness, flat nasal bridge with full tip, and prominent cheeks. **C,** This infant has periorbital fullness, flat nasal bridge, thick lips with decreased Cupid's bow, pouty lower lip, and low-set, full cheeks. **D,** Infant profile showing dolichocephaly (increased antero-posterior diameter of head), a higher nasal bridge than in the neonate, full nasal tip, pouty lower lip, long neck, sloping shoulders, and part of pectus excavatum.

22q11.2 DELETION SYNDROME

A deletion of chromosome 22q11.2 has been identified in the majority of patients with DiGeorge syndrome, VCFS, and conotruncal anomaly face syndrome, leading to the realization that these clinical entities all reflect features of the same genomic disorder (McDonald-McGinn et al, 1997). The list of findings associated with 22q11.2 deletion is extensive and varies by patient. Estimates indicate that 22q11 deletion occurs in approximately 1 in 3000 live births (Burn and Goodship, 1996). This disorder is the most common microdeletion syndrome occurring in humans and is a significant health concern in the general population.

The phenotype is characterized by a conotruncal cardiac anomaly and often aplasia or hypoplasia of the thymus and parathyroid glands. The majority of patients with a deletion can receive a diagnosis as newborns or infants with significant cardiovascular malformations, including interrupted aortic arch type B, truncus arteriosus, or tetralogy of Fallot, along with functional T-cell abnormalities and hypocalcemia. In addition, facial dysmorphia may be present (Figure 20-8), including hooded eyelids, hypertelorism, overfolded ears, bulbous nasal tip, a small mouth, and micrognathia. Since the initial report by DiGeorge in 1968, the spectrum of associated clinical features has been expanded to include anomalies such as palatal anomalies,

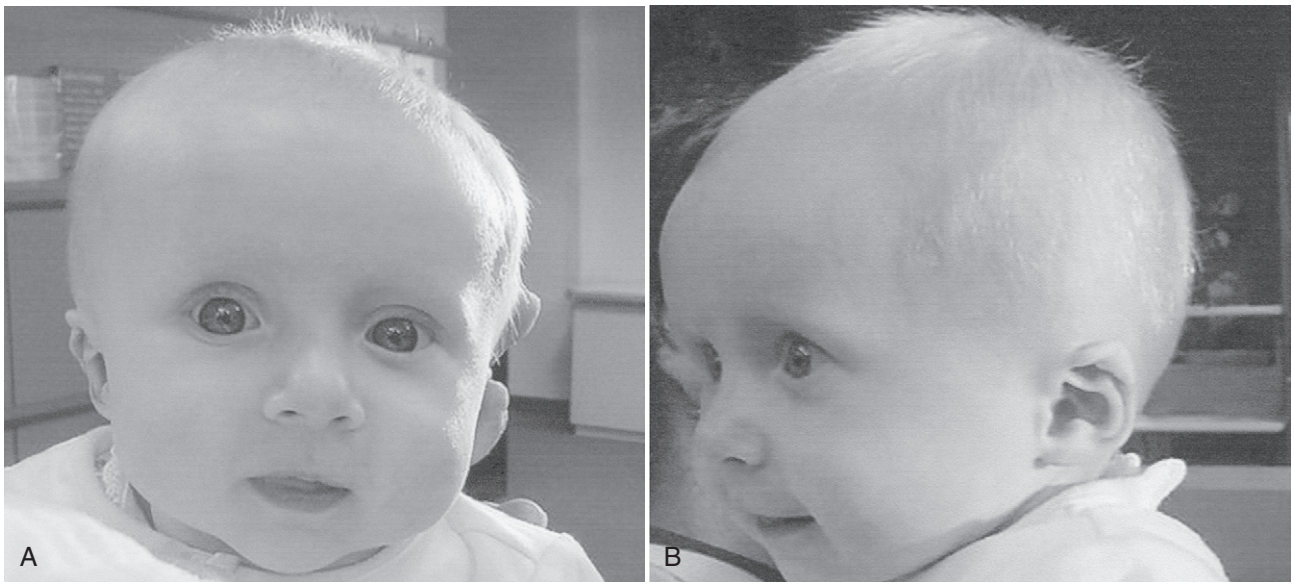

FIGURE 20-8 Facial differences associated with 22q deletion.

vascular rings, feeding and swallowing problems, gastroesophageal reflux, renal agenesis, and hypospadias (McDonald-McGinn et al, 1997). Before advances in the medical and surgical management of children with complex congenital cardiac disease and immune deficiencies, this disorder was associated with significant morbidity and mortality.

Developmental delays or learning disabilities have been reported in most patients with 22q11.2 deletion, and a wide range of developmental and behavioral findings have been observed in young children (Emanuel et al, 2001). In the preschool years, children with a 22q11.2 deletion were most commonly found to be hypotonic and developmentally delayed with language and speech difficulties. Severe or profound retardation was not seen, and one third of patients functioned within the average range.

The vast majority of patients (80% to 90%) have the same large deletion, approximately 2.4 to 3 Mb, that is detected by FISH (Figure 20-9) or DNA microarray. The deletion remains unchanged when inherited from an affected parent. However, the phenotype can be widely variable, even within a family. Although smaller recurrent deletions that are half the size of the common deletion occur (1.5 Mb), a smaller size does not indicate milder symptoms, making genotype-phenotype correlations difficult. To date, no explanation for the great phenotypic variability has been forthcoming, and it is currently an area of active investigation (Emanuel and Shaikh, 2001).

Most 22q11 deletions occur as de novo events, with less than 10% of them being inherited from an affected parent. The prevalence of these de novo 22q11.2 deletions indicates an extremely high mutation or rearrangement rate within this genomic region that is probably related to the presence of recombination-permissive duplicated DNA sequences, segmental duplications, or low copy chromosome 22–specific repeats in 22q11

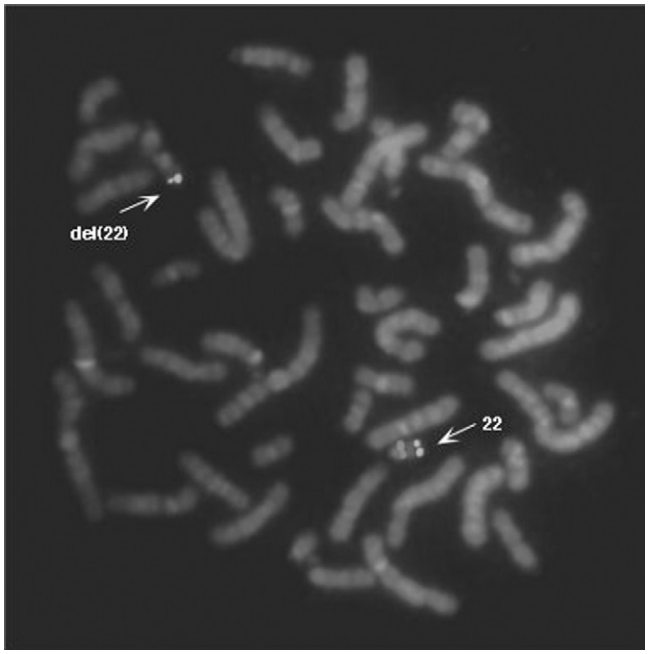

FIGURE 20-9 *(See also Color Plate 4.)* Fluorescence in situ hybridization study of a 22q deletion. *(Courtesy Beverly S. Emanuel.)*

(Emanuel and Shaikh, 2001; Emanuel and Saitta, 2007; Shaikh et al, 2007).

NEW MICRODELETION AND MICRODUPLICATION SYNDROMES

As mentioned previously, several newly identified genetic syndromes have been described with the increased use of DNA microarrays (Slavotinek, 2008). These regions are frequently flanked by segmental duplications, which is the likely reason for their prevalence in diverse patient populations, as well as the fact that there are reciprocal

rearrangements (deletion or duplication). Almost all of the patients with these deletions or duplications were not initially recognized based on their clinical features, but were instead ascertained by microarray analysis.

Deletions of 1q21.1 of 1.35 Mb have been seen in patients with variable presentations including developmental and behavioral abnormalities, mild facial dysmorphia, and microcephaly (Brunetti-Pierri et al, 2008; Mefford et al, 2008). The 3q29 microdeletion syndrome is approximately 1.6 Mb and was initially discovered (Willatt et al, 2005) in patients with mild-to-moderate mental retardation, microcephaly, and nonspecific facial dysmorphia. Duplications of this region have also been described in patients with developmental delays, mental retardation, and microcephaly (Lisi et al, 2008). The 15q13.3 region is distal to the more commonly known 15q11-q13 locus associated with Prader-Willi and Angelman syndromes. Patients with the 1.5-Mb deletion of 15q13.3 have variable phenotypes, but typically manifest with seizures or abnormal electroencephalograms (Sharp et al, 2008). A smaller 680-kb deletion has also been described in a range of patients with neurobehavioral phenotypes (Shinawi et al, 2009). Interestingly, this deletion is often maternally inherited, suggesting that there might be an imprinting mechanism involved. A recurrent 550-kb deletion of 16p11.2 has been discovered in approximately 1% of patients with autism (Weiss et al, 2008), and the reciprocal duplication associated with attention deficit-hyperactivity disorder and schizophrenia (McCarthy et al, 2009; Shinawi et al, 2010). 17q21.31 deletions involving approximately 500 to 650 kb were also found in patients with developmental delays, learning disabilities, and variable facial dysmorphia (Koolen et al, 2008; Shaw-Smith et al, 2006).

DISORDERS OF IMPRINTED CHROMOSOMES

A growing recognition of mechanisms regulating gene expression has emerged in the last decade. Two of the most exciting concepts with important clinical correlates are imprinting and uniparental disomy. The term *genomic imprinting* implies that a whole region of a chromosome or a group of genes in a given region are subject to a difference in their expression that depends on whether they reside on the maternally inherited or paternally inherited chromosome. In these cases, a genetic disorder might manifest according to the parent from which the genomic region was inherited. The genes in an imprinted region are not necessarily mutated, but they are marked such that the cell can distinguish between the maternal and paternal copies and coordinate expression on the basis of that distinction. At the molecular level, it appears that differences in the methylation of the DNA, and its replication and regulation at the transcriptional level, appear to be involved in this mechanism. This mechanism has become an area of important research advancements, and there are now more than 100 known or predicted genes and chromosomal regions thought to be important in human disease (www.geneimprint.com/site/genes-by-species).

PRADER-WILLI SYNDROME

It has been demonstrated that occasionally, instead of inheriting one copy of each chromosome from each parent, both copies of a given chromosome can come from the same parent. This phenomenon, known as *uniparental disomy* (UPD), is associated with advanced maternal age. It becomes a significant issue when the involved chromosome is imprinted or has regions on it that are imprinted.

Prader-Willi syndrome (PWS) involves the loss of activity from the paternally derived proximal long arm of chromosome 15 (15q11). This loss can occur through deletion or disruption of this region or through maternal uniparental disomy such that no paternal chromosome 15 is present (Nicholls et al, 1989). Newborns have pronounced central hypotonia, hyporeflexia, and a weak cry. The poor tone manifests as sucking and swallowing difficulties that can lead to failure to thrive and the need for feeding tubes in infancy. Facial differences that have been described include bifrontal narrowing, almond-shaped eyes, and a small, downturned mouth. Genitalia are often hypoplastic, with cryptorchidism being common in boys with this syndrome. The commonly reported small hands and feet are not usually demonstrated in the newborn. Strabismus and hypopigmentation relative to the family are also common.

A history of poor fetal activity during the pregnancy can often be elicited, especially if the mother has had prior pregnancies. Consistent with the hypotonia, breech presentation and perinatal insults are found more frequently than usual. The extreme hypotonia begins to improve in the first year of life, as does motor development, although developmental delay is the rule, especially for gross motor skills and speech. The feeding improves in the first few years of life and gives way to often uncontrollable hyperphagia and obesity. This issue and other behavioral problems, including severe temper tantrums and obsessive-compulsive disorder, are encountered throughout life. The majority of patients manifests mild to moderate mental retardation. Early diagnosis and preemptive implementation of behavioral therapy are essential components of the optimal management of these issues.

Deletions of the region critical in Prader-Willi syndrome have been demonstrated in up to 70% of patients. The deletion can be detected by DNA microarray or FISH analysis using a probe specific for this region of chromosome 15. A small number of patients have a disruption of this area as the result of a chromosomal translocation. To date, no single gene in this region has been implicated as the cause, but expression of the genes in this region is under intense investigation. It has been noted, however, that patients who have Prader-Willi syndrome as a result of a deletion of the region are more likely to be hypopigmented. This feature has been attributed to deletion of a gene involved in pigmentation, the so-called P gene (Rinchik et al, 1993). Recurrence risks are negligible in cases in which de novo deletions are found and sporadic occurrence is usually encountered.

Approximately 20% to 25% of patients with Prader-Willi syndrome show maternal UPD that can be detected by means of a molecular assay designed to assess specific

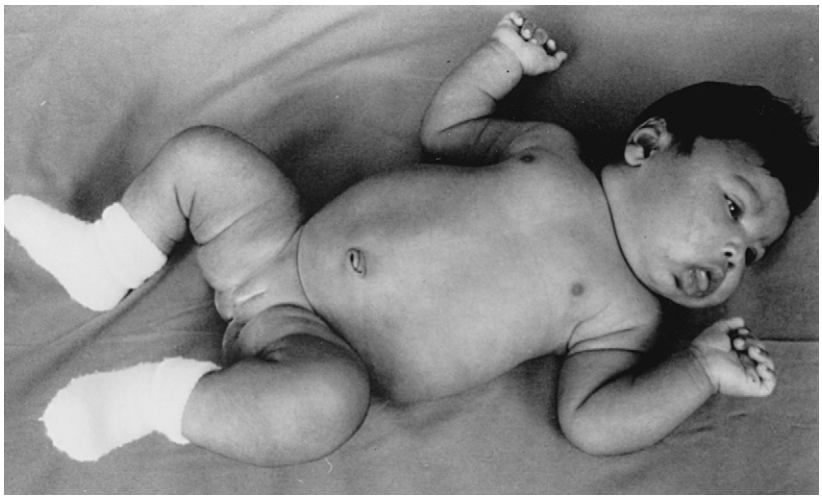

FIGURE 20-10 Macrosomic infant with macroglossia and lax abdominal musculature. These findings are typical of Beckwith-Wiedemann syndrome. *(From Viljoen DL, Jaquire Z, Woods DL: Prenatal diagnosis in autosomal dominant Beckwith-Wiedemann syndrome*, Prenat Diagn *11:167-175, 1991.)*

methylation differences between maternal and paternal alleles. Methylation analysis is abnormal in more than 99% of affected individuals, but will not determine whether the cause is attributed to a deletion or maternal UPD. Further study is required if an abnormal result is obtained. A maternal age effect has been demonstrated in UPD cases, and recurrence risks in families without deletions are estimated at 1 in 1000. In addition, this region of the genome is subject to regulation by imprinting. Large chromosome-specific segmental duplications are found in 15q11 and have been implicated in mediating the recurrent deletion of this genomic region (Emanuel and Shaikh, 2001; Emanuel and Saitta, 2007).

ANGELMAN SYNDROME

Loss of genetic material from the 15q11 region from the maternal copy of chromosome 15 is associated with Angelman syndrome. Clinical features are not evident in the newborn period and infancy, but include significant mental retardation, seizures, ataxic gait, tongue thrusting, inappropriate bursts of laughter, and facial differences including protruding jaw, wide mouth, thin upper lip, and widely spaced teeth. The mental retardation and hypopigmentation overlap with the features of Prader-Willi syndrome, but Angelman syndrome is a distinct entity.

Seventy percent to 75% of patients have a deletion of 15q11 that is detectable by FISH analysis. A small percentage (3% to 5%) have evidence of paternal isodisomy (two paternal copies) of the entire chromosome 15, with no apparent maternal chromosome. Unlike in Prader-Willi syndrome, Angelman syndrome has been associated with mutations in a single gene, *UBE3A*—an enzyme involved in the ubiquitin pathway of protein degradation, detected in up to 10% of patients. In addition, mutations of an imprinting center locus on chromosome 15 are thought to be associated with 1% to 2% of Angelman phenotypes (Shaffer et al, 2001). Methylation analysis can be performed and will detect abnormalities in approximately 75% to 80% of patients, because of a deletion or UPD. If methylation analysis is normal but Angelman syndrome is still suspected, UBE3A sequence analysis should be considered. The vast majority of cases result from a sporadic event, and the risk of recurrence can be best evaluated once the genetic mechanism has been determined for a given patient.

BECKWITH-WIEDEMANN SYNDROME

Beckwith-Wiedemann syndrome affects approximately 1 in 14,000 newborns and manifests as an overgrowth syndrome in the neonatal period. The characteristic findings are macrosomia, abdominal wall defect, and macroglossia (Figure 20-10). Affected babies are large for gestational age with proportionate length and weight. Infants of mothers with diabetes also manifest with macrosomia, but are more likely to have a weight disproportionately greater than length. Advanced bone age is also noted in Beckwith-Wiedemann syndrome. Hemihypertrophy caused by asymmetric growth is common, as is visceromegaly of various organs, including the spleen, kidneys, liver, pancreas, and adrenal glands.

Other characteristic features of the syndrome are macroglossia, linear creases of the earlobe with indentations on the posterior helix, and severe hypoglycemia. Although the hypoglycemia responds quickly to therapy, it can be present for several months; therefore recognition of the condition and immediate therapeutic intervention are critical in these cases. The hypoglycemia resolves spontaneously with age, and the physical diagnostic features also become less prominent with age, making the diagnosis more difficult to ascertain.

Equally important is the establishment of routine ultrasonographic surveillance at regular intervals, because children with Beckwith-Wiedemann syndrome are at increased risk of malignant tumors, especially Wilms' tumor. The estimated risk is as high as 8% for patients with hemihypertrophy. Many centers currently perform ultrasonography at 3-month intervals until the school-age years (approximately 8 years old). Monitoring of serum alpha-fetoprotein levels at the same intervals until age 4 years has proved valuable, as several cases of hepatoblastoma have also been reported and detected with this adjunct study.

Although most cases of Beckwith-Wiedemann appear to arise de novo, up to 15% may be familial. In familial cases,

the transmission is autosomal dominant, because of mutations of the *CDKN1C* gene in 40% of familial cases, but only 5% to 10% of de novo cases. In addition, this region of the genome (11p15.5) appears to be imprinted such that the maternal allele is not usually expressed. The insulin-like growth factor type 2 (*IGF2*) gene is located in this region and encodes an important factor involved in fetal growth. Mutations causing overexpression of the paternal allele or underexpression of the maternal allele can result in an imbalance of expression leading to the overgrowth and tumor formation encountered in these patients. Paternal UPD has proved to be a mechanism involved in 10% to 20% of sporadic cases of Beckwith-Wiedemann syndrome. A method for detecting methylation abnormalities at two distinct genetic loci within 11p15 accounts for approximately 60% of patients and is related to the overexpression of the *IGF2* gene. Therefore all the available testing methods combined can detect the cause in approximately 85% of the patients with Beckwith-Weidemann syndrome. The recurrence risk for future affected siblings or offspring of the proband depends on the specific genetic abnormality causing the disorder and can range from low (UPD, methylation abnormality) to as high as 50% (*CDKN1C* mutation).

RUSSELL-SILVER SYNDROME

Russell-Silver syndrome presents in neonates with intrauterine growth retardation followed by postnatal growth deficiency. The head size is usually normal, causing a relative macrocephaly that may have the appearance of hydrocephalus. Facial features can include a broad and prominent forehead, triangular-shaped face with a small chin, and downturned corners of the mouth. The fingers can show brachydactyly, camptodactyly, or more commonly fifth-finger clinodactyly. Other concerns involve limb-length discrepancy, delayed bone age, café au lait macules, hypospadias in males, developmental delays, diaphoresis, and hypoglycemia during the first 3 years of life. These patients are often examined by a geneticist as a toddler with growth retardation, proportionate short stature, and normal head circumference. When evaluating patients with growth retardation, it becomes important to know the prenatal and postnatal growth parameters, because they might provide a clue to the diagnosis of Russell-Silver syndrome.

The molecular mechanisms underlying the pathogenesis show that Russell-Silver syndrome is likely caused by abnormalities of imprinted genes. Maternal UPD of chromosome 7 is present in 7% to 10% of patients, and the symptoms are likely caused by overexpression of the maternal *GRB10* gene that suppresses activity of various growth factor receptors. In approximately 35% of the patients, imprinting abnormalities of 11p15.5 occur because of a loss of the paternally expressed *IGF2* gene, leading to decreased prenatal and postnatal growth. This finding contrasts with some patients with Beckwith-Wiedemann syndrome, in whom *IGF2* is overexpressed causing increased growth. To that end, patients with Russell-Silver syndrome do not have a significantly increased risk for neoplasia compared to patients with Beckwith-Wiedemann syndrome, and routine cancer surveillance protocols are typically not recommended.

SUMMARY

This chapter has summarized the rapidly expanding field of chromosomal and genomic disorders, concentrating on those that commonly manifest in the newborn. The widespread development and clinical implementation of molecular cytogenetic techniques have allowed the identification of subtle rearrangements that were previously undetectable. These advances now enable the discernment of new syndromes in which the chromosomal anomaly may be defined before a characteristic phenotype is recognized. In addition, a greater understanding of the role of segmental duplications and their effects on human genetic disorders as well as of the influence of mechanisms that regulate gene expression, such as imprinting, is emerging. The tremendous advances in genomics led by the completion of the Human Genome Project and the development of new molecular diagnostic tools present new challenges for clinicians to better diagnose, understand, and care for patients with genetic disorders and their families.

PART VI

METABOLIC AND ENDOCRINE DISORDERS OF THE NEWBORN

CHAPTER 21

INTRODUCTION TO METABOLIC AND BIOCHEMICAL GENETIC DISEASE

Stephen Cederbaum

Inborn errors of metabolism or biochemical genetic disorders are one type of genetic disease that may be encountered in the neonatal period as an acute or more indolent illness. In these disorders, a mutation in a gene leads to an absent or defective gene product or enzyme and results in the accumulation of the precursor of the enzyme or a byproduct of it, a shortage of the product of the enzymatic reaction, or a combination of both. In reality the effects of many inborn errors on normal physiology are much more profound, causing many changes in gene expression and normal biochemical function. One example is a case of propionic acidemia in which interference with the mitochondrial respiratory apparatus is rarely measured except by the ascertainment of an elevated blood lactate level, but which may be much more frequent and represent only the most obvious and easily measured alteration.

Inborn errors of metabolism may be inherited by any genetic mechanism—autosomal dominant, autosomal recessive, sex-linked recessive, or through a mutation in the independently inherited mitochondrial genome (mtDNA), which leads to a circumstance in which the mother alone passes the abnormal DNA to all of her children, but the affected or carrier father to none of his offspring.

Most inborn errors are inherited as autosomal recessive conditions, with the carrier parents rarely expressing any obvious metabolic phenotype. A small minority is inherited in a sex-linked recessive or codominant manner, and they will be discussed in the context of their particular disease. Examples would be ornithine transcarbamylase deficiency (a urea cycle disorder) and Fabry disease (a lysosomal storage disorder), the latter not appearing in the neonatal period.

When viewed from the perspective of disease mechanism, most genetic disorders, whether single gene or involving imbalance of chromosomal materials, could be considered to be inborn errors of metabolism. One or more changes in the DNA result in either altered gene expression or expression of a mutated gene, which then lead secondary to an altered product of the reaction or reactions. We will not use this expansive and grandiose interpretation of inborn errors, but rather confine ourselves to the more traditional definition described in the first paragraph. Thus disorders such as cystic fibrosis and spinal muscle atrophy, considered inborn errors that require broader interpretation, will not be considered.

The advent of newborn screening in the early part of the 1960s for phenylketonuria (PKU) established a new paradigm for approaching inborn errors of metabolism and making the diagnosis and treatment prior to the symptomatic presentation, and hence preventing rather than treating the condition. This approach has proved to be remarkably successful for PKU and congenital hypothyroidism, with few patients becoming mentally retarded. In subsequent years the menu of tests expanded gradually, but it has greatly expanded in the last decade with the implementation of expanded newborn screening using tandem mass spectrometry (MS/MS) technology, which allows for ascertainment of a constellation of disorders and should alter the probability of, and the diagnostic testing for, inborn errors when incorporated into the diagnostic algorithms of the ill newborn. Moreover, the advancing technology permits some of the newborn dried blood spot to be used for a wider palette of tests, some of which may already be available. The consequences of this expansion have a downside for the neonatologist and the neonatal intensive care unit staff members. For a variety of reasons the sick and premature newborn, usually receiving intravenous alimentation and having immature or damaged organs, is far more likely to have a false-positive newborn screening test and require follow-up testing. It is important to recognize that a number of traditionally tested diseases are outside of this class of disorders, such as hypothyroidism, congenital adrenal hyperplasia, cystic fibrosis, and hemoglobinopathies.

When considering inborn errors of metabolism, it is important to consider the molecular basis of mutation. Large deletions of a gene are certain to eliminate enzymatic function and any residual gene product. Smaller deletions, especially if they remove one or more of the in-phase coding triplets, may permit a stable protein to be made and to function to some extent. Most small deletions, however, cause the synthesis of unstable and out-of-phase proteins that do not function and have a short half-life within the cell. Some single-based change mutations can introduce a stop codon, causing the synthesis of the polypeptide to halt abruptly and leave a nonfunctional enzyme. Single-base changes introducing a new amino acid vary in their effects from complete loss of activity to a lesser impact, and finally to having no effect whatsoever. When considering that the mutation test is then all modulated through the unique genetic background of the individual, there is no single final phenotype, severity, or time of onset for any genetic disorder. This variation must be considered when any diagnosis, genetic or not genetic, is considered.

CLASSIFICATION OF INBORN ERRORS OF METABOLISM

Each professional uses classification systems to permit effective reasoning as to possible causes of a symptom complex. A system for understanding inborn errors of metabolism is shown in Box 21-1. Each group has common characteristics, modes of presentation, types of molecules involved, and tests that would be applied. Because the demarcation between the groups is not sharp, other systems can see them differently. This discussion is restricted to those disorders that may be symptomatic in the newborn period or in early infancy, whereas many severe disorders would be unlikely to be associated with neonatal disease and will be given less emphasis. The disorders more commonly seen in the neonatal period are listed in Box 21-2.

The first group consists of newborns with progressive lethargy, poor suck, neurologic deterioration, and often death. They have inborn errors of amino acids, the urea cycle, organic acids, or sugar metabolism. This group of patients is the product of normal pregnancies and deliveries and becomes ill after 36 hours of life, when the maternal circulation no longer cleanses the accumulating small molecules from the fetal or infant blood and the offending metabolites accumulate in intoxicating amounts (Box 21-3). Examples include maple syrup urine disease, methylmalonic and propionic acidemias, galactosemia, and ornithine transcarbamylase deficiency. The general characteristics are given in Box 21-4; they are the disorders for which expanded newborn screening may lead to earlier detection and a more rapid diagnosis. These patients' condition is most likely to resemble sepsis, and they should be treated with antibiotics. Most disorders manifesting acutely in the newborn period will be detected by the newborn screen, with only some urea cycle disorders and lactic acidoses likely to be missed by this screening panel. When diagnosed, these conditions are

BOX 21-1 Classification of Inborn Errors of Metabolism, 2007

Small molecule disorders
- Amino acids
- Organic acids
- Sugars

Lysosomal storage disorders
- Mucopolysaccharides
- Sphingolipids
- glycolipids

Energy metabolism disorders
- Oxidation disorders
- Fatty acid mobilization and metabolism disorders
- Glycogen storage diseases

Peroxisomal and membrane biogenesis disorders
Carbohydrate-deficient glycoprotein disorders
Cholesterol biosynthetic disorders
Disorders of biogenic amines, folate, and pyridoxine
Transport disorders
Purine and pyrimidine metabolism disorders
Receptor disorders

BOX 21-2 Common Types of Inborn Errors of Metabolism With Newborn Presentation

- Amino acid disorders
- Organic acid disorders
- Disorders of ammonia metabolism
- Disorders of carbohydrate metabolism
- Disorders of gluconeogenesis or hypoglycemia
- Disorders of fatty acid oxidation
- Primary lactic acidoses (respiratory chain defects)
- Disorders of vitamin or metal metabolism
- Storage diseases (infrequently)
- Peroxisomal disorders
- Disorders of sterol metabolism
- Congenital defects in glycosylation

BOX 21-3 Metabolic Diseases With Newborn Coma Secondary to Toxic Metabolite Accumulation or Mitochondrial Failure

- Galactosemia
- Inborn errors of ammonia metabolism
- Maple syrup urine disease
- Nonketotic hyperglycinemia
- Methylmalonic acidemia with or without homocystinuria
- Propionic acidemia
- Isovaleric acidemia
- Multiple carboxylase deficiency
- Glutaric aciduria type 2
- Fatty acid oxidation defects
- Primary lactic acidosis
- Pyruvate dehydrogenase deficiency
- Pyruvate carboxylase deficiency
- Mitochondrial respiratory chain or electron transport chain defects

BOX 21-4 Characteristics of Small Molecule Disorders

- High levels of metabolites in body fluids
- Normal physical phenotype
- Neonatal presentation
- Periods of stability and instability
- Considered to be intoxication disorders
- Can often be treated by external manipulation

Lysosomal storage disorders (format)
- Usually born normally
- Course is progressive, relentless, and indolent
- Deposition of material seen clinically and microscopically
- May be deforming
- Cannot be addressed exogenously

Disorders of energy metabolism
- Mixed presentation between the first two categories
- Can be catastrophic at presentation
- May be present at birth or develop later
- Usually progressive
- May cause malformations
- May have episodes of deterioration
- Usually not treatable by exogenous means
- May be tissue specific or preferential

treated with dialysis, limitation of protein intake except for galactosemia, fluid, and caloric support, and some specific interventions. The association of identifying physical and laboratory characteristics and various disorders is listed in Tables 21-1 and 21-2. The individual disorders are discussed in Chapters 22 and 23. When a diagnosis of a metabolic disorder appears likely, plasma amino acids, urine organic acids, plasma acylcarnitine, and plasma carnitine tests should be repeated, and ammonia and lactate should be determined.

The second major category of inborn errors is the lysosomal storage diseases. This group of disorders results from defective function of a catabolic hydrolase located in the lysosome that is generally responsible for breaking down complex glycosaminoglycans and sphingolipids that are products of normal cellular turnover (see Box 21-4). Unlike the small molecule disorders in which the metabolites are found freely circulating in the body fluid compartments, these compounds accumulate intracellularly, are not removed by the maternal circulation, and are present in limited amounts in the body fluids. They most often cause no apparent symptoms in the newborn period or early infancy, because the pathologic metabolites accumulate slowly with time. Exceptions to this finding are the severe form of α-glucosidase deficiency or Pompe disease, the neonatal form of α-galactosidase deficiency, or Krabbe disease and galactosialidosis. These findings are discussed in Chapter 23, and some are listed in Table 21-1. The disorders of mucopolysaccharides and glycolipids lead to the characteristic features pejoratively and inappropriately referred to as *gargoylism*, which consist of an exaggerated eyebrow, coarse-appearing facies, thick skin, hirsutism, and multiple abnormalities of the bones and joints seen on a radiograph. Attention to the disorder is often drawn by the hepatosplenomegaly. The metabolites are synthesized in the body and are not influenced by dietary intake.

TABLE 21-1 Unique or Characteristic Physical Findings in Inborn Errors* (Major Examples)

Finding	Error
Hepatomegaly	Galactosemia Glycogen storage diseases Gluconeogenic defects Disorders of fatty acid oxidation and transport Mitochondrial respiratory or electron transport chain defects Hereditary tyrosinemia type 1 Urea cycle defects Peroxisomal defects Niemann-Pick disease type C Congenital defects in glycosylation
Hepatosplenomegaly	Gangliosidoses Niemann-Pick disease type C Mucopolysaccharidoses Wolman disease Ceramidase deficiency
Macrocephaly	Glutaric acidemia type 1 Canavan disease
Microcephaly	Mitochondrial respiratory or electron transport chain defects Leigh disease Methylmalonic acidemia with homocystinuria
Coarse facial features	Gangliosidosis Mucolipidoses Mucopolysaccharidosis type VII Sialidosis Galactosialidosis
Macroglossia	Pompe disease Gangliosidoses Mucopolysaccharidoses Mucolipidoses
Dystonia or extrapyramidal signs	Gaucher disease type 2 Glutaric acidemia type 1 Krabbe disease Crigler-Najjar syndrome Biopterin defects
Macular "cherry red spot"	G_{M1} gangliosidosis Galactosialidosis Niemann-Pick disease type A Tay-Sachs disease (G_{M2} gangliosidosis)
Retinitis pigmentosa	Mitochondrial respiratory or electron transport chain defects Sjögren-Larsson syndrome Peroxisomal disorders Abetalipoproteinemia
Optic atrophy or hypoplasia	Pyruvate dehydrogenase complex deficiency Mitochondrial disorders Leigh disease Peroxisomal disorders
Corneal clouding or opacities	Mucolipidoses Mucopolysaccharidoses Steroid sulfatase deficiency
Cataracts	Galactosemia Lowe syndrome Mitochondrial respiratory or electron transport chain defects Peroxisomal disorders Congenital defects in glycosylation
Dislocated lens	Methionine synthetase deficiency Sulfite oxidase deficiency
Bone or limb deformities or contractures	Storage, peroxisomal, or connective tissue disorders Inborn errors of cholesterol biosynthesis
Thick skin	Mucolipidoses Gangliosidoses Mucopolysaccharidoses
Desquamating, eczematous, or vesiculobullous skin lesions	Acrodermatitis enteropathica Organic acidemias Early-onset forms of porphyria
Ichthyosis	Gaucher disease type 2 Steroid sulfatase deficiency
Alopecia	Multiple carboxylase deficiency
Steely or kinky hair	Menkes disease
Persistent diarrhea	Glucose galactose malabsorption Congenital lactase deficiency Congenital chloride diarrhea Sucrase isomaltase deficiency Acrodermatitis enteropathica Congenital folate malabsorption Wolman disease Galactosemia

*For discussion of specific disorders, see Chapters 22 and 23.

TABLE 21-2 Characteristic or Unique Laboratory or Diagnostic Testing Outcomes in Inborn Errors (Major Examples)

Outcome	Error
Metabolic acidosis with or without increased anion gap	Organic acidemias Maple syrup urine disease Fatty acid oxidation defects Ketothiolase deficiency Ketogenesis defects Disorders of pyruvate metabolism Mitochondrial respirator or electron transport chain defects, including Leigh disease Galactosemia Glycogen storage disease type 1 Gluconeogenesis defects
Respiratory alkalosis	Urea cycle disorders
Hyperammonemia	Urea cycle disorders Methylmalonic acidemia Organic acidemias Fatty acid oxidation disorders
Ketosis	Organic acidemias Maple syrup urine disease Glutaric acidemia type 2 Ketogenesis defects Glycogen storage disease type 1 Gluconeogenesis disorders
Lactic acidosis	Mitochondrial respiratory or electron transport chain defects, including Leigh disease Pyruvate dehydrogenase complex deficiency Pyruvate carboxylase deficiency Organic acidemias Glutaric acidemia type 2 Fatty acid oxidation defects Ketogenesis defects Glycogen storage disease type 1 Gluconeogenesis disorders
Hypoglycemia	Hyperinsulinism Glycogen storage disease type 1 Gluconeogenesis disorders Maple syrup urine disease Glutaric acidemias Fatty acid oxidation defects Ketogenesis defects Galactosemia Severe liver failure Mitochondrial respiratory or electron transport chain defects
Lipemia	Glycogen storage disease type 1 Lipoprotein lipase deficiency
Positive urinary-reducing substances	Galactosemia Hereditary fructose intolerance Lowe syndrome
Discolored urine	Alkaptonuria Tryptophan malabsorption
Leukopenia	Organic acidemias Glycogen storage disease type 1B Barth syndrome Pearson syndrome
Thrombocytopenia	Organic acidemias Pearson syndrome
Anemia	Organic acid disorders Wolman disease Pearson syndrome Severe liver failure Galactosemia
Vacuolated lymphocytes or neutrophils	Lysosomal storage disorders
Cardiomegaly	Pompe disease Barth syndrome Fatty acid oxidation defects Mitochondrial respiratory or electron transport chain defects Carbohydrate-deficient glycoprotein syndrome
Electrocardiographic abnormalities	Pompe disease (short PR interval, large QRS interval) Fatty acid oxidation disorders Mitochondrial respiratory or electron transport chain defects
Ventricular hypertrophy	Pompe disease Organic acidemias Glutaric acidemia type 2 Fatty acid oxidation defects Mitochondrial respiratory or electron transport chain defects, including Leigh disease
Dysostosis multiplex	Gangliosidoses Mucopolysaccharidoses Mucolipidoses Sialidosis
Stippled calcifications of patellae	Peroxisomal disorders Cholesterol biosynthetic defects
Adrenal calcifications	Wolman disease
Rhizomelica	Rhizomelic chondrodysplasia punctata
Hair abnormalities	Menkes disease Argininosuccinicaciduria
Basal ganglia lesions on MRI	Organic acidemias (later in life) Pyruvate dehydrogenase complex deficiency Mitochondrial respiratory or electron transport chain defects, including Leigh disease
Cerebellar atrophy or hypoplasia	Pyruvate dehydrogenase complex deficiency Mitochondrial respiratory or electron transport chain defects, including Leigh disease Carbohydrate-deficient glycoprotein syndrome
Agenesis of corpus callosum	Pyruvate dehydrogenase complex deficiency Pyruvate carboxylase deficiency Mitochondrial respiratory or electron transport chain defects

MRI, Magnetic resonance imaging.

The third important category of metabolic disorders is insufficient generation of energy by the mitochondrial machinery. These disorders can be caused by the inability to provide substrates such as glucose in glycogenoses; the inability to deliver substrate to the site of oxidation, such as the fatty acid and carnitine transport disorders; the inability to break down fatty acids in a stepwise fashion to provide reduced flavin adenine dinucleotide to be oxidized; or the deficient function of the mitochondrial respiratory pathway and energy-generating system itself. These disorders have characteristics in between those of the acute, small molecule disorders and the storage disorders

Box 21-5 Signs and Symptoms of Inborn Errors in the Newborn

- Neonatal catastrophe (life threatening)
- Poor suck and feeding
- Gastrointestinal problems, vomiting
- Respiratory distress
- Cardiac failure
- Neurologic abnormalities: alertness, tone, seizures
- Organomegaly
- Ocular abnormalities
- Cutaneous changes

Box 21-6 Metabolic Diseases With Congenital Malformations or Dysmorphic Features

- Cholesterol biosynthetic disorders
- Peroxisomal disorders
- Glutaric aciduria type 2
- Primary lactic acidoses
- Congenital defects in glycosylation
- Lysosomal storage disorders
- Menkes disease

(see Box 21-4). They differ from the small molecule disorders in the possible onset immediately at birth or before, and from storage disorders in the generally normal physical features with hepatomegaly alone, a regular feature of glycogen storage disorders. The small molecule and energy-generating disorders are discussed in Chapter 22 and the lysosomal storage disorders are discussed in Chapter 23.

Of the remaining groups that are encountered less frequently, the peroxisomal biogenesis disorders, carbohydrate-deficient glycoprotein disorders, and Smith-Lemli-Opitz syndrome (a cholesterol biosynthetic disorder) are discussed in Chapter 23. Other disorders are too infrequent to be considered in a general neonatology textbook. Disorders of biogenic amines are discussed in Chapter 22 and in greater depth in Chapter 63 on neonatal seizures, along with consideration of pyridoxine and folate disorders.

SIGNS AND SYMPTOMS OF INBORN ERRORS

The limited symptomatic repertoire of the sick newborn is well established, but it is worth repeating. For this reason, the first thought when confronting a newborn in deteriorating condition, with lethargy, poor suck, temperature instability, and neurologic abnormalities, is sepsis (Box 21-5). Most metabolic specialists have never confronted a sick newborn who has not had a "septic workup" and who is not receiving standard antibiotics. The issue then becomes when to perform a metabolic workup. The standard answer is that it should be performed when the neonatologist is concerned that the newborn in extremis does not fit the pattern that they expect from a child with sepsis or hypoxia. That threshold would vary by individual. Negative results of tests for infectious agents, a nonconfirmatory white count, hypoglycemia, unexpectedly severe acidosis, or hyperammonemia could be important triggers. Although dysmorphic features are not characteristic of inborn errors, there are some that may have subtle or occasionally pronounced abnormality on a physical examination; they are listed in Box 21-6 and in Table 21-2.

Modern neonatology has one tool that was previously unavailable: the expanded newborn screen. This screening will diminish the probability of many disorders, and the newborn screening follow-up hotline should be on the speed dial of every neonatal intensive care unit. The only acutely presenting disorders not ascertained by these studies are most hyperammonemias and lactic acidoses. These test results are available immediately in any tertiary or secondary care hospital. With a high level of concern and near normal levels of lactate and ammonia, the standard battery of metabolic studies should be performed only when the index of suspicion for a metabolic disorder is particularly high and no alternative explanation for the poor condition of the patient is likely. When deemed necessary, these studies should include plasma amino acids, plasma acylcarnitine levels, and urinary organic acids. The abnormalities associated with individual disorders are discussed in Chapter 22.

EMERGENCY TREATMENT

An acutely ill child with an inborn error of metabolism is an emergency, and rapid rescue treatment is mandatory. When considering a differential diagnosis, special emphasis should be placed on disorders for which there is treatment, as opposed to those for which there is no treatment. As with all acutely ill patients, supportive care, including cardiorespiratory, hemodynamic status, fluids, and electrolytes, is the mainstay of treatment. Transfer from institution to institution should not be performed unless the patient's condition is stable and there is adequate vascular access for emergency treatment. Transfer to a tertiary care center with experience in caring for these children is desirable and should be performed as quickly as possible.

Virtually all disorders require a maximum source of calories (150 calories/kg is desirable, but 120 calories/kg is a minimum target) to prevent or diminish catabolism, and glucose is the most important part of this, especially in the absence of primary lactic acidemia or acidosis. As much lipid as is safe should be added to compensate for the caloric deficit.

Hemodialysis, and especially extracorporeal membrane oxygenation, will remove most metabolites rapidly, but these are extreme interventions in a newborn. These interventions should be performed routinely in extreme and symptomatic hyperammonemia (ammonia levels of 400 mol/L or more), and many would consider dialysis in severe acidosis caused by acids other than lactate or ketones. Once a diagnosis is established, specific therapy can be initiated. It is important to emphasize that during this period of generic therapy, prolonged deprivation of exogenous protein or amino acids will cause endogenous protein breakdown and exacerbate the metabolic process. As a result, protein is added to the intravenous support fluids after 36 to 48 hours, beginning with 0.25 to 0.5 g/kg/day and increasing gradually to maintenance levels of 1.2 to 1.5 g/kg/day, pending a definitive diagnosis and assuming that it is tolerated.

CHAPTER 22

Inborn Errors of Carbohydrate, Ammonia, Amino Acid, and Organic Acid Metabolism

Stephen Cederbaum and Gerard T. Berry

The inborn errors of carbohydrate, ammonia, amino acid, and organic acid metabolism have one factor in common: all can be associated with acute, life-threatening disease during the newborn period. The most notable exception in this broad group of small-molecule disorders is phenylketonuria (PKU). There are often few signs secondary to classic PKU in the first 6 months of life, underscoring the importance of newborn screening in establishing the diagnosis of this disease. Although this chapter will present the most common phenotype for these disorders, special emphasis will be placed on the neonatal presentations. The fact that a number of the more mild forms can manifest later merely emphasizes the importance of newborn screening in their mitigation. The disorders that constitute each group are listed in Boxes 22-1 to 22-4. The interrelationships among the major metabolites, biochemical cycles, and organelle pathways in the most critical facets of intermediary metabolism are simplified and depicted in Figure 22-1. The primary lactic acidosis and mitochondrial respiratory chain disorders, as well as the defects in fatty acid oxidation, are included in the section on inborn errors of organic acid metabolism.

INBORN ERRORS OF CARBOHYDRATE METABOLISM

HEREDITARY GALACTOSEMIA

Galactose-1-Phosphate-Uridyltransferase Deficiency

The three enzymes of the galactose metabolic pathway that are responsible for the rapid conversion of galactose to glucose in the liver after ingestion of dietary lactose or the breakdown of endogenous galactose-containing compounds are galactokinase, galactose-1-phosphate uridyl transferase (GALT), and uridine diphosphate (UDP) galactose-4-epimerase (Figure 22-2). All three enzymes have been associated with inborn errors of galactose metabolism (Berry et al, 2006; Fridovich-Keil and Walter, 2008). Although a deficiency of any of the three enzymes can lead to galactose accumulation in plasma, the term *galactosemia* refers to GALT deficiency, the most common of the three enzyme deficiencies in the newborn period. The frequency of clinically significant galactosemia is estimated at 1 in 60,000 births in the United States, but would be higher if the more frequent partial deficiencies are considered. The clinical syndrome of transferase-deficiency galactosemia has changed since the advent of newborn screening. In instances of the rapid availability of newborn screening results (3 to 4 days of life) patients rarely require hospitalization. In the past, a severe multiorgan toxicity syndrome was a much more common occurrence, associated with unlimited intake of lactose in the proprietary formula or breast milk. Because death from *Escherichia coli* sepsis can occur with only 1 to 2 weeks of exposure to galactose, the incidence of the disorder in the prescreening era was estimated to be less than 1 in 200,000 births. Today, even when picked up later after screening, the disorder is rarely fatal because the liver dysfunction is reversible and sepsis is largely prevented.

If patients survive the neonatal period and there is no diagnosis, the most common initial clinical signs of GALT deficiency is poor growth, irritability, lethargy, vomiting, and poor feeding. Jaundice may be present in the first few weeks of life and can persist. Initially the hyperbilirubinemia may be indirect and is only later associated with an elevation of the direct component as well. The current tendency to change formulas can mask the disease if a non–lactose-containing formula is substituted fortuitously. With continual lactose ingestion, multiorgan toxicity syndrome ensues, which is associated with liver disease that can progress to cirrhosis with portal hypertension, splenomegaly, ascites, renal tubular dysfunction, and sometimes full-blown renal Fanconi syndrome. Anemia, primarily caused by decreased red blood cell (RBC) survival, and lethargy; brain edema associated with a bulging fontanel

BOX 22-1 Inborn Errors of Carbohydrate Metabolism

- Hereditary galactosemia
- Glycogen storage diseases
- Hereditary fructose intolerance
- Fructose-1,6-bisphosphatase deficiency

BOX 22-2 Inborn Errors of Ammonia Metabolism

- Ornithine transcarbamylase deficiency
- Argininosuccinicaciduria
- Citrullinemia
- Carbamylphosphate synthetase deficiency
- Transient hyperammonemia of the newborn

BOX 22-3 Inborn Errors of Amino Acid Metabolism

- Maple syrup urine disease
- Hereditary tyrosinemia type 1
- Nonketotic hyperglycinemia
- Methionine synthetase deficiency
- Phenylketonuria

BOX 22-4 Inborn Errors of Organic Acid Metabolism

- Methylmalonic acidemia
- Propionic acidemia
- Isovaleric acidemia
- Multiple carboxylase deficiency
- Glutaric acidemia type 1
- Fatty acid oxidation disorders
  - Glutaric acidemia type 2
  - Very-long-chain acyl-CoA dehydrogenase deficiency
  - Medium-chain acyl-CoA dehydrogenase deficiency
  - Short-chain acyl-CoA dehydrogenase deficiency
  - Long-chain 3-hydroxy acyl-CoA dehydrogenase deficiency
  - Carnitine transporter defect
  - Carnitine palmitoyltransferase type I deficiency
  - Carnitine palmitoyltransferase type II deficiency
  - Acylcarnitine translocase deficiency
- Defects in ketone metabolism
  - Ketothiolase deficiency
  - Succinyl-CoA: 3-ketoacid-CoA transferase deficiency
  - 3-Hydroxy-3-methylglutaryl-CoA lyase deficiency
- Primary lactic acidoses
  - Pyruvate dehydrogenase complex deficiency
  - Pyruvate carboxylase deficiency
  - Phosphoenolpyruvate carboxykinase deficiency
  - Mitochondrial respiratory/electron transport chain defects
    - Barth syndrome
    - Pearson syndrome
    - Leigh disease

CoA, Coenzyme A.

can also occur. Cataracts may be evident in the first few weeks of life. However, some infants are born with congenital cataracts that are associated with abnormalities of the embryonal lens; they are central in nature and require slit-lamp examination for documentation.

After initiation of a lactose-free diet in the newborn period, the problems related to liver and kidney disease, anemia, and brain edema usually disappear, unless there has been severe organ damage such as hepatic cirrhosis. Most infants begin to grow and develop at a normal rate. However, patients treated prospectively can manifest long-term complications related to speech defects, delay in language acquisition, learning problems, frank mental retardation, autistic features, and hypergonadotropic hypogonadism in most of the females. The cause of these so-called diet-independent complications is unknown. Patients with galactosemia continue a lactose-restricted diet for their entire lives, although many lapse as they get older and may not suffer from detectable consequences. A minority of patients with GALT deficiency develop a neurodegenerative condition. One of the first abnormalities to be detected—albuminuria—reflects a poorly understood renal glomerular component. This component develops within 24 to 48 hours of ingestion of lactose and disappears as quickly after elimination of lactose from the diet. In addition to hyperbilirubinemia, there may be mild to severe elevations of serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels and various abnormalities related to renal tubular dysfunction, such as hyperchloremic metabolic acidosis, hypophosphatemia, glucosuria, and generalized aminoaciduria. Vitreous hemorrhages are newly recognized complications in the newborn period.

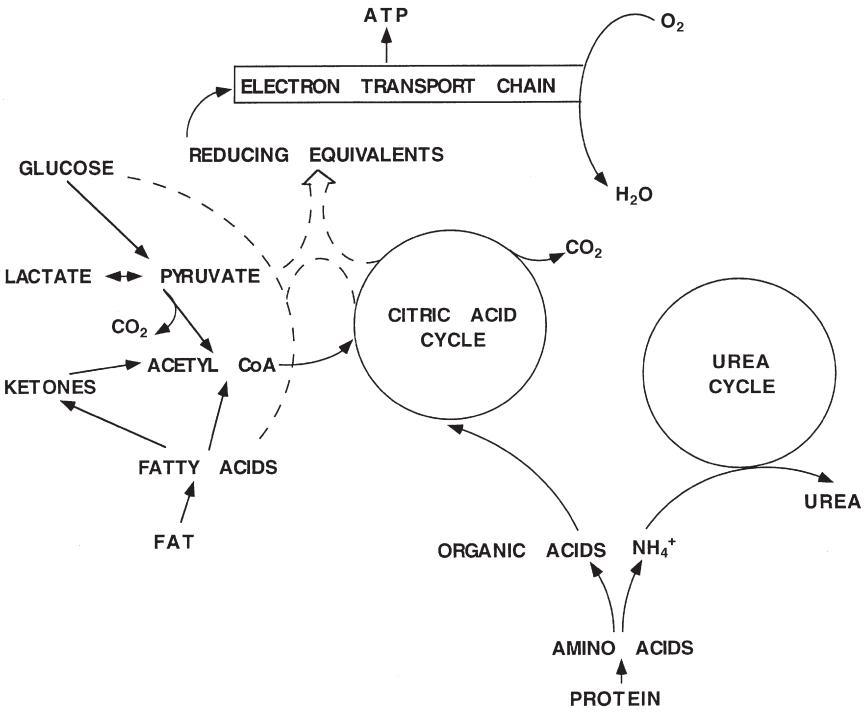

FIGURE 22-1 Intermediary metabolism interactions among the glycolytic, citric acid cycle, mitochondrial respiratory–electron transport chain, amino acid, organic acid, and urea cycle pathways. Defects in these primarily catabolic pathways are the chief source of inborn errors of metabolism that involve the small, simple—not the large—complex molecules. *ATP,* Adenosine triphosphate. *(Adapted from Cowett RM, editor:* Principles of perinatal-neonatal metabolism, *ed 2, New York, 1998, Springer-Verlag, p 800.)*

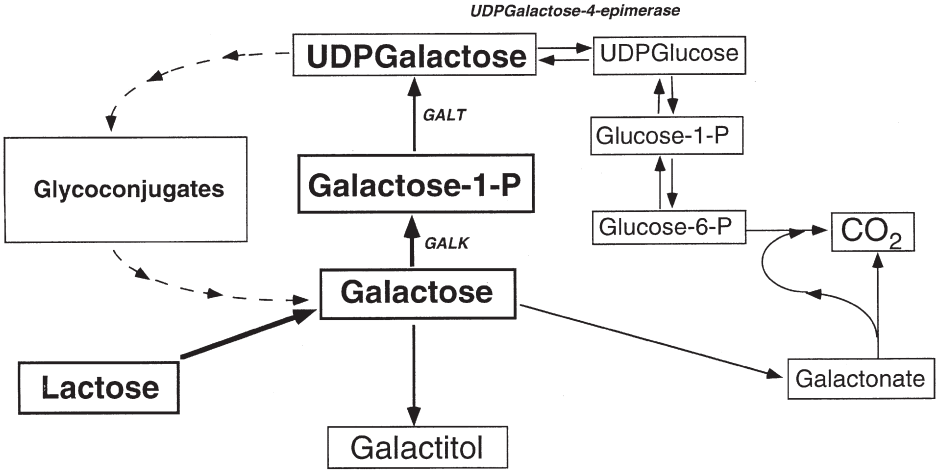

FIGURE 22-2 The important reactions in the galactose metabolic pathway are shown in relation to exogenous, via lactose primarily, and endogenous de novo synthesis of galactose. The reactions catalyzed by enzymes that have not been well delineated or are purported to exist are shown by *broken lines*. Carbon skeletons exit the galactose pool via galactokinase (GALK)–mediated conversion to galactose-1-phosphate (galactose-1-P), aldose reductase–mediated conversion to galactitol, and as galactonate. In patients with severe galactose-1-P-uridyltransferase (GALT) deficiency, there is little or no conversion of galactose-1-P to uridine diphosphate galactose (UDPgalactose). The epimerization of UDPglucose to UDPgalactose by UDPgalactose-4-epimerase, the utilization of UDPgalactose in the synthesis of glycoconjugates such as glycoproteins, and their subsequent degradation may constitute the pathways of de novo synthesis of galactose. *(Adapted from Berry GT, Nissim I, Gibson JB, et al: Quantitative assessment of whole body galactose metabolism in galactosemic patients*, Eur J Pediatr *156:S44, 1997.)*

When an infant's condition is initially diagnosed, either through the newborn screening program or because of the recognition of clinical signs, blood galactose levels may be as high as 5 to 20 μmol/L, and the RBC galactose-1-phosphate level is significantly elevated, as are urine galactitol levels. During this phase of severe hypergalactosemia, positive reducing substances are present in the urine. After the patient starts a lactose-free diet, the RBC galactose-1-phosphate levels in patients with classic galactosemia fall, but they never return to the normal range, remaining mildly elevated for the lifetime of the patient.

As noted in the newborn screening chapter, a patient's condition can be ascertained by elevated plasma galactose levels, reduced levels of GALT, or both. Because newborn blood spots can be obtained before significant lactose ingestion occurs, screening by galactose in plasma alone is unsatisfactory. Many programs screen for GALT deficiency alone and sacrifice diagnosis of the far less frequent and less lethal kinase and epimerase deficiencies. Many modern screening follow-up programs eschew the measurement of RBC galactose-1-phosphate levels and instead confirm the enzymatic deficiency with a quantitative assay and perform mutation analysis. Mutation analysis can identify those with a poorer prognosis and those who are unlikely to exhibit clinical symptoms. The mutations also provide information for genetic counseling and prenatal diagnosis, with the latter also performed effectively by enzymatic means. A GALT variant labeled the *Duarte variant*, after its place of discovery, is far more frequent than the more severe mutations and gives approximately three fourths of the activity of the normal allele. Compound heterozygotes for this allele (*D2*) and a null allele (*G*) have approximately 25% of normal activity in red blood cells and are not associated with clinical symptoms.

GLYCOGEN STORAGE DISEASES

The glycogen storage diseases (GSDs) can be divided into those types that primarily affect the liver and those that affect striated muscle (Kishnani et al, 2001; Smit et al, 2006). With some forms, such as GSD type 3 or debrancher deficiency, both striated muscle and the liver may be affected. According to European prevalence data, the overall frequency of GSD is 1 in 20,000 to 25,000 (Kishnani et al, 2001). With the exceptions of GSD type 2 and or Pompe disease, a lysosomal defect, most of the patients with glycogenosis do not come to clinical attention in the newborn period. With the exception of a form of phosphorylase kinase deficiency, which is labeled as *type IX* and is inherited in a sex-linked recessive manner, all are inherited in an autosomal recessive manner. Patients with the three most common forms of GSD—types 1, 3, and 6—have a phenotype that mimics a small-molecule disorder, because glucose homeostasis is affected.

Glucose-6-Phosphatase Deficiency

GSD type 1 is caused by decreased activity of glucose-6-phosphatase, the enzyme that is perched at the terminus of both glycogenolysis and gluconeogenesis. Several different biochemical abnormalities can result in this phenotype, now classified as GSD types 1a, 1b, and 1c. The enzyme that resides on the anticytoplasmic side of internal membrane spaces of the hepatocyte catalyzes the hydrolysis of glucose-6-phosphate to glucose and phosphate. Impairments in the transport of either glucose-6-phosphate (type 1b–much less frequent than type 1a) or phosphate (type 1c–extremely rare) may cause decreased function of this enzyme. The frequency of GSD type 1 is estimated to be 1 in 100,000 births, with most cases being type 1a.

This condition infrequently manifests in the neonatal period, because "demand" feeding or feeding at short

intervals prevent symptomatic hypoglycemia and hepatomegaly has usually not yet occurred. The major clinical findings are poor growth and enlarged abdominal girth as a result of hepatomegaly, and any of the signs that may be related to hypoglycemia. The major laboratory findings are fasting hypoglycemia, ketosis, lactic acidosis, hyperlipidemia (i.e., hypertriglyceridemia), and hyperuricemia. In patients with type 1b disease caused by a defect in the microsomal transporter of glucose-6-phosphate, there may be a history of recurrent infections because of neutropenia and defective neutrophil function and inflammatory bowel disease that may be present in the first year of life. Diagnosis used to be based on hepatic enzyme analyses, but molecular diagnostic testing is currently the first choice. The most important aspect of therapy is the prevention of brain damage from hypoglycemia and growth failure. The mainstay of therapy is frequent feedings and restriction of lactose and sucrose (Kishnani et al, 2001; Smit et al, 2006). The use of continuous nasogastric feedings or uncooked cornstarch, particularly during the night, has significantly improved the care of affected children, and although it does not correct all the biochemical perturbations, it does improve growth and can prevent hypoglycemic spells. Intercurrent illness with increased glucose utilization is particularly hazardous and a careful plan for emergencies is essential. The leukopenia of type 1b is helped by a regimen of granulocyte colony stimulating factor.

Lysosomal α-1,4-Glucosidase Deficiency

GSD type 2, or Pompe disease, is a deficiency of the lysosomal enzyme α-glucosidase. The clinical presentation of patients is most often in the newborn or early infancy period with symptoms of heart failure. The frequency is estimated at 1 in 100,000 births. There is usually marked cardiomegaly with massive biventricular cardiac wall thickening and a typical abnormal electrocardiogram, confirming biventricular hypertrophy and with a short PR interval. Decreased cardiac output can lead to heart failure and passive congestion. Infants may also have generalized hypotonia because of a skeletal myopathy. There is increased deposition of glycogen within the lysosomes of striated muscle. Except in the instance of passive congestion, the liver is not usually enlarged. Diagnosis is based on enzyme analysis in dried blood spots or leukocytes (Goldstein et al, 2009; Pompe Disease Diagnostic Working Group et al, 2008; Zhang et al, 2008). Cardiac transplantation has been performed to prevent death in infancy. Onset of symptoms as late as adulthood occurs when the mutations in one or both of the alleles cause less complete enzyme loss.

In the last several years enzyme replacement therapy for this disorder has been developed and has had a favorable effect on the outcome. More than half of the patients with infantile onset, for whom the disease had previously been fatal within the first year, can now be rescued with varying degrees of residual disability. Patients with adolescent and adult onset may do better depending on the speed with which the diagnosis was made, therapy initiated, and the degree of irreversible muscle damage that has occurred.

HEREDITARY FRUCTOSE INTOLERANCE

Fructose-1,6-Bisphosphate Aldolase B Deficiency

Hereditary fructose intolerance is a rare disorder caused by a deficiency of the enzyme fructose-1,6-bisphosphate aldolase in liver (Steinmann et al, 2001). The enzyme deficiency results in an impairment in the conversion of fructose-1-phosphate to glyceraldehyde and dihydroxyacetone phosphate and therefore in the effective metabolism of fructose. The disorder is inherited as an autosomal recessive trait. Symptoms are triggered by eating fructose or sucrose, which produces fructose. The signs begin when juices and fruit are added to the infant diet and are mitigated by the aversion that the infant develops to these foods and drinks. The major clinical findings are pallor, lethargy, poor feeding, vomiting, loose stools, poor growth, hepatomegaly, and any sign that could be related to hypoglycemia. The major laboratory findings consist of hypoglycemia; hypophosphatemia; elevations of serum ALT and AST, including any of the findings that may be associated with hepatocellular disease; and the presence of reducing substances in the urine. The liver disease may be severe. Patients may be jaundiced with hyperbilirubinemia. There may be bleeding diathesis. In addition to liver disease, renal tubular dysfunction can lead to the renal Fanconi syndrome. The intuition of the physician is crucial in establishing the diagnosis. Previously an intravenous fructose tolerance test was performed under controlled circumstances, to determine whether serum phosphate and glucose levels decrease and serum AST and ALT values rise after 15 to 30 minutes of fructose administration. In the past, confirmation depended on enzyme analysis, but molecular diagnostic testing is more widely available now and avoids both the risk of provocative testing and the laborious enzymatic analysis. The treatment consists of elimination of dietary fructose and sucrose. Many patients enter adulthood with excellent teeth and an aversion to foods containing sucrose or fructose.

FRUCTOSE-1,6-BISPHOSPHATASE DEFICIENCY

Deficiency of the enzyme fructose-1,6-bisphosphatase results in an inability to hydrolyze fructose-1,6-bisphosphate to fructose-6-phosphate (Steinmann et al, 2001). It is a rare disorder. This enzyme is indispensable in gluconeogenesis. The main clinical features are hypoglycemia and signs related to glucose deprivation in the central nervous system (CNS). The symptoms are due primarily to inadequate food intake and not fructose ingestion, although fructose may exacerbate the abnormalities induced by fasting adaptation. Enlargement of the liver because of diffuse steatosis may be present only during periods of fasting and enhanced gluconeogenesis. The laboratory findings consist of hypoglycemia, ketosis, and lactic acidosis. The acidosis caused by accumulation of lactic, 3-hydroxybutyric, and acetoacetic acids can be severe in this disease. Diagnosis depends on enzymatic or mutation analysis. The therapy consists primarily of avoidance of fasting and the need for gluconeogenesis.

Inborn Errors of Ammonia Metabolism

Inborn errors of the urea cycle, because they manifest in infancy, exemplify the small-molecule weight disorders in which symptoms occur episodically, are exacerbated by protein catabolism, and can be treated by the control of catabolic stimuli, dietary modification, and the enhanced removal of offending metabolites. Four disorders in particular cause the majority of cases that occur in the newborn period and in infancy; they are carbamyl phosphate synthetase I deficiency, ornithine transcarbamylase (OTC) deficiency, argininosuccinate (ASA) synthetase deficiency (citrullinemia), and ASA lyase deficiency (argininosuccinic acidemia). The other four genetic disorders of the urea cycle, *N*-acetylglutamate synthase deficiency, arginase deficiency, ornithine transporter deficiency, and citrin deficiency, are rare or do not manifest with neonatal hyperammonemia, or both. In aggregate, disorders of the urea cycle may be as frequent as 1 in 25,000 births or more. The entire cycle is outlined in Figure 22-3 and will be important in understanding the therapeutic modalities.

One round through the urea cycle condenses two molecules of toxic ammonia and one molecule of bicarbonate to form a molecule of urea that is nontoxic and is readily excreted in the urine. *N*-Acetylglutamate, the product of the first enzyme in the cycle, is an obligatory activator of carbamyl phosphate synthetase. These two reactions and OTC, which is responsible for citrulline synthesis, occur in the mitochondrion. The next three reactions occur in the cytoplasm after citrulline is transported out of the mitochondrion. The transport of ornithine back into the mitochondrion and the shuttling of aspartate to the cytoplasm are clearly imperative and account for the two other genes that cause urea cycle defects.

With the exception of arginase deficiency, each of these enzyme deficiencies has been associated with disease in the newborn period. Clinical presentation in the newborn period is similar for all these defects (Brusilow and Horwich, 1995; Leonard, 2006). Almost all the infants are well in the first 12 to 24 hours of life until they begin to feed poorly, vomit, hyperventilate, become irritable and lethargic, and become comatose, usually with seizures. When these diseases are not treated aggressively, they are almost always fatal. The treatment requires specific therapy to lower the waste nitrogen burden, including the toxic substance ammonia, and address the increased intracranial pressure. The severe encephalopathic and life-threatening features may be related in large part to brain edema. Chronic hepatomegaly has been reported in patients with argininosuccinic aciduria, whereas hepatomegaly is evident only during hyperammonemic episodes in the other urea cycle disorders. Acute hyperammonemia is associated with transaminase elevation and liver synthetic dysfunction, but these are rarely more than transient. Histologic examination of the liver shows modest fatty infiltration and fibrosis. Children with argininosuccinic aciduria can also manifest a specific abnormality of the hair known as *trichorrhexis nodosa*.

The main laboratory finding in the urea cycle defects (UCDs) is a plasma ammonium elevation. Plasma ammonium values may vary in different laboratories. In general, however, with automated chemistry testing for ammonia, the normal plasma values in older infants, children, and adults range between 10 and 35 μmol/L. However, the normal plasma ammonium value in newborns may occasionally be as high as 110 μmol/L but is usually somewhat lower. In patients with newborn-onset UCDs who are acutely ill, the plasma ammonium levels are often higher than 1000 or 2000 μmol/L. Patients with UCDs usually do not have metabolic acidosis unless they are in a terminal state with vascular collapse or respiratory failure. Instead, the characteristic acid-base abnormality associated with hyperammonemia is respiratory alkalosis caused by the effect of ammonia on the respiratory control centers in the brainstem.

The various UCDs can usually be distinguished on the basis of the pattern and levels of plasma amino acids. Because citrulline is the product of the carbamyl phosphate synthetase type 1 (CPS-I) and OTC reactions and the substrate for ASA synthetase, its value is critical. In newborn-onset *N*-acetylglutamate synthase (NAGS), CPS-I and OTC deficiencies, plasma citrulline concentrations may be undetectable and are always low. With OTC deficiency, there is increased urinary orotate excretion secondary to carbamyl phosphate accumulation and pyrimidine synthesis. With NAGS or CPS-I deficiency, carbamyl phosphate production is decreased or absent, and orotate excretion is decreased. In citrullinemia, the eponymous amino acid citrulline has markedly elevated concentrations. With argininosuccinic aciduria, plasma citrulline concentration is moderately elevated, in the range of 100 to 300 μmol/L, and can be readily detected during a study of plasma by amino acid analysis.

Because the ability of infants with these disorders to excrete waste nitrogen as urea is impaired, therapy is initially focused on the reduction of nitrogen intake by decreasing dietary protein and providing essential amino acids or the ketoacid analogues. This approach theoretically permits adequate growth without an excessive nitrogen load. Excessive protein leads to hyperammonemia, but too much restriction of protein during long-term therapy leads to poor growth and can provoke catabolism to maintain essential amino acid levels. Actually this approach fails when the patient is in a catabolic state and in negative nitrogen balance, as occurs in the catastrophically ill infant presenting in the first week of life with massive hyperammonemia. For such an infant with hyperammonemia and coma, the mainstay of therapy is dialysis treatment. Hemodialysis (or extracorporeal membrane oxygenation) is the most effective way of reducing plasma ammonium levels, because it affords the greatest clearance of ammonia (Rutledge et al, 1990). Continuous arteriovenous hemofiltration (CAVH) provides a lower clearance rate, but has the added benefit of continuous use and a lesser likelihood of major swings in intravascular volume that can exacerbate an already fragile state and cerebral edema. Ammonia clearance with peritoneal dialysis is only approximately one tenth that of CAVH and is not recommended for specific UCD therapy in the newborn period. Ammonia is not cleared effectively by exchange transfusion.

While the intensive care personnel are waiting for dialysis to be started, alternative waste nitrogen therapy using intravenous sodium benzoate, sodium phenylacetate (together as Ammonul), and, for patients with

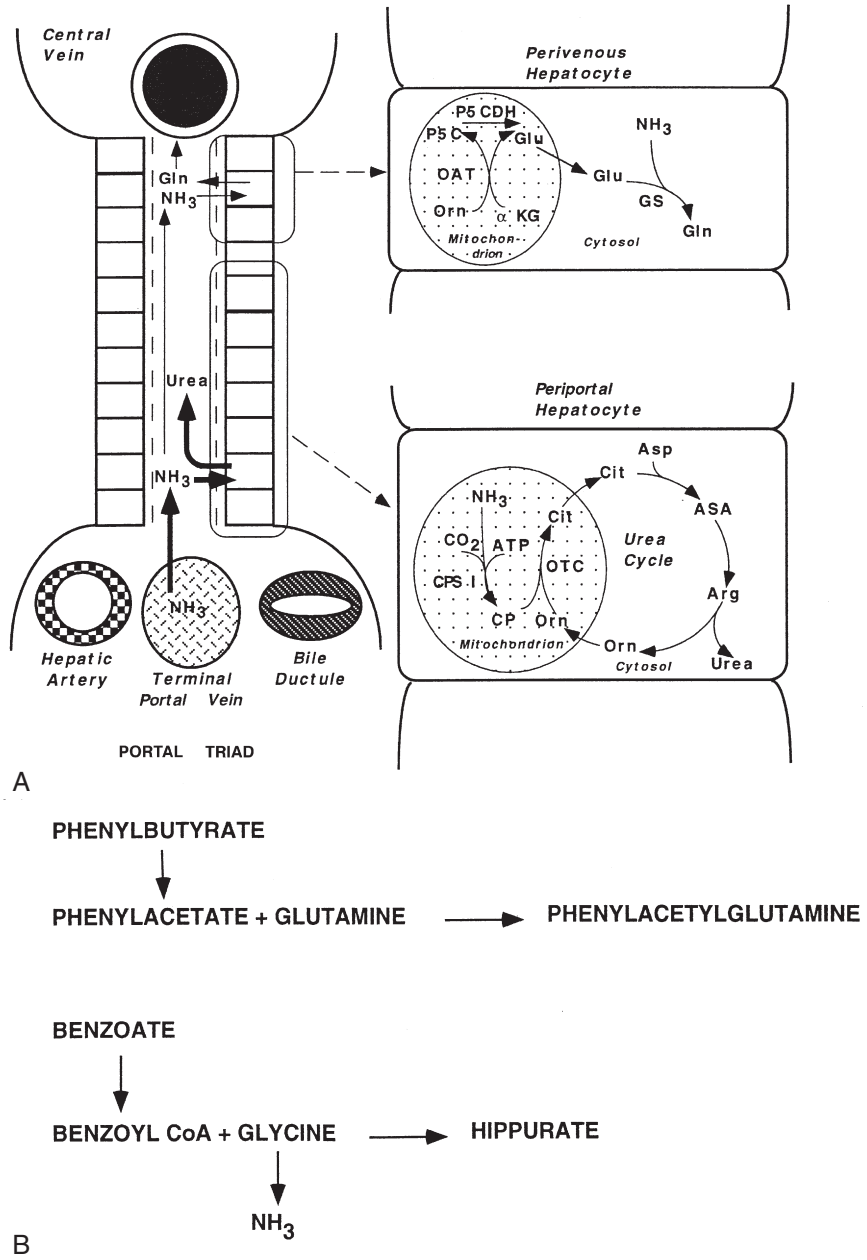

FIGURE 22-3 **A,** Depicted is the nonhomogeneous distribution of enzymes involved in ammonia metabolism in hepatocytes of an acinar sinusoid as they are linearly distributed from the portal triad to the region of the central vein or terminal hepatic venule. The specific enzymatic reactions are shown for an individual periportal and perivenous hepatocyte. The glutamine synthetase (GS) and ornithine aminotransferase (OAT) enzyme activities are expressed exclusively in the one- to three-cell layers surrounding the central vein—that is, the region of zone 3 of the liver lobule—whereas the urea cycle enzymes are concentrated within the periportal hepatocytes. However, the urea cycle enzyme activities are higher in zone 1 immediately surrounding the portal triad than in the middle zone 2. The hepatocytes are shown as *squares*, the hepatic mitochondria as *shaded circles*, and the lining of the space of Disse as the *broken lines* on either side of the linear array of hepatocytes. *Arg*, Arginine; *ASA*, argininosuccinate; *Asp*, aspartate; *ATP*, adenosine triphosphate; *Cit*, citrulline; *CP*, carbamylphosphate; *CPS-I*, carbamylphosphate synthetase type 1; *Gln*, glutamine; *Glu*, glutamate; α-*KG*, α-ketoglutarate; NH_3, ammonia; CO_2, CO_2 or bicarbonate; *Orn*, ornithine; *P5C*, pyrroline 5-carboxylate; *P5CDH*, pyrroline-5-carboxylate dehydrogenase. **B,** The medications sodium phenylacetate and phenylbutyrate and sodium benzoate promote alternative waste nitrogen disposal by participating in these two mitochondrial reactions. *(Adapted from Tuchman M, et al: Hepatic glutamine synthetase deficiency in fatal hyperammonemia after lung transplantation*, Ann Intern Med *127:447, 1997.)*

ASA synthetase and ASA lyase deficiencies especially, arginine hydrochloride should be given (Brusilow, 1991; Brusilow and Batshaw, 1979; Brusilow et al, 1979). The medications and the proper dose for a bolus and 24-hour sustaining infusions of Ammonul are available from Ucyclyd Pharma (Scottsdale, Arizona). This product is rarely stocked except in pharmacies of tertiary care metabolic centers. Arginine hydrochloride is thought to be helpful in NAGS, CPS-I, and OTC deficiencies and is given at a continuous dose of 250 mg/kg per 24 hours. A dose of 600 mg/kg/day is recommended for ASA lyase particularly and for citrullinemia. Arginine supplementation the body arginine

pool, and in citrullinemia and argininosuccinic acidemia it increases ornithine to promote synthesis of citrulline and ASA. ASA contains both waste nitrogen atoms destined for excretion as urea and has a renal clearance rate equal to the glomerular filtration rate, provided that it is continuously synthesized and excreted. Accordingly, ASA should serve as an effective substitute for urea as a waste nitrogen product. The excretion of citrulline, which contains only one molecule of ammonia, also exceeds that of ammonia, although it does not appear to be eliminated as efficiently as ASA.

Sodium benzoate promotes ammonia excretion when it is conjugated with glycine to form hippurate, which is cleared by the kidney at fivefold the glomerular filtration rate (see Figure 22-3).Theoretically, 1 mole of waste nitrogen is synthesized and excreted as hippurate for each mole of benzoate administered. The hippurate synthetic mechanism resides primarily in the hepatic mitochondria and depends on an intact mitochondrial energy system for adenosine triphosphate (ATP) synthesis. The glycine consumed in this reaction can be replaced by either serine or the glycine cleavage pathway. Sodium phenylacetate, as well as sodium phenylbutyrate, which is used for long-term therapy in the absence of sodium benzoate, conjugates with glutamine to form phenylacetylglutamine, which is excreted by the kidney (see Figure 22-3). Sodium phenylbutyrate is converted to phenylacetate in the liver. Glutamine contains two nitrogen atoms, whereas glycine contains one. Two moles of waste nitrogen are removed for each mole of phenylacetate administered. This acetylation reaction occurs in the kidney and the liver.

The outcome for patients with severe newborn-onset CPS-I and OTC deficiencies is poor. Sometimes dialysis therapy cannot rescue severely affected boys with X-linked OTC deficiency in the first few days of life (Enns et al, 2008). Prospectively administered alternative pathway therapy in conjunction with high-calorie fluids usually prevents death and severe hyperammonemia in patients known from family studies or prenatal diagnosis to be at risk. This therapy is done best in collaboration with an expert in the treatment of urea cycle disorders. Even after institution of successful therapy, the morbidity and mortality rates are high in these severely affected patients and mental retardation is common in survivors (Brusilow and Horwich, 1995). There is a significant correlation between the duration of newborn hyperammonemic coma and the developmental quotient score at 12 months of age (Msall et al, 1984). Four of five reported children in whom duration of coma was 2 days or less had normal intelligence quotient scores, whereas all seven children in whom coma lasted 5 days or longer were severely mentally retarded. Currently liver transplantation is recommended for patients with CPS-I and OTC deficiencies in the newborn period. The patient should have almost no residual enzyme activity and grow to a sufficient size for the treatment to be feasible and safe. Early diagnosis and treatment is important because of the devastating effects of prolonged newborn hyperammonemic coma.

Mutational analysis of DNA is available for all of these disorders at www.genetests.org. If the lesion in a particular family is known, prenatal diagnosis by means of direct DNA analysis is also feasible. With the exception of OTC deficiency, all the UCDs are inherited as autosomal recessive traits.

TRANSIENT HYPERAMMONEMIA OF THE NEWBORN

Transient hyperammonemia of the newborn is a distinct clinical syndrome that was first identified by Ballard et al (1978). The disease usually develops in premature infants during the course of treatment for respiratory distress syndrome. The plasma ammonium level may be enormously elevated, as high as that found in any of the patients with the most severe type of UCD. Its onset is usually in the first 24 hours after birth, when the infant is undergoing mechanical ventilatory support. Affected babies can manifest all the signs associated with hyperammonemic coma. The diagnosis may not be obvious, however, because many of these same infants are receiving sedatives and muscle relaxants to optimize therapy of their life-threatening pulmonary disease and an ammonia level is not determined. Important clues are the absence of deep tendon reflexes, the absence of normal newborn reflexes, and a decrease or absence of response to painful stimuli. As with hyperammonemic coma in UCD, this medical emergency requires dialysis therapy.

The cause of this disease is unknown. The plasma amino acid levels are similar to those found in CPS-I or OTC deficiency. Investigators have hypothesized that the disorder may be caused by impairment of hepatic mitochondrial energy production or shunting of portal blood away from the liver, such as in patent ductus venosus. The mortality rate in transient hyperammonemia of the newborn is high. A patient who can be treated early and aggressively may survive the episode. There is no evidence that any of the survivors have suffered any further episodes of hyperammonemia, nor has there been any further evidence of impaired ammonia metabolism.

INBORN ERRORS OF AMINO ACID METABOLISM

MAPLE SYRUP URINE DISEASE

Branched-Chain 2-Keto Dehydrogenase Complex Deficiency

Maple syrup urine disease (MSUD) is a rare inborn error of amino acid metabolism (Chuang et al, 2001; Wendel and de Baulny, 2006). It is inherited as an autosomal recessive trait and is caused by a deficiency of the enzyme branched-chain 2-keto dehydrogenase (BCKAD) complex. This enzyme catalyzes the conversion of each of the 3-ketoacid derivatives of the branched-chain amino acids (BCAAs)—leucine, isoleucine, and valine—into their decarboxylated coenzyme metabolites within the mitochondria (Figure 22-4). The disease occurs in 1 in 200,000 newborn infants around the world, but in the Mennonite communities of the United States, the frequency is 1 in 358 because of a founder effect for a point mutation in the $E_1\alpha$ gene. The most common presentation of the disorder occurs in the newborn period. Other forms with later onset caused by less complete enzyme deficiencies occur, but they are not the subject of this chapter. The newborn

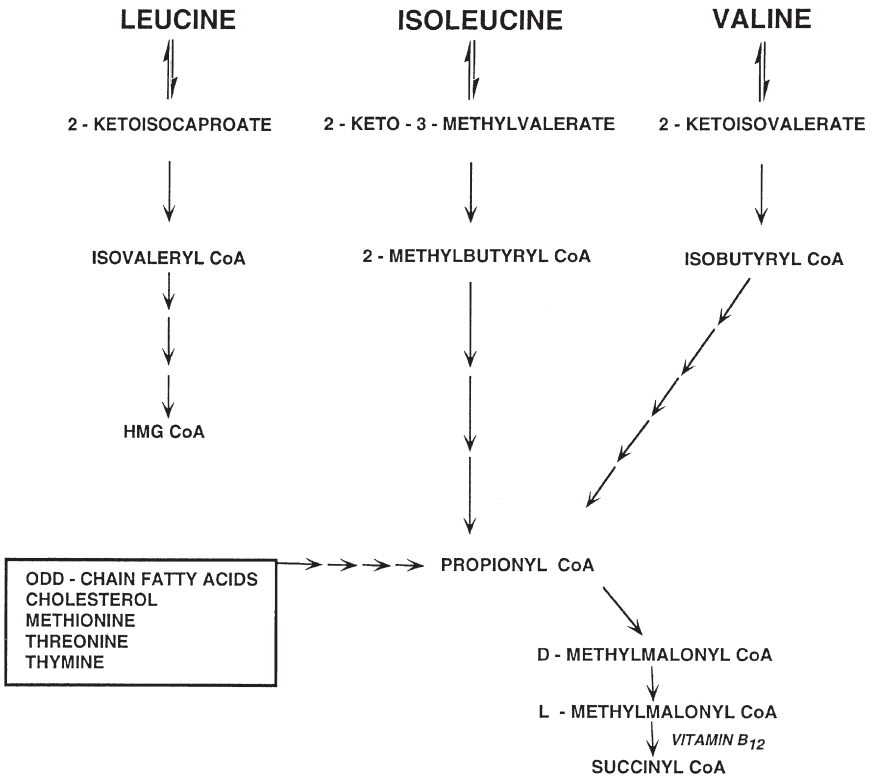

FIGURE 22-4 The branched-chain amino acids leucine, isoleucine, and valine are reversibly transaminated to their corresponding 2-keto analogues, which are substrates for the single decarboxylase (branched-chain 2-keto dehydrogenase) enzyme deficient in maple syrup urine disease. Reduced activity of isovaleryl coenzyme A (CoA) dehydrogenase, the next enzyme in the leucine degradative pathway, is the cause of isovaleric acidemia. The immediate precursor of ketones, 3-hydroxy-3-methylglutaryl CoA (HMG-CoA), is the final product of the leucine catabolic pathway. However, its production more strongly depends on the oxidation of fatty acids as in ketogenesis and in cholesterol biosynthesis. Propionyl CoA, which accumulates in both propionic and methylmalonic acidemia, can be synthesized from isoleucine, valine, odd-chain fatty acids, cholesterol, methionine, threonine, and thymine. The adenosyl form of vitamin B_{12} is the important cofactor in the L-methylmalonyl CoA mutase–catalyzed conversion of l-methylmalonyl-CoA to the citric acid cycle intermediate, succinyl CoA.

presentation is associated with a severe and catastrophic illness and usually results in death without specific medical intervention. Typically the infants are well at birth; only after 2 or 3 days of ingestion of breast milk or formula do they begin to manifest poor feeding and regurgitation. Lethargy becomes evident; the cry may be shrill and high pitched. There may be hypotonia alternating with hypertonia and opisthotonic posturing. The odor of maple syrup may be detected in saliva, on the breath, in urine and feces, and in cerumen obtained from the ear. The babies become more and more obtunded and eventually lapse into a deep coma. The anterior fontanel may be bulging. Seizures may develop. The life-threatening encephalopathic features may simply be related to brain edema (Chuang et al, 2001).

The clinical biochemical laboratory hallmark is metabolic acidosis. The anion gap may be raised, but not necessarily. There is almost always ketonuria. The plasma ammonium values are usually normal. The complete blood count is usually normal. The levels of the plasma BCAAs leucine, isoleucine, and valine are elevated, with striking elevation in leucine, the probable toxic metabolite. The normal ranges for plasma leucine, isoleucine, and valine in the newborn period are 29 to 152 μmol/L, 11 to 87 μmol/L, and 71 to 236 μmol/L, respectively. In patients who are critically ill, the leucine levels may range between 1900 and 6900 μmol/L. In the past, almost every newborn infant who was recognized to have MSUD and was severely ill was treated with peritoneal dialysis in a tertiary care center. The treatment was clinically successful in most instances, but it did not allow for as rapid a rate of reduction in plasma BCAA levels as did hemodialysis or CAVH (Rutledge et al, 1990).

It is now clear that a nutritional approach works as well as peritoneal dialysis in newborns with MSUD (Berry et al, 1991; Chuang et al, 2001; Morton et al, 2002; Parini et al, 1993; Wendel and de Baulny, 2006). It is best performed with the use of a BCAA-free modified parenteral nutrition solution for infants and older children with acute metabolic decompensation, but this is rarely available in any center that does not have a larger Mennonite population. Protein-free intravenous alimentation augmented with a low-volume, enteral solution of the 17 nonbranched chain amino acids for 24 to 48 hours is satisfactory. An insulin drip may also be necessary to curtail the effects of the catabolic stimulus (Berry et al, 1991; Wendel et al, 1982). On the basis of the rate of plasma leucine decline, the staff at Children's Hospital of Philadelphia have found that this nutritional therapy is comparable to peritoneal dialysis when plasma leucine levels are as high as 1908 to 3053 μmol/L. However, CAVH or hemodialysis may achieve more rapid normalization of the plasma BCAAs and their corresponding branched-chain ketoacids when the levels of leucine are in the range of 4580 to 6870 μmol/L. Newborn infants with an odor of maple syrup, a metabolic

acidosis, and ketonuria require immediate metabolic consultation assistance and a confirmatory plasma amino acid quantitation. This is truly a medical emergency with a high risk of death and permanent brain damage. Most patients who are successfully treated by 7 days of age do not have mental retardation. Patients whose diagnosis and therapy are delayed—and perhaps even in those whose disorder is diagnosed in the first week of life, but who have suffered such severe damage because of increased intracranial pressure—often have substantial decreases in developmental or intelligence quotient, as well as signs compatible with spastic diplegia or quadriplegia.

Expanded newborn screening is going to lead to a changed picture for this disorder. In jurisdictions in which the turnaround time for the program are as fast as 3 to 4 days of life, the patient will likely be less ill and the diagnosis will be known. The outcome will be better because less risk of permanent damage will have occured.

The mainstay of long-term therapy for patients with MSUD who survive the newborn period is a special formula devoid of the BCAAs. The amount of BCAAs necessary to sustain growth but maintain plasma leucine, isoleucine, and valine levels in the normal range is supplied with a regular proprietary formula in limited amounts. In the first week of life, this amount is approximately 100 mg of leucine per kilogram of body weight daily and 50 mg/kg daily of both isoleucine and valine. The BCAA requirements, and thus the rates of utilization of the BCAAs for protein accretion, drop rapidly in the first year of life in conjunction with the decline in growth velocity in young infants. As with PKU, it is imperative that the administration of the special amino acid formula be carefully monitored by means of frequent plasma amino acid quantitations. One of the most common errors made in the treatment of MSUD is the failure to administer adequate amounts of supplemental isoleucine and valine solutions to maintain normal plasma levels, because proprietary formulas alone do not always meet the needs of each growing baby (i.e., adequate amounts of each BCAA are not supplied by a formula alone). Deficiency of BCAAs can result in a severe exfoliative rash and anemia. The rash may mimic that of severe acrodermatitis enteropathica (Giacoia and Berry, 1993).

As with many of the inborn errors of amino acid, organic acid, and ammonia metabolism, protein administration in the infant whose disease is controlled and who is in metabolic balance with diet therapy must be discontinued during periods of intercurrent infections because catabolism, possibly driven by counterregulatory hormones or cytokines, triggers metabolic decompensation through the release of branched-chain ketoacid from skeletal muscle. Metabolic decompensation is further exacerbated by poor nutritional intake. It is imperative that during these times, adequate calories and fluids be given to prevent the crisis from escalating into a medical emergency.

In selected instances, a molecular diagnosis of MSUD may be undertaken; this diagnosis is especially useful in targeted populations such as the Mennonites. Rarely patients may have a defect in the enzyme 2(E_2) component (Danner et al, 1985) or, as discussed in the Primary Lactic Acidosis section, in the enzyme 3(E_3) component. The rare patient with MSUD may respond favorably to high-dose thiamine therapy with a reduction in BCAAs and a lower need for protein restriction.

HEREDITARY TYROSINEMIA TYPE 1 OR HEPATORENAL TYROSINEMIA

Fumarylacetoacetate Hydrolase Deficiency

Tyrosinemia type 1 is caused by a deficiency of the enzyme fumarylacetoacetate hydrolase (Tanguay et al, 1995). This enzymatic reaction is distal in the phenylalanine and tyrosine pathway, and the disorder is actually an inborn error of organic acid metabolism, with hypertyrosinemia being a secondary and variable biochemical effect. Tyrosinemia type 1 is a rare disease inherited in an autosomal recessive manner. The highest incidence is found in those of French-Canadian ancestry as a result of a founder effect (De Bracketeer and Larochelle, 1990).

The phenotype is variable. At one extreme, the patient is in early infancy and has severe, usually fatal disease in which liver disease dominates the clinical picture. At the other end of the spectrum is a more chronic phenotype, and patients exhibit hypophosphatemic rickets related to renal Fanconi syndrome. These patients usually also have evidence of liver disease, although milder. Most of the patients with severe liver disease phenotype do not come to clinical attention in the newborn period. Careful search, however, may reveal laboratory findings compatible with this disease, even in newborn infants. In the phenotype seen in early infancy, the clinical findings are hepatomegaly, a bleeding diathesis, and jaundice. Ascites is not uncommon. The laboratory findings consist of abnormal liver function and dysfunction tests with increases in serum AST, ALT, and direct and indirect bilirubin; prolongations of PT and PTT; and findings related to renal Fanconi syndrome, such as glycosuria, hypophosphatemia, hypouricemia, proteinuria caused by β_2-microglobulin hyperexcretion, and generalized amino aciduria and organic aciduria.

More specific laboratory abnormalities consist of an abnormally high serum alpha-fetoprotein level. There may be an elevation of plasma tyrosine; however, the hypertyrosinemia and a more prominent hypermethioninemia are caused by a secondary impairment in liver function. The most important metabolites are those related to the substrate, fumarylacetylacetic acid, the handling of which is defective. Increased levels of the diagnostic metabolite succinylacetone can be detected on urine organic acid quantitation by gas chromatography–mass spectrometry (GC-MS) in most instances and even more sensitively by an isotope dilution method, and in RBCs by the δ-aminolevulinic acid dehydratase inhibition assay. As in all metabolic disorders, the metabolite abnormalities may not be present or detectable at all times.

Newborn screening methods are likely to alter the phenotype of this disorder. Increasingly, analysis of blood spot succinylacetone is being added to the expanded newborn screening panels and will likely lead to preemptive diagnosis and treatment in the majority of cases. The false-negative rate for this analysis is not known at this time. Newborn screening by older methods has been performed in Quebec for many years.

In the past, most of the infants with the hepatic form of tyrosinemia type 1 died in early to late infancy. However, a medical therapy has been developed that uses the agent 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione

(NTBC), which inhibits *p*-hydroxyphenylpyruvate dioxygenase (Lindstedt et al, 1992), thus blocking the conversion of *p*-hydroxyphenylpyruvate, the transamination product of tyrosine, to fumarylacetoacetate and thereby retarding the synthesis and accumulation of succinyl acetate and succinyl acetone. This therapy has been used successfully to improve liver and renal function as well as to normalize or improve the various laboratory abnormalities. It is unclear, however, whether NTBC therapy will eliminate the need for liver transplantation, which has been the mainstay of long-term therapy until recently.

One of the most devastating complications for older infants with tyrosinemia type 1 who have been stabilized clinically and biochemically is the development of hepatocellular carcinoma. This development is prevalent in tyrosinemia treated with diet, and most patients who survive infancy or who have a chronic phenotype succumb to liver cancer. It is recommended that NTBC therapy be started in infants who are acutely ill while they are waiting for a liver transplantation, which may be deferred until the third year of life, while monitoring the liver for development of a hepatoma. Early treatment with NTBC surely retards the development of tumors, but patients receiving therapy develop hepatomas and preemptive transplantation, although at a later age. Liver transplantation is still a highly prevalent therapy. Most liver transplantations have been successful, and the patients have done well with immunosuppressive therapy with only minimal persistent evidence of renal tubular dysfunction while eating a normal diet.

Hepatorenal tyrosinemia has no direct effect on the nervous system, and most patients are free of neurologic findings and mental retardation. Because succinylacetone can inhibit delta-amino levulinic acid dehydratase, the enzyme deficient in a rare type of acute intermittent porphyria, porphyria symptoms have frequently occurred in the pre-NTBC era and have proved fatal in some instances.

Hepatorenal tyrosinemia is not to be confused with transient tyrosinemia of the newborn, which is prevalent in premature infants and is probably the most common disturbance of amino acid metabolism in man; it is secondary to a delayed maturation of *p*-hydroxyphenylpyruvate dioxygenase activity (Levine et al, 1939; Tanguay et al, 1995) or with the hypertyrosinemia secondary to liver disease. Current screening methods are unlikely to detect this condition that was found frequently in the past.

NONKETOTIC HYPERGLYCINEMIA

Glycine Cleavage Complex Deficiency

Nonketotic hyperglycinemia is a rare defect of glycine metabolism (Dulac and Rolland, 2006; Hamosh and Johnston, 1995.) and is inherited as an autosomal recessive trait. The disorder is caused by deficient activity of the glycine cleavage enzyme complex (GCC), which consists of the products of four genes. Its frequency is fewer than 1 in 200,000 newborn infants. Although several variant forms exist, most infants who come to clinical attention in the newborn period—presumably most patients with this disease—have a severe, catastrophic illness that mimics the most acute forms of ammonia, amino acids, or organic acid metabolism. The infants may be healthy at birth but begin to show severe hypotonia and seizures after 12 to 36 hours. They quickly become comatose, and there is a loss of all the newborn and deep tendon reflexes.

The clinical findings are predominantly those of an acute encephalopathy. The electroencephalogram (EEG) usually shows a characteristic pattern of spike and slow waves. The babies may have hiccups from diaphragmatic spasms. The main laboratory finding is an elevation of plasma glycine and a proportionally higher elevation of glycine in the cerebrospinal fluid (CSF). Unfortunately, plasma glycine levels may be normal in the newborn period. The urine glycine is usually also elevated. The most common diagnostic criterion is the raised CSF–plasma glycine ratio. Values greater than 0.08 are considered to be diagnostic, whereas those between 0.04 and 0.08 are highly suspicious of the diagnosis. The amino acid serine, which is also a product of the defective enzyme reaction, is depressed in plasma, and there is a corresponding increase in the glycine-to-serine ratio in body fluids. Prenatal CNS lesions have been reported (Dobyns, 1989).

The pathophysiology of this brain disease is not well understood; it is believed that glycine, an active neurotransmitter, may interfere with the activity of specific chloride channels, thus perturbing the membrane potential and depolarization of neurons. There also appears to be an impairment in alpha-motor neuron outflow tract activity, producing a clinical state that mimics Werdnig-Hoffmann disease. No acidosis or ketosis is seen in this disease—thus the name, *nonketotic hyperglycinemia*. Many of the disorders of organic acid metabolism, such as methylmalonic acidemia and propionic acidemia, are also associated with elevations of plasma glycine, presumably because of a secondary impairment in the GCC, and have been referred to in the past as the *ketotic hyperglycinemia syndromes*.

Although many therapies have been tried in this disease—such as protein restriction, benzoate to trap glycine as the byproduct hippurate, strychnine to affect the lower motor neuron function, and dextromethorphan to block *N*-methyl-D-aspartate receptors—there is no generally effective treatment. The seizures are variably controlled and life may be prolonged, but no meaningful improvement occurs in most instances. Many affected babies die in the newborn period despite medical support with assisted ventilation, and most others die within 2 to 4 years. A transient form of nonketotic hyperglycinemia has also been reported in newborns (Luder et al, 1989; Schiffmann et al, 1989). Valproate may result in hyperglycinemia because of secondary inhibition of the GCC, as is postulated to explain secondary hyperglycinemia in disorders of organic acid metabolism, such as propionic acidemia. Milder forms exist and milder symptoms appear at a later age. This disorder cannot be diagnosed by newborn screening.

METHIONINE SYNTHETASE DEFICIENCY, OTHER DISORDERS OF HOMOCYSTEINE REMETHYLATION AND CYSTATHIONINE SYNTHASE DEFICIENCY

In humans, the essential amino acid methionine is converted to homocysteine, and in the process a methyl group is transferred to an acceptor molecule from

S-adenosylmethionine that serves as a donor for methyl groups in many different reactions (see Figure 22-5) (Mudd et al, 1995). Subsequently the homocysteine may either be completely metabolized through the cysteine pathway to sulfate or it may be remethylated back to methionine to maintain the critical levels of methionine. Defective methionine remethylation or a deficiency in methionine synthetase leads to a form of homocystinemia (the name *homocystinuria* is anachronistic and does not reflect the current reality of ascertainment or testing as well as does *homocystinemia*). Patients with classic homocystinemia, caused by a deficiency of the cystathionine beta-synthase enzyme, rarely manifest signs in early infancy (Mudd et al, 1995). In contrast, patients with methionine synthetase deficiency or methionine remethylation defect may come to clinical attention in the newborn period (Rosenblatt and Fenton, 2001). The patients may have either an abnormality in vitamin B_{12} metabolism, which can also produce methylmalonic acidemia and homocystinuria, or an isolated defect in folate metabolism or the methionine synthetase enzyme (Rosenblatt and Fenton, 2001). In this reaction the methyl group from 5-methyltetrahydrofolate, which is derived from 5,10-methylene tetrahydrofolate, is transferred to methylcobalamin and subsequently to homocysteine.

The clinical findings associated with the methionine synthetase deficiencies are poor growth and development. There may be severe cortical atrophy and possible brain lesions caused by thromboses of the arteries or veins, as in classic homocystinuria. Infrequently they can manifest as an acute intoxicating disorder in the newborn period. The laboratory findings consist of an elevation in plasma homocysteine values and a normal or decreased methionine value. Often the homocysteine values are not as elevated as in classic cystathionine β-synthetase deficiency. If there is a defect in folate or vitamin B_{12} metabolism that produces secondary impairment in methionine synthetase activity, there may also be megaloblastic anemia.

Some patients with a defect in cobalamin metabolism respond to treatment with high doses of intramuscular hydroxycobalamin. The treatment of methionine synthesis deficiency is a normal protein intake or methionine supplementation to restore methionine levels in plasma to normal and to restore CNS pools of methionine, which may be critical in one-carbon transfer reactions. It is also possible to retard homocysteine accumulation and restore methionine levels by administering betaine, which can enhance remethylation of homocysteine to methionine through the alternate betaine methyltransferase pathway. Some investigators have also used pharmacologic doses of cobalamin, folate, and pyridoxine to stimulate flux through either the methionine synthetase or the classic homocysteine pathway. Unfortunately, if infants with this type of disorder are not treated early, there is usually a permanent and devastating effect on cognitive and motor function. Milder and occasionally asymptomatic forms are known.

Classic homocystinemia caused by cystathionine synthase deficiency can be ascertained by expanded newborn screening in a minority of cases. The elevated methionine that is the critical detected metabolite may require several days to become apparent; that is unfortunate because cystathionine synthetase deficiency is a treatable disorder. Expanded newborn screening has altered the landscape for several B_{12} processing defects. Ascertainment of elevated methylmalonic acid with the C3 acylcarnitine, the C4 dicarboxylacyl carnitine, or both usually allows for earlier diagnosis and treatment, with apparent mitigation of long-term effects. These disorders are more common than classical homocystinemia, the latter having a frequency in most populations of 1 in 200,000 births or less.

PHENYLKETONURIA

Phenylalanine Hydroxylase Deficiency

PKU is the most common inborn error of amino acid metabolism that can result in mental retardation (Scriver et al, 2001; Walter et al, 2006). Its frequency is between 1 in 10,000 to 1 in 25,000 births, depending on where in the United States it is studied. There are areas of the world such as Ireland, Turkey, and Iran in which it is more frequent, and others such as Finland, Japan, and among Ashkenazi Jews in which it is less prevalent. PKU is caused by a defect in the activity of the enzyme phenylalanine hydroxylase, which converts phenylalanine to tyrosine, a reaction that resides primarily in the liver. Thus in PKU it is the deficiency of this liver enzyme that results in brain disease. Because of the paucity of findings in the newborn period or early infancy, PKU usually was not diagnosed until late infancy or later until newborn screening was instituted. It is important for physicians caring for newborns to be aware of the pitfalls of screening, which are summarized in Chapter 27. This disease, inherited as an autosomal recessive trait, exemplifies the interaction of a gene and the manipulatable environment (i.e., diet) in the expression of a disease (Scriver et al, 2001).

After birth, the baby with PKU who is undergoing normal postnatal catabolism, or ingesting adequate amounts of breast milk or a proprietary formula, will experience a gradual and persistent increase in plasma phenylalanine levels. The cutoff value for newborn screening differs by jurisdiction, but both phenylalanine value and the phenylalanine:tyrosine ratio are considered when calling a presumptive positive. The diagnosis is rarely missed if testing occurs after 24 hours of age. By 5 to 7 days of age in the untreated patient, the eponymous phenylketone is found in urine, and another side product of phenylalanine accumulation, phenylacetic acid, may impart the characteristic "mousey" odor to urine and the patient. This odor may be detected when levels of phenylalanine exceed 600 to 900 μmol/L, but it is not detected in every patient. With modern newborn screening programs, the neonatologist will rarely see a case of PKU in the hospital and will usually be dealing with a patient who has a preemptive diagnosis and is treated as an outpatient. Greater detail about the disorder can be obtained in Scriver et al (2001), but a synopsis will be given here.

In the first 6 months of life, the affected babies may have difficulty with feeding and vomiting. In some instances, persistent vomiting has been associated with the diagnosis of pyloric stenosis, for which corrective surgery has been performed, perhaps inappropriately. Developmental delay is usually evident in the second 6 months of life. Patients may have seizures, sometimes infantile spasms in early

infancy associated with a hypsarrhythmic EEG pattern. Persistent elevation of plasma phenylalanine levels greater than 600 μmol/L may be sufficient to result in mental retardation.

The mechanism of brain disease in PKU is still unknown. It may be related to the effect of high phenylalanine levels on the transport of amino acids across the blood-brain barrier and then into brain neurons or glial elements. The plasma levels of tyrosine may be decreased, especially in patients who are not receiving tyrosine supplementation in the special amino acid powder used as a daily nutrient. Investigators have speculated for many years that hypotyrosinemia has a role in the CNS deficits, because tyrosine (only a liver enzyme) cannot be synthesized within the CNS by phenylalanine hydroxylase (a liver enzyme). Older infants often exhibit long tract findings, such as spastic quadriparesis and spastic quadriplegia. The untreated infant demonstrates microcephaly acquired postnatally and may also have severe behavioral problems in addition to a diagnosis of autism. Typical findings consist of elevated serum plasma phenylalanine levels, normal or subnormal plasma tyrosine levels, and increased urinary excretion of phenylpyruvic acid, phenyllactic acid, and phenylacetic acid (rarely measured routinely, but easily seen if urine organic acids are studied).

The mainstay of therapy is a low-protein diet and the use of a special amino acid–containing formula that does not include phenylalanine. The patient must receive an adequate amount of phenylalanine from protein in proprietary formulas and later from table foods, which is tracked by means of a phenylalanine exchange system, to allow for the normal daily utilization of phenylalanine for protein synthesis while maintaining plasma phenylalanine levels in a range as close as possible to normal, but less than 360 μmol/L. As the patient ages, care-givers may have to be content with levels less than 600 μmol/L. Deviations from normal plasma levels are believed to be associated with chronic, perhaps acute, effects on brain function and testing performance; therefore the diet should be maintained for life. More recently, other forms of therapy have been used. Preparations of the large neutral amino acids that compete for the same transporter as phenylalanine may be given, especially to patients who cannot comply with the low–natural protein diet, and more importantly the mandatory daily ingestion of the medical food devoid of phenylalanine, but replete with unpalatable amino acids. Positive effects have been frequently claimed, but few carefully controlled studies are available. The positive effects of this supplement have variously been attributed to competition with phenylalanine absorption in the gastrointestinal tract, competition for transport into the brain, and repletion of neurotransmitters. A small fraction of patients with full-blown PKU respond favorably to high doses of tetrahydrobiopterin, the natural cofactor for phenylalanine hydroxylase, with a substantial fall in plasma phenylalanine levels and an increased tolerance for natural protein. The more mild forms of hyperphenylalaninemia are even more responsive. The therapy is expensive. Injections or implantations of a reservoir in which there is an enzyme that breaks down phenylalanine in the body are in the early phases of testing.

The phenylalanine hydroxylase gene has been cloned and sequenced, and the mutations responsible for most abnormalities in humans are known. DNA sequencing and mutational analysis can be used to identify carriers in families and to provide a scientific rationale during family counseling.

In rare cases, patients with hyperphenylalaninemia have severe disease not because of deficiency of the phenylalanine hydroxylase apoenzyme, but because of deficiency of the active cofactor of this enzyme, tetrahydrobiopterin. Several defects in the metabolism of biopterin can produce this type of hyperphenylalaninemia. Patients with these uncommon types of PKU usually come to attention in the newborn period because of severe seizure activity. Patients with biopterin deficiency can have evidence of severe brain damage despite treatment with a low-phenylalanine diet. Brain damage may be related to deficiencies of other neurotransmitters whose synthesis also depends on adequate levels of tetrahydrobiopterin. These various other defects, such as the dihydropteridine reductase, 6-pyruvoyl tetrahydropterin synthetase, and the guanosine triphosphate cyclohydrolase deficiencies, can be ascertained by urinary measurements of neopterin and biopterin in urine. They are responsive to therapy with neurotransmitter replacement and tetrahydrobiopterin.

If women with PKU are poorly treated during pregnancy, their children may be born with microcephaly and congenital heart defects. Mental retardation is common. Adequate treatment before 8 weeks' gestation is essential, and control of phenylalanine levels before pregnancy is most desirable.

INBORN ERRORS OF ORGANIC ACID METABOLISM

Defects in the catabolism of the BCAAs are responsible for most of the disorders of organic acid metabolism (Figure 22-5). Typical examples are methylmalonic, propionic, and isovaleric acidemias. An organic acid is any organic compound that contains a carboxy functional group but no α-amino group as in an amino acid. In this section, we consider the disorders of fatty acid oxidation, ketone body metabolism, and lactic acid metabolism as well as the more classic inherited defects in organic acid metabolism.

Until recently, these disorders were diagnosed only after symptoms have appeared. It is now more common to be confronted with an asymptomatic or early symptomatic patient and a good idea of the diagnosis. As discussed earlier, acidosis and encephalopathy are usually the hallmarks of these syndromes when they manifest in the newborn period.

METHYLMALONIC ACIDEMIA

L-Methylmalonyl–Coenzyme A Mutase Deficiency

Methylmalonic acidemia, along with propionic acidemia, is thought to be the most common of disorders of organic acid metabolism (Fenton et al, 2001; Wendel and de Baulny, 2006). Although more than one enzyme defect may result in methylmalonic acidemia, all are inherited as autosomal recessive traits. In California, defects in cobalamin metabolism are more frequent than apoenzyme deficiency, specifically L-methylmalonyl–coenzyme a (CoA)

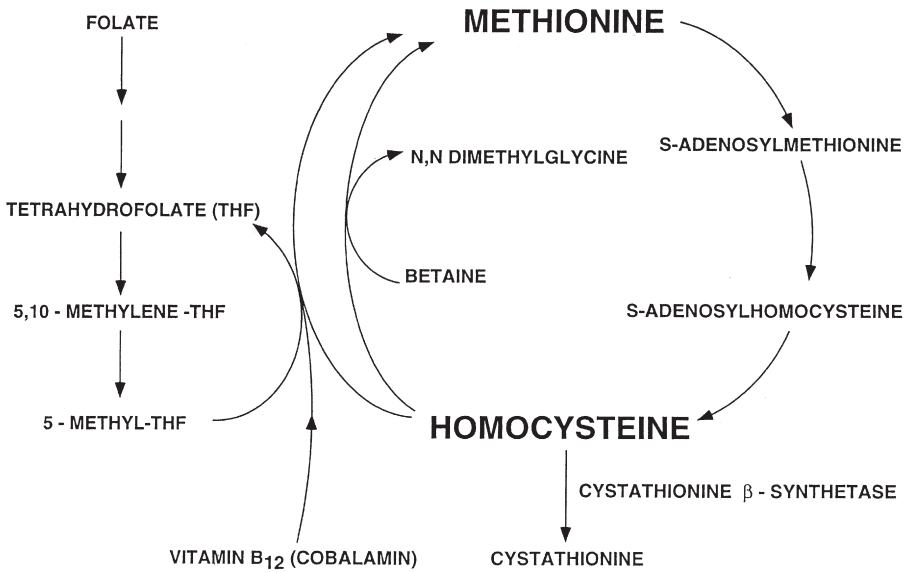

FIGURE 22-5 The pathways, metabolites, and vitamin cofactors important in the interconversion of methionine and homocysteine are shown in this abbreviated scheme of the trans-sulfuration pathway. In a methyl-transfer reaction, homocysteine is converted to methionine; the reaction is catalyzed by a cobalamin-containing enzyme, 5-methyl-tetrahydrofolate-homocysteine methyltransferase or methionine synthase. An alternate reaction involves betaine-homocysteine methyltransferase. Therefore vitamin B_{12} and folate are important vitamins in homocysteine and methionine metabolism. The 5,10-methylene tetrahydrofolate (THF) derived from dietary folate is converted to 5-methyl THF by the enzyme 5,10-methylene THF reductase. In classic homocystinuria, the deficient enzyme is the cystathionine β-synthetase, which catalyzes the conversion of homocysteine to cystathionase, a precursor of cysteine. This pathway is readily operative in the adult, so that cysteine is a nonessential amino acid. In newborn infants, however, synthesis of cysteine does not occur at the same rate as in adults. Adenosylmethionine-dependent methyl transfer may be extremely important in the central nervous system. Most of the patients who come to clinical attention in the newborn period have defects in the remethylation of homocysteine to methionine; therefore these patients may have a severe deficiency of adenosylmethionine in the brain and spinal cord.

mutase (see Figure 22-4). This enzyme is present in mitochondria, and it depends on adenosyl-cobalamin for activity. Impaired function can result from either a mutation of the L-methylmalonyl-CoA mutase apoenzyme or deficient availability of the adenosyl form of vitamin B_{12}. The latter may result from impaired cellular metabolism of vitamin B_{12}, including defective activity of the enzyme adenosylcobalamin synthetase. Some patients, but not usually newborn infants with methylmalonic acidemia caused by apoenzyme deficiency, are responsive to pharmacologic therapy with vitamin B_{12}. Methylmalonic acidemia, therefore, is one of the important disorders that can be considered a vitamin-responsive inborn error of metabolism. Because of deficient activity of L-methylmalonyl-CoA mutase, the substrate L-methylmalonyl-CoA accumulates in mitochondria and is subsequently hydrolyzed to methylmalonic acid. Methylmalonic acid is capable of diffusing out of cells in which it is being produced, so it may be detected in excess in blood, CSF, and urine of patients with these various forms of the disease. The precursors of L-methylmalonyl-CoA are the BCAAs isoleucine and valine, in addition to methionine, threonine, thymine, and odd-chain fatty acids (see Figure 22-4).

There are many different phenotypes of methylmalonic acidemia that range from severe, catastrophic newborn-onset disease in the first week of life to an almost benign form that has been detected in adults with partial L-methylmalonyl-CoA mutase deficiency. Most patients in the newborn period have a severe phenotype. Dialysis therapy is not effective in some of the patients in the first week of life with catastrophic illness, possibly because of a delay in diagnosis and treatment or the breakdown of other systems, including the heart and circulation. The most striking presentation is in the second or third day of life. The baby is usually well at birth, as with UCDs, but then gradually begins to manifest problems with feeding, vomiting, lethargy, and perhaps seizures. There may be respiratory distress as a symptom of metabolic acidosis. The important laboratory findings include metabolic acidosis usually associated with an increased anion gap, ketosis, and hyperammonemia. The elevation of plasma ammonium may be as high as in severe newborn-onset hyperammonemic syndromes. Because ketonuria is relatively uncommon in newborn infants, even in stressed infants with hypoglycemia caused by poor feeding, and because diabetes mellitus is so uncommon in the newborn period, the physician caring for newborn infants must always consider an inborn error of organic acid metabolism when confronted with an acutely ill baby with ketosis. Other laboratory findings are thrombocytopenia, leukopenia, and anemia caused by effects of the metabolite on hematopoietic elements in bone marrow. Plasma amino acid analysis may reveal elevations of several amino acids, such as glycine and alanine. Secondary carnitine deficiency with elevations of carnitine esters is expected (Chalmers et al, 1984). Methylmalonic acid is detected at high levels in urine with GC-MS. Older patients with methylmalonic acidemia during crisis have suffered acute pancreatitis and devastating lesions to the basal ganglia.

The diagnosis can be confirmed with an assay of the activity of L-methylmalonyl-CoA mutase enzyme in cultured skin fibroblasts. In addition, various other disturbances in vitamin B_{12} metabolism can be studied by analyzing skin fibroblasts in culture. It is more common

to dissect the condition clinically, ascertain the response to vitamin B_{12}, and use mutation analysis to confirm the exact site of the genetic lesion.

The treatment of acute disease consists of protein restriction, empirical therapy with vitamin B_{12} (1 mg/day intramuscularly), intravenous fluids with 10% glucose and sodium bicarbonate to correct dehydration, electrolyte imbalance and acidosis, high-calorie feeds via a nasogastric tube, and often dialysis. The use of carnitine (25 to 200 mg/kg/day intravenously or orally) is often recommended, but its usefulness as an acute treatment has not been proved. The treatment of chronic state centers on the judicious use of a low-protein diet, an amino acid supplement low in the MMA precursors, carnitine to alleviate free carnitine deficiency, and appropriate calories and fluid. Vitamin B_{12} is used only when a specific and reproducible response is noted.

Most diagnoses are ascertained by expanded newborn screening. If the results are rapidly available, the outlook for the neonatal period may be improved. Episodes of decompensation will still occur. Patients who are particularly brittle or who develop renal failure receive either liver, kidney, or combined liver-kidney transplants, but their efficacy at curing the primary disease process has not been proved.

PROPIONIC ACIDEMIA

Propionyl Coenzyme A Carboxylase Deficiency

Propionic acidemia was the first classic defect in organic acid metabolism to be described in humans (Fenton et al, 2001; Wendel and de Baulny, 2006). The first patient, described by Childs et al in 1961, was sick on the first day of life with severe metabolic acidosis and ketosis. He responded to massive alkali therapy and survived the newborn period. He subsequently suffered multiple episodes of metabolic decompensation with ketoacidosis, usually precipitated by infections or protein ingestion. He also had developmental delay, a seizure disorder, and episodic neutropenia and thrombocytopenia. He died at 7 years old. His sister also demonstrated ketosis and metabolic acidosis in the first week of life, but because of better control of her disease, there were few severe episodes of decompensation in the first and second decades of life.

Propionic acidemia, which is caused by a selective deficiency of propionyl-CoA carboxylase, is inherited as an autosomal recessive trait. This disorder was originally called *ketotic hyperglycinemia*, because of elevations in plasma glycine along with ketosis. The precursors of propionyl-CoA include the amino acids isoleucine, valine, methionine and threonine, thymine, and odd-chain fatty acids (see Figure 22-4). Of the several hundred patients described with this disease, most clinical presentations are in the newborn period with poor feeding, vomiting, lethargy, and hypotonia. The patients commonly have seizures and hepatomegaly. The metabolic acidosis may be severe with or without an increase in the anion gap. Ketosis is usually present, but not always. Patients who survive may often show choreoathetosis, because of persistent damage to the basal ganglia. Usually episodes of metabolic decompensation characterized by acidosis and ketosis can be precipitated by excessive protein intake or more commonly infection, with the attendant catabolism. Such episodes can result in permanent neurologic damage. Subsequent findings therefore include developmental delay, seizures, cerebral atrophy, and EEG abnormalities. During the acute attacks, leukopenia, thrombocytopenia, and less rarely anemia, probably caused by suppression of maturation of bone marrow hematopoietic precursors, may be exacerbated.

The diagnosis can be confirmed with GC-MS analysis. The urine has excess concentrations of various propionate metabolites, such as methyl citrate, propionylglycine, 2-methyl-3-hydroxybutyrate, 2-methylacetoacetate, and several other, rarer compounds. The plasma glycine value may be elevated, and during acute attacks the plasma ammonium value is frequently increased. The enzyme activity of propionyl-CoA carboxylase can be assayed in white blood cells or extracts of cultured skin fibroblasts for definitive diagnosis. Numerous mutations have been described in the two genes that encode the subunits of this multimeric enzyme.

Therapy consists of a low-protein diet and adequate calories. As in MMA, there is secondary carnitine deficiency with elevations of propionylcarnitine. The use of L-carnitine to relieve a deficiency of free carnitine and promote greater urinary excretion of propionylcarnitine to lower mitochondrial propionyl-CoA levels is not proved. Because intestinal bacteria can also contribute to propionate production, antimicrobial therapy with metronidazole has been used during an acute attack and for long-term therapy. In the acutely ill newborn, the immediate treatment consists of elimination of protein, total parenteral nutrition, administration of an adequate amount of calories (10% glucose intravenously or a nonprotein formula, or both, via nasogastric tube infusion), administration of alkali to eliminate metabolic acidosis, and platelet transfusion if warranted by thrombocytopenia. Patients frequently require hemodialysis, because of severe acidosis and coma. It is unclear whether administration of sodium benzoate and sodium phenylacetate, as in the treatment of hyperammonemia associated with UCDs, is of benefit to the patient with secondary hyperammonemia. Several patients with propionic acidemia have undergone liver transplantation with mixed success. Episodes of acidosis are often recurrent between 1 and 3 years of age, after which some ability to modulate the effects of catabolism occurs.

Most patients with this condition are now ascertained by expanded newborn screening. If the results are rapidly available, the outlook for the neonatal period may be improved. Episodes of decompensation will still occur.

ISOVALERIC ACIDEMIA

Isovaleryl–Coenzyme A Dehydrogenase Deficiency

Isovaleric acidemia is caused by a selective deficiency of the enzyme isovaleryl-CoA dehydrogenase (Sweetman and Williams, 2001; Wendel and de Baulny, 2006). It is inherited as an autosomal recessive trait. There are two major phenotypes; an acute form manifests as catastrophic disease in the newborn period, and the late-onset type is characterized by

chronic, intermittent episodes of metabolic decompensation. The degree of enzyme deficiency and the mutations differ between the two extreme presentations. In the acute form, the infants become extremely sick in the first week of life. There is usually a history of poor feeding, vomiting, lethargy, and seizures. The characteristic sweaty feet or rancid cheese odor caused by isovaleric acid is noted on the body or in urine, especially if it is acidic. Metabolic acidosis is present, usually with an elevated anion gap and ketosis. There may be secondary hyperammonemia, thrombocytopenia, neutropenia, and sometimes anemia, resulting in pancytopenia. The babies usually lapse into a coma. Dialysis therapy may be necessary. As with other organic acid disorders for which an amino acid determines organic acid production (see Figure 22-4), treatment also consists of protein restriction, intravenous fluids with glucose, and perhaps sodium bicarbonate, protein-free formula with calories via nasogastric tube, glycine (250 mg/kg/day), and carnitine supplementation (Sweetman and Williams, 2001). Intravenous L-carnitine may be beneficial. The excretion of isovaleric acid as the glycine conjugate is highly efficient, and symptomatic relief can occur rapidly. Glycine is often available in compounding pharmacies that make their own IV alimentation solutions.

In the chronic, intermittent form of isovaleric acidemia, patients have repeated episodes of metabolic decompensation precipitated by infections, primarily or excessive protein intake. Some of these episodes may mimic Reye syndrome. The same therapeutic principles are applied as for the treatment of the neonatal disorder. The mainstay of long-term therapy is a diet with limited natural protein, a valine-free amino acid supplement, and long-term administration of glycine (Berry et al, 1988), which enhances the production of the nontoxic compound isovalerylglycine and serves to reduce the free levels of isovaleric acid in body fluids. In addition, carnitine administration can augment the excretion of isovaleryl carnitine (Berry et al, 1988; Mayatepek et al, 1991). The benefit of carnitine treatment in the chronic state, however, remains unproved. Some patients who remain largely asymptomatic are ascertained through the expanded newborn screening programs.

Newborn screening and the rapid treatment protocols can alter the outlook for this condition. In the prescreening era, many patients with neonatal onset could not be saved, and a number of those with the more indolent forms have been retarded. This situation should change with preemptive treatment.

The diagnosis can be made from marked elevations of isovalerylglycine in urine. There is usually also increased excretion of 3-hydroxyisovaleric acid. The enzyme isovaleryl-CoA dehydrogenase can be assayed in extracts of cultured skin fibroblasts. As with many other conditions, the typical metabolic profile should allow confirmation directly by mutation analysis bypassing the enzyme assay.

MULTIPLE CARBOXYLASE DEFICIENCY

There are two enzymatic defects leading to deficiency of the same suite of carboxylase enzymes, holocarboxylase synthetase deficiency and biotinidase deficiency (Wolf, 2001). All the carboxylase enzymes—propionyl-CoA carboxylase, pyruvate carboxylase, 3-methylcrotonyl-CoA carboxylase, and acetyl-CoA carboxylase—require covalent linkage with biotin for normal activity. In holocarboxylase synthetase deficiency, the enzyme that catalyzes the covalent linkage of biotin to a lysine residue of these various carboxylases is deficient. In the second form of the disorder, the absence of the enzyme biotinidase does not allow for biotin recycling after a carboxylase enzyme is degraded, and hydrolyzed biotinidase deficiency does not usually manifest in the newborn period.

Patients with severe deficiency in holocarboxylase synthetase, however, characteristically are catastrophically ill in the newborn period. Patients have severe metabolic acidosis with lactic acidosis and become comatose. As with biotinidase deficiency, administration of biotin is life saving. Holocarboxylase synthetase deficiency is one of the few disorders of organic acid metabolism for which the administration of a vitamin in megadoses produces a dramatic turnabout in clinical and laboratory findings. Diagnosis depends on GC-MS analysis of urine and the demonstration of markedly increased levels of lactate, 3-methylcrotonylglycine, and propionate metabolites. In most patients the affinity of the holocarboxylase synthetase enzyme for biotin is diminished, and for the biochemical disturbances to normalize or improve, patients need between 10 and 60 mg of biotin daily. The enzyme deficiency can be confirmed in cultured skin fibroblasts or by mutation analysis. The disorder is inherited as an autosomal recessive trait.

Both biotinidase deficiency, ascertained by direct enzyme assay, and holocarboxylase synthetase deficiency are detected in the expanded newborn screening panels. The outcomes should alter because of this earlier diagnosis.

GLUTARIC ACIDEMIA TYPE 1

Glutaryl–Coenzyme A Dehydrogenase Deficiency

An isolated deficiency of glutaryl-CoA dehydrogenase causes glutaric acidemia type 1 (GA-1) (Goodman and Frerman, 2001). Multiple phenotypes are known. In the most dramatic presentation, which accounts for fewer than half of the known patients with GA-1, the illness develops acutely in the first year of life, usually after an infection or other catabolic event. Acute encephalopathy is followed by the development of what appears to be a severe form of extrapyramidal cerebral palsy (Hoffmann et al, 1991). The affected infants have incurred bilateral damage to the caudate and putamen in the basal ganglia, resulting in an incapacitating dystonic syndrome. Some patients have a slowly progressive course with developmental delay, hypotonia, dystonia, and dyskinesia in the first 2 years of life. Other patients are relatively asymptomatic.

In general, GA-1 is not a disorder that is associated with acute disease in the newborn period. However, macrocephaly at birth is common (Goodman and Frerman, 2001). The etiology of any of the CNS lesions is unknown, but toxicity caused by dicarboxylic acid accumulation has been postulated. Magnetic resonance imaging (MRI) of the head typically shows bilateral widening of the Sylvian fissures associated with hypoopercularization, resulting in the "bat-wing" appearance. Sometimes the fluid accumulation mimics subdural hygromas, and a few patients have

been noted to have subdural hematomas. The congenital nature of these findings suggests that GA-1 has its onset in utero and affects CNS development. Usually infants do not demonstrate bilateral damage to the basal ganglia in the newborn period. Diagnosis depends on the demonstration of glutaric acid and 3-hydroxyglutaric acid in urine and is confirmed by the demonstration of deficiency of glutaryl-CoA dehydrogenase activity or protein levels on Western blot analysis in cultured fibroblasts, or more commonly by mutation analysis.

Newborn screening may be complicated in this disorder. Whereas the majority of patients have positive findings of elevated C5DC in the newborn acylcarnitine profile, a minority with severe disease may have normal or near normal results. These same patients might not show the characteristic elevation of 3-hydroxyglutarate in urine. For this reason an initial elevation of C5DC in urine can and should elicit the close attention of a metabolic specialist who then must help to interpret results of the follow-up testing.

A rare disorder, GA-1 is especially common in Saulteaux-Ojibway Indians of Canada (Greenberg et al, 1995) and in the Old-Order Amish of Lancaster County, Pennsylvania (Morton et al, 1991). A low-protein diet can help in the treatment of these patients; acute illnesses, usually viral in nature, should be treated vigorously with fluids containing glucose and adequate amounts of calories to prevent or diminish catabolism. Bicarbonate may be necessary to correct acid-base imbalance. Carnitine has also been used to reduce mitochondrial glutaryl-CoA levels.

FATTY ACID OXIDATION DISORDERS

Glutaric Acidemia Type 2 or Multiple Acyl Coenzyme A Dehydrogenase Deficiency

Glutaric acidemia type 2 (GA-2) is characterized by deficiency of multiple acyl-CoA dehydrogenase enzymes (Goodman and Frerman, 2001; Stanley et al, 2006). All these dehydrogenase proteins have in common the binding of a protein called *electron transfer flavoprotein* (ETF). This protein is responsible for accepting electrons in any of these oxidative dehydrogenation reactions from the flavin adenine dinucleotide (FAD) cofactor. A mutation in any of the three genes that encode the protein subunits of either ETF or the ETF dehydrogenase, which is responsible for further transferring the electrons from ETF to coenzyme Q_{10} within the mitochondria leads to this condition. Deficiency of riboflavin, a component of FAD, or its transport may also lead to this condition. Among the compounds accumulating in this condition are short-, medium-, and long-chain fatty acids, glutaric and isovaleric acids, dimethylglycine, and sarcosine.

The three major phenotypes of GA-2 are (1) a newborn-onset type with congenital anomalies, (2) a newborn-onset type without anomalies, and (3) a milder or later-onset type, sometimes called *mild acyl-CoA dehydrogenase deficiency* or *ethylmalonic adipic aciduria*.

Severely affected newborn patients with GA-2 often have multiple malformations, may be premature, and are usually ill within the first week of life (Frerman and Goodman, 2001). The patients demonstrate hypotonia, encephalopathy, hepatomegaly, hypoglycemia, and metabolic acidosis; often the odor of isovaleric acid is present. There may be facial dysmorphism consisting of a high forehead, low-set ears, hypertelorism, and a hypoplastic midface. The kidneys may be palpably enlarged, associated with large renal cysts; they may also have rocker-bottom feet, muscular defects of the inferior abdominal wall, and anomalies of the external genitalia, including hypospadias and chordee. Most of the patients with GA-2 and multiple malformations do not survive the first weeks of life. In some, the malformations are not so noticeable, and only renal cysts are identified at autopsy. Some of these patients have cardiomyopathy. In contrast, some of these infants can survive the newborn period.

The phenotype in the third form of GA-2 is highly variable. Some patients are relatively free of disease and have intermittent episodes of vomiting, dehydration, hypoglycemia, and acidosis during childhood or adult life. In some, there may be hepatomegaly and muscle disease.

Laboratory studies in patients with the newborn-onset type usually show severe metabolic acidosis with lactate elevation and increased anion gap, mild to moderate hyperammonemia, and hypoglycemia without a moderate or large ketonuria. The liver function and dysfunction test results may be abnormal, with increases in serum transaminases and prolongations of PT and PTT. A chest radiograph may show heart enlargement because of hypertrophic cardiomyopathy. Abdominal ultrasonography or computed tomography may reveal renal cysts. The diagnosis is made from the characteristic pattern of organic acid metabolites on urine GC-MS analysis. It consists of glutarate; ethylmalonate; 3-hydroxyisovalerate; 2-hydroxyglutarate; 5-hydroxyhexanoate; adipic, suberic, sebacic, and dodecanedioic acids; isovalerylglycine; isobutyrylglycine; and 2-methylbutyrylglycine. The ketones, acetoacetic acid, and 3-hydroxybutyric acid are usually not present or are only minimally elevated if present, being inappropriate for the degree of fatty acid metabolites that indicate free fatty acid mobilization and the potential for enhanced ketogenesis. The renal cystic disease may also be associated with evidence of impaired renal tubular function. Generalized aminoaciduria may be present. The amino-containing compound sarcosine may be elevated in serum as well as in urine. There may be secondary carnitine deficiency, and abnormal carnitine esters such as isovalerylcarnitine and butyrylcarnitine can be detected in blood. The ETF and ETF dehydrogenase deficiency can be detected through the use of specific antibodies on Western blot analysis of cultured skin fibroblasts or of functional assays in skin cells. Mutation analysis in this condition as in others may be superseding the more cumbersome enzyme studies.

Prenatal diagnosis can be achieved by demonstration of glutarate in amniotic fluid, from results of dehydrogenase assays in cultured amniocytes, or by mutation analysis. Despite much debate, criteria for newborn screening have not been well established, and many false positive tests have occurred for this rare disorder.

Although treatment with intravenous glucose, riboflavin, carnitine, and diets low in protein and fat generally have not been successful for catastrophically ill newborns, there has been some success in patients with milder or later-onset disease. Riboflavin is suggested to be administered to

the newborn with severe disease, but riboflavin at a dose of 100 to 300 mg/day has been effective in only a few older patients (Gregersen et al, 1982; Harpey et al, 1983). The rationale for this therapy is that riboflavin, being a precursor of FAD, increases the concentrations of FAD and allows for better interaction with mutated and defective ETF or ETF dehydrogenase proteins. Finally, some artificial electron acceptors such as methylene blue have been used in the newborn period without success.

VERY-LONG-CHAIN, MEDIUM-CHAIN, AND SHORT-CHAIN ACYLFATTY ACID OXIDATION DEFECTS

Fatty acids are oxidized in a complex process by which they are taken up into the cell and transported into the mitochondrion for beta oxidation and energy production. There are at least 31 enzymes involved in the process and defects in the majority have been described. Of these many disorders, the most frequent are those of carnitine metabolism and transport, and various steps in the beta oxidation pathways. The presentations are sufficiently different to bear independent description, but in general they all have hypoketotic hypoglycemia and energy deficits. Most spare the CNS.

When severe, the defects have been associated with coma, hypoglycemia, liver disease, cardiac, and skeletal myopathy (Roe and Ding, 2001; Stanley et al, 2006). All of these defects involve abnormalities in enzymes that participate in or facilitate the mitochondrial beta oxidation of fatty acids. In general the pathophysiology associated with these disorders has the potential to put the patient in a life-threatening condition in which there is a state of catabolism and enhanced liberation of free fatty acids by adipose stores. The most prevalent disorders will be discussed here.

Medium-Chain Acyl-Coenzyme A Dehydrogenase Deficiency

The most common of these disorders is the medium-chain acyl-CoA dehydrogenase (MCAD) deficiency, with a frequency of approximately 1 in 20,000 births in Northern European populations (Roe and Ding, 2001; Stanley et al, 2006). Most patients' disease does not manifest until late infancy, but some with the most severe enzyme deficiencies manifest in the first days of life and may die without explanation, something recently appreciated with the advent of expanded newborn screening. It is also a well-known cause of sudden infant death syndrome having been found in 2% to 3% of cases in which it has been investigated. The typical patient is an older infant who, after an infection, experiences anorexia, vomiting, dehydration, lethargy, and hypoglycemia that may be associated with seizures. Similarly, older patients have features that mimic those of Reye syndrome and can die because of brain edema.

In MCAD deficiency, the initial episode is associated with a high mortality rate. If not diagnosed by newborn screening, the laboratory studies usually show hypoglycemia and an absence of moderate to large ketones in urine that would be expected to accompany hypoglycemia. The plasma ammonium values may be mildly elevated, the liver may be enlarged, and serum ALT and AST levels may be slightly increased. During an acute episode, urine GC-MS analysis of organic acids characteristically shows increased levels of adipic, suberic, and sebacic acids as well as their unsaturated and hydroxylated analogues. However, this result is not pathognomonic of a disorder of fat metabolism, because infants who are fed medium-chain triglyceride–enriched formulas also show dicarboxylic aciduria. Acylcarnitine studies of plasma from patients with MCAD deficiency demonstrates increased levels of C8, C6, and C10 species. Urine also contains glycine conjugates such as suberylglycine and hexanoylglycine. A secondary carnitine deficiency can be present. The MCAD enzyme can be assayed in cultured skin fibroblasts, but mutation analysis is the more common means of confirming the diagnosis.

After the MCAD gene was cloned and sequenced, a large number of more common and private mutations were identified. The most conspicuous gene is *R329E*, a highly prevalent mutation in people of Northern European ancestry and known to cause a severe enzyme deficiency. The major treatment is avoidance of fasting for more than 12 hours, especially in association with an intercurrent illness. Some practitioners are more conservative and advocate fasting of no more than 4 to 6 hours in the first year of life, whether sick or well. Although not of proven efficacy, many physicians recommend a moderately fat-restricted diet for these patients. It is thought that once the disease is diagnosed and preventive programs are instituted, the disease should not be life threatening or fatal.

With the advent of newborn screening, a larger group of patients has been found and some more common mutations in these patients have never been seen in a case ascertained because of symptoms. Finding these individuals has given rise to the notion that many patients found by newborn screening are destined never to become symptomatic. Whereas ascertainment of such mutations can be reassuring, too little is known about them to allow complete reassurance and full relaxation of preventive precautions. Newborn screening also finds individuals heterozygous for a severe mutation when no other mutation is found. These patients are considered to be biochemically manifesting heterozygotes and are thought to be at no medical risk from this condition.

Very-Long-Chain Acyl-Coenzyme A Dehydrogenase Deficiency

Most of the patients with a previous diagnosis of long-chain acyl-CoA dehydrogenase (LCAD) deficiency (Roe and Ding, 2001; Stanley et al, 2006) actually had very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency (Yamaguchi et al, 1993). Patients with this disease may be ill in the newborn period because of liver disease with hypoglycemia, cardiomyopathy, and skeletal myopathy. The membrane-bound VLCAD—as opposed to the soluble LCAD, whose specific metabolic role is unknown—is the main enzyme for initiating oxidation of free fatty acids that are derived from adipose stores, such as palmitic, stearic, and oleic acids. The fasting state may include coma. In its absence, however, the patients may exhibit hypotonia, hepatomegaly, and cardiomegaly. With an acute metabolic decompensation, urine organic acid analysis may demonstrate dicarboxylic aciduria. There may be a secondary carnitine deficiency with

increased concentrations of long-chain fatty acids (LCFAs) bound to carnitine.

VLCAD deficiency can be fatal; sudden death in early infancy has been reported. Therapy is directed toward replenishment of glucose, calorie administration, and treatment of any potential brain edema. The myopathy and cardiomyopathy, however, may proceed even in the absence of fasting. Most investigators suggest a reduction in dietary fat intake, supplementation in medium-chain triglycerides, and maintenance of an adequate intake of essential fatty acids. Diagnosis can be made through enzyme assay in cultured skin fibroblasts, but commonly by mutation analysis.

Expanded newborn screening has expanded our horizons in this disorder as it has for MCAD deficiency. In addition to patients who may be homozygous for two mild mutations or compound heterozygous for a mild mutation, and who are at much reduced clinical risk, heterozygotes for a pathologic mutation and a wild type gene have been found and are presumably at no greater risk than others in the population.

Short-Chain Acyl-Coenzyme A Dehydrogenase Deficiency

The short-chain acyl-CoA dehydrogenase deficiency is a disorder mired in controversy (Roe and Ding, 2001; Stanley et al, 2006). Patients with a severe enzyme deficiency are infrequent, and the majority of them have no symptoms attributable to the disorder, as judged by the variability of symptoms in those ascertained symptomatically and the absence of obvious disease in similarly affected siblings. The situation is further complicated by extensive mutation analysis, especially in those ascertained through positive newborn screens. Because of the prevalence of common polymorphisms that impair but do not eliminate enzymatic activity, the majority of ascertained individuals have no symptoms and appear unlikely to develop them. This problem has led some people to declare the disorder harmless and to pay no attention to it. Other more sober voices accept it as a benign disease and disorder in the majority of patients, but recognize the possibility that a small minority may become symptomatic and treat them appropriately by warning the parents to react to unusual and unexpected symptoms. There tends to be some acrimony at meetings from members of the most extreme positions on either end of the spectrum.

Acylcarnitine analysis on either newborn screen or later shows elevated C4 carnitine. Organic acid analysis shows elevated levels of ethylmalonic and methylsuccinic acids, with higher levels tending to occur with greater enzyme deficiencies. Diagnosis can be made by assaying the short-chain acyl-CoA dehydrogenase enzyme in cultured skin fibroblasts and by a fatty acid oxidation profile in these same cells. Mutation analysis is now the norm for this condition.

Long-Chain 3-Hydroxy Acyl-Coenzyme A Dehydrogenase Deficiency

The long-chain 3-hydroxy acyl-CoA dehydrogenase deficiency is associated with acute illness, fasting-induced hypoglycemia, hypoketosis, cardiomegaly, and muscle weakness (Roe and Ding, 2001; Stanley et al, 2006). As with VLCFA oxidative abnormalities, some older patients may have episodes of illness associated with elevated serum creatine phosphokinase levels and myoglobinuria. A few patients have had sensory motor neuropathy and pigmentary retinopathy. Half the patients do not survive. Some patients may have severe liver disease with fibrosis in addition to necrosis and steatosis. Women who are carriers for this disease may also manifest the HELLP syndrome when carrying an affected child.

The diagnosis was made in symptomatic individuals and was suggested by symptoms and demonstration of longer chain 3-hydroxydicarboxylic acids on urine organic acid analysis. Enzymatic diagnosis can be made in lymphocytes or in skin fibroblasts. More commonly the diagnosis is confirmed by a combination of clinical biochemical abnormalities and DNA mutation analysis. The majority of moderate to severe cases are diagnosed by expanded newborn screening and follow-up.

Treatment of this disorder has involved frequent high-carbohydrate feedings, dietary fat restriction, and supplementation with uncooked cornstarch. Administration of medium-chain triglycerides may be helpful. Carnitine and riboflavin have also been tried without benefit. A high level of parental vigilance is required to begin therapy quickly at signs of metabolic decompensation. Liver and neurologic disease can progress despite any intervention. The outcome of severely affected patients is guarded.

Carnitine Transporter Defect and Deficiencies of Carnitine Palmitoyltransferase I and II and Acylcarnitine Translocase

Carnitine is essential for fatty acid oxidation because transport of LCFAs into mitochondria depends on an adequate amount of carnitine and the presence of two enzymes that covalently link carnitine to fatty acid or remove the linkage and one transporter that carries it across the inner mitochondrial membrane (Roe and Ding, 2001; Stanley et al, 2006). These enzymes are carnitine palmitoyltransferase I and II and a carnitine translocase. Cellular levels of carnitine in turn depend on a sodium-dependent carnitine transporter.

Primary carnitine deficiency appears to be associated with a carnitine transporter defect (Roe and Ding, 2001; Stanley et al, 2006). Patients with the transporter defect may present with symptoms in infancy or in childhood, but rarely in the newborn period. Earliest reports concern the extended newborn period or early infancy. The disease is characterized by hypoketotic hypoglycemia, hyperammonemia, elevations of transaminases, cardiomyopathy, and skeletal muscle weakness. In some of the older patients, cardiomyopathy may be the presenting sign. The characteristic laboratory finding in this disease is extremely low plasma carnitine levels. The total carnitine levels are usually less than 10 μmol/L in plasma. A dicarboxylic aciduria is not usually evident on urine organic acid analysis.

Newborn screening has altered our view of this disorder. Most cases are ascertained with low carnitine on screening and are usually diagnosed with mutation analysis and the failure of carnitine levels to rise in the postnatal period. Most physicians treat the disorder with carnitine to raise

plasma carnitine levels while the evaluation is in progress. Newborn screening has also ascertained asymptomatic and affected mothers and has altered our perception of this condition and its severity. In addition, largely asymptomatic mothers affected with an organic acidemia and low carnitine levels in the mother and fetus have been detected.

This disorder is the only one in which pharmacologic administration of carnitine has dramatic effects on the clinical and laboratory abnormalities. The treatment is 100 to 200 mg/kg/day of L-carnitine. Repletion of plasma carnitine levels is the benchmark by which the efficacy of treatment is judged, but the degree of repletion of tissue levels (skeletal muscle and heart) is inferred but rarely demonstrated. Treatment is successful in the short, intermediate, and longer terms, but no information on the lifespan of these patients who appear healthy is available.

Carnitine Palmitoyltransferase Type I Deficiency

Carnitine palmitoyltransferase type I (CPT-I) is responsible for covalently linking LCFAs such as palmitate to carnitine. Although one patient with deficiency of CPT-I came to attention in the newborn period, most come to attention in early to late infancy (Roe and Ding, 2001; Stanley et al, 2006). The clinical findings are hypoketotic hypoglycemia, encephalopathy, and hepatomegaly; there is usually no evidence of cardiomyopathy or skeletal myopathy in CPT-I deficiency. Renal tubular acidosis, which is caused by impaired distal hydrogen ion secretion, has rarely been reported. Characteristic laboratory findings are the absence of dicarboxylic aciduria and high plasma levels of total carnitine and free carnitine; however, the plasma acylcarnitine profile is not abnormal. The definitive diagnosis rests on measuring CPT-I enzyme activity in cultured skin fibroblasts or mutation analysis. Frequent feeding, reduction of dietary fat, supplementation with medium-chain triglycerides, and avoidance of fasting all have been beneficial in the long-term management of patients with CPT-I deficiency. These patients are now often found by expanded newborn screening because of an abnormal ratio of carnitine to the carnitylated long-chain fatty acids.

Acylcarnitine Translocase Deficiency

Acylcarnitine translocase deficiency is an exceedingly rare defect. It was initially reported in a male infant who suffered a cardiac arrest at 36 hours of age in association with fasting stress and ventricular dysrhythmias (Roe and Ding, 2001; Stanley et al, 2006). Because of the failure to transport long-chain acylcarnitines across the intermitochondrial membrane after the synthesis by CPT-I, the patient had very low total plasma levels of carnitine, most of which was long-chain esterified carnitine; he also had recurrent episodes of hypoglycemia, vomiting, gastroesophageal reflux, and mild chronic hyperammonemia as well as severe skeletal myopathy and mild hypertrophic cardiomyopathy. The continuous nasogastric feeding of a low-fat, high-carbohydrate formula failed to normalize clinical abnormalities, and the patient died at 3 years of age. At that time, liver failure had also developed. Pathophysiologic findings in this patient suggested that accumulation of long-chain acylcarnitine species may be toxic for several organs, including heart, liver, and skeletal muscle. In addition, the acute development of ventricular dysrhythmias may be related to accumulation of such species in cardiac tissue. It is often considered to be almost invariably fatal or very serious, but the probability is that more mild cases with reduced but not absent transporter activity have not been found.

Carnitine Palmitoyltransferase Type II Deficiency

There are two phenotypes of carnitine palmitoyltransferase type II (CPT-II) deficiency (Roe and Ding, 2001; Stanley et al, 2006). The enzyme is responsible for the hydrolysis of LCFA bound to carnitine after transport across the intermitochondrial membrane. Most of the patients reported with CPT-II deficiency have a mild deficiency of the enzyme and in adulthood exhibit episodes of muscle weakness and myoglobinuria brought on by prolonged exercise. The other phenotype is caused by a more serious enzyme defect and manifests in early infancy. The first detailed report was of a 3-month-old boy with hypoketotic hypoglycemia, coma, seizures, hepatomegaly, cardiomegaly, cardiac arrhythmias associated with an increase in long-chain acylcarnitine levels in tissues, and the absence of urinary dicarboxylic aciduria. The enzyme is also expressed in renal tissue and skeletal muscle. Renal dysgenesis has been noted in three patients (Zinn et al, 1991). Reports of onset in the newborn period associated with an abnormal physical appearance and MRI (Hug et al, 1991) and in later infancy have been recorded. Several mutations have been described. Decreased activity of the CPT-II enzyme may be demonstrated in cultured skin fibroblasts.

DEFECTS IN KETONE METABOLISM

After LCFAs are broken down first to medium-chain and finally to short-chain fatty acids such as acetoacetyl CoA, they must be converted in the liver to 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) before hydrolysis to acetoacetate, the ketone body used by the body for energy. Depending on the mitochondrial redox potential—that is, the ratio of the reduced form of nicotinamide adenine dinucleotide (NAD) to its oxidized form ($NADH/NAD^+$)—some of the acetoacetate is converted to 3-hydroxybutyrate, and both ketone bodies are transported out of liver mitochondria and hepatocytes into blood, where they may be used by other tissues, especially brain. Acetoacetyl CoA derived from the last turn of the beta oxidation spiral together with acetyl CoA forms HMG-CoA in a reaction catalyzed by HMG-CoA synthetase. Normally, acetoacetyl CoA can also be hydrolyzed to acetyl CoA by the mitochondrial acetoacetyl-CoA thiolase. Patients with a deficiency of this thiolase do not have a defect in ketone body synthesis but, rather, metabolic acidosis associated with excess ketosis (Mitchell and Fukao, 2008; Stanley et al, 2006).

The clinical features of the thiolase deficiency are variable. Severe acute metabolic decompensation has been reported in infants, but there are also asymptomatic adults with the disorder. The episodes are heralded by fasting or increased protein intake, because isoleucine is a precursor

of 2-methylacetoacetyl CoA, which is also a substrate for the mitochondrial acetoacetyl-CoA thiolase enzyme. Therefore this block leads to a defect in distal catabolism of isoleucine and in processing of the precursor of ketone body formation—namely, acetoacetyl-CoA. Cardiomyopathy has been identified in rare patients. The characteristic urinary metabolite pattern detected on urine organic acid analysis is the presence of isoleucine metabolites, such as 2-methylacetoacetate, 2-methyl-3-hydroxybutyrate, and triglylglycine. During acute decompensation, lactate and the traditional ketone bodies are detected in excess amounts in the urine. Some older children have been mistakenly identified as having ketotic hypoglycemia because glycine may be elevated in plasma. Deficiency in the mitochondrial acetoacetyl-CoA thiolase can be demonstrated in cultured skin fibroblasts and by mutation analysis. Treatment of acute episodes consists of intravenous glucose and administration of alkali to correct metabolic acidosis, which may be severe. Long-term therapy involves mild protein restriction, avoidance of fasting, and prompt attention to any intercurrent illness or development of ketonuria.

The synthesis of acetoacetate from HMG-CoA depends on the HMG-CoA lyase enzyme. A deficiency of this enzyme represents the most profound defect in ketone body synthesis (Roe and Ding, 2001; Stanley et al, 2006). Approximately one third of patients with this disease are in the first week of life. In this subgroup of patients, the onset is dramatic and the disease is catastrophic, being characterized by vomiting, lethargy, coma, seizures, hepatomegaly, hypoglycemia, little or no ketones in urine, and hyperammonemia. Most of the complications are related to severe effects of hypoglycemia on the CNS in addition to acidemia, which may be profound. The characteristic urine metabolites detected by GC-MS analysis are 3-hydroxy-3-methylglutaric acid, 3-methylglutaconic acid, and 3-hydroxyisovaleric acid. Only small, inappropriate amounts of acetoacetic acid and 3-hydroxybutyric acid may be detected. Lactate values may be elevated during the acute metabolic decompensation. Inherited as an autosomal recessive trait, the HMG-CoA lyase deficiency can be demonstrated in cultured skin fibroblasts or by mutation analysis. Treatment of the acute episode consists of administration of intravenous glucose and alkali to correct metabolic acidosis. Most long-term therapy consists of a high-carbohydrate diet. Some patients treated with protein-restricted diets, but the most important element in long-term care is the avoidance of fasting.

The last defect to be discussed in the area of disturbances in ketone body metabolism is the succinyl-CoA 3-ketoacid-CoA transferase deficiency (Mitchell and Fukao, 2008; Stanley et al, 2006). In this disease, the ketone bodies, acetoacetic acid, and 3-hydroxybutyric acid are synthesized adequately in the liver, but they cannot be metabolized in the extrahepatic tissues because of the failure of activation of acetoacetate to acetoacetyl CoA by the transferase enzyme. Conversion to a CoA derivative is required for hydrolysis to acetyl CoA for final metabolism in the Krebs citric acid cycle. This disorder is rare, and most of the affected patients in the newborn period do not survive. Such patients usually exhibit severe ketosis and lactic acidosis. The hallmark of the disease is persistent ketosis, even after correction of overt metabolic acidosis and the institution of frequent feedings with the avoidance of fasting. Plasma values of acetoacetate and 3-hydroxybutyrate are always mildly to moderately elevated, resulting in intermittent ketonuria. The most important aspect of therapy is the avoidance of fasting, during which acidosis and ketosis can be overwhelming. The gene that encodes this enzyme has been cloned, and several mutations have been detected.

PRIMARY LACTIC ACIDOSIS

The term *congenital lactic acidosis* (CLA) refers to a group of diseases in which impaired lactate metabolism is caused by a defect in the mitochondrial respiratory or electron transport chain (ETC), or the tricarboxylic acid (TCA; Krebs) cycle, in which there is a primary defect in pyruvate metabolism that secondarily leads to impaired lactate handling (see Figure 22-1) (De Meirleir et al, 2006; Munnich, 2006; Munnich et al, 2001; Robinson, 2001). However, there are a limited number of reports on inborn errors of the TCA cycle. Most of the information on CLA focuses on mitochondrial ETC, pyruvate dehydrogenase (PDH) complex, and pyruvate carboxylase (PC) defects, all of which have been reviewed (De Meirleir et al, 2006; Munnich, 2006; Munnich et al, 2001; Robinson, 2001) with more detailed information on conditions that must be treated more superficially in this chapter.

Some patients with CLA present have overwhelming lactic acidosis in the neonatal period. In others, lactate may be elevated only in CSF, a "cerebral" lactic acidosis syndrome and present more indolently. Depending on the nature of the enzyme deficiency, lactate, pyruvate, and alanine levels can be elevated in the blood. The ratio of blood lactate to pyruvate (L:P ratio) can be helpful in distinguishing the different types of inborn errors. For example, the L:P ratio is often normal (10 to 20) in PDH complex and modestly elevated in PC deficiencies, but can be greatly elevated in an ETC defect. Unlike most of the disorders previously considered in this chapter, these conditions are not detectable by newborn screening and become apparent only when a patient's symptoms are recognized.

Pyruvate Dehydrogenase Deficiency

Pyruvate Dehydrogenase Complex Deficiency

PDH is a complex of three primary enzymes— plus a phosphatase, a kinase, and at least one other element of less known function—that combine as a multimer with a very large molecular weight and a number of copies of each enzyme. The first enzymatic step is a decarboxylation reaction catalyzed by a heterodimeric system consisting of the E-1α subunit, encoded by a gene on the X-chromosome, and E-1β, which is autosomally encoded as are all the other subunits in this complex. Defects in all the known genes have been reported, but mutations in the X-linked E-1α outnumber all others by far and may represent as much as 25% of known causes in patients with CLA.

Severe PDH deficiency sometimes manifests in the neonatal period with profound lactic acidosis, elevated blood lactate and pyruvate, elevated plasma alanine, and congenital anomalies of the brain noted on MRI, including absent or underdeveloped corpus callosum, heterotopic migration deficits, and a somewhat typical dysmorphic appearance. Typically, the L:P ratio is normal and distinguishes it from disorders of the mitochondrial respiratory chain.

The patients are hypotonic and respirator dependent and have a poor prognosis. The diagnosis is rarely known immediately, and the standard intravenous support of high glucose exacerbates the metabolic acidosis and worsens the outlook for the patient. The diagnosis is inferred when all the clinical biochemical data are collated and can be confirmed by an enzymatic deficiency in lymphocytes or cultured skin fibroblasts or by mutation analysis of the E-1α gene in particular. The enzyme assay is difficult in the most experienced hands, and it is difficult to understand the high residual activity that is often recorded.

The majority of patients are more indolent on clinical presentation, with developmental delay that may resemble Leigh syndrome, and they may have a modest elevation of lactate, with pyruvate being the most telling biochemical marker of the disease. This group of patients often respond well biochemically to a high-fat and low-carbohydrate diet. Fat, as acetyl CoA, enters the energy pathway after the block, whereas glucose must traverse the PDH reaction to provide all but minimal energy generation.

Other defects of the PDH complex including two other subunits, the activating and deactivating enzymes, and a subunit X of unknown function are rare and usually result in chronic psychomotor retardation syndrome in late infancy and childhood. The E_3 subunit defect causes a unique syndrome, because the subunit is important in the PDH complex, the BCKAD complex, and the α-ketoglutarate dehydrogenase complex. Therefore these patients have multiple deficiencies involving the BCAA as in MSUD, as well as Krebs cycle metabolites that are indicative of a block in the TCA cycle. Most of the patients are later than the newborn period and have severe progressive neurodegenerative disease. The key laboratory findings are elevations of lactic acid in blood, BCAAs in plasma, and detection of α-ketoglutarate in urine by urine organic acid analysis. PDH phosphatase deficiency is a rare cause of congenital lactic acidosis. Other than the E_3 deficiency, other defects in PDH are responsive, at least biochemically to the high-fat, low-carbohydrate diet.

Pyruvate Carboxylase Deficiency

Pyruvate carboxylase is an enzyme that is involved in gluconeogenesis and that adds bicarbonate to pyruvate to form oxaloacetate, a compound also involved in replenishing intermediates of the tricarboxylic acid cycle. There are two main types of PC deficiency (De Meirleir et al, 2006; Robinson, 2001). Type A is characterized by lactic acidosis in the newborn period and delayed development. However, the disease is of a chronic nature. In type B, the catastrophic form of the disorder, the infant is acutely ill, usually in the first week of life, with encephalopathy, severe metabolic acidosis with lactic acidosis, and hyperammonemia (De Meirleir et al, 2006; Munnich et al, 2001; Robinson, 2001). The mortality rate in this form is high.

As discussed earlier, PC is a biotin-containing enzyme. Most of the patients with a type B form of PC deficiency have been of French or English origin. Unlike patients with a type A defect, in whom the blood L:P ratio is normal because both lactate and pyruvate are comparably elevated, patients with the type B defect often have an elevated L:P ratio. Because of the importance of the PC product oxaloacetate in providing adequate cellular levels of aspartate, citrulline metabolism in the urea cycle is defective, leading to elevations of plasma citrulline and plasma ammonium concentrations. Although PC is also an important enzyme in gluconeogenesis, hypoglycemia has not been commonly reported. The liver may be enlarged. There is no effective treatment for PC deficiency when it is associated with progressive neurodegeneration. The gene that encodes the PC subunits, of which four combine to make an active enzyme, has been cloned and sequenced. An expanding number of mutations have been identified and provide a basis for prenatal diagnosis. PC deficiency may be detected in cultured skin fibroblasts or in liver biopsy samples.

Phosphoenolpyruvate Carboxykinase Deficiency

Phosphoenolpyruvate carboxykinase enzyme also functions in gluconeogenesis, and there are two forms in liver, one in the cytosol and the other in the mitochondrial compartment. It is an exceedingly rare disorder. Patients do not usually come to attention until childhood with hypotonia, failure to thrive, hepatomegaly, lactic acidosis, and hypoglycemia. Although there is no adequate experience in identifying the optimal therapy for these patients, it is reasonable to assume that frequent feedings and avoidance of fasting are important in avoiding severe metabolic imbalance.

Mitochondrial Respiratory Chain or Electron Transport Chain Defects

Oxidative phosphorylation is the key process performed by the mitochondria of cells. Any inborn error of metabolism that involves the tightly coupled and regulated process of mitochondrial energy metabolism may have profound effects on health and disease, because oxidative phosphorylation is the process by which we convert nutrients into energy. The various derivatives of the nutrients, such as pyruvate and fatty acids, are converted to CO_2 in mitochondria. The energy derived from such controlled chemical combustion is harnessed by allowing the reducing equivalents (in the form of NADH or the reduced form of flavin adenine dinucleotide [$FADH_2$], which are derived from such metabolism) to combine with oxygen to form water, and in the process the synthesis of ATP is coupled to the orderly flow of electrons down the respiratory chain components.

The important components in the mitochondrial respiratory chain are complex 1 (NADH dehydrogenase), complex 2 (ETF dehydrogenase), complex 3 (cytochromes *b*, c_1) and the terminal complex in this chain, and complex 4, which is cytochrome *c* oxidase (COX) (Shoffner, 1995). In addition, there is a complex 5, or ATP synthetase, and an adenine nucleotide translocase, which permits transport of adenosine diphosphate into and ATP out of the mitochondria. Complex 2 is involved primarily in fatty acid oxidation and oxidation of succinate derived from the Krebs cycle, because the reducing equivalents extracted from fatty acids, glutaric acid, and succinate flow from ETF into complex 2. The polypeptides that compose these various complexes are derived from both the nuclear genes and the genes on mitochondrial DNA (mtDNA). Except for complex 2, mtDNA is important in production of the subunits of all the respiratory chain

complexes. CLA involving the ETC components has been associated with both nuclear and mtDNA mutations. In addition to the actual complex components, there are many more genes responsible for the assembly of various subunits into the functional complexes, all of which are encoded in nuclear DNA (nDNA). There are estimates that defects in any one of more than 500 genes can result in an ETC deficiency.

On the basis of molecular diagnostic testing, the oxidative phosphorylation diseases can be divided into the following four genetic groups (Shoffner, 1995):

- Group 1: nDNA mutations
- Group 2: mtDNA point mutations
- Group 3: mtDNA deletions and duplications
- Group 4: unidentified genetic defects

The relationship between phenotype and mtDNA mutations is not straightforward, probably because of the phenomenon of heteroplasmy. Mitochondria with their unique mtDNA are inherited solely from the mother. Random segregation of mitochondria having mtDNA mutations leads to heteroplasmy and, ultimately, a variable concentration of defective mitochondria within cells and among tissues (Wallace et al, 1988). Much of our understanding of the detailed molecular mechanisms that contribute to or produce the ETC gene disturbances concern the mtDNA mutations, although the application of molecular methodology and increasingly inexpensive mass sequencing is allowing more definition of the nDNA disorders that compose the majority of the ETC disease seen in newborn and infancy periods. With the exceptions of the neurogenic muscle weakness, ataxia, and retinitis pigmentosa (NARP caused predominantly by mutations at position 8993 of the mitochondrial genome), only a minority of the mtDNA defects actually are known to manifest in the newborn period (Wong, 2007). Other examples of syndromes caused by mtDNA mutations are the MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like—episodes position 3243), MERRF (myoclonic epilepsy with ragged-red—fiber position A8344G), Leber hereditary optic neuropathy (Wallace et al, 1988), and sporadic deletion–duplication syndromes such as Pearson syndrome (Di Donato, 2009). The diseases that affect young infants are benign infantile mitochondrial myopathy, cardiomyopathy, or both; lethal infantile mitochondrial disease; lethal infantile cardiomyopathy; subacute necrotizing encephalomyopathy (SNE) or Leigh disease; Pearson syndrome; Alpers' disease; and the most dramatic form, with presentation often in the first few days of life, during which an acid-base disturbance dominates the clinical picture (Carrozzo et al, 2007; Gibson et al, 2008). The hallmarks of mitochondrial disease are almost always multisystem involvement and unambiguous lactate acidemia or acidosis. Although some debate exists as to whether lactate elevation is present in all mitochondrial disorders that present in life, it is a virtual requirement for such a diagnosis in newborns and early infants.

The nuclear encoded mitochondrial DNA depletion syndromes, which may include fatal hepatopathy, are caused by mutations in the *SUCLG1*, *SUCLA2*, *MPV17*, *RRM2B*, *PEO1*, *TP*, *POLG1*, *DGUOK*, and *TK2* genes. The ribosomal translational defects (*EFG1* and *EFT*μ genes) are the relatively new groups of mitochondrial diseases (Di Donato, 2009; DiMauro and Schon, 2008). Both are part of the group I genetic disease types.

The diagnostic tools to unravel these disorders have proliferated recently. We assess lactate in the CSF after lumbar puncture, lactate (among other metabolites) in the brain by magnetic resonance spectroscopy (MRS) during an MRI, more readily obtained in a sick newborn than previously, and DNA technology that has become faster and less expensive and includes full sequencing of the mitochondrial genome. Older and still useful technologies such as muscle biopsy with histologic analysis by light and electron microscopy, mitochondrial complex assay on either fresh (preferred, but infrequently available) or flash-frozen tissue and skin fibroblast studies are still available. In fatal cases, a rapid autopsy and proper preservation of tissue specimens are essential. Finally, a newer and increasingly frequently diagnosed family of disorders includes mitochondrial depletion syndromes caused by a number of genetic defects in the mtDNA synthesis apparatus or the availability of nucleotides. A less frequent, newly recognized family of disorders are the coenzyme Q biosynthetic disorders, diagnosed reliably only by coenzyme Q_{10} levels in muscle, and not in plasma.

Although the subject of much debate, there is no credible evidence that mitochondrial disease is treatable, with the obvious exception of a small minority caused by coenzyme Q deficiency. Given the inability to identify these patients quickly, it is reasonable to treat acutely ill patients with presumed mitochondrial disorders with high doses of coenzyme Q. However, indiscriminant use of this cofactor is to be discouraged.

Benign Infantile Mitochondrial Myopathy, Cardiomyopathy, or Both

Benign infantile mitochondrial myopathy is associated with congenital hypotonia and weakness at birth, feeding difficulties, respiratory difficulties, and lactic acidosis. In this poorly understood, developmental-like disorder, only skeletal muscle appears to be affected, and histochemical analyses show a COX deficiency that returns to normal levels after 1 to 3 years of age. An nDNA mutation in a gene important in a fetal isoform of an ETC polypeptide specific for muscle oxidative phosphorylation was hypothesized to be the cause of this problem. A developmental switch from the defective fetal gene to the adult form may be responsible for the gradual improvement. It was thought to be the only example of a developmental defect in oxidative phosphorylation that is probably nuclear encoded and in which the treatment is only supportive during the early newborn period to prevent death from respiratory disease. However, a recent study suggests that the etiology may be a maternally inherited, homoplasmic m.14674T>C mt_tRNA^{Glu}: mutation (Horvath et al, 2009).

The form also associated with cardiomyopathy may be a variant of the benign isolated myopathy and involves striated muscle in both skeletal and cardiac muscle. It manifests in the newborn period with lactic acidosis and a cardiomyopathy that improves during the first year of life. The exact gene defect is unknown. More attention must be paid to these two disease entities, because with early optimal medical care, affected infants may have an excellent prognosis.

Lethal Infantile Mitochondrial Disease

Infants with lethal infantile mitochondrial disease are severely ill in the first few days or weeks of life or in the extended newborn period. They exhibit hypotonia,

CASE STUDY

A boy was born to nonconsanguinous, healthy parents after a full-term gestation. Biventricular hypertrophy with a predominant right-sided component had been observed on fetal ultrasonography at 24 weeks' gestation. He was delivered by cesarean section because of variable decelerations, and he emerged without meconium staining or passage. Respiratory distress developed shortly after birth. An echocardiogram showed concentric right ventricular hypertrophy with elevated right ventricular pressure (70 mm Hg). Initial laboratory studies showed acute metabolic acidosis (blood lactate >18 mmol/L; arterial pH, 6.91).

His weight was 2.36 kg (10th percentile), his length was 46 cm (5th percentile), and his head circumference was 31 cm (5th percentile). He had a right ventricular heave and an intermittent fourth heart sound. There was no liver enlargement. Muscle bulk was normal, and deep tendon reflexes were intact. Metabolic investigations showed persistent arterial lactic acidemia (range, 3 to 11 μmol/L) with increased pyruvate (range, 0.02 to 0.44 μmol/L). The L:P ratio ranged from 25 to 290. The activities of the respiratory chain complexes II, III, and IV were normal in cultured skin fibroblasts. A left quadriceps muscle biopsy was used for histochemical analysis and to prepare a 10% extract for respiratory chain studies. Histochemical analysis showed no ragged-red fibers with the modified Gomori trichrome stain, but a diffusely weak response to staining for cytochrome *c* oxidase (COX, ETC complex 4). Biochemical analysis showed markedly reduced COX activity, contrasting with normal activities of other complexes. Direct sequencing of the three COXs and all 22 transfer RNA genes of mtDNA, all the COX-assembly nuclear genes known to harbor pathogenic mutations (*SURF1, SC01, SC02, COX10,* and *COX15*), and the two other nuclear ancillary genes (*COX11* and *COX17*) showed no mutations. Southern blot analysis showed no deletions, but results were inconclusive regarding mtDNA depletion. However, sequencing of the two genes known to be associated with the myopathic (Saada et al, 2001) and the hepatocerebral (Mandel et al, 2001) mtDNA depletion syndromes (*TK2* and *dGK*) did not show any mutations.

A series of echocardiograms documented biventricular, hypertrophic, nonobstructive cardiomyopathy. The patient died on the seventh hospital day after a sudden episode of hemoglobin desaturation. An autopsy was performed 4 hours after death. The right ventricle was found to be thickened and enlarged, with relative sparing of the left side. The pulmonary vasculature of the lungs showed hypertrophy that extended to the most distal vessels. Routine microscopic findings in skeletal muscle were normal, and the CNS was without microscopic or macroscopic abnormalities.

This baby had a fatal syndrome defined clinically by prenatal cardiomyopathy and severe pulmonary hypertension in the newborn period. The syndrome was caused by isolated ETC complex 4 deficiency. The pathophysiology centered on the heart and lungs. How much disease was caused by the involvement of other organs remains unclear. This case is an example of a mitochondrial metabolic disorder, but without a specific molecular genetic cause. A more extensive evaluation by current methods might or might not have revealed a diagnosis.

muscle weakness, failure to thrive, and severe lactic acidosis. Death often occurs by 6 months of age and almost always is associated with overwhelming lactic acidosis. Skeletal muscle shows lipid and glycogen accumulation and abnormally shaped mitochondria on electron microscopic examination. Hepatic dysfunction may be a prominent finding in these patients. Generalized proximal renal tubular dysfunction may occur, leading to the renal Fanconi syndrome. The ETC defects reported in these patients include defects in complexes 1, 3, and 4. Original reports concerned infants with a phenotype resembling severe Werdnig-Hoffman disease with COX deficiency and renal Fanconi syndrome.

Lethal Infantile Cardiomyopathy

Defects of the mitochondrial respiratory chain have varied neonatal presentations and are commonly caused by isolated COX deficiency (Shoffner, 1995). Clinical features of COX deficiency reflect involvement of one or more tissues and include encephalopathy, myopathy, cardiomyopathy, liver disease, and nephropathy (Munnich et al, 2001). The heterogeneous clinical features are due, in part, to the dual genetic control of COX. The three catalytic subunits—COX I, COX II, COX III—are encoded by mtDNA, whereas the remaining subunits (COX IV to COX VIII) are encoded by nDNA. In addition, the proper assembly of COX requires several nDNA-encoded proteins. The various syndromes caused by COX deficiency are only partially understood at the genetic level. Most infants with isolated complex IV deficiency are likely to have nDNA gene defects in COX assembly genes, including *SURF1*, *SCO2*, *COX15*, *COX10*, *SC01*, and *LRPPRC* (Di Mauro and Schon, 2008).

Subacute Necrotizing Encephalomyelopathy or Leigh Disease

Probably because of a failure to recognize the clinical signs, infants with SNE or Leigh disease usually come to clinical attention after the newborn period. This disease is characterized as a progressive neurodegenerative disorder with severe hypotonia, seizures, extrapyramidal movement disorders, optic atrophy, and defects in automatic ventilation or respiratory control (Finsterer, 2008; Leigh, 1951). It is clear that there are many causes of SNE. As discussed earlier, PDH complex deficiency (PDHE1 alpha-subunit and PDHX1) can lead to Leigh disease. Patients with defects in the ETC have also been reported to have findings compatible with SNE. The mtDNA mutation causing NARP is an example. Reported nuclear gene defects include ETC complex I (NDUFS1), complex II (SDHA), complex IV (SURF1, COX15), coenzyme Q_{10} biosynthetic defects, mitochondrial ribosomal translational defects, and SUCLA2. Many neuropathologists believe that the diagnosis of SNE depends on an analysis of CNS tissue at autopsy. However, MRI characteristically shows bilateral symmetrical lesions of the basal ganglia as occurs in other mitochondrial disorders.

There is no effective treatment for this disease, unless the cause is a specific inability to synthesize coenzyme Q_{10}. It is possible that most of the patients with Leigh disease have disturbances in nuclear-encoded genes. Although, as discussed later, the NARP lesion caused by a group 2 mtDNA mutation is one important cause in early infancy. Clearly, this is not one disease entity, because the specific neuropathologic findings for SNE have also been reported in a patient with Menkes' disease, in which there is a secondary ETC complex 4 deficiency, because copper is an important metal cofactor of COX.

The following clinical findings have been noted in infants with SNE: optic atrophy, ophthalmoplegia, nystagmus, respiratory abnormalities, ataxia, hypotonia, spasticity, seizures, developmental delay, psychomotor retardation, myopathy, and renal tubular dysfunction. Some patients may manifest hypertrophic cardiomyopathy, liver dysfunction, and microcephaly. The neuropathologic lesions include demyelination, gliosis, necrosis, relative neuronal sparing, and capillary proliferation in specific brain lesions.

There are lesions of the basal ganglia, which are bilaterally symmetrical, as well as of the brainstem, cerebellum, and the cerebral cortex to a lesser degree. Commonly, elevation in blood lactate is only slight to moderate, as well as intermittent, in this diverse group of patients. In some instances, lactate values may be elevated only in the CSF. The most commonly reported biochemical abnormalities are deficiencies in COX, complex 4 NADH dehydrogenase, or complex 1 and PDH. In a few rare patients, the abnormality in oxidative phosphorylation has been reported to be secondary to NARP mutation. This involves a T:C transition at base pair 8993 of the adenosine triphosphatase (ATPase) 6 gene, changing a leucine to a proline at position 156 in the ATPase 6 polypeptide. Investigators have speculated that defects such as those in COX and the NADH dehydrogenase, when associated with neuropathology of Leigh disease, are caused by nuclear gene mutations and not mtDNA gene defects such as the NARP point mutation in the ATPase 6 gene.

The diseases in group 3 (see earlier), exemplified by the Kearns-Sayre and chronic progressive external ophthalmoplegia syndromes, are genetic but not familial and are caused by mtDNA deletions or duplications that are spontaneous mutations. These disorders do not usually come to clinical attention in infancy. The only example of such a mutation manifesting in early infancy is the Pearson syndrome. This disorder is systemic and primarily affects the hematopoietic system and pancreas function. The characteristics are severe macrocytic anemia with varying degrees of neutropenia and thrombocytopenia. Bone marrow examination shows normal cellularity, but extensive vacuolization of erythroid and myeloid precursors, hemosiderosis, and ringed sideroblasts. This disease of the bone marrow can lead to death in infancy. However, patients who are able to recover or who benefit from aggressive therapy may demonstrate other signs of this systemic disorder in late infancy or childhood, such as poor growth, pancreas dysfunction, mitochondrial myopathy, lactic acidosis, and progressive neurologic damage.

Barth Syndrome

Barth syndrome is an X-linked disorder associated with cardiomyopathy, skeletal muscle disease, and neutropenia (Yen et al, 2008). Skeletal muscle shows abnormal mitochondrial morphology. Important laboratory findings include decreased plasma-free carnitine, increased urinary excretion of 3-methylglutaconate on GC-MS analysis of urine organic acids, and decreased levels of serum cholesterol in early infancy. Positional cloning identified a gene for this disorder on Xq28 that encodes for a phospholipid remodeling enzyme, cardiolipin acyl transferase. Several mutations have been identified. It has been hypothesized that the organic acid 3-methylglutaconate accumulates because of defective mitochondrial transport. Patients must be supported from birth to early infancy. It is possible that if severe cholesterol deficiency can be avoided, affected infants may survive and may be relatively free of cardiomyopathy during childhood. Of diagnostic importance, not all patients with 3-methylglutaconic aciduria have Barth syndrome. A few have isolated leucine-dependent 3-methylglutaconyl-CoA hydratase deficiency or Costeff syndrome, but most have ill-defined mitochondropathies.

Unidentified Genetic Defects

A number of diseases are believed to be caused by mitochondrial respiratory chain problems, but the specific mutations remain unknown. These disorders constitute the group 4 mutations, or the disorders of unknown inheritance (Shoffner, 1995). Alpers disease was once one such example. It has also been called *progressive infantile poliodystrophy*. Infants and children with this progressive disease experience progressive cerebral cortical damage, sometimes also involving the cerebellum, basal ganglia, and brainstem; in some, liver disease may progress to cirrhosis. The neuropathologic lesions consist of spongiform or microcystic cerebral degeneration, gliosis, necrosis, and capillary proliferation Seizures are prominent, including myoclonus. Laboratory abnormalities include abnormal NADH oxidation or complex 1 defects, impaired pyruvate handling, PDH complex deficiency, TCA cycle malfunction, and decreased mitochondrial cytochrome $a + a_3$ content. This disorder is caused by mutations in one or more gene defects associated with mtDNA depletion, such as the autosomal recessive disease caused by mutations in the DNA polymerase gamma 1 (*POLG1*) gene and can usually be defined by mutation analysis.

Early Lethal Lactic Acidosis

In an unknown fraction of patients with primary disturbances in mitochondrial oxidative phosphorylation or ETC defects, massive lactic acidosis develops within 24 to 72 hours after birth. Commonly the condition is untreatable, because it is relentless and unresponsive to alkali therapy. Dialysis is a remedy but not a cure. Often, affected infants have no obvious organ damage early in the course or evidence of malformations; this is also true for infants with the PDH complex deficiency, which is probably a more common cause of overwhelming acidosis in the first week of life. In addition, acidemia per se can easily cause the coma or impaired cardiac contractility that may be encountered. Some infants have survived with aggressive therapy.

The care of babies with these different forms of severe lactic acidosis almost always brings an ethical dilemma to the forefront for physicians and nurses of the neonatal intensive care unit as well as for the babies' families. To further complicate the issues, enzymatic and molecular analyses usually are not immediately available. The disease in most patients probably remains idiopathic, and no DNA mutation, nuclear or mitochondrial, will be identified without extensive, expensive, and extremely inconvenient and Herculean efforts. A rigid approach to care is impractical and unwise. Decisions regarding management must be individualized, because the mitochondrial dysfunction and resultant pathophysiology can vary among infants.

CHAPTER 23

Lysosomal Storage, Peroxisomal, and Glycosylation Disorders and Smith-Lemli-Opitz Syndrome in the Neonate

Janet A. Thomas, Carol L. Greene, and Gerard T. Berry

Lysosomal storage diseases (LSDs), peroxisomal disorders, congenital disorders of glycosylation (CDGs), and Smith-Lemli-Opitz (SLO) syndrome are single-gene disorders, most of which demonstrate autosomal recessive inheritance. The combined incidence of LSDs has been reported to be 1 in 1500 to 8000 live births in the United States, Europe, and Australia (Fletcher, 2006; Meikle et al, 2006; Staretz-Chacham et al, 2009; Stone and Sidransky, 1999; Wenger et al, 2003; Winchester et al, 2000). The incidence of peroxisomal disorders is estimated to be more than 1 in 20,000. The most current estimate for SLO syndrome is 1 in 20,000, and a similar frequency of 1 in 20,000 is estimated for the congenital disorders of glycosylation.

These four categories of metabolic diseases involve molecules important in cell membranes and share overlapping clinical presentations. Clinical presentations are heterogeneous, with a broad range of age at presentation and severity of symptoms. All are chronic and progressive. Age of onset varies from prenatal to adulthood, and severity can range from severe disability and early death to nearly normal lifestyle and life span. For each condition, interfamilial variability is greater than intrafamilial variability. The genetic and clinical characteristics of conditions in these categories that can manifest in the neonatal period (except Pompe disease, which is addressed in Chapter 22) are also summarized in Tables 23-1 to 23-3.

Important presentations that should lead the neonatologist to consider these disorders in the differential diagnosis are as follows:

1. In utero infection—hepatosplenomegaly and hepatopathy, possibly with extramedullary hematopoiesis
2. Nonimmune hydrops fetalis, ichthyotic or collodion skin, or both
3. Neurologic only—early and often difficult to control seizures, hypertonia or hypotonia, with or without altered head size and with or without eye findings
4. Coarse facial features with bone changes, dysostosis multiplex, or osteoporosis
5. Dysmorphic facial features with or without major malformations
6. Rarely, known family history or positive prenatal diagnosis

Only for the last three presentations are these conditions likely to be considered early in the differential diagnosis. Most babies with these conditions are born to healthy, nonconsanguineous couples with normal family histories, and these disorders are usually considered late, if at all, as in Case Study 1.

LYSOSOMAL STORAGE DISORDERS

Lysosomes are single-membrane–bound intracellular organelles that contain enzymes called *hydrolases*. These lysosomal enzymes are responsible for splitting large molecules into simple, low-molecular-weight compounds, which can be recycled. The materials digested by lysosomes and derived from endocytosis and phagocytosis, are separated from other intracellular materials by the process of autophagy, which is the main mechanism whereby endogenous molecules are delivered to lysosomes. The common element of all compounds digested by lysosomal enzymes is that they contain a carbohydrate portion attached to a protein or lipid. These glycoconjugates include glycoproteins, glycosaminoglycans, and glycolipids.

Glycolipids are large molecules with carbohydrates attached to a lipid moiety. Sphingolipids, globosides, gangliosides, cerebrosides, and lipid sulfates all are glycolipids. The different classes of glycolipids are distinguished from one another primarily by different polar groups at C1. Sphingolipids are complex membrane lipids composed of one molecule each of the amino alcohol sphingosine, a long-chain fatty acid, and various polar head groups attached by a β-glycosidic linkage. Sphingolipids occur in the blood and nearly all tissues of the body, the highest concentration being found in white matter of the central nervous system (CNS). In addition, various sphingolipids are components of the plasma membrane of practically all cells. The core structure of natural sphingolipids is ceramide, a long-chain fatty acid amide derivative of sphingosine. Free ceramide, an intermediate in the biosynthesis and catabolism of glycosphingolipids and sphingomyelin, composes 16% to 20% of normal lipid content of stratum corneum of the skin. Sphingomyelin, a ceramide phosphocholine, is one of the principal structural lipids of membranes of nervous tissue.

Cerebrosides are a group of ceramide monohexosides with a single sugar, either glucose or galactose, and an additional sulfate group on galactose. The two most common cerebrosides are galactocerebroside and glucocerebroside. The largest concentration of galactocerebroside is found in the brain. Glucocerebroside is an intermediate in the synthesis and degradation of more complex glycosphingolipids.

Gangliosides, the most complex class of glycolipids, contain several sugar units and one or more sialic acid residues. Gangliosides are normal components of cell membranes and are found in high concentrations in ganglion cells of the CNS, particularly in nerve endings and dendrites. G_{MI} is the major ganglioside in brain of vertebrates.

CASE STUDY 1

C.J. was a 2200-g girl, born to a 24-year-old mother (third pregnancy, second viable child) after a 32-week gestation, by cesarean section performed for fetal distress. Pregnancy was complicated by the finding on ultrasonography of fetal hydrops and ascites and possible hepatosplenomegaly at 24 weeks' gestation. Fetal blood sampling showed a hematocrit of 31% and elevations of γ-glutamyl-transferase and aspartate transaminase values. Results of viral studies were negative, and chromosomes were normal. At delivery, the infant was limp and blue with a heart rate of 60 beats/min. Physical examination and chest radiograph showed marked abdominal distention, hepatosplenomegaly, multiple petechiae and bruises, a bell-shaped thorax, generalized hypotonia, talipes equinovarus, contractures at the knees, a large heart, and hazy lung fields with low volumes. Disseminated intravascular coagulopathy and evidence of liver disease developed rapidly, with elevated aspartate transaminase, γ-glutamyl-transferase, and increasing hyperbilirubinemia. The patient's condition was maintained with a ventilator and treatment with antibiotics for possible sepsis.

Results of evaluations for bacterial and viral agents were negative. Metabolic studies, including ammonia, lactate, very long chain fatty acids (VLCFAs), and urine amino and organic acids, yielded unremarkable measurements. The white blood cells were noted to have marked toxic granularity consistent with overwhelming bacterial sepsis or metabolic storage disease.

The patient experienced continued cardiorespiratory deterioration, had bilateral pneumothoraces and pneumopericardium, and died on the third day of life. Consent for autopsy was obtained from the family. A standard autopsy was performed and showed the presence of large, membrane-bound vacuoles within hepatocytes, endothelial cells, pericytes, and bone marrow stromal cells, which are typical of a metabolic storage disorder. Similar cells were also found within the placenta. There was no evidence of an infectious cause. Unfortunately, because a lysosomal storage disorder was not considered as a possible cause at the time of death, no frozen tissue or cultured fibroblasts were available to pursue the diagnosis. As a result of efforts by a research laboratory and the recurrence of disease in the couple's subsequent pregnancy, a diagnosis of β-glucuronidase deficiency, or mucopolysaccharidosis type VII, was confirmed.

CASE STUDY 2

M.E. was born by normal spontaneous vaginal delivery, at full term according to dates based on early ultrasonography, with weight of 2.2 kg, length of 45 cm, and head circumference of 31.5 cm. On the basis of physical examination, gestational age was assessed as 36 weeks. A heart murmur was noted, and investigation showed the presence of a small ventricular septal defect with no hemodynamic significance. Submucous cleft palate was noted. Examination for dysmorphic features showed simple, posteriorly rotated ears, mild epicanthic folds, micrognathia, and unilateral simian crease. Tone was moderately decreased. Irritability and severe feeding problems were noted, and gavage feeding was required; growth was poor despite adequate calories. The results of a karyotype analysis were normal, and the results of studies for velocardiofacial syndrome were negative. Vomiting developed, and further evaluation showed no acidosis, hypoglycemia, or hyperammonemia. Liver-associated values and cholesterol level were normal, as were results of studies of amino acids, organic acids, and acylcarnitine profile. Vomiting became more severe and did not respond to elemental formula, and pyloric stenosis was detected. Feeding problems persisted after successful surgical correction. Delivery of more than 140 kcal/kg by gavage was poorly tolerated, but resulted in weight gain; however, length and head growth remained poor.

SLO syndrome was suggested despite the normal cholesterol value obtained on analysis in the hospital laboratory. Studies performed in a specialized laboratory showed the 7- and 8-dehydrocholesterol values to be elevated and the cholesterol value decreased. Cholesterol supplementation led to some improvement in behavior and feeding. A decrease to 110 kcal/kg/day was tolerated without worsening of growth, and weight for height gradually returned to normal. A review of records confirmed that the pregnancy had been accurately dated by ultrasonography at 10 weeks' gestation, confirming that M.E. was small for gestational age and microcephalic at birth, with subsequent growth typical for SLO syndrome. The incorrect assessment of gestational age as 36 weeks on examination was found to result from a failure to appreciate the effect of hypotonia on the findings for gestational age. The family was counseled about autosomal recessive inheritance, including the availability of prenatal diagnosis.

CASE STUDY 3

H.K. was born at term to healthy parents by cesarean section performed for breech presentation after an otherwise uncomplicated pregnancy. Hypotonia and dysmorphic features were noted in the delivery room, including inner epicanthic folds, flat occiput, large fontanels, shallow orbital ridges, low nasal bridge, micrognathia, redundant skin folds at the neck, and unilateral simian crease. Brushfield spots were present. Investigation of a heart murmur revealed patent ductus arteriosus and a small atrial septal defect. There was mild hepatomegaly but normal liver function, no acidosis, and no hypoglycemia. Suck was poor, and gavage feeding was required.

Karyotype was normal and there was no evidence of trisomy 21 in blood in 50 interphase cells examined. The option of skin biopsy to search further for evidence of mosaicism for trisomy 21 was considered. Thyroid function values were normal. Urine amino and organic acid values were normal, as was the acylcarnitine profile. Plasma VLCFA analysis showed elevation consistent with a diagnosis of Zellweger syndrome, along with a typical increase in pipecolic acid value and impaired capacity for fibroblast synthesis of plasmalogens. The baby died at 3 months of age, and autopsy showed polymicrogyria and small hepatic and renal cysts. The family was counseled about autosomal recessive inheritance, including the availability of prenatal diagnosis.

Gangliosides function as receptors for toxic agents, hormones, and certain viruses, are involved in cell differentiation, and they can also have a role in cell-cell interaction by providing specific recognition determinants on the surface of cells.

Ceramide oligosaccharides (i.e., globosides) are a family of cerebrosides that contain two or more sugar residues, usually galactose, glucose, or *N*-acetylgalactosamine. Glycosaminoglycans and oligosaccharides are essential constituents of connective tissue, parenchymal organs, cartilage, and the nervous system.

Glycosaminoglycans, also called *mucopolysaccharides*, are complex heterosaccharides consisting of long sugar chains rich in sulfate groups. The polymeric chains are bound to specific proteins (core proteins). Glycoproteins contain oligosaccharide chains (long sugar molecules) attached covalently to a peptide core. Glycosylation occurs in the endoplasmic reticulum and Golgi apparatus. Most glycoproteins are secreted from cells and include transport proteins, glycoprotein hormones, complement factors, enzymes, and enzyme inhibitors. There is extensive diversity in the composition and structure of oligosaccharides.

CASE STUDY 4

M.J. had hypotonia at birth after an uncomplicated pregnancy. Minor dysmorphic features were noted, including high nasal bridge, large ears, and inverted nipples. Feeding difficulties were significant, and growth was poor. Findings on head ultrasonography were unremarkable, as were those of head magnetic resonance imaging, although the radiologist questioned whether the cerebellum might be slightly small. Results of a karyotype analysis were normal. Hypothyroidism, discovered on newborn screening, was promptly treated and closely monitored. There was no acidosis or hypoglycemia, and liver enzyme values were normal; results of amino and organic acid analyses and acylcarnitine profile were all normal.

The baby was discharged on a diet providing 130 kcal/kg/day. On follow-up, growth remained poor, and development was severely delayed. At 6 months of age, she was admitted to the hospital for an episode of acutely altered mental status and low blood pressure. Mild acidosis, borderline elevations of lactate and ammonia, and significant elevation of liver enzymes all resolved over the course of the hospital stay. Cardiac ultrasonography showed mild ventricular dysfunction, which also resolved. Amino and organic acid values were normal, as was the acylcarnitine profile. Urine oligosaccharide levels showed an unusual pattern, and urine mucopolysaccharide values were normal.

At 2 years of age, developmental delay remained marked, and hypotonia persisted with reflexes absent. The creatinine phosphokinase level was normal, but liver function values were again abnormal. Because mitochondrial disease was suspected, the patient was scheduled for liver biopsy, but clotting values were abnormal. A congenital disorder of glycosylation was suspected, and a transferrin assay confirmed the diagnosis. A review of neonatal records revealed a comment from a neurology consultant about the unusual distribution of fat on the buttocks and thighs of M.J. as a neonate. The family was counseled about autosomal recessive inheritance, including availability of prenatal diagnosis.

The degradation of glycolipids, glycosaminoglycans, and glycoproteins takes place especially within lysosomes of phagocytic cells, related to histiocytes and macrophages, in any tissue or organ. A series of hydrolytic enzymes cleaves specific bonds, resulting in sequential, stepwise removal of constituents such as sugars and sulfate, and degrading complex glycoconjugates to the level of their basic building blocks. Lysosomal storage diseases most commonly result when an inherited defect causes significantly decreased activity in one of these hydrolases. Other causes are failure of transport of an enzyme, substrate, or product. Whatever the specific cause, incompletely metabolized molecules accumulate, especially within the tissue responsible for catabolism of the glycoconjugate. Additional excess storage material may be excreted in urine. The mechanisms of cellular dysfunction and damage in the majority of LSDs remain unknown. Various hypotheses have been offered, such as a pivotal disturbance in the normal process of autophagy (Ballabio and Gieselmann, 2009; Kiselyov et al, 2007). In this pathophysiologic construct, endoplasmic reticulum membrane engulfment of cellular components, such as mitochondrial derivatives targeted for destruction, is perturbed. As a consequence, deleterious pathways become activated, leading to unwanted ubiquitination of targeted molecules and apoptosis.

Lysosomal storage diseases are classified according to the stored compound. Clinical phenotype depends partially on the type and amount of storage substance. There are more than 50 different LSDs and a significant fraction, approximately 20 LSDs, may have manifestations in the newborn infant (Staretz-Chocham et al, 2009). The disorders selected for discussion in this chapter are all known to manifest in the neonatal period.

CLINICAL PRESENTATIONS

Table 23-1 summarizes the clinical characteristics of the neonatal presentations of lysosomal storage disorders.

Niemann-Pick A Disease (Acute, Sphingomyelinase Deficient)

Etiology

Niemann-Pick A disease is caused by a deficiency of sphingomyelinase. Sphingomyelinase catalyzes the breakdown of sphingomyelin to ceramide and phosphocholine, and its deficiency results in sphingomyelin storage within lysosomes. Cholesterol is also stored, suggesting that its metabolism is tied to that of sphingomyelin. Sphingomyelin normally composes 5% to 20% of phospholipid in liver, spleen, and brain, but in these disorders it can compose up to 70% of phospholipids. Patients with Niemann-Pick A disease usually have enzyme activity less than 5% of normal.

Clinical Features

Clinical features of this disorder may appear in utero or up to 1 year of age. Affected infants usually have massive hepatosplenomegaly (hepatomegaly greater than splenomegaly), constipation, feeding difficulties, and vomiting with consequent failure to thrive. Patients eventually appear strikingly emaciated with a protuberant abdomen and thin extremities. Neurologic disease is evident by 6 months of age, with hypotonia, decrease or absence of deep tendon reflexes, and weakness. Loss of motor skills, spasticity, rigidity, and loss of vision and hearing occur later. Seizures are rare. A retinal cherry-red spot is present in about half of cases, and the electroretinographic findings are abnormal. Respiratory infections are common. The skin may have an ochre or brownish yellow color, and xanthomas have been observed. Radiographic findings consist of widening of medullary cavities, cortical thinning of long bones, and osteoporosis. In the brain and spinal cord, neuronal storage is widespread, leading to cytoplasmic swelling together with atrophy of cerebellum. Bone marrow and tissue biopsy samples may show foam cells or sea-blue histiocytes, which represent lipid-laden cells of the monocyte-macrophage system. Similarly, vacuolated lymphocytes or monocytes may be present in peripheral blood. Tissue cholesterol levels may be threefold to tenfold of normal, and patients may have a microcytic anemia and thrombocytopenia. Death occurs by 2 to 3 years of age.

Niemann-Pick C Disease

Etiology

Niemann-Pick C disease is caused by an error in the intracellular transport of exogenous low-density lipoprotein (LDL)–derived cholesterol, which leads to impaired esterification of cholesterol and trapping of unesterified cholesterol in lysosomes. The incidence may be higher than

TABLE 23-1 Lysosomal Storage Disorders in the Newborn Period: Genetic and Clinical Characteristics of Neonatal Presentation

Disorder	Onset	Facies	Neurologic Findings	Distinctive Features	Eye Findings	Cardiovascular Findings	Dysostosis Multiplex	Hepatomegaly/ Splenomegaly	Defect	Gene Location Molecular Findings	Ethnic Predilection
Niemann-Pick A disease	Early infancy	Frontal bossing	Difficulty feeding, apathy, deafness, blindness, hypotonia	Brownish-yellow skin, xanthomas	Cherry-red spot (50%)	–	–	++/+	Sphingomyelinase deficiency	*ASM* gene at 11p15.1-p15.4 3 of 18 mutations account for approximately 92% of mutant alleles in the Ashkenazi population	1:40,000 in Ashkenazi Jews with carrier frequency of 1:60
Niemann-Pick C disease	Birth to 3 mo	Normal	Developmental delay, vertical gaze paralysis, hypotonia, later spasticity	–	–	–	–	+/++	Abnormal cholesterol esterification	*NPC1* gene at 18q11 accounts for >95% of cases; *HE1* gene mutations may account for remaining cases	Increased in French Canadians of Nova Scotia and Spanish Americans in the southwest United States
Gaucher disease type 2	In utero to 6 mo	Normal	Poor suck and swallow, weak cry, squint, trismus, strabismus, opsoclonus, hypertonic, later flaccidity	Congenital ichthyosis, collodion skin	–	–	–	+/++	Glucocerebrosidase deficiency	1q21; large number of mutations known; five mutations account for approximately 97% of mutant alleles in the Ashkenazi population, but approximately 75% in the non-Jewish population	Panethnic
Krabbe disease	3-6 mo	Normal	Irritability, tonic spasms with light or noise stimulation, seizures, hypertonia, later flaccidity	Increased CSF protein	Optic atrophy	–	–	–/–	Galactocerbrosidase deficiency	14q 24.3-q32.1; >60 mutations with some common mutations in specific populations	Increased in Scandinavian countries and in a large Druze kindred in Israel
G_{M1} gangliosidosis	Birth	Coarse	Poor suck, weak cry, lethargy, exaggerated startle, blindness, hypotonia, later spasticity	Gingival hypertrophy, edema, rashes	Cherry-red spot (50%)	–	+	+/+	β-Galactosidase deficiency	3 pter-3p21; heterogeneous mutations; common mutations in specific populations	Panethnic
Farber disease type I	2 wk to 4 mo	Normal	Progressive psychomotor impairment, seizures, decreased reflexes, hypotonia	Joint swelling with nodules, hoarseness, lung disease, contractures, fever, granulomas, dysphagia, vomiting, increased CSF protein	Grayish opacification surrounding retina in some patients, subtle cherry-red spot	Occasional	–	Hepatomegaly in 50%, splenomegaly less common	Lysosomal acid ceramidase	8p21.3-22; 9 disease-causing mutations identified	Panethnic

Farber disease types II and III	Birth to 9 mo (≤20 mo)	Normal		Joint swelling with nodules, hoarseness	Normal macula, corneal opacities	–	–	HSM less common than in type I		8p21.3-p22	Panethnic
Farber disease type IV (neonatal)	Birth	Normal	Nodules not consistent findings	Corneal opacities (1/3)	–	–		++/++		Unknown	Panethnic
Congenital sialidosis	In utero to birth	Coarse, edema	Mental retardation, hypotonia	Neonatal ascites, inguinal hernias, renal disease	Corneal clouding	–	+	+/+	Neuraminidase deficiency	*NEU 1* gene (sialidase) at 6p21	Panethnic
Galactosialidosis	In utero to birth	Coarse	Mental retardation, occasional deafness, hypotonia	Ascites, edema, inguinal hernias, renal disease, telangiectasias	Cherry-red spot, corneal clouding	Cardiomegaly progressing to failure	+	+/+	Absence of a protective protein that safeguards neuraminidase and beta-galactosidase from premature degradation	20q13.1	Panethnic
Wolman disease	First weeks of life	Normal	Mental deterioration	Vomiting, diarrhea, steatorrhea, abdominal distention, failure to thrive, anemia, adrenal calcifications	–	–	–	+/+	Lysosomal acid lipase deficiency	10q23.2-q23.3; variety of mutations identified	Increased in Iranian Jews and in non-Jewish and Arab populations of Galilee
Infantile sialic acid storage disease	In utero to birth	Coarse, dysmorphic	Mental retardation, hypotonia	Ascites, anemia, diarrhea, failure to thrive	–	Congestive heart failure	+	+/+	Defective transport of sialic acid out of the lysosome	*SLC17A5* gene at 6q	Panethnic
I-cell disease	In utero to birth	Coarse	Mental retardation, deafness	Gingival hyperplasia, restricted joint mobility, hernias	Corneal clouding	Valvular disease, congestive heart failure, cor pulmonale	++	+++/+++	Lysosomal enzymes lack mannose-6-PO_4 recognition marker and fail to enter the lysosome (phosphotransferase deficiency, 3-subunit complex [$\alpha_2\ \beta_2\ \gamma_2$])	Enzyme encoded by two genes; α and β subunits encoded by gene at 12p; γ subunit encoded by gene at 16p	Panethnic
Mucolipidosis type IV	Birth to 3 mo	Normal	Mental retardation, hypotonia	—	Severe corneal clouding, retinal degeneration, blindness	–	–	–/–	Unknown; some patients with partial deficiency of ganglioside sialidase	*MCOLN1* gene at 19p13.2-13.3 encoding mucolipin; two founder mutations accounting for 95% of mutant alleles in Ashkenazi population	Increased in Ashkenazi Jews
Mucopolysaccharidosis type VII	In utero to childhood	Variable coarseness	Mild to severe mental retardation	Hernias	Variable corneal clouding	Variable	++	Variable	β-Glucuronidase deficiency	*GUSB* gene at 7q21.2-q22; heterogeneous mutations	Panethnic

–, Not seen; +, typically present, usually not severe; ++, usually present, and moderately severe; +++, always present, usually severe; *CSF*, cerebrospinal fluid; *HSM*, hepatosplenomegaly.

1 in 150,000 births (Wraith et al, 2009). Cell lines from patients can be divided into two complementation groups, NPC1 and NPC2, corresponding to different genes (Millat et al, 2001). In each group, the primary defect is abnormal cholesterol esterification, but the enzyme responsible for cholesterol esterification—acetyl coenzyme A (CoA) acetyltransferase (ACAT)—is not deficient. The storage of sphingomyelin is secondary. It has been suggested that the defect is in transport of cholesterol out of the lysosome, making cholesterol unavailable to ACAT (Natowicz et al, 1995). Sphingomyelinase activity appears normal or elevated in most tissues, but is partially deficient (60% to 70%) in fibroblasts from most patients with this disorder. Storage of sphingomyelin in tissues is much less than in Niemann-Pick A or B disease and is accompanied by additional storage of unesterified cholesterol, phospholipids, and glycolipids in the liver and spleen. Only glycolipids are increased in the brain.

Clinical Features

The age of onset, clinical features, and natural history of Niemann-Pick C disease are highly variable. Onset can occur from birth to 18 years of age. Fifty percent of children with onset in the neonatal period have conjugated hyperbilirubinemia, which usually resolves spontaneously but is followed by neurologic symptoms later in childhood. In the severe infantile form, hepatosplenomegaly is common, accompanied by hypotonia and delayed motor development. Further mental regression is usually evident by the age of 1 to 1.5 years, in association with behavior problems, vertical supranuclear ophthalmoplegia, progressive ataxia, dystonia, spasticity, dementia, drooling, dysphagia, and dysarthria. Seizures are rare. Foam cells and sea-blue histiocytes may be found in many tissues. Neuronal storage with cytoplasmic ballooning, inclusions, meganeurites, and axonal spheroids are also seen. Death may occur in infancy or as late as the third decade of life. Niemann-Pick C disease can also manifest as fatal neonatal liver disease, often misdiagnosed as fetal hepatitis. Patients with mutations in the *NPC2* gene (*HE1*) may have remarkable features consisting of pronounced pulmonary involvement leading to early death caused by respiratory failure (Millat et al, 2001).

Gaucher Disease Type 2 (Acute Neuropathic)

Etiology

Three types of Gaucher disease have been defined. Type 1, the nonneuropathic form, is the most common and is distinguished from types 2 and 3 by the lack of CNS involvement. Type 1 disease most commonly manifests in early childhood, but may do so in adulthood. Type 2 disease, the acute neuropathic form, is characterized by infantile onset of severe CNS involvement. Type 3 disease, the subacute neuropathic form, is also late in onset with slow neurologic progression. Almost all types of Gaucher disease are caused by a deficiency of lysosomal glucocerebrosidase and result in storage of glucocerebroside in visceral organs; the brain is affected in types 2 and 3. Although there is significant variability in clinical presentation among individuals with the same mutations, there is a clear correlation between certain mutations and clinical symptoms involving the CNS (Beutler and Grabowski, 2001). The enzyme splits glucose from cerebroside, yielding ceramide and glucose. A few patients with Gaucher disease type 2 have a deficiency of saposin C, a cohydrolase required by glucocerebrosidase.

Clinical Features

Typically, the age of onset of Gaucher disease type 2 is approximately 3 months, consisting of hepatosplenomegaly (splenomegaly predominates) with subsequent neurologic deterioration. Hydrops fetalis, congenital ichthyosis, and collodion skin, however, are well-described presentations (Fujimoto et al, 1995; Ince et al, 1995; Lipson et al, 1991; Liu et al, 1988; Sherer et al, 1993; Sidransky et al, 1992). In a review of 18 cases of Gaucher disease manifesting in the newborn period, Sidransky et al (1992) found that eight of the patients had associated dermatologic findings and six patients had hydrops. The etiology of the association of such findings and Gaucher disease is unclear, although the enzyme deficiency appears to be directly responsible (Sidransky et al, 1992). Ceramides have been shown to be major components of intracellular bilayers in epidermal stratum corneum, and they have an important role in skin homeostasis (Fujimoto et al, 1995). Therefore Gaucher disease should be considered in the differential diagnosis for infants with hydrops fetalis and congenital ichthyosis. For the subset of patients in the prenatal period or at birth, death frequently occurs within hours to days, or at least within 2 to 3 months.

Krabbe Disease (Globoid Cell Leukodystrophy)

Etiology

The synonym for Krabbe disease, globoid cell leukodystrophy, is derived from the finding of large numbers of multinuclear macrophages in cerebral white matter that contain undigested galactocerebroside. Disease is caused by a deficiency of lysosomal galactocerebroside β-galactosidase, which normally degrades galactocerebroside to ceramide and galactose. Deficiency of the enzyme results in storage of galactocerebroside. Galactocerebroside is present almost exclusively in myelin sheaths. Accumulation of the toxic metabolite psychosine, also a substrate for the enzyme, has been postulated to lead to early destruction of oligodendroglia. Impaired catabolism of galactosylceramide is also important in pathogenesis of the disease.

Clinical Features

Age of onset ranges from the first weeks of life to adulthood. The typical age of onset of infantile Krabbe disease is between 3 and 6 months, but there are cases of early onset in which neurologic symptoms are evident within weeks after birth. Symptoms and signs are confined to the nervous system; no visceral involvement is present. The clinical course has been divided into three stages. In stage I, patients who appeared relatively normal after birth exhibit hyperirritability, vomiting, episodic fevers, hyperesthesia, tonic spasms with light or noise stimulation, stiffness, and seizures.

Peripheral neuropathy is present, but reflexes are increased. Stage II is marked by CNS deterioration and hypertonia that progresses to hypotonia and flaccidity. Deep tendon reflexes are eventually lost. Patients with stage III disease are decerebrate, deaf, and blind with hyperpyrexia, hypersalivation, and frequent seizures. Routine laboratory findings are unremarkable except for an elevation of cerebrospinal fluid protein. Cerebral atrophy and demyelination become evident in the CNS, and segmental demyelination, axonal degeneration, fibrosis, and macrophage infiltration are common in the peripheral nervous system. The segmental demyelination of peripheral nerves is demonstrated by the finding of decreased motor nerve conduction. The white matter is severely depleted of all lipids, especially glycolipids, and nerve and brain biopsies show globoid cells. Death from hyperpyrexia, respiratory complications, or aspiration occurs at a median age of 13 months.

G_{M1} Gangliosidosis

Etiology

Infantile G_{M1} gangliosidosis is caused by a deficiency in lysosomal β-galactosidase. The enzyme cleaves the terminal galactose in a β linkage from oligosaccharides, keratan sulfate, and G_{M1} ganglioside. Deficiency of the enzyme results in storage of G_{M1} ganglioside and oligosaccharides. Clinical severity correlates with the extent of substrate storage and residual enzyme activity. The same enzyme is deficient in Morquio disease type B.

Clinical Features

Age of onset ranges from prenatal to adult. Infantile or type 1 G_{M1} gangliosidosis may be evident at birth as coarse and thick skin, hirsutism on the forehead and neck, and coarse facial features consisting of a puffy face, frontal bossing, depressed nasal bridge, maxillary hyperplasia, large and low-set ears, wide upper lip, moderate macroglossia, and gingival hypertrophy. These dysmorphic features, however, are not always obvious in the neonate. A retinal cherry-red spot is seen in 50% of patients, and corneal clouding is often observed. Shortly after birth, or by 3 to 6 months of age, failure to thrive and hepatosplenomegaly become evident, as does neurologic involvement with poor development, hyperreflexia, hypotonia, and seizures. Cranial imaging shows diffuse atrophy of the brain, enlargement of the ventricular system, and evidence of myelin loss in white matter.

The neurologic deterioration is progressive, resulting in generalized rigidity and spasticity and sensorimotor and psychointellectual dysfunction. By 6 months of age, skeletal features are present, including kyphoscoliosis and stiff joints with generalized contractures, and striking bone changes are seen—vertebral beaking in the thoracolumbar region, broadening of shafts of the long bones with distal and proximal tapering, and widening of the metacarpal shafts with proximal pinching of four lateral metacarpals. Tissue biopsy samples demonstrate neurons filled with membranous cytoplasmic bodies and various types of inclusions as well as foam cells in the bone marrow. Death generally occurs before 2 years of age. A severe neonatal-onset type of G_{M1} gangliosidosis with cardiomyopathy has also been described (Kohlschütter et al, 1982).

Farber Lipogranulomatosis

Etiology

Farber lipogranulomatosis results from a deficiency of lysosomal acid ceramidase. Ceramidase catalyzes the degradation of ceramide to its long-chain base, sphingosine, and a fatty acid. Clinical disease is a consequence of storage of ceramide in various organs and body fluids.

Clinical Features

Four types of Farber lipogranulomatosis can manifest in the neonatal period. Type I, classic disease, is a unique disorder with onset from approximately 2 weeks to 4 months of age. Patients exhibit hoarseness progressing to aphonia, feeding and respiratory difficulties, poor weight gain, and intermittent fever caused by granuloma formation, and swelling of the epiglottis and larynx. Palpable nodules appear over joints and pressure points, and joints become painful and swollen. Later, joint contractures and pulmonary disease appear. Liver and cardiac involvement can occur, and patients can have a subtle retinal cherry-red spot. Severe and progressive psychomotor impairment can occur, as can seizures, decreased deep tendon reflexes, hypotonia, and muscle atrophy. Affected patients die in early infancy, usually from pulmonary disease.

Type 2, or intermediate, Farber lipogranulomatosis manifests from birth to 9 months of age as joint and laryngeal involvement and nodules. Death occurs in early childhood. Type 3 disease (mild) manifests slightly later, from approximately 2 months to 20 months of age, with survival into the third decade. Clinically types 2 and 3 are both dominated by subcutaneous nodules, joint deformity, and laryngeal involvement. Liver and pulmonary involvement may be absent. Two thirds of patients have a normal intelligence quotient. Type 4, or neonatal visceral, Farber lipogranulomatosis manifests at birth as hepatosplenomegaly caused by massive histiocyte infiltration of the liver and spleen, with infiltration also in the lungs, thymus, and lymphocytes. Subcutaneous nodules and laryngeal involvement may be subtle. Death occurs by 6 months of age.

In all types of Farber lipogranulomatosis, tissue biopsy samples show granulomatous infiltration, foam cells, and lysosomes with comma-shaped, curvilinear tubular structures called *Farber bodies*. Cerebrospinal fluid protein may be elevated in patients with type 1 disease.

Sialidosis

Etiology

Sialidosis is caused by a deficiency of neuraminidase, which is responsible for the cleavage of terminal sialyl linkages of several oligosaccharides and glycopeptides. The defect results in multisystem lysosomal accumulation of sugars rich in sialic acid.

Clinical Features

Type I sialidosis is characterized by retinal cherry-red spots and generalized myoclonus with onset generally in the second decade of life. Type II is distinguished from type I by the early onset of a progressive, severe phenotype with somatic features. Type II is often subdivided

into juvenile, infantile, and congenital forms. Congenital sialidosis begins in utero and manifests at birth as coarse features, facial edema, hepatosplenomegaly, ascites, hernias, and hypotonia, and occasionally frank hydrops fetalis. Radiographs demonstrate dysostosis multiplex and epiphyseal stippling. Delayed mental development is quickly apparent. The patient may have recurrent infections. Severely dilated coronary arteries, excessive retinal vascular tortuosity, and an erythematous macular rash may also be features of this disease (Buchholz et al, 2001). Most patients are stillborn or die before 1 year of age. Age of onset for the infantile form of sialidosis ranges from birth to 12 months. Clinical features are coarse facial features, organomegaly, dysostosis multiplex, retinal cherry-red spot, and mental retardation. Death occurs by the second or third decade. In both types of sialidosis, vacuolated cells can be seen in almost all tissues, and bone marrow foam cells are present.

Galactosialidosis

Etiology

Galactosialidosis results from a deficiency of two lysosomal enzymes, neuraminidase and β-galactosidase. The primary defect in galactosialidosis has been found to be a defect in protective protein–cathepsin A, an intralysosomal protein that protects the two enzymes from premature proteolytic processing. The protective protein has catalytic and protective functions, and the two functions appear to be distinct. Deficiency of enzymes results in the accumulation of sialyloligosaccharides in tissue lysosomes and in excreted body fluids.

Clinical Features

Galactosialidosis has been divided into three phenotypic subtypes based on age at onset and severity of clinical manifestations. Most cases occur in adolescence and adulthood, but early infantile and late infantile presentations occur. Patients develop early infantile galactosialidosis between birth and 3 months of age with ascites, edema, coarse facial features, inguinal hernias, proteinuria, hypotonia, and telangiectasias, and, occasionally, frank hydrops fetalis. Patients subsequently demonstrate organomegaly, including cardiomegaly progressing to cardiac failure, psychomotor delay, and skeletal changes, particularly in the spine. Ocular abnormalities can occur, including corneal clouding and retinal cherry-red spots. Death occurs at an average age of 8 months, usually from cardiac and renal failure. Galactosialidosis can be a cause of recurrent fetal loss or recurrent hydrops fetalis.

Late infantile galactosialidosis manifests in the first months of life as coarse facial features, hepatosplenomegaly, and skeletal changes consistent with dysostosis multiplex. Cherry-red spots and corneal clouding may also be present. Neurologic involvement may be absent or mild. Valvular heart disease is a common feature, as is growth retardation, partially because of spinal involvement and often in association with muscular atrophy. Early death is not a feature of the late infantile form. Vacuolated cells in blood smears and foam cells in bone marrow are present in all forms of galactosialidosis.

Wolman Disease

Etiology

Wolman disease is caused by lysosomal acid lipase deficiency, which is an enzyme involved in cellular cholesterol homeostasis and responsible for hydrolysis of cholesterol esters and triglycerides. The result of enzyme deficiency is defective release of free cholesterol from lysosomes, which leads to upregulation of LDL receptors and 3-hydroxy-3-methylglutaryl-CoA reductase activity. De novo synthesis of cholesterol and activation of receptor-mediated endocytosis of LDL then occur, leading to further deposition of lipid in lysosomes. The result is the accumulation of cholesterol esters and triglycerides in most tissues of the body, including the liver, spleen, lymph nodes, heart, blood vessels, and brain. An extreme level of lipid storage occurs in cells of the small intestine, particularly in the mucosa. In addition, neurons of the myenteric plexus demonstrate a high level of storage, with evidence of neuronal cell death, which may account for prominence of gastrointestinal symptoms (Wolman, 1995).

Clinical Features

Clinical presentation of Wolman disease is within weeks of birth, with evidence of malnutrition and malabsorption, including symptoms of vomiting, diarrhea, steatorrhea, failure to thrive, abdominal distention, and hepatosplenomegaly. Adrenal calcifications may be seen on radiographs, and adrenal insufficiency appears. The presence of adrenal calcifications in association with hepatosplenomegaly and gastrointestinal symptoms is strongly suggestive of Wolman disease. Later, mental deterioration becomes apparent. Laboratory findings include anemia secondary to foam cell infiltration of the bone marrow and evidence of adrenal insufficiency. The serum cholesterol level is normal. Death usually occurs before 1 year of age.

Infantile Sialic Acid Storage Disease

Etiology

Infantile sialic acid storage disease is caused by a defective lysosomal sialic acid transporter that is responsible for efflux of sialic acid and other acidic monosaccharides from the lysosomal compartment. The defective transporter results in greater storage of free sialic acid and glucuronic acid within lysosomes and increased sialic acid excretion.

Clinical Features

Infantile sialic acid storage disease often manifests at birth as mildly coarse features, hepatosplenomegaly, ascites, hypopigmentation, and generalized hypotonia. Mild dysostosis multiplex may be seen on radiographs. Failure to thrive and severe mental and motor retardation soon appear. Cardiomegaly may be present. Corneas are clear, but albinoid fundi have been reported (Lemyre et al, 1999). Vacuolated cells are seen on a tissue biopsy sample, and electron microscopy demonstrates swollen lysosomes filled with finely granular material. CNS changes include myelin loss, axonal spheroids, gliosis, and neuronal storage. Death occurs in early childhood. Infantile sialic acid storage disease can also manifest as fetal ascites, nonimmune

fetal hydrops, or infantile nephrotic syndrome (Lemyre et al, 1999).

I-Cell Disease (Mucolipidosis Type II)

Etiology

In normal cells, targeting of enzymes to lysosomes is mediated by receptors that bind a mannose-6-phosphate recognition marker on the enzyme. The recognition marker is synthesized in a two-step reaction in the Golgi complex. It is the enzyme that catalyzes the first step of this process, uridine diphosphate–*N*-acetylglucosamine: lysosomal enzyme *N*-acetylglucosaminyl-1-phosphotransferase, that is defective in I-cell disease. As a result, the enzymes lack the mannose-6-phosphate recognition signal, and the newly synthesized lysosomal enzymes are secreted into the extracellular matrix instead of being targeted to the lysosome. Consequently, multiple lysosomal enzymes are found in plasma in 10- to 20-fold their normal concentrations. Affected cells, especially fibroblasts, show dense inclusions of storage material that probably consists of oligosaccharides, glycosaminoglycans, and lipids; these are the inclusion bodies from which the disease name is derived. This disorder is found more frequently in Ashkenazi Jews, because of a putative founder effect.

Clinical Features

I-cell disease can manifest at birth as coarse features, corneal clouding, organomegaly, hypotonia, and gingival hyperplasia. Birthweight and length are often below normal. Kyphoscoliosis, lumbar gibbus, and restricted joint movement are often present, and there may be hip dislocation, fractures, hernias, or bilateral talipes equinovarus. Dysostosis multiplex may be seen on radiographs. Severe psychomotor retardation, evident by 6 months of age, and progressive failure to thrive occur. The facial features become progressively more coarse, with a high forehead, puffy eyelids, epicanthal folds, flat nasal bridge, anteverted nares, and macroglossia. Linear growth slows during the first year of life and halts completely thereafter. The skeletal involvement is also progressive, with development of increasing joint immobility and claw-hand deformities. Respiratory infections, otitis media, and cardiac involvement are common complications. Death usually occurs in the first decade of life because of cardiorespiratory complications.

Mucolipidosis Type IV

Etiology

Although mucolipidosis type IV is associated with a partial deficiency of the lysosomal enzyme ganglioside sialidase, a deficiency of mucolipin 1 (TRPML1), a member of the transient receptor potential TRMPL subfamily of channel proteins, is the cause of the disorder (Bargal et al, 2000; Sun et al, 2000). Mutations in the *MCOLN1* gene result in lysosomal storage of lipids such as gangliosides, plus water-soluble materials such as glycosaminoglycans and glycoproteins in cells from almost all tissues.

Clinical Features

The age of onset for mucolipidosis type IV ranges from infancy to 5 years. Presenting features are corneal clouding (may be congenital), retinal degeneration, blindness, hypotonia, and mental retardation. Survival of affected patients into the fourth decade of life has been reported (Chitayat et al, 1991). Cytoplasmic inclusions are noted in many cells, including those in conjunctiva, liver, and spleen, as well as fibroblasts.

Mucopolysaccharidosis Type VII (Sly Disease)

Etiology

Sly disease is a member of a group of lysosomal storage disorders that are caused by a deficiency of enzymes catalyzing the stepwise degradation of glycosaminoglycans. Skeletal and neurologic involvement is variable. There is a wide spectrum of clinical severity among the mucopolysaccharidoses and even within a single enzyme deficiency. Most of these disorders manifest in childhood, but type VII is included in this chapter because of its well-recognized neonatal and infantile presentations. Sly disease is caused by β-glucuronidase deficiency and results in lysosomal accumulation of glycosaminoglycans, including dermatan sulfate, heparan sulfate, and chondroitin sulfate, causing cell, tissue, and organ dysfunction.

Clinical Features

Sly disease can manifest as a wide spectrum of severity. Patients with the early-onset or neonatal form may have coarse features, hepatosplenomegaly, moderate dysostosis multiplex, hernias, and nonprogressive mental retardation. Corneal clouding is variably present. Frequent episodes of pneumonia during the first year of life are common. Short stature becomes evident. Granulocytes have coarse metachromic granules. A severe neonatal form associated with hydrops fetalis, and early death has been recognized frequently. Milder forms of the disease with later onset are also known.

DIAGNOSIS, MANAGEMENT, AND PROGNOSIS

Growing recognition of lysosomal storage disorders in the neonate has led to expansion of the spectrum of possible clinical presentation in the newborn period. Diagnostic tools and options for treatment also continue to advance. For example, efforts are currently underway to develop newborn screening for mucopolysaccharidoses (Whitley et al, 2002), with the goal to offer treatment with enzyme infusion or bone marrow transplantation (BMT) to affected babies (Vogler et al, 1999). The state of New York has implemented newborn screening for Krabbe disease using dried blood spots. The test uses a tandem mass-spectrometry–based enzyme analysis (Li et al, 2004a). This test has resulted in a fairly large number of positive newborn screens for Krabbe disease, most of which appear to be false positives, including enzyme perturbations that are not linked with clinical disease (Duffner et al, 2009).

As a consequence, an expert advising panel, the Krabbe Consortium of New York State, has been generated to establish standardized clinical evaluation guidelines. The goal is to help physicians determine which infant with a positive newborn screen may express disease and require treatment, such as hematopoietic stem cell transplantation in early infancy. The neonatologist is urged to work closely with appropriate experts to explore diagnostic and treatment protocols on an individual basis. Larger panels of multiplex testing for various other LSDs are in the testing stages (Li et al, 2004b) and some states in the United States are poised to begin implementing LSD newborn screening. Currently a federal advisory committee actively reviews and makes recommendations to the U.S. Secretary of Health and Human Services about the introduction of new newborn screening tests in the United States, with the aim of vetting proposed tests for need, cost effectiveness, and availability of effective and timely therapy.

Recognizing lysosomal storage disorders in the newborn period can be difficult, because they often mimic more common causes of illness in newborns, such as respiratory distress, nonimmune hydrops fetalis, liver disease, and sepsis. The initial step in the diagnosis of these disorders is to consider them in the differential diagnosis of a sick or unusual-appearing newborn. At times the phenotype may suggest a specific diagnosis, such as respiratory distress and painful, swollen joints in Farber lipogranulomatosis or gastrointestinal symptoms, hepatosplenomegaly, and adrenal calcifications in Wolman disease. Subtle dysmorphic features, coarsening of features, and radiographic evidence of dysostosis multiplex are also strong indications that lysosomal storage disorders should be considered. Routine laboratory findings are often normal or nonspecific. Affected infants do not have episodes of acute metabolic decompensation. Anemia and thrombocytopenia may be seen because of bone marrow involvement. Vacuolated cells may be found in peripheral blood, but the absence of this finding does not exclude lysosomal storage disease. Elevated cerebrospinal fluid protein is seen in Krabbe disease and Farber lipogranulomatosis type I.

Nonimmune hydrops fetalis deserves special mention. The physician must consider LSDs as the cause of nonimmune hydrops fetalis or unexplained ascites in the affected newborn infant. The following LSDs are potential causes: sialidosis type II, MPS types VII and IV, ISSD, Salla disease, galactosialidosis, Gaucher disease type II, G_{M1} gangliosidosis, I-cell disease, Niemann-Pick disease types A and C, Wolman disease, and Farber's disease (Staretz-Chacham et al, 2009). The mechanisms of edema are unclear. Furthermore, not all of the 13 LSDs routinely appear in the neonatal period.

Directed analysis of urine is helpful for conditions in which characteristic metabolites are excreted in urine. One- or two-dimensional electrophoresis or thin-layer chromatography can detect excess excretion of urine glycosaminoglycans, oligosaccharides, or free sialic acid, but all urinary tests for the diagnosis of lysosomal storage disorders can have false-negative results. Examination of bone marrow or other tissues may demonstrate storage macrophages in Gaucher disease and in Niemann-Pick disease types A and C. Small skin or conjunctival biopsy specimens may demonstrate storage within lysosomes in most of these disorders.

Definitive diagnosis for all lysosomal storage disorders, except for Niemann-Pick C disease, is confirmed by enzymatic assays in serum, leukocytes, fibroblasts, or a combination of these. The diagnosis of Niemann-Pick C disease requires measurement of cellular cholesterol esterification and documentation of a characteristic pattern of filipin-cholesterol staining in cultured fibroblasts during LDL uptake. Analysis of DNA mutations may be helpful for the diagnosis of Niemann-Pick C disease, Gaucher disease, and some other conditions, and it will become increasingly available for other conditions. An imperfect genotype-phenotype correlation impedes the use of mutation analysis as a prognostic tool. In addition, prenatal diagnosis is available for most lysosomal storage disorders through the use of enzyme assays performed on amniocytes or chorionic villus cells or measurements of levels of stored substrate in cultured cells or amniotic fluid. As mutation analysis becomes more prevalent, it will increasingly substitute for biochemical and enzymatic methods.

These conditions must also be considered in the dying infant, and the neonatologist must be prepared to request the appropriate samples for diagnosis at the time of death. In surviving patients, treatment and management must be considered. All the lysosomal storage disorders are chronic and progressive conditions for which there is no curative treatment. Gene transfer therapy holds promise, but is not currently available for lysosomal storage disorders. With few exceptions, current standard medical management is supportive and palliative. Patients must be continually reassessed for evidence of disease progression and associated complications. These complications manifest at variable ages and can include hydrocephalus, valvular heart disease, joint limitation, and obstructive airway disease.

For several disorders, particularly neonatal Gaucher disease and Niemann-Pick C disease, splenectomy may be indicated to improve severe anemia and thrombocytopenia. This procedure enhances the risk of serious infections, and it can accelerate the progression of disease at other sites. Patients with Krabbe disease may have significant pain of radiculopathy and spasms, and alleviation of that pain is important for the patient's comfort. The administration of glutamic acid transaminase inhibitor, vigabatrin, has been used in a small number of patients with Krabbe disease, because part of the pathology may involve a secondary deficiency of γ-aminobutyric acid (Barth, 1995). Low-dose morphine has also been reported to improve the irritability associated with this disorder (Stewart et al, 2001).

Enzyme replacement therapy with imiglucerase (Cerezyme), a recombinant enzyme, is available for Gaucher disease. Although enzyme replacement therapy has successfully reversed many of the systemic manifestations of the disease, it has been suggested that enzyme replacement therapy should not be given to patients with Gaucher disease type 2 who already have severe neurologic signs, because no substantial improvement has been demonstrated to occur in the neurologic symptoms of patients treated (Erikson et al, 1993; Gaucher disease, 1996).

Bone marrow transplantation has been tried for a variety of lysosomal storage disorders. The rationale for the

procedure is that circulating blood cells derived from the transplanted marrow become a source of the missing enzyme. Results of bone marrow transplantation in disorders of glycosaminoglycans show that after successful engraftment, leukocyte and liver tissue enzyme activity normalizes, organomegaly decreases, and joint mobility increases. Skeletal abnormalities stabilize but do not improve. Whether brain function can be improved in patients with CNS disease remains questionable. Some patients maintained their learning capability or intelligence quotient, but others continued to deteriorate. Clinical experience and studies in animal models indicate that BMT before the onset of neurologic symptoms can prevent or delay the occurrence of symptoms, whereas there is no clear benefit if transplantation is performed when symptoms are already present (Hoogerbrugge et al, 1995). BMT in patients with nonneuropathic Gaucher disease can result in complete disappearance of all symptoms; however, the procedure is associated with significant risks (Hoogerbrugge et al, 1995) that must be balanced against lifelong enzyme replacement therapy. Currently it is unclear to what extent patients with the neuropathic types of Gaucher disease (types 2 and 3) would benefit from transplantation; therefore it is generally not recommended.

BMT has also been attempted in a small number of patients with infantile Krabbe disease, Farber lipogranulomatosis, and Niemann-Pick A disease. The outcome after transplantation for these few patients has been poor, with continued disease progression and death. Krivit et al (2000) reported successful long-term bone marrow engraftment in a patient with Wolman disease that resulted in normalization of peripheral leukocyte lysosomal acid lipase enzyme activity. The patient's diarrhea resolved; cholesterol, triglyceride; and liver function values normalized; and the patient attained developmental milestones. Lysosomal storage diseases are not all equally amenable to BMT, and the use of BMT as a treatment modality for most lysosomal storage disorders remains uncertain. In a small number of cases, BMT has been performed in utero after prenatal diagnosis showing an affected infant, and experimental protocols are available for families who wish to pursue this option.

The goal of therapy for a dietary protocol proposed for the treatment of Wolman disease is reduced accumulation of storage material in intestine and phagocytes. The diet, which should be started as soon as the diagnosis of Wolman disease is suggested, consists of (1) discontinuing breastfeeding or feeding with a formula containing triglycerides and cholesterol esters and (2) keeping the infant on a fatty ester–free diet (Wolman, 1995). The diet should include all necessary vitamins, including fat-soluble vitamins. In addition, daily smearing of the skin of a different extremity with a small amount (10 to 50 μL) of sunflower or safflower oil or preferably soy, canola, flax, cod liver, or algal oil is required for preventing essential fatty acid deficiency, which complicates the restricted diet (Wolman, 1995). The absorption of fatty acids through skin spares the gastrointestinal tract from accumulation and is associated with the formation of phospholipids and triglycerides (Wolman, 1995). Preliminary results of this approach suggest that treatment appears to halt disease progression.

CONGENITAL DISORDERS OF GLYCOSYLATION

ETIOLOGY

Previously called *carbohydrate-deficient glycoprotein syndromes*, CDGs are a large and increasing family of genetic diseases resulting from deficient glycosylation of glycoconjugates, mainly glycoproteins and glycolipids. Most extracellular proteins, such as serum proteins (e.g., transferrin and clotting factors), most membrane proteins, and several intracellular proteins (e.g., lysosomal proteins), are glycosylated proteins. Glycosylation, the addition of sugar chains (glycans) to proteins, occurs in every human cell and serves a number of functions, including aiding in correct folding of the nascent protein, participating in cell adhesion phenomena, protecting against premature proteolytic destruction, and modifying biologic function (Grünewald, 2007). The glycans are defined by their linkage to the protein N-glycan or O-glycan. N-Glycosylation consists of the assembly of a glycan on and in the endoplasmic reticulum and its attachment to a particular asparagine of target proteins, followed by remodeling of this glycan mainly in Golgi (Jaeken and Matthijs, 2007); therefore it is a two-part process of assembly and processing. O-Glycosylation consists of assembly of a glycan and its attachment to a serine or threonine of a target protein, or the attachment of a monosaccharide (mannose, fructose, or xylose) to one of these amino acids. No processing pathway is present in O-glycosylation (Jaeken and Matthijs, 2007). Combined N- and O-glycosylation defects and lipid glycosylation defects have also been described (Jaeken and Matthijs, 2007).

Given the ubiquitous occurrence of glycoproteins and the number of apparent genes involved in glycosylation (more than 200; approximately 1% of the human genome), it is not surprising that the number of described CDG defects is increasing rapidly and clinical manifestations are diverse (Jaeken, 2006; Jaeken et al, 2008; Morava et al, 2008b). Currently, 21 disorders in protein N-glycosylation, 12 in protein O-glycosylation, five in both protein N- and O-glycosylation, and two in lipid glycosylation have been described (Jaeken, 2006; Jaeken and Matthijs, 2007; Marklová and Albahri, 2007). The number of described disorders is expected to continue to grow.

The disorders of N-glycosylation have been divided into two primary categories. CDG-I disorders result from defects in N-glycan assembly (designated CDG-Ia to -Im). On isoelectrofocusing of serum transferrin, the most widely used screening test for N-glycosylation disorders, a type I pattern is observed. This pattern is characterized by a decrease of anodal fractions and an increase of disialotransferrin and asialotransferrin. A type II pattern, showing an increase of trisialofractions, monosialofractions, or both is seen in CDG-II defects, which represent defects in N-glycan processing (designated CDG-IIa-IIf).

O-Glycosylation defects have been found to be causative in a number of muscular dystrophies with reduced glycosylation of α-dystroglycan. These disorders, collectively referred to as α-*dystroglycanopathies*, encompass previously described disorders, such as Walker-Warburg syndrome, muscle-eye-brain disease, Fukuyama congenital muscular

dystrophy, and limb-girdle muscular dystrophy (Mercuri et al, 2009; Topaloglu, 2009). Six known or putative glycosyltransferase genes have been identified in these disorders (Godfrey et al, 2007). In general, this is a heterogeneous group of autosomal recessive disorders with a wide spectrum of clinical severity, and it shares the common pathologic feature of hypoglycosylated α-dystroglycan (Godfrey et al, 2007). α-Dystroglycan is a major component of the dystrophin-associated glycoprotein complex that forms a link between the actin-associated cytoskeleton and extracellular matrix. It is a highly glycosylated peripheral membrane protein that binds many of its extracellular matrix partners through its carbohydrate modifications (Godfrey et al, 2007). In the dystroglycanopathies, these modifications are either absent or reduced, resulting in decreased binding of ligands (Barresi and Campbell, 2006). O-Glycosylation defects have also been described in hereditary multiple exostoses syndrome, familial tumoral calcinosis, Schneckenbecken dysplasia, spondylocostal dysostosis type 3, Peters plus syndrome, and the progeria variant of Ehlers-Danlos syndrome (Grünewald, 2007; Jaeken et al, 2008; Jaeken and Matthijs, 2007).

Combined N- and O-glycosylation defects are important because they appear to affect trafficking in the glycosylation machinery (Grünewald, 2007). The disruption of multiple glycosylation pathways is caused by mutations of the conserved oligomeric Golgi (COG) complex. This large complex spanning eight subunits plays a key role in protein transport between the endoplasmic reticulum and Golgi and within the Golgi complex (Grünewald, 2007; Jaeken, 2006). COG7 deficiency, first described in two siblings with poor intrauterine growth, dysmorphic features, encephalopathy, cholestatic liver disease, and perinatal asphyxia, shows a partial combined N- and O-glycosylation defect caused by decreased transport of CMP-sialic acid and UDP-galactose into Golgi and reduced activity of two glycosyltransferases involved in the galactosylation and sialylation of O-glycans (Jaeken, 2006). An autosomal recessive cutis laxa syndrome has recently been found to be also associated with a combined glycosylation defect (Morava et al, 2008a).

Two disorders of lipid glycosylation have been described. Amish infantile epilepsy was the first identified and is caused by a defect of lactosylceramide α-2,3 sialyltransferase (GM3 synthase; Jaeken, 2006). This enzyme catalyzes the initial step in the biosynthesis of most complex gangliosides from lactosylceramide (Jaeken and Matthijs, 2007). The defect causes accumulation of lactosylceramide associated with decreased gangliosides of the GM3 and GD3 series (Jaeken, 2006). Glycosylphosphatidylinositol deficiency is the second disorder in glycolipid glycosylation described, but the first reported genetic defect in glycosylation of the glycosylphosphatidylinositol (GPI) anchor (Jaeken and Matthijs, 2007). Glycosylphosphatidylinositol-anchored proteins have heterogeneous functions as enzymes or adhesion molecules. Finally, the term *CDG-x* indicates syndromes with strong evidence for a glycosylation defect, but in which the defective gene has yet to be identified (Jaeken and Matthijs, 2007). This clinically heterogeneous group is also growing rapidly.

CLINICAL FEATURES

The phenotypic spectrum of CDG defects is extremely broad and ranges from mild to severe disease and from a single-organ system to multisystem disease. Clinical features alone are insufficient to define the CDG subtype. CDG should be considered a possible diagnosis in any unexplained clinical condition, but especially in multiorgan disease with neurologic involvement. Discussion of the clinical presentation of all forms of CDG is beyond the scope of this chapter (Table 23-2).

CDG-Ia is the classic and most common presentation. The basic defect in CDG-Ia is a deficiency of the enzyme phosphomannomutase, which is required for the early steps of protein glycosylation (Jaeken, 2006; Jaeken et al, 2001; van Schaftingen and Jaeken, 1995). Patients with CDG-Ia at birth exhibit dysmorphic features consisting of a high nasal bridge, prominent jaw, large ears, and inverted nipples, feeding difficulties, and subsequent growth failure, hypotonia, lipocutaneous abnormalities (including prominent fat pads on the buttocks), and mild to moderate hepatomegaly. The clinical progression of this disorder is divided into four stages. In stage I—the infantile, multisystem stage—patients show evidence of multisystem involvement, including variable strokelike episodes, thrombotic disease, liver dysfunction, pericardial effusions and cardiomyopathy, proteinuria, and retinal degeneration. The coagulopathy likely stems from the number of clotting and anticlotting proteins that are *N*-linked glycoproteins. Mental retardation, peripheral neuropathy, and decreased nerve conduction velocities are observed. Strabismus and alternating esotropia are present in almost all patients, and retinitis pigmentosa and abnormalities of the electroretinogram are present in most. Cranial imaging shows varying degrees of cerebral, cerebellar, and brainstem hypoplasia. Electroencephalogram results are usually normal. Liver biopsy samples typically show steatosis and fibrosis, and multicystic changes in kidneys have been noted.

Stage II, the childhood stage, is characterized by ataxia and mental retardation. Skeletal abnormalities may become more prominent, consisting of contractures, kyphoscoliosis, pectus carinatum, and short stature. Stage III, generally occurring in the teenage years, is characterized primarily by lower extremity atrophy. Adulthood, or stage IV, is characterized by hypogonadism. In general, patients have an extroverted disposition and happy appearance. Approximately 20% of patients die during the first year of life because of severe infection, liver failure, or cardiac insufficiency.

Patients with CDG-Ib are unique among patients with these disorders. They may have vomiting, diarrhea, hypoglycemia, and liver disease (coagulopathy, hepatomegaly, hepatic fibrosis). In addition, they often have a protein-losing enteropathy (also seen in CDG-Ih; Jaeken and Matthijs, 2007). Development is normal. The remaining forms of CDG-I and CDG-II are similar in presentation to type Ia. Additional features include seizures, normal cerebellar development, delayed myelination, optic atrophy, blindness, frequent infections, hypoventilation and apnea, and further dysmorphic features such as adducted thumbs, high-arched palate, coarse facies, widely spaced nipples, and low-set ears.

TABLE 23-2 Common Congenital Disorders of Glycoprotein

	Types of CDG							
Findings	**Ia**	**Ib**	**Ic**	**Id**	**Ie**	**IIa**	**IIb**	**x**
Enzyme defect	Phosphomannomutase	Phosphomannose isomerase	α1,3-Glucosyltransferase	α1,3-Mannosyl transferase	Dol-P-Man synthase	GlcNAc transferase 2	Glucosidase I	Unknown
Dysmorphic features	+	+/–	+/–	+/–	+	+	+	+
Psychomotor retardation	+	–	+	+	+	+	+	+
Hypotonia	+	+/–	+	+	+	+	+	+
Cerebellar hypoplasia	+	–	+/–	–	+/–	–	–	–
Seizures	+/–	+/–	+/–	+	+	+	+	–
Eye findings	Strabismus, esotropia	–	Strabismus	Optic atrophy	Cortical blindness	–	–	–
Liver disease	+	+	–	–	+	+	+	–
Coagulopathy	+	+	+	–	+	+	+	–
Other	Multiorgan involvement, peripheral neuropathy, subcutaneous fat distribution, inverted nipples, strokelike episodes, cardiomyopathy, ataxia, microcephaly, hypothyroidism	Protein-losing enteropathy, cyclic vomiting, diarrhea, hypoglycemia	Microcephaly, feeding difficulties, ataxia	Microcephaly, reduced responsiveness, adducted thumbs	Microcephaly, delayed myelination	Stereotype behavior, frequent infections, ventricular septal defect, widely spaced nipples, delayed myelination	Early death, generalized edema, hypoventilation, apnea, demyelinating polyneuropathy	Leukocyte adhesion deficiency syndrome type II (guanosine diphosphate–fucose transporter); phenotype: elevated peripheral leukocytes, absence of CD 15, Bombay blood group phenotype, failure to thrive, recurrent infections, short arms and legs, simian crease

+, Present; –, absent; +/–, occasionally present.

The phenotypic presentation of dystroglycanopathy is extremely variable. At the severe end of the spectrum are individuals with Walker-Warburg syndrome, muscle-eye-brain disease, and Fukuyama congenital muscular dystrophy. These conditions are characterized by congenital muscular dystrophy with severe structural brain and eye abnormalities and death typically before the age of 1 year (Godfrey et al, 2007; Jaeken, 2006; Jaeken and Matthijs, 2007). Toward the more mild end of the spectrum are individuals in adulthood with limb-girdle muscular dystrophy with no brain or eye involvement (Godfrey et al, 2007; Jaeken and Matthijs, 2007). Intermediate phenotypes lie between the two extremes.

The presence of carbohydrate-deficient transferrin in serum and cerebrospinal fluid is a distinctive biochemical feature of CDG. Laboratory findings are often nonspecific (e.g. elevated liver function studies or hypoalbuminemia), but concentrations of plasma glycoproteins such as α_1-antitrypsin, thyroxin-binding globulin, and transferrin are frequently abnormal (Marklová and Albahri, 2007). Clotting factors such as factors V, XI, II, X, antithrombin III, proteins C and S, and thyroid hormones (triiodothyronine, thyroxine, and reverse T3) are also frequently decreased (Marklová and Albahri, 2007; Morava et al, 2008b). Abnormal clotting is an important indicator of a glycosylation disorder (Morava et al, 2008b).

DIAGNOSIS

CDG should be considered in newborns with several of the following features:

- Neurologic signs, including hypotonia, hyporeflexia, or seizures
- Ophthalmic signs, including abnormal eye movements, cataracts, glaucoma, optic nerve atrophy, or retinitis pigmentosa
- Hepatic and gastrointestinal signs such as ascites or hydrops, hepatomegaly, diarrhea, and protein-losing enteropathy
- Endocrinologic signs, including hyperinsulinemic hypoglycemia and hypothyroidism
- Signs of renal or cardiac disease
- Congential muscular dystrophy
- Congenital joint contractures
- Dysmorphic features, microcephaly, structural brain anomalies, or abnormal skin findings

Isoelectrofocusing of serum transferrin is the screening method of choice, but only to detect defects of N-glycosylation. Confirmatory enzyme assays or molecular studies are required to pinpoint the specific defect. Urine oligosaccharide analysis, Bombay blood phenotype, serum apoC-III screening, or membrane bound sialyl-Lewis^X antigen may be helpful in distinguishing subclasses of CDG II disease (Marklová and Albahri, 2007). If suspicion of CDG remains, further structural analysis of the lipid-linked oligosaccharide (LLO) and the peptide-protein *N*-linked oligosaccharide should follow, if available (Marklová and Albahri, 2007). Patients with CDG can often be identified through neonatal screening for congenital hypothyroidism, because of an associated thyroid-binding globulin deficiency and an increased thyroid-stimulating hormone level. Prenatal diagnosis by transferrin isoelectric focusing is not reliable. Prenatal diagnosis is possible in all types of CDG for which the molecular defect is known (Grünewald, 2007). The vast majority of CDG disorders are autosomal recessive disorders or presumed autosomal recessive disorders; hereditary multiple exostoses syndrome is autosomal dominant.

TREATMENT AND MANAGEMENT

The treatment and management for most types of CDGs are primarily supportive and palliative. There is no curative or corrective treatment. In infancy, evidence of multisystem involvement and the resulting complications must be treated promptly. There is substantial mortality in the first years of life because of severe infection or vital organ failure (Grünewald, 2007; Jaeken, 2006). The exception is treatment of CDG-Ib with oral mannose therapy. In this disorder, oral mannose effectively bypasses the impaired pathway and allows glycosylation to continue (Freeze, 1998; Jaeken, 2006; Jaeken and Matthijs, 2007). Therapy improves the protein-losing enteropathy and liver disease (Grünewald, 2007). Oral fucose therapy has also been used in patients with CDG-IIc, a GDP-fucose transporter defect (Grünewald, 2007). Therapy appears to improve the fucosylation of glycoproteins and to improve control of recurrent infections, but it has no effect on neurologic complications of the disorder (Grünewald, 2007).

PEROXISOMAL DISORDERS

DISORDERS OF PEROXISOME BIOGENESIS

Peroxisomes are single-membrane–bound cellular organelles that contain no internal structure or DNA and are characterized by an electron-dense core and a homogeneous matrix. Peroxisomes are found in all cells and tissues except mature erythrocytes, and they are in highest concentration in the liver and kidneys. They are formed by growth and division of preexisting peroxisomes and are randomly destroyed by autophagy. Their half-life is 1.5 to 2 days. Peroxisomal proteins are encoded by nuclear genes, synthesized in cytosol, and imported posttranslationally into the peroxisome. The import of proteins into the peroxisome is mediated by receptors and requires adenosine triphosphate hydrolysis.

Peroxisomes contain enzymes that use oxygen to oxidize a variety of substrates, thereby forming peroxide. The peroxide is decomposed within the organelle by the enzyme catalase to water and oxygen. This process protects the cell against peroxide damage through compartmentalization of peroxide metabolism within the organelle. Peroxisomes can also function to dispose of excess reducing equivalents and may contribute to thermogenesis, producing heat from cellular respiration (Gould et al, 2007).

More than 50 enzymes have been found within peroxisomes (Gould et al, 2001). The proteins have multiple functions, both synthetic and degradative (Wanders et al, 2001). The primary synthetic functions are plasmalogen synthesis and bile acid formation. Plasmalogens constitute 5% to 20% of phospholipids in cell membranes and 80% to 90% of phospholipids in myelin. They are involved in platelet activation and may also protect cells against oxidative stress. Degradative functions include (1) β-oxidation of VLCFA (≥C23), fatty acids (down to C8 to C6), long-chain dicarboxylic acids, prostaglandins, and polyunsaturated fatty acids; (2) oxidation of bile acid intermediates, pipecolic acid and glutaric acid (intermediates in lysine catabolism), and phytanic acid; (3) deamination of D- and L-amino acids, (4) metabolism of glycolate to glyoxylate; (5) polyamine degradation (spermine and spermidine); and (6) ethanol clearance. At least 16 conditions caused by single peroxisomal enzyme deficiencies have been confirmed (Wanders et al, 2007).

Peroxisomal disorders constitute a clinically and biochemically heterogeneous group of inherited diseases that result from the absence or dysfunction of one or more peroxisomal enzymes. Conditions in which multiple peroxisomal enzymes are affected can result from a disturbance of biogenesis or the organelle. Pathophysiology apparently involves either deficiency of necessary products of peroxisomal metabolism or excess of unmetabolized substrates. Disorders with similar biochemical defects may have markedly different clinical features, and disorders with similar clinical features may be associated with different biochemical findings. General features of peroxisomal disorders, each of which can manifest or be evident in the newborn period, are as follows:

- Dysmorphic craniofacial features
- Neurologic dysfunction, primarily consisting of severe hypotonia, possibly associated with hypertonia of the extremities and seizures
- Hepatodigestive dysfunction, including hepatomegaly, cholestasis, and prolonged hyperbilirubinemia

Rhizomelic shortening of the limbs, stippled calcifications of epiphyses, renal cysts, and abnormalities in neuronal migration may also be seen.

Peroxisomal biogenesis disorders are composed of at least 12 complementation groups (Matsumoto et al, 2001). All involve defects in proteins targeted to the organelle. Genes and proteins required for peroxisomal biosynthesis are referred to as *peroxins* and are encoded by *PEX* genes. The *PEX* genes responsible for disease in most human patients are known, and more than 50% of patients with peroxisomal biogenesis disorders have mutations in *PEX1* (Moser, 2000; Steinberg et al, 2006). This section We discusses the peroxisomal disorders that can manifest in the newborn period.

Zellweger syndrome is the prototype of neonatal peroxisomal disease. It is a disorder of peroxisome biogenesis caused by failure to import newly synthesized peroxisomal proteins into the peroxisome. The proteins remain in the cytosol, where they are rapidly degraded. In this condition, peroxisomes are absent from liver hepatocytes or exist as "ghosts." Neonatal adrenoleukodystrophy and infantile Refsum disease are also disorders of peroxisome biogenesis in which, as in Zellweger syndrome, disruption of function of more than one peroxisomal enzyme is demonstrable. A few residual peroxisomes, however, may be seen in the liver. These disorders represent a continuum of clinical severity. Rhizomelic chondrodysplasia punctata is caused by a defect in a subset of peroxisomal enzymes. In this disorder, liver peroxisomes are demonstrable and normal in number, but their distribution and structure are abnormal.

There is circumstantial evidence that in utero elevations of VLCFAs may be key to congenital CNS abnormalities. Powers and Moser (1998) proposed that VLCFAs and phytanic acid that accumulate in these peroxisomal disorders are incorporated into myelin and cell membranes, and that alteration of normal constituents of the membrane adversely affects membrane function. Specifically, these investigators suggest that abnormal constituents accelerate cell death and impede neuronal migration, accounting for the conspicuous CNS abnormalities in disorders of peroxisomal biogenesis.

To date, four disorders of peroxisomal fatty acid β-oxidation have been defined: acetyl-CoA oxidase deficiency, D-bifunctional protein deficiency, peroxisomal thiolase deficiency, and 2-methylacyl-CoA racemase deficiency (Wanders et al, 2007). The clinical presentation of the first three disorders resembles that of biogenesis disorders. Individuals with the fourth disorder have a late-onset neuropathy.

Clinical Presentations

Table 23-3 summarizes the clinical features of disorders of peroxisome biogenesis that can present in the neonate.

Zellweger Syndrome

Zellweger syndrome is most often evident at birth, with affected babies having dysmorphic facial features including large fontanels, high forehead, flat occiput, epicanthus, hypertelorism, upward-slanting palpebral fissures,

TABLE 23-3 Disorders of Peroxisomal Biogenesis in the Newborn Period

Feature	Zellweger Syndrome	Neonatal Adrenoleukodystrophy	Infantile Refsum Disease	Rhizomelic Chondrodysplasia Punctata
Onset	**Birth**	**Birth to 3 mo**	**Birth to 6 mo**	**Birth**
Facies	High forehead, large fontanels, upward-slanting palpebral fissures, hypoplastic supraorbital ridges, epicanthic folds, micrognathia, abnormal ears	Milder features of Zellweger syndrome	Epicanthic folds, midface hypoplasia, low-set ears	Depressed nasal bridge, hypertelorism, microcephaly
Neurologic findings	Weakness, hypotonia, seizures, psychomotor retardation, sensorineural hearing loss	Hypotonia, seizures, slow psychomotor development and neurodegeneration	Mild hypotonia, normal early development followed by degeneration, ataxia, sensorineural hearing loss	Severe psychomotor retardation
Ophthalmologic findings	Cataracts, glaucoma, corneal clouding, retinitis pigmentosa, optic nerve dysplasia, Brushfield spots	Retinopathy	Retinitis pigmentosa	Cataracts
Other findings	Hepatomegaly, multicystic kidneys, congenital heart disease, growth failure, chondrodysplasia punctata	Impaired adrenal function	Hepatomegaly, anosmia, diarrhea	Severe shortening of proximal limbs, joint contractures, ichthyosis
Diagnosis	↑ plasma VLCFA, phytanic acid, pipecolic acid, and bile acid intermediates, ↓ plasmalogens	Same as for Zellweger syndrome	Same as for Zellweger syndrome	↑ phytanic and pipecolic acids, ↓ plasmalogens, normal VLCFA and bile acid intermediates

VLCFA, Very-long-chain fatty acid; ↑, elevated; ↓, reduced.

hypoplastic supraorbital ridges, abnormal ears, severe weakness and hypotonia, hepatomegaly, multicystic kidneys, and congenital heart disease. Seizures, feeding difficulties, and postnatal growth failure soon manifest. Ophthalmologic examination may detect cataracts, corneal clouding, glaucoma, optic atrophy, retinitis pigmentosa, and Brushfield spots. Somatic sensory evoked responses and electroretinograms are abnormal. Hearing assessment often shows an abnormal brainstem auditory evoked response consistent with sensorineural hearing loss. Skeletal radiographs demonstrate epiphyseal stippling, and cranial imaging shows leukodystrophy and neuronal migration abnormalities. Hepatic cirrhosis and severe psychomotor retardation occur later. Laboratory analysis may demonstrate abnormal liver function values, hyperbilirubinemia, or hypoprothrombinemia. Death usually occurs within the first year of life, the average life span being 12.5 weeks.

Neonatal Adrenoleukodystrophy

Clinically, neonatal adrenoleukodystrophy is similar to, but less severe than, Zellweger syndrome. Differences include less dysmorphology, absence of chondrodysplasia punctata and renal cysts, and fewer neuronal and gray matter changes. Patients with neonatal adrenoleukodystrophy may have striking white matter disease, however, and often show degenerative changes in adrenal glands. They also have slow psychomotor development followed by neurodegeneration that usually begins before the end of the first year of life. Disease progression is slower than that observed in Zellweger syndrome, and longer survival is usual, to an average of approximately 15 months of age.

Infantile Refsum Disease

Patients with infantile Refsum disease also have relatively mild dysmorphic features, such as epicanthic folds, midface hypoplasia with low-set ears, and mild hypotonia. Early neurodevelopment is normal, possibly up to 6 months of age, but then slow deterioration begins. Later, sensorineural hearing loss (100%), anosmia, retinitis pigmentosa, hepatomegaly with impaired function, and severe mental retardation are evident. Patients learn to walk, although their gait may be ataxic and broad based. Diarrhea and failure to thrive may also be seen. Chondrodysplasia punctata and renal cysts are absent. Neuronal migration defects are minor, and adrenal hypoplasia occurs. The life span of patients with infantile Refsum disease ranges from 3 to 11 years.

Rhizomelic Chondrodysplasia Punctata

Patients with rhizomelic chondrodysplasia punctata at birth have facial dysmorphia, microcephaly, cataracts, rhizomelic shortening of extremities with prominent stippling, and coronal clefting of vertebral bodies. The chondrodysplasia punctata is more widespread than in Zellweger syndrome and may involve extraskeletal tissues. Infants with this disorder have severe psychomotor retardation from birth onward and severe failure to thrive. In addition, patients may have joint contractures, and 25% experience ichthyosis. Neuronal migration is normal. Life span is usually less than 1 year.

DISORDERS OF PEROXISOMAL β-OXIDATION

D-Bifunctional protein deficiency is more rare than peroxisomal biogenesis disorders and results in a phenotype similar to Zellweger syndrome. In general, children have severe CNS involvement consisting of profound hypotonia, uncontrolled seizures, and failure to acquire any significant developmental milestones. Children are usually born full term without evidence of intrauterine growth restriction. Dysmorphic features, similar to those seen in Zellweger syndrome, are notable in most children. In most cases, neuronal migration is disturbed with areas of polymicrogyria and heterotopic neurons in the cerebrum and cerebellum. Death generally occurs before 1 year of age, but survival to at least 3 years of age is possible.

Acetyl-CoA oxidase deficiency is less common. Patients exhibit global hypotonia, deafness, and delayed milestones with or without facial dysmorphic features. Patients may demonstrate early developmental gains, but then show regression of skills. Retinopathy with extinguished electroretinograms, failure to thrive, hepatomegaly, areflexia, and seizures have also been reported.

One patient with peroxisomal thiolase deficiency has been described (Goldfischer et al, 1986). The child had marked facial dysmorphia, muscle weakness, and hypotonia. She demonstrated no psychomotor development during her 11 months of life. Autopsy showed renal cysts, atrophic adrenal glands, minimal liver fibrosis, hypomyelination in cerebral white matter, foci of neuronal heterotopia, and a sudanophilic leukodystrophy (Goldfischer et al, 1986).

X-linked adrenoleukodystrophy is the most common peroxisomal disorder, because of altered function of a membrane transport protein ABCD1 that affects metabolism of VLCFAs, and does not usually present in the neonatal period. However, three patients with contiguous deletions involving the *ABCD1* gene have exhibited a phenotype similar to peroxisomal biogenesis disorders (Corzo et al, 2002).

DIAGNOSIS, MANAGEMENT, AND PROGNOSIS OF PEROXISOMAL DISORDERS

The key to diagnosing peroxisomal disease is a high index of suspicion. Peroxisomal disorders should be considered in newborns with dysmorphic facial features, skeletal abnormalities, shortened proximal limbs, neurologic abnormalities (including hypotonia or hypertonia), ocular abnormalities, and hepatic abnormalities. Babies with abnormal visual, hearing, or somatosensory evoked potentials should also be considered for these diagnoses.

Peroxisomal disorders are not associated with acute metabolic derangements or abnormal routine laboratory tests. Measurements of VLCFAs, phytanic acid, pipecolic acid, bile acid intermediates, and plasmalogens are required for diagnosis. Zellweger syndrome is associated with elevations of VLCFAs, phytanic acid, pipecolic acid, and bile acid intermediates, and a decrease in plasmalogen synthesis. Neonatal adrenoleukodystrophy and infantile Refsum disease have similar biochemical findings; however, the defect in plasmalogen synthesis and the degree of VLCFA accumulation are less severe. Laboratory findings in rhizomelic

chondrodysplasia punctata are elevations of phytanic and pipecolic acids, a decrease in plasmalogen, and normal levels of VLCFAs and bile acid intermediates. Therefore screening that uses only levels of VLCFAs fails to detect rhizomelic chondrodysplasia punctata. D-Bifunctional protein deficiency is associated with deficient oxidation of C23:0 and pristanic acid, leading to elevations of pristanic acid and, to a lesser extent, phytanic acid. This deficiency results in an elevated pristanic acid-to-phytanic acid ratio, which is generally not elevated in peroxisomal biogenesis disorders. Abnormal VLCFA and elevation of varanic acid (an intermediate metabolite in β-oxidation) are also seen. Accumulation of bile acid intermediates is a variable finding. Abnormalities in phytanic acid and plasmalogens are age dependent. The elevation of phytanic acid might not be demonstrable in young infants, and reduction in red blood cell plasmalogen levels may not be evident in children older than 20 weeks (Gould et al, 2007). A liver biopsy may be a useful adjunct diagnostic tool to assess for the presence or absence and structure of peroxisomes. Definitive diagnoses for all types of peroxisomal disease require cultured skin fibroblasts for measurement of VLCFA levels and their β-oxidation and, as needed, assay of the peroxisomal steps of plasmalogen synthesis, phytanic acid oxidation, subcellular localization of catalase, enzyme assays, and immunocytochemistry studies. Prenatal diagnosis with a variety of methods is available (Steinberg et al, 2005). DNA diagnosis is possible for most patients, but is "challenging for the Zellweger syndromes spectrum since 12 *PEX* genes are known to be associated with this spectrum of peroxisomal biogenesis disorders" (Steinberg et al, 2006). DNA study for deletions also has a role in diagnostic evaluations in some cases before counseling for recurrence risk, as demonstrated by the neonatal presentation of cases with deletion of the *ABCD1* gene on the X chromosome (Corzo et al, 2002). The complexities of prenatal diagnosis emphasize the need for studies of tissue on the proband to determine the potential for and appropriate strategies to offer in prenatal diagnosis for any family.

One of the more interesting recent developments in peroxisomal disease is the preliminary work on combined liquid chromatography-tandem mass spectroscopy application for blood spot–based newborn screening. It is targeted at conditions with abnormal VLCFAs, especially X-linked adrenoleukodystrophy, that typically manifest in childhood and for which presymptomatic therapy may alter the course of the usual progressive disease. The method is promising, but still under investigation (Hubbard et al, 2006).

Treatment for all peroxisomal disorders in the newborn period remains supportive. These disorders are chronic, progressive diseases with no currently available curative therapy. Setchell et al (1992) described the effects of administration of primary bile acids on liver function in a 6-month-old infant with Zellweger syndrome. The effects included normalization of serum bilirubin and liver enzyme levels and a decrease in hepatic inflammation, bile duct proliferation, and canalicular plugs. The patient also showed an improvement in growth and neurologic function (Setchell et al, 1992).

Martinez (1992) reported the use of docosahexaenoic acid ethyl ester in two patients with neonatal adrenoleukodystrophy. Both patients had an increase in erythrocyte omega fatty acid levels and plasmalogens accompanied by significant improvement in clinical parameters, including alertness, motor performance, vocabulary, and visual evoked responses. Martinez et al (2000) also reported on the effects of docosahexaenoic acid supplementation in 13 patients with generalized peroxisomal disorders. The effects were normalization of blood docosahexaenoic acid levels, increased plasmalogen concentrations, decreased plasma VLCFAs, and improvement to near normal of liver enzymes. Although patients with severe neonatal Zellweger syndrome presentation did not benefit, patients with milder peroxisomal biogenesis disorders—in which clinical course is more variable—experienced improvement in vision, liver function, muscle tone, and social contact. Three patients showed normalization of brain myelin, and myelination improved in three others (Martinez et al, 2000).

In addition, a "triple" dietary approach consisting of oral administration of ether lipids, decreased phytanic acid intake, and the oral administration of glyceryl trioleate and glyceryl trierucate (Lorenzo's oil) leads to biochemical improvement and may have value in patients with mild forms of peroxisomal biogenesis defects (Gould et al, 2007). Although treatment protocols are available for infants affected with disorders of peroxisomal biogenesis, improvement in long-term outcome remains limited in all but the mildly affected patients. However, treatment involving diet and bone marrow transplant, when appropriate, has been demonstrated to significantly improve the outcome of some patients affected with adrenoleukodystrophy (Moser et al, 2001).

SMITH-LEMLI-OPITZ SYNDROME

ETIOLOGY

Smith-Lemli-Opitz syndrome is a well-recognized autosomal recessive malformation syndrome, with an estimated incidence ranging from 1 in 10,000 to 70,000 in various populations (Porter, 2008; Yu and Patel, 2005). Because of the identification of an underlying biochemical defect, SLO syndrome has been reclassified as an inborn error of metabolism. In 1993, it was discovered that SLO syndrome is caused by a defect in cholesterol biosynthesis that results in low levels of cholesterol and elevated levels of 7-dehydrocholesterol (7DHC) and its isomer, 8-dehydrocholesterol (8DHC). Patients have markedly reduced activity of the enzyme 7DHC reductase, the enzyme responsible for conversion of 7DHC to cholesterol (Porter, 2008; Salen et al, 1995; Waterham and Clayton, 2006), which is located on chromosome 11 (Kelley and Hennekam, 2000; Waterham and Clayton, 2006). Cholesterol is a major lipid component of cellular membranes such as myelin, and it is an important structural component of lipid rafts, which play a major role in signal transduction (Porter, 2008; Yu and Patel, 2005). In addition, bile acids, steroid hormones, neuroactive steroids, and oxysterols are all synthesized from cholesterol (Merkens et al, 2009; Porter, 2008). The possible role of these various pathways in the etiology of SLO syndrome is still being defined (Merkens et al, 2009; Porter, 2008).

The cause of the clinical phenotype of SLO syndrome may be related to deficient cholesterol, deficient total sterols, the toxic effects of either 7DHC or compounds derived from 7DHC, or a combination of these factors (Porter, 2008; Yu and Patel, 2005). A single underlying pathologic mechanism is unlikely (Porter, 2008).

The pivotal connection between cholesterol and SLO syndrome involves development and differentiation of the vertebrate body plan, although additional metabolic effects have not been ruled out. Among those proteins exerting decisive influence on patterning during embryogenesis are the Hedgehog proteins. One variant, Sonic hedgehog (Shh), becomes covalently linked to cholesterol at the protein's amino-terminal signaling domain. This linkage is needed to restrict the locus of action of Shh to the region of plasma membrane. Although it was originally suggested that failure to modify Shh could account for multiplicity of structural abnormalities in patients with SLO syndrome (Farese and Herz, 1998), the process is thought to be more complex and to involve other signaling proteins such as Patched (PTCH) and Smoothened (SMO) (Farese and Herz, 1998; Kelley and Hennekam, 2000; Porter, 2008).

CLINICAL FEATURES

Recognition of the biochemical defect in SLO syndrome provided the diagnostic test required to recognize the most mild and most severe cases, substantially expanding the clinical spectrum of the condition. Classic SLO syndrome is often evident at birth; affected patients have microcephaly and facial dysmorphism, including bitemporal narrowing, ptosis, epicanthic folds, anteverted nares, broad nasal tip, prominent lateral palatine ridges, micrognathia, and low-set ears. Other features are 2- to 3-syndactyly of toes (found in 95% of patients), small proximally placed thumbs, and occasionally postaxial polydactyly and cataracts. Males usually have hypospadias, cryptorchidism, and a hypoplastic scrotum, but may have ambiguous or female genitalia. Pyloric stenosis, cleft palate, pancreatic anomalies, Hirschsprung disease, and lung segmentation defects have also been reported. Hypotonia progressing to hypertonia and moderate to severe mental deficiencies are also present. Feeding difficulties and vomiting are common problems in infancy. Irritable behavior and shrill screaming may also pose problems during infancy. Older children frequently have hyperactivity, self-injurious behavior, sleep difficulties, and autistic characteristics. Cranial imaging studies show (and autopsy confirms) defects in brain morphogenesis, including hypoplasia of frontal lobes, cerebellum, and brainstem, dilated ventricles, irregular gyral patterns, and irregular neuronal organization.

Historically, approximately 20% of patients die within the first year of life, although others may survive for more than 30 years. Life expectancy appears to correlate inversely with the number and severity of organ defects and with the kinds and numbers of limb, facial, and genital abnormalities (Kelley and Hennekam, 2000; Tint et al, 1995). Developmental outcomes are also highly variable, ranging from severe mental retardation to normal intelligence. Development of treatment protocols for SLO syndrome may contribute to improvements in prognosis, but improved recognition of more mildly affected patients may explain the increasing reports of SLO syndrome in patients with mild mental retardation or normal intelligence (Jezela-Stanek et al, 2008). Testing for SLO syndrome has been suggested for all patients with idiopathic intellectual impairment, behavioral anomalies, or both, when associated with nonfamilial two- and three-toe syndactyly and failure to thrive (Jezela-Stanek et al, 2008).

DIAGNOSIS

The diagnosis of SLO syndrome is based on findings of elevated levels of 7DHC and 8DHC. Plasma cholesterol levels are usually but not always low; as many as 10% of patients at all ages have normal cholesterol levels (Kelley and Hennekam, 2000). In addition, the standard method for analysis of cholesterol in most hospital laboratories identifies 7DHC and 8DHC as cholesterol. Therefore most laboratories report normal cholesterol levels in patients who have low cholesterol, but elevations of 7DHC and 8DHC sufficient to bring the total level into the "normal" range (Kelley and Hennekam, 2000; Porter, 2008). The difference between mild and more severe disease appears to be one of degree; the enzyme defect is more severe and the block is more complete in patients with severe disease (Kelley and Hennekam, 2000; Tint et al, 1995). Clinical severity in SLO syndrome correlates best with either reduction in absolute cholesterol levels or the sum of 7DHC plus 8DHC expressed as a fraction of total sterol (Waterham and Clayton, 2006). Recently, maternal apolipoprotein E (ApoE) genotype was implicated in phenotype heterogeneity (Witsch-Baumgartner et al, 2004). Maternal ApoE2 genotypes were associated with a severe SLO syndrome phenotype, whereas ApoE genotypes without the E2 allele were associated with a milder phenotype (Witsch-Baumgartner et al, 2004; Yu and Patel, 2005).

Confirmation of diagnosis via molecular analysis is available. Genotype-phenotype correlation, however, is relatively poor (Jezela-Stanek et al, 2008; Porter, 2008). Prenatal diagnosis is possible. A mother carrying an affected fetus may have an abnormally low unconjugated estriol value. Ultrasonography detects many but not all affected fetuses, and biochemical analysis of amniotic fluid and of chorionic villus samples is accurate and unambiguous in most cases (Kelley and Hennekam, 2000). A direct correlation between the level of 7DHC in amniotic fluid and clinical severity has been demonstrated; however, a similar correlation does not exist for the level of cholesterol (Yu and Patel, 2005). When molecular mutations are known, analysis may be useful.

TREATMENT

There are two goals of therapy for SLO syndrome: to increase the level of cholesterol in plasma and other body fluids and to lower the level of 7DHC. Treatment consists of providing exogenous cholesterol, in the form of either dietary cholesterol or cholesterol suspension, to replenish body stores of cholesterol and downregulate the patient's endogenous cholesterol synthesis, thus decreasing the amount of 7DHC produced. A goal of cholesterol supplementation of 20 to 60 mg/kg per day was

initially advocated, but doses higher than 300 mg/kg per day have been used without adverse outcome (Irons et al, 1995; Kelley and Hennekam, 2000). In infants with SLO syndrome, the use of breast milk should be encouraged because it supplies approximately 133 mg/L of cholesterol (Irons et al, 1995).

Providing bile acids to facilitate adequate absorption of dietary cholesterol is controversial, especially because fat malabsorption is unusual and certain bile acids can decrease tissue uptake of cholesterol (Kelley and Hennekam, 2000). Dietary cholesterol supplementation appears to restore both adrenal and bile salt deficiencies (Yu and Patel, 2005). Steroid replacement therapy may still be needed during times of stress or illness. Use of 3-hydroxy-3-methyl-CoA (HMG-CoA) lyase inhibitors such as lovastatin has also been suggested as a mechanism to decrease levels of 7DHC. However, because the results of animal studies suggest that downregulation of cholesterol synthesis might not decrease 7DHC, and because of concern about a decrease in the synthesis of other essential isoprenoid compounds, HMG-CoA reductase inhibitors are not routinely used in therapy (Kelley and Hennekam, 2000). Furthermore, this treatment could be theoretically detrimental in patients with SLO syndrome with little or no enzyme activity (Yu and Patel, 2005). Statins may also impair dietary cholesterol absorption (Merkens et al, 2009). In addition, a retrospective study of simvastatin use in patients with SLO syndrome failed to demonstrate a positive effect on anthropometric measures or behavior (Haas et al, 2007).

Although many questions remain about optimal therapy and outcomes, therapeutic interventions appear to increase plasma cholesterol levels, decrease 7DHC levels, and improve irritability, behavior, and growth (Elias et al, 1997; Irons et al, 1995; Kelley and Hennekam, 2000; Waterham and Clayton, 2006). Parents reported children to be more alert, active, and happier during therapy. Therapy was well tolerated. Unfortunately, a study of 14 patients with SLO syndrome indicated that cholesterol supplementation had hardly any effect on developmental progress (Sikora et al, 2004). Treatment probably does not significantly change sterol levels in brain which are dependent on de novo cholesterol synthesis because of limited ability of cholesterol to cross the blood-brain barrier (Porter, 2008; Waterham and Clayton, 2006). Direct delivery of cholesterol to the CNS by low-pressure catheter infusions has been proposed, but not tested (Yu and Patel, 2005). Gene therapy, the use of neuroactive steroids, and inhibition of glycosphingolipids are also being investigated as possible therapeutic options in SLO syndrome (Merkens et al, 2009).

For maximal benefit, it has been suggested that treatment should begin prenatally, because SLO syndrome has many features that are consistent with in utero involvement of the disease process. Antenatal supplementation by fetal intravenous and intraperitoneal transfusions of fresh frozen plasma were shown to increase fetal cholesterol in one patient (Irons et al, 1999). Treatment should otherwise begin as soon as possible after birth or as soon as the diagnosis is confirmed. Patients with severe SLO syndrome may need gavage or gastrostomy feeding for management of reflux and gastrointestinal dysmotility, and many have protein allergies and require elemental formulas. Growth is often a problem, but the temptation to overfeed must be avoided because overfeeding would contribute to feeding problems and could not rescue intrauterine growth restriction in severe SLO syndrome (Kelley and Hennekam, 2000).

CHAPTER 24

Skeletal Dysplasias and Connective Tissue Disorders

David L. Rimoin and George E. Tiller

The skeletal dysplasias, or osteochondrodysplasias, are disorders of the development and growth of cartilage and bone. The connective tissue disorders involve abnormalities of the cells' supporting and connecting structures in the matrix. In one series of 126,316 deliveries monitored over 15 years, the incidence of skeletal dysplasias was 2.14 in 10,000 (Rasmussen et al, 1996). With the growing use and accuracy of ultrasonography for prenatal care, a greater number of osteochondrodysplasias and connective tissue disorders are diagnosed prenatally.

The skeletal dysplasias have been classified into 37 groups on the basis of radiologic criteria (Superti-Furga and Unger, 2007). Other classifications vary according to molecular, clinical, pathologic, and radiographic criteria and may be confusing. For example, osteogenesis imperfecta (OI) can be classified as either a skeletal dysplasia or a connective tissue disorder. This chapter focuses on several of the more common skeletal dysplasias (see Table 24-1 for an expanded list) and connective tissue disorders that manifest prenatally or perinatally, but the discussion is not exhaustive. The osteochondrodysplasias have been reviewed extensively elsewhere (Cohen, 2006; Superti-Furga et al, 2001; Unger et al, 2007).

There are a large number of different connective tissue molecules, including collagens (over two dozen types), elastin, fibrillin (two types), and microfibril-associated glycoproteins. These molecules are components of tissues such as bone, cartilage, skin, vascular media, tendon, ligaments, and basement membrane in many organs. The heritable disorders of connective tissue are varied, may be very dissimilar clinically, and may manifest in utero or at any age postnatally. Those that may manifest at birth include the infantile (neonatal) form of Marfan syndrome, congenital contractural arachnodactyly (Beals syndrome), cutis laxa, Ehlers-Danlos syndrome, and Menkes disease.

CLINICAL SPECTRA OF DISORDERS WITH COMMON MOLECULAR BASES

The number of clinically distinguishable skeletal dysplasias and connective tissue disorders is extensive. With advances in molecular knowledge, several different dysplasias have been recognized to have mutations in the same genes. In some of these disorders, clinical similarities noted previously suggested a common etiology. One such clinical spectrum includes achondroplasia, hypochondroplasia, severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN), and thanatophoric dysplasia, all of which are caused by mutations in the fibroblast growth factor receptor 3 (*FGFR3*) gene (Bellus et al, 1995; Shiang et al, 1994; Vajo et al, 2000; Wilcox et al, 1998). Another spectrum of disorders includes Stickler syndrome, Kniest dysplasia, spondyloepimetaphyseal dysplasia, spondyloepiphyseal dysplasias, hypochondrogenesis, achondrogenesis type II, and recessive multiple epiphyseal dysplasia, all of which are caused by mutations in the gene for collagen type II, *COL2A1* (Spranger et al, 1994; Winterpacht et al, 1993). With other disorders, the common etiology is not as obvious clinically: diastrophic dysplasia, atelosteogenesis type II, and achondrogenesis type 1B are all caused by mutations in the diastrophic dysplasia sulfate transporter (*DTDST*) gene (Bonafe and Superti-Furga, 2007; Hastbacka et al, 1994, 1996; Superti-Furga et al, 1996). The obverse is also evident, wherein a specific clinical entity (e.g., multiple epiphyseal dysplasias) may be caused by a mutation in one of several genes—a concept known as *genetic heterogeneity*.

APPROACH TO DIAGNOSIS

An early and precise diagnosis is important for prognosis, optimal immediate- and long-term management, accurate genetic counseling about recurrence risk, and identification of other possibly affected family members or disease carriers. An example is the group of disorders with punctate calcifications ("stippling") in epiphyses, called *chondrodysplasia punctata*. There are more than three types, each of which has a different cause and mode of inheritance: autosomal recessive, X-linked recessive, and X-linked dominant (see Table 24-1). As in any uncommon genetic condition, multiple factors may be required to arrive at the correct diagnosis: a complete physical examination, three-generation family history, radiologic studies, and biochemical or molecular tests.

Most skeletal dysplasias cause short stature, which can be proportionate or disproportionate. The disproportion may be evident as a short-limbed or short-trunk form of dwarfism. If the limbs are affected, there may be segmental shortening of the upper arms and thighs (rhizomelia), forearms and legs (mesomelia), or hands and feet (acromelia). Most skeletal dysplasias that manifest at birth involve short limbs. Accurate measurements of length (on a firm surface), arm span, and head and chest circumferences must be plotted on standard growth curves, with calculation of upper and lower body segment ratios to objectively assess disproportion.

Other skeletal characteristics can give important clues for specific disorders:

- Children with achondroplasia and thanatophoric dysplasia have large heads (macrocephaly). Cloverleaf skull deformity is present in some forms of thanatophoric dysplasia.
- A relatively long chest is seen in asphyxiating thoracic dystrophy.
- In achondroplasia the hand is short and the fingers form a trident configuration. In diastrophic dysplasia, there are distinctive "hitchhiker" thumbs.

TABLE 24-1 Skeletal Dysplasias Manifesting Prenatally or Perinatally

Dysplasia	Skeletal Features	Nonskeletal Features	Radiographic Features	Inheritance; Gene	Comments
Lethal					
Achondrogenesis type IB	Soft cranium; round face; short, round chest; very short limbs	Polyhydramnios	Poorly ossified calvarium; ribs short with fractures (beading); nonossified vertebrae; small pelvis; short broad femurs with metaphyseal spikes, short broad tibiae, and fibulae	AR; DTDST (diastrophic dysplasia sulfate transporter)	Same gene as diastrophic dysplasia and atelosteogenesis II
Achondrogenesis type II, hypochondrogenesis	Large head, flat face with cleft palate; short trunk; very short limbs (micromelia)	Fetal hydrops; distended abdomen;	Lack of vertebral mineralization; short limbs (all segments); enlarged cranium with normal ossification	AD; *COL2A1* (type II collagen)	Same gene as for spondyloepiphyseal dysplasia congenita, spondyloepimetaphyseal dysplasia, Stickler syndrome, Kniest syndrome
Asphyxiating thoracic dystrophy	Normal face; narrow, long chest; variable limb shortening	Lethal pulmonary insufficiency	Normal calvarium and vertebrae; very short ribs with anterior cupping; short limbs with wide proximal femoral metaphyses; premature ossification of proximal femoral epiphysis	AR	Survivors may have renal disease; possibly a variant of short-rib polydactyly III
Atelosteogenesis					
Type I	Flat face with cleft palate, micrognathia; very narrow chest; very short limbs (rhizomelic) with equinovalgus deformities; joint dislocations	Prematurity; stillbirth	Flat vertebrae with coronal and sagittal clefts, scoliosis, short ribs (11 pairs), small pelvis with enlarged sacrosciatic notch, short limbs, "drumstick" humeri and femurs, absent fibulas, short metacarpals triangular first metacarpals, dislocated knees	AD; filamin B	Filamin B mutations also seen in boomerang dysplasia, Larsen syndrome, and spondylocarpotarsal syndrome
Type II	Cleft palate, narrow chest, short limbs with dislocations, equinovarus deformities, gap between first and second digits	Laryngeal stenosis; patent foramen ovale	Occasional coronal and sagittal vertebral clefts; short ribs; normal sacrosciatic notch; short "dumbbell" humeri and femurs, small fibulas; large second and third metacarpals; small round midphalanges	AR; *DTDST* (diastrophic dysplasia sulfate transporter)	Same gene as for diastrophic dysplasia, achondrogenesis type IB, and some forms of multiple epiphyseal dysplasia (MED)
Campomelic dysplasia	Large cranium; small face with flat nose bridge, small chin (cleft soft palate); small, narrow chest; bowed thighs and legs, with dimple on leg	Polyhydramnios, congenital cardiac abnormalities, female external genitalia in XY males	Large dolichocephalic calvarium with shallow orbits; short and wavy ribs, often 11 pairs; hypoplastic scapula; small, flat vertebrae; tall, narrow pelvis; relatively long, thin limbs with bent femurs and short tibiae	AD (most are new mutations); *SOX9*	
Chondrodysplasia punctata, rhizomelic type 1 (*RCDP1*)	Face flat; very flat nasal bridge and tip; proximal shortening of limbs	Cataracts; joint contractures; ichthyosiform erythroderma	Wide coronal vertebral clefts; short humeri and femurs; stippled epiphyses of long bones, pelvis and periarticular areas; trapezoid ilia	AR; *PEX7* (peroxisome biogenesis factor 7)	Survivors may live a few years, with severe growth and mental retardation; biochemical abnormalities are decreased RBC plasmalogens and increased phytanic acid
Short-rib polydactyly					Heterogeneous ciliopathies

Continued

TABLE 24-1 Skeletal Dysplasias Manifesting Prenatally or Perinatally—cont'd

Dysplasia	Skeletal Features	Nonskeletal Features	Radiographic Features	Inheritance; Gene	Comments
Types I and III	Hydropic appearance, round flat face, micrognathia, extremely narrow chest, very short limbs, postaxial polydactyly	Cardiac, renal, anal malformations	Normal calvarium; very short, horizontal ribs; flat, wide intervertebral disc spaces; small pelvis; short limbs with lateral and medial metaphyseal spurs	AR; *DYNCH2H1* (dynein heavy chain 1B for type III only)	
Types II and IV	Hydropic; short face, flat nose, CLP; low-set ears; narrow chest, protuberant abdomen; moderately short limbs	Cardiac, renal, respiratory malformations	Very short, horizontal ribs; normal pelvis and vertebrae; short limbs with round metaphyses; premature epiphyseal ossification; polydactyly	AR; NEK1 (never in mitosis gene A-related kinase 1 for type II only)	
Thanatophoric dysplasia	Large cranium, proptosis, flat nasal bridge, narrow chest, very short limbs (all segments)	Polyhydramnios, hydrocephalus, brain anomalies, congenital cardiac abnormalities	Large calvarium, short base, small foramen magnum, cloverleaf skull (type 2); short, splayed, cupped ribs; small, very flat, U-shaped vertebrae; short, small, flat pelvis; short, bowed limbs; metaphyseal flare with spike	AD (most are new mutations); *FGFR3* (fibroblast growth factor receptor 3)	Same gene as for achondroplasia, hypochondroplasia, SADDAN
Nonlethal					
Achondroplasia	Large cranium; frontal bossing, flat nose bridge, short neck; slightly narrow chest; proximal limb shortening, short trident hands; short proximal and middle phalanges; joint laxity; thoracolumbar kyphosis	Hypotonia: delayed motor milestones; spinal stenosis causes spinal compression; small foramen magnum can cause hydrocephalus and apnea	Large calvarium, small foramen magnum, short base; diminished lumbosacral interpedicular space, short pedicles; short ribs with anterior cupping; short humeri and femurs; relatively long fibulas; metaphyseal flare; small iliac wings	AD (most are new mutations); *FGFR3*	Same gene as for hypochondroplasia, SADDAN, and thanatophoric dysplasia
Chondrodysplasia punctata, X-linked recessive	Hypoplasia of the distal phalanges; severe hypoplasia of nose; short stature	Cataracts; hearing loss; congenital ichthyosis, anosmia, and hypogonadism (in contiguous gene deletion patients)	Distal phalangeal hypoplasia; stippled epiphyses of long bones; paravertebral stippling	XLR; *ARSE* (arylsulfatase E)	Usually milder than X-linked dominant form; variable clinical severity, with neonatal death to longevity and diagnosis in adulthood
Chondrodysplasia punctata, X-linked dominant (Conradi-Hunermann syndrome)	Asymmetric rhizomesomelia	Congenital cataracts; ichthyosis; patchy alopecia	Stippled epiphyses of long bones; paravertebral stippling; tracheal calcifications	XLD; *ESP* (3β-hydroxy Δ8-Δ7 sterol isomerase)	Severe form of disease; usually lethal in males; females vary from stillborn to mild (diagnosis in adulthood); elevated 8(9)-cholestenol
Diastrophic dysplasia	Normal cranium; cleft palate; micrognathia; normal chest at birth; very short limbs; thumbs proximally placed and adducted (hitchhiker thumb); severe equinovarus of feet; limited movement of many joints	Cystic masses in auricles (cauliflower ears) during infancy; deafness caused by lack or fusion of ossicles; narrow external auditory canal	Premature ossification of rib cartilage; narrow L1-L5 interpedicular spaces; scoliosis; short limbs; disproportionately short ulna and fibula (mesomelia); broad flared metaphyses; ovoid first metacarpals; variable symphalangism of proximal interphalangeal joints	AR; *DTDST* (diastrophic dysplasia sulfate transporter)	Same gene as atelosteogenesis II, achondrogenesis type IB, and some forms of multiple epiphyseal dysplasia (MED); intrafamilial variability; normal life span if tracheomalacia or scoliosis do not impair respiratory function; normal intelligence

TABLE 24-1 Skeletal Dysplasias Manifesting Prenatally or Perinatally—cont'd

Dysplasia	Skeletal Features	Nonskeletal Features	Radiographic Features	Inheritance; Gene	Comments
Kniest syndrome	Large cranium; flat face with large eyes, flat nasal bridge, cleft palate; short limbs with proximal shortening (more severe in lower limbs), enlarged joints, flexion contractures	Infancy: tracheomalacia; childhood: myopia and retinal detachment, hearing loss, delayed motor development, normal intelligence	Frontal and maxillary hypoplasia with shallow orbits; slightly short ribs; flat vertebrae with coronal clefts; small pelvis with irregular acetabular roof; short limbs with broad, flared metaphyses (dumbbell), lateral bowing of femurs and tibiae; slightly short and broad tubular bones of hands and feet; epiphyses at knees not ossified	AD; *COL2A1* (type II collagen)	Same gene as for spondyloepiphyseal dysplasia congenita, spondyloepimetaphyseal dysplasia, Stickler syndrome, hypochondrogenesis, achondrogenesis type II
Spondyloepiphyseal dysplasia congenita	Flat face, cleft palate, short limbs	Infancy: tracheomalacia; childhood: myopia and retinal detachment, hearing loss, normal intelligence	Frontal and maxillary hypoplasia, flat vertebrae, small pelvis with irregular acetabular roof, short limbs, normal hands and feet	AD; *COL2A1* (type II collagen)	Same gene as for spondyloepimetaphyseal dysplasia, Stickler syndrome, hypochondrogenesis, achondrogenesis type II, Kniest syndrome

AR, Autosomal recessive; *AD*, autosomal dominant; *RBC*, red blood cell; *CLP*, cleft lip with or without cleft palate; *XLR*, X-linked recessive; *XLD*, X-linked dominant.

- Clubfeet may occur in diastrophic dysplasia, Kniest dysplasia, spondyloepiphyseal dysplasias, and OI type II.
- Postaxial polydactyly occurs in short-rib polydactyly and asphyxiating thoracic and chondroectodermal dysplasias. Occasionally, preaxial polydactyly can also occur in the short-rib dysplasias.
- Multiple joint dislocations can manifest at birth in Larsen syndrome, Ehlers-Danlos syndrome type VII, atelosteogenesis, and Desbuquois syndrome.

The presence of extraskeletal abnormalities may provide additional clues to diagnosis, as follows:

- Cleft palate may occur in campomelic, Kniest, spondyloepiphyseal, short-rib polydactyly (Majewski), atelosteogenesis types I and II, hypochondrogenesis, and diastrophic dysplasias.
- Congenital cataracts are frequent in some forms of chondrodysplasia punctata.
- Congenital cardiac defects occur in short-rib polydactyly dysplasias and Ellis van Creveld syndrome.

CLINICAL TESTING

Radiographs of the entire skeleton, including the skull, hands, feet, and lateral spine, are essential for accurate diagnosis. Atlases dedicated to skeletal dysplasias are essential for this purpose (Lachman, 2006; Spranger et al, 2002), even to the experienced radiologist or neonatologist. Ultrasound images of the brain, heart, and kidneys may be helpful if anomalies in those organs are suspected. Detailed family history and measurements of family members may be helpful; more mildly affected members might have gone without a diagnosis. Molecular investigations may be necessary to arrive at the proper diagnosis; given their complexity, such analyses should be considered after consultation with a clinical geneticist.

If the infant or fetus dies, specimens of cartilage and skin fibroblasts should be obtained for histochemical tests, biochemical assays, and molecular analysis; these can be used to make or confirm diagnoses and permit accurate future prenatal diagnosis. Even if the molecular or enzymatic basis of the condition is not understood at the time, the tissue may be useful in the future. If photographs and skeletal radiographs were not obtained premortem, they should be obtained postmortem.

DISORDERS OF BONE FRAGILITY

OSTEOGENESIS IMPERFECTA TYPES II AND III

OI is characterized by increased bone fragility. There are classically four major clinical types: types II and III are the most severe, manifesting prenatally and perinatally (Byers, 2002; Steiner et al, 2005). However, fractures at birth can occur in OI type I. Further heterogeneity in OI has recently been described.

Presentation

OI type II (perinatal lethal type) is estimated to affect 1 in 20,000 to 60,000 infants. Affected infants may be born prematurely, with low birthweight and disproportionately short stature. The limbs are short and bowed with extra, circular skin creases; the hips are abducted and flexed. The head is soft and boggy, and minimal calvarial bone can be felt. The sclerae are dark blue and the chest is narrow. The infant cries with handling because there are many fractures at different stages of healing. Sixty percent of affected babies are stillborn or die during the first day of life, and 80% die by 1 month. With the growing use of ultrasonography, affected fetuses may be detected in the early second trimester because of

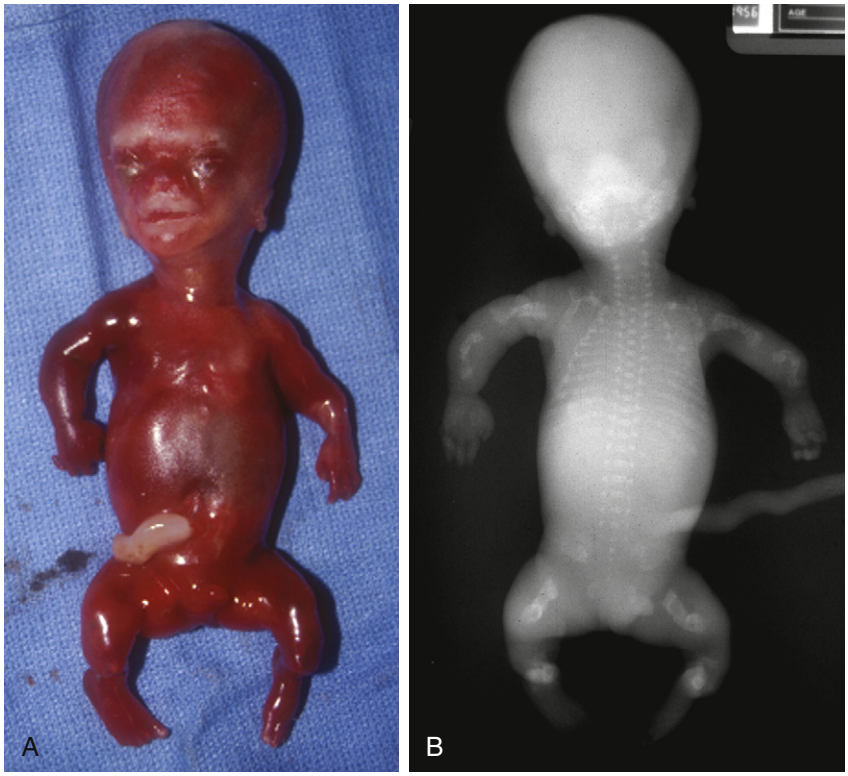

FIGURE 24-1 *(See also Color Plate 5.)* **Osteogenesis imperfecta type II. A,** A 20-week fetus. The limbs are angulated and deformed from multiple fractures. **B,** Radiograph of fetus (20 weeks' gestation) showing an absence of ossification in the calvarium, short telescoped or crumpled humeri and femurs, and short and wavy ribs with fractures.

short and bowed or angulated limbs and narrow thoraces (Figure 24-1).

OI type III (progressive deforming type) can manifest prenatally, perinatally, and in the first 2 years of life. Prenatal and perinatal clinical features resemble those in OI type II, but are less severe (Figure 24-2), and perinatal death is not uncommon. If not present at birth, fractures and deformations of the limbs develop in the first and second years. The highest prevalence of fractures in OI, up to 200, occur in type III. Extremely short stature, with adult heights of 92 to 108 cm, can result from microfractures in growth plates. The head may be large because the calvarium is soft with a large anterior fontanel. The sclerae may be blue initially, but are white by puberty. The head assumes a triangular shape, with a bossed, broad forehead and a tapered, pointed chin. Later in childhood, dentinogenesis imperfecta and hearing loss may develop. Severe kyphoscoliosis may occur, leading to cardiopulmonary compromise, which is the major cause of early death.

Radiographic Features

Radiographs show the femurs in OI type II to be short, broad, and "telescoped" or "crumpled." The tibiae are short and bowed or angulated, and the fibulae may be thin (see Figure 24-1, *B*). There is minimal to no calvarial mineralization. The acetabulae and iliac wings may be somewhat flattened. The ribs are short, wavy, and thin or broad, with "beading" from callus formation at fetal fracture sites.

In OI type III, the femurs are short and deformed, but not crumpled as in OI type II (see Figure 24-2, *B* and *C*). The other long bones are thinner than usual, with healing fractures incurred in utero, bowing, and deformations. The calvarium is undermineralized with a large anterior fontanel, and there are many Wormian bones (small islands of bone in the suture spaces; see Figure 24-2, *D*). The ribs are thin and gracile.

Etiology

OI is most commonly caused by mutations in one of the two genes for type I collagen (*COL1A1* and *COL1A2*), the predominant protein building block of bone. More clinically severe forms of OI are the result of qualitatively abnormal collagen synthesis, rather than decreased production (Byers, 2002).

Inheritance

A fetus or infant with OI type II or III is usually the result of a spontaneous dominant-acting gene mutation, but there is a small risk of recurrence (approximately 6%) in subsequent siblings because of parental somatic or gonadal mosaicism. The parent is usually asymptomatic but may have minimal manifestations, such as short stature. Most cases of OI are inherited as autosomal dominant traits, although rare recessive forms have been shown to be caused by mutations in the cartilage-associated protein CRTAP (Barnes et al, 2006), prolyl 3-hydroxylase (LEPRE1), and cyclophylin B (van Dijk et al, 2009).

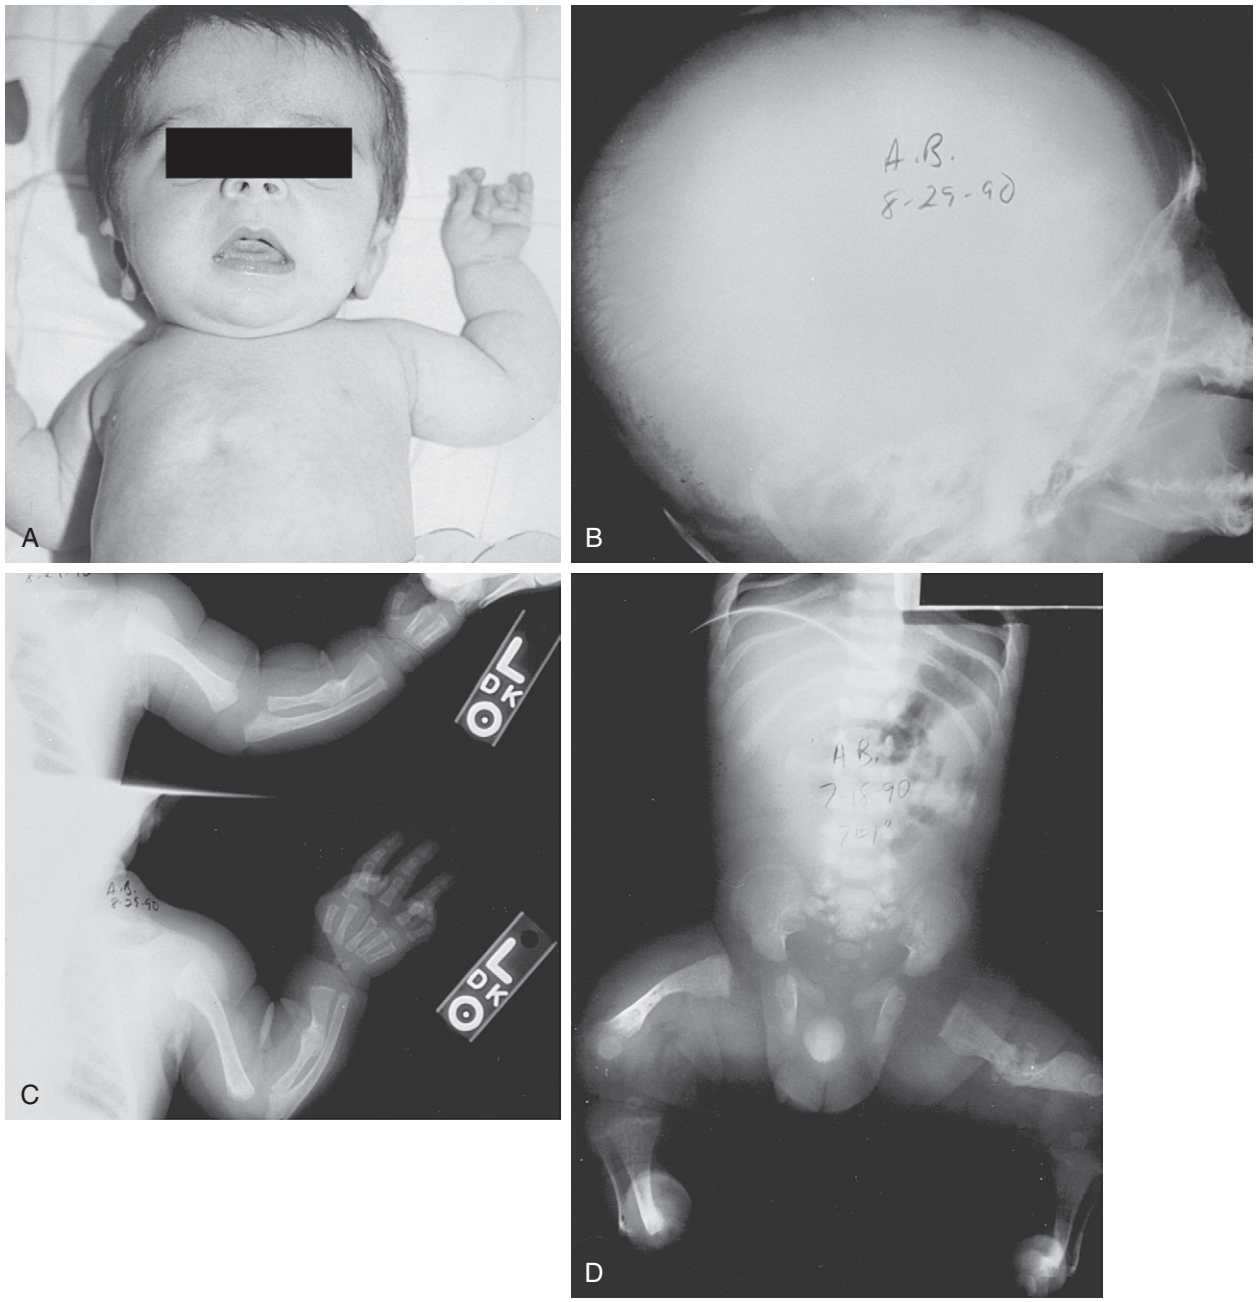

FIGURE 24-2 Osteogenesis imperfecta type III. A, Neonate with normal face, short neck, slightly short limbs. **B,** Radiograph shows that the calvarium is undermineralized with Wormian bones. **C,** Radiograph shows the upper limbs, which have bowed humeri and callus in the ulnae. **D,** Radiograph shows lower limbs with moderately short, thick femora, and angulated tibiae and fibulae. (*Courtesy Paige Kaplan, Children's Hospital of Philadelphia, Philadelphia, Penn.)*

Differential Diagnosis

Other lethal skeletal dysplasias may have similar abnormalities to those in OI type II and may be difficult to distinguish by prenatal ultrasonography; however, in experienced hands they can be differentiated based on several ultrasound findings. Krakow et al (2008) did a retrospective analysis of 1500 prenatally diagnosed cases of skeletal dysplasias. The three most common prenatal-onset skeletal dysplasias were osteogenesis imperfecta type 2, thanatophoric dysplasia, and achondrogenesis 2, accounting for almost 40% of cases. Postnatal radiographs clearly reveal distinctive differences among thanatophoric dysplasia, campomelic dysplasia, achondrogenesis, and perinatal hypophosphatasia, among others.

Management

If the diagnosis of OI is made prenatally, cesarean delivery has not been shown to decrease fracture rate or improve survival rate of severely affected fetuses (Cubert et al, 2001). Those severely affected with OI II are not expected to survive the neonatal period. In OI type III, the neonate needs careful handling to minimize pain and prevent further fractures. Analgesia alleviates pain. Consideration can

be given to treatment with bisphosphonates (using intravenous pamidronate), which increase bone density, reduce the frequency of fractures and pain, possibly prevent short stature and deformations, and permit ambulation (Aström et al, 2007). It is prudent to treat only severely affected children in whom the clinical benefits outweigh potential long-term effects.

Handling an Infant With Osteogenesis Imperfecta

When changing the diapers of an infant with OI, place a hand behind the buttocks with the forearm supporting the legs. Similarly, when the infant is lifted the buttocks, head, and neck must be supported. The infant can be laid on a pillow to be carried. To transport the infant, an infant seat that reclines as much as possible and allows easy placement or removal should be used. The seat can be padded with egg crating or 1-inch foam. A layer of foam can be placed between the seat's harnesses and the child for extra protection. The car seat must always be placed in the back seat. Sling carriers and "umbrella" strollers should not be used for infants with OI because they do not give sufficient leg, head, and neck support.

PERINATAL HYPOPHOSPHATASIA

Presentation

Perinatal hypophosphatasia is a lethal condition characterized by short, deformed limbs, a soft skull, blue sclerae, and undermineralization of the entire skeleton, so that many bones cannot be visualized and may seem absent on radiography. In the skull, only the base can be visualized radiologically. There may be rachitic changes and fractures. Seizures that are responsive to pyridoxine may occur. There is polyhydramnios during pregnancy, and death can occur in utero. The disorder affects approximately 1 in 100,000 live births; neonatal death is common (Whyte, 2000).

Radiographic Features

The radiologic features of perinatal hypophosphatasia include polyhydramnios (prenatal); underossification, especially of the calvarium and long bones (with marked variability); small thoracic cavity; short, bowed limbs; spurs in the middle portion of the forearms and lower legs; and dense vertebral bodies.

Etiology

Mutations in the *ALPL* gene are responsible for deficiency of the tissue-nonspecific isoenzyme of alkaline phosphatase (TNSALP), thus causing perinatal hypophosphatasia. The serum alkaline phosphatase (ALP) value is low. Serum values of inorganic pyrophosphate and pyridoxal 5′-phosphate (putative natural substrates for TNSALP) may be elevated, and urinary phosphoethanolamine is elevated (Mornet and Nunes, 2007).

TNSALP acts on multiple substrates: the essential function of TNSALP is in osteoblastic bone matrix mineralization. TNSALP hydrolyzes inorganic pyrophosphate to phosphate, thought to be critical in promoting osteoblastic mineralization. If TNSALP is deficient, there is extracellular accumulation of inorganic pyrophosphate, which inhibits hydroxyapatite crystal formation and mineralization of the skeleton. TNSALP is also needed for delivery of pyridoxal-5-phosphate into cells where it is a cofactor (vitamin B_6).

Inheritance

Perinatal hypophosphatasia is inherited as an autosomal recessive trait, with a 25% recurrence risk in future pregnancies. Prenatal diagnosis is optimized through the use of ultrasonography, assay of TNSALP activity in amniocytes, DNA mutation analysis if the previously affected infant's mutation was known, or a combination of these methods.

Differential Diagnosis

Differential diagnoses are osteogenesis imperfecta type II and achondrogenesis.

Management

Treatment is primarily supportive and directed toward minimizing pain and discomfort. Clinical trials with bone-targeted human recombinant enzyme replacement therapy are underway.

FGFR3 SPECTRUM

ACHONDROPLASIA

Presentation

Achondroplasia is the most common of the nonlethal chondrodysplasias; it affects 1 in 25,000 live births. It is characterized by short stature with short limbs, particularly rhizomelic (proximal) and acromelic (hands) shortening with trident hand configuration, large head with frontal prominence ("bossing"), flat nasal bridge and midface, long narrow trunk, joint laxity, and development of thoracolumbar kyphosis ("gibbus") in infancy (Figure 24-3).

The foramen magnum and cervical spinal canal may be narrow and can cause compression of the spinal cord. Standards have been published for foramen magnum size in achondroplasia (Hecht et al, 1985). Compression of the lower brainstem and cervical spinal cord can lead to hypotonia, central apnea, retardation, quadriparesis, and (rarely) sudden death (Pauli et al, 1984). Perinatal or infantile death can occur, but is unusual. Infants often sleep with their neck hyperextended, and symptoms can be exaggerated by neck flexion (Danielpour et al, 2007).

Radiographic Features

The calvarium is large with a relatively small foramen magnum and a short base. The lateral cerebral ventricles may be large, but hydrocephalus is not a common

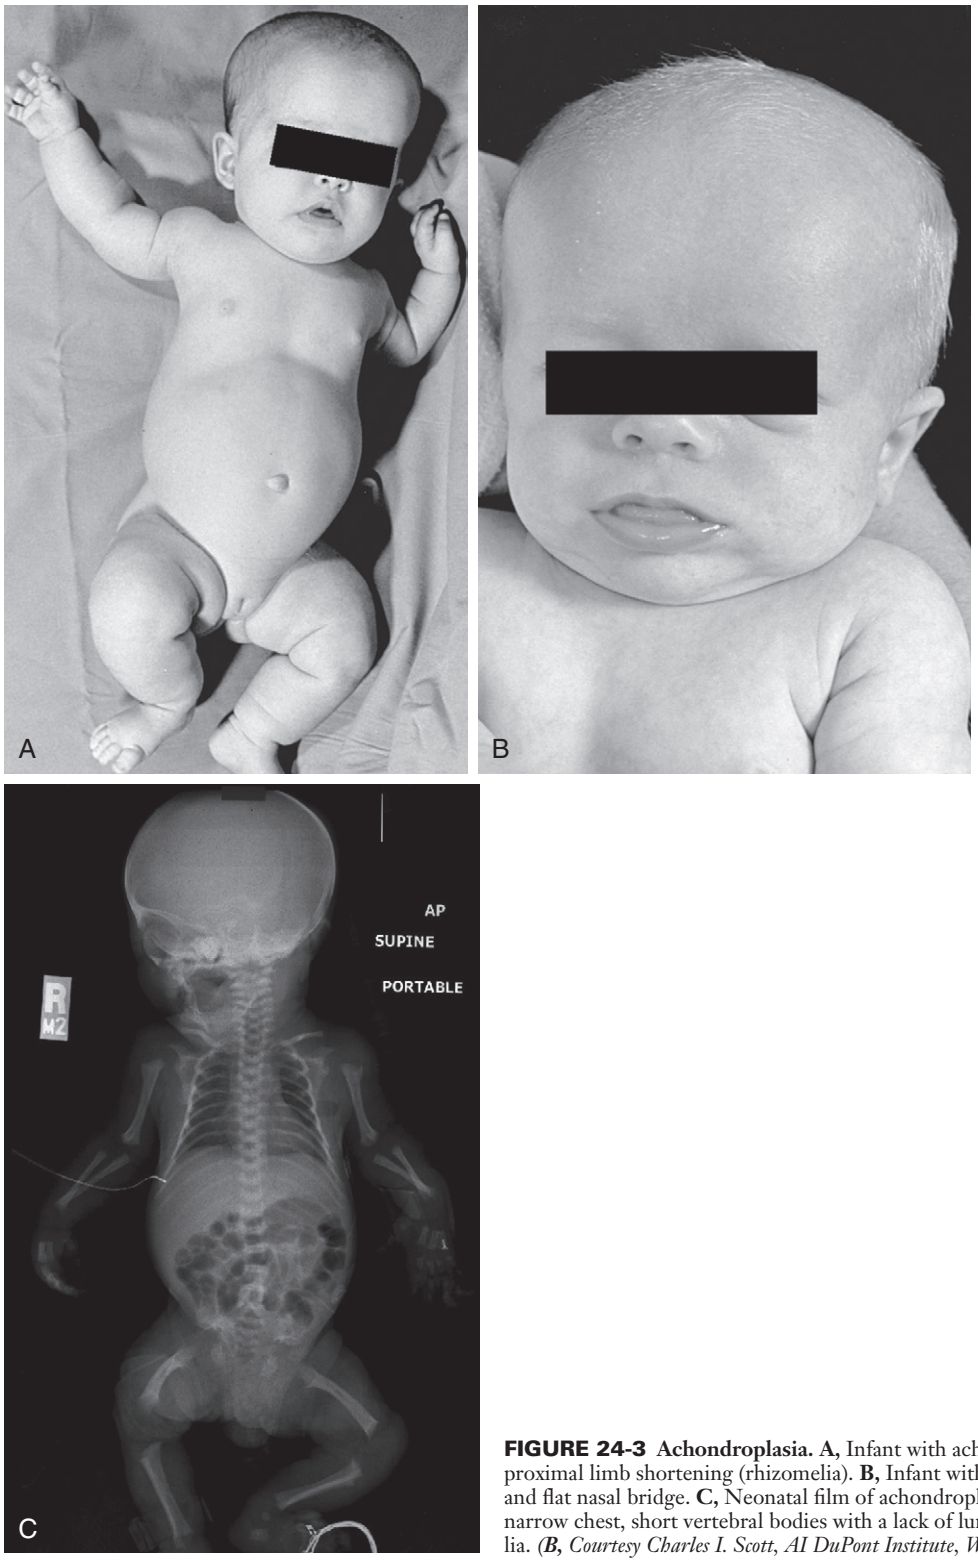

FIGURE 24-3 Achondroplasia. A, Infant with achondroplasia has macrocephaly and proximal limb shortening (rhizomelia). **B,** Infant with achondroplasia exhibits frontal bossing and flat nasal bridge. **C,** Neonatal film of achondroplasia illustrates a large skull, a somewhat narrow chest, short vertebral bodies with a lack of lumbar interpediculate flare, and rhizomelia. *(**B,** Courtesy Charles I. Scott, AI DuPont Institute, Wilmington, Del.)*

complication. The proximal long bones (humeri and femurs) are short, including the femoral neck. Fibulae are longer than tibiae. There is metaphyseal flaring. The hand is short with a trident configuration of the fingers, with short proximal and middle phalanges. Vertebrae are small and cuboid with short pedicles, and there may be anterior beaking of the first or second lumbar vertebrae; there is lack of flare of the interpedicular distance in the lumbar vertebrae. The pelvis has squared iliac wings ("elephant ear" appearance), a narrow greater sciatic notch, and flat acetabular roofs. Compression of the cervical cord, if present, can be ascertained with magnetic resonance imaging cerebrospinal fluid flow studies in flexion and extension.

Etiology

The cause of achondroplasia is a mutation of the gene for fibroblast growth factor receptor 3 (*FGFR3*). The FGFR3 protein is a membrane-spanning tyrosine kinase receptor, which may form dimers with other gene family members *FGFR1*, *FGFR2*, and *FGFR4*. The heterodimers serve as receptors for several fibroblast growth factors (Cohen, 2006). More than 97% of persons with achondroplasia have a mutation in the transmembrane domain of the *FGFR3* gene, in which glycine is substituted by arginine (Gly380Arg; Shiang et al, 1994). The same gene is mutated at different sites in hypochondroplasia, thanatophoric dysplasia, SADDAN, Muenke craniosynostosis, and Crouzon craniosynostosis syndrome with acanthosis nigricans (Vajo et al, 2000). Histopathologic examination demonstrates a defect in the organization and maturation of the cartilage growth plates of long bones because of differing degrees of constitutive activation of the receptor.

Inheritance

The inheritance pattern in achondroplasia is autosomal dominant. Approximately 80% of cases are sporadic occurrences in a family, representing new mutations. Cases may be associated with advanced paternal age, with molecular confirmation that the new mutations are of paternal origin. Affected individuals are fertile, and achondroplasia is transmitted as a fully penetrant autosomal dominant trait, meaning that each person who inherits the mutant gene will manifest the condition.

Differential Diagnosis

Differential diagnoses are SADDAN (Vajo et al, 2000) hypochondroplasia (Bellus et al, 1995).

Management

The infant with achondroplasia is often hypotonic; together with the large head, the hypotonia leads to delayed motor milestones. Development of thoracolumbar kyphosis may be exacerbated by unsupported sitting before truncal muscle strength is adequate; therefore infants should not be carried in flexed positions (including soft sling-carriers and umbrella strollers). Rear-facing car safety seats should always be used. Most infants lose their kyphosis and develop lumbar lordosis when they begin walking.

Hydrocephalus may occasionally develop during the first 2 years, so the head circumference and body length should be carefully measured and plotted on standard achondroplasia growth charts (Trotter et al, 2005). Routine imaging of the skull and brain is not recommended; however, development of hyperreflexia, hypotonia, or apnea may herald the development of clinically significant cord compression. Surgical decompression at the foramen magnum or the upper cervical spine may prevent neurologic damage, although most patients usually gain motor milestones late but spontaneously, because the foramen grows faster than the cord.

The upper airway in individuals with achondroplasia is small, often leading to obstructive apnea, snoring, and chronic serous otitis media beyond infancy. Treatment may consist of tonsillectomy, adenoidectomy, and placement of myringotomy tubes. Parents should be counseled about the clinical and hereditary aspects of the disorder and given a copy of the guidelines for health supervision of children with achondroplasia issued by the American Academy of Pediatrics (Trotter et al, 2005).

THANATOPHORIC DYSPLASIA

Presentation

Thanatophoric dysplasia is one of the most common lethal dysplasias (Unger et al, 2007), occurring in 1 in 45,000 births. It is characterized by extremely short limbs, long narrow trunk, large head with bulging forehead, prominent eyes, flat nasal bridge, wide fontanel, and occasionally cloverleaf skull deformity (Figure 24-4). It is differentiated into types I and II on the basis of radiologic features. Death occurs in the neonatal period from respiratory insufficiency. Polyhydramnios is common during pregnancy.

Radiographic Features

Femurs are short, flared at the metaphyses with a medial spike, and are bowed (type I) or straight (type II); other long bones are also short and bowed (see Figure 24-4). The calvarium is large with a short base and small foramen magnum; cloverleaf skull is sometimes present in type I and is severe in type II. Vertebrae are strikingly flat (platyspondyly) with a U- or H-shape in anteroposterior projection and uniform interpediculate narrowing. Ribs are short, cupped, and splayed anteriorly (Lachman, 2006).

Etiology

Thanatophoric dysplasia represents the severe end of the FGFR3 spectrum. In thanatophoric dysplasia type I, the most common mutation in the extracellular domain is a substitution of arginine at position 248 by cysteine (Arg248Cys), but other mutations have been described throughout the gene. In all studied cases of thanatophoric dysplasia type II, there is a substitution of lysine at position 650 by glutamate (Lys650Glu; Wilcox et al, 1998).

Inheritance

All cases of thanatophoric dysplasia, as with most cases of achondroplasia and hypochondroplasia, occur sporadically and result from new autosomal dominant mutations. Nevertheless, there may be a small risk of recurrence to siblings of a sporadic case, possibly caused by gonadal mosaicism.

Differential Diagnosis

Differential diagnoses are OI types II and III, achondroplasia (severe), achondrogenesis, and hypochondrogenesis.

Management

If the condition is diagnosed prenatally, the couple should receive genetic counseling and anticipate neonatal death. If the diagnosis is suggested after delivery and radiographically confirmed, management is solely supportive, with death from pulmonary insufficiency usually occurring within hours to days.

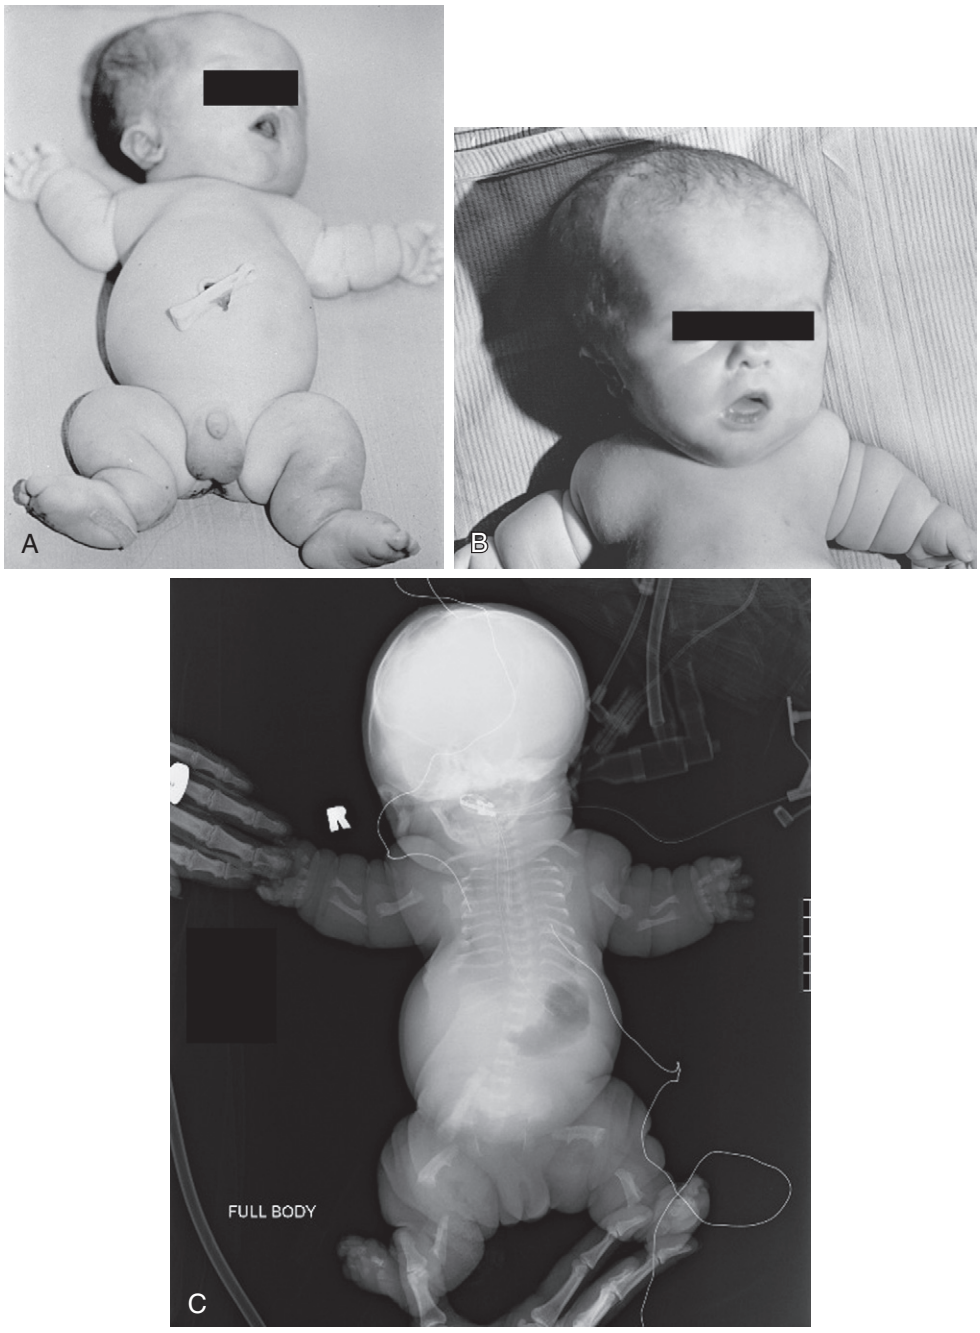

FIGURE 24-4 *(See also Color Plate 6.)* **Thanatophoric dysplasia. A,** Neonate with thanatophoric dysplasia has a large head, narrow chest, short limbs, extra creases on the limbs, short hands with trident fingers, and angulated abducted thighs. **B,** Neonate with thanatophoric dysplasia has a face with a bossed forehead, flat nose bridge, short neck, very short limbs with extra creases, and trident fingers. **C,** Radiograph of an infant with thanatophoric dysplasia demonstrates a large calvarium, short ribs with anterior splaying, flat vertebral bodies (platyspondyly), and short bowed femurs with medial metaphyseal spike. ***(B,*** *Courtesy Montreal Children's Hospital, Montreal, Quebec, Canada.)*

COL2A1 SPECTRUM

SPONDYLOEPIPHYSEAL DYSPLASIA CONGENITA

Presentation

Spondyloepiphyseal dysplasia congenita (SEDC) manifests with shortened neck, trunk and limbs, normal-sized hands and feet, flat facial profile, and occasional cleft palate and clubfoot (Unger et al, 2007). The name is derived from the spinal (spondylo-) and growth plate (epiphyseal) involvement. *Congenita* indicates that the condition is present from birth.

Radiographic Features

Radiographic features include ovoid or pear-shaped vertebral bodies in infancy, with platyspondyly more evident at a later age; odontoid hypoplasia evident in early childhood; midface hypoplasia; retrognathia; mild rhizomelia

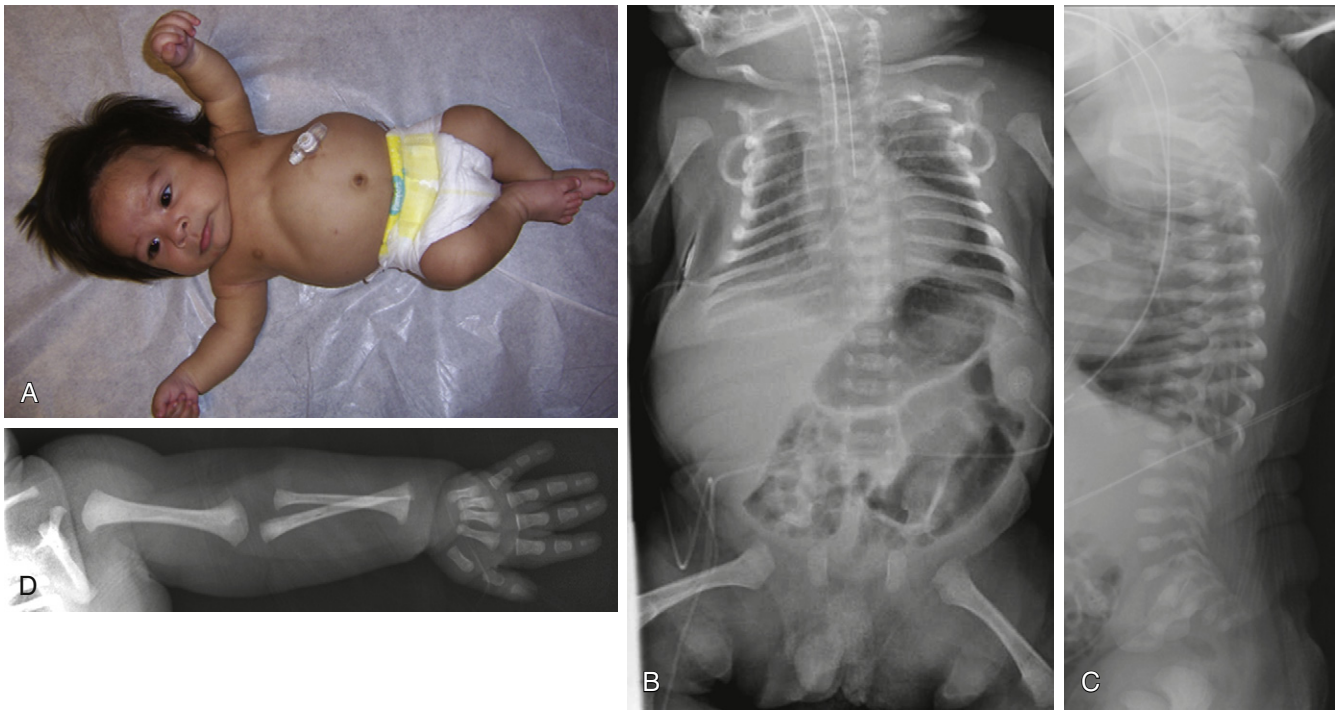

FIGURE 24-5 *(See also Color Plate 7.)* **Spondyloepiphyseal dysplasia congenita. A,** A 2-month-old infant demonstrating short neck, trunk, and limbs. Note the flat facial profile and normal size of hands and feet. **B,** Anteroposterior radiograph reveals platyspondyly and short chest. **C,** Lateral radiograph reveals platyspondyly. **D,** Upper limb radiograph reveals rhizomelia, mesomelia, and a normal-sized hand.

and mesomelia (Figure 24-5); absent ossification of the os pubis; apparent decreased bone age caused by epiphyseal involvement; and development of coxa vara, variable kyphosis, and scoliosis in childhood

Etiology

SEDC is caused by mutations in the gene for type II collagen (*COL2A1*), the predominant protein building block of cartilage. Mutations in *COL2A1* are also responsible for Kniest dysplasia, some forms of spondyloepimetaphyseal dysplasia and Stickler syndrome, and the perinatal lethal disorders achondrogenesis type II and hypochondrogenesis (Spranger et al, 1994; Tiller et al, 1995; Winterpacht et al, 1993).

Inheritance

SEDC is inherited in an autosomal dominant pattern. Offspring of affected individuals are at 50% risk for inheriting the disorder. Recurrence risk for unaffected parents is approximately 6%, because of parental gonadal mosaicism.

Differential Diagnosis

Differential diagnoses are the milder form of hypochondrogenesis and Morquio syndrome.

Management

Neonates may require intubation because of upper airway compromise. Care must be given when manipulating the cervical spine (as in endotracheal intubation), because of odontoid hypoplasia. C1-C2 fusion may be required in early childhood to stabilize the cervical spine. Annual hearing screens are recommended during childhood. Regular ophthalmologic evaluation (semiannually before school age) is essential to detect early development of retinal detachment and to manage myopia. Osteoarthritis is a common feature in early adulthood, often requiring hip arthroplasty.

ACHONDROGENESIS II–HYPOCHONDROGENESIS

Presentation

The severe end of the COL2A1 spectrum manifests with fetal hydrops and maternal polyhydramnios, severe short trunk and limbs, and fetal or neonatal death caused by pulmonary hypoplasia.

Radiographic Features

Radiographic features include prenatal polyhydramnios, a large calvarium with normal ossification, midface hypoplasia, retrognathia, platyspondyly with underossification of the vertebral bodies (achondrogenesis II), short chest with a protuberant abdomen, marked shortening of all tubular bones (Figure 24-6), and small iliac wings.

Etiology

Achondrogenesis II–hypochondrogenesis is caused by mutations in the gene for type II collagen (*COL2A1*), the predominant protein building block of cartilage (Mortier et al, 2000).

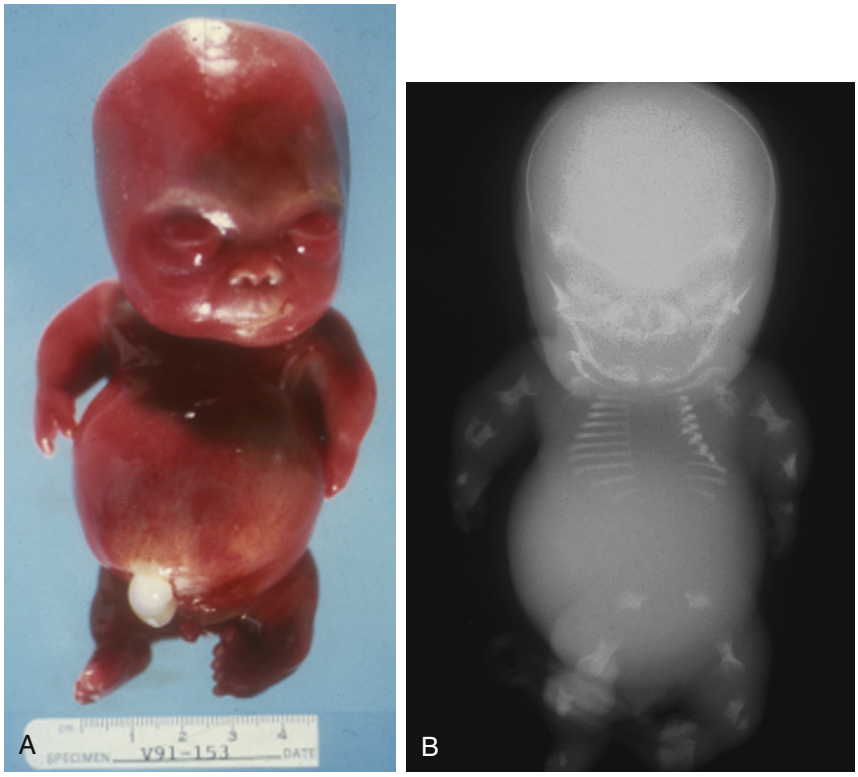

FIGURE 24-6 Achondrogenesis type II. A, This 20-week fetus demonstrates small chest and short limbs. **B,** This radiograph demonstrates poor ossification of vertebral bodies and short limbs.

Inheritance

All cases of achondrogenesis II–hypochondrogenesis are caused by spontaneous dominant-acting mutations in *COL2A1*. Recurrence risk has been reported as high as 6%, because of parental gonadal mosaicism (Forzano et al, 2007).

Differential Diagnosis

Differential diagnoses are achondrogenesis type I and osteogenesis imperfecta types II and III.

Management

If the condition is diagnosed prenatally, the couple should receive genetic counseling and anticipate neonatal death. If the diagnosis is suggested after delivery and radiographic confirmation is obtained, management is solely supportive, with death from pulmonary insufficiency usually occurring within hours to days.

DTDST SPECTRUM

DIASTROPHIC DYSPLASIA

Presentation

Newborns with diastrophic dysplasia exhibit limb shortening, cystic ear swelling, hitchhiker thumbs (developing several days after birth), spinal deformities (especially cervical kyphosis), and contractures of the large joints (Figure 24-7). Clubfoot and ulnar deviation of the fingers may also be present. On occasion the disease can be lethal at birth, but most individuals survive the neonatal period (Bonafe and Superti-Furga, 2007).

Radiographic Features

The most characteristic clinical and radiologic feature is the proximally-placed hitchhiker thumb, with ulnar deviation of the fingers. Cervical kyphosis is a frequent finding. Long bones are moderately shortened and thick, with mild metaphyseal flaring, rounding of the distal femur, and bowing of the radius and tibia. Severe talipes equinovarus may be present. Iliac wings are hypoplastic, with flat acetabular roofs. The chest can be narrow, bell shaped, or both. Narrowing (lack of flare) of the interpedicular distance in the lumbar spine is reminiscent of achondroplasia.

Etiology

Diastrophic dysplasia is caused by mutations in the diastrophic dysplasia sulfate transporter gene (*DTDST*), which also cause the lethal disorders achondrogenesis type 1B and atelosteogenesis type 2, as well as a rare recessive form of multiple epiphyseal dysplasia. The gene product is a sulfate-chloride exchanger of the cell membrane (Superti-Furga et al, 1996); this affects incorporation of sulfate into proteoglycans (mucopolysaccharides), especially chondroitin sulfate B–containing proteoglycans, which are prevalent in cartilage.

FIGURE 24-7 Diastrophic dysplasia. A, This infant has prominent eyes, small chin, slightly narrow chest, proximally placed angulated thumbs, and short limbs. **B,** Neonate profile showing small chin, swollen ears, and short neck. Note the proximally placed, angulated thumb. **C,** View of the neonate's hand shows the proximally placed angulated thumb and mild syndactyly. *(Courtesy Paige Kaplan, Children's Hospital of Philadelphia, Philadelphia, Penn.)*

Inheritance

Diastrophic dysplasia is inherited in an autosomal recessive pattern. Siblings of affected individuals are at 25% risk for inheriting an abnormal allele from both carrier parents.

Differential Diagnosis

Differential diagnoses are atelosteogenesis type II (part of the DTDST spectrum), spondyloepiphyseal dysplasia, and arthrogryposis.

Management

Mechanical ventilation may be required because of small chest circumference and a floppy airway. Maintenance of joint mobility and proper positioning through physical therapy is essential. Serial casting and or surgical correction of clubfeet may be required. Cervical kyphosis can impede endotracheal intubation and can result in cord compression, but may resolve spontaneously during infancy.

ACHONDROGENESIS 1B

Presentation

Achondrogenesis type IB is characterized by short stature, extremely short limbs, a relatively large head with a round face, short nose, small mouth, soft skull, and very short neck (Borochowitz et al, 1988). Polyhydramnios during pregnancy, premature delivery, and hydrops are common. The affected infant is stillborn or dies within hours of birth.

Radiographic Features

The long bones are extremely short, with square, globular, or triangular shapes and medial spikes in the metaphyses of the femurs (Figure 24-8). The calvarium and vertebrae are poorly ossified (type IB), and the ribs are short.

Etiology

Achondrogenesis type 1B is caused by mutations in the *DTDST* gene (see Diastrophic dysplasia, earlier).

Inheritance

Achondrogenesis 1B is inherited in an autosomal recessive pattern. Siblings of affected individuals are at 25% risk for inheriting an abnormal allele from both carrier parents.

Differential Diagnosis

Differential diagnoses are atelosteogenesis type II (part of DTDST spectrum), achondrogenesis type II, and hypochondrogenesis.

Management

If the condition is diagnosed prenatally, the couple should receive genetic counseling and anticipate neonatal death. If the diagnosis is suggested after delivery and radiographic confirmation is obtained, management is solely supportive, with death from pulmonary insufficiency usually occurring within hours to days.

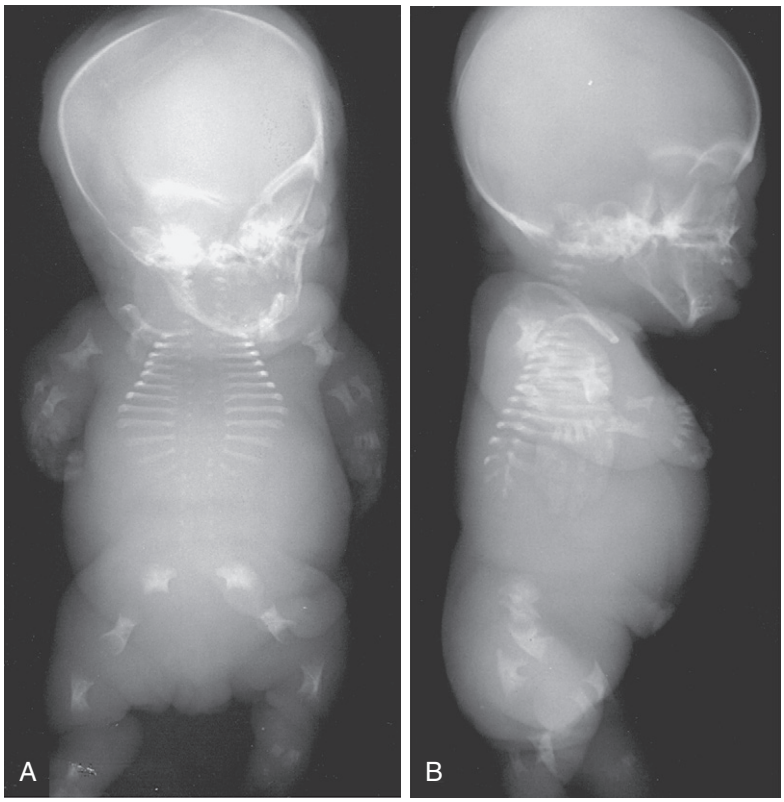

FIGURE 24-8 **A** and **B,** Achondrogenesis type IB. Cervical, thoracic, and lumbar vertebral bodies are not ossified, the sacrum is not ossified, the ribs are short, and the limbs are extremely short with medial femoral metaphyseal spikes. *(Courtesy Elaine Zackai, Children's Hospital of Philadelphia, Philadelphia, Penn.)*

OTHER SKELETAL DYSPLASIAS

CAMPOMELIC DYSPLASIA

Presentation

Campomelic dysplasia is characterized by short stature (birth length of 35 to 49 cm), large dolichocephalic skull, large anterior fontanel, high forehead, flat face, widely spaced eyes with short palpebral fissures, low-set ears, cleft soft palate, micrognathia, relatively long and slender thighs and upper arms, short bowed legs with dimples in the midshaft (in most cases), narrow chest, and kyphoscoliosis (Figure 24-9). Sex reversal or ambiguous genitalia affects 75% of the chromosomal males; there may be internal and external genital abnormalities (from mild anomalies to complete sex reversal) in XY males (Meyer et al, 1997; see Figure 24-9, *A* and *B*). Absence of the olfactory bulbs and tracts as well as heart and renal malformations may occur. Death, usually in infancy, results from pulmonary hypoplasia, tracheomalacia, or cervical spinal instability. Survivors are usually globally developmentally delayed. A few more mildly affected people without bowed limbs have been reported (Unger et al, 2008).

Radiographic Features

The most characteristic finding is midshaft angulation (campomelia) of the femurs, although it is not a constant finding. Other features include hypoplastic, undermineralized cervical vertebrae and thoracic pedicles; narrow iliac wings with dislocated hips; brachydactyly; clubfeet; anterior bowing of tibia; bell-shaped chest with thin, wavy ribs (with only 11 pairs); and scapular hypoplasia.

Etiology

Campomelic dysplasia is caused by mutations in or near the SRY-related HMG-Box gene 9 (*SOX9;* Tommerup, 1993). *SOX9*, with homology to the *SRY* gene, is a transcription factor involved in both bone formation and testis development.

Inheritance

Campomelic dysplasia is an autosomal dominant trait. Most cases are new sporadic occurrences in a family; recurrence caused by gonadal mosaicism has been reported (Smyk et al, 2007).

Differential Diagnosis

Differential diagnoses are osteogenesis imperfecta types II and III, diastrophic dysplasia, kyphomelic dysplasia, thanatophoric dysplasia, and spondyloepiphyseal dysplasia congenita (severe).

Management

Survival beyond the newborn period is rare; therefore support is primarily directed toward comfort measures. In survivors, care must be given to the cervical spine, which may be unstable. Chromosomal studies to determine gender and pelvic ultrasonography to examine internal genitalia

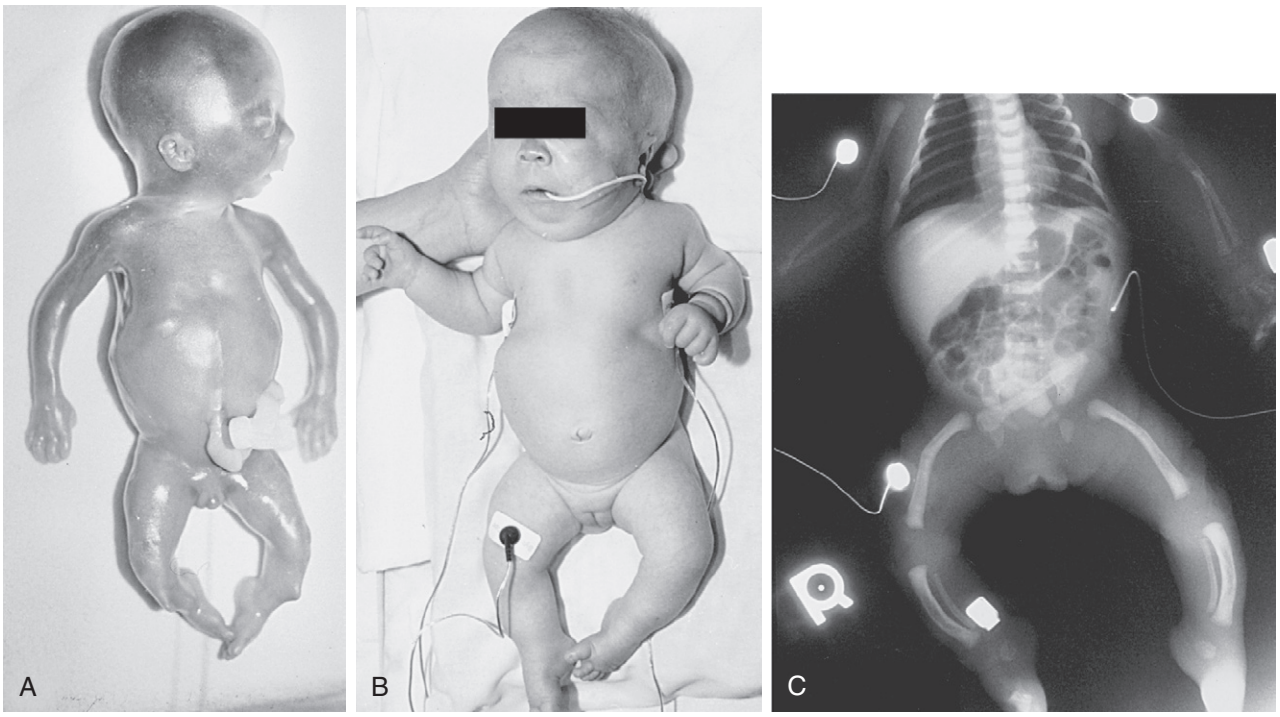

FIGURE 24-9 Campomelic dysplasia. A, 46,XY female 22-week-old fetus with normal head, long philtrum, micrognathia, low-set ears, mild narrowing of chest, proximally placed thumbs, and bowed or angulated lower limbs resembling those of osteogenesis imperfecta type II but less shortened. The external genitalia are female. **B,** Neonate with the long-limb form of the disorder has a relatively large head, micrognathia, narrow chest, and bowing of lower limbs with characteristic dimpling of lower leg. **C,** Radiograph shows the narrow chest, the relatively long, thin limb bones with bowing of the femurs and tibiae, and a long, narrow pelvis. *(Courtesy Paige Kaplan, Children's Hospital of Philadelphia, Philadelphia, Penn.)*

may be performed. Cleft palate may be repaired in those able to feed orally, and clubfeet may require casting or surgical correction.

CONNECTIVE TISSUE DISORDERS

CONGENITAL (NEONATAL, INFANTILE) MARFAN SYNDROME

Presentation

Infants with neonatal congenital Marfan syndrome (cMS) have a long, thin body and can have an aged appearance because of a lack of subcutaneous tissue and wrinkled, sagging skin (Morse et al, 1990; Figure 24-10). The craniofacial features include dolichocephaly, deep-set eyes with large or small corneas (and occasionally cataracts), high nasal bridge, high palate, small pointed chin with a horizontal skin crease, and large simple or crumpled ears. The fingers and toes are long and thin (arachnodactyly). Some joints are hyperextensible, and others have flexion contractures causing clubfoot, dislocated hips, or adducted thumbs. Infants tend to exhibit hypotonia with low muscle mass. Lenses are usually not subluxated at birth. The most important cause of morbidity and mortality is severe cardiovascular disease, which affects almost every neonate with cMS—namely, mitral and tricuspid valve prolapse and insufficiency and aortic root dilatation. The ascending aorta may be dilated and tortuous. Many infants die in the first year of life from congestive heart failure. Survivors have chronic hypotonia and contractures, are unable to walk, and require many surgical procedures.

Radiographic Features

Radiographic features include pectus deformity, spontaneous pneumothorax, dural ectasia, aortic root dilatation, and mitral valve prolapse. Many of these features may not be present in the newborn period.

Etiology

Congenital MS is caused by mutations in the gene encoding fibrillin 1 (*FBN1*; Dietz et al, 1991). Fibrillin is a glycoprotein associated with microfibrils, which form linear bundles in the matrices of many tissues, such as aorta, periosteum, perichondrium, cartilage, tendons, muscle, pleura, and meninges. There are two regions in *FBN1* in which many mutations causing cMS occur; these lie among exons 24 to 27 and exons 31 and 32 (Dietz, 2009). Molecular analysis does not yield mutations in all cases.

Inheritance

Marfan syndrome is an autosomal dominant disorder. Most neonates with cMS are sporadic occurrences within a family (Dietz et al, 1991; Morse et al, 1990). However, there is one well-documented neonate with cMS whose father had classic Marfan syndrome except for average height (Lopes et al, 1995).

Differential Diagnosis

Differential diagnoses are congenital contractural arachnodactyly (CCA), autosomal recessive cutis laxa, and Loeys-Dietz syndrome.

FIGURE 24-10 Congenital Marfan syndrome. A, Neonate with long, thin trunk and limbs (particularly the feet), lack of adipose tissue, and multiple skin creases giving an aged appearance. The ears are large and simple, and the chin is small with a horizontal crease. There are flexion contractures at the joints. **B,** The neonate's face shows laxity of skin, typical horizontal chin crease, and a pointed chin. The fingers are long with adduction contractures of the thumbs, which extend past the edge of the palm, and floppy wrists. **C,** Lateral view of the neonate's head showing simple, large ears and redundant skin on the neck. *(Courtesy Paige Kaplan, Children's Hospital of Philadelphia, Philadelphia, Penn.)*

Management

Patients require annual ophthalmologic and cardiac evaluation throughout childhood. Cardioselective beta-blockers, such as atenolol, are often implemented at the first signs of aortic root dilatation. The angiotensin II antagonist losartan has also shown promise in this regard (Brooke et al, 2008). Children should be screened for the development of scoliosis.

CONGENITAL CONTRACTURAL ARACHNODACTYLY (BEALS SYNDROME)

Presentation

CCA (Beals syndrome) is characterized by a thin, wasted appearance with minimal muscle and fat mass (similar to neonatal Marfan syndrome). Distinctive features include arachnodactyly with contractures of the large and small joints (Figure 24-11, *A*), as well as crumpled, overfolded helices of the external ear. Cardiovascular involvement is usually limited to mitral valve prolapse, but aortic root dilatation may occasionally develop (Godfrey, 2007).

Radiographic Features

Features are nonspecific and include elongated proximal phalanges; contractures of digits, ankles, knees, and hips; thin, gracile tubular bones; and gradual development of kyphoscoliosis.

Etiology

CCA is caused by mutations in the fibrillin 2 gene.

Inheritance

CCA is inherited in an autosomal dominant manner, with many patients representing the result of spontaneous mutations. Offspring of affected individuals are at 50% risk for inheriting the condition. Gonadal mosaicism has been described in CCA (Putnam et al, 1997).

Differential Diagnosis

Differential diagnoses are cMS, cutis laxa, and distal arthrogryposis.

Management

Proper nutrition is essential to ensure adequate weight gain. Joint contractures respond to physical therapy, but occasionally surgical release may be required. Surveillance for development of spinal curvature and aortic root dilatation, although rare, are essential throughout childhood.

EHLERS-DANLOS SYNDROMES

Presentation

The Ehlers-Danlos syndromes (EDSs) are a clinically and genetically heterogeneous group of connective tissue disorders, which are characterized by varying degrees of joint and skin hypermobility, excessive bruising, abnormal wound healing, and fragility of tissues (Steinmann et al, 2002; Wenstrup and de Paepe, 2008). This group of disorders was reclassified in 1997 (Beighton et al, 1998). The classic type (formerly type I) and the arthrochalasia type (formerly type VII) are the most likely to manifest in the newborn period. Type I is often characterized by premature delivery of an affected fetus as a result of a rupture of the fragile amniotic membranes. The infant may be floppy and in the breech position. There may be joint laxity and joint instability. In type VII, the major involvement is in the ligaments and joint capsules. Large and small joints are hypermobile and dislocatable; severe congenital dislocation of hips occurs.

In vascular (formerly type IV) EDS, the greatest danger is to the pregnant affected woman, for whom there is a high risk of uterine and arterial rupture. Although there is a 50% risk that the fetus will be affected, the problems of blood loss and prematurity are more important in the newborn period than the disorder itself.

Radiographic Features

Radiographic features are dependent on the particular type of EDS. Congenital hip dislocation may be evident on plain films. Hydronephrosis, bladder diverticula, and spontaneous pneumothorax may occur occasionally. Aortic dilatation and arterial aneurysms may be evident by echocardiography and other imaging modalities, but only occur in patients of school age or older.

Etiology

Mutations in two of the genes for type V collagen (*COL5A1* and *COL5A2*) are demonstrable in some cases of classic EDS (Malfait and de Paepe, 2005). The vascular type is caused by mutations in the gene for type III collagen, *COL3A1*. The arthrochalasia type is caused by mutations in either gene for type I collagen (*COL1A1* or *COL1A2*), which result in loss of the N-proteinase cleavage site of the protein.

Inheritance

Most types of EDS are inherited as autosomal dominant traits. Each child of an affected person has a 50% chance of inheriting and manifesting the disorder, although there can be marked intrafamilial variability (Malfait and de Paepe, 2005). One form of the arthrochalasia type, also referred to as *dermatosparaxis*, is inherited in an autosomal recessive pattern, and is caused by deficiency of procollagen N-peptidase. The kyphoscoliotic form (formerly type VI) is also inherited in an autosomal recessive pattern and is caused by a deficiency of lysyl hydroxylase, an enzyme that aids in crosslinking of collagen fibrils.

Differential Diagnosis

Differential diagnoses are cMS, congenital contractural arachnodactyly, and Larsen syndrome.

Management

Trauma should be avoided because of skin fragility. Effective closure of surgical wounds is challenging because of a tendency for dehiscence (Wenstrup and Hoechstetter, 2004).

CUTIS LAXA

Presentation

Cutis laxa is a genetically heterogeneous disorder, meaning that mutations in several different genes may be responsible for the phenotype. As such, the presentation can be highly varied. Infantile forms may exhibit loose, furrowed skin, a large anterior fontanelle, hypotonia, hernias, and congenital hip dislocation (see Figure 24-11, *B*) (Kaler, 2005; van Maldergem et al, 2011).

Radiographic Features

Radiographic features are in part dependent on the genetic form of the disorder. Nonspecific features include a large anterior fontanel, congenital hip dislocation, and hernias. The X-linked form may exhibit occipital horns. Arterial tortuosity, aortic root dilatation, and cortical and cerebellar anomalies may be seen in some forms, as well as gastrointestinal and urinary tract diverticula.

Etiology

The relatively mild, autosomal dominant form of cutis laxa is caused by mutations in the elastin gene, *ELN*. The X-linked recessive form (occipital horn syndrome) is caused by mutations in the *ATP7A* gene (allelic with Menkes syndrome). Autosomal recessive forms may be caused by mutations in the fibulin 4 (*FBLN4*) and fibulin

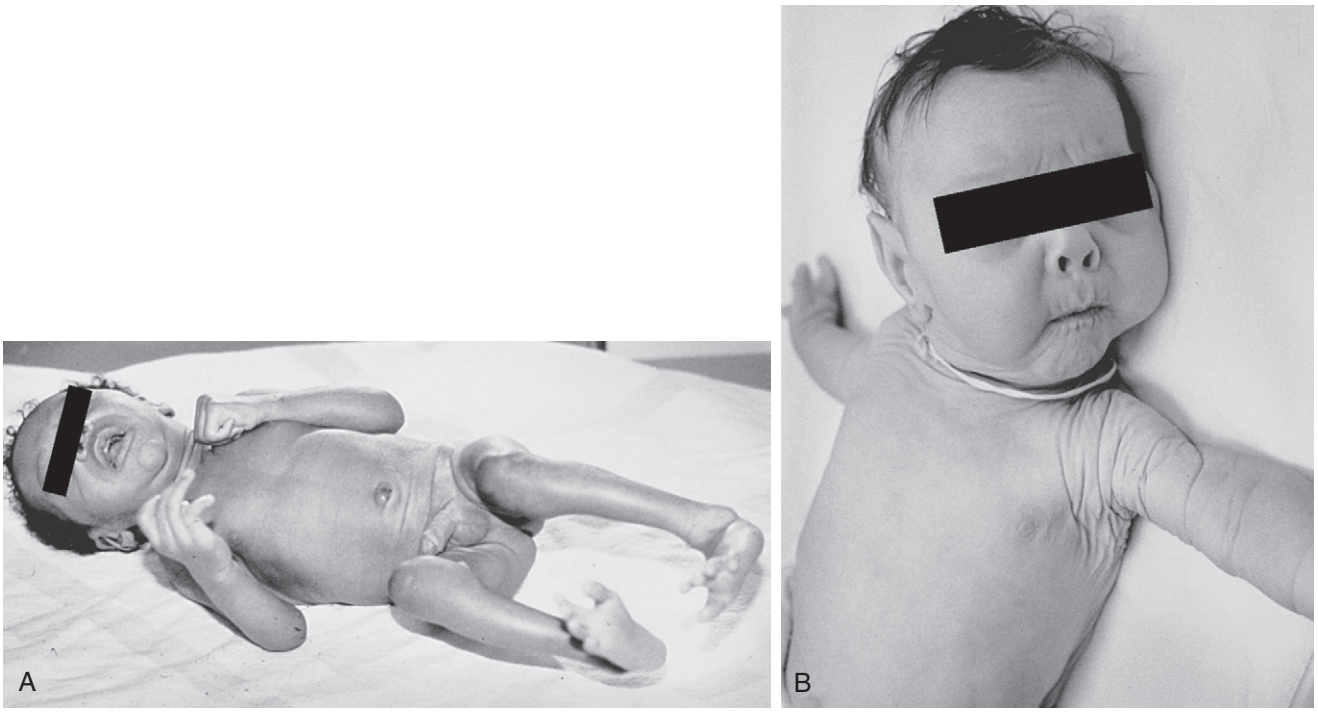

FIGURE 24-11 **A,** Congenital contractural arachnodactyly (Beals syndrome). This infant has a long, thin trunk and limbs, contractures of joints, and crumpled ears. **B,** Infant with cutis laxa. *(Courtesy Montreal Children's Hospital, Montreal, Quebec, Canada.)*

5 (*FBLN5*) genes or the A2 subunit of the V-ATPase gene (*ATP6V0A2*). Biochemical clues as to the etiology in a particular patient may include decreased serum copper and ceruloplasmin (X-linked form), and abnormal serum sialotransferrin isoelectric focusing in cases caused by ATP6V0A2 mutations.

Inheritance

Because cutis laxa is genetically heterogeneous, modes of inheritance include autosomal dominant, autosomal recessive, and X-linked recessive. The latter two modes are usually responsible for forms with neonatal and infantile presentation.

Differential Diagnosis

Differential diagnoses are EDS, Menkes syndrome, gerodermia osteodysplastica, and de Barsy syndrome.

Management

Serious childhood complications include developmental delay, pulmonary emphysema, aortic root dilatation, and arterial tortuosity. Annual ophthalmologic and cardiac examinations are essential, and referral to special education programs may be indicated.

MENKES SYNDROME

Presentation

Menkes syndrome often appears in the newborn period with nonspecific neurologic manifestations. Typically, developmental delay is evident in the first 2 to 3 months of life, with failure to thrive, seizures, and severe ocular manifestations. Changes in the appearance of the hair include hypopigmentation, brittleness, patchy alopecia, and twisted shafts seen by light microscopy (i.e., pili torti; Figure 24-12). Early death is common and may occur in infancy (Kaler, 2010). Serum copper and ceruloplasmin concentrations are low, and the plasma dopamine-to-norepinephrine ratio may be elevated (Goldstein et al, 2009).

Radiographic Features

Features may evolve during infancy and may include bladder diverticula (seen on bladder ultrasound and voiding cystourethrogram [VCUG]), tortuous vessels (on echocardiogram, magnetic resonance imaging with contrast), gastric polyps (on upper GI), metaphyseal spurring, osteopenia, and Wormian bones on plain radiographs (Lachman, 2006; see Figure 24-12).

Etiology

Menkes syndrome is caused by mutations in a copper-transporting adenosine triphosphatase gene, *ATP7A* (Kaler et al, 1994). This enzyme takes part in the final processing of a number of copper-dependent enzymes, including dopamine beta-hydroxylase, tyrosinase, lysyl oxidase, superoxide dismutase, and cytochrome c oxidase. As a result, several physiologic processes and cellular functions are impaired, including collagen cross-linking, pigment production, and neurotransmission (Goldstein et al, 2009).

Inheritance

Menkes syndrome is an X-linked recessive disorder; therefore only males are affected. Female carriers may exhibit pili torti in some hair shafts because of lyonization (Moore

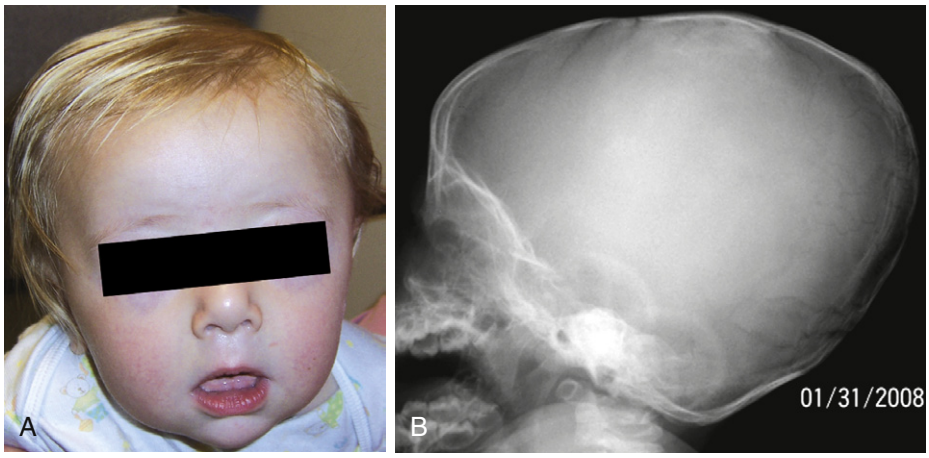

FIGURE 24-12 *(See also Color Plate 8.)* **Menkes syndrome. A,** Note blonde hair, fair complexion, and epicanthal folds in this 11-month-old Hispanic boy. **B,** Note multiple Wormian bones near the occiput.

and Howell, 1985). Sons born to carrier females have a 50% risk for manifesting the disease.

Differential Diagnosis

Differential diagnoses are cutis laxa (the occipital horn form is allelic), EDS, neonatal cMS, biotinidase deficiency, mitochondrial myopathies, nutritional copper deficiency, and organic aciduria.

Management

Early diagnosis allows for parenteral copper supplementation therapy (Kaler et al, 2008), but this is not effective in all patients. Patients should be monitored for the development of seizures, as well as a propensity for bone fragility, poor wound healing, and vascular fragility leading to excessive bleeding, hemorrhagic strokes, and subdural hematomas. Bladder diverticula may result in urinary retention and urinary tract infections and should be surgically corrected. Patients are at risk for moderate to severe developmental delay, and they should be referred to infant stimulation and early intervention programs.

PART VII

Care of the Healthy Newborn

CHAPTER 25

Initial Evaluation: History and Physical Examination of the Newborn

Jeffrey B. Smith

The central focus of this chapter is the medical evaluation of the apparently well newborn in the first few days after birth in a hospital setting. Obtaining the history, performing the physical examination, and judging the significance of risk factors and findings all require skill and experience. For brevity, we mostly refer to the person evaluating the newborn as a *pediatrician*. In some institutions, the routine evaluation is performed by a general pediatrician, family practitioner, or pediatric nurse practitioner, and the neonatologist enters the well baby nursery only as a consultant. In other institutions, the neonatologist has direct responsibility for patients in the normal nursery in addition to the neonatal intensive care unit (NICU). In either setting, the neonatologist should develop and maintain proficiency in the evaluation of the normal newborn, a task that requires an approach and set of skills somewhat different than the evaluation of the NICU patient, who typically has a known symptom or high-risk condition. In the normal nursery, the vast majority of newborns are healthy and will not require medical intervention; therefore a primary goal is to identify the small minority with problems that have the potential to cause serious morbidity if not detected in a timely fashion. This goal includes identifying psychosocial and medical problems. For the healthy majority, the evaluation provides the basis for appropriate parental reassurance and education. For this reason, the emphasis of the discussion in this chapter is on common problems, variations of normal, and subtle abnormalities. Some symptoms and findings that suggest significant illness are also described, but the discussion in this chapter is not intended to provide a complete differential diagnosis or guide to management. Physical findings pertinent to specific diseases and organ systems are described with greater detail in other sections throughout the book. Evaluation of the dysmorphic infant is described in Chapter 19. Laboratory studies helpful in the routine care of the healthy newborn are discussed in Chapter 26.

HISTORY

The medical history of the newborn begins with pertinent information about the mother's past medical and pregnancy history, the current pregnancy, and the family. Information about the current pregnancy, labor, and delivery is central at the time of delivery, but the infant's postnatal history becomes progressively more important in the subsequent hours and days. An outline of basic components of the prenatal and newborn history is presented in Table 25-1. The history is potentially gathered from multiple sources, including records of prenatal outpatient visits and laboratory studies; the records of the mother's current and prior hospitalizations; the delivery record; newborn records created by nurses and other personnel; direct communications from the obstetrician, midwife, and nurses; and interviews with the mother and other family members. Most of the prenatal history is collected and recorded by members of the obstetric team. Systems should be in place to ensure that the pediatrician responsible for the newborn is directly informed about high-risk conditions in a timely manner, but the pediatrician has an independent responsibility to review the information available in the maternal record. From a potentially large amount of information, a key task for the pediatrician is to efficiently identify and highlight the portions that are relevant to the newborn's current situation and the task at hand.

To ensure that important information is not overlooked, a systematic approach to the collection and recording of the history is essential. Structured data systems, preferably electronic, can help to ensure that essential information is not missed. However, information gathering must be prioritized appropriately, because the relative importance of specific parts of the history depends on the clinical situation. For example, the physician paged to attend the emergency delivery of a fetus in distress should focus information gathering in the few minutes available on what is directly relevant to preparations for resuscitation. At that moment, it is not necessary to know the results of prenatal testing of the mother for hepatitis B. For the stable infant sent to room-in with the mother and for the critically ill infant admitted to the NICU, it becomes important to obtain this information in the next few hours, so that hepatitis B vaccine can be administered within the recommended 12 hours after birth if the mother does not have a documented negative test result for hepatitis B infection.

For the healthy newborn, history gathering at the time of the initial encounter after birth will emphasize the prenatal history (including maternal and family history), the delivery and neonatal transition, the initiation of feeding, and any symptoms or parental concerns that have manifested since birth. A major goal of the initial evaluation is

TABLE 25-1 Components of the Prenatal and Newborn History

Category	Typical Components of the History
Maternal identification	Name, medical record number, age, gravidity, parity, estimated gestational age
Maternal medical history	Allergies Significant past illnesses, hospitalizations, and surgeries Chronic illnesses, especially diabetes Chronic medications Psychiatric history
Previous pregnancies	Dates, routes of delivery, complications, and outcomes Breastfeeding history
Family history	General health status and history of family members Congenital anomalies, metabolic disorders, hearing impairment Food and other allergies of parents and siblings
Psychosocial history	Family structure, care of previous children Availability of support for parents (extended family, others) Living accommodations, access to transportation Language, racial or ethnic group, parental education level Smoking, alcohol, drugs of abuse Family strife, domestic violence
Current pregnancy	Estimated gestational age (and how determined) Singleton or multiple fetuses Fertilization history (e.g., assisted reproduction) Prenatal care (when started, number of visits, provider) Maternal blood type and screening for unusual isoimmune antibodies Screening for group B streptococcal colonization Other prenatal screening for infectious diseases* Glucose tolerance test results Results of maternal drug screening, if applicable Occupational or other exposure to teratogens Sexual contact with high-risk group Genetic screening tests Ultrasound studies and amniocentesis Complications, hospitalizations Prescription and nonprescription medications; herbal remedies Breastfeeding plans; plans for well-child care after discharge
Labor	Spontaneous, induced, augmented Duration of first and second stages Rupture of membranes: spontaneous versus artificial, duration Amniotic fluid: clear, meconium stained, bloody, foul smelling Signs of infection: fever, increased white blood cell count, uterine tenderness, tachycardia Antibiotics during labor and the indication Other medications during labor Fetal monitoring abnormalities
Delivery and delivery room stabilization	Route and presentation Indication for cesarean section, vacuum, or forceps, if applicable Stabilization and resuscitation measures; time to spontaneous breathing Apgar scores Placental abnormalities, if noted Cord blood gases, if obtained Ease versus difficulty of transition Medications administered (erythromycin eye drops, vitamin K) Abnormalities noted on initial examination
Postnatal history	Nursing or parental concerns Growth parameters (weight, length, head circumference, and percentiles) Vital signs, daily weights Glucose checks Activity and alertness Breastfeeding (frequency, duration, quality of latch) Bottle feeding (amount, frequency, reason) Voiding, wet diapers Meconium and transitional stools Procedures (lumbar puncture, circumcision) Results of laboratory tests and imaging studies

*Prenatal screening performed in accordance with medical recommendations and local regulations commonly include tests for group B *Streptococcus*, hepatitis B, syphilis, gonorrhea, and for immunity to rubella; it may also include tests for chlamydia, tuberculosis, HIV, and hepatitis C.

to identify risk factors for problems that may develop in the next few days, such as early-onset neonatal sepsis or exacerbated hyperbilirubinemia. Identification of psychosocial risk factors is also an important goal, and it remains important throughout the hospitalization. At the time of the predischarge evaluation, the key goal is to determine whether the infant can be discharged home safely. The prenatal and perinatal history will have already been documented and reviewed, so information-gathering for the predischarge evaluation will focus on the interval history, mostly collected from the nursing records and the parents.

Because of the frequency and potential morbidity of early onset neonatal sepsis, the presence or absence of risk factors for sepsis should be assessed as part of the initial evaluation of every newborn. Historical risk factors for early onset sepsis include prolonged rupture of the fetal membranes (18 hours or more), a maternal body temperature of 38° C or higher, uterine tenderness, foul-smelling or purulent amniotic fluid, an elevated maternal white blood cell count or left shift, and fetal or maternal tachycardia. Maternal colonization with group B streptococci is also considered a risk factor unless adequate intrapartum prophylaxis was administered or the fetal membranes were intact until delivery by cesarean section (American Academy of Pediatrics, 1997). Poor tolerance of labor, manifested by an unexplained need for resuscitation or a slow transition, can be a nonspecific symptom of sepsis.

Whereas gathering the history and performing the physical examination are distinct activities, described by convention in separate parts of a note, they are not performed in isolation. Knowledge of specific concerns, events, and risk factors in the history should prompt a more focused or detailed examination of the relevant body region or organ system than otherwise might be done. Conversely, specific questioning prompted by physical examination findings will often elicit information that was not volunteered in the earlier routine history gathering, such as a family history of a specific anomaly. When a note is written, the history, the physical examination, and laboratory studies are the data upon which the current assessment and plan of care are based. Once documented, the assessment and plan also become part of the patient's ongoing history.

PHYSICAL EXAMINATION

Physical examination requires skills whose refinement can continue to reward and challenge the pediatrician and neonatologist throughout a professional lifetime. No matter how experienced the practitioner, every examination represents an opportunity to add to or refine one's knowledge of significant abnormalities and of the wide range of variation of common, benign conditions. Nevertheless, the examiner knows that most newborns are in fact healthy; therefore one of the practical challenges of performing the routine newborn examination is to maintain a high level of vigilance and thoroughness throughout every examination.

The examination of the healthy newborn entails a complete physical examination in the sense that all parts of the body are examined. However, no actual examination or its write-up can be complete in the sense of exhaustively exploring and explicitly documenting all possible findings. The degree of detail that is appropriate is a matter of judgment that will vary with the presenting situation and the findings discovered during the examination. Distinct subtypes of the newborn examination include examinations in the delivery room, at admission, and at discharge from the normal nursery, in addition to examinations initiated in response to specific concerns.

EVALUATION AT BIRTH

At the time of birth, attention focuses on the initiation of air breathing and cardiorespiratory stability. The assessment of successful adaptation or a need for resuscitation is described in Chapter 28. The infant whose condition remains unstable or who has major anomalies that are apparent on initial inspection will be transferred to an NICU for further evaluation and management.

DELIVERY ROOM DISPOSITION

The infant whose condition stabilizes after delivery, with or without intervention, is evaluated to determine whether the infant can remain with the mother. This examination centers on assessment of the adequacy of the cardiorespiratory transition, and it also includes a basic inspection for congenital anomalies such as imperforate anus or other problems that may indicate a need for admission to an NICU or observation nursery. Passage of a thin catheter through both nostrils and into the stomach can be done in the delivery room to rule out choanal and esophageal atresia. For routine deliveries, the delivery room discharge examination is often done by the obstetrician or nurse-midwife. If the pediatrician is present, the examination at this time can be expanded to serve as the nursery admission exam.

NURSERY ADMISSION EXAMINATION

For babies not requiring admission to an NICU or observation unit, this examination is done after the infant completes transition, and usually by 24 hours after birth. The purpose of a complete physical examination is to efficiently detect problems that, if present, are inapparent or may soon develop. This examination is the main focus of this chapter. The initial physical examination of the patient admitted to the NICU is similar, except that examination in the NICU should be initiated immediately after admission, and parts of the NICU examination may need to be modified or delayed because of physiologic instability or limited accessibility. Whether in the nursery or the NICU, the identification of historical risk factors or the detection of symptoms or abnormalities requires that the basic examination be expanded to focus additional attention on the areas relevant to the differential diagnosis.

TARGETED OR PROBLEM-DIRECTED EXAMINATION

When the physician is called to evaluate an infant because of specific symptoms or concerns, the examination will naturally focus on aspects relevant to those issues. Because

the nonspecific nature of many symptoms in the infant often implies a large differential diagnosis, even the targeted examination will often need a wide focus. The daily follow-up examination can be regarded as a variety of targeted examination, guided by the infant's overall condition. For healthy infants remaining in the hospital for several days after birth, areas of active attention always include the infant's neurologic and cardiorespiratory stability, hydration status, feeding and elimination behavior, and jaundice.

NURSERY DISCHARGE EXAMINATION

The discharge examination is similar in scope to the well-baby admission examination, but with a slightly altered emphasis, based on the additional information provided by the period of observation in the hospital, and by the goal of determining whether the infant is ready for routine care at home. The discharge examination is still a complete physical examination that encompasses the entire body. However, it is not necessary for the discharge examination to duplicate all portions of the admission examination, provided that it was performed by the same person or specific aspects of the admission examination were sufficiently well documented by a trusted colleague. For example, it is unnecessary to repeat a search for physical anomalies that do not change with time, such as examination of the oral cavity for cleft palate, or to check again for red retinal reflexes if they were already found to be normal. Nevertheless, it is often more efficient to repeat the entire examination than to verify the completeness of an earlier examination by another. When the hospital stay is short, a combined admission-discharge examination is appropriate.

EVALUATION OF GESTATIONAL AGE

If the obstetric estimate of the gestational age is uncertain or appears unreliable, the gestational age of the newborn infant can be estimated based on physical examination criteria. No individual feature is a reliable guide to the gestational age, but scoring systems that use multiple features of physical and neuromuscular maturity have been evaluated extensively (Amiel-Tison, 1968; Dubowitz et al, 1970). The New Ballard Score is probably the most widely used in contemporary practice (Ballard et al, 1991). Detailed descriptions and a video demonstration of this examination are available at www.ballardscore.com.

ENVIRONMENT OF EXAMINATION

The environment in which the examination is performed can significantly affect the reliability of the examination via effects on the examiner or on the baby. The examiner must be aware of the limitations produced by a suboptimal environment and adjust the approach to the examination to compensate, arrange for the infant to be moved, or defer selected parts of the examination when appropriate. Important environmental considerations include lighting, room temperature, and the levels of background noise and other distractions. An often overlooked source of distraction is a situation that forces the examiner into a physically awkward or uncomfortable position, such as tall examiner bending over a low bed or examining table. If possible, the infant's clinical state and tolerance for handling can also have a major effect on the conduct of the examination. The wise examiner will postpone the examination of a hungry, crying infant if possible, and try to return when the infant is fed and calm.

The healthy infant is typically examined in a warmer bed in the delivery room or in a bassinet in the mother's room or in the nursery. An open warmer bed provides the best access to the patient, allowing the infant to be kept warm while completely undressed during the examination. The presence of a warmer bed in the delivery room adds to the advantages of performing the nursery admission examination soon after delivery, but often this is not practical. Most examinations of the healthy newborn are done with the infant in a bassinet, starting with the infant dressed in at least a shirt and hat, and wrapped in blankets. An adequate well-baby examination can be performed under these conditions, but the sequence of the examination should be modified to minimize the time the infant is fully undressed. The examiner must take extra care to ensure that the examination is complete and the entire skin surface is visualized at some point during the examination.

Performing the examination in the presence of the parents allows the examiner to show how the infant responds to handling, and to demonstrate immediately any findings that require explanation or reassurance. Watching the examination may stimulate the parents to ask questions that might otherwise not occur to them until later, and it provides the physician an immediate opportunity for further education. On the other hand, interruptions from parents and other family members can interfere with the examiner's train of thought, risking inadvertent distraction and omissions. In large, busy nurseries, it may be more practical for the pediatrician to examine a series of infants in the nursery and then report the results of the examination to each set of parents afterward. Specific findings should be demonstrated to the parents at that time, if appropriate. Regardless of whether the parents are present for the examination, the results of the examination should be communicated promptly. Parents may be anxious about findings that the pediatrician believes are of little consequence, and vice versa. Prompt and sensitive communication of the examination findings helps to build parents' trust, whereas delayed or poor communication can undermine the parents' relationship with the physician and the hospital.

CLINICAL APPROACH TO THE NEWBORN EXAMINATION

An important challenge of the newborn examination is the need to maintain a high level of vigilance and thoroughness, while projecting an attitude of comfortable reassurance appropriate to the reality that the overwhelming majority of newborns seen in the well-baby nursery are in fact healthy. Although the eyes and fingers of the experienced examiner will detect many abnormalities by pattern recognition alone, even the most expert examiner can miss important findings unless a disciplined, systematic approach is used. However, the desire to ensure that no

essential aspect of the examination is missed or slighted needs to be balanced with the infant's limited tolerance for handling. It may seem easier to avoid omissions if the examiner always performs the examination in the same sequence, but a rigid approach that fails to adjust to the state and activity of the individual infant may yield a suboptimal examination that is inefficient and unnecessarily stressful for infant, parent, and examiner.

The physical examination of the newborn includes measurements of the weight, length, and head circumference, which must be compared with standardized growth data (Figure 25-1) to determine whether the infant is small (<10th percentile), appropriate, or large (>90th percentile) for gestational age (Battaglia and Lubchenco, 1967). The body temperature, heart rate, and respiratory rate are typically recorded at regular intervals by nurses, but the pediatrician should also consciously evaluate the heart and respiratory rate at the time of examination. The blood pressure is not routinely measured in healthy newborns, but the blood pressure should be checked in all four extremities if the history or examination suggest a problem with the circulation. Of the standard physical examination techniques, the most important in the examination of the newborn is observation. Palpation and auscultation are also important, whereas percussion is of relatively limited use. The routine examination also includes specific physical maneuvers for examining the hips and for eliciting a variety of reflex responses. A stethoscope, an ophthalmoscope, and a tape measure are the only pieces of equipment generally needed. A source of light for transillumination is helpful for specific purposes. Pulse oximetry can enhance early detection of critical congenital heart disease, but further study is needed to determine whether this procedure should become a standard of care in the routine assessment of the neonate (Mahle et al, 2009).

Sensitivity to the infant's state and responses can greatly facilitate the examination and make it less stressful for the infant and less time-consuming for the examiner. The newborn infant generally responds more slowly to a stimulus than does an older child or adult, and the response tends not to remain localized to the area of the stimulus. For example, a gentle touch to the face or extremity of a sleeping infant, or merely loosening a blanket, typically results in some limited initial movement of the area touched, followed with a slight delay by a wave of movement that spreads to involve the whole body, and which may be accompanied by partial arousal. If the examiner waits a few seconds for this wave of response to fully subside before proceeding to move or touch the infant again, the infant will often settle and remain asleep. With a series of such gentle, well-spaced interactions, the examiner can often complete important portions of the examination without waking the infant. If, however, the examiner provides a new stimulus soon after the first, before the secondary movements have finished spreading and while the infant is partially aroused, the new stimulus is likely to reinforce the initial stimulation and provoke full awakening and a crying.

The examination should begin with a deliberate pause to observe the infant in an undisturbed state. Before the infant is moved or undressed, the examiner should actively observe the infant and mentally note as much information as possible, including the state of alertness or sleep, color of visible portions of the skin and mucous membranes, respiratory rate and any audible sounds or signs of increased work of breathing, posture, spontaneous activity, and quality of cry. Throughout the examination, the examiner should alternate between focusing attention on specific elements of the examination (e.g., listen for a heart murmur, closely scrutinize a scalp lesion) and maintaining a global awareness of the infant's overall responses and activity. The experienced examiner's general impression of whether the patient is sick or healthy is an important part of the evaluation.

If the infant is sleeping or in a quiet alert state, the examiner will usually begin by gently uncovering the chest. Depending on the type of clothing the infant is wearing, it may be best at first to lift the shirt or gown just enough to slide the stethoscope underneath. Because the heart sounds and a soft murmur, if present, can be obscured easily by

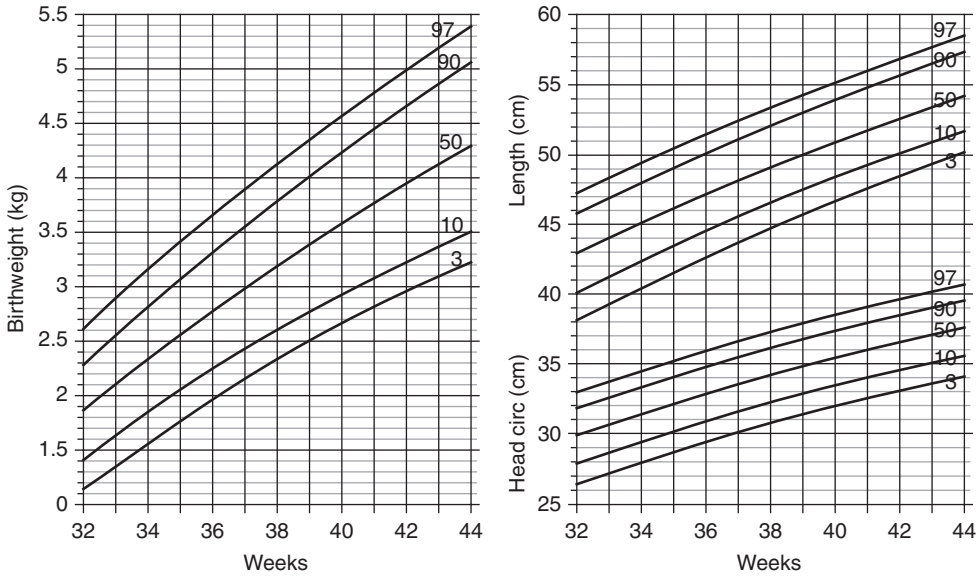

FIGURE 25-1 Fetal-infant growth chart for 32 to 44 weeks' gestation. *(Redrawn from Fenton TR: A new growth chart for preterm babies: Babson and Benda's chart updated with recent data and a new format.* BMC Pediatr *3:13, 2003. The complete chart for 22 to 50 weeks' gestation can be downloaded from http://members.shaw.ca/growthchart.)*

crying, the precordial area is usually auscultated first. If the infant remains quiet, the clothing can be removed further, and the stethoscope can be moved to other locations on the chest to expand the area of auscultation for breath and heart sounds, and then to the abdomen to listen for bowel sounds. If the infant is already crying or awakens and starts crying vigorously, auscultation can be deferred in favor of other parts of the examination. Auscultation of the chest can be performed later, after the infant has become quiet.

If the infant is lightly dressed and is being examined on an open warming bed, all clothing can be removed after the initial auscultation of the chest and abdomen; this allows the entire body to be easily observed throughout the examination with a systematic head-to-toe approach. If the infant is in an open crib, he or she may become cold and upset if undressed fully at the beginning of the examination. In this environment, it is preferable to allow the infant to remain at least partially clothed for as long as possible. For example, start by examining the head, and after replacing the infant's hat, open the shirt to finish examining the anterior chest and abdomen, closing but not buttoning or snapping the shirt while moving to examine the hips, genitalia, and lower extremities, and finally removing the shirt to examine the upper extremities and back. However, proceeding in this way requires extra attention on the part of the examiner to ensure that no parts of the examination are missed.

An experienced examiner can accomplish a thorough examination of the newborn more quickly than a novice, largely because of the acquired skill in handling the infant and minimizing wasted or redundant motions. Although there is no substitute for experience, the trainee's skill will develop more rapidly if close attention is paid to developing a fluid approach to the examination as a whole. The following paragraphs provide one example; each experienced examiner will develop his or her own preferred sequence. Further details of specific parts of the examination are described in subsequent sections.

After the initial moment of observation and auscultation of the anterior chest and abdomen, begin examining the head. Using both hands, gently encircle and palpate the entire scalp while inspecting parts of the scalp that are visible in this position (the back of the head and neck will be inspected later). Gently turn the head to one side (noting any limitation of range of motion), and inspect that side of the head, including the ear, and then the side of the neck. Roll the infant's head gently while working the fingers around the neck to the other side, palpating the neck and clavicular areas and applying gentle traction on the skin as needed to open the neck creases to allow full visualization. After reaching the other side of the neck, inspect the ear and side of the head. Next, proceed to the face, attending first to overall features of shape and symmetry and then focusing sequentially on the skin, eyes, nose, mouth, and oral cavity.

With the shirt open in front, inspect and palpate the anterior chest. Observe the respiratory pattern, noting the presence or absence of retractions. Additional auscultation of the chest may be done at this time, if not completed earlier. Open the diaper, and inspect and palpate the abdomen and umbilicus. Palpate the femoral pulses. One may examine the genitalia and perineum at this time, or wait until after the examination of the hips and lower extremities, described next.

Inspect the lower extremities. Check the range of motion of the hips and perform the Barlow and Ortolani maneuvers. Palpate the legs, sliding the examiner's hands from the hips down to the ankles. The examiner should place the thumbs on the soles of the feet, with the fingers around the back of the ankles. From this position, the examiner can smoothly check the alignment of the feet, elicit the plantar grasp, and then slide the thumbs up along the outer edge of the soles to elicit Babinski's reflex. Next, lift and abduct the legs into a frog-leg position to provide a full view of the perineum and anus. Inspect the genitalia by gently retracting the labia majora in females, or depressing the skin at the base of the penis in males. Inspect and palpate the scrotum and testes. After this, the diaper can be refastened.

Attention next turns to the upper extremities. The shirt should be removed completely to allow unobstructed observation of the overall shape, symmetry, and movements of the arms and hands. With the infant supine, turn the head to elicit the asymmetric tonic neck reflex on each side. Palpate the whole arm gently, starting with one of the examiner's hands on each of the baby's shoulder's, and then slide down to the baby's hands, noting any swelling or discontinuities. Inspect the hands, fingers, nails, and palms. If the infant's hand is tightly fisted, do not attempt to pry the fingers open. Instead, gently flex the wrist to 90 degrees, which will cause the fingers to relax naturally. Inspect the palms, and then elicit the palmar grasp reflex. Without releasing the baby's hands, one can then perform the pull-to-sit maneuver. The examiner places his or her hand behind the infant's head and neck to provide support as the infant is gently lowered back toward the bed. When the infant's head and shoulders are a few inches from the bed, the examiner drops his or her hand rapidly to elicit the Moro reflex.

Next, place the hands on either side of the chest, under the arms at the shoulders, and raise the baby to an upright position, noting the strength and tone of the shoulder muscles. Lower the infant, still in an upright position, and try to elicit the supporting and stepping reflexes. Turn the infant to a prone position, suspended on the examiner's hand. Observe the infant's posture and tone, and elicit the incurvation response. Inspect the infant's back, from the vertex of the head down to the sacrum (pulling the diaper down, if needed). Gently place the infant back in the crib, and dress the infant. The red reflex examination can be performed at this time, or at any suitable moment when the eyes are open spontaneously.

The preceding description assumes routine findings throughout. The examiner should always be prepared to deviate from his or her preferred sequence in response to changes in the infant's state or if abnormalities are found that require a more extended examination of particular features. However, it remains important for the examiner to complete the entire examination and not become distracted by a prominent finding. On occasion, portions of an examination need to be deferred; this is more common in the NICU, because of patient instability, than in the well-baby nursery. In either environment, any limitations of the examination should be clearly documented, with the need for reexamination listed explicitly in the plan of care.

SKIN

The entire skin surface should be inspected during the course of the examination, with attention to the color, moisture, temperature, texture, and elasticity of the skin, the pattern and depth of skin creases, and the presence and character of any local alterations or lesions. The skin appendages—nails and hair—are inspected along with the skin, with attention to the color, size, shape, and any lesions of the nails, and to the growth pattern, color, texture, and distribution of scalp and body hair. Lighting must be adequate and consistent. Natural light is best, although not always available. Phototherapy lights must be turned off during the examination. Typically the skin in different regions of the body is examined sequentially during the course of the routine examination, but if abnormalities are seen, it can be helpful to reexamine the infant in a fully undressed state and in a warm environment, so that all parts of the body can be directly compared. The size, shape, location, distribution, and time course of lesions are all important for differential diagnosis.

Skin color is a composite of the infant's basic skin pigmentation, the adequacy of perfusion, the amounts of oxygenated and deoxygenated hemoglobin in the local circulation, and, at times, internal staining of skin by extravasated blood or pigmented molecules such as bilirubin. The skin can also be stained externally by in utero exposure to meconium or postnatally by foreign substances applied to the skin. The newborn is typically much more pink or red than the mother, because of the healthy infant's high hemoglobin level. With excessive hemoglobin levels, as in polycythemia or twin-twin transfusion, a deeply red or purple-red color (plethora) is evident. Pallor may be caused by anemia or poor perfusion. Central oxygenation is usually best evaluated by observing the color of the tongue and oral mucous membranes, because the color of lips can be misleading. Visual detection of central cyanosis requires approximately 5 g of desaturated Hb per 100 mL of blood, and may not be apparent in the presence of significant anemia (Snider, 1990). Cyanosis of the perioral area, hands, and feet (acrocyanosis), which is common in the first 24 hours after birth or if the infant is cold, is due to relatively poor perfusion of those areas, resulting in increased O_2 extraction by the tissues and an increase in the concentration of deoxyhemoglobin. Because skin color is dependent on perfusion, it can be a sensitive indicator of systemic perfusion. However, the infant's peripheral color can vary markedly and rapidly with activity and the local environmental temperature. Transient mottling of skin of the extremities and trunk (cutis marmorata) is common in newborn infants in response to cold. If mottling does not resolve with warming, other conditions should be considered, including hypertension and hypothyroidism. Harlequin color change is a striking but infrequently observed transient asymmetry of color and perfusion, in which one side of the body is vasodilated, with a clear line of demarcation at the midline.

The yellow-orange color of jaundice caused by unconjugated bilirubin becomes obvious if serum bilirubin levels are sufficiently high, but it can be difficult to detect at more moderate levels. Typically, jaundice first becomes apparent in the face and then progresses distally as bilirubin levels continue to rise. The detection of mild-to-moderate jaundice is easier if the infant's foot is lifted so that the face and foot can be seen side by side in the same visual field, with the foot providing a built-in control for the infant's basic skin pigmentation. This is particularly helpful in the black or brown infant, in whom mild jaundice is more difficult to detect than in the white infant, and in the Asian infant whose skin tones can exaggerate the appearance of mild jaundice.

A transient period of generalized erythema may be noted a few hours after birth, usually by the parents, often during a bath or with vigorous crying, resolving within minutes to an hour. Sometimes called *erythema neonatorum*, it appears to be associated with successful completion of neonatal transition of the circulation, and it rarely recurs with the same intensity after the first episode (Fletcher, 1998).

Skin creasing is affected by both development and movement. Creasing increases if movement is constrained, as in the fetus near term. An absence of creasing on the palms or soles of a term or near-term neonate can be caused by a prolonged lack of movement secondary to a neuromuscular disorder. Edema stretches the skin and obscures normal skin folds and creases. Edematous skin pits with gentle pressure. The distribution of edema is affected by gravity and thus changes with position. In contrast, lymphedema (as in Turner syndrome) tends to accentuate the creases, and is less affected by gravity (Fletcher, 1998).

Injuries caused by iatrogenic trauma in utero or at delivery are common; they include scars from injury by an amniocentesis needle, minor lacerations and abscesses from fetal scalp electrodes or fetal blood gas sampling, scalpel lacerations during cesarean section, and ecchymoses and abrasions from forceps or vacuum. Trauma can also occur from pressure on the fetus during labor, particularly over bony prominences. Such pressure may be involved in the development of subcutaneous fat necrosis, an uncommon condition hypothesized to be caused by hypoxic injury to fat and manifested by firm, subcutaneous nodules and plaques (Cohen, 2008). The lesions usually resolve spontaneously after several months, but can become inflamed and fluctuant and are occasionally associated with the late development of significant hypercalcemia. Aplasia cutis congenita is a focal lesion characterized by congenital absence of some or all layers of skin (Figure 25-2) and can

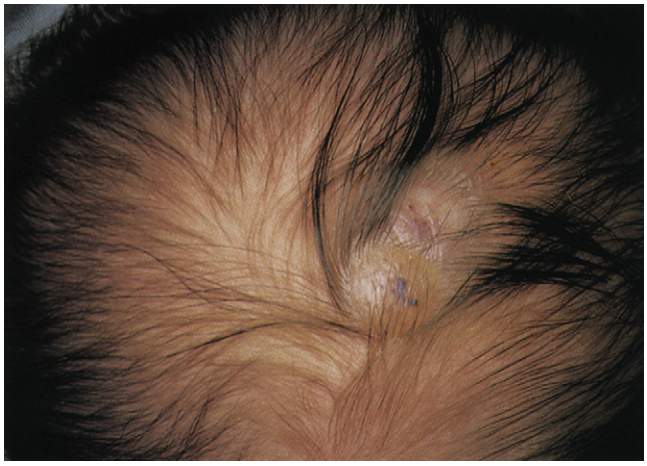

FIGURE 25-2 Aplasia cutis congenita. Lesions are usually single, but in this case there are two adjacent lesions near the vertex—one bullous and one membranous. *(Reprinted from Rudolph AJ:* Atlas of the newborn, vol 4, *Hamilton, Ont, Canada, 1997, BC Decker, p 30.)*

BOX 25-1 Common and Uncommon Causes of Skin Lesions in Neonates

PUSTULAR, VESICULOPUSTULAR, AND VESICULOBULLOUS LESIONS

- Common or benign: erythema toxicum neonatorum, transient neonatal pustular melanosis, miliaria crystallina, miliaria rubra, sucking blisters, neonatal acne (benign cephalic pustulosis)
- Infectious: herpes simplex, varicella, staphylococcal pustulosis, bullous impetigo, congenital candidiasis, syphilis, scabies
- Chronic or recurrent: epidermolysis bullosa, mastocytosis, epidermolytic hyperkeratosis, acropustulosis of infancy
- Positive Nikolsky's sign: epidermolysis bullosa, staphylococcal scalded skin syndrome
- Other: incontinentia pigmenti

NODULES AND PLAQUES

- Common or benign: milia, Ebstein's pearls, Bohn's nodules, sebaceous hyperplasia
- Yellow: sebaceous nevus, juvenile xanthogranuloma
- Brown or black: congenital pigmented nevus, epidermal nevus
- Other: subcutaneous fat necrosis, dermoid cyst, fibroma, infantile myofibromatosis, hamartomas, malignant tumors, leukemia

PAPULOSQUAMOUS AND SCALING LESIONS

- Common or benign: physiologic desquamation
- Healthy infant: atopic dermatitis, contact dermatitis, seborrheic dermatitis, local candida dermatitis, psoriasis
- Ill infant: acrodermatitis enteropathica, Langerhans cell histiocytosis, syphilis
- Other: ichthyosis syndromes, collodion baby, harlequin baby

EROSIONS AND ULCERATIONS

- Common or benign: sucking blisters, traumatic injury (e.g., scalp electrode, diaper erosions, reaction to adhesives)
- Other: aplasia cutis congenita, herpes simplex, epidermolysis bullosa, toxic epidermal necrolysis

ALTERED PIGMENTATION

- Common or benign: Mongolian spots, transient neonatal pustular melanosis, isolated café au lait macules
- Increased pigmentation: Mongolian spots, transient neonatal pustular melanosis, café au lait macules, lentigines, incontinentia pigmenti
- Decreased pigmentation: ash leaf macule, nevus depigmentosus, piebaldism, albinism
- Purpuric or erythematous: petechiae, dermal hematopoiesis ("blueberry muffin" lesions), neonatal lupus erythematosus

VASCULAR AND LYMPHATIC LESIONS

- Common or benign: Nevus simplex or salmon patch, petechiae on the presenting part, small hemangioma
- Other vascular: complicated hemangioma, vascular malformation, port-wine stain
- Lymphatic: cystic hygroma, lymphangioma, lymphedema

Data from Cohen B: *Pediatric dermatology,* ed 3, Philadelphia, 2005, Mosby; Eichenfield LF, Frieden IJ, Esterly NB, editors: *Neonatal dermatology,* (See also Color Plate 9.) *ed 2,* Philadelphia, 2008, Elsevier Saunders; and Fletcher MA: *Physical diagnosis in neonatology,* Philadelphia, 1998, Lippincott-Raven.

occur sporadically or in association with chromosomal defects or other malformations (Kos and Drolet, 2008). It occurs most often on the scalp near the vertex and can be mistaken for a traumatic injury.

Some common and uncommon skin conditions that may be seen in the newborn are outlined in Box 25-1. Fortunately, most of the skin findings encountered during the routine examination are due to a relatively few common

FIGURE 25-3 *(See also Color Plate 9.)* Erythema toxicum neonatorum with erythematous macules, wheals, and pustules. Pustules predominate in this example. At times, patchy or confluent areas of erythema occur without pustules. *(Reprinted from Eichenfield LF, Frieden IJ, Esterly NB, editors:* Neonatal dermatology, *ed 2, Philadelphia, 2008, Elsevier Saunders, p 88.)*

conditions, mostly benign, that are described in the following paragraphs. If unusual or unfamiliar lesions that fall outside the examiner's "comfort zone" are observed, consultation with an appropriate subspecialist should be arranged.

Erythema toxicum neonatorum, or erythema toxicum, is the most common skin rash in the newborn, occurring in up to 70% of term infants (Howard and Frieden, 2008; Lucky, 2008). Lesions can be present at birth, but in most cases the lesions are first noted at 1 to 2 days. The lesions are seen predominately on the face and trunk, but can appear anywhere on the body except the palms and soles. New lesions may continue to appear for approximately 1 week while older lesions resolve. The typical lesion is an isolated elevated erythematous papule or pustule 1 to 2 mm in diameter, surrounded by an irregular area of erythema 1 to 3 cm in diameter (Figure 25-3). When extensive, the lesions can occur in clusters or become nearly confluent. Diagnosis can usually be made by appearance alone, but a scraping of the pustule will reveal an almost pure infiltrate of eosinophils if confirmation is needed in atypical cases.

Transient neonatal pustular melanosis is a self-limited process with lesions that evolve through three distinct phases (Howard and Frieden, 2008; Lucky, 2008; Figure 25-4). Initially, a superficial vesicopustule appears, which after rupturing leaves a fine collarette of scale around the unroofed pustule, which is without erythema. The final stage is a hyperpigmented macule that gradually disappears. The condition is most common in African American infants. In some cases, only the second or third stages are seen at birth, the initial stage presumably having occurred in utero.

Miliaria crystallina is the result of superficial obstruction of the sweat ducts, producing small, crystal-clear vesicles that resemble water droplets (Figure 25-5). It is mostly seen in warm climates or febrile infants. The vesicles are fragile and can be removed by wiping the skin with a soft damp cloth (Howard and Frieden, 2008; Lucky, 2008). Miliaria rubra, also called *heat rash* or *prickly heat*, results from sweat duct obstruction deeper in the epidermal layer, and is more

FIGURE 25-4 Transient neonatal pustular melanosis. The first stage consists of small superficial pustules, without inflammation **(A)**. Collarettes of scale, the second stage, may be seen at birth without evident pustules **(B),** or may develop postnatally after pustules have ruptured **(C)**. Small hyperpigmented macules remain in the final stage **(D),** gradually fading over weeks or months. *(Reprinted from Eichenfield LF, Frieden IJ, Esterly NB, editors:* Neonatal dermatology, *ed 2, Philadelphia, 2008, WB Saunders, p 89.)*

FIGURE 25-5 *(See also Color Plate 10.)* **Miliaria crystallina.** The tiny, clear vesicles resemble water droplets, with no signs of inflammation. *(Reprinted from Rudolph AJ:* Atlas of the newborn, vol 4, *Hamilton, Ont, Canada, 1997, BC Decker, p13.)*

FIGURE 25-6 *(See also Color Plate 11.)* **Neonatal cephalic pustulosis (neonatal acne).** Small, red papules and pustules are seen on the cheeks and forehead, with some extension into the scalp. Comedones are absent. *(Reprinted from Eichenfield LF, Frieden IJ, Esterly NB, editors:* Neonatal dermatology, *ed 2, Philadelphia, 2008, WB Saunders, p 90.)*

common after the first week. Occasionally miliaria rubra will look sufficiently pustular as to mimic lesions caused by staphylococcal, candidal, or herpes simplex.

Sucking blisters and calluses result from vigorous sucking on a hand or forearm in utero, and they can cause a tense, fluid-filled blister, which when ruptured forms an erosion or a callus. The lesion is most often solitary, but may be bilateral, and is without inflammation. A sucking pad or callus may develop on the lips postnatally as a result of vigorous and frequent nursing.

Neonatal cephalic pustulosis, or neonatal acne may occasionally be seen at birth, but more typically appears later, with a mean age of onset of 2 to 3 weeks (Howard and Frieden, 2008; Lucky, 2008). It is characterized by inflammatory, erythematous papules and pustules located primarily on the cheeks with extension over the face and into the scalp (Figure 25-6). It can be difficult to distinguish clinically from miliaria rubra, but both are benign conditions and biopsy is not warranted.

Infectious causes of skin lesions are relatively uncommon in the immediate newborn period, but often need to be considered in the differential diagnosis. Superficial skin infections of *Staphylococcus aureus* are rarely present at birth, but can develop within the first few days. Thrush and candidal diaper dermatitis, common later but not immediately after birth, usually pose no diagnostic difficulty. Congenital candidiasis, which is uncommon, typically manifests within the first day with a papulovesicular eruption that progresses to pustules, followed by crusting and desquamation (Figure 25-7). Lesions can be widespread and may appear on any part of the body, including the palms and soles (Carder,

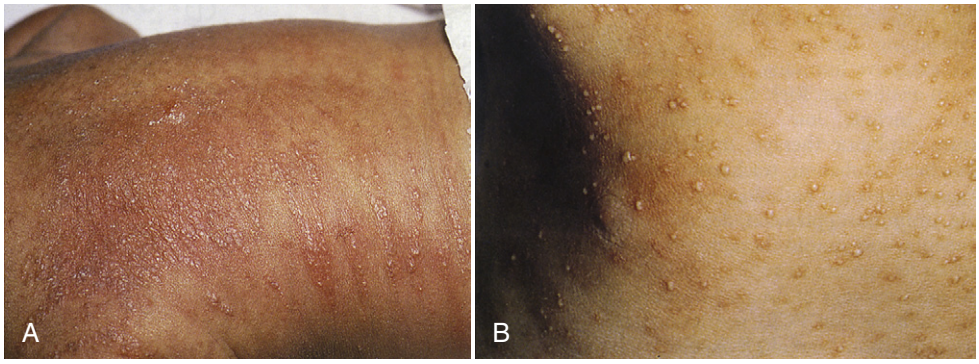

FIGURE 25-7 *(See also Color Plate 12.)* **Congenital candidiasis.** The rash may be a diffuse, erythematous pustular eruption **(A)** or have diffusely distributed but distinct pustules **(B)**. In premature infants, a diffuse scaldlike erythematous dermatitis may be seen (not shown). *(Reprinted from Eichenfield LF, Frieden IJ, Esterly NB, editors:* Neonatal dermatology, *ed 2, Philadelphia, 2008, Elsevier Saunders, p 214.)*

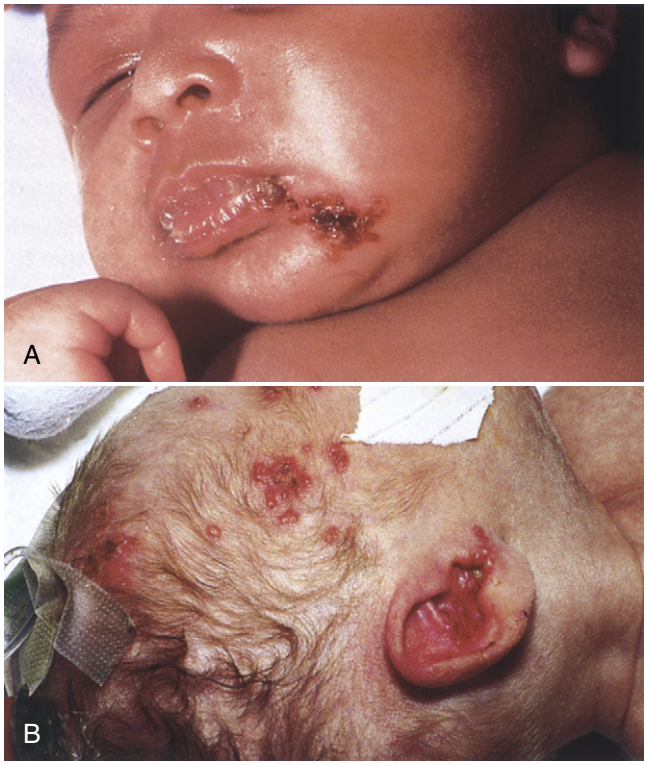

FIGURE 25-8 *(See also Color Plate 13.)* **Herpes simplex. A,** The first signs of herpes infection in this neonate were eroded vesicles at the corner of the mouth. **B,** Herpetic vesicles on the face, scalp, and ear of an infant with respiratory distress and hepatitis. *(Reprinted from Cohen B:* Pediatric dermatology, *ed 3, Philadelphia, 2005, Mosby, p 36.)*

FIGURE 25-9 *(See also Color Plate 14.)* Desquamation on the palms **(A)** and soles **(B)** of an infant with congenital syphilis. *(Reprinted from Rudolph AJ:* Atlas of the newborn, vol 4, *Hamilton, Ont, Canada, 1997, BC Decker, p 108.)*

2008; Darmstadt et al, 2000). Neonatal herpes simplex is unlikely in the first few days after birth, unless the fetal membranes were ruptured for many days, but it must be considered whenever vesicles are seen in the newborn. The skin lesions of herpes simplex start as small, 2- to 4-mm vesicles on an erythematous base, become pustular after 1 to 3 days, and develop an eschar (Friedlander and Bradley, 2008; Figure 25-8). The mucosal lesions are usually shallow ulcerations. The "blueberry muffin" skin lesions of congenital rubella and cytomegalovirus, caused by dermal hematopoiesis, are unlikely to be seen as an isolated finding. Affected infants typically have multiple stigmata of congenital infection including growth retardation, microcephaly, and hepatosplenomegaly. Cutaneous findings of congenital syphilis are present in only a minority of infected infants, but they classically involve the palms, soles, and perioral and anogenital areas (Dinulos and Pace, 2008; Howard and Frieden, 2008). The rash is highly variable, taking papulosquamous, vesiculobullous, macular erythematous, annular, and polymorphous forms. Desquamation limited to the palms and soles, with no rash or peeling elsewhere, is suggestive of congenital syphilis (Figure 25-9).

Milia, Ebstein's pearls, and Bohn's nodules are epidermal inclusion cysts (Lucky, 2008; Figure 25-10). Milia are tiny epidermal inclusion cysts seen primarily on the face and scalp in small numbers; they are smooth, firm, white papules with no associated erythema. They may be present at birth or appear somewhat later, and they generally resolve spontaneously within a few months. Larger inclusion cysts, which usually occur singly, are called *pearls;* the foreskin and the ventral surface of the penis and scrotum are common locations. Epidermal inclusion cysts located on the palate are called *Ebstein's pearls*, and those on the alveolar ridge are called *Bohn's nodules*.

Sebaceous hyperplasia occurs mostly on the face, especially on the nose and upper lip. It is due to hypertrophy of the sebaceous glands caused by androgenic hormonal stimulation in utero, and it gradually resolves over several weeks. It is characterized by sheets of smooth, yellow-white papules with the regular spacing of involved follicles and no surrounding erythema (Figure 25-11).

Physiologic desquamation occurs in many full-term infants. These infants will have some dry skin with fine

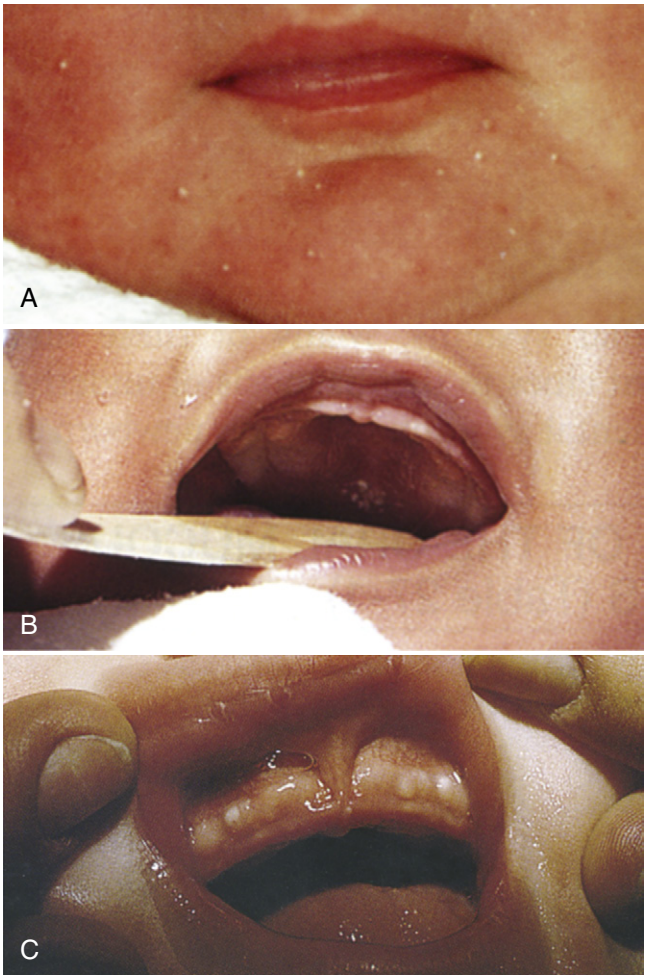

FIGURE 25-10 **Epidermal inclusion cysts.** Milia are most commonly seen on the face **(A),** but can occur anywhere on the body. Ebstein's pearls occur on the midline of the hard palate, most commonly near the junction with soft palate **(B)**. Bohn's nodules are found along the gum margins and on the lateral palate **(C)**. Dental lamina cysts (not shown) are similar inclusions located on the crest of the alveolar ridge. *(Reprinted from Fletcher MA:* Physical diagnosis in neonatology, *Philadelphia, 1998, Lippincott-Raven, p124* **[A];** *and Eichenfield LF, Frieden IJ, Esterly NB, editors:* Neonatal dermatology, *ed 2, Philadelphia, 2008, Elsevier Saunders, pp 503-504* **[B** and **C]**.)

FIGURE 25-11 *(Supplemental color version of this figure is available online at www.expertconsult.com.)* **Sebaceous hyperplasia.** Sheets of tiny, white-yellow follicular papules, without inflammation, are seen on the nose. *(Reprinted from Eichenfield LF, Frieden IJ, Esterly NB, editors:* Neonatal dermatology, *ed 2, Philadelphia, 2008, Elsevier Saunders, p 87.)*

desquamation at 1 to 2 days of age, particularly on the hands and feet. A more exaggerated variety of physiological desquamation is common in postmature infant (born at greater than 41 ⅐ weeks post-menstrualage). These infants are often born with dry, thickened skin that cracks and peels extensively and then normalizes spontaneously over the course of approximately 1 week. The condition is usually not difficult to distinguish from the rare inherited disorders of cornification (ichthyosis) that manifest in the neonatal period (Irvine and Paller, 2008). These disorders include Harlequin ichthyosis (caused by mutations in the *ABCA12* gene) and "collodion babies" who appear encased in a thickened, shiny skin that resembles collodion, a phenotype associated with a number of different ichthyotic conditions.

Mongolian spots (dermal melanocytosis) are macular areas of a slate grey, blue-grey, blue-black, or deep brown color. The distinctive appearance is due to the presence of melanocytes located in the dermis, instead of their typical site at the dermal-epidermal junction. The spots are most commonly located on the lower back and buttocks, but can occur elsewhere. Mongolian spots in this location—which are common in East Asian, East African, Native American, and Polynesian infants—tend to fade over several years, whereas similarly appearing lesions that occur elsewhere on the body may never resolve (Gibbs and Makkar, 2008; Lucky, 2008). Dermal melanocytosis in the area of the first and second divisions of the trigeminal nerve is called the *nevus of Ota*. The nevus of Ito is a similar lesion occurring on the neck, upper back, and shoulders in the area of the posterior supraclavicular and lateral brachial cutaneous nerves. Unlike Mongolian spots, these nevi do not become less pigmented with time, and malignant melanoma or malignant nevi can develop within them, though rarely.

Café au lait macules are tan-brown macules that can occur anywhere on the body. They are common as an isolated finding in the newborn and are generally benign, but can be markers of other conditions (Gibbs and Makkar, 2008). The presence of six or more café au lait macules greater than 5 mm in diameter is considered presumptive evidence of neurofibromatosis type 1. Multiple large café au lait macules with irregular borders may be a manifestation of the McCune-Albright syndrome.

The salmon patch (or nevus simplex) is a benign vascular lesion consisting of erythematous macules or patches frequently seen at the nape of the neck ("stork bite"), on the eyelids and glabella ("angel's kisses"), and somewhat less frequently on the nose and upper lip (Lucky, 2008; Figure 25-12). The lesions are caused by dilated capillaries in the upper dermis, with normal overlying skin. Those on the face usually fade or resolve completely within 1 to 2 years, but 25% to 50% of those on the neck persist throughout life (Lucky, 2008).

After vaginal delivery of a healthy infant, it is not unusual or concerning to see petechiae on the presenting part (i.e. the part of the fetus closest to the pelvic inlet of the birth canal at the onset of labor) or on other areas of the body subjected to localized pressure during delivery. A tight nuchal cord can cause extensive ecchymoses and petechiae on the entire head. Widespread petechiae are abnormal, however, and are suggestive of thrombocytopenia or platelet dysfunction.

Hemangiomas are soft, pink-red, compressible vascular tumors composed of proliferating endothelial cells. Small

FIGURE 25-12 *(See also Color Plate 15.)* Salmon patches are commonly seen on the glabella, eyelids, nose, or upper lip, either singly or in all these locations **(A),** and on the nape of the neck **(B)**. *(Reprinted from Eichenfield LF, Frieden IJ, Esterly NB, editors:* Neonatal dermatology, *ed 2, Philadelphia, 2008, Elsevier Saunders, p. 95.)*

FIGURE 25-13 This infant with the Sturge-Weber syndrome has a port-wine stain in the distribution of the ophthalmic division of the facial nerve. *(Reprinted from Cohen B:* Pediatric dermatology, *ed 3, Philadelphia, 2005, Mosby, p 49.)*

hemangiomas are recognized at or shortly after birth in 1% to 3% of healthy term infants and become apparent in 10% of all infants by 1 month old (Cohen, 2005). Hemangiomas are more common in female infants by 2:1 to 9:1 as compared with males. The incidence is much higher (22% to 30%) in preterm infants weighing less than 1000 g, but only slightly higher (15%) in those weighing 1000 to 1500 g (Amir et al, 1986; Enjolras and Garzon, 2008). Infantile hemangiomas typically undergo a period of growth beyond that of surrounding tissues for 6 to 12 months, typically followed by spontaneous involution. Approximately 25% regress by 2 years of age, 40% to 50% regress by 4 years of age, 60% to 75% regress by 6 years of age, and 95% regress by adolescence (Cohen, 2005). Before the hemangioma becomes obvious, careful examination may reveal a precursor lesion manifesting as telangiectasias surrounded by an area of pallor or as pale, erythematous, or bruise-like macules and patches. In contrast, vascular malformations are nonproliferative lesions, usually present at birth. The Kasabach-Merritt phenomenon occurs in association with specific types of large vascular tumors that cause platelet trapping and severe thrombocytopenia, and is not associated with the true hemangioma of infancy (Enjolras and Garzon, 2008). In the rare Klippel-Trenaunay syndrome, capillary malformation and varicose veins are associated with overgrowth of an affected limb.

Port-wine stains are capillary malformations evident at birth as pink or red patches that grow proportionately with the child and persist throughout life (Enjolras and Garzon, 2008). The initial pink-red color typically changes to a deeper red or purple hue with age. Approximately 10% of port-wine stains that involve the area supplied by the ophthalmic (V1) branch of the trigeminal nerve (Figure 25-13) are associated with seizures, arterial brain malformations, and ocular abnormalities that constitute the Sturge-Weber syndrome (Enjolras et al, 1985).

HEAD

The head is mainly examined by inspection and palpation. The overall size, shape, and features of the skull should be noted. The head circumference (maximal occipital-frontal circumference) should be measured in every neonate and plotted on an appropriate growth chart (see Figure 25-1). The measurement of the head circumference is subject to error and can be significantly affected by molding of the skull during labor, so the head circumference should be measured again if the result appears discordant with the visual examination or with the infant's weight and length, and repeated after molding has resolved. The soft tissue of the scalp should be examined for swelling, ecchymoses, and other evidence of injury because of the forces of labor, and for iatrogenic injuries including those from application of a vacuum device,

placement of scalp electrodes, fetal blood sampling, and lacerations with a scalpel during cesarean section.

The quantity of scalp hair present in the newborn is highly variable, but abnormalities in the distribution, texture, and patterning of the hair are potentially informative. The hair usually forms a single whorl near the vertex, but double whorls occur in approximately 5% of newborns. Abnormal placement or the presence of more than two whorls may be a marker of abnormal brain development (Smith and Gong, 1974).

The infant skull is composed of several bony plates, separated by sutures and fontanels. This structure allows the skull to deform during labor (Figure 25-14). The entire surface of the skull should be palpated to identify the location and size of the major fontanels and assess for discontinuities. The soft tissue over a fontanel should normally be flat; a raised or bulging fontanel suggests that intracranial pressure is increased. It is common to find a palpable discontinuity at a suture, because of vertical displacement of a skull bone relative to its neighbor as a result of molding. In some cases, one bone can truly override the other. Such discontinuities at a suture must be distinguished from the step-off of a displaced skull fracture. Premature fusion of one or more of the cranial sutures, or craniosynostosis, results in a variety of abnormal skull shapes, depending on which sutures are involved (Fletcher, 1998; Volpe, 2008). Fusion of the saggital suture produces a narrow skull elongated in the anterior-posterior dimension (scaphocephaly or dolichocephaly). Fusion of the coronal sutures causes a widened skull that is shortened in the anterior-posterior dimension (brachycephaly). Unilateral closure of either a coronal or lambdoid suture causes an oblique deformity (frontal or occipital plagiocephaly, respectively). Closure of a metopic suture produces a triangular skull with a prominent, narrow forehead (trigonocephaly). Depending on the timing of the fusion, the skull shape may be abnormal at birth or become visibly deformed later. The fused suture typically has a palpable elevation or ridge, which must be distinguished from displacement of a normal suture caused by molding. In the absence of craniosynostosis or overriding, normal mobility at a suture can be verified by gently applying alternating pressure to the bones on either side of the suture line.

Caput succedaneum is a diffuse edematous swelling of the scalp caused by pressure during delivery that results in fluid accumulation external to the periosteum. The caput is boggy, has diffuse edges, is not limited by suture lines, and most commonly is located over the vertex. It is usually present at birth and resolves over several days. In contrast, a cephalohematoma is caused by hemorrhage under the periosteum; it forms a distinct, firm bump laterally that does not cross suture lines (Figure 25-15). The cephalohematoma may not appear until several hours after birth, and it often increases in size over the first 12 to 24 hours. It typically remains palpable for 2 to 3 weeks, during which time it may develop a calcified rim. Unlikely a cephalohematoma, a subgaleal hematoma is not confined by the

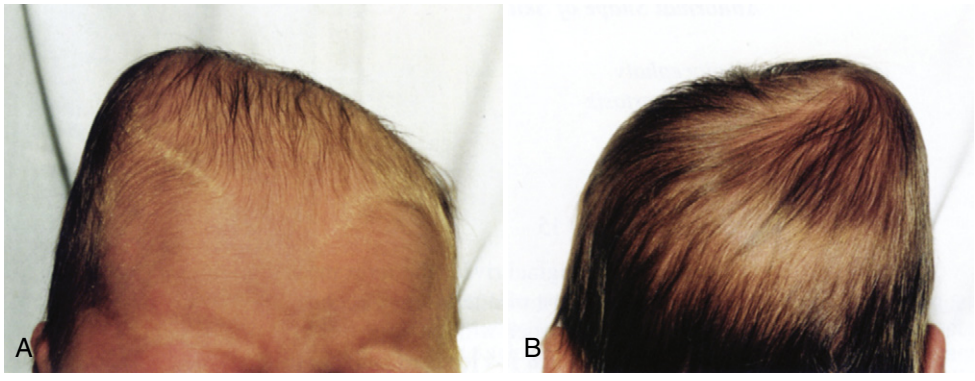

FIGURE 25-15 *(See also Color Plate 16.)* Anterior **(A)** and posterior **(B)** views of a large cephalohematoma under the periosteum of the right parietal bone. *(Reprinted from Fletcher MA:* Physical diagnosis in neonatology, *Philadelphia, 1998, Lippincott-Raven, p 185.)*

periosteum and can involve massive blood loss. Depending on the volume of blood that has accumulated, it can be palpated as a firm or fluctuant mass with poorly defined edges that may extend onto the neck or forehead. Large subgaleal hematomas are uncommon, but potentially life threatening.

Craniotabes (or craniomalacia) is a softening of the skull, most commonly involving the parietal bones near the vertex. Gentle pressure on the involved bone produces a sudden collapse, with recoil when the pressure is released, similar to the way a ping-pong ball collapses when squeezed. It has usually been attributed to localized bone resorption or interference with ossification caused by prolonged pressure on the fetal skull from the maternal pelvis, but it may be associated with maternal vitamin D deficiency in some populations (Yorifuji et al, 2008).

A localized defect in the skull can occur in association with aplasia cutis congenita. A small soft-tissue mass or bulge at the occiput or in the midline of the forehead near the bridge of the nose may be caused by an encephalocele protruding through a small defect in the skull. Large encephaloceles and major neural tube defects will be obvious if present. Hydranencephaly, if suspected, can be detected by transillumination of the skull.

FACE

The face and facial expressions should be observed throughout the course of the entire examination. In addition, there should be a moment when attention is directed to the overall arrangement and proportion of the features of the face as a whole. It is helpful to view the face from the front, in profile, and looking down from the top of the head. Important characteristics to note include the symmetry and expressiveness of the face, both at rest and during crying, and the relative sizes, spacing, and orientation of the features. After this overview, specific attention should be paid to the ears, eyes, eyebrows, eyelids, nose and nasal passages, lips, palate, and mouth. Suggested abnormalities should be described as precisely as possible. Measurements of the facial features are not part of the routine newborn examination, but comparison with reference nomograms can be helpful if dysmorphism is suspected (see Chapter 19).

EARS

The external ear is a relatively common site of minor anomalies. The external ear develops from the first and second branchial arches, from which the six hillocks of His grow, migrate, and fuse to form the pinna. Most of the pinna derives from the second branchial arch. The third arch contributes the tragus, antitragus, and anterior wall of the canal (Figure 25-16). The position and orientation of each ear should be noted, as well as the size, shape, and structure of the helix, and any signs of trauma. The ear is palpated to assess the firmness and recoil of the cartilage and to detect any masses or abnormalities of texture. The skin near the pinna is examined for skin tags, pits, and sinus tracts. Minor variations in the shape of the ear and ear lobe are common, and they usually have only cosmetic significance. A lop ear is characterized by downward folding of the superior helix caused by underdevelopment of the upper third of the pinna; this needs to be distinguished from folding caused by positioning in utero. A cup ear is a protruding ear with an excessively concave concha. Microtia implies a severely dysplastic and malformed ear, and it is often associated with abnormalities of the middle ear and other malformations.

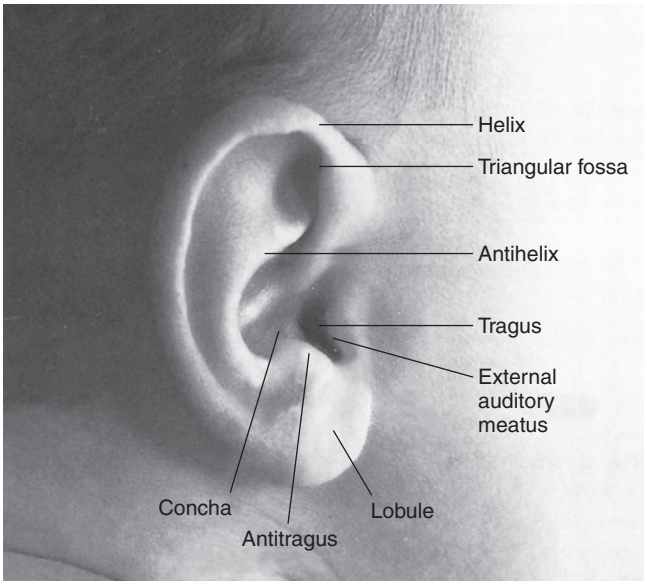

FIGURE 25-16 Anatomy of the external ear. *(Reprinted from Fletcher MA:* Physical diagnosis in neonatology, *Philadelphia, 1998, Lippincott-Raven, p 285.)*

Assessment of hearing by observation of behavioral responses has been essentially replaced in the routine examination by automated testing of hearing before hospital discharge (American Academy of Pediatrics, 2007; US Preventive Services Task Force, 2008). Otoscopy to inspect the eardrum is not part of the routine examination in the immediate newborn period. The eardrum is more horizontal in neonates than in adults, lying almost parallel to the external canal. Movement of the eardrum is more difficult to detect than in older infants, and visualization of the eardrum is often impeded by the presence of amniotic debris, vernix, or blood in the ear canal. Moreover, findings typical of otitis media in older infants (dullness of the tympanic membrane, decreased light reflex and translucence, and diminished mobility) may be present in healthy newborns.

EYES

As part of the inspection of the face, the size, spacing, and orientation of the eyes, lids, and eyebrows should be assessed. In microphthalmos the entire eye is small, whereas microcornea can be an isolated finding in an otherwise normal eye. Hypertelorism implies that the spacing between the bony orbits is excessively wide. In telecanthus, the inner canthi are displaced laterally, giving a false impression of hypertelorism. Hypotelorism is often associated with holoprosencephaly, Trisomy 13, and other genetic abnormalities. The palpebral fissures are downslanting if the medial canthi are higher than the lateral canthi, and upslanting if the lateral canthi are higher. Ptosis can be difficult to detect reliably in the neonate

unless it is severe or unilateral. It may be congenital or caused by trauma or inflammation. Transient episodes of gaze disconjugation are common in otherwise healthy newborns, but persistent eye deviation requires follow-up. Obstruction at both ends of the lacrimal sac produces a mucocele (or dacryocele), which appears as a bluish subcutaneous mass that can be mistaken for a hemangioma or an encephalocele. Mucoceles can sometimes extend into the nasal passages and cause respiratory distress.

The routine examination of sclera, cornea, and internal portions of the newborn eye is often limited by the presence of significant eyelid edema in the first few days after birth. If the corneas and conjunctivae cannot be adequately visualized during spontaneous eye opening or with gentle lid retraction, it is normally preferable to defer further examination of the eyes until the swelling recedes, rather than to attempt to retract the lids forcibly. A coloboma is a congenital defect in the formation of the eye, which can affect any or all of the external or internal structures of the eye. Colobomas of the iris, most frequently located inferomedially and producing a keyhole-shaped pupil, are the most common type visible on external examination. As part of the routine examination, the lower lid of each eye should be retracted so that the entire pupil is visible, if not the entire cornea. If a coloboma of the lid or iris is seen, ophthalmologic evaluation of internal structures of the eye is advisable. Cloudy corneas represent glaucoma until proven otherwise and require prompt ophthalmologic evaluation even if obvious enlargement of the cornea and globe (buphthalmos) is not present. Small subconjunctival hemorrhages are common in newborns, particularly after vaginal delivery, and do not indicate trauma unless other findings are present.

An examination of the red reflex of the eyes should be performed in all neonates before discharge from the nursery and at subsequent health supervision visits (American Academy of Pediatrics, 2008). Anything that interferes with the transmission of light through the normally transparent parts of the eye on its path to the fundus and back to the examiner will result in an abnormality of the red reflex. Problems potentially detected by the red reflex examination include cataracts, aqueous and vitreous opacities, and retinal abnormalities including tumors and chorioretinal colobomas. High-refractive errors and strabismus may also produce abnormalities or asymmetry of the red reflex. Dark spots in the red reflex, a markedly diminished reflex, the presence of a white reflex, or asymmetry of the reflexes are indications for immediate referral to an ophthalmologist experienced in neonatal evaluation (American Academy of Pediatrics, 2008). The red reflex examination is to be rated as normal when the reflections of the two eyes viewed both individually and simultaneously are equivalent in color, intensity, and clarity, and there are no opacities or white spots within the area of either or both red reflexes (American Academy of Pediatrics, 2008). The red reflex examination is vital for early detection of vision-threatening and potentially life-threatening abnormalities, including retinoblastoma. Unfortunately, the sensitivity of the routine red reflex examination for retinoblastoma is low, and most retinoblastomas are first detected by family members rather than pediatricians, despite routine screening (Abramson et al, 2003).

NOSE

The nose should be inspected for deformities, with attention to the size, shape, and symmetry of the various components of the nose, including the nostrils, columella, alae nasi, and the bridge, root, and tip. Asymmetries of the nose caused by in utero compression are common and need to be distinguished from malformations. Passage of a catheter beyond the nasopharynx via each nare, usually done in the delivery room, rules out choanal atresia but does not ensure that the size of the nasal passages is adequate for normal breathing. The quality and volume of air flow through each nostril can be evaluated by listening with the bell of a stethoscope or by observing the deflection of a wisp of cotton placed under the nostril. With the mouth closed, the infant should be able to breath comfortably via each nostril separately; this can be assessed by briefly occluding each nostril with the examiner's fingertip. If unilateral atresia or stenosis is present, the infant will exhibit signs of distress when the patent nostril is occluded. Flaring of the alae nasi may occur as the sole or initial symptom of mild respiratory distress, or it may accompany grunting and retractions.

MOUTH AND ORAL CAVITY

The lips, perioral area, and oral cavity should be inspected both at rest and during crying. The shape of the philtrum should be evaluated when the mouth is relaxed, because stretching of the upper lip during crying can give a false impression of a flat philtrum, which is suggestive of fetal alcohol syndrome. Perioral cyanosis is common and benign in normal infants in the immediate newborn period, whereas cyanosis of the tongue and mucous membranes is always abnormal and requires immediate investigation. The mucous membranes will be moist and shiny with saliva if the infant is well hydrated. Excessive oral secretions can be caused by esophageal atresia or impaired swallowing. An excessively short frenulum that restricts protrusion of the tongue can be a cause of feeding difficulty.

In the routine examination, the oral cavity is usually inspected without the use of a tongue depressor or other instruments. Epstein's pearls, Bohn's nodules, and dental lamina cysts (Figure 25-10) are common findings that should be indicated to the parents as benign. With patience and some adjustment of the head position, the entire palate and much of the pharynx can often be visualized. The tonsils are normally inconspicuous in neonates. The uvula is short but highly mobile. The soft palate elevates during crying if cranial nerves (CNs) IX and X are intact.

Inspection of the oral cavity is supplemented by palpation with a gloved finger to assess the shape and integrity of the palate, and to feel for natal teeth and masses. Although clefting of the lip and anterior palate will be obvious at a glance, an isolated cleft of the posterior palate may be missed unless deliberately sought by palpation. Eliciting the sucking reflex allows the strength and coordination of sucking to be assessed. In the routine examination of a vigorous, alert infant, elicitation of a gag reflex is unnecessarily upsetting to the infant and is normally avoided. The gag reflex should be tested if the infant is neurologically depressed or has difficulty swallowing.

NECK

It is usually convenient to combine palpation of the neck for lymphadenopathy and masses with palpation of the clavicles. The entire skin surface of the neck should be visualized and palpated, while turning the head and retracting the skin to open the neck creases and folds. The range of motion of the head and neck is evaluated at the same time. Congenital muscular torticollis at birth is commonly but not invariably accompanied by a palpable fibrous tumor (fibromatosis colli) in the shortened sternocleidomastoid muscle. Nonmuscular causes of torticollis include tumors of the posterior fossa or cervical spine and malformations of the cervical spine. A short neck, low hairline at the back of the head, and restricted mobility of the upper spine are characteristic features of the Klippel-Feil syndrome. Redundant skin or a webbed neck may be seen in Trisomy 21 and in Turner and Noonan syndromes. Cystic hygromas are soft, fluctuant masses that transilluminate and are usually unilateral. Branchial cleft cysts or sinuses are also found laterally, from the level of the mastoid to the center of the sternocleidomastoid muscle. Thyroglossal duct cysts are located in the midline high in the neck or under the chin. Further investigation is needed if the larynx or trachea are displaced from the midline, or if enlargement of the thyroid gland is suspected.

CHEST WALL

Although evaluation of the heart and lungs is a central focus of the examination of the chest, the skin, soft tissue, and bony structures of the thorax should not be neglected. The position of the nipples and the presence of any accessory nipples should be noted. The definition and stippling of the areola and the size of the breast bud are developmental features helpful as part of scoring for gestational age estimation. Transient galactorrhea occurs in approximately 5% of term neonates (Madlon-Kay, 1986). Variations in the shape of the xiphoid process are common, and parents can be reassured that a prominent or bifid xiphoid is benign and will usually become much less apparent as the infant grows. A mildly depressed sternum (pectus excavatum) or protuberant one (pectus carinatum) is usually of no clinical consequence. A small, bell-shaped chest in an infant with respiratory distress may reflect lung hypoplasia or a disorder of skeletal growth. An increase in the anterior-posterior diameter of the chest (barrel chest) may reflect an increase in the intrathoracic volume caused by air trapping from meconium aspiration or pneumothorax. Palpation of the chest wall may reveal irregularities or tenderness, and crepitus may be felt at the site of a fractured clavicle or rib. Crepitus can also be caused by dissection of air into the subcutaneous tissue from a pneumothorax or pneumomediastinum, but this is an unlikely occurrence in an asymptomatic infant.

LUNGS AND RESPIRATION

The respiratory examination begins with observing the color of the tongue and mucous membranes, respiratory rate, breathing pattern, and work of breathing. Respiratory problems are unlikely to be found in an infant who is centrally pink and breathing comfortably at a relaxed rate. In the normal newborn, the abdomen expands smoothly with each contraction of the diaphragm, while the chest moves inward slightly.

The respiratory rate of the newborn infant is highly variable when the infant is awake, changing with activity such as feeding and crying. Tachypnea during sleep is more clearly associated with respiratory problems than is tachypnea during awake states. During a routine examination of the healthy infant, it is not necessary to measure the exact respiratory rate, as long as it is clearly within a normal range in an asymptomatic infant, but the respiratory rate should be determined if tachypnea or an unusually slow rate is seen. Because short pauses and brief periods of rapid breathing are common in normal newborns, accurate measurement of the respiratory rate requires counting for a full minute, preferably when the infant is asleep or at least not crying. During crying, the quality and vigor of vocalization are assessed, and the infant is observed for changes in color and perfusion. Central cyanosis that only appears during crying may be caused by cardiac or respiratory disease and requires further evaluation. Cyanosis that resolves during crying may be due to choanal atresia or stenosis, apnea, or hypoventilation.

The classic symptoms of respiratory distress are nasal flaring, grunting, and retractions. Nasal flaring and mild grunting are common in the immediate postnatal period, but in the healthy newborn they should resolve within 15 to 20 minutes after birth. Increasing respiratory distress caused by decreasing lung compliance is typically reflected in a progression from nasal flaring, or mild tachypnea, or both; to nasal flaring plus mild or intermittent grunting; and then to flaring, grunting, and increasingly severe retractions. The respiratory rate generally decreases as the work or effort of breathing increases, as indicated by the development of grunting and increasing retractions. When respiratory distress is mild, intermittent grunting at a slower respiratory rate may alternate with periods of mild tachypnea. As grunting becomes more severe, the expiratory phase becomes increasingly prolonged. The length of the grunt, rather than its loudness, correlates with the severity of distress. Intermittent mild grunting can be misinterpreted by parents as crying. The rhythm of grunting and its occurrence at the end of expiration are key features that help to distinguish it from other vocalizations. Retractions require a forceful inspiratory effort and decreased lung compliance, and they may be absent or less prominent than expected in an infant with neuromuscular depression.

Nasal congestion, airway obstruction, and airway secretions can produce sounds that are audible without a stethoscope. Noisy or congested nasal breathing and intermittent sneezing not associated with upper respiratory infection is common in the first few days after birth. A hoarse cry suggests an abnormality affecting the vocal cords. Because intubation of vigorous infants born through meconium-stained amniotic fluid is no longer routine (Halliday and Sweet, 2001), hoarseness or stridor caused by vocal cord trauma in healthy term infants is less common than previously. Inspiratory stridor is due to narrowing or partial obstruction of the upper airway. The presence and loudness of the stridor depends on respiratory effort as well as the extent of airway narrowing, so that stridor worsens with forceful inspiration during crying. Stridor during

crying in an infant with no respiratory distress when quiet is often due to tracheolaryngomalacia, and it is usually benign. Stridor that is present during quiet breathing or present during both inspiration and expiration suggests the presence of a more significant airway obstruction that requires further evaluation.

In the routine examination of the infant who is observed to be centrally pink and breathing comfortably in room air, brief auscultation of the chest of a sleeping or quiet infant is usually sufficient to ensure that the breath sounds are clear, and that air entry is adequate and equal bilaterally. Sounds are not well localized in the neonate, and the infant might not remain quiet for long, so attention to the quality of the breath sounds is usually more helpful than attempting to compare multiple sites. Detection of abnormal lung sounds including crackles, wheezes, and rhonchi requires further assessment. If more detailed examination is indicated, auscultate over the four major quadrants anteriorly, on the sides, and on the upper and lower back bilaterally. Diaphragmatic hernia manifesting in the neonatal period usually causes significant respiratory distress, but rarely a small diaphragmatic hernia is detected by the presence of bowel sounds in the chest in an asymptomatic infant. Spontaneous cough, which is abnormal in neonates, is most commonly caused by infection or aspiration.

Percussion of the chest, rarely done as part of routine examination of newborn, can be useful for estimating the position of the upper margin of the liver. Percussion can also be used to detect a large effusion or lung consolidation, but infants with these conditions will have other symptoms of respiratory distress, so the diagnosis will rely on imaging studies and not the physical examination. Transillumination can be useful for supporting a rapid diagnosis of pneumothorax in a distressed infant, but it is not reliable for detecting a small pneumothorax that produces minimal symptoms.

Respiratory symptoms are sensitive but nonspecific indicators of illness in the newborn, because alterations in respiration (including apnea) can accompany illness of many different etiologies. Common causes of subtle or mild respiratory distress detected in the routine evaluation include retained fetal lung fluid (transient tachypnea of the newborn), spontaneous pneumothorax, neonatal sepsis, pneumonia, meconium or amniotic fluid aspiration, and congenital heart disease. Any infant with respiratory distress should be transferred to an NICU or observation nursery for further evaluation, monitoring, and treatment.

CARDIOVASCULAR

The evaluation of the cardiovascular system during the routine examination has two major goals: to assess the current status of the circulation and to detect signs of congenital heart disease, particularly the critical, ductal-dependent forms that can produce rapid clinical deterioration in the newborn period. Although detection of heart disease is important, abnormal circulatory findings in the newborn are more often secondary to other problems, including sepsis, hypovolemia, anemia, and hypoglycemia. The cardiovascular system undergoes marked changes after birth involving the transition to air breathing, the progressive decrease of pulmonary vascular resistance, and the closure of the ductus arteriosus. These changes affect the physical examination of healthy infants and those with congenital heart disease; therefore the time after birth is always an important consideration in the interpretation of the examination.

Physical examination of the cardiovascular system is not limited to examination of the heart and pulses. It also requires attention to the infant's general behavior and activity, to respiratory symptoms, to the color of the tongue and oral mucosa, and to the temperature, color and perfusion of all regions of the body. These features will usually be inspected at different times during the course of the routine examination, but they should be reevaluated during the heart and chest examination if cardiovascular abnormalities are suspected.

Important features of the pulses are the rate, rhythm, volume and character. The heart rate of the resting well newborn averages 120 to 130 beats/min, with high variability. Transient sinus tachycardia during vigorous crying is common, but persistent tachycardia with a rate greater than 160 beats/min suggests a need for further investigation. A low resting heart rate caused by sinus bradycardia (80 to 100 beats/min) during sleep is common in healthy full-term infants. Isolated premature beats can be noted occasionally in otherwise healthy infants and are almost always benign. The femoral pulses in a normal neonate are not easy to palpate, and they are easily obliterated with pressure. They usually receive a grade of 2 on the traditional scale of 0 to 4. A patent ductus arterious will not cause bounding pulses until the pulmonary vascular resistance has dropped enough to allow significant left-to-right shunting. Uniformly weak pulses suggest a low output state, usually accompanied by signs of poor perfusion. If a decrease or delay of the femoral relative to the brachial pulses is detected, measurement of the blood pressure in all four extremities can reveal a gradient in the blood pressure caused by coarctation of the aorta. However, normal pulses and four-limb blood pressures do not rule out a coarctation if the ductus arteriosus remains open.

The precordial area and heart are examined by inspection, palpation, and auscultation. A precordial impulse can be visible in normal newborns, especially during activity, but visible prominence of the precordial area together with a palpably increased cardiac impulse suggest cardiomegaly or a hyperdynamic state. Displacement of the cardiac impulse to the right suggests dextrocardia or a shift in the mediastinum. Thrills are rarely palpable in the newborn.

Auscultation of the heart should be performed with specific questions in mind, with attention attuned sequentially for heart sounds, clicks, murmurs, and other abnormal sounds. Most sounds and murmurs in the newborn are relatively high-pitched, so the diaphragm is usually used initially. The bell can be used for further evaluation of low-pitched sounds, if needed. The first heart sound, produced by closure of the mitral and tricuspid valves, is usually single in newborns and best heard in the precordial area. The second sound, produced by closure of the aortic and pulmonary valves, is usually best heard at the left upper sternal border. With focused attention, slight splitting of the second sound and its variation with respiration can be appreciated. Third and fourth heart sounds are abnormal in the newborn. Systolic ejection clicks may be heard in some normal neonates in the first several hours after birth, but ejection clicks are abnormal after this period (Johnson, 1990).

The timing, location, intensity, radiation, quality, and pitch are important characteristics of heart murmurs that can help to distinguish physiologic from pathologic murmurs. With repeated examination, physiologic heart murmurs may be detected in as many as 60% of infants during the first 48 hours (Johnson, 1990). These murmurs are most commonly systolic ejection murmurs that are transient and soft (grade I or II), and they are usually attributed to flow through a closing ductus arteriosus or to increasing flow across the pulmonic valve as pulmonary vascular resistance drops. Vibratory systolic murmurs resembling Still's murmur can be heard in some newborns. A murmur detected on a routine newborn examination that is not clearly physiologic needs further evaluation.

Detection of a suspicious murmur is the most common reason for further evaluation in an otherwise asymptomatic newborn, but absence of a murmur does not rule out congenital heart disease. Examples include transposition of the great arteries and atrioventricular (AV) canal defect. A decrease or loss of a murmur can be an ominous sign that accompanies clinical deterioration associated with ductal closure in an infant with ductal-dependent pulmonary or systemic blood flow.

Pathologic murmurs detected in the first few hours of life are usually caused by obstruction of ventricular outflow such as aortic stenosis or pulmonic stenosis; they are crescendo-decrescendo murmurs, usually grade II or III. This type of murmur may also be caused by subaortic stenosis associated with hypertrophic cardiomyopathy in a macrosomic infant of a mother with diabetes. Murmurs associated with defects that produce left-to-right shunting usually appear after a few days, when the pulmonary vascular resistance has dropped sufficiently. Pansystolic murmurs (which include and obscure the first heart sound) that are heard soon after birth are most commonly caused by AV valve insufficiency, whereas left-to-right shunting through a ventricular septal defect produces a pansystolic murmur that typically appears only after 1 to 2 days. Diastolic murmurs are rare in newborns. A continuous murmur in a neonate usually represents an aortopulmonary communication or an arteriovenous fistula. The location of an extrathoracic arteriovenous fistula may be revealed by auscultation of a bruit, most commonly in the head or liver.

ABDOMEN

Examination of the abdomen begins with observation of the configuration, fullness, and movement with respiration of the abdominal wall. Major abdominal wall abnormalities such as omphalocele, gastroschisis, prune belly syndrome, and bladder extrophy will be obvious on initial inspection in the delivery room and may be diagnosed prenatally. Although a large omphalocele will never be missed, a small one may produce only a slight widening of the umbilicus and proximal umbilical cord (Figure 25-17). If such an omphalocele is not detected in the delivery room before the umbilical cord is clamped and cut, the intestine within it may be damaged. The abdomen of the neonate ranges from flat to moderately protuberant, with substantial variation depending on feeding and the passage of gas and meconium. A markedly distended abdomen suggests the possibility of significant ascites, a large mass, or an intestinal obstruction. A proximal obstruction such as esophageal or duodenal atresia does not cause abdominal distension, however. A sunken or scaphoid abdomen may be seen in the infant with respiratory distress caused by a diaphragmatic hernia. The umbilicus should be inspected for meconium staining, for signs of infection, and for the rare occurrence of pallor and edema or the visible discharge of urine caused by a patent urachus. At 1 or 2 days after birth, slight redness of the periumbilical skin is common, because of irritation from the cord clamp, and needs to be distinguished from an omphalitis or cellulitis. Counting of the umbilical vessels is best done in the delivery room, on the freshly cut cord.

FIGURE 25-17 A small omphalocele that could be injured if the cord were to be clamped too close to its insertion. *(Reprinted from Rudolph AJ: Atlas of the newborn, vol 4, Hamilton, Ont, Canada, 1997, BC Decker, p 109.)*

If the infant is asleep or resting quietly, it is prudent to auscultate for bowel sounds before proceeding to palpate the abdomen. Palpation should be initially gentle and superficial, to detect any signs of tenderness and the presence of an enlarged liver or spleen. Tenderness must be distinguished from the tendency of the infant to stiffen the abdominal muscles in reaction to the touch of the examiner's fingers, which are usually colder than the infant's skin. If the examiner's fingers remain in gentle contact within the same spot, the temperature difference will disappear in a moment, and the baby will usually relax and allow the examiner to proceed without a struggle. In the healthy infant, the liver edge may be at or slightly above the right costal margin, or palpable 1 to 2 cm below. The spleen is rarely palpable unless it is enlarged. Gentle palpation of the lower abdomen can detect an enlarged bladder, which is the most common cause of a midline abdominal mass in neonates. Deep palpation to detect small masses or enlargement of the kidneys is most easily done soon after birth, before the infant has fed much, and when the infant is quiet. However, a satisfactory examination can be done even in a crying infant by keeping the fingers in position, and gradually increasing the depth of palpation each time the infant briefly relaxes the abdominal muscles while taking a breath between cries. It is helpful to support the flank with one hand while palpating for the kidney with the other, or to palpate with the thumb while supporting the flank with fingers of the same hand. Percussion of the

abdomen is not particularly helpful in routine examination, but it can sometimes help to define the boundaries of an enlarged liver or bladder.

GENITALIA AND PERINEUM

Brief inspection after delivery is usually sufficient to identify the infant as male or female. The evaluation and management of the infant with ambiguous genitalia is discussed in Chapter 92. In both male and female infants, a soft swelling or bulge in the inguinal area may be due to an inguinal hernia. The bulge typically appears or increases in size during crying and is easily reduced with gentle pressure when the infant relaxes. The perineum is inspected to locate the anus and assess the tone of the anal sphincter. Absence of a normal anal opening should be detected as part of the initial evaluation in the delivery room. However, external observation of an apparently normal anus does not guarantee internal patency of the anus, which is best confirmed by the normal passage of meconium.

The genitalia are mainly examined by inspection, supplemented by palpation, with the infant in a supine, frog-leg position. In the newborn male, the foreskin normally covers the entire head of the penis, which is adherent to the glans. The urethral opening is usually hidden by the foreskin and need not be visualized if the foreskin is intact. The foreskin is typically incomplete if hypospadias is present, which allows the abnormal position of the urethral opening to be identified easily. Congenital chordee, a ventral angulation of the head of the penis, may accompany hypospadias or occur in isolation. Chordee can be missed unless the examiner straightens the penis by gently retracting the skin along the shaft towards the base of the penis. In infants who have a generous pad of subcutaneous fat at the base of the penis, this maneuver also helps to avoid a false impression that the penis is short. Dribbling of urine or a weak stream, if observed, is suspicious for bladder dysfunction or urethral obstruction. The scrotal sac and inguinal areas are palpated to locate the testes and assess their size. The scrotal rugae usually appear at approximately 36 weeks' gestation and cover the entire scrotum at term. Enlargement of the scrotal sac is most commonly caused by a hydrocele. Transillumination can help to distinguish a hydrocele from swelling because of congenital testicular torsion or other masses. Bowel sounds may be audible in a scrotum enlarged by an inguinal hernia.

During the inspection of the female genitalia, the examiner must gently retract the labia majora laterally to allow full visualization. The sizes and positions of the labia minora, clitoris, urethra, and vaginal opening should be noted. Relative prominence of the labia minora is normal in preterm infants. Partial labial fusion and an increase in the size of the clitoris may represent virilization caused by congenital adrenal hyperplasia or related endocrine abnormalities. The posterior fourchette should be at least 1 cm from the anal opening. Enlargement of the uterus because of hydrometrocolpos may produce a protruding perineal mass. Vaginal tags and mucoid vaginal discharge are common at birth, resulting from exposure to maternal estrogen. A slightly bloody vaginal discharge (pseudomenses) caused by hormonal withdrawal is common in healthy females during the first week after birth.

BACK

The back is inspected for asymmetry or abnormal positioning of the shoulders, ribs, and hips. Major neural tube defects and large masses such as a large sacrococcygeal teratoma will be detected prenatally or on initial inspection in the delivery room. In the routine examination, the lumbosacral area should be inspected carefully for the presence of deep or unusual dimpling of the skin over the sacrum, for sinus tracts, for unusual tufts of hair, and for small masses such as a lipoma or hemangioma, any of which may be associated with spina bifida occulta or tethering of the spinal cord. The spine is inspected for straightness and palpated for the integrity and alignment of the posterior spinous processes.

MUSCULOSKELETAL SYSTEM

Routine assessment of the musculoskeletal system begins with plotting the height, weight, and head circumference on appropriate growth charts. Detailed measurements of the limbs and trunk can be made if growth appears disproportionate, but they are not part of the routine examination. The infant's posture, muscle mass, and movements should be observed. As the different parts of the body are surveyed during the course of the examination, any limitation in the normal range of joint motion and any localized swelling or tenderness should be noted. Major limb or skeletal malformations will usually be appreciated on initial inspection in the delivery room, but minor anomalies such as supernumerary digits, syndactyly, or nail hypoplasia can be missed if a disciplined approach is not taken. Lack or restriction of normal movement of an extremity can be caused by trauma, most commonly a fractured humerus or clavicle, or by an intrinsic abnormality of the joint or limb. Although they generally require no treatment, fractures of the clavicle are sufficiently common that the clavicles should be specifically examined in every newborn. Crepitus and tenderness at the site of a clavicle fracture may be more easily detected if the examiner palpates a clavicle with one hand while using the other to elevate and rotate the ipsilateral shoulder.

Deformations caused by in utero positioning are not always easy to distinguish from malformations on an initial examination. Mild inward bowing of the lower legs and feet is common in newborns. If an inward-turning foot can be brought easily to a neutral position, a clubfoot deformity is unlikely, and the angulation of the foot can be expected to normalize spontaneously.

EXAMINATION OF THE HIPS

Assessment for developmental dysplasia of the hip (DDH) is an important component of the examination of every newborn (American Academy of Pediatrics, 2000; Sewell et al, 2009). Frank dislocations, partial dislocations, and instability of the humoral head in the socket can be detected by examination in the newborn period. Nevertheless, DDH is not always detectable at birth. Statistical risk factors for DDH include a positive family history, female sex, and breech presentation. In addition to the Ortolani and Barlow maneuvers, the examination also involves a focused inspection for indirect clues related to the possible presence of DDH.

During general inspection of the infant, attention should be paid to the resting posture and spontaneous movements; any asymmetry or unusual positioning of the legs should be noted. Asymmetry of the gluteal or femoral skin folds may be a sign of unilateral hip dislocation. A unilateral dislocation may also produce an apparent inequality of leg length, seen either with the legs in extension (Thomas' sign) or with the feet flat on the bed and the knees bent (Galeazzi's sign). A restricted range of motion, particularly abduction, is a clue that may detect either unilateral or bilateral dislocations.

The dislocation of the femoral head during a Barlow maneuver or its relocation during an Ortolani maneuver produces what is called a *clunk* that must be distinguished from high-pitched clicks of the hip that are common and benign. Clunks and clicks are perceived by palpation and are not actually audible. The key element defining the clunk is a distinct sensation of abrupt movement of the femoral head as it passes over the rim of acetabulum and drops into or out of the socket. A dislocated or dislocatable hip has the distinctive clunk, whereas a subluxable hip is characterized by a feeling of looseness or sliding without a distinct clunk (American Academy of Pediatrics, 2000). Both maneuvers are performed with the infant supine, starting with the legs held in neutral rotation and the hips flexed to 90 degrees but not more. Each hip is examined separately. For the Ortolani maneuver, the index and middle fingers of the examiner's hand are placed along the greater trochanter with the thumb placed along the inner thigh near the knee. The other hand stabilizes the pelvis. The examiner gently abducts the hip by rotating the thumb outward while lifting anteriorly with the fingers. A distinct sensation of movement is felt when a posteriorly dislocated hip relocates during abduction. For the Barlow maneuver, the index and middle fingers are also positioned along the greater trochanter, but the examiner's hand is rotated so that the base of the thumb is on top of the knee. The maneuver is performed by adducting the leg until the knee is in the midline, and then applying gentle pressure to the knee in a downward direction along the adducted femur. A clunk is felt if this maneuver induces the femoral head to exit the acetabulum posteriorly. Minimal force is used in either maneuver.

The examination is considered positive for DDH if a clunk of dislocation or reduction is elicited during the Barlow or Ortolani maneuvers, in which case prompt referral to an orthopedist is strongly recommended. The examination is considered equivocal if the Barlow and Ortolani test results are negative, but warning signs such as asymmetric creases, apparent or true leg length discrepancy, or limited abduction are found. In this case, the recommended next step in evaluation is a follow-up examination of the hips by a pediatrician at 2 weeks (American Academy of Pediatrics, 2000).

NEUROLOGIC EXAMINATION

The neurologic system is assessed during the course of the general newborn examination and by performing some specific maneuvers to elicit neonatal reflexes. Because the healthy infant's responses vary with the state of alertness, and because the infant's tolerance for prolonged examination is limited, eliciting a perfect response to each maneuver should not be expected. Fortunately, there is sufficient redundancy in the routine examination that it is not difficult in most cases for the examiner to be satisfied that the infant is neurologically normal. When the examination is not fully reassuring, repeating selected parts of the examination at a later time may be more helpful in clarifying findings than attempting an extended examination at one time. The newborn screening examination includes assessment of the infant's alertness, spontaneous activity, posture, muscle tone and strength, head control, and responses to manipulation and handling.

The overall assessment of alertness, tone, and activity is one of the most important components of the newborn examination. Diminished alertness, tone, or spontaneous activity are sensitive but nonspecific indicators of illness that are much more likely the result of other causes, such as neonatal sepsis, than a specific neurologic abnormality. The typical healthy newborn is easily awakened from sleep and remains alert through the remainder of the routine examination, shifting among states of quiet alertness, active alertness, and crying. The examiner's initial attempt to quietly auscultate the breath and heart sounds of a sleeping infant is often foiled by the infant's prompt arousal and crying. The healthy newborn demonstrates a vigorous cry when upset, but is able to self-console or to be consoled with holding, sucking, or feeding. An infant who is stuporous or difficult to arouse is clearly abnormal and needs further evaluation, as does an infant who is unusually irritable or inconsolable. The typical newborn will be rather alert for several hours after delivery, but may then provoke parental concern by becoming relatively sleepy and uninterested in feeding for the remainder of the first 24 hours. As long as the infant continues to be easily arousable and the examination result remains otherwise normal, parents can be reassured that the infant will likely begin feeding much more vigorously on the second day. Decreases in tone or alertness occurring 1 day or more after birth in a previously vigorous infant are not normal and require prompt investigation for sepsis or other problems, including inborn errors of metabolism that can cause progressive symptoms starting a few days after birth because of accumulation of toxic metabolites.

Because the newborn cannot respond to verbal questions or commands, assessment of the infant's sensory functions in the routine examination depends on observation of the strength and quality of the infant's movements in response to handling during the examination and to specific local stimulation, such as the elicitation of the palmar and plantar grasp reflexes and the rooting and sucking reflexes. Assessment of vision in the routine newborn examination is limited to observing pupillary constriction and a blink response to light, which are subcortical responses, and to observing the infant's visual attentiveness. The healthy term newborn is expected to be able to visually fixate on and follow the examiner's face, but failure to observe this response during the course of the routine examination is common, because it can take more time and patience to elicit than are available. Hearing can be evaluated behaviorally by observing the infant's responses to the ringing of a bell and other sounds. However, behavioral testing can only detect profound, bilateral hearing loss, and it has been effectively replaced in the routine newborn examination by automated hearing tests (American Academy of Pediatrics, 2007; US Preventive Services Task Force, 2008).

The assessment of motor function relies on the observation of the infant's posture and spontaneous movements, observation of the infant's general responses to stimulation and handling, and the elicitation of specific reflexes. The healthy term newborn normally maintains a resting posture with elbows, hips, and knees strongly flexed. The scarf sign, forearm recoil, square window of the wrist, the heal-to-ear maneuver, and popliteal angle are measures of tone and flexibility commonly scored in the gestational age assessment (Ballard et al, 1991; Dubowitz et al, 1970). The active tone and strength of upper extremity muscle groups are routinely assessed by eliciting the palmar grasp and by arm traction during the pull-to-sit maneuver. Lower extremity strength and tone are assessed during the general examination of hips and feet, and by testing for the supporting reaction, stepping reflex, Babinski's reflex, and ankle clonus. The neck flexors may be evaluated during the standard pull-to-sit maneuver, or by lifting the shoulders to pull the baby to a sitting position. The neck extensors can be evaluated by tilting the infant forward from a sitting position, or evaluated along with truncal tone by suspending the infant in a prone position with the examiner's hand under the chest (ventral suspension maneuver).

When observing the infant's movements, the examiner should note any asymmetry and pay attention to qualitative characteristics such as the relative smoothness versus jerkiness or tremulousness of movement. Unusual jitteriness may be a symptom of hypoglycemia or hypocalcemia, especially in infants of mothers with diabetes, infants that are small or large for gestational age, or infants who were exposed to opiates or other drugs in utero and are experiencing withdrawal. Passive restraint of an extremity should inhibit jittery movements, but will not stop the rhythmic contractions of clonic seizure activity. In addition to clonic movements, signs of neonatal seizures can include tonic posturing, repetitive stereotyped movements of the face or extremities, tonic horizontal eye deviation or nystagmoid jerking, staring or blinking, apnea, and unexplained changes in heart rate or blood pressure. Although it is uncommon to observe an actual seizure during the routine newborn examination, the pediatrician or neonatologist is frequently called to evaluate an infant because of concern about unusual movements seen by a parent or nurse. In the otherwise healthy newborn who is fully alert and responsive, jerky or abrupt movements that are evoked by stimulation (e.g., startles), that can be suppressed by passive restraint (e.g. jitteriness), and that are not accompanied by autonomic changes or changes in alertness are unlikely to be seizures. Transient episodes of disconjugate gaze are also not unusual in normal newborn infants, particularly when the infant is entering or awakening from sleep.

Neonatal Reflexes

The neonatal or primitive reflexes frequently tested during routine examination of the newborn include the Moro reflex, the asymmetrical tonic neck reflex, truncal incurvation (Galant reflex), the palmar and plantar grasp reflexes, the Babinski's reflex, and the placing and stepping reflexes. The Moro reflex can be elicited following the pull-to-sit maneuver, by lowering the infant until there is only a slight space between the neck and bed, and then allowing the infant to fall back suddenly. Alternatively, the Moro response can be elicited by the "drop" method: the examiner lifts the baby completely off the bed, supporting the head and trunk with both hands and keeping the baby supine, and then rapidly lowers the baby by approximately 4 to 8 inches. The complete Moro reflex involves a quick bilateral abduction of the arms and extension of the forearms with full opening of the hands, followed by smoother and slower return of the hands toward the midline, with curling of the fingers. The startle reflex is similar to the Moro reflex, but without full extension or hand opening, and may occur spontaneously or be evoked by a sudden noise or movement.

The position of the neck affects the tone of the extremities via the asymmetrical tonic neck reflex. This should be kept in mind during observation of the infant's spontaneous movements, because it can cause a false impression of asymmetry if the position of the neck is not taken into account. To test the asymmetric tonic neck reflex, turn the infant's head 90 degrees to one side for 15 seconds, keeping the infant lying on the back with the shoulders horizontal. In the complete response, the ipselateral arm and leg will extend and the contralateral arm and leg will flex, producing the "fencing" posture. The test is then repeated with the head turned to the other side. Observation of the complete response is reassuring, but its absence is not necessarily abnormal, because partial and unidirectional responses are common in normal newborns. However, an unusually sustained or exaggerated response is abnormal.

The truncal incurvation reflex is elicited with the infant held in ventral suspension by stroking lightly down the back on one side, and then the other. The normal response is for the infant to curve the spine strongly, concave toward the stimulated side.

The supporting, placing, and stepping reflexes are elicited with the infant held upright. The supporting reaction is elicited by lowering the infant vertically until both feet touch the surface of the bed or table. A positive response, usually seen after a slight delay, is partial extension at the hips and knees, as though the infant is attempting to stand and support his or her weight. The stepping reaction is tested by lowering the infant so that one foot touches the surface, with the infant tilted slightly forward. The infant should flex that leg and extend the other, as though taking a step. The response can sometimes be sustained for several alternating steps. The placing reaction is elicited by lifting the infant to bring the dorsum of one foot in contact with the underside of a table or bassinet edge. In a positive response, the infant lifts the foot up and places it on the top surface.

Babinski's reflex, which is normal in neonates, consists of dorsal flexion of the big toe and spreading of the other toes in response to stroking the foot laterally. Firm pressure on the sole of the foot, in contrast, will elicit a plantar grasp. The deep tendon reflexes are usually not elicited during routine examination of the well newborn, but they are helpful as part of a more complete examination if neurologic abnormalities are suspected. The pectoralis, biceps, brachioradialis, thigh adductor, crossed adductor, knee jerk, and ankle jerk reflexes are the most readily elicited (Volpe, 2008). Ankle clonus may be elicited by quickly dorsiflexing the foot, which in a healthy term infant should produce no more than approximately

five beats of alternating extension and flexion with rapidly decaying intensity.

Brachial Plexus Injury

Although fortunately not common, brachial plexus injury is one of the more frequent neurologic abnormalities found in the otherwise healthy newborn, occurring in about 0.5 to 2 per 1000 live births. Often there is a history of difficult delivery because of shoulder dystocia. Brachial plexus injury can occur in isolation or in conjunction with fractures of the clavicle or humerus. Typical findings in Erb's palsy are an inability to abduct and externally rotate the shoulder, flex the elbow, and supinate the forearm because of injury to C5-C6 (Volpe, 2008). If C7 is involved, wrist and finger extension are also weak (Figure 25-18). A distal brachial plexus injury involving C8-T1 causes weakness of wrist and finger flexion.

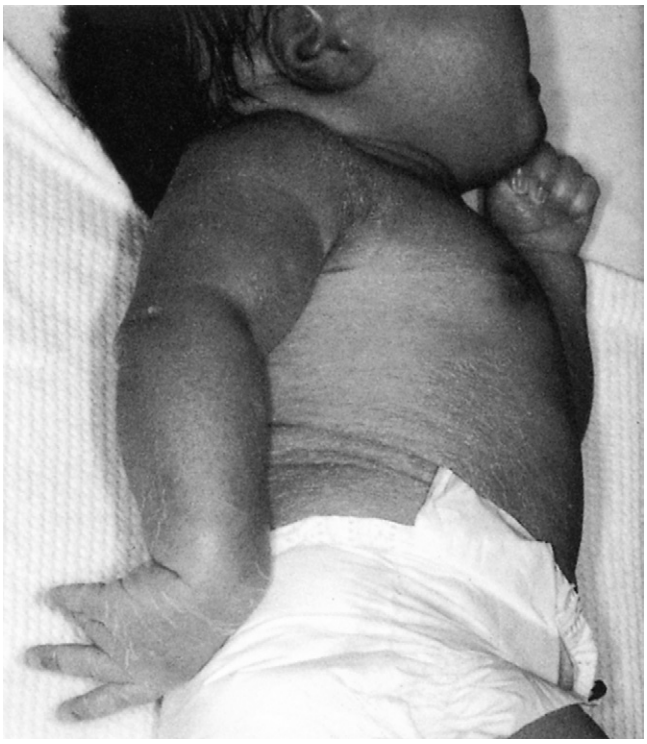

FIGURE 25-18 Hand and arm position in an infant with Erb's palsy involving C5, C6, and C7. *(Reprinted from Fletcher MA:* Physical diagnosis in neonatology, *Philadelphia, 1998, Lippincott-Raven, p 450.)*

Cranial Nerves

Observation and maneuvers during the routine examination provide at least partial assessment of all the cranial nerves (Volpe, 2008) except for the olfactory nerve (CN I), which is not routinely tested. Visual attentiveness, the ability to fix and follow, eyelid closing in response to light, and the pupillary light reflex require the optic nerve (CN II). The pupillary light reflex also tests the oculomotor nerve (CN III). Extraocular movements are controlled by CNs III, IV, and VI. Vertical gaze is difficult to assess in neonates, but horizontal gaze in both directions can usually be verified by observing spontaneous eye movements or by the rotation test. The examiner performs the rotation test by turning in place while holding the infant upright and supporting the back of the head. If vestibular functions (CN VIII) are intact, the infant will turn the head in the direction of rotation or, if the head is restrained, turn the eyes in that direction. Eliciting rooting or a facial grimace in response to touching the face tests the sensory portion of the trigeminal nerve (CN V). The corneal reflex can be tested by touching the cornea with a wisp of sterile cotton, but this is not part of the routine newborn examination. CNs V, VII, IX, X, and XII are all involved in normal sucking and swallowing. The motor portion of CN V controls the muscles of mastication, which are involved in the jaw-closing phase of the suck and are assessed during elicitation of the suck when the infant bites down on the examiner's finger. Although not part of the routine examination, the masseter or jaw-jerk reflex can be elicited by placing the forefinger of one hand on the infant's relaxed chin and tapping it with the forefinger of the other hand.

The facial nerve (CN VII) is required for pursing of the lips in sucking, as well as normal facial expression and tone. Compression of the facial nerve by in utero positioning or by forceps injury are common causes of unilateral facial weakness in the newborn period (Figure 25-19). CNs IX and X are needed for normal swallowing and the gag reflex. CN XII is involved in the milking action of the tongue during sucking and swallowing. Taste, mediated by CN VII (anterior two thirds of the tongue) and IX (posterior third) is not evaluated in the routine examination. Sternocleidomastoid function (CN XI) is assessed by evaluating head flexion and lateral rotation. Because head control is often poor in normal newborns, it can be difficult to detect an abnormality unless it is unilateral. However, an asymmetric abnormality of a sternocleidomastoid is caused more commonly by torticollis than dysfunction of CN XI. The vestibular portion of CN VIII is assessed by the rotation test, as noted previously, or by the doll's eye maneuver. The auditory portion of CN VIII is best assessed using brainstem auditory evoked responses, rather than behavioral responses to auditory stimulation.

FIGURE 25-19 *(See also Color Plate 17.)* **Unilateral facial weakness in two infants.** There is mild facial asymmetry with flattening of the nasolabial folds at rest **(A** and **C)** and more obvious asymmetries of the grimace and eye closing during crying **(B** and **D)**. The weakness is on the infant's left side in **A** and **B,** and on the infant's right side in **C** and **D**. *(Reprinted from Fletcher MA:* Physical diagnosis in neonatology, *Philadelphia, 1998, Lippincott-Raven, p 457.)*

CHAPTER 26

Routine Newborn Care

James A. Taylor, Jeffrey A. Wright, and David Woodrum

Two central paradoxes underlie the care of healthy newborn infants. First, although birth is perhaps the oldest and most natural of all human processes, the infant mortality rate has been extraordinarily high until recently. The second paradox in providing newborn care is that neonates are at once the healthiest and most vulnerable patients in medicine. Recent medical history is replete with examples of the pendulum swinging too far in each direction around these paradoxes. The promotion of scheduled feeding using infant formulas rather than breastfeeding is an example of the medicalization of neonatal care. Conversely, recent resistance to treatments that prevent uncommon but disastrous conditions represent a denial of the benefits provided by medical care.

Therefore optimal care of a normal neonate is an attempt to balance these competing forces. Systems of care should be designed to support the concept that newborn infants are extraordinarily healthy and require little intervention beyond promotion of breastfeeding. Interventions for which there is evidence that the benefits far outweigh the risks should be provided as unobtrusively as possible. Simultaneously, while promoting natural care for these newborns, health care providers need to be vigilant for the early identification of neonates who are at risk for conditions such as dehydration, sepsis, and severe hyperbilirubinemia.

The goal of this chapter is to provide an evidence base for the promotion of healthy newborn care by parents, the rationale for monitoring full-term neonates for various conditions, a risk-benefit analysis of common treatments, and the significance of common prenatal and postnatal findings. Rather than providing a comprehensive prescription for the care of these infants, it is hoped that the reader will integrate the information provided in this chapter with expert opinion and clinical experience to determine the proper care of healthy newborns.

INITIAL ASSESSMENT

Timing of the initial assessment of a full-term newborn is dependent on the condition of the infant and parental preference. In most instances a health care professional who is present at the birth will make a general appraisal of the infant and alert the child's provider if there is an acute problem necessitating an immediate evaluation. Usually the neonate will be healthy and the assessment can be timed so as not to interfere with breastfeeding, bonding with the family, and routine care.

Before examining a healthy newborn, the mother's medical history should be reviewed to identify issues that would affect the care or prognosis of the infant. For example, a history of diabetes in the mother would lead to glucose testing in the neonate. Maternal drug use should be assessed for possible teratogenic effects, possibility of symptoms of withdrawal in the infant, and compatibility with breastfeeding. It is important to review the pregnancy history and focus on estimated gestational age, the results of screening for genetic conditions, and the results of prenatal ultrasound examinations. Perinatal events such as type of delivery, length of time that membranes were ruptured, and Apgar scores should also be reviewed. Finally, it is critical to review the mother's social history to insure that the newborn will be raised in a nurturing environment and to identify high-risk situations for which interventions are needed before or shortly after discharge from the newborn nursery.

The results of several laboratory tests commonly performed on pregnant women will determine the need for treatment or monitoring during the newborn nursery stay. These tests include maternal HIV, hepatitis B surface antigen status, and syphilis. The mother's blood type, Rh status, and antibody test results are useful in identifying newborns with an increased risk of hyperbilirubinemia. It is important to note the results of testing for maternal colonization with group B *Streptococcus* (GBS) and the type and timing of antenatal antibiotic prophylaxis in mothers with a positive test result for GBS.

The infant's weight, length, and head circumference should be measured shortly after birth and plotted on a standardized chart. Although the most common reason for a significant discrepancies among weight, height, and head circumference percentiles is an inaccurate measurement, a valid discrepancy warrants close clinical observation or testing. Glucose testing may be indicated for newborns found to be small or large for gestational age. If the estimated gestational age of the infant is inconsistent with the growth parameters a formal evaluation using a Dubowitz-Ballard assessment of gestational age may be helpful.

When examining a newborn infant for the first time, the initial focus is directed toward an overall assessment of the child's health. Observation and auscultation of the chest allows for detection of an irregular heart rate, murmur, or acute lung condition such as pneumothorax. The heart rate and respiratory rate can be measured. Normal values for heart and respiratory rate in a newborn infant are 100 to 160 beats/min and 35 to 60 breaths/min. Evaluation of skin color may be useful for identifying cyanotic congenital heart disease or pulmonary conditions in a neonate. If uncertainty exists about the presence of cyanosis, oxygen saturation can be measured quickly with a pulse oximeter. The newborn's tone, general posture, and movement should be assessed; abnormalities may be indicative of an acute or chronic central nervous system problem or sepsis.

There are several purposes for the rest of physical examination, including maternal reassurance and education about normal variations. Asymptomatic conditions can be

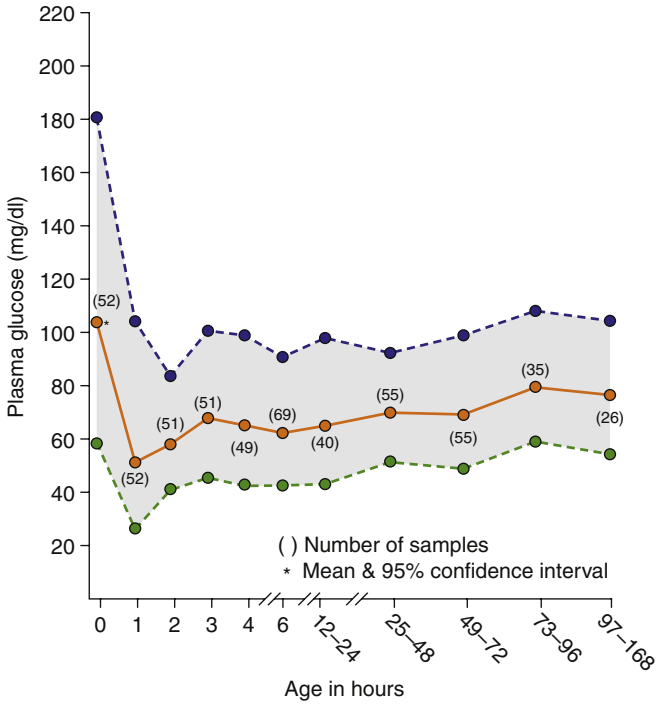

FIGURE 26-1 Predicted plasma glucose values during the first week of life in healthy term neonates appropriate for gestational age. (*Adapted from Srinivasan G et al: Plasma glucose values in normal neonates: a new look.* J Pediatr *109:114, 1986.*)

diagnosed, such as some types of congenital heart disease or developmental dysplasia of the hips. Finally, the examination is a useful screen for rare but serious conditions.

ROUTINE TESTING

GLUCOSE

The fetal blood glucose level is approximately 80% of the maternal level. After birth and separation of the infant from its major energy supply, the infant's glucose falls by an average factor of 0.5. Over the next several hours, it gradually increases to a level approaching that of older infants (Figure 26-1). Critical factors involved in this normal adaptive process include transient inhibition of the infant's insulin secretion and an increase in the counter regulatory hormones, including growth hormone, cortisol, epinephrine, and glucagon (Polin et al, 2004). The end result is the promotion of liver glycogen breakdown, gluconeogenesis, and tissue lipolysis. Given this normal sequence of events, there is no reason to routinely screen the blood glucose in infants who are products of uncomplicated pregnancies, labor, and delivery. Clinical scenarios that might be expected to alter the normal sequence of events and indicate the need for early glucose screening include:

- A pregnancy history of maternal treatment with β-agonists or intrapartum intravenous glucose
- Infants of diabetic mothers
- Infants demonstrating intrauterine growth restriction
- Premature infants
- Infants delivered after in utero or intrapartum fetal distress

BOX 26-1 Clinical Signs Compatible With Hypoglycemia

- Poor feeding
- Lethargy
- Hypotonia
- Irritability
- Tremor
- Seizure-like activity
- Apnea

- Infants with midline facial anomalies, which might be markers for pituitary deficiency
- Infants demonstrating hepatomegaly, suggesting glycogen storage disease
- Any infant showing clinical signs of hypoglycemia (Box 26-1)

The treatment approach to confirmed hypoglycemia depends on the glucose level, the presence of symptoms, or both (see Chapter 94).

NEWBORN METABOLIC SCREENING

Newborn screening for metabolic disorders began in 1962 when 29 states participated in a trial of testing for phenylketonuria. With the implementation of screening programs, criteria were proposed for determining which conditions should be screened. It was recommended that only disorders that were important health problems be included in screening programs. The condition should be detectable before the onset of significant symptoms. Importantly, a specific treatment to prevent adverse clinical consequences from the disorder should be available, and the screening program for the condition should be cost effective (Tarini, 2007). Based on these criteria, conditions such as congenital hypothyroidism and congenital adrenal hyperplasia were slowly added to newborn screening tests in many states, and subsequently conditions such as sickle cell disease were added. Although there is no specific treatment for sickle cell disease, there was evidence that the use of a newborn screening program to identify infants with the disorder led to early initiation of penicillin treatment, which resulted in fewer deaths from sepsis than when disease was identified at the onset of symptoms (Vichinsky et al, 1988). Given the demonstrable effectiveness of early identification, sickle cell disease met criteria for newborn screening.

The advent of tandem mass spectrometry in the 1990s revolutionized newborn metabolic screening. With this technology it is possible to test for a multitude of conditions using a small sample of blood. In 1995, the average number of conditions included in state-mandated screening programs was eight; by 2005 this had increased to 19, with some states testing for up to 46 conditions. Unfortunately, this increase in newborn screening has been controversial. Some of the conditions included do not meet the established criteria for screening, in that there are no known effective treatments, and in some cases it is not known whether the targeted condition always leads to disease. In addition, with increasing numbers of tests come increasing numbers of false-positive results, with the

resulting parental anxiety and potential for the overuse of medical services (Tarini et al, 2006).

In an attempt to define a rational list of disorders for which newborn screening is appropriate, the American College of Medical Genetics used an iterative process to identify 29 "core conditions" that should be included in mandatory screening programs (Watson et al, 2006). As of 2009, approximately 25 of these conditions were included in the screening panels of at least 48 states (National Newborn Screening and Genetics Resource Center, 2009). The most common disorders included in newborn metabolic screens in the United States are congenital hypothyroidism (1 case per 3000 to 4000 infants) and sickle cell disease (American Academy of Pediatrics [AAP] Newborn Screening Task Force, 2000). The incidence of phenylketonuria is approximately 1 in 15,000. For many of the core conditions for which screening is recommended, incidence rates are in the range of 1 in 100,000 to 1 in 200,000 (Kaye et al, 2006). For some disorders, the incidence rate is unknown.

The expansion in newborn screening programs presents a challenge to health care providers. It is difficult to remain knowledgeable about all of the conditions that are screened, the incidence of the various conditions, and their natural histories and treatments. Fortunately, many states have informative Web sites providing up-to-date information for parents and health care professionals. In addition, the American College of Medical Genetics maintains online information for health care practitioners, including synopses of conditions commonly included in screening programs and appropriate management of infants with a positive result (accessible at http://www.acmg.net/resources/policies/ACT/condition-analyte-links.htm).

HEARING SCREEN

Newborn hearing screening has become nearly universal in the United States. Thirty states plus Guam, Puerto Rico, and the District of Columbia have established mandatory early hearing screening programs, and 17 states plus Guam, Puerto Rico, and the District of Columbia require all health insurers to cover the test (National Conference of State Legislatures, 2009). Newborn hearing screening and early intervention is endorsed by the AAP (AAP Joint Committee on Infant Hearing, 2007), and the U.S. Preventive Services Task Force (2008). Many nurseries now use a two-step screen, first using automated otoacoustic emissions screening followed by auditory brainstem response done in those who fail the otoacoustic emissions screening.

Before universal screening, there were questions about the utility of newborn hearing screening, including whether the false-positive rate creates more harm than the benefit of detecting a small number of infants with hearing loss (approximately 1 in 1000 newborns) and whether early intervention is effective (Keren et al, 2002). The specificity of a two-step screening program for hearing loss approaches 0.99. However, even with this high specificity, there at least six false-positive screens for every true positive screening result, because of the low rate of hearing loss (Nelson et al, 2008). The effect of false-positive screens has been minimally investigated. In one study, at 6 months of age, parents of newborns with false-positive screens continued to express worries about their child's hearing after subsequent testing confirmed normal hearing. Fortunately, using standardized measures, there was no evidence of an increase in general anxiety these parents compared with parents of babies with normal newborn hearing screens (van der Ploeg et al, 2008).

False-negative screens are also a concern, because the equipment used is designed for screening and because most auditory brainstem response screening is designed to detect moderate or greater hearing loss. As a result, there is a chance that the screen will be falsely negative in approximately 2% of newborns (Johnson et al, 2005), and pediatricians should continue surveillance of hearing status during childhood.

The results of recent studies have shown improved reading and communication skills in hearing-impaired children identified during the period of universal newborn hearing screening. Furthermore, hearing-impaired children who enroll in treatment programs during the first 3 months of life have better language outcomes at school age (McCann et al, 2009; Vohr et al, 2008). Investigators in a Belgian study found that a cause for hearing loss can be determined in approximately half of children identified by newborn screening, of which 60% have genetic origins and 19% have cytomegalovirus infection (Declau et al, 2008).

It is challenging to ensure that all children with positive newborn screening test results have confirmatory audiologic testing and begin treatment by 3 to 6 months of age. The number of patients lost to follow-up remains problematic in many areas, and services such as amplification may take time to arrange. Efforts must be made to improve these problems for hearing screening programs to be maximally effective.

PRENATAL ULTRASOUND SCREENING FOR BIRTH DEFECTS

Second-trimester ultrasound screening for fetal anomalies has become increasingly routine. Major fetal organ system abnormalities can, for the most part, be identified and referred for appropriate fetal and neonatal management. There are, however, a number of ultrasound findings that have a variable natural history, may or may not be markers for serious conditions, and do not always result in a definitive prenatal workup. These findings often do not fit within the pediatric lexicon, and they can present a challenge to the pediatrician regarding parent counseling and determining management in the neonatal period.

Central Nervous System Findings

Choroid plexus cysts are found in 1% to 3% of second-trimester fetal ultrasound examinations. They are transient, functionally benign in nature, and resolve spontaneously before term. If one or more choroid plexus cysts are found in isolation on prenatal ultrasound examination, no adverse effect on fetal growth and development has been noted. Therefore, without other risk factors, no further evaluation is needed in an infant with this isolated finding and a benign prenatal course. Choroid plexus cysts are believed to be a "soft marker" for aneuploidy (particularly trisomy

18) when associated with other fetal anomalies or with maternal risk factors such as maternal age. In such situations, begin an appropriate prenatal evaluation, such as karyotyping (DiPietro et al, 2006; Lopez and Reich, 2006; Sohaey, 2008b).

Agenesis of the corpus callosum is reported to occur in 0.01% to 0.7% of unselected postnatal populations. Aneuploidy has been reported in 10% to 20% of children with this prenatal ultrasound finding. Major organ system abnormalities are reported to occur in up to 60% of such fetuses. Notably, when absence of the corpus callosum is an isolated fetal ultrasound finding, the reported rate of a relatively normal developmental outcome ranges from 50% to 75%. Well-conducted, long-term studies are lacking. Postnatal follow-up for infants with a history of a finding of agenesis of the corpus callosum on prenatal ultrasound examination should include, at a minimum, close long-term clinical assessment (Chadie et al, 2008; Fratelli et al, 2007; Woodward, 2008).

Mild ventriculomegaly is a relatively uncommon fetal ultrasound finding that may be a soft marker for aneuploidy, fetal infection, or other central nervous system abnormalities. As such, it is recommended that serial imaging studies be undertaken, in some cases including a more extensive workup. In the presence of a benign fetal assessment, most infants appear to do reasonably well after delivery. Close pediatric developmental followup and serial imaging studies are important to consider (Leitner et al, 2009; Melchiorre et al, 2009; Sohaey and Filipek, 2008).

Cardiac Findings

Echogenic cardiac focus is an incidental ultrasound finding in 3% to 4% of healthy fetuses. Notably, there is an increased incidence of twofold to threefold in Asian populations. It is said to be a soft marker for chromosomal abnormalities when associated with other screening abnormalities. If the results of a physical examination of a newborn are normal and there are no other ultrasound findings, no further evaluation is needed (Borgida et al, 2005; Koklanaris et al, 2005; Ouzounian et al, 2007; Sohaey, 2008b).

Gastrointestinal Findings

Echogenic bowel, when noted to be present during a second-trimester ultrasound examination and determined to be grade 0 or 1 (i.e., less echogenic than bone) is a normal variant. Density greater than that of bone (grade 2 to 3) is abnormal and is potentially a marker for cystic fibrosis, trisomy 21, gastrointestinal anomalies, or in utero infection. Isolated echogenic findings are considered benign with a good prognosis and require no special workup or postnatal management (Al-Kouatly et al, 2001; Patel et al, 2004; Sohaey, 2008a).

Cholelithiasis is an uncommon third-trimester fetal ultrasound finding that needs to be differentiated from hepatic calcification. Cholelithiasis is a benign condition requiring no special evaluation or treatment. An imaging examination at 1 year of age for a child with this prenatal finding may be helpful in documenting expected resolution (Agnifili et al, 1999; Sohaey, 2008b).

Hepatic calcifications are uncommon fetal ultrasound findings; they are often isolated, single and, in a low-risk pregnant patient, of no significance. When numerous, hepatic calcifications may be markers for fetal aneuploidy, infection, meconium peritonitis, hepatic tumor, or vascular insult. Twenty percent are associated with some form of fetal pathology. Neonatal management depends on the prenatal workup and the clinical presentation in the newborn period (Oh, 2008; Simchen et al, 2002).

Urinary Tract Findings

Mild fetal pelviectasis is one of the more common abnormalities detected by second-trimester ultrasound examination, with a reported incidence of 0.5% to 5% in unselected pregnant populations. Diagnostic criteria vary, but generally include a second-trimester renal pelvis diameter of 4 to 10 mm and 7 to 10 mm during the third trimester. Some authors consider mild fetal pelviectasis to be a soft marker for trisomy 21. When mild fetal pelviectasis is an isolated finding, the prognosis is good and the condition usually resolves either in utero or during early childhood. In a meta-analysis, it was reported that 11% of children with a history of mild fetal pelviectasis demonstrated postnatal pathology. Authors of a prospective cohort follow-up study reported uropathy in 18% of the patients. There is a lack of consensus as to postnatal management, with some authorities recommending close clinical assessment and others recommending follow-up renal ultrasound examinations at approximately 1 week and 1 month of life (Coelho et al, 2007; Lee et al, 2006; Sohaey and Arnold, 2008).

CAR SEAT TRIALS

The observation that preterm infants had episodes of hypoxia when monitored in car seats led the AAP to recommend in 1991 that preterm infants should be observed and monitored for apnea, bradycardia, or oxygen desaturation in their car safety seat before hospital discharge—the so-called car seat challenge (AAP Committee on Injury and Poison Prevention and Committee on Fetus and Newborn, 1991, 1996; Bull et al, 1999). In the United States, the car seat challenge expanded to include late preterm infants, most of whom did not have respiratory problems during their newborn hospital stay. It has been reported that 25% of late preterm infants do not fit securely into standard car safety seats, and 12% of healthy late preterm infants have apneic or bradycardic events in their car seats (Merchant et al, 2001).

The authors of a Cochrane Review questioned whether car seat trials actually prevent morbidity or mortality, and whether there are adverse effects of not passing this test, such as prolonging the hospital stay or creating parental anxiety. Their review did not disclose any randomized trials, and they concluded that "it is unclear whether undertaking a car seat challenge is beneficial or indeed whether it causes harm" (Pilley and McGuire, 2006). Since then, there has been one randomized trial in healthy term infants comparing car seats to car beds, and no differences were found in rates of oxygen desaturation or apneic

events (Kinane et al, 2006). Further study is needed to determine whether car seat trials in late preterm neonates are warranted.

ROUTINE AND COMMON MEDICAL TREATMENTS

PREVENTION OF OPHTHALMIA NEONATORUM AND CONJUNCTIVITIS

Approximately15% to 20% of babies will develop conjunctivitis in the first few weeks of life. Conjunctivitis can be caused by a sexually transmitted bacteria, normal skin or nasopharyngeal flora, or chemical irritation (Krohn et al, 1993). In addition, eye discharge can be caused by obstruction of the nasolacrimal duct rather than from the conjunctivitis. The most worrisome infection is that from *Neisseria gonorrhea*, which can be invasive to the cornea in a matter of hours and lead to blindness. Despite effective preventive measures known since the 1880s, there are still thousands of children blinded by this infection worldwide each year.

Most states in the United States have laws or regulations that require administration of topical antibiotic ointment to the conjunctivae of babies within a few hours of birth. This practice has been effective in reducing the cases of blindness caused by gonococcal conjunctivitis. It is moderately effective in preventing conjunctivitis caused by chlamydia.

Parents may question the need to expose all babies to eye medication, especially if the mother has been tested and found to be without gonorrhea or chlamydia. Some countries have stopped routine administration of eye prophylaxis. In those countries, an increase in infection, primarily caused by chlamydia, has been noted. With informed consent, parents can opt out of eye prophylaxis for their newborn.

There is lay literature recommending the instillation of colostrum or breast milk into the eyes of babies to prevent or treat conjunctivitis. Although colostrum has antimicrobial action, its efficacy has not been adequately studied.

Povidone-iodine solution has been shown to be more effective and cause less irritation than erythromycin ointment. It is also less expensive, but is not yet approved for this use by the U.S. Food and Drug Administration (Isenberg et al, 1995). Whether instillation of povidone-iodine in the eyes may affect newborn thyroid screens—as has been reported with use of this solution on umbilical cord stumps—is not clear (Lin et al, 1994).

VITAMIN K

Vitamin K is necessary for biologic activation of several human proteins, most notably coagulation factors II, VII, IX, and X. Because placental transfer is limited, cord blood levels of vitamin K_1 (phylloquinone) are 30-fold lower than maternal levels. Intestinal bacteria synthesize menaquinone (vitamin K_2), which has 60% of the activity of phylloquinone. However, neonates have a decreased number of bacteria in their gut that manufacture vitamin K_2; levels of this form of vitamin K are not found in the livers of infants until they are 2 to 3 months old. Therefore newborn infants are deficient in vitamin K at birth and are at risk for significant bleeding. Fortunately intramuscular vitamin K rapidly activates clotting factors, greatly decreasing this risk.

Three presentations of vitamin K–deficient bleeding (VKDB) have been described. Early VKDB manifests in the first 24 hours after birth. It is not prevented by postnatal administration of vitamin K, and it usually occurs in infants born to mothers who are taking medications that inhibit vitamin K. Common medications that inhibit vitamin K include many anticonvulsants, isoniazid, rifampin, warfarin, and some antibiotics such as cephalosporins. Early VKDB is frequently serious because of intracranial and intraabdominal hemorrhage. It is estimated that in neonates at risk for early VKDB, the incidence is as high as 12% (Van Winckel et al, 2009). Classic VKDB occurs in infants during the first week of life. Although the clinical presentation is often mild, blood loss can be significant, and intracranial hemorrhages have been reported. Although estimates vary, the incidence of classic VKDB in the absence of vitamin K supplementation is likely 0.25% to 1.7% (AAP Committee on Fetus and Newborn, 2003). Late VKDB occurs in infants between the ages of 2 and 12 weeks and is usually severe. The mortality rate from late VKDB is approximately 20%, and 50% of children with this disorder have intracranial hemorrhages. Late VKDB is associated with exclusive breastfeeding. Human milk contains only 1 to 4 μg/L of vitamin K, whereas commercially available formula contains 50 μg/L or greater. In neonates who do not receive supplemental vitamin K, the incidence of late VKDB is estimated at 4.4 to 7.2 in 100,000 (or 1 in 15,000 to 1 in 20,000; Van Winckel et al, 2009). Vitamin K administered shortly after birth is effective in preventing classic and late VKDB. Since 1961 the recommended dose of vitamin K for term infants born in the United States has been 1 mg given intramuscularly. However, the results of a study suggesting an association between intramuscular vitamin K given at birth and childhood cancer created controversy regarding this practice (Golding et al, 1990, 1992). The results of subsequent studies have indicated conclusively that there is no increased risk for solid tumors in children given intramuscular vitamin K; however, the possibility that there is a slightly increased risk for leukemia cannot be excluded (Puckett and Offringa, 2000). Because of concerns regarding an increased risk of childhood cancers, a switch to oral vitamin K occurred in some countries, but not in the United States. It is apparent that a single oral dose of vitamin K has an efficacy similar to an intramuscular dose in preventing classic VKDB, but offers less protection against late VKDB. Repeated doses of an oral vitamin K preparation until an infant is 8 to 12 weeks old increases the efficacy of this route of administration. However, it is not clear that even multiple doses of an oral formulation of vitamin K are as effective as a single intramuscular dose, given at birth. In a multinational review, rates of late VKDB in infants receiving various regimens of oral vitamin K were mostly in the range of 1.2 to 1.8 in 100,000 compared with 0 cases in 325,000 children receiving an intramuscular dose (Cornelissen et al, 1997). The oral regimens assessed included a dose at birth of 1 mg. Reported rates of VKDB in infants who received

2 mg orally at birth, with doses repeated subsequently, are lower but still somewhat higher than in neonates treated with intramuscular vitamin K (Busfield et al, 2007; Von Kries et al, 2003). Early data from the Netherlands, where infants received 1 mg orally at birth and 25 mcg daily for up to 12 weeks, suggested that this regimen was as efficacious as an intramuscular dose (Cornelissen et al, 1997). However, in a subsequent study from the Netherlands, the rate of late VKDB was 3.2 in 100,000 in a group of infants with undiagnosed biliary atresia who had been treated with this dosing schedule (van Hasselt et al, 2008). Unrecognized cholestatic liver disease is a significant risk factor for VKDB. Finally, no cases of late VKDB were found among 396,000 Danish infants who received an oral dose of 2 mg of vitamin K at birth and 1 mg weekly until the age of 3 months (Hansen et al, 2003).

Risks from intramuscular vitamin K include pain at the injection site and the possibility of a serious medication error. The risks of a significant complication from the injection are probably negligible; in one study, zero significant complications were reported after 420,000 injections (Von Kries, 1992). In the United States, oral administration is complicated by the lack of an oral vitamin K preparation being licensed for newborns. In some settings, infants have received the intramuscular preparation orally; however, tolerance may be a problem, and the efficacy of this preparation when given orally might not be comparable to the oral formulations used in Europe. In addition, compliance with repeated doses of oral vitamin K in infants may be suboptimal. Finally, it is unknown whether the use of repeated administration of oral vitamin K in the dose range of 1 to 2 mg each week is associated with an increased risk of childhood cancers.

For parents who have questions regarding the best method to prevent classic and late VKDB, the clinician is advised to discuss the pros and cons of intramuscular versus oral vitamin K. If the parents choose oral administration, a dose of 2 mg of vitamin K should be given shortly after birth, with subsequent doses until the infant is at least 4 weeks old if he or she is breastfed. In a policy statement, the AAP suggests that, if an oral vitamin K formulation becomes licensed for use in the United States, a dose of 2 mg can be given at birth and repeated at 1 to 2 weeks of age and at 4 weeks of age for neonates whose parents decline intramuscular vitamin K (AAP Vitamin K Ad Hoc Task Force, 1993).

CIRCUMCISION

Neonatal circumcision is a polarizing issue for health care professionals and parents. Those who favor routine circumcision highlight health benefits such as decreased urinary tract infections (UTIs), reduced risk of penile cancer, and possibly lower rates of sexually transmitted diseases, including HIV (Schoen, 2008). Those who oppose the procedure indicate that the number of circumcisions needed to be performed to prevent one of these outcomes (i.e., the number needed to treat [NNT]) is large, the risks of the procedure balance out these benefits, circumcision leads to loss of sexual sensation, and subjecting a neonate to a painful procedure without clear benefits may be unethical (Andres, 2008).

It is clear that circumcision reduces the risk of UTI by approximately 10-fold; however, given the low incidence of UTI in male infants, 100 boys need to be circumcised to prevent one UTI. Similarly, although circumcision has been shown to prevent penile cancer, it is an extremely rare condition and the NNT is about 900 (Christakis et al, 2000). There has been recent interest in circumcision as a method for preventing HIV. The results of studies in three African countries indicate that circumcision reduces the risk of HIV infection by 56%. Because the incidence of HIV in these countries is high, the calculated NNT is approximately 72 (Mills et al, 2008). Given the same efficacy, the NNT to prevent one case of HIV infection in Canada, where the incidence is 13 in 100,000, or in the United States, where the incidence is 23 in 100,000, is greater than 5000 (Andres, 2008; Hall et al, 2008).

Circumcision is generally a safe procedure. Although some increased bleeding is reported after 1% of circumcisions, the rate of significant complications is approximately 0.2% (Christakis et al, 2000; Gee and Ansell, 1976; Wiswell and Geschke, 1989). Bleeding, sometimes requiring suturing of a vessel, is the most common significant complication, followed by penile injury and infection. Infection is more common after a circumcision using a Plastibell rather than a Gomco clamp; hemorrhage is reportedly similar after either technique (Gee and Ansell, 1976).

Circumcision is an uncomfortable experience for the neonate. Small amounts of sucrose solutions can be offered to the baby for soothing. Pain from the actual surgery can be significantly decreased with the use of a dorsal penile nerve block or ring block. In one study, 65% of infants who had received a dorsal nerve block had no or minimal response to the initial clamping of the foreskin (Taeusch et al, 2002).

A poor cosmetic outcome can be caused by removal of too little foreskin. It has been estimated that 1-9.5% of circumcisions are redone because of parental concern regarding the appearance. In a prospective study, among boys younger than 3 years who had been circumcised using either a Plastibell or with a Mogen clamp, the glans was fully exposed in only 35.6%. However, in older circumcised males the glans was fully exposed in more than 90% (Van Howe, 1997). This finding suggests that parents of a circumcised infant should be counseled that the vast majority of properly done circumcisions will lead to an acceptable cosmetic appearance over time.

In the United States, the Gomco clamp is the most commonly used apparatus for performing circumcisions, followed by the Plastibell and Mogen clamp (Stang and Snellman, 1998). The use of the Mogen clamp leads to shorter procedures and, reportedly, less pain and bleeding than the other techniques (Kurtis et al, 1999; Taeusch et al, 2002). However, less foreskin is removed with the Mogen clamp than with the other two techniques (Alanis and Lucidi, 2004).

HEPATITIS B VACCINE

The implementation of routine hepatitis B immunization during infancy has been associated with a dramatic decrease in the incidence of this infection. Between 1990

(before routine vaccination of infants) and 2004 the overall incidence of acute hepatitis B in the United States declined by 75%, and by 94% among children and adolescents (Centers for Disease Control and Prevention, 2005). The Centers for Disease Control and Prevention and the AAP recommend that the initial dose of the three-dose hepatitis B immunization series be given in the newborn nursery; however, this recommendation is far from being followed universally. In 1999, it was estimated that 54% of newborns in the United States received a dose of hepatitis B vaccine at birth. However, at that time a recommendation was made to suspend birth dosing until vaccines were made that did not contain thimerosal (a preservative containing mercury). Even after a thimerosal-free hepatitis B vaccine was produced, many newborn nurseries in the United States did not immediately resume newborn immunization programs. This issue, combined with the reluctance of some parents to have their newborns immunized, has led to continued suboptimal rates of administration of the birth dose of hepatitis B vaccine (Clark et al, 2001). Among infants born in the United States between 2003 and 2005, it was estimated that 50.1% received a dose of the vaccine by the age of 3 days (Centers for Disease Control and Prevention, 2008).

There are at least two advantages of providing the first dose of hepatitis B vaccine during the newborn nursery stay. First, newborns who receive a dose at birth are more likely to complete their hepatitis B immunization series on time than those who receive a first dose later (Yusuf et al, 2000). Second, because a dose of hepatitis B vaccine given within 12 hours of birth can prevent vertical transmission of hepatitis B infections in 75% to 90% of cases, early provision of immunization serves as a safety net in cases where there has been an error in identifying a mother who is positive for hepatitis B surface antigen (Centers for Disease Control and Prevention, 2005).

The main disadvantage of providing a dose of hepatitis B vaccine during the nursery stay is that it can complicate documentation of hepatitis B immunization status in a child by increasing the number of vaccination providers. There is no evidence that administration of a dose of hepatitis B vaccine at birth leads to more evaluations for sepsis because of adverse events related to the immunization.

ONGOING CARE

UMBILICAL CORD CARE AND SINGLE UMBILICAL ARTERY

Umbilical cord care recommendations vary from "dry cord care" to the use of dyes and cleansing with alcohol, soap and water, or antiseptics. Concern over the possible toxic effects of dye and antiseptics led many hospitals in the United States to adopt the dry cord care method of cord care. Unfortunately this method may be responsible for causing an increase in the risk for omphalitis (Janssen et al, 2003; Simon and Simon, 2004). In addition, the results of a randomized trial in Nepal indicate that cord care using topical chlorhexidine reduces the risk of developing omphalitis; however, that population may be at higher risk compared with those born in the United States (Mullany et al, 2006).

Because omphalitis is rare, and its more severe complication necrotizing fasciitis is even rarer, large trials are needed to determine which cord care regimen is best for preventing these complications. Until such trials are conducted, there is no clear advantage of one regimen over another. Providers caring for newborns need to keep these diagnoses in mind and encourage parents to report redness around the umbilical cord stump.

A single umbilical artery is detected in about 4 out of 1000 births. There is an association of the single umbilical artery with a number of congenital anomalies, including renal or genitourinary malformations, cardiac malformations, and chromosomal anomalies such as Down syndrome. In this era of near universal use of prenatal fetal ultrasonography, any associated anomalies are usually discovered (Deshpande et al, 2009; Johnson and Tennenbaum, 2003). Unless there are abnormalities noted on physical examination, there is no need to repeat diagnostic ultrasound examinations after birth in a child with a single umbilical artery.

BREASTFEEDING

There is voluminous evidence that the optimal feeding for normal neonates is human milk provided via the mother's breast. From this most preferred feeding there is a continuum to least preferred feeding that includes: maternal milk given by an artificial method, donor human milk (although this is rarely used by most health care facilities), and commercially available infant formula. It is incumbent on health care professionals and health care systems to vigorously promote the optimal feeding for normal newborns. This promotion includes education to prospective mothers, knowledge of the characteristics of human milk and the normal course of lactation, organization of health care facilities to optimize the initiation of breastfeeding after delivery, early recognition of suboptimal breastfeeding and interventions to correct problems, and adoption of a parsimonious list of contraindications to breastfeeding.

Nutritional Composition of Human Milk

Although the composition varies among mothers, by age of the child, and even within a feeding, the nutritional components of mature human milk can be summarized (Picciano, 2001). The caloric content of human milk is approximately 0.67 Kcal/mL (20 Kcal/ounce). Approximately 50% of these calories are provided by the lipid components. Importantly, human milk contains omega-3 fatty acids. Lactose is the principal carbohydrate, providing approximately 40% of the calories. The protein in human milk is divided into two categories, casein and whey, that are provided in a 40:60 ratio. The sodium content of human milk is low, averaging approximately 7 mEq/L. With the exception of vitamins D and K, the amounts of minerals and micronutrients available are all adequate for optimal infant growth. The evolutionary advantage afforded by the relatively low concentrations of vitamin D and vitamin K in human milk is unclear.

Healthy newborns receive surprisingly little breast milk in the first few days of life. Average intake of colostrum during the first day of life is approximately 10 mL/kg and

20 mL/kg during the second 24 hours of life (Casey et al, 1986; Evans et al, 2003). Maternal milk production dramatically increases during the period from 36 to 96 hours of life; this increase in quantity is accompanied by a change from colostrum to mature milk (Casey et al, 1986; Saint et al, 1984). The increase in milk production is perceived by the mother as breast fullness. In one study, mothers noted that their breasts were noticeably fuller when their infants were an average of 53 hours old. This finding was closely correlated with the mean age (58 hours) when infants transferred greater than 15 mL of milk from the breast (Dewey et al, 2003).

Given the low volume of milk provided initially, neonates have a decrease in weight and an increase in serum sodium during the first few days of life (Marchini and Stock, 1997). Average maximal weight loss in breastfed infants is 5% to 7% of birthweight and occurs between 48 and 72 hours of life (Macdonald et al, 2003; Marchini and Stock, 1997; Rodriguezet al, 2000). With the onset of copious production of mature milk, neonates begin to gain weight and their serum sodium levels fall (Marchini and Stock, 1997). Infants fed human milk regain their birthweight, on average, by the age of 8.3 days; 97.5% have regained their birthweight by 21 days of age (Macdonald et al, 2003).

Health Benefits of Human Milk

There is copious research on numerous health benefits for infants who are breastfed. The list of benefits that have been found include: decreased incidence of conditions such as gastrointestinal infections, lower respiratory tract disease, otitis media, hypertension, obesity, diabetes, allergies, and asthma; improved cognitive development; and reduced risk of sudden infant death syndrome (Hoddinott et al, 2008). Unfortunately, because it is unethical to conduct individual randomized controlled trials on breastfeeding, most of these benefits have been documented in observational studies. Such studies are subject to numerous problems that might bias the results toward the null hypothesis or an overestimation of the benefits (Kramer et al, 2009). Perhaps the biggest problem with observational studies on breastfeeding is that there is significant confounding by socioeconomic status, for which it is difficult to adequately account in analyses.

The best evidence of the health benefits of breastfeeding comes from a large trial conducted in Belarus. Health care professionals at participating hospitals were randomly assigned to receive training on promoting breastfeeding using the Baby-Friendly Hospital Initiative (BFHI) developed by the World Health Organization and the United Nations Children's Fund (BFHI is further described in a following section) or to continue to provide standard care. A total of 17,046 mother-infant dyads were enrolled in the study (Kramer et al, 2001). All participating infants were born at 37 weeks' gestation or later and weighed more than 2500 g; all the mothers intended to breastfeed their infants. The rate of any breastfeeding at 3 months old was significantly higher among infants born in BFHI hospitals than at control sites (43% and 6%, respectively). Rates of breastfeeding were also significantly higher at BFHI locations at 6 and 12 months of age. Most pertinent, rates of gastrointestinal infection and atopic dermatitis were significantly lower in babies who had been born at BFHI hospitals. These data provide strong evidence for a significant beneficial effect of breastfeeding.

BOX 26-2 Baby-Friendly Hospital Initiative: Ten Steps to Successful Breastfeeding

1. Maintain a written breastfeeding policy that is routinely communicated to all health care staff.
2. Train all health care staff in the skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help mothers initiate breastfeeding within 1 hour of birth.
5. Show mothers how to breastfeed and how to maintain lactation, even if they are separated from their newborns.
6. Give infants no food or drink other than breast milk unless medically indicated.
7. Practice "rooming-in"—allow mothers and infants to remain together 24 hours a day.
8. Encourage unrestricted breastfeeding (i.e., on demand).
9. Give no pacifiers or artificial nipples to breastfeeding infants.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.

Among children enrolled in the original study who were assessed at 6.5 years of age, the verbal intelligence quotient of those born at BFHI hospitals was 7.5 points higher than those born at control sites (Kramer et al, 2008). Whether this finding was related to the components in the breast milk or from the physical act of breastfeeding is unclear; regardless of the mechanism, the effect is profound. In other follow-up studies, no difference between the two groups of children were found in the rates of asthma, allergy, or obesity (Kramer et al, 2007); however, the design of the study provides a conservative estimate of the effects of breastfeeding.

Promotion of Breastfeeding

Given the demonstrable improvements in outcomes, health care providers should promote breastfeeding as the preferred method of feeding newborn infants and facilitate its initiation during the newborn nursery stay. As a comprehensive program, implementation of the 10 steps of the BFHI (Box 26-2) has been shown to significantly increase the rates of breastfeeding (Kramer et al, 2001). There is evidence to support the efficacy of each of the 10 separate steps, although for some of the steps, such as excluding pacifiers, the evidence is contradictory (Cramton et al, 2009; O'Connor et al, 2009).

From a practical standpoint there are several evidence-based interventions during the newborn nursery stay that increase the rate or prolongation of breastfeeding. These interventions include the use of frequent demand feedings as opposed to a rigid feeding schedule, early skin-to-skin contact between mother and infant, professional advice on breastfeeding techniques, and exclusion of commercial formula from discharge packs (Anderson et al, 2003; Britton et al, 2007; Donnelly et al, 2000; Renfrew et al, 2000).

Breastfeeding Problems

The vast majority of difficulties with breastfeeding are related to a delay in transfer of adequate quantities of human milk to the infant. Delayed lactogenesis occurs in 20% to 30% of mothers; however, in most instances the primary problem is related to infant breastfeeding behaviors in the first few days of life. Although the clinical correlate is not well defined, weight loss of greater than 10% of birthweight is considered excessive in breastfed infants. Studies on breastfed neonates indicate that approximately 10% of infants lose more than 10% of their birthweight during the first few days of life (Dewey et al, 2003).

It is important to identify mother-infant dyads who are at risk for breastfeeding problems, so that early interventions can prevent excessive weight loss. Mothers with previous breast surgery, particularly breast reduction, are at increased risk of primary insufficient lactation. Flat or inverted nipples can also make breastfeeding more difficult. Prolonged labor and cesarean delivery have been associated with delayed onset of milk production (Dewey et al, 2003).

The adequacy of breastfeeding behaviors can be assessed during the newborn nursery stay using scoring systems such as the Infant Breastfeeding Assessment Tool. Low scores on this measure during the first day of life are moderately predictive of excessive weight loss in the neonate (Dewey et al, 2003). Decreased numbers of voids and stools in the newborn are also helpful in identifying children with breastfeeding problems, but this information is most useful after day 3 of life.

Supplementation of Breastfeeding

It is usually unnecessary to provide any nutrition or fluid to full-term breastfed infants beyond human milk. Dextrose water or commercial formula may be needed in neonates with hypoglycemia who are not responsive to breastfeeding. Supplementation may also be indicated in newborns who have lost more than 10% of birthweight or have decreased urine and stool output. Supplementation should be considered a temporary intervention, and its provision should not interfere with the onset of successful breastfeeding.

Contraindications to Breastfeeding

The few absolute contraindications to breastfeeding include maternal HIV infection, untreated tuberculosis in the mother, evidence of current cocaine use or antimetabolite drugs in the mother, and galactosemia in the neonate (Gartner et al, 2005). There are a myriad of other drugs for which there is concern regarding long-term neurodevelopmental outcomes in the infant. Selective serotonin reuptake inhibitors are commonly used to treat depression and anxiety in young women. Among drugs in this category, sertraline and paroxetine are thought to be the safest for use in breastfeeding mothers, whereas fluoxetine and citalopram are believed to have the most potential for toxicity in the neonate (Field, 2008). Overall there have been few adverse effects noted with use of any of these drugs, and generally the potential risks associated with these medications are thought to be outweighed by the benefits of breastfeeding (Field, 2008). Similarly, although methadone is detectable in the breast milk of women receiving this medication, serum levels in neonates are low and unlikely to cause a significant effect (Jansson et al, 2008).

Hepatitis C virus RNA has been found in the milk of mothers infected with this virus. Despite this finding, transmission of infection via breastfeeding has not been documented. Maternal hepatitis C infection is not considered a contraindication to breastfeeding (Gartner et al, 2005).

BOTTLE FEEDING

Commercial formula that provides adequate nutrition, vitamins, and minerals is available for infants of mothers who do not wish to breastfeed their infants or when breastfeeding is contraindicated or impossible. There are three major categories of formula used in neonates: cow milk–based, soy, and hydrolyzed formula. Of these, cow milk–based formula is used most commonly. The main carbohydrate in cow milk–based formula is lactose. Soy formulas were developed for infants with a possible cow's milk allergy. Because the main carbohydrate in soy formulas is sucrose or corn syrup, soy formula can be used in neonates with possible galactosemia. Protein hydrolysate formulas were initially developed for use in infants who are highly intolerant to cow's milk protein (Kleinman, 2009). These formulas are purported to lead to fewer allergies in babies and children than does cow milk–based formula, but the evidence for this is limited (Osborn and Sinn, 2006). All extensively hydrolyzed formulas are lactose free (Kleinman, 2009). These formulas are indicated in infants with definitive evidence of cow's milk protein allergy because 10% to 14% of them also have a soy allergy (Bhatia and Greer, 2008).

Standard preparations of formulas available for use in healthy term neonates provide 0.67 Kcal/mL. Most formulas are fortified with 10 to 12 mg/L of iron; however, some low-iron cow milk–based formulas are available. It is recommended that all formula-fed newborns receive the iron-fortified products. Vitamin D at the concentration of approximately 400 IU/L is provided in all the commercially available formulas (Kleinman, 2009).

Mothers who elect to bottle-feed report feeling unsupported for their decision by health care professionals, and up to 50% feel pressured to breastfeed (Lakshman et al, 2009). Although the benefits of breastfeeding should be provided to mothers who have not decided how to feed their babies, the role of health care providers is to support the decision of those who have elected to bottle-feed. It is also important to provide practical education about bottle-feeding to these parents; this is frequently neglected in many newborn nurseries (Lakshman et al, 2009).

Newborns who are bottle-fed can feed ad libitum beginning shortly after birth. Average formula intake in term newborns during the first day of life is 15 to 20 mL/kg and 40 to 45 mL/kg during the second day. During the nursery stay, neonates who are formula fed typically lose less weight than breastfed infants (Dollberg et al, 2001).

ANTICIPATORY GUIDANCE

A primary duty of providers of newborn care is to ensure that parents of new infants have the knowledge and skills to provide for normal growth and development. Parents

who are taught about normal newborn development and behavior have more realistic expectations about the work involved and look upon their child with more fondness. Conversely, before discharge from the newborn nursery, it is important to assess the parents' ability to provide a safe and nurturing environment for the neonate. Parents showing concerning behaviors, possibly leading to abuse or neglect, should have supervision and interventions to help them, possibly leading to termination of parental rights (Davidson-Arad et al, 2003; Wattenberg et al, 2001).

There are several major challenges for parents of normal newborns: sleep deprivation, learning to calm a crying infant, significant life changes, and the new worries that come with being responsible for a totally dependent being. Postpartum depression is more common and of longer duration than previously thought, and it occurs in at least 10% of mothers. This condition is related to sleep deprivation and has major and long-lasting effects on infant homeostasis and development (Chaudron, 2003).

Anticipatory guidance should be given to help prepare new parents for the common tasks of newborn care and to educate them about the many normal variations in newborn behavior. Learning how to soothe a baby is one of the first needed parenting tasks. Providers can help by giving suggestions to reduce crying and to better cope with infants who are more sensitive and harder to soothe (Barr et al, 2009).

Most parents have questions about feeding, elimination, bathing, cord care, genital care, jaundice, and common rashes. There are numerous checklists of educational topics that can be overwhelming to new parents. In addition, learning styles can vary, with some preferring written materials and while others preferring audio-visual materials or hands-on demonstration. Ideally, education should be targeted toward the topics of interest and with the appropriate materials for learning style (Dusing et al, 2008).

Mothers are often not in a good learning state in the immediate postpartum period because of pain, postpartum hormonal changes, and the stress of being in a hospital. However, there is heightened receptivity to change during this period, so attempts to teach or make lifestyle changes (e.g., smoking cessation) may be more effective. There is some evidence that providing parental education using tools such as interactive video and computers may be superior to traditional teaching (Snowdon et al, 2009; Trepka et al, 2008).

Given the obstacles to providing meaningful education during the nursery stay, it is probably better for practitioners to focus on a few key points of anticipatory guidance rather than reciting a litany of instructions. There is also a philosophical choice in deciding whether to emphasize the overall health of a newborn or to concentrate on prevention or identification of illness. There is little evidence for the efficacy of most anticipatory guidance provided to parents during the newborn nursery stay. A notable exception is the advice to put infants to sleep in the supine position (described in the following section). There is also emerging evidence that education about the normality of inconsolable crying in infants helps parents cope with this stressful situation, and it could reduce the risk of shaken baby syndrome (Barr et al, 2009).

Sleep Position

With the exception of immunizations, no child health intervention in the past two decades has resulted in a larger decrease in postneonatal infant mortality than the "Back to Sleep" campaign. The remarkable change in the predominant sleep position of infants from prone to supine has led to a 30% to 50% reduction in the rate of sudden infant death syndrome (SIDS) in the United States (AAP Task Force on Sudden Infant Death Syndrome, 2005). A multipronged effort including brochures, public service announcements, and education provided by health care professionals was used to affect the change in sleep position (Willinger et al, 2000). Obviously education provided to parents during the newborn nursery stay is a crucial determinant of the sleep position of an infant. In addition to providing education, there is evidence that parents model sleep position for their babies after how they saw nurses and physicians place their neonate in the bassinet in the newborn nursery (AAP Task Force on Sudden Infant Death Syndrome, 2005; Colson and Joslin, 2002). Therefore it is crucial that neonates are placed on their backs to sleep in the newborn nursery. In addition, there is an additive effect of both physicians and nurses recommending the supine sleep position (Willinger et al, 2000).

In addition to supine position, there are other factors related to the sleep environment that can effect the risk of SIDS in a newborn infant. It is recommended that infants sleep on firm surfaces and without excessive bedding such as pillows. Many experts also recommend against co-sleeping between parents and infants; however, this topic is controversial and the evidence is somewhat contradictory. Similarly, although use of a pacifier has been found to reduce the risk of SIDS, there is a reluctance to recommend these devices because of concerns about reducing breastfeeding (AAP Task Force on Sudden Infant Death Syndrome, 2005; Willinger et al, 2000).

DISCHARGE AND FOLLOW-UP

For infants born in the United States at 35 weeks' gestation or later, the average length of the initial hospital stay is 48 to 52 hours (Datar and Sood, 2006; Kuzniewicz et al, 2009; Paul et al, 2009). Because approximately 50% of infants born by vaginal delivery are discharged before the age of 48 hours, and because up to 40% of those born by cesarean delivery are discharged before 72 hours of age, a large proportion of neonates are discharged before the age of 3 to 4 days, when bilirubin levels typically peak and breastfeeding is well established (Paul et al, 2006). It is recommended that infants discharged before 48 hours have a follow-up appointment with a provider within 48 hours (AAP Committee on Fetus and Newborn, 2004). This follow-up can be accomplished either by a visit to a health care provider or via a home nursing visit.

Risk factors for readmission after an initial hospital stay of less than 48 to 72 hours include gestational age less than 39 weeks (and especially less than 37 weeks),

primiparous mother, and Asian race (presumably because of an increased risk of hyperbilirubinemia) (Burgos et al, 2008; Grupp-Phelan et al, 1999; Liu et al, 1997; Paul et al, 2006). Consideration of a longer nursery stay is suggested for infants with one or more of these risk factors. In addition, early discharge is not recommended for term newborns who have not voided, passed at least one stool, or demonstrated adequate breastfeeding (AAP Committee on Fetus and Newborn, 2004). However, there is little evidence to support these recommendations.

COMMON PROBLEMS DURING THE NURSERY STAY

HYPOTHERMIA AND HYPERTHERMIA

Upon leaving the womb, a newborn is immediately challenged with maintaining a normal body temperature. If a neonate is not quickly dried at birth, he or she may lose up to 1° C body temperature per minute. Healthy term babies are able to increase heat production through glycogenolysis and nonshivering thermogenesis for minutes to a few hours, depending on environmental conditions (Aylott, 2006). Babies typically have a decline in body temperature during the first hour of life with a gradual increase during the following 12 hours (Li et al, 2004). By the second day of life, the infant's body temperature becomes more stable, but heat loss can occur again with bathing or other stresses (Takayama et al, 2000).

Being too cold or too hot causes metabolic stress to the newborn, so efforts to maintain a steady and neutral thermal environment should be provided. The best practice is to dry the baby immediately after delivery and place the infant skin-to-skin with the mother. Although the AAP and the American College of Obstetricians and Gynecologists jointly recommend keeping infants' core temperatures within the narrow range of 36.5° to 37° C, in one study of healthy term newborns the average temperature was 36.5° C, with a normal range from 36.0° to 37.9° C (Takayama et al, 2000). Thin babies tend to have lower body temperatures, and heavier babies tend to have higher body temperatures. Hypothermia should be managed by placing the baby skin-to-skin with a parent or under a radiant warmer.

Standard practice at most nurseries is to measure axillary temperatures, probably because of reports in the 1960s and 1970s of perforations caused by rectal thermometers; however, axillary temperatures may not always accurately reflect core temperature (Hutton et al, 2009).

An elevated body temperature at birth generally reflects the intrauterine temperature and is not usually a sign of sepsis (Baumgart, 2008). Isolated hyperthermia during labor is associated with neonatal encephalopathy, occurring in approximately 1 in 2000 births (Blume et al, 2008). After the first 3 to 4 days of life, increased temperatures are most likely caused by dehydration from suboptimal breast milk supply (Maayan-Metzger et al, 2003). A single increased temperature in an otherwise normally behaving newborn is not a strong predictor of infection, but has been reported as a sign of intracranial hemorrhage (Fang et al, 2008).

ELIMINATION

Voiding

Approximately 15% of healthy newborns void at the time of delivery, and 95% void by 24 hours of age. The cause of delayed voiding is likely a consequence of stress on the infant during labor and delivery (Vuohelainen et al, 2007; 2008), which is a protective mechanism for the baby. Normally no intervention is needed once homeostatic adaption to extrauterine life is stable.

The differential diagnosis of delayed voiding (defined as no urine output by 24 to 48 hours of age) includes renal and postrenal causes. With the frequent use of prenatal ultrasound examination, it is unusual that a significant renal anomaly is discovered because of a delay in voiding. Most infants with bilateral renal agenesis have other findings, such as oligohydramnios or Potter sequence. Unilateral renal agenesis does not usually give symptoms of decreased urine output. Renal vascular thrombosis can also cause anuria, and babies with this condition are usually ill. Severe cystic kidney disease can involve urinary outflow obstruction. The diagnosis of cystic kidneys is usually made after the newborn period, or it is found incidental to evaluation of other anomalies and not because of delayed voiding.

Postrenal causes of delayed voiding include neuropathic bladder dysfunction and anatomic obstruction of urinary flow by anomalies in ureters, the bladder, or the urethra. Persistent or recurrent bladder distention after catheterization is found with occult lower spinal cord anomalies. Presacral teratoma or other tumors can cause compression and urinary blockage as well. In male infants, there is the possibility of posterior urethral valves. Physical findings of loose abdominal skin or musculature and a distended bladder suggest this diagnosis.

In a healthy-appearing newborn with a normal result on prenatal ultrasound examination, the absence of enlarged kidneys or palpable suprapubic mass, allowing up to 72 hours for a spontaneous first void, will avoid excessive testing. In fussy neonates, infants with other genitourinary abnormalities, enlarged kidneys, or distended bladder, testing should begin immediately. Ultrasound examination of bladder, kidneys, and posterior urethra is often diagnostic.

Normal newborns have decreased renal concentrating ability and excessive extracellular free water at birth. As a result, neonates will continue to void despite low intake of fluids. This process is normal, with excess fluid volumes being intrinsically protective against dehydration. Conversely, delayed voiding is not indicative of dehydration in the first 72 hours of life.

Defecation

Similar to the first void, the first passage of meconium occurs by an average of 7 hours of age. One third of newborns pass meconium before their first feeding. Late preterm newborns tend to pass meconium later than term infants, and 32% of preterm infants do not pass meconium in the first 2 days of life. In the first few days of life, intake is not well correlated with meconium output. However,

the number of wet and soiled diapers reflects adequacy of breast milk production on day 4 of life. Fewer than four soiled diapers on day 4 correlates with inadequate milk production (Nommsen-Rivers et al, 2008). By 2 weeks of age, breastfed infants pass feces more frequently than bottle-fed infants; they also have larger variability in time between bowel movements (Sievers et al, 1993).

Because 99.7% of healthy newborns pass meconium by 34 hours of age, those who are delayed beyond that time deserve extra vigilance during examination to avoid missing obstructions, such as an imperforate anus (Metaj et al, 2003). A baby with abdominal distention or vomiting and delayed stooling deserves evaluation for a possible gastrointestinal tract obstruction.

JAUNDICE

There are few conditions in newborn infants that create as much controversy and clinician and parental angst as does hyperbilirubinemia. Since the discovery of phototherapy in 1956 and its integration into medical care in the 1960s, the standard management of neonatal jaundice in the United States has gone through three distinct phases. Until the early 1990s, clinicians visually monitored full-term neonates during their 2- to 5-day newborn nursery stay and obtained serum bilirubin levels on those with significant jaundice. Phototherapy was begun when the total bilirubin was 15 mg/dL, and an exchange transfusion was indicated if the level rose to 20 mg/dL (Watchko et al, 1983). The wisdom of this approach was challenged by several significant events. First, there was a growing awareness of the increase in costs associated with the prolonged hospitalization of a healthy infant for phototherapy to treat a relatively modest level of hyperbilirubinemia. Second, Kemper et al (1989, 1990) conducted a series of studies documenting that mothers of neonates who received phototherapy were at risk of overmedicalizing their children. Finally and most significantly, informal and formal reviews of data on jaundice in full-term newborns, without hemolytic disease, revealed that the risk of kernicterus in such infants was extraordinarily low (Newman and Maisels, 1992; Watchko et al, 1983).

Based on this evidence, a "kinder and gentler" approach to the management of hyperbilirubinemia in term infants was advocated, leading to the AAP practice parameter in 1994 (AAP Provisional Committee for Quality Improvement and Subcommittee on Hyperbilirubinemia, 1994). Under this guideline, phototherapy for a healthy, 72-hour-old, full-term newborn was not definitively recommended unless the serum bilirubin was 20 mg/dL or greater. Unfortunately, publication of this guideline corresponded to a shortening of the nursery stay by term infants to as little as 24 hours. Therefore infants were discharged home before their levels of bilirubin peaked at 3 to 4 days of life, and there were numerous reports of infants with extremely high bilirubin levels and a general impression that the incidence of kernicterus was increasing. In retrospect, it does not appear that the incidence of kernicterus increased, but case reports and anecdotal evidence led to significant consternation by clinicians, parents, and quality assurance organizations (Burke et al, 2009).

Because newborns are usually discharged well before bilirubin levels reach their peak, it is clear that predictive models were needed to assess risk in newborns who are discharged early. Bhutani et al (1999) developed a nomogram based on data from neonates in whom serum bilirubin levels were measured multiple times. Infants who had initial bilirubin levels above the 95th percentile for any time period were significantly more likely to have "significant hyperbilirubinemia" detected in subsequent bilirubin measurements. These data were used in the development of the 2004 AAP practice guideline (AAP Subcommittee on Hyperbilirubinemia, 2004b). With this iteration of the guideline, clinicians are provided hourly guidance on levels of bilirubin for which phototherapy or exchange transfusions are indicated. Separate curves for low-risk, medium-risk, and high-risk neonates have been developed. Internet-based tools are available that provide the appropriate management for an infant with a specific bilirubin at a specific hour of life.

Although the AAP bilirubin nomogram provides useful information, there are some caveats. First, in the study by Bhutani et al (1999), 39.5% of infants with an initial bilirubin level greater than the 95th percentile had significant hyperbilirubinemia at subsequent testing. Therefore more than 60% of such infants had less severe hyperbilirubinemia when retested. The nomograms for medium- and high-risk infants are based almost exclusively on expert opinion rather than actual data. Given these limitations, it is important for the clinician to determine management of a jaundiced neonate on an individual basis, remaining cognizant of the infant's medical condition, social situation, and parental preferences.

There are numerous neonatal conditions that increase the risk for hyperbilirubinemia (Dennery et al, 2001); chief among these is hemolysis secondary to maternal antibodies to red blood cell antigens. Thankfully, hemolysis secondary to antibodies to Rh factor is rare because of proper management of Rh-negative mothers. Because there is no way to prevent hemolysis from an ABO incompatibility, it may be useful to test cord blood from neonates born to mothers with blood type O for blood type and the presence of antibodies on their red cells (i.e., Coombs' test) at birth. The increase in bilirubin secondary to ABO compatibility is highly variable, even with a positive direct Coombs' test. Some infants will have an early and dramatic rise in serum bilirubin and evidence of hemolysis, whereas in others no effect can be detected clinically. In addition to ABO incompatibility, some women will have antibodies to minor red cell antigens that can usually be diagnosed prenatally. In most instances the increases in bilirubin associated with antibodies against minor antigens are mild.

Other neonatal conditions that are risk factors for hyperbilirubinemia include bruising secondary to birth trauma and polycythemia. Decreased intake of breast milk can lead to decreased passage of stool. Because intestinal bacteria break down conjugated bilirubin to the unconjugated form, a decrease in stooling can lead to increased reabsorption of this unconjugated bilirubin (enterohepatic circulation). Breastfeeding is a significant risk factor for hyperbilirubinemia particularly when intake is limited. The propensity for developing significant jaundice is variable in

different racial groups. Asian and American Indian infants are at the highest risk for significant hyperbilirubinemia (Dennery et al, 2001). Finally, late preterm infants are at significantly increased risk for significant hyperbilirubinemia and kernicterus.

Traditionally, visual assessment has been used to judge whether a newborn infant has significant jaundice. This method of assessment is moderately accurate, but may be sufficient to rule out the need for serum bilirubin testing in many full-term newborns with no risk factors for jaundice (Moyer et al, 2000; Riskin et al, 2008). Transcutaneous bilirubinometers offer a noninvasive method for screening for hyperbilirubinemia. Depending on the technology and brand used, these instruments generally provide estimates of transcutaneous bilirubin (TcB) that correlate well with serum values. However, in practice it is not clear whether categorical estimates of the severity of neonatal jaundice using the transcutaneous meter are actually better than a visual assessment (Kaplan et al, 2008). Because the TcB may be lower or higher than the serum level in actual clinical practice, it should be considered as a screening tool only. Serum bilirubin testing remains the standard on which management decisions are based. Transcutaneous testing may be warranted for infants with risk factors for significant hyperbilirubinemia, even in the absence of significant jaundice.

Unless levels are high enough to require an exchange transfusion, phototherapy is effective for treating an infant with significant hyperbilirubinemia. Although repeated measurements of direct bilirubin are not cost effective, one assessment is helpful before or immediately after initiating phototherapy to rule out direct hyperbilirubinemia (Newman et al, 1991). An assessment of the potential for hemolysis as the etiology of the elevated bilirubin, possibly including a review of maternal and infant blood type, direct Coombs' test, hematocrit, reticulocyte count, and red cell morphology may also be useful.

There is no conclusive evidence as to whether continuous phototherapy leads to more rapid reduction in serum bilirubin levels than does intermittent treatment (AAP Subcommittee on Hyperbilirubinemia, 2004b; Lau and Fung, 1984). Unless bilirubin levels are approaching exchange transfusion levels, it is probably reasonable to discontinue treatment for several minutes to 1 hour at frequent intervals to allow parents to feed and hold their baby. Serial bilirubin measurements are needed to determine the adequacy of therapy and to determine when phototherapy can be discontinued. A rebound bilirubin level obtained 24 hours after discontinuation of phototherapy may be helpful in some clinical situations.

RESPIRATORY COMPLICATIONS

The term or late preterm fetus accomplishes the transition from dependency on the placenta to the newborn cardiorespiratory system, for the most part, without incident. After birth, pulmonary blood flow increases, fetal shunts reverse and begin to close, spontaneous breathing effort is initiated, and fetal lung fluid is cleared. Effective cardiorespiratory function, as represented by an absence of respiratory distress (nasal flaring, grunting, chest wall retractions, a respiratory rate of greater than 60 per minute) and an oxygen saturation in the middle 90s should be established by several hours of age (Levesque et al, 2000; O'Brien et al, 2000).

This normal sequence of events fails to occur in 2% to 8% of infants born at 34 weeks; gestation or later (Farchi et al, 2009; Hansen et al, 2008; Yoder et al, 2008). It is important to keep in mind that initial presenting symptoms are relatively nonspecific. Agrawal et al (2003) studied a large number of consecutive births in an attempt to determine the frequency and nature of different early-onset respiratory disorders and found that more than half did not meet specific diagnostic criteria. When confronted with a neonate with early onset respiratory symptoms, the most important diagnostic considerations include:

- Complex structural cardiac system anomalies; incidence estimated to be between 0.2% and 0.3%, often but not always identified by in utero imaging studies
- Diaphragmatic hernia, incidence estimated to be between 0.04% and 0.08%, commonly identified by second-trimester ultrasound (de Buys Roessingh and Dinh-Xuan, 2009)
- Respiratory distress syndrome (RDS); incidence estimated to vary between 0.45% and 2.4%, depending on the population studied; risk increased in the late preterm and infants delivered by cesarean section, particularly if accomplished before labor (Jain et al, 2009; Tita et al, 2009; Yoder et al, 2008)
- Persistent pulmonary hypertension of the newborn; incidence of 0.1% to 0.3%; often occurs in association with other acute respiratory conditions; questionable increased risk with maternal selective serotonin reuptake inhibitor treatment (Andrade et al, 2009; Chambers et al, 2006; Konduri and Kim, 2009)
- Meconium aspiration syndrome; incidence reported to vary between 2% and 9% of infants delivered through meconium-stained amniotic fluid (7% to 20% of all deliveries); risk increased in infants delivered after 40 weeks' gestation, intrapartum distress, or both (Bhutani, 2008; Liu and Harrington, 2002)
- Spontaneous pneumothorax; incidence between 0.1% and 0.8%; infants born by cesarean delivery may be at increased risk (Benterud et al, 2009; Zanardo et al, 2007)
- Transient tachypnea of the newborn (TTNB); incidence variable between 0.3% and 3.9%; risk factors include late prematurity and cesarean section; initial diagnosis sometimes difficult to differentiate from pneumonia and early RDS (Guglani et al, 2008; Jain et al, 2009; Tita et al, 2009; Yoder et al, 2008)
- Pneumonia; incidence difficult to determine, with one recent retrospective report estimated rate at 0.3%; risk factors include maternal chorioamnionitis and prolonged ruptured membranes; sometimes difficult to differentiate from RDS and/or TTNB (Yoder et al, 2008)

A review of the maternal history—particularly pregnancy, labor, and delivery—can provide useful diagnostic information. For example, the results of a second-trimester ultrasound examination could reveal the possibility of a cardiac defect or diaphragmatic hernia. A positive

maternal GBS test result without adequate treatment, prolonged rupture of amniotic membranes, or evidence of chorioamnionitis suggests the possibility of pneumonia. For infants with respiratory distress born by cesarean section before the onset of labor, a diagnosis of RDS should be considered and assessment of gestational age should be performed. Finally, TTNB is a diagnosis of exclusion; it is prudent to rule out other causes before it is considered as the cause of respiratory distress in a term neonate.

In most cases minimal initial diagnostic efforts for a term newborn with unsuspected respiratory distress should include a chest radiograph and assessment of the arterial oxygen saturation. The results of these studies, in combination with maternal history, should provide information helpful to: (1) establish initial management, such as the need for supplemental oxygen, continuous monitoring, or both; (2) determine the need for further work-up or treatment, possibly including an echocardiogram, laboratory testing, and treatment for possible sepsis; or (3) give a referral for further specialty consultation, intensive care, or both (in severe cases).

CARDIOVASCULAR ISSUES

Congenital heart disease is a relatively common condition in newborns, with an estimated incidence of 81 cases per 10,000 live births (Reller et al, 2008). Ventricular septal defect (VSD) is by far the most common defect, accounting for more than 30% of all cases. The increasing accuracy of prenatal ultrasound examination has greatly improved the early diagnosis of complex congenital heart disease. The results of population-based reviews indicate that the sensitivity of routine prenatal ultrasound examination in identifying selected congenital defects is as high as 70% and ranges as high as 85% for hypoplastic left heart (Chew et al, 2007; Rasiah et al, 2006). For mothers at high risk of delivering a newborn with congenital heart disease, the use of fetal echocardiography is helpful for delineating the anatomy and significance of specific lesions. However, many of the most common defects, particularly VSD, are not typically detected prenatally.

In the absence of a prenatal diagnosis, detection of congenital heart disease is by physical examination. Sequential examinations are most helpful. At birth, many babies have loud murmurs that are thought to be from either a closing ductus arteriosus or tricuspid regurgitation (Silberbach and Hannon, 2007). These murmurs are transient and not indicative of disease. Conversely, murmurs associated with VSDs may not be heard for several days when the pressures on the right side of the heart have dropped enough to permit a significant shunting of blood from left to right. Although the ratio of pathologic to benign murmurs is higher in newborns than in older children, most of the murmurs heard during the newborn nursery stay in a healthy neonate are not clinically significant. Characteristics that increase the likelihood that a murmur signifies the presence of congenital heart disease include an intensity of 3/6 or greater, a harsh quality, occurrence during all of systole or into diastole, and being heard best at the lower sternal border or right upper border (Mackie et al, 2009). In a healthy newborn, the most common presentation of congenital heart disease is a somewhat harsh systolic murmur that is heard best at the lower left sternal border in an asymptomatic infant, indicative of a VSD.

In addition to auscultation, it is helpful to assess a newborn with a murmur for dysmorphic features and other anomalies, because these findings increase the likelihood that the murmur is indicative of congenital heart disease. It is important to evaluate the adequacy of femoral pulses to rule out coarctation of the aorta. Femoral pulses may be difficult to palpate in a neonate; if there is uncertainty, upper and lower extremity blood pressures can be measured. Although it is not a good screening tool, measurement of oxygen saturation may be helpful in diagnosing a cyanotic lesion in a child with a murmur or other signs of heart disease, particularly because hypoxia is frequently difficult to detect in newborns (Mahle et al, 2009). Chest radiographs and electrocardiograms are usually of limited value in evaluating healthy newborns with murmurs (Mackie et al, 2009; Oeppen et al, 2002).

Full-term neonates frequently have alterations in cardiac rhythm and rate. Heart rates in full-term infants can range as high as 200 beats/min or as low as 80 beats/min. These values are usually indicative of normal variation and are not clinically meaningful unless there are other signs of illness or if there is a lack of variability in rate with stimulation or attempts at calming the newborn. Arrhythmias are also not uncommon, occurring in approximately 1% of newborns (Oeppen et al, 2002). By far, the most common arrhythmia in a healthy-appearing, full-term newborn is from premature atrial contractions (Larmay and Strasburger, 2004; Southall et al, 1981). These contractions are almost always benign and are usually transient. If there is concern about an irregular rhythm in a newborn, an electrocardiogram can be obtained. With premature atrial contractions, the irregular beat is initiated by a P wave. Although the QRS complex may be widened, it is always be preceded by the P wave. In most cases no further work-up is needed. Cardiology consultation may be warranted if premature atrial contractions are persistent or if widened QRS complexes are seen on an electrocardiogram.

POSSIBLE NEONATAL SEPSIS

Group B *Streptococcus* Screening and Intrapartum Antibiotics

Since the 1970s, GBS has been a major cause of neonatal sepsis (Schuchat, 1998). The implementation of intrapartum antibiotic prophylaxis (IAP) to prevent early-onset GBS disease in neonates was associated with an 80% decrease in the rate of infection (Phares et al, 2008). The currently recommended strategy to prevent GBS disease is to obtain rectovaginal cultures on all pregnant women at 35 to 37 weeks' gestation and to administer penicillin or ampicillin during labor to those colonized with the bacteria. In situations where the mother's GBS status is unknown before the onset of labor, IAP is advised for those with certain risk factors for neonatal infection (Box 26-3; Schrag et al, 2002). A third strategy may become available with the development of rapid strep testing, which can be done intrapartum. Overall, it is estimated that IAP can reduce

BOX 26-3 Risk Factors for Group B *Streptococcus* Sepsis in Newborns

- Delivery before 37 weeks' gestation
- Maternal fever during labor (body temperature >38.5° C)
- Prolonged rupture of membranes (>18 hours)
- Chorioamnionitis (maternal fever >38.5° C, tender uterus, fetal tachycardia)
- Prior child with group B *Streptococcus* disease
- Group B *Streptococcus* infection during pregnancy (urinary tract infection or bacteremia)
- Young maternal age
- African American race
- Hispanic ethnicity
- Meconium-stained amniotic fluid
- Newborn low absolute neutrophil count (e.g., immature:total ratio >0.2)

the risk of early-onset GBS disease by 83% (Ohlsson and Shah, 2009). The overall rate of early-onset disease in the United States is approximately 0.3 to 0.4 cases per 1000 live births (Centers for Disease Control and Prevention, 2009; Van Dyke et al, 2009).

Unfortunately, despite an effective strategy to prevent the infection, the rate of GBS disease in the United States increased between 2003 and 2006 (Centers for Disease Control and Prevention, 2009). Much of this increase was seen in African American infants. Although the rate of infection was 2.8-fold higher in premature infants than term newborns, 72% of the cases of GBS disease during this period were in full-term neonates. In addition, although 93% of mothers of infants in this series with GBS had been screened, IAP was administered to only 20%. Finally, although GBS cultures are highly accurate, there is always the possibility of a false-negative screen. In one review, 61% of infants with GBS disease were born to mothers with a negative test result before delivery (Van Dyke et al, 2009). These statistics highlight the need for continued vigilance for signs of GBS infection in term newborns by health care providers, even in an era of surveillance and IAP.

Guidelines for prevention of GBS sepsis indicate that neonates are adequately treated only if IAP is administered at least 4 hours before delivery (Schrag et al, 2002). There is no clinical evidence to support this recommendation; it is based on expert opinion and is used to provide a margin of safety. However, there is evidence that penicillin given 2 hours before delivery is 90% effective in preventing GBS sepsis, and IAP provided less than 2 hours prior to delivery may be less effective (Illuzzi and Bracken, 2006). Blood levels are higher in the neonate than in the mother, even 30 minutes after a dose of penicillin, but the clinical importance of this has not been studied (Colombo et al, 2006).

Term infants whose mothers have received IAP for a positive GBS screen at least 4 hours before delivery can be safely discharged at 24 hours of age if there are no signs or symptoms of infection (Ohlsson and Shah, 2009). One area of consternation is how long to observe term newborns when antibiotics were not given more than 4 hours before delivery. In the current guidelines it is recommended that such infants be monitored in the hospital for at least 48 hours after birth. The pressure for early newborn discharge has led some to compromise this period of observation. Most infants with sepsis manifest it early in life—many at birth, and nearly all by 12 hours of age (Escobar et al, 2000). Among a group of 172 term infants with documented early-onset GBS infection, 95% had presenting symptoms within 24 hours after delivery. More importantly, among the 33 neonates in this study that had GBS infection despite IAP, 31 had signs of infection before 24 hours of age (93.9%; 95% confidence interval, 79.8% to 99.3%; Bromberger et al, 2000). These data suggest, but do not definitively indicate, that some term newborns born to GBS positive mothers who received IAP less than 4 hours before delivery can be discharged by 48 hours of age. This decision is best made on an individual basis considering all risk factors, examination of the baby, vital sign stability, the results of any available laboratory tests, and parental wishes.

Assessment of Term Newborn for Possible Sepsis

The decision to remove a baby from the care of his or her parents during the period of initial homeostasis, and bonding should not be done without significant concern for the well-being of the infant. These decisions can have permanent effects on the parent-child relationship (Paxton and Nyington, 2001; Pearson and Boyce, 2004). Conversely, neonatal sepsis is such a dangerous and potentially rapidly progressive condition that any suggestive signs and symptoms cannot be ignored. It is between these extremes that the provider dwells and must make decisions often based on uncertainty and vague information.

The strongest predictor of sepsis is whether the baby is ill. This predictor can be somewhat challenging to determine given the limited repertoire of behaviors in newborns. Neonates typically have erratic temperature, poor feeding, periods of lethargy, and crying, all of which can also be symptoms of infection. Some of the earliest signs of infection include resting tachypnea or tachycardia, especially with reduced heart rate variability and transient decelerations (Griffin et al, 2005). This level of early identification requires continuous monitoring which, although routinely used on premature infants, is not routinely performed on term newborns. Because the infection entry portal is often the lungs, increased respiratory rate or increased work of breathing are the most common symptoms noted (Andersen et al, 2004). Fever is not a common symptom in an infected newborn, and usually babies with high temperatures are found to have other causes, especially after 24 hours of age (Maayan-Metzger et al, 2006). Decreased skin perfusion or mottling and decreased or increased tone are also worrisome signs.

GBS is not the only cause of sepsis in newborns. Coliforms were the dominant cause in the 1950s, and current causes may involve a natural cycle in the dominant bacteria causing sepsis. There are also sporadic cases of sepsis caused by enterococci, *Serratia* spp., and gram-negative bacteria such as *Escherichia coli*, *Proteus* spp., and *Klebsiella* spp. Although the decision of whether to evaluate or treat a neonate for possible sepsis cannot be informed only by

the GBS status of the mother, and because other causes of infections are rare, most guidelines focus on GBS sepsis risk.

In general, the physical examination is as good as laboratory testing in identifying ill newborns (Escobar et al, 2000). Laboratory tests can aid in the prediction that a baby is ill, but testing is also viewed as invasive by parents, so it is often helpful to carefully explain the tests and how the results will be used to make decisions. There is no one single test that has shown superiority, and opinion on testing varies. Among the most useful tests are the absolute neutrophil count, immature-to-total neutrophil ratio, and the procalcitonin level (Carrol et al, 2002; van Rossum et al, 2004). The C-reactive protein or erythrocyte sedimentation rate may help, but have lower predictive values (Galetto-Lacour et al, 2003).

The decision to start testing or treating a term newborn for suspected sepsis should be multivariate and include: (1) risk factors during pregnancy, labor, and delivery (see preceding section); (2) current age in hours of the newborn; (3) presence of concerning signs and symptoms; and (4) physical examination. One single finding, such as an elevated temperature in an otherwise normally behaving newborn, is not usually sufficient evidence to start intravenous antibiotics. If the status of a term newborn is not rapidly changing, the use of close observation and periodic reassessment of risk factors and findings may prevent unnecessary testing or treatment.

CHAPTER 27

Newborn Screening

Inderneel Sahai and Harvey L. Levy

Newborn screening is directed primarily at disorders in which the clinical complications develop postnatally. In metabolic diseases, these complications result from biochemical abnormalities that appear after birth, when the infant is no longer protected by fetal-maternal exchange. For example, the infant with phenylketonuria (PKU) has a normal blood phenylalanine level at birth, but within a few hours demonstrates hyperphenylalaninemia. The infant with congenital hypothyroidism (CH) is also protected in utero, most likely from placental transfer of maternal thyroxine (T_4). If the hyperphenylalanemia in PKU is not controlled by diet or the hypothyroidism in CH is not corrected by supplemental T_4, the infant begins to show signs of developmental delay and subsequently becomes mentally retarded. If therapy begins during the first weeks of life, mental retardation in both disorders is prevented.

PKU was the first metabolic disorder known to benefit from dietary therapy. This fact was established by the middle 1950s. By the late 1950s, it was evident that the diet could prevent mental retardation if initiated in the neonatal period. Detecting PKU in all affected infants at that early age, before irreversible brain damage occurred, then became the challenge. This challenge entailed neonatal screening for a biochemical marker of the disease. In 1962, Guthrie developed a simple bacterial assay for phenylalanine that required only a small amount of whole blood soaked into filter paper (Guthrie and Susi, 1963). Therefore infants in newborn nurseries could be routinely tested for PKU in blood specimens obtained by lancing the heel and blotting the drops of blood onto a filter paper card. This filter paper blood specimen (dried blood spot specimen) could be mailed to a central laboratory for PKU testing. An increased concentration of phenylalanine in the specimen indicated PKU in the infant.

By the middle 1960s, many states had established routine newborn screening programs for PKU using the Guthrie method. Infants with PKU were identified in larger numbers than anticipated and were showing normal development while receiving treatment (O'Flynn, 1992). The success of PKU screening led to the addition of tests for other metabolic diseases, including galactosemia, maple syrup urine disease (MSUD), and homocystinuria. These additional tests could be performed on the same blood specimen obtained for PKU screening. Over time, a test was added for the endocrine disorder congenital hypothyroidism, followed by screening tests for sickle cell disease, congenital adrenal hyperplasia (CAH), biotinidase deficiency, cystic fibrosis, and others.

In 1990, tandem mass spectrometry (MS/MS) was first applied to the Guthrie specimen, opening a new era in newborn screening (Levy, 1998; Millington et al, 1990). This technology allowed for the accurate detection of numerous biochemical markers with a single assay, thereby making redundant several assays traditionally used in screening for metabolic disorders. Furthermore, it enabled analysis of biomarkers not detectable by previous methodologies, thus greatly expanding the spectrum of conditions identifiable in the neonate (Levy and Albers, 2000). By the early 1990s, Naylor (Chace and Naylor, 1999) and Rashed et al (1995) began using this technology to routinely screen neonates for more than 20 biochemical disorders with high specificity and an extremely low rate of false-positive results. Currently most programs in the United States and screening programs in Europe and elsewhere have integrated MS/MS into newborn screening, and many are screening for more than 50 individual conditions (http://genes-r-us.uthscsa.edu).

In order to standardize screening panels nationwide, the American College of Medical Genetics has recommended a panel of 29 core conditions for screening (Table 27-1). An additional 25 secondary conditions were listed for which test results could be reported (American College of Medical Genetics, 2006). These secondary conditions, revealed in the course of screening for the 29 core conditions, are not well known or documented treatment is unavailable.

Molecular diagnostic techniques (i.e., DNA analysis) are also commonly used in newborn screening, predominantly as secondary tests for diseases such as cystic fibrosis or medium-chain acyl-CoA dehydrogenase deficiency (MCADD). Molecular testing substantially improves the positive predictive value of a primary screening result that is based on metabolite testing only (Ranieri et al, 1994; Wilcken et al, 1995; Ziadeh et al, 1995). With the initiation of pilot screening for severe combined immunodeficiency syndrome wherein the markers measured are DNA molecules (i.e., T cell receptor excision circles), the role of molecular technology has extended into primary marker analysis (Baker et al, 2009; Vogt, 2008). The use of molecular testing in screening will most likely expand further with advances in DNA technology.

Screening for neuroblastoma, the most common solid tumor of childhood, was formerly being performed in Japan and some European programs measuring vanillylmandelic acid and homovanillic acid in urine collected from infants (Sawada, 1993). However, this screening was abandoned because it failed to identify individuals with poor-prognosis neuroblastoma, instead identifying infants who had a form of neuroblastoma that either spontaneously regressed or could be effectively treated after clinical detection (Woods et al, 2003).

SCREENING PROCEDURE

SPECIMEN

The blood specimen is generally obtained from the heel of the infant. This simple sampling method, conceived and introduced by Guthrie and Susi (1963), has had an

TABLE 27-1 Core Disorders Recommended for Screening by American College of Medical Genetics

Disorder	Acronym	Primary Marker
Metabolic Disorders Detected Using Tandem Mass Spectrometry		
Organic acid disorders		
Beta-ketothiolase deficiency (mitochondrial acetoacetyl CoA thiolase deficiency)	BKT	C5:1/C5OH
Cobalamin defects A, B	CBL (A,B)	C3
Isovaleric acidemia*	IVA	C5
Glutaric aciduria I	GA-I	C5DC
3-Hydroxy 3-methylglutaryl-CoA lyase deficiency*	HMG	C5OH/C5-3M-DC
Multiple carboxylase deficiency*	MCD	C3/C5OH
3-Methylcrotonyl-CoA carboxylase deficiency	3MCC	C5OH
Methylmalonic aciduria (mutase)*	MMA	C3
Propionic acidemia*	PA	C3
Fatty acid oxidation defects		
Carnitine uptake defect (carnitine transporter defect)	CUD	C0
Long-chain hydroxyacyl-CoA dehydrogenase deficiency*	LCHAD/D	C16OH/C18:1OH
Medium-chain acyl-CoA dehydrogenase deficiency	MCAD/D	C8
Trifunctional protein deficiency*	TFP	C16OH/C18:1OH
Very-long-chain acyl-CoA dehydrogenase deficiency	VLCAD/D	C14:1/C14
Amino acid disorders		
Argininosuccinic aciduria (argininosuccinate lyase deficiency)*	ASA	ASA
Citrullinemia I (argininosuccinate synthase deficiency)*	CIT-I	Citrulline
Phenylketonuria	PKU	Phenylalanine
Maple syrup urine disease*	MSUD	Leucine
Homocystinuria	HCY	Methionine
Tyrosinemia type I	TYR-I	Tyrosine
Other Metabolic Disorders		
Biotinidase deficiency	BIOT	Biotinidase activity
Galactosemia*	GALT	Total galactose, GALT activity
Endocrine Disorders		
Congenital adrenal hyperplasia*	CAH	17-Hydroxyprogesterone
Congenital hypothyroidism	CH	T_4, TSH
Hemoglobin Disorders		
Sickle cell anemia	HbSS	Hb variants
Sickle cell disorder	HbS/C	Hb variants
Hemoglobin S/β-thalassemia	HbS/betaTh	Hb variants
Other Disorders		
Cystic fibrosis	CF	Immunoreactive trypsinogen
Hearing	HEAR	

GALT, Galactose-1-phosphate uridyl transferase; *T_4*, thyroxine; *TSH*, thyroid-stimulating hormone.
*Can manifest acutely in the first week of life.

enormous effect on newborn screening. The specimen is easily obtained and easily and inexpensively sent by mail to a central testing facility. There are no complications in obtaining the specimen from the newborn, contrary to early fears that its collection would lead to infection or result in excessive bleeding.

SPECIMEN COLLECTION PROCEDURE

The blood specimen should be obtained from the lateral or the medial side of the heel (Figure 27-1). Blood should be applied to only one side of the filter paper card, but it should saturate each circle on the card. Contamination of the filter paper specimen with iodine, alcohol, petroleum jelly, stool, urine, milk, or a substance such as oil from the fingers can adversely affect the results of the screening tests. In addition, exposure to heat and humidity can inactivate enzymes and produce false results. The specimen should be dried in air at room temperature for at least 3 hours before being placed in an envelope.

Specimens are sometimes collected in capillary tubes, by venipuncture of a dorsal vein or from a central line, and then spotted on filter paper. There is little or no substantial difference in analyte levels between blood collected

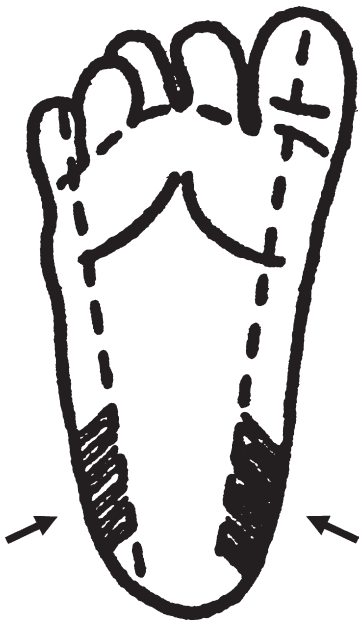

FIGURE 27-1 *Hatched areas* at medial and lateral sides of the heel in this drawing of the sole indicate the proper sites for a heel stick in the newborn.

directly from the heel and that collected by any of these other methods (Lorey and Cunningham, 1994). However, there is the danger of introducing amino acids from total parental nutrition solutions given through a central line into blood collected from this line, resulting in a false-positive increase in amino acids or interference in some molecular assays by the heparin from the line. In general, it is preferable that blood for screening be spotted on filter paper directly from the heel.

TIMING OF COLLECTION

Newborn screening encompasses a gamut of conditions, each with its own ideal screening period during which there is the greatest chance of diagnosing the disorder and before onset of symptoms. As a result, it is worth noting that recommendations on the timing of specimen collection, although appropriate for the majority, may not be ideal for all conditions on the screening panel. In congenital adrenal hyperplasia, in which the symptoms can manifest within the first week of life, the optimal time for collection of the specimen is within 24 to 48 hours after birth. Formerly there was concern that with the newborn screening specimen collected early, often during the first day of life, some infants with metabolic disorders or CH might not have a sufficient degree of abnormality for identification. However, MS/MS methodology with its improved sensitivity and specificity has considerably improved the reliability of screening for metabolic conditions in early specimens (Chace and Naylor, 1999) and using thyroid-stimulating hormone (TSH) as the primary marker for CH, or as a second-tier test when T_4 is the primary marker, has similarly allowed early screening for CH to be reliable.

Specimen collection timings vary around the world. In Europe and Australia, most screening specimens are collected within 48 to 72 hours, whereas specimens in the United Kingdom are not collected until the infant is 5 to 8 days old (U.K. Newborn Screening Progam Centre, 2008). In the United States, most screening specimens are collected within 24 to 72 hours after birth. The specimen should be obtained from every newborn infant before nursery discharge or by the third day of life, whichever is first. In infants whose initial specimen was obtained within the first 24 hours of life, as may happen with the practice of early nursery discharge, a second blood specimen should be obtained no later than 7 days of age to be certain that a diagnosis is not missed.

Special circumstances require specific attention to newborn blood specimen collection. Premature infants or those with very low birthweight, as well as infants who are sick and those in neonatal intensive care units (NICUs), are at a risk of unreliable screening owing to factors such as the unique physiology of the infant, therapeutic interventions, and a focus on critical activities in caring for the very sick neonate. Consequently, a single specimen is inadequate for screening in this subpopulation, and additional specimens should be collected for retesting. Serial screening with collection of three specimens—upon admission to the NICU, between 24 and 48 hours of life, and at discharge or at 28 days of life, whichever is sooner—has been proposed as an adequate and efficient protocol for this population (Clinical and Laboratory Standards Institute, 2009). In addition, some programs recommend screening every month until discharge for babies who continue to remain in the NICU.

A blood specimen should be collected from any infant who is being transferred to a different hospital or to a NICU, regardless of age. The first specimen should be collected before transfer, and a second specimen at the receiving hospital by 4 days of age. This dual collection policy covers the infant from whom a newborn specimen might not have been obtained in the turmoil that frequently accompanies the transfer of neonates.

In a newborn who is to receive a blood transfusion, a screening specimen should be collected before transfusion, and a second specimen should be collected 2 days after the transfusion. In addition, a third screening specimen should be obtained 2 months after the transfusion, when most of the donor red blood cells (RBCs) have been replaced. This practice ensures reliable testing for analytes present in RBCs, if a pretransfusion specimen has not been obtained.

Newborn screening tests are usually performed in a centralized state, provincial, or regional laboratory. In a regional program, the specimens may be received by the state program and then delivered to the regional state or private laboratory, or they may be sent directly to the regional laboratory. In either case, the individual state programs serve as the state data and follow-up centers.

SCREENING TESTS

The testing procedure begins with the punching of small discs (each usually 3 mm in diameter) from the screening specimen. These small discs are then analyzed by various methodologies for the individual markers being sought. Amino acids and acylcarnitines, the markers for the majority of screened metabolic conditions, are simultaneously measured by MS/MS (Rinaldo et al, 2004). MS/MS is

superior in terms of accuracy of measurement of the individual analytes when compared with alternate methods originally used for screening amino acids, such as bacterial assays or fluorometric techniques.

Immunoassays, including fluoroimmunoassay and enzyme-linked immunosorbent assays, are used to test for endocrinopathies such as congenital hypothyroidism and CAH, for infectious diseases such as congenital toxoplasmosis and human immunodeficiency virus (HIV) seropositivity, and for cystic fibrosis. Hemoglobin electrophoresis of blood eluted from the filter paper disc is used for sickle cell disease screening. An enzyme assay is often used to screen for galactosemia and is always used to screen for biotinidase deficiency. Molecular assays are applied to quantify T cell receptor excision circles in dried blood to screen for severe combined immunodeficiency syndrome. More commonly, molecular assays are used to identify known mutations in certain disorders as a second-tier test. Several platforms, such as DNA microarrays and microsphere-based assays, can multiplex several molecular and immunological assays for high-throughput screening and are being used by screening programs (Dobrowolski et al, 1999; Green and Pass, 2005; McCabe and McCabe, 1999).

SECONDARY TESTS

An abnormal finding on a newborn screening test is not diagnostic of a disorder. Abnormalities in the newborn specimen can be transient or artifactual. Accordingly, when an abnormality is identified, the original specimen is retested for the analyte that was abnormal. Additional tests can be performed by the screening laboratory to substantiate the finding and improve the specificity of screening (Matern et al, 2007; Rinaldo et al, 2006).

In screening for congenital hypothyroidism, many programs initially measure T_4 in the original newborn blood specimen. Specimens in which a low T_4 level is found are further tested for an increased level of TSH, which would indicate congenital hypothyroidism. A normal TSH level would suggest transiently low T_4, a common finding in premature infants, or T_4-binding globulin deficiency. Some screening programs have adopted screening protocols in which the primary analysis is for TSH, and T_4 is measured as a second-tier test in specimens with high concentrations of TSH. Similarly, in screening for galactosemia an elevated galactose measurement in a specimen can trigger the analysis of galactose-1-phosphate uridyltransferase (GALT) enzyme activity as a second-tier test.

Second-tier molecular testing is also performed in some screening laboratories. For example, in screening for cystic fibrosis, an initial out-of-range primary marker prompts DNA analysis to identify several specific pathogenic mutations (Comeau et al, 2004; Rock et al, 2005; Wilcken et al, 1995). Screening programs following this two-tiered immunoreactive trypsinogen-DNA approach can identify up to 99% of patients with cystic fibrosis and report a positive predictive value ranging between 1/9.5 to 1/25 (Grosse et al, 2004). Molecular assays to detect disease-causing mutations are currently used as second-tier tests for several other disorders, and their use is likely to expand with advances in DNA technology. These uses include testing for the prevalent c.985A>G mutation in MCADD, the predominant E474Q mutation in long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency (LCHADD; Dobrowolski et al, 1999), and a panel of several GALT mutations in galactosemia screening.

The final interpretation of the screening results is based on the primary analysis and, if available, the results of second-tier testing. However, it is important to realize that screening is not intended to be diagnostic; abnormal screening results must be supported by confirmatory investigations. These studies require additional specimens and are performed by clinical laboratories or sometimes by the screening laboratory.

PHYSICIAN CONTACT FOR ABNORMAL RESULTS

Table 27-2 indicates disorders or other reasons for abnormal screening results, sorted according to the primary analyte usually used to screen for the condition. For example, a low T_4 level together with an elevated TSH concentration indicates congenital hypothyroidism, and a marked elevation of 17-hydroxyprogesterone (17-OHP) indicates the likelihood of CAH. An elevation of an acylcarnitine could indicate an organic acid or fatty acid oxidation disorder.

Any infant for whom such a screening result is reported should be evaluated by the primary care provider as soon as possible to facilitate the next steps towards the confirmation and management of the disorder. However, several conditions screened for are extremely rare, and primary health care professionals might not have sufficient information available to be able to direct appropriate intervention in screen-positive infants. To overcome the challenge, readily accessible, one- to two-page explanations of the possible disorders represented by the abnormality and the recommended confirmatory tests, known as *ACT sheets* and *confirmatory algorithms* (Kaye et al, 2006), are available on the Web site of the American College of Medical Genetics (www.acmg.net/resources/policies/ACT/condition-analyte-links.htm).

Although all specimens with a metabolite concentration that crosses its threshold are considered screen-positive, all screen-positive results are not associated with the same likelihood of being associated with a disorder. Most infants with a positive screening result that is only mildly abnormal are less likely to have a disorder (see later discussion of false-positive results) than are infants with analyte concentrations that are several fold above the cutoff. Applying a uniform approach for all positive results in terms of urgency of intervention or battery of tests suggested can result in unnecessary parental anxiety and medical costs. However, if recommendations for further action and workup are customized in accordance with the potential significance of the abnormality, both parental anxiety and costs associated with false-positive results can be reduced. To achieve this goal, some programs subcategorize positive screening results. The New England Newborn Screening Program uses primary marker concentrations, second-tier analyses, biomarker profiles for markers analyzed by MS/MS, and acuity of the likely disorder to subcategorize out-of-range screening results (Sahai et al, 2007). The primary care providers are supplied with category-based, customized fact sheets when a positive screening result is reported

TABLE 27-2 Disorders or Other Reasons for Abnormal Screening Results Sorted by Primary Marker Analyzed

Marker		Disorders	Possible Causes of False Positives
Markers Analyzed Using Tandem Mass Spectrometry			
Free carnitine (C0)	Low	CUD	Poor feeding, maternal CUD
Free carnitine (C0)	High	CPT-I	Carnitine supplementation
Propionylcarnitine (C3)	High	MMA, PA, CBL (A,B)	Hemolysis,* maternal biotin deficiency, carrier of associated disorders
Butyrylcarnitine (C4)	High	SCADD/EE/IBDD	Hypoglycemia from other causes,* FIGLU elevation
Tigylcarnitine (5:1)	High	BKT deficiency	VLBW neonate
Isovalerylcarnitine (C5)	High	IVA	Antibiotics containing pivalic acid, IVA/MBCD carrier, VLBW neonate, neonate receiving total parental nutrition, FAS hemoglobin profile*
Glutarylcarnitine (C5DC)	High	GA-I	MCADD carrier, twin or multiple births*
3-Methylglutarylcarnitine (C5-3M-DC)	High	HMG	Severe respiratory distress, neonates receiving ECMO*
Hydroxyisovalerylcarnitine (C5OH)	High	3MCC	Maternal MCC, maternal biotin deficiency
Octanoylcarnitine (C8)	High	MCADD	MCADD carrier, MCT supplementation
Tetradecenenoylcarnitine (C14:1)	High	VLCADD	Carrier
Hydroxyhexadecanoylcarnitine (C16OH)	High	LCHADD/TFP	Carrier
Hexadecanoylcarnitine (C16)	High	CPT-II	Severe hemolysis*
Arginine (Arg)	High	ARG	Hyperalimentation
Argininoscuccinic acid (ASA)	High	ASA	—
Citrulline (Cit)	Low	OTC/CPS/NAGS	Poor feeding*
Citrulline (Cit)	High	CIT-I	Hyperalimentation
Phenylalanine (Phe)	High	PKU	Hyperalimentation, specimen contaminated with artificial sweetener*
Leucine (Leu)	High	MSUD	Hyperalimentation, hydroxyprolinemia
Methionine (Met)	High	HCY	Hyperalimentation
Tyrosine (Tyr)	High	TYR-I	Prematurity, transient immaturity of enzyme
Markers analyzed by assays other than tandem mass spectrometry			
Biotinidase activity (Bio)	Low	BIOT	Exposure of specimen to heat, improper drying
Total galactose (T-Gal)	High	GALT	GALE deficiency, GALK deficiency, contamination with milk/cream
Activity GALT	Low	GALT	Exposure of specimen to heat
17-Hydroxyprogesterone (17-OHP)	High	CAH	Physiologic stress (seen commonly in NICU babies), VLBW, EDTA in specimen
T_4/TSH	Low/High	CH	Neonates in NICU, maternal thyroid medications
Immunoreactive trypsinogen (IRT)	High	CF	VLBW neonate, NICU
T cell receptor excision circles (TREC)	Low	SCID	Other immunodeficiencies, Di George syndrome, heparin in specimen*

BIOT, biotinidase deficiency; *BKT*, beta-ketothiolase deficiency; *CAH*, congenital adrenal hyperplasia; *CBL*, cobalamin defect; *CF*, cystic fibrosis; *CH*, congenital hypothyroidism; *CIT-I*, citrullinemia I; *CPT*, carnitine palmitoyltransferase deficiency; *CUD*, carnitine uptake defect; *ECMO*, extracorporeal membrane oxygenation; *EDTA*, ethylenediamine tetraacetic acid; *EE*, ethylmalonic encephalopathy; *FIGLU*, formiminoglutamic; *GA-I*, glutaric aciduria I; *GALE*, uridine diphosphate galactose-4-epimerase; *GALK*, galactokinase; *GALT*, galactosemia; *HCY*, homocystinuria; *HMG*, 3-hydroxy 3-methylglutaryl-CoA lyase deficiency; *IBDD*, Isobut yryl-CoA dehydrogenase deficiency; *IVA*, isovaleric acidemia; *LCHADD*, long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency; *MBCD*, 2-methylbutyryl-CoA dehydrogenase deficiency; *MCC*, methylcrotonyl-CoA carboxylase; *MCT*, medium-chain triglycerides; *MSUD*, maple syrup urine disease; *MMA*, methylmalonic aciduria; *MCADD*, medium-chain acyl-CoA dehydrogenase deficiency; *NICU*, neonatal intensive care unit; *PA*, propionic acidemia; *PKU*, phenylketonuria; *SCADD*, Short-chain acyl-CoA dehydrogenase; *SCID*, severe combined immune deficiency; *TFP*, trifunctional protein deficiency; *TYR-I*, tyrosinemia type I; *VLBW*, very low birthweight; *VLCADD*, very-long-chain acyl-CoA dehydrogenase deficiency.
*Associations observed in the New England Newborn Screening Program.

(Sahai and Eaton, 2008). These sheets include information on disorders associated with the marker, estimated likelihood of being affected, clinical presentations of likely disorders, factors contributing to false positives, and recommendations for further management. The follow-up recommendations can range from immediate admission to a hospital, where further evaluation and therapy for the illness can be initiated without delay, to simply repeating the filter paper analysis on a sample collected a few days later. Other programs approach this problem differently, but with the same goal in mind, providing the primary care providers with the information needed to put the result in the appropriate context for the family.

Any infant for whom an abnormal screening result is reported should be seen as soon as possible and evaluated with a careful history and physical examination. When specific guidelines based on the individual results are not provided by the screening program, and the infant is ill or

the likely disorder manifests acutely within the first few days of life (see Table 27-1), a specialist should be contacted. The infant may need to be admitted to the hospital where further evaluation and therapy for the illness can be initiated without delay.

If the infant is active and alert with good feeding and shows no abnormal signs on initial evaluation, and the suspected disorder does not require immediate attention, a second filter paper blood specimen can be obtained and sent to the screening laboratory for repeated testing, or confirmatory testing can be performed on a less urgent basis. In many cases, confirmatory testing or referral to a specialist is required only if the second test indicates the presence of a disorder. However, the follow-up of an initial positive screening result can vary. In some programs, more specific confirmatory testing is the first response to a presumptive positive newborn screen, with a less intense time frame for individuals in whom the level of suspicion is lower.

The physician should contact the screening laboratory when an infant whose screen has been reported as normal or whose screening results have not yet been reported has symptoms that suggest a metabolic disorder. The screening laboratory can check the results in the infant's newborn specimen. If the testing has been completed and the newborn specimen is retained in storage, the laboratory may wish to recover the specimen and repeat the tests. The physician should also contact the screening laboratory for the results of repeated tests and inform the family of the results as soon as possible. If the second result is normal, the duration of the family's anxiety may be shortened.

SCREENED DISORDERS

Following are brief summaries of the categories of the most common disorders detected by newborn screening. There is no attempt to describe any of the disorders in detail or their rare variants.

METABOLIC DISORDERS

Amino Acid Disorders

The amino acid disorders are caused by an enzymatic defect in the catabolic pathway of amino acids, with consequent accumulation of specific amino acids above the block. Screening relies on the detection of these elevated amino acids in the newborn specimen. The clinical manifestations may be a result of the toxic effects of the accumulating amino acid and metabolites produced by alternate pathways, a deficiency of the products of the normal pathway, or both. PKU is the best-known example of an amino acid disorder and is the paradigm for screened disorders in the newborn.

In addition to PKU, MSUD and homocystinuria are historically significant in the context of screening, because they are among the original metabolic conditions for which screening was performed before the introduction of MS/MS and therefore the expansion of screening. Screening for other amino acid disorders, such as the urea cycle defects and tyrosinemia type I, became possible only with the advent of MS/MS technology.

In PKU, the cardinal screening feature is an increased level of phenylalanine. PKU should always be identified by newborn screening. If untreated, patients with PKU experience severe mental retardation and other neurologic abnormalities. The average incidence of the disorder is approximately 1 in 12,000 live births. With screening by MS/MS, PKU can reliably be identified as early as the first day of life (Chace et al, 1998). Not all infants with an elevation of phenylalanine have PKU. Mild elevations can indicate benign mild hyperphenylalaninemia. Liver disease, such as that associated with galactosemia, tyrosinemia type I or citrin deficiency, can also produce increased phenylalanine. Therefore treatment for PKU should never be started on the basis of a positive screening test result alone. The dietary therapy is complicated and can be hazardous to an infant who does not have PKU. If the screening test reveals a marked elevation of phenylalanine (≥6 mg/dL) and the metabolic profile (including reduced tyrosine) is supportive of PKU, the infant should be referred directly to a metabolic center for confirmatory testing and prompt consideration of dietary treatment. If the screening level of phenylalanine is only slightly increased, retesting a second specimen before initiating a complete diagnostic work-up may suffice.

The primary indicator for MSUD in the newborn blood specimen is an increase in leucine. To improve the specificity for MSUD of an abnormal leucine measurement, some screening programs also report the ratio between leucine and a reference amino acid or alloisoleucine analysis as a second-tier test (Matern et al, 2007). The average incidence of classic MSUD is 1 in 185,000. MSUD can be a fulminant disease associated with severe ketoacidosis, vomiting, and lethargy, and it can progress rapidly to coma and death. Consequently, the finding of a substantially increased leucine level in the newborn blood specimen should prompt an immediate telephone call from the screening program to the attending physician. If the infant is ill, he or she should be transported immediately to an NICU at a medical center with a metabolic specialist. Confirmatory plasma and urine specimens should be obtained, and emergency therapy should be initiated. Plasma amino acid analysis in an infant with MSUD will show marked increases in leucine, isoleucine, and valine as well as alloisoleucine (the branched-chain amino acids). The urine specimen will test strongly positive for ketones and will contain large quantities of the branched-chain ketoacids and amino acids. The characteristic odor reminiscent of maple syrup, which appears earliest in cerumen and only later in urine, will probably be detected on a cotton-tipped swab inserted in the infant's ear. Milder variants of MSUD can be missed by newborn screening (Bhattacharya et al, 2006). A newborn with the intermediate variant might not have a blood leucine elevation, or the increase may be so mild as to be below the cutoff value. In the intermittent variant, the blood leucine concentration is normal in the newborn period, becoming elevated only in later infancy or childhood during acute metabolic episodes precipitated by febrile illness or surgery.

Individuals with homocystinuria are clinically normal at birth but, if untreated, may develop ectopia lentis (dislocation of the lens), thromboembolism, osteoporosis, and mental retardation. The worldwide frequency of all forms

of homocystinuria has been estimated at 1 in 344,000, but may be considerably higher (Skovby et al, in press). The newborn blood screening marker for detecting homocystinuria is an increased level of methionine. Homocysteine can be measured as a second-tier analysis to improve specificity (Matern et al, 2007). The diagnosis of homocystinuria may be missed if the blood methionine concentration is not elevated at the time the newborn specimen is collected (Whiteman et al, 1979). Reducing the cutoff value for methionine can substantially increase the frequency of identified infants (Peterschmitt et al, 1999), but may also result in an increased number of false-positive results. A high methionine level alone is not diagnostic of homocystinuria. Liver disease of a nonmetabolic nature can produce a strikingly high methionine level, as can isolated hypermethioninemia (methionine-S-adenosyltransferase [MAT] I/III deficiency), a metabolic disorder that may be benign. Two additional rare disorders also produce hypermethioninemia: glycine-N-methyltransferase deficiency associated with liver disease (Luka et al, 2002; Mudd et al, 2001) and S-adenosylhomocysteine hydrolase deficiency, which may result in developmental delay and hypotonia (Baric et al, 2004). Furthermore, transient hypermethioninemia may occur in newborn infants. Confirmation of the disorder requires quantitative amino acid analyses of plasma and urine. In the infant with homocystinuria, homocystine is usually detectable in plasma and urine, plasma total homocysteine is increased as is methionine, and cystine is reduced. In isolated hypermethioninemia, methionine is markedly increased in plasma, but there is no detectable homocystine in plasma or urine and the plasma cystine concentration is normal. Hypermethioninemia secondary to liver disease owing to tyrosinemia type I, or to nonspecific liver disease, is usually accompanied by increased tyrosine.

The three urea cycle disorders currently screened by MS/MS analysis are citrullinemia, argininosuccinic acidemia, and arginase deficiency. Citrullinemia and argininosuccinic acidemia produce hyperammonemia, often in the neonatal period, accompanied by poor feeding, tachypnea, lethargy, and vomiting. Respiratory alkalosis is characteristic. Severe hyperammonemia in the newborn is a medical emergency and should trigger prompt consultation with a metabolic specialist or referral to an NICU at a metabolic center. Discontinuation of protein and the provision of intravenous fluids with high caloric content are the first steps to take. L-Arginine or L-citrulline, as well as the "scavenger drugs" sodium phenylbutyrate and sodium benzoate, may be administered. Hemodialysis might be required to control the neurotoxic hyperammonemia, which can lead to irreversible brain damage, coma, and death. It is hoped that with early identification through newborn screening, patients with urea cycle disorders will be protected by presymptomatic therapy in the neonatal period. Arginase deficiency can also present acutely with hyperammonemia as described earlier, although more frequently it manifests as developmental delay and spastic diplegia in childhood with a milder degree of hyperammonemia (Crombez and Cederbaum, 2005).

Tyrosinemia type I is an amino acid disorder that can be diagnosed by finding an elevation of succinylacetone in MS/MS analysis (Allard et al, 2004). However, the preanalytic processing required for succinylacetone is more involved than that required for the amino acids and acylcarnitines. As a result, succinylacetone is not currently measured by all screening programs. These programs may rely on elevations of tyrosine for identification of this disorder. Unfortunately, moderate elevations of tyrosine that are transient occur frequently in neonates, especially those who have low birthweights and are sick, necessitating frequent requests for repeated screening with virtually no detection of tyrosinemia type I. Unfortunately moderate transient elevations of tyrosine occur frequently in neonates, especially those who have low birthweights and are sick, necessitating frequent requests for repeated screening. Virtually no cases of tyrosinemia type I have been detected based on elevated tyrosine because almost all infants with tyrosinemia type I have had normal tyrosine levels when screened (Frazier et al, 2006). Consequently, the newborn detection of tyrosinemia type I by a tyrosine marker alone is ineffective. Tyrosinemia type I leads to liver and renal tubular disease and can later result in hepatocellular carcinoma. It is treated with administration of 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC; Orfadin) and a diet low in phenylalanine and tyrosine. Tyrosinemia types II and III are identified by an increased level of tyrosine in newborn screening. Tyrosinemia type II can result in mental retardation, painful hyperkeratoses, and keratoconjunctivitis, and it is treated by a low tyrosine-phenylalanine diet. Tyrosinemia type III seems to be benign, although developmental delay has been reported occasionally (Ellaway et al, 2001).

Medium-Chain Acyl-CoA Dehydrogenase Deficiency and Other Fatty Acid Oxidation Disorders

The fatty acid oxidation disorders include those in which the long-chain fatty acids cannot traverse the mitochondrial membranes to be oxidized within the mitochondrial matrix (i.e., the carnitine palmitoyltransferase disorders) and those that constitute defects in fatty acid oxidation per se. In either category, the problem is the inability to fully oxidize fatty acids. Fatty acid oxidation is essential to supply energy as adenosine triphosphate via the Krebs cycle and as ketones in the presence of a low supply of glucose. The disorders involving defective transport concern carnitine, whereas those with defective oxidation are named according to the enzyme that is deficient (see Table 27-1). The clinical consequence of these disorders is fasting intolerance resulting in hypoketotic hypoglycemia, lethargy, hyperammonemia, metabolic acidosis, hepatomegaly, and sometimes sudden death. Cardiomyopathy is an additional feature of very-long-chain acyl-CoA dehydrogenase deficiency (VLCADD) and long-chain hydroxyacyl CoA dehydrogenase deficiency (LCHADD). Each fatty acid disorder is associated with a specific or almost specific acylcarnitine pattern on MS/MS analysis.

The most common fatty acid oxidation disorder is MCADD. Tragically, before newborn screening was available, this disorder was often diagnosed only retrospectively after a sudden unexplained death, usually when postmortem examination revealed a fatty liver. This devastating outcome and a frequency of 1:15,000 to 1:20,000 (Zytkovicz

et al, 2001), comparable with that of PKU, made MCADD the primary reason for the addition of MS/MS technology to newborn screening. To reduce the rate of false-positive results in screening for MCADD, some programs have added molecular testing of the c.985A>G MCAD mutation as second-tier screening. Because this mutation occurs in as many as 90% of persons with MCADD, this additional analysis of a newborn blood specimen with an elevation of the octanoylcarnitine marker for MCADD substantially improves the predictive value of the screening abnormality (Zytkovicz et al, 2001).

The treatment for fatty acid oxidation disorders is avoidance of fasting with high-carbohydrate, low-fat feedings and, of critical importance, prompt attention to acute illnesses in which vomiting occurs. Carnitine supplementation may be beneficial. Medium-chain triglycerides (i.e., MCT oil) is given for the long-chain disorders VLCADD and LCHADD. Any infant with a fatty acid oxidation disorder should be evaluated at a metabolic center. Most of these disorders are treatable, but screening enables early diagnosis and genetic counseling for the family even when early treatment may not be effective, such as in neonatal carnitine palmitoyltransferase II deficiency (CPT-II) (Albers et al, 2001a).

Organic Acid Disorders

Organic acid disorders are a heterogenous group of disorders with a combined frequency of approximately 1 in 50,000 (Zytkovicz et al, 2001). Many of them can be identified through MS/MS screening (see Table 27-1). The marker for this disease group, as for the fatty acid oxidation disorders, is an abnormal acylcarnitine pattern. If a screening result suggests an organic acidemia, a metabolic specialist should be consulted immediately. The major organic acid disorders identified in newborn screening are propionic acidemia, the methylmalonic acidemias, and isovaleric acidemia.

The organic acidemias can manifest in the neonatal period with a life-threatening, sepsis-like picture of feeding difficulties, lethargy, vomiting, and seizures. Metabolic acidosis virtually always accompanies this presentation, and hyperammonemia is common. In this situation, protein administration should be discontinued and replaced by administration of intravenous fluids with high caloric content and carnitine. The hyperammonemia rarely requires specific treatment. The effects of early diagnosis and treatment on the clinical and neurologic development of individuals affected by an organic acid disorder are currently under investigation (Albers et al, 2001b).

Galactosemia

Galactosemia typically manifests in the neonatal period as failure to thrive, vomiting, and liver disease (Hughes et al, 2009). Death from bacterial sepsis, usually caused by *Escherichia coli*, occurs in a high percentage of untreated neonates (Levy et al, 1977). The average incidence of the disorder is 1 in 62,000.

Some screening programs use a metabolite assay for total galactose (galactose and galactose-1-phosphate) to detect galactosemia. Other programs screen the newborn specimen with a specific enzyme assay for activity of GALT, undetectable in severe galactosemia. The enzyme assay identifies only galactosemia, whereas the metabolite assay also identifies other galactose metabolic disorders, such as deficiencies of galactokinase and epimerase. Severe neonatal liver disease and portosystemic shunting caused by anomalies in the portal system can also increase the galactose level.

The most rapid confirmatory test for a positive result in galactosemia screening is urine testing for reducing substance. In almost all cases of severe galactosemia, this test produces a strongly positive reaction. Galactosemia with residual GALT activity, however, may be accompanied by a negative or only slightly positive result for urine reducing substance. If the urine contains reducing substance and the infant has clinical signs of galactosemia (e.g., poor feeding, jaundice, hepatomegaly), a blood specimen for confirmatory testing should be collected, and milk feeding (breast or formula) should be discontinued with substitution of a nonlactose formula such as soy or elemental. The infant should then be referred immediately to a pediatric metabolic center, where confirmatory testing should include the measurement of RBC galactose-1-phosphate and an enzyme assay for RBC GALT activity (Levy and Hammersen, 1978). Molecular testing for GALT mutations may also be performed. Approximately 70% of the patients with galactosemia carry the Q188R mutation (Elsas and Lai, 1998). Variant galactosemia is produced by mutations such as S135L. The N314D mutation produces the benign Duarte variant.

If the urine test is negative for reducing substance, the newborn screening result is most likely to be false-positive or to indicate a benign GALT enzyme variant (e.g., Duarte variant). Nevertheless, urine-reducing substance may be absent in infants with clinically significant variants of galactosemia. Consequently, follow-up testing should be performed for all infants with an initial positive galactosemia screening result.

Biotinidase Deficiency

Biotin recycling is necessary for the maintenance of sufficient intracellular biotin to activate carboxylase enzymes. Biotinidase is a key enzyme in biotin recycling. Lack of biotinidase activity results in reduced carboxylase activities and an organic acid disorder known as *multiple carboxylase deficiency* (Wolf and Heard, 1991). The clinical features of the disorder are developmental delay, seizures, hearing loss, alopecia, and dermatitis. The developmental delay and seizures usually manifest at 3 to 4 months of age. Death during infancy has also been reported.

Initiating biotin therapy in early infancy, when the disorder is presymptomatic, seems to prevent all the features of biotinidase deficiency. For this reason, a screening test has been developed and added to newborn screening in a number of newborn screening programs throughout the world (Hart et al, 1992). The frequency of identified newborns in these programs has a wide range, from 1:30,000 to 1:235,000. The average frequency is approximately 1 in 70,000. Almost all identified infants have been asymptomatic and have remained normal with biotin treatment.

ENDOCRINE DISORDERS

Congenital Hypothyroidism

Congenital hypothyroidism is the most common disorder identified by routine newborn screening. It is found in 1:3000 to 1:5000 screened infants (Dussault, 1993). The major clinical features of untreated congenital hypothyroidism are growth retardation and delayed cognitive development leading to mental deficiency. If treatment with pharmacologic doses of T_4 is initiated early, growth and mental development are normal.

Two screening approaches are used (Pass and Neto, 2009). One method is primary screening for low T_4 with secondary screening for high TSH. The second method is primary screening for high TSH levels. Either procedure reliably identifies congenital hypothyroidism. Nevertheless, affected infants can be missed with either approach. This situation may be due to a lack of the identifying marker abnormality at the time of specimen collection. Specifically, the T_4 level during the first 24 hours of life in an affected infant might not yet be sufficiently decreased for identification because of persistence of maternally transmitted T_4. Moreover, in the premature infant with congenital hypothyroidism, it might take 2 weeks or more for a TSH elevation to develop (Larson et al, 2003).

The reported false-positive rates of screening for congenital hypothyroidism range from approximately 0.05% to as high as 4% (Pass and Neto, 2009). Infants with false-positive results have transiently low T_4 or elevated TSH levels. Many of those with low T_4 levels are premature infants with a normal TSH concentration or infants with perinatal stress and elevated TSH levels. To avoid missing congenital hypothyroidism, screening programs require a second blood specimen from each of these infants. In addition to false-positive results, a low T_4 level with a normal TSH value can result from benign T_4-binding globulin deficiency (Dussault, 1993; Mandel et al, 1993) or hypothyroidism secondary to pituitary deficiency.

Infants with a positive screening test result should not be labeled as having congenital hypothyroidism until diagnostic testing confirms the disorder. This is especially true if the TSH concentration reported by the screening program is normal. If congenital hypothyroidism is confirmed, however, administration of T_4 should be started without delay to prevent irreversible brain damage.

Congenital Adrenal Hyperplasia

CAH caused by steroid 21-hydroxylase deficiency occurs in 1:16,000 to 1:20,000 births (White, 2009). Infants with the salt-losing form of CAH can rapidly become hyperkalemic and die precipitously, often without a specific diagnosis. The clinical diagnosis may be suspected in the newborn girl because of ambiguous genitalia. However, the diagnosis is usually not suspected in boys and in girls with atypical forms of CAH in which ambiguous genitalia may not occur. Infant girls with ambiguous genitalia might not be recognized as having CAH if the ambiguity is not obvious, or they could be misassigned as boys if the ambiguity is advanced. Because accurate gender assignment and initiation of hormone therapy as soon as possible are critical to a favorable prognosis in CAH, newborn screening is important in leading to early diagnosis and prompt therapy with pharmacologic doses of hydrocortisone. Consequently, testing for CAH has been incorporated into routine newborn screening in most programs.

Screening is based on identifying elevated levels of 17-OHP, the preferred substrate for 21-hydroxylase, and is usually measured using an immunoassay. Unfortunately, compared with other neonatal screening assays, the specificity of the CAH assay is low and false-positive results in newborn screening for CAH are relatively common, with the rate often as high as 0.5%. The finding may be due to a truly increased 17-OHP, as in perinatal stress and early specimen collection (within the first 24 hours of life), or to cross-reacting steroids, such as in prematurity and low birthweight (al Saedi et al, 1996). Cross-reacting steroids are produced by residual fetal adrenal cortex or result from decreased metabolic clearance by an immature liver.

A decidedly increased level of 17-OHP suggests CAH, and the infant should be referred to a pediatric endocrinologist for management. A second blood specimen is usually requested from infants found to have slight to moderately increased 17-OHP. If the infant shows signs of illness or has ambiguous genitalia, serum electrolytes should be measured. If these results indicate hyponatremia and hyperkalemia, the infant should be hospitalized without delay, and the electrolyte imbalance should be corrected immediately. Pediatric endocrinology consultation should also be sought. It may be possible to improve the positive predictive value by second-tier screening using DNA-based methods or liquid chromatography followed by tandem mass spectrometry, but currently these methods are not widely used by newborn screening programs.

SICKLE CELL DISEASE

In most newborn screening programs in the United States, the blood specimen is routinely tested for hemoglobin abnormalities. The major goal of this testing is to identify infants with sickle cell disease so that they can be given penicillin prophylaxis to prevent pneumococcal septicemia. Additional benefits of early detection are early referral to a comprehensive sickle cell program and early education and genetic counseling for parents (Smith and Kinney, 1993). Unfortunately, the long-term complications are not yet preventable.

Sickle cell screening is usually performed by means of hemoglobin electrophoresis of blood eluted from a disc of the Guthrie specimen. This procedure identifies sickle cell disease, sickle cell trait, and several other abnormal hemoglobins. Other than sickle cell disease, most of these abnormalities are benign. It is especially critical to differentiate the common and benign sickle cell trait from the much rarer sickle cell disease (homozygosity for S hemoglobin). For example, sickle cell disease affects approximately 1 in 600 African American persons, whereas sickle cell trait (carrier status for S hemoglobin) is present in 1 in 12. Infants with sickle cell trait do not have complications and should not be stigmatized as having sickle cell disease.

When sickle cell disease is confirmed, penicillin prophylaxis should be initiated as soon as possible, and the infant should be referred to a sickle cell disease center or

hematologist. The combination of screening and careful follow-up has been highly effective in preventing pneumococcal sepsis in infants with sickle cell disease.

CYSTIC FIBROSIS

The frequency (1:2000 to 1:3000) and severity of cystic fibrosis explain its inclusion in routine newborn screening. As with sickle cell disease, therapy that can prevent the ultimate complications of cystic fibrosis is not yet available. However, early and usually presymptomatic diagnosis through screening leads to early nutritional therapy, pancreatic enzyme replacement, and antibiotic prophylaxis for pulmonary infection. Data from newborn screening suggest better growth, prevention of vitamin deficiency in early infancy, and some advantage in terms of pulmonary status later in life in children identified by screening (Farrell et al, 2001; McKay and Wilcken, 2008; Southern et al, 2009). Other benefits of newborn screening are identifying the parents' genetic potential for producing additional children with cystic fibrosis and, through presymptomatic identification, allowing the family to avoid months or years of delay in the correct diagnosis of a child with chronic respiratory problems or poor growth (Farrell and Mischler, 1992).

The analyte marker in newborn screening for cystic fibrosis is increased immunoreactive trypsinogen (IRT). Transient increases in IRT are common in healthy newborns as a result of perinatal stress or for unknown reasons. Consequently, the rate of false-positive results in cystic fibrosis screening using only IRT is relatively high. To reduce this rate, screening programs have adopted a second-tier DNA analysis for a panel of cystic fibrosis mutations when the specimen has increased IRT (Ferec et al, 1995). Despite this two-tiered approach to screening, a substantial number of infants who do not have cystic fibrosis must undergo a sweat test or complete DNA sequencing of the cystic fibrosis gene before the diagnosis can be eliminated.

SPECIFIC ISSUES IN NEWBORN SCREENING

CRITERIA FOR NEWBORN SCREENING

Under the auspices of the World Health Organization, Wilson and Jungner (1968) published a set of criteria for screening for disease that have generally been accepted as required for population screening. The ten criteria state that (1) the condition be an important health problem, (2) there be accepted treatment, (3) facilities for diagnosis and treatment be available, (4) there be a recognizable latent or early symptomatic stage, (5) there should be a suitable test, (6) the test should be acceptable to the population, (7) the natural history of the condition should be understood, (8) there should be a policy prescribing whom to treat, (9) the cost of case finding should be economically balanced in relation to medical care as whole, and (10) case-finding should be a continuing process.

These criteria were developed at a time when newborn screening was in its beginning stages and with screening for adult disorders in mind. For example, regarding to the first criterion, Wilson and Jungner recognized that the term *important* is relative; whereas diabetes was prevalent, treatment might not influence outcome while PKU was rare, but it warranted screening because of the serious consequences that would be prevented by early discovery and treatment.

There is a question as to the current relevance of the Wilson-Jungner criteria for newborn screening. Ideally, all the criteria should be applied to newborn screening. However, advances in technology have caused this application to be questioned (Green and Pollitt, 1999; Levy, 1999). As an example, screening using MS/MS allows detection of serious disorders for which there may not be acceptable or agreed upon therapy, or in which the natural history is largely unknown, challenging the criterion that the disorder included in screening have acceptable treatment. How is this dilemma resolved? The answer is not yet available. It is hoped that the experience and findings from expanded newborn screening will be used to develop a new set of criteria that will apply to newborn screening. These criteria will likely retain the essence of the Wilson-Jungner compilation, but with important modifications that could be applied to any new screening venture.

FALSE-POSITIVE RESULTS

The majority of positive results in newborn screening, particularly when this result is only mildly or moderately abnormal, are not due to a disorder. Unfortunately, because screening is primarily based on a quantitative measure, false-positive results must be addressed. Metabolite concentrations vary among individuals, and the distribution curves of the markers from affected and unaffected populations are expected to be different (Figure 27-2). In screening, a value that separates the two distribution curves is established as a cutoff.

The cutoff values of the quantitative biomarkers are established by the individual screening laboratories, and they can vary among the different laboratories because of variations in the testing technology. In general, the cutoff value should be set such that it is greater than the 99th percentile of the concentration in normal neonates and less than the 5th percentile of the concentration in affected neonates (Rinaldo et al, 2006). However, for disorders that are extremely rare, the population of affected neonates may be so small that establishing an appropriate cutoff becomes a challenge. In such cases, the laboratory may empirically set a cutoff at 3 to 4 SD from the population mean and adjust the values with experience to minimize the false positives without compromising the sensitivity. Specimens in which the concentration crosses the established cut-off are considered screen-positive. The metabolite concentration in a majority of unaffected individuals is below the cutoff value, but in a small proportion it crosses this threshold. The positive screening results that are not caused by a disorder are considered false positives. Because of some degree of overlap in the distribution curves of the affected and unaffected populations, these false positives cannot be entirely eliminated without compromising the sensitivity of screening. Furthermore other physiologic factors, such as immaturity of enzymes or stress and therapeutic interventions, can skew

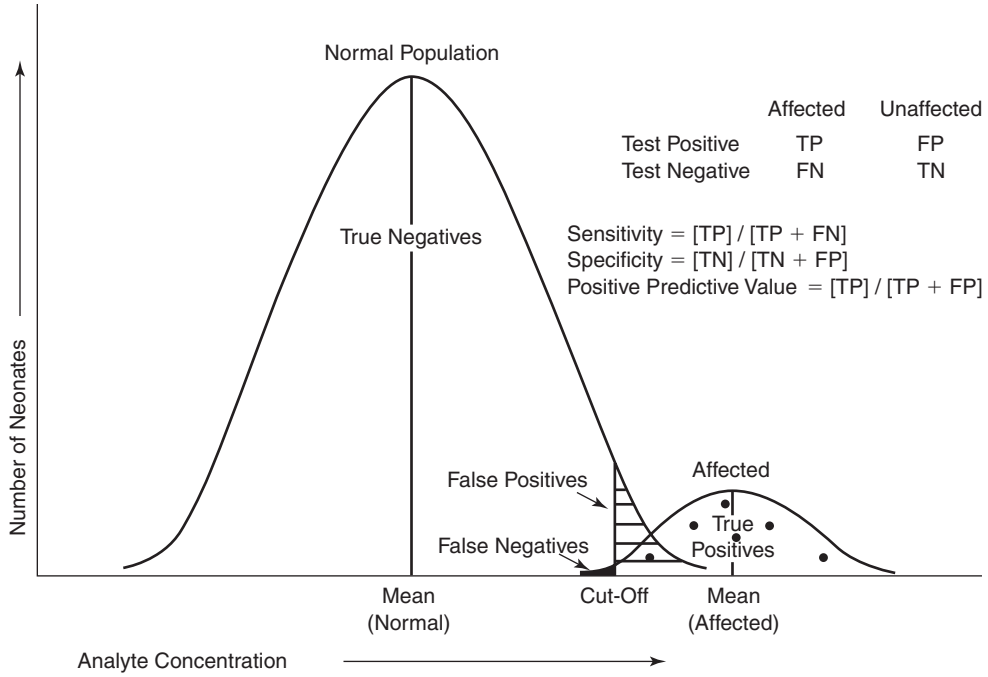

FIGURE 27-2 Distribution of quantitative markers measured in screening. For most conditions, the distribution in the unaffected or normal population overlaps that in the affected individuals. The number of false positives *(FP)*, false negatives *(FN)*, true positives *(TP)*, and true negatives *(TN)* depends on the established cutoff.

the concentrations of certain metabolites and lead to false-positive screening results. Currently, indicators measured using immunoassays (e.g.,17-OHP in CAH and T_4 in congenital hypothyroidism) or enzymatic activity (low GALT activity in galactosemia) are associated with the highest false-positive rates.

The false-positive results are more common in preterm and low-birthweight infants than in full-term infants. For example, up to 85% of preterm infants have transiently low T_4 levels (Paul et al, 1998). Transient increases in 17-OHP are another common abnormality in infants who are preterm or have low birthweights or have experienced perinatal stress (Pang and Shook, 1997). In addition, transient tyrosinemia is commonly observed in preterm and low-birthweight infants, although it can also occur in full-term infants (Levy et al, 1969).

Artifacts produced in the collection or transport of the Guthrie specimen account for some false-positive results. As mentioned in the discussion of the specimen collection procedure, collection of the specimen from a central line can result in mixing with amino acids in total parental nutrition solution and a false increase of amino acids in the specimen. Contamination with milk (or any drink containing milk) can result in a false elevation in galactose and the mistaken suspicion of galactosemia. Prolonged exposure to heat can reduce the activity of GALT in the specimen and produce a false impression of galactosemia when the enzyme assay is used to screen for this disorder. This error is common during the summer, especially when the specimens remain in a mailbox for a period of time. Some factors known to be associated with false positives are shown in Table 27-2 (Sahai et al, 2009).

With the substitution of MS/MS for the traditional bacterial or specific assays, such as those for PKU and MSUD, the number of false-positive results is distinctly lower. For PKU screening, the false-positive rate is reported at 0.05% compared with 0.23% by earlier methods (Levy, 1998). In addition, with MS/MS the multiplexed approach allows for a profile of analytes rather than a single analyte level (e.g., phe/tyr ratio vs. only a phenylalanine level for PKU identification), further improving the specificity of screening (Chace et al, 1998; Schulze et al, 1999). Therefore the average positive predictive value for primary markers analyzed by MS/MS, previously reported to be 8% to 10% (Schulze et al, 2003; Wilken et al, 2003), can be improved substantially if the marker is evaluated in context with other metabolites that are screened or when a tiered approach is applied (Frazier et al, 2006; Sahai et al, 2007).

Second-tier assays, such as molecular assays for cystic fibrosis or secondary immunoassays for hypothyroidism, are commonly performed to reduce the false-positive rates for primary markers analyzed by immunoassays or enzymatic assays. Nevertheless, false-positive results cannot be entirely eliminated; therefore it is important to reassure the parents that not every abnormal result of newborn screening inevitably implies a disorder and that transient or nonspecific abnormalities are common. Although all infants with an abnormal screening result must undergo repeated testing, the families should be informed that an initial positive result might have no medical implications. This approach can alleviate excessive anxiety and prevent unnecessary diagnostic procedures and treatment.

INCREASED DETECTION BY SCREENING

For certain disorders screened by MS/MS, many more infants are identified than the expected numbers based on clinical identification. The greatest increases are in the fatty acid oxidation disorders, including short-chain acyl-CoA dehydrogenase deficiency SCADD, MCADD,

VLCADD, and carnitine deficiency, and in three organic acid disorders (glutaric acidemia type I, 3-methylcrotonyl-CoA carboxylase deficiency, and 3-ketothiolase deficiency; Wilken et al, 2003).

Although some of the excess detection by screening could represent cases that were symptomatic but not diagnosed clinically, it is likely that the greater part of the excess represents infants with benign or milder forms of the disorders who would not come to clinical attention. Notably, Spiekerkoetter et al (2003) identified a frequent mutation in asymptomatic patients with VLCADD detected by newborn screening, and Ensenauer et al (2004) found a common, mild, and perhaps asymptomatic mutation in patients with isovaleric acidemia identified by screening.

MISSED CASES

Infants with congenital hypothyroidism, PKU, intermittent MSUD, glutaric acidemia, tyrosinemia I, and other screened disorders have been undetected by newborn screening. Laboratory or program errors were reported as the most common cause of these missed cases (Holtzman et al, 1974). In some instances, a specimen was never collected, such as when infants were transferred to another hospital. However, in screening for a multitude of disorders, each with its own biomarker that varies with time and physiologic states, an occasional affected neonate may have normal biomarker concentrations in the newborn specimen simply because the timing of collection was not ideal for the particular condition. Therefore physicians must exercise clinical judgment and not fall into the trap of excluding a diagnosis because an infant has presumably been screened. Specific testing for metabolic and endocrine disorders should be performed in any infant or child with symptoms that suggest the presence of such a disorder, regardless of the assumed or actual newborn screening result.

THE FUTURE

Many factors are impinging on newborn screening, including rapidly advancing technology, new and increasingly available therapeutic approaches to previously untreatable disorders, and family support groups and influential citizens or legislators who are heavily invested in individual disorders that may or may not be ready for inclusion as screening tests. To address these pressures, a committee convened by the American College of Medical Genetics and the Maternal and Child Health Division of the U.S. Department of Health and Human Services meets regularly to study newly proposed newborn screening tests (and those currently recommended) to judge their suitability for inclusion in the screening panels. One new candidate for screening severe combined immunodeficiency has passed through a careful vetting process and has been recommended for inclusion in the standard panel. Other candidate conditions being considered are the lysosomal storage disorders and adrenoleukodystrophy, for which enzyme or early bone marrow therapies are available and are being studied, Fragile X syndrome, and the Smith-Lemli-Opitz syndrome. These disorders will be judged on the basis of frequency, severity, availability of preemptive therapies, and the cost and robustness of the screening test itself. Some disorders have been included in isolated state panels on the basis of the political influences mentioned above.

Finally, there is the issue of retention of blood spots for future study. Despite multiple safeguards to protect the identity and anonymity of individuals, parents and civil libertarians are concerned that retention of these blood spots poses a threat to the privacy of individuals and that the specimens should be destroyed. If this view prevails, a resource of great value in the development of new and more effective tests, and one that is increasingly recognized as the avatar of personalized medicine, will be lost.

CHAPTER 28

Resuscitation in the Delivery Room

Tina A. Leone and Neil N. Finer

The transition from fetal to neonatal life is a dramatic and complex process involving extensive physiologic changes that are most obvious at the time of birth. Individuals who care for newly born infants must monitor the progress of the transition and be prepared to intervene when necessary. In the majority of births this transition occurs without a requirement for any significant assistance. However, when the need for intervention arises, the presence of providers skilled in neonatal resuscitation can be life saving. Each year approximately 4 million children are born in the United States (Martin et al, 2008) and more 30-fold as many are born worldwide. It is estimated that approximately 5% to 10% of all births will require some form of resuscitation beyond basic care, making neonatal resuscitation the most frequently practiced form of resuscitation in medical care. Throughout the world approximately 1 million newborn deaths are associated with birth asphyxia (Lawn et al, 2005). Whereas early effective newborn resuscitation will not eliminate all early neonatal mortality, such intervention will save many lives and significantly reduce subsequent morbidities.

Attempts at reviving nonbreathing infants immediately after birth have occurred throughout recorded time with references in literature, religion, and early medicine. Although the organization and sophistication have changed, the basic principle and goal of initiating breathing have remained constant. During the last 20 years, attention has focused on the process of neonatal resuscitation. Resuscitation programs in other areas of medicine were initiated in the 1970s in an effort to improve knowledge about effective resuscitation and provide an action plan for early responders. The first such program was focused on adult cardiopulmonary resuscitation (Kattwinkel, 2006). These programs then began increasing in complexity and becoming more specific to different types of resuscitation needs. With the collaboration of the American Heart Association and the American Academy of Pediatrics, the Neonatal Resuscitation Program (NRP) was initiated in 1987 and was designed to address the specific needs of the newly born infant. The NRP textbook (Kattwinkel, 2006) now includes specific recommendations for the preterm infant. Various groups throughout the world also provide resuscitation recommendations that are more specific to the practices in certain regions. An international group of scientists, the International Liaison Committee on Resuscitation meets on a regular basis to review available resuscitation evidence for all the different areas of resuscitation and puts forth a summary of its review (Chamberlain, 2005).

The overall goal of the NRP is similar to other resuscitation programs, in that it intends to teach large groups of individuals of varying backgrounds the principles of resuscitation and provide an action plan for providers. Similarly, a satisfactory end result of resuscitation would be common to all forms of resuscitation, namely to provide adequate tissue oxygenation to prevent tissue injury and restore spontaneous cardiopulmonary function. However, when comparing neonatal resuscitation with other forms of resuscitation, several distinctions can be noted. First, the birth of an infant is a more predictable occurrence than most events that require resuscitation in an adult, such as an arrhythmia or a myocardial infarction. Although not every birth will require resuscitation, it is more reasonable to expect that skilled individuals can be present when the need for neonatal resuscitation arises. It is possible to anticipate with some accuracy which newborns will more likely require resuscitation based on perinatal factors and thus allow time for preparation. The second distinction of neonatal resuscitation compared with other forms of resuscitation involves the unique physiology involved in the normal fetal transition to neonatal life. The fetus exists in the protected environment of the uterus where temperature is closely controlled, the lungs are filled with fluid, continuous fetal breathing is not essential, and the gas exchange organ is the placenta. The transition that occurs at birth requires the newborn infant to increase heat production, initiate continuous breathing, replace the lung fluid with air, and significantly increase pulmonary blood flow so that gas exchange can occur in the lungs. The expectations for this transitional process and knowledge of how to effectively assist the process help to guide the current practice of newborn resuscitation.

FETAL TRANSITION TO EXTRAUTERINE LIFE

The complete transition from fetal to extrauterine life is complex and much more intricate than can be discussed in these few short paragraphs, but a basic knowledge of these processes will contribute to the understanding of the rationale for resuscitation practices. The key elements necessary for a successful transition to extrauterine life involve changes in thermoregulation, respiration, and circulation. In utero the fetal core temperature is approximately 0.5° C greater than the mother's temperature (Gunn and Gluckman, 1983). Heat is produced by metabolic processes and is lost over this small temperature gradient through the placenta and skin (Gilbert et al, 1985). After birth the temperature gradient between the infant and the environment becomes much greater and heat is lost through the skin by radiation, convection, conduction, and evaporation. The newborn infant must begin producing heat through other mechanisms such as lipolysis of brown adipose tissue (Dawkins and Scopes, 1965). If heat is lost at a pace greater than it is produced, the infant will develop hypothermia. Preterm infants are at particular risk because of increased heat loss through immature skin, a greater surface area–to–body weight ratio, and decreased brown adipose tissue stores.

The fetus lives in a fluid-filled environment, and the developing alveolar spaces are filled with lung fluid. Lung fluid production decreases in the days before delivery (Kitterman et al, 1979), and the remainder of lung fluid is reabsorbed into the pulmonary interstitial spaces after delivery (Bland, 1988). As the infant takes the first breaths after birth, a negative intrathoracic pressure of approximately 50 cm H_2O is generated (Vyas et al, 1986). The alveoli become filled with air, and with the help of pulmonary surfactant the lungs retain a small amount of air persisting at the end of exhalation, which is known as the *functional residual capacity* (FRC). Although the fetus makes breathing movements in utero, these efforts are intermittent and are not required for fetal gas exchange. Continuous spontaneous breathing is maintained after birth by several mechanisms, including the activation of chemoreceptors, the decrease in hormones that inhibit respirations, and the presence of natural environmental stimulation.

Spontaneous breathing can be suppressed at birth for several reasons, most critical of which is the presence of acidosis secondary to compromised fetal circulation. The natural history of the physiologic responses to asphyxia and acidosis has been described by researchers evaluating animal models. Geoffrey Dawes described the breathing response to acidosis in different animal species (Dawes, 1968). He noted that when pH was decreased, animals typically had a relatively short period of apnea followed by gasping. The gasping pattern then increased in rate until breathing ceased again for a second period of apnea. The physiologic effects that occur with worsening acidosis are noted in Figure 28-1. Dawes also noted that the first period of primary apnea could be reversed with stimulation, whereas the second period, secondary or terminal apnea, required assisted ventilation to ultimately establish spontaneous breathing. The first sign of improvement was noted to be an increase in heart rate. Further recovery was noted when the newborn begins gasping again. The secondary period of apnea varies in duration depending on the duration of asphyxia and degree of acidosis. In the clinical situation, the exact timing of onset of acidosis is generally unknown; therefore any observed apnea may be either primary or secondary. This finding is the basis of the resuscitation recommendation that stimulation may be attempted in the presence of apnea, but if not quickly successful, assisted ventilation should be initiated promptly. Without the presence of acidosis, a newborn may also develop apnea because of recent exposure to respiratory suppressing medications such as narcotics, anesthetics, and magnesium. These medications cross the placenta when given to the mother and may depress the newborn's respiratory drive, depending on the time of administration and dose.

Fetal circulation is unique because gas exchange takes place in the placenta. In the fetal heart, oxygenated blood returning via the umbilical vein is mixed with deoxygenated blood from the superior and inferior venae cavae, and it is distributed differentially throughout the body. The most oxygenated blood is directed toward the brain, and the most deoxygenated blood is directed toward the placenta. Thus blood returning from the placenta to the right atrium is preferentially streamed via the foramen ovale to the left atrium and ventricle and then to the ascending aorta, providing the brain with the most oxygenated blood. Fetal channels, including the ductus arteriosus and foramen ovale, allow most blood flow to bypass the lungs with their intrinsically high vascular resistance. As a result, pulmonary blood flow is approximately 8% of the total cardiac output. In the mature postnatal circulation, the lungs must receive 100% of the cardiac output. When the low-resistance placental circulation is removed after birth, the infant's systemic vascular resistance increases while the pulmonary vascular resistance begins to fall as a result of pulmonary expansion, increased arterial and alveolar oxygen tension, and local vasodilators. These changes result in a dramatic increase in pulmonary blood flow. The average fetal oxyhemoglobin saturation as measured in fetal lambs is approximately 50% (Nijland et al, 1995), but ranges in different sites within the fetal circulation between values of 20% and 80% (Teitel, 1988). The oxyhemoglobin saturation rises gradually over the first 5 to 15 minutes of life to 90% or greater as the air spaces are cleared of fluid. A diagram of the blood flow patterns in the fetus and normally transitioning newborn is shown in Figures 28-2 and 28-3. In the face of poor transition secondary to asphyxia,

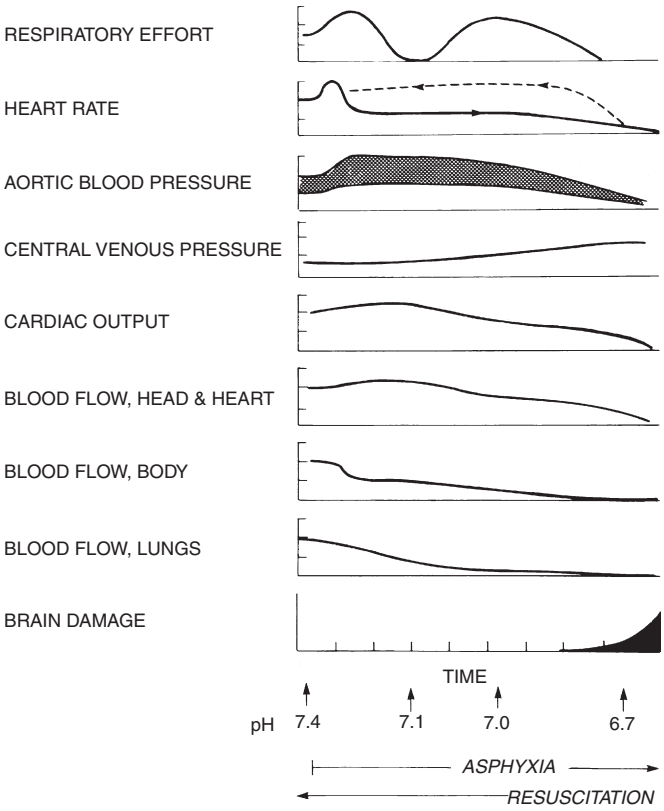

FIGURE 28-1 The sequence of cardiopulmonary changes with asphyxia and resuscitation. Time is on the horizontal axis. Asphyxia progresses from left to right; resuscitation proceeds from right to left. Units of time are not given. If there is complete interruption of respiratory gas exchange, the entire process of asphyxia from extreme left to right could occur in approximately 10 minutes. It could take much longer with an asphyxiating process that only partly interrupts gas exchange or does so completely, but only for repeated brief periods. With resuscitation, the process reverses, beginning at the point to which asphyxia has proceeded. (*Adapted from Dawes G:* Foetal and neonatal physiology, *Chicago, 1968, Year Book; and Avery GN:* Neonatology, *Philadelphia, 1987, JB Lippincott.*)

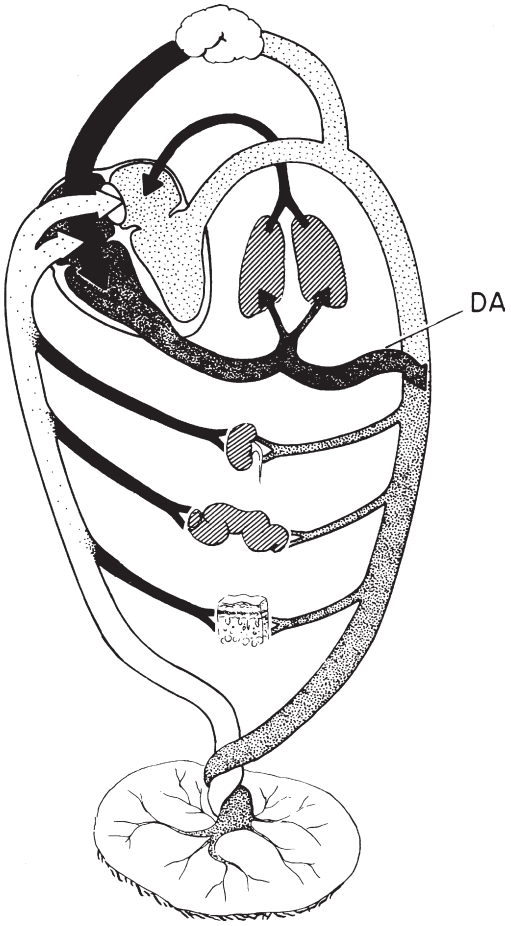

FIGURE 28-2 Fetal circulation. Oxygenated blood leaves the placenta by way of the umbilical vein (*vessel without stippling*). The blood flows into the portal sinus in the liver (not shown), and a variable portion of it perfuses the liver. The remainder passes from the portal sinus through the ductus venosus into the inferior vena cava, where it joins blood from the viscera (represented by the kidney, gut, and skin). Approximately half of the inferior vena cava flow passes through the foramen ovale to the left atrium, where it mixes with a small amount of pulmonary venous blood. This relatively well-oxygenated blood (*light stippling*) supplies the heart and brain by way of the ascending aorta. The other half of the inferior vena cava stream mixes with superior vena cava blood and enters the right ventricle (blood in the right atrium and ventricle has little oxygen, which is denoted by *heavy stippling*). Because the pulmonary arterioles are constricted, most of the blood in the main pulmonary artery flows through the ductus arteriosus (DA), so that the descending aorta's blood has less oxygen (*heavy stippling*) than blood in the ascending aorta (*light stippling*). (*From Avery GN:* Neonatology, *Philadelphia, 1987, JB Lippincott.*)

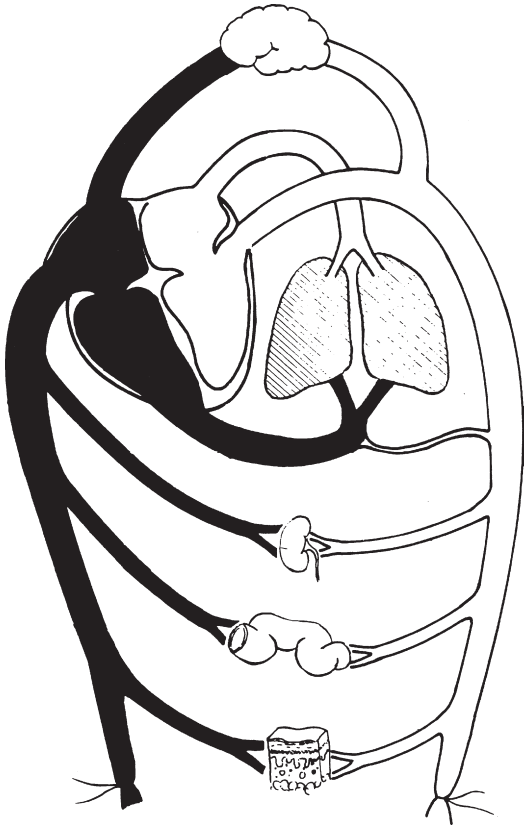

FIGURE 28-3 Circulation in the normal newborn. After expansion of the lungs and ligation of the umbilical cord, pulmonary blood flow increases and left atrial and systemic arterial pressures increase while pulmonary arterial and right heart pressures decrease. When the left atrial pressure exceeds right atrial pressure, the foramen ovale closes so that all of the inferior and superior vena cava blood leaves the right atrium, enters the right ventricle, and is pumped through the pulmonary artery toward the lung. With the increase in systemic arterial pressure and decrease in pulmonary arterial pressure, flow through the ductus arteriosus becomes left to right, and the ductus constricts and closes. The course of the circulation is the same as in the adult. (*From Avery GN:* Neonatology, *Philadelphia, 1987, JB Lippincott.*)

meconium aspiration, pneumonia, or extreme prematurity, the lungs might not be able to develop efficient gas exchange; therefore the oxygen saturation might not increase as expected. In addition, in some situations the normal reduction in pulmonary vascular resistance does not fully occur, resulting in persistent pulmonary hypertension and decreased effective pulmonary blood flow with continued right-to-left shunting through the aforementioned fetal channels. Right-to-left shunting will lead to persistent hypoxemia and potentially to significant newborn illness requiring intensive care until the circulatory pattern adjusts to extrauterine life. The circulatory pattern associated with poor transition is noted in Figure 28-4.

ENVIRONMENT AND PREPARATION

The environment in which the infant is born should facilitate the transition to neonatal life as much as possible and should be able to readily accommodate the needs of a resuscitation team when necessary. Hospitals vary in the approach to the details of how to prepare for resuscitation. For example, some hospitals have a separate room designated for resuscitation where the infant will be taken after birth, whereas others have the delivery room adjacent to the neonatal intensive care unit (NICU) and the infant is resuscitated in the NICU if necessary. Hospitals may bring all the necessary equipment into the delivery room when resuscitation is expected or have every delivery room equipped for any resuscitation. Wherever the resuscitation will take place, a few key elements must be considered. The room should be warm enough to prevent excessive newborn heat loss, bright enough to assess the infant's clinical status, and large enough to accommodate the necessary personnel and equipment to care for the baby.

When no added risks to the newborn are identified, the term birth frequently occurs without the attendance of a

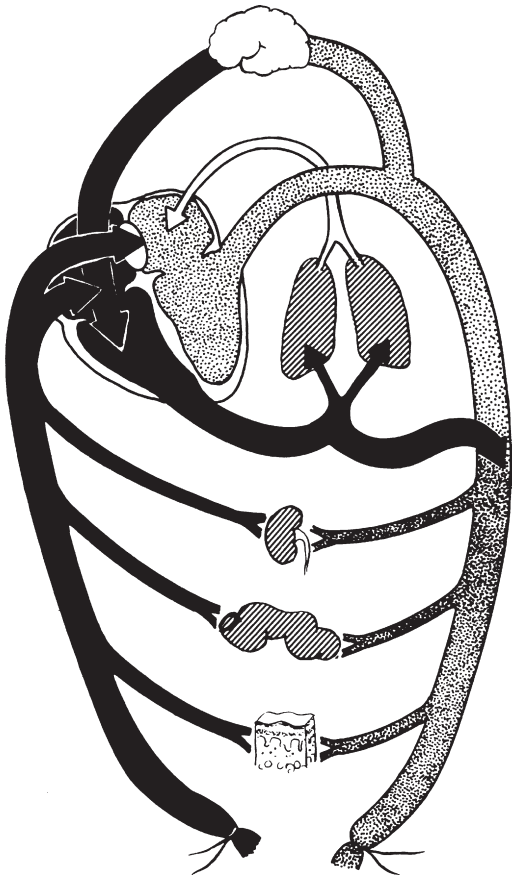

FIGURE 28-4 Circulation in an asphyxiated newborn with incomplete expansion of the lungs. Pulmonary vascular resistance is high, pulmonary blood flow is low (normal number of pulmonary veins), and flow through the ductus arteriosus is high. With little pulmonary arterial flow, left atrial pressure decreases below right atrial pressure, the foramen ovale opens, and vena cava blood flows through the foramen into the left atrium. Partially venous blood goes to the brain via the ascending aorta. The blood of the descending aorta that goes to the viscera has less oxygen than that of the ascending aorta (*heavy stippling*), because of the reverse flow through the ductus arteriosus. Therefore the circulation is the same as in the fetus, except that there is less well-oxygenated blood in the inferior vena cava and umbilical vein. (*From Avery GN:* Neonatology, *Philadelphia, 1987, JB Lippincott.*)

specific neonatal resuscitation team. However, it is recommended that one individual be present who is responsible only for the infant and can quickly alert a neonatal resuscitation team if necessary. Even the best neonatal resuscitation triage systems will not anticipate the need for resuscitation in all cases. Using a retrospective risk assessment scoring system, 6% of newborns requiring resuscitation were not be identified based on risk factors (Smith et al, 1985). Similarly, a recent review found that when a risk-based determination of neonatal resuscitation team attendance at deliveries was used, 22% of infants at attended deliveries required at least assisted ventilation (Aziz et al, 2008). These investigators found that the most significant risk factors were preterm birth, emergency cesarean section, and meconium-stained amniotic fluid. Other significant risk factors for the need for resuscitation are listed in Table 28-1. Antenatal determination of risk allows the resuscitation team to be present for the delivery and to be more thoroughly prepared for the situation.

TABLE 28-1 Risk Factors for Neonatal Resuscitation

Maternal Factors	Fetal Factors	Intrapartum Factors
Maternal hypertension	Preterm delivery	Opiates in labor
Maternal infection	Breech presentation	Rupture of membranes >18 hours
Multiple gestation (preterm)	Shoulder dystocia	Meconium-stained amniotic fluid
		Nonreassuring fetal heart rate patterns
		Emergency cesarean section
		Prolapsed cord

Data from Aziz K et al: Ante- and intra-partum factors that predict increased need for neonatal resuscitation, *Resuscitation* 79:444-452, 2008.

The composition of the neonatal resuscitation team will vary tremendously among institutions. Probably the most important factor in how well a team functions is how the group has prepared for the delivery. Preparation involves both the immediate tasks of readying equipment and personnel for an individual situation as well as the more broad institutional preparation of training team members and providing appropriate space and equipment. We believe that when there is a strong suspicion that the newborn infant will be born in a compromised state, a minimum of three team members should be present, including one member with significant previous experience leading neonatal resuscitations. Each team member is assigned tasks that are performed on a regular basis. The leader is expected to ensure that the appropriate interventions are performed and that they are performed well. All team members are encouraged and expected to speak up if a problem is noticed or if they believe an alternate course would be beneficial. It seems logical that teams that regularly work together and divide tasks in a routine manner will have a better chance of functioning smoothly during a critical situation. Institutions can facilitate team readiness with regular review of practices and mock codes or simulator training to practice uncommon scenarios. In our institution, University of California San Diego (UCSD), video-taped resuscitations are reviewed twice monthly with representatives from all disciplines involved in the resuscitation team (Carbine et al, 2000); this is done as a quality-assurance procedure and allows for ongoing identification of areas needing improvement. In addition, this practice provides an opportunity for education and discussion about potential solutions to repetitive problems of newborn resuscitation. UCSD also instituted a supplemental training program for pediatric trainees to obtain experience in a preclinical situation (Garey et al). These training sessions allow adequate time to review scenarios in detail, and trainees are given the opportunity to prepare and operate the equipment and practice procedures on an individualized basis. Others have used simulators to provide additional resuscitation training (Halamek, 2008). All of these training elements help to prepare teams for future resuscitations.

When preparing for a resuscitation that will occur in the immediate short-term period, additional aspects must be addressed. The most important element in preparing for the resuscitation is the discussion that occurs among the team members who will participate. This discussion, known as a *prebrief*, is an essential part of improving communication during resuscitation and involves reviewing the clinical information, reviewing the available resources and introducing the individuals who will participate, assigning tasks to individuals, and making equipment as readily available as possible. A discussion of the overall plan will help team members know what to expect and how to address problems that could occur. We have formalized this process by creating a prebrief checklist for the team to review while preparing for the delivery. Checklists are considered one of the most important methods of preventing medical errors. A briefing after the resuscitation (i.e., a postbrief) allows team members to address positive and negative aspects of the resuscitation. This briefing is an important element in the preparation for future resuscitations, because team members can immediately identify how to improve the care being provided. An example of our current checklist with prebrief and postbrief documentation is shown in Figure 28-5. To better train the staff in these techniques, UCSD instituted training in crew resource management, a methodology developed for training air crews from the late 1970s that evolved from a careful evaluation of the role of human error in air crashes (Cooper et al, 1980).

ASSESSMENT

Immediately after birth the infant's condition is evaluated by general observation and measurement of specific parameters. Typically a healthy newborn will cry vigorously and maintain adequate respirations. The color will transition from blue to pink over the first 2 to 5 minutes, the heart rate will remain in the range of 140 to 160 beats/min, and the infant will demonstrate adequate muscle tone with some flexion of the extremities. The overall assessment of an infant who is having difficulty with the transition to extrauterine life will often reveal apnea, bradycardia, hypotonia, and cyanosis or pallor. After the initial steps of resuscitation, interventions are based mainly on the evaluation of respiratory effort and heart rate, which need to be assessed continually throughout the resuscitation. Heart rate can be monitored by auscultation or palpation of the cord pulsations, with auscultation being the more reliable method (Owen and Wyllie, 2004). The continuous monitoring of this parameter gives providers an ongoing indication of the effectiveness of interventions.

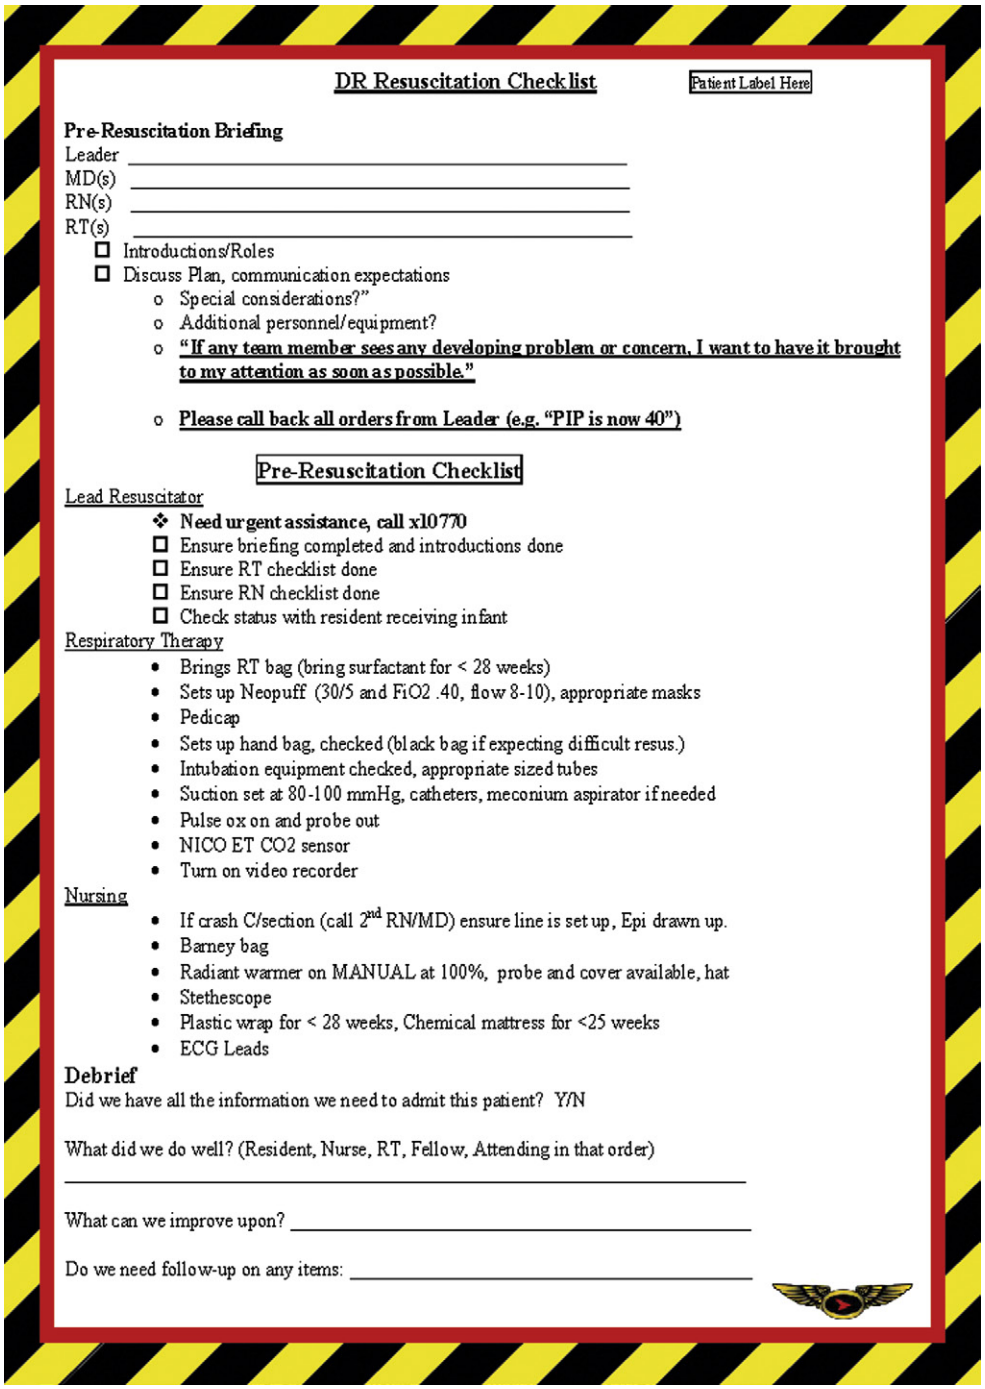
The use of more sophisticated monitoring devices, such as a pulse oximeter or electrocardiographic leads, can be helpful during resuscitation. A pulse oximeter can provide the resuscitation team with a continuous audible and visual indication of the newborn's heart rate throughout the various steps of resuscitation while allowing all team members to perform other tasks. In addition, the pulse oximeter can be used as a more accurate measure of oxygenation than the evaluation of color alone, which is an unreliable measure of the infant's oxygen saturation (O'Donnell et al, 2007). Whenever interventions beyond brief positive-pressure ventilation by mask are required, a pulse oximeter should be considered. Electrocardiographic monitoring may be helpful, but at this point has been infrequently evaluated in the delivery room and does not provide information about oxygenation.

The overall assessment of a newborn was quantified by Virginia Apgar in the 1950s with the Apgar score (Apgar, 1953). The score describes the infant's condition at the time it is assigned and consists of a 10-point scale, with a maximum of 2 points assigned for each of the following categories: respirations, heart rate, color, tone, and reflex irritability. Table 28-2 shows the detailed components of the score. Although the components of the score include items that are assessed for determining interventions, the score itself is not used to determine the need for interventions. The score was initially intended to provide a uniform, objective assessment of the infant's condition and was used as a tool to compare different practices, especially obstetric anesthetic practices. Despite the intent of objectivity, there is often disagreement in score assignment among various practitioners (O'Donnell et al, 2006). Low scores are associated with increased risk of neonatal mortality (Casey et al, 2001), but have not been predictive of neurodevelopmental outcome (Nelson and Ellenberg, 1981). Interpreting the score when interventions are being provided may be difficult, and current recommendations suggest that clinicians should document the interventions used at the time the score is assigned (American Academy of Pediatrics Committee on Fetus and Newborn and American College of Obstetricians and Gynecologists and Committee on Obstetric Practice, 2006).

INITIAL STEPS: TEMPERATURE MANAGEMENT AND MAINTAINING THE AIRWAY

In the first few seconds after birth, all infants are evaluated for signs of life and a determination of the need for further assistance is made. This evaluation is done both formally as described in the NRP and informally as the initial care providers observe the infant in the first few moments of life. When the determination is made that further assistance and formal resuscitation are necessary, the infant is then placed on a radiant warmer and positioned appropriately for resuscitation to proceed. Appropriate positioning includes placing the infant supine on the warmer in such a way that care providers have easy access. In addition, the head should be in a neutral or "sniffing" position to facilitate maintenance of an open airway. Frequently the oropharynx contains fluid that can be removed by suctioning with a standard bulb syringe.

An infant born through meconium-stained amniotic fluid is at risk for aspirating meconium and developing significant pulmonary disease, known as *meconium aspiration syndrome*, which may also be accompanied by persistent pulmonary hypertension. For many years, routine management of all infants with meconium-stained amniotic fluid included suctioning of the mouth and pharynx once the head was delivered, but before the shoulders were delivered, and endotracheal intubation and tracheal suctioning in an attempt to remove any meconium from the trachea and prevent the development of meconium



DR Resuscitation Checklist Patient Label Here

Pre-Resuscitation Briefing

Leader _____
MD(s) _____
RN(s) _____
RT(s) _____

- ☐ Introductions/Roles
- ☐ Discuss Plan, communication expectations
  - o Special considerations?"
  - o Additional personnel/equipment?
  - o **"If any team member sees any developing problem or concern, I want to have it brought to my attention as soon as possible."**
  - o **Please call back all orders from Leader (e.g. "PIP is now 40")**

Pre-Resuscitation Checklist

Lead Resuscitator

- ❖ **Need urgent assistance, call x10770**
- ☐ Ensure briefing completed and introductions done
- ☐ Ensure RT checklist done
- ☐ Ensure RN checklist done
- ☐ Check status with resident receiving infant

Respiratory Therapy

- Brings RT bag (bring surfactant for < 28 weeks)
- Sets up Neopuff (30/5 and FiO2 .40, flow 8-10), appropriate masks
- Pedicap
- Sets up hand bag, checked (black bag if expecting difficult resus.)
- Intubation equipment checked, appropriate sized tubes
- Suction set at 80-100 mmHg, catheters, meconium aspirator if needed
- Pulse ox on and probe out
- NICO ET CO2 sensor
- Turn on video recorder

Nursing

- If crash C/section (call 2nd RN/MD) ensure line is set up, Epi drawn up.
- Barney bag
- Radiant warmer on MANUAL at 100%, probe and cover available, hat
- Stethescope
- Plastic wrap for < 28 weeks, Chemical mattress for <25 weeks
- ECG Leads

Debrief

Did we have all the information we need to admit this patient? Y/N

What did we do well? (Resident, Nurse, RT, Fellow, Attending in that order)

_____

What can we improve upon? _____

Do we need follow-up on any items: _____

FIGURE 28-5 Delivery room resuscitation checklist form.

TABLE 28-2 The Apgar Score

Feature Evaluated	0 Points	1 Point	2 Points
Heart rate (beats/min)	0	<100	>100
Respiratory effort	Apnea	Irregular, shallow, or gasping respirations	Vigorous and crying
Color	Pale, blue	Pale or blue extremities	Pink
Muscle tone	Absent	Weak, passive tone	Active movement
Reflex irritability	Absent	Grimace	Active avoidance

aspiration syndrome. Routine suctioning of the mouth and nose before delivery of the shoulders has been shown to be of no benefit in decreasing the incidence of meconium aspiration syndrome, ventilation for meconium aspiration syndrome, or mortality (Vain et al, 2004). Recognizing that intubation may not be necessary for all infants and that the procedure may be associated with complications, a more selective approach was evaluated in randomized controlled trials (Wiswell et al, 2000). A metaanalysis of studies that have evaluated this question supported the notion that universal endotracheal suctioning does not result in a lower incidence of meconium aspiration syndrome or improve mortality compared with selective endotracheal

suctioning (Halliday, 2000). The likelihood that an infant with meconium-stained amniotic fluid will develop meconium aspiration syndrome is increased in the presence of fetal distress. The selective approach to endotracheal suctioning requires a quick evaluation of the infant after delivery. If the infant is vigorous with good respiratory effort, normal heart rate, and normal tone, the steps of resuscitation proceed as usual. However, if the infant is not vigorous and has poor respiratory effort, a heart rate less than 100 beats/min, or decreased tone, rapid endotracheal intubation for suctioning is currently indicated, although this has not been evaluated in a standardized manner. When endotracheal intubation for suctioning is performed, the resuscitation team must continue to adequately monitor the infant and may need to proceed quickly to providing assisted ventilation if bradycardia is present.

Whereas temperature control is important for all newborn infants, it is particularly important for the extremely preterm infant. Preterm infants are commonly admitted to the NICU with core temperatures well below 37° C. In a population-based analysis of all infants younger than 26 weeks' gestation, more than one third of these preterm infants had an admission temperature of less than 35° C (Costeloe et al, 2000). More disturbing is the fact that these infants with hypothermia on admission survived less often than those with admission temperatures greater than 35° C. Admission temperatures can be improved in preterm infants by immediately covering the infant's body with polyethylene wrap before drying the infant (Vohra et al, 2004). With this approach the infant's head is left out of the wrap and is dried, but the body is not dried before wrap application. Other measures for maintaining infant temperatures include performing resuscitations in a room that is kept at an ambient temperature of approximately 27° to 30° C, using radiant warmers with servo-controlled temperature probes placed on the infant within minutes of delivery, and the use of accessory prewarmed mattress or heating pads for the tiniest infants. Hats are routinely used as a method of decreasing heat loss, but they have not been shown to be consistently effective (McCall et al, 2008). It is important to note that as a required safety feature, radiant warmers substantially decrease their power output after 15 minutes of continuous operation at full power. If this decrease in power is unrecognized, the infant will be exposed to much less radiant heat. By applying the temperature probe and using the warmer in servo-controlled mode, the temperature output will adjust as needed and the power will not automatically decrease.

ASSISTING VENTILATION

As the newborn infant begins breathing and replaces the lung fluid with air, the lungs become inflated and an FRC is established and maintained. With inadequate development of FRC, the infant will not be able to oxygenate and will develop bradycardia if inadequate FRC is prolonged. Providing assisted ventilation when the infant's spontaneous breathing is inadequate is probably the most important step in newborn resuscitation. The indications for providing assisted ventilation (positive-pressure ventilation) include apnea or bradycardia of less than 100 beats/min. Positive-pressure ventilation can be delivered noninvasively with a pressure delivery device and a face mask or invasively with the same pressure delivery device and an endotracheal tube. Pressure delivery devices can include self-inflating bags, flow-inflating or anesthesia bags, and t-piece resuscitators, each with its own advantages and disadvantages. The self-inflating bag is easy to use for inexperienced personnel and will work in the absence of a gas source. However, the self-inflating bag requires a reservoir to provide nearly 100% oxygen and does not consistently provide adequate positive end expiratory pressure (PEEP). These devices can deliver very high pressure if not used carefully. Although they have pressure blow-off valves, these valves do not always open at the target blow-off pressures (Finer et al, 1986). An anesthesia bag or flow-inflating bag requires a gas source for use, allows the operator to vary delivery pressures continuously based on the felt compliance, but requires significant practice to develop expertise. However, using a test lung and intermittent airway occlusion, experienced anesthesiologists were unable to recognize the increased resistance from an airway obstruction using only their hands (Spears et al, 1991). A t-piece resuscitator is easy to use, requires a gas source, and delivers the most consistent levels of pressure, but requires intentional effort to vary the pressure levels (Hoskyns et al, 1987). The flow-inflating bag and t-piece resuscitator allow the operator to deliver continuous positive airway pressure (CPAP) or PEEP relatively easily (Bennett et al, 2005; Finer et al, 2001).

A level of experience is required to perform assisted ventilation using a face mask and resuscitation device, and this is especially true for an infant with extremely low birthweight. It is important to maintain an open airway for pressure to be transmitted to the lungs. The procedure of obtaining and maintaining an open airway includes at minimum clearing fluid with a suction device, holding the head in a neutral position, and sometimes lifting the jaw slightly anteriorly. The face mask must make an adequate seal with the face in order for air to pass to the lungs effectively. No device will adequately inflate the lungs if there is a large leak present between the mask and the face. Wood et al (2008) measured face mask leaks of more than 55% when participants were evaluated, providing positive pressure to manikins at baseline. The amount of the leak was able to be decreased to approximately 30% with specific instruction (Wood et al, 2008). Until recently there were no masks that were small enough to provide an adequate seal over the mouth and nose for the smallest infants. Such masks are now readily available and facilitate bag-mask resuscitation of small infants. Signs that the airway is open and air is being delivered to the lungs include visual inspection of chest rise with each breath and improvement in the clinical condition, including heart rate and color. The use of a colorimetric carbon dioxide detector during bagging will allow confirmation that gas exchange is occurring by the observed color change of the device, or it will alert the operator of an obstructed airway by not changing color (Leone et al, 2006). Airway obstruction is common in the preterm infant during positive-pressure ventilation immediately after birth (Finer et al, 2009). It is important to remember that these devices will not change color in the absence of pulmonary blood flow, as occurs with inadequate cardiac output. At times, multiple maneuvers are

required to achieve an open airway, such as readjusting the head and mask positions, choosing a mask of more appropriate size, and further suctioning of the pharynx. Alternate methods of providing an open airway include the use of a nasopharyngeal tube (Lindner et al, 1999), a laryngeal mask airway device (Grein and Weiner, 2005), or an endotracheal tube.

The amount of pressure provided with each breath during assisted ventilation is critical to establishing lung inflation and therefore adequate oxygenation. Although it is important to provide adequate pressure for ventilation, excessive pressure can contribute to lung injury. Achieving the correct balance of these goals is not simple and is an area of resuscitation that requires more study. A single specific level of inspiratory pressure will never be appropriate for every baby. Initial inflation pressures of 25 to 30 cm H_2O are probably adequate for most term infants. The NRP textbook (Kattwinkel, 2006) recommends initial pressures of 20 to 25 cm H_2O for preterm infants. The first few breaths may require increased pressure if lung fluid has not been cleared, as occurs when the infant does not initiate spontaneous breathing. Newborn infants with specific pulmonary disorders such as pneumonia or pulmonary hypoplasia also frequently require increased inspiratory pressure. It has been shown that using enough pressure to produce visible chest rise is associated with hypocarbia on admission blood gas evaluation (Tracy et al, 2004), and excessive pressure may decrease the effectiveness of surfactant therapy (Bjorklund et al, 1997). It may be possible to establish FRC without increasing peak inspiratory pressures by providing a few prolonged inflations (3 to 5 seconds of inspiration), although the use of prolonged inflations has not been associated with better outcomes than conventional breaths during resuscitation (Lindner et al, 2005). Choosing the actual initial inspiratory pressure is less important than continuously assessing the progress of the intervention. A manometer in the circuit during assisted ventilation provides the clinician with an indication of the administered pressure, although if the airway is blocked this pressure is not delivered to the lungs. The volume of air delivered to the lungs seems to be more important than the absolute pressure delivered in the development of lung injury. Tidal volume can be monitored with respiratory function monitors that are placed in the respiratory circuit (Schmolzer et al, 2010). The most critical component of continued assessment is evaluation of the infant's response to the intervention. If the condition of the infant does not improve after initiating ventilation, then the ventilation is most likely inadequate. In our experience the two most likely reasons for inadequate ventilation are a blocked airway and insufficient inspiratory pressure. The occluded airway can be noted using a colorimetric carbon dioxide device as described previously, and frequently it can be corrected with changes in position or suctioning while inadequate pressure is corrected by adjusting the ventilating device.

The use of continuous pressure throughout the breathing cycle seems to be beneficial for establishing FRC and improving surfactant function (Hartog et al, 2000; Michna et al, 1999; Siew et al, 2009); this is accomplished during assisted ventilation with the use of PEEP or with CPAP when additional inspiratory pressure is not needed. In the absence of PEEP, a lung that has been inflated with assisted inspiratory pressure will lose on expiration most of the volume that had been delivered on inspiration. This pattern of repeated inflation and deflation is frequently thought to be associated with lung injury. In preterm infants, a general approach of using CPAP as a primary mode of respiratory support in NICUs has been associated with a low incidence of chronic lung disease (Ammari et al, 2005; Avery et al, 1987; Van Marter et al, 2000; Vanpee et al, 2007). Recently, te Pas and Walther (2007) evaluated a ventilation strategy that included the use of a I-piece resuscitator and a nasopharyngeal tube to deliver a prolonged breath followed by CPAP, compared with the use of a self-inflating bag to deliver positive pressure ventilation when needed without any CPAP provided until infants reached the NICU. Infants treated with the prolonged breath and CPAP required less endotracheal intubation and had lower rates of bronchopulmonary dysplasia. The use of CPAP compared with endotracheal intubation and mechanical ventilation as the initial mode of respiratory support was evaluated in the Continuous Positive Airway Pressure or Intubation at Birth (COIN) trial (Morley et al, 2008), but the intervention did not begin until after 5 minutes of life and therefore cannot inform the decision about the use of these therapies as immediate resuscitative interventions. The recently completed Surfactant Positive Airway Pressure and Pulse Oximetry Trial (SUPPORT Study Group 2010. Available at http://clinicaltrials.gov/ct2/show/NCT00233324?term=neonatal+respiratory+support&rank=15) evaluated the use of CPAP versus intubation and surfactant use in the first hour of life as the primary respiratory support for preterm infants. These trials suggest that CPAP is beneficial for improving some short-term outcomes associated with prematurtiy. Although these trials do not evaluate these therapies specifically in the resuscitation period, the respiratory support provided shortly after birth should probably mimic the support provided in the NICU after delivery.

If assisted ventilation is necessary for a prolonged period of time or if other resuscitative measures have been unsuccessful, ventilation must be provided by a more secure device such as an endotracheal tube. If it has been difficult to maintain an open airway while ventilating via a face mask, an appropriately placed endotracheal tube will provide a stable airway. This stability will allow more consistent delivery of gas to the lungs and therefore provide for the ability to establish and maintain FRC. At this time intubation is required for administering surfactant, and it can be used to administer other medications such as epinephrine if necessary for resuscitation. Finally, for non-vigorous infants born through meconium-stained amniotic fluid, intubation is performed for suctioning of the airway.

The intubation procedure is often critical for successful resuscitation, requires a significant amount of skill and experience to perform reliably, and may be associated with serious complications. The placement of a laryngoscope in the pharynx often produces vagal nerve stimulation, which leads to bradycardia. A photograph of the desired view of the larynx is shown in Figure 28-6. Assisted ventilation must be paused for the procedure, which if prolonged can lead to hypoxemia and bradycardia. Intubation has been shown to increase blood pressure

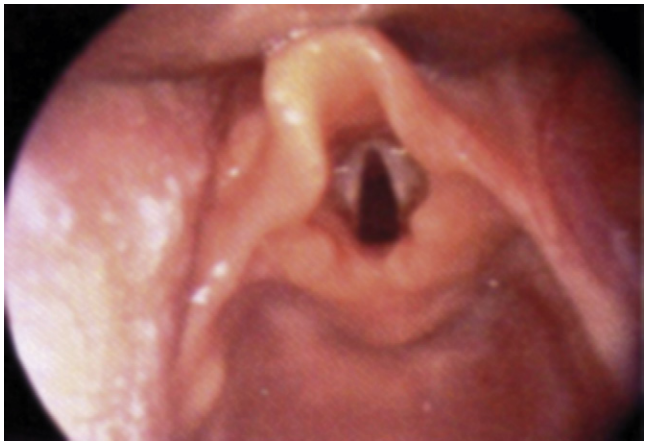


FIGURE 28-6 *(See also Color Plate 18.)* View of the glottis and vocal cords as the laryngoscope is gently lifted. (*From American Heart Association, American Academy of Pediatrics: Kattwinkel J, editor:* Neonatal resuscitation textbook, *ed 5, Elk Grove Village, Ill., 2006, American Academy of Pediatrics.*)

and intracranial pressure (Kelly and Finer, 1984). Trauma to the mouth, pharynx, vocal cords, and trachea are all possible complications of intubation. Performing the intubation procedure when the infant already has bradycardia and hypoxemia can lead to further decline in heart rate and oxygenation (O'Donnell et al, 2006). In addition, hypoxia and bradycardia are more likely when intubation attempts are prolonged beyond 30 seconds. Therefore it is most appropriate to make an attempt to stabilize the infant with noninvasive ventilation before performing the procedure, limiting each attempt to 30 seconds or less (Lane et al, 2004), and allow time for the infant to recover with noninvasive ventilation between attempts. If misplacement of the endotracheal tube in the esophagus goes unrecognized, the infant may experience further clinical deterioration. Clinical signs that the endotracheal tube has been correctly placed in the trachea include auscultation of breath sounds over the anterolateral aspects of the lungs (near the axilla), mist visible in the endotracheal tube, chest rise, and clinical improvement in heart rate and color or oxygen saturation. The use of a colorimetric carbon dioxide detector to confirm intubation significantly decreases the amount of time necessary to determine correct placement of the endotracheal tube from approximately 40 seconds to less than 10 seconds (Aziz et al, 1999; Repetto et al, 2001); this is the primary method of determining endotracheal tube placement.

Successful placement of the endotracheal tube is not always easy and is sometimes not possible. Airway anomalies may make alternate methods of airway management necessary. A laryngeal mask airway is one such alternative that has been described for use in patients with Pierre Robin sequence or other airway anomalies (Yao et al, 2004). Some practitioners have reported using the laryngeal mask airway for all positive-pressure delivery after birth, with success noted in infants as small as 1.2 kg (Gandini and Brimacombe, 1999). Administration of medications including surfactant and epinephrine through this device has undergone preliminary investigations (Chen et al, 2008; Trevisanuto et al, 2005).

TRANSITIONAL OXYGENATION AND OXYGEN USE

It is critical to remember that fetal arterial oxygen levels are much lower than newborn arterial oxygen levels. The transition from fetal to newborn levels does not take place instantaneously. Using pulse oximetry in the immediate newborn period, several investigators have established that this transition with an ultimate oxygen saturation level greater than 90% takes 5 to 15 minutes to occur in infants who do not otherwise require resuscitation. For term and preterm nonresuscitated infants, the median interquartile range (IQR) of oxygen saturation at 3 minutes was 76% (64% to 87%) and at 5 minutes was 90% (79% to 91%; Kamlin et al, 2006). Expected oxygen saturation levels are slightly lower for preterm compared with term and for infants delivered via cesarean section compared with those delivered vaginally (Rabi et al, 2006). Oxygen saturation levels measured in preductal sites are 5% to 10% higher than those measured from postductal sites for approximately 15 minutes of life (Mariani et al, 2007). A great deal of variability occurs in the saturation values among different healthy individuals during the first 5 minutes of life, but a resuscitation team can expect that there be a steady, albeit slow, increase in levels over several minutes. If values are below a threshold at different time points or not progressively increasing, intervention should be considered.

The use of pure oxygen for ventilation became routine practice in resuscitation simply because it seemed logical that oxygen would be beneficial. However, the recognition that oxygen could also be toxic led some investigators to question this previously well accepted practice. The toxicity of oxygen is anticipated when the cellular antioxidant capacity is impaired, as occurs during the reperfusion phase following an hypoxic-ischemic insult. After animal studies showed the potential harmful effects of oxygen (Poulsen et al, 1993; Rootwelt et al, 1992), clinical trials were conducted to evaluate the effects of oxygen use during resuscitation of depressed infants. Several worldwide trials have compared the use of pure (100%) oxygen with room (ambient) air (21% oxygen) as the initial ventilating gas for asphyxiated newborns. These trials found that air was as successful as oxygen in achieving resuscitation, and infants resuscitated with air had a shorter time to initiate spontaneous breathing and less evidence of oxidative stress (Ramji et al, 2003; Saugstad et al, 1998; Vento et al, 2001, 2003). Metaanalyses of several of the trials indicated that infants resuscitated with air had a lower risk of mortality than those resuscitated with pure oxygen (Rabi et al, 2007; Tan et al, 2005). These trials have been criticized because they were not all strictly randomized, and some sites were in developing countries; however, metaanalysis of the strictly randomized trials, which were mostly done in European centers, demonstrates significant benefit for survival with the use of air compared with pure oxygen (Saugstad et al, 2008).

The preterm infant may be more susceptible to any harmful effects of excessive oxygen exposure, because of decreased antioxidant enzyme capacity. Some of the infants in the previous oxygen trials were preterm, but few weighed less than 1000 g. Review of the outcomes for preterm infants (<37 weeks' gestation) demonstrated an

even greater reduction in death for those initially resuscitated with room air compared with oxygen (Saugstad et al, 2005). NICUs generally attempt to reduce oxygen toxicity by limiting the amount of oxygen administered to newborns using an upper limit for oxygen saturation and adjusting supplemented oxygen levels to maintain saturation levels within that limit. The unlimited use of oxygen during resuscitation exposes the preterm infant to higher oxygen saturation levels than would routinely be accepted in the NICU. Several small trials of oxygen use during resuscitation of preterm infants have been performed in the last 3 years. Among 42 preterm infants younger than 32 weeks' gestation treated with either pure oxygen for 5 minutes or a targeted oxygen strategy beginning with 21% oxygen, all infants were provided some level of supplemental oxygen (Wang et al, 2008). Infants initiated on pure oxygen had higher pulse oximeter saturation (Spo_2) levels during transition, but did not have any differences in heart rate, need for intubation, or survival. The infants provided air from the start of resuscitation all required an increase in inspired oxygen to obtain the specified oxygen saturation targets. Using 30% versus 90% oxygen at the start of resuscitation and adjusting the concentration based on the clinical status of the infant, Escrig et al (2008) found that infants initially receiving 30% oxygen had lower overall exposure to oxygen without any adverse effects. The group receiving 30% oxygen received increased oxygen concentrations up to approximately 55% at 5 minutes, but both groups received similar oxygen concentrations after 4 minutes of life, with a level of approximately 35% by 15 minutes of life (Escrig et al, 2008). In a more recent study, these investigators also reported a decrease in the incidence of bronchopulmonary dysplasia in infants initially receiving 30% oxygen compared with 90% oxygen (Vento et al, 2009). Finally, the Room Air versus Oxygen Administration during Resuscitation (ROAR) study was a blinded, randomized controlled trial in 106 infants at 32 weeks' gestation or less comparing three oxygen strategies: one group received 100% throughout (HOB), one received 100% initially (MOB), and one received 21% (LOB) initially; the last two groups had the oxygen concentration titrated to keep Spo_2 at 85% to 92%. Spo_2 levels were below the specified target range 61% of the time in the LOB group and were above the target range 49% of the time in the HOB group (p <0.001; Rabi et al, 2008). Larger trials of preterm infants treated with different oxygen strategies are necessary to determine the long-term effects of resuscitation with different oxygen concentrations. Oxygen use in the first minutes of life could affect survival and common neonatal morbidities associated with prematurity and free radical disease, such as neurodevelopmental impairment, retinopathy of prematurity, bronchopulmonary dysplasia, and necrotizing enterocolitis.

The use of oxygen concentrations between 21% and 100% requires compressed air and a blender. Different organizations throughout the world have provided differing recommendations on the use of oxygen for newborn resuscitation. The most recent review of evidence for the updated NRP guidelines suggest that resuscitation could begin with either air or blended oxygen; if blended oxygen is unavailable, air is preferred to pure oxygen. The suggested goal for oxygen saturation values is the IQR at each minute (Kattwinkel et al, 2010). Our approach has been to begin with 40% oxygen and adjust slowly, attempting to mimic the gradual transition in Spo_2 values that occur in healthy newborns transitioning from fetal oxygenation levels with an expected increase in Spo_2 from the fetal level of approximately 50% to a target of 85% to 90% by 7 to 8 minutes, an increase of approximately 5% per minute. Figure 28-7 demonstrates continuous physiologic data during the first 10 minutes of life for an infant resuscitated using a targeted oxygen strategy.

ASSISTING CIRCULATION

In newborn infants, the need for resuscitative measures beyond assisted ventilation is extremely rare. Additional circulatory assistance can include chest compressions, administration of epinephrine, and volume infusion. In a large urban delivery center with a resuscitation registry, 0.12% of all infants delivered received chest compressions, epinephrine, or both during 1991 to 1993 (Perlman and Risser, 1995), and 0.06% of all infants delivered received epinephrine during 1999 to 2004 (Barber and Wyckoff, 2006). Ventilation remains the most critical priority in neonatal resuscitation; however, if adequate ventilation is provided for 30 seconds, and bradycardia with a heart rate less than 60 beats/min persists, chest compressions are initiated. Further attention to ventilation with the use of increased pressures or intubation may be required. Chest compressions are preferably provided with two thumbs on the sternum while both hands encircle the chest with (Menegazzi et al, 1993). The chest is then compressed in a 3:1 ratio coordinated with ventilation breaths.

Further circulatory support may be necessary if adequate chest compressions do not result in an increase in heart rate after 30 seconds. Epinephrine is then indicated as a vasoactive substance, which increases blood pressure by α-receptor agonism, improves coronary perfusion pressure, and increases heart rate by β-receptor agonism. Intravenous administration of epinephrine is more likely to be effective than endotracheal administration. The intravenous dose of 0.01 to 0.03 mg/kg (0.1 to 0.3 mL/kg of a 1:10,000 solution) is currently recommended. Early placement of an umbilical venous catheter is critical to delivering intravenous epinephrine quickly enough to be effective. In order to place an umbilical catheter as quickly as possible, it is necessary to have the equipment readily available and to begin the procedure as soon as possible. This could be accomplished by the lead resuscitator assigning the task of placing the catheter as soon as chest compressions are initiated. If there is any prenatal indication that substantial resuscitation will be required, the necessary equipment for umbilical venous catheter placement should be prepared before delivery as completely as possible. Epinephrine can be given by endotracheal tube, but the efficacy of this delivery method is not as certain; therefore an increased dose (0.05 to 0.1 mg/kg) is recommended. Epinephrine doses can be repeated every 3 minutes if heart rate does not increase. Excessive epinephrine can result in hypertension, which in preterm infants may be a factor in the development of intraventricular hemorrhage. However, the risks

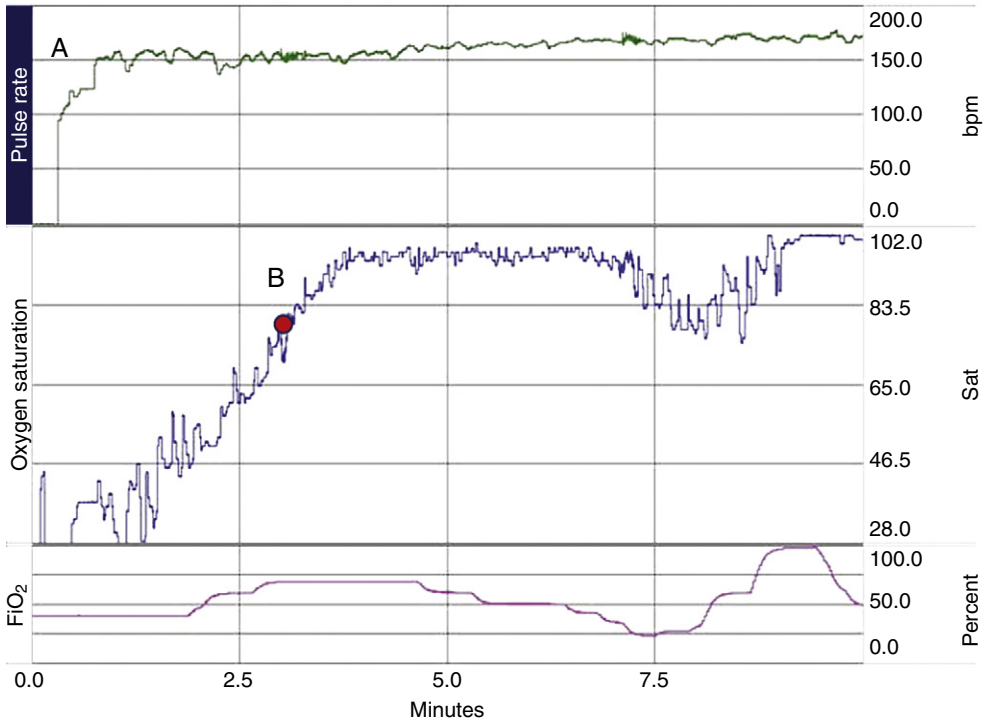

FIGURE 28-7 Tracing of physiologic data during transition. The pulse rate, oxygen saturation, and oxygen concentration (FiO_2) measured within 30 seconds of birth are displayed here. The pulse oximeter is placed on the infant's right hand as soon as possible. Point *A* shows when the pulse oximeter begins working. Point *B* shows the oxygen saturation (SpO_2) at 3 minutes (approximately 80%). This infant was initially treated with 40% oxygen, and the concentration was adjusted to achieve SpO_2 of 85% to 90% by 5 minutes of life. When the oxygen is weaned down to 21% at approximately 7.5 minutes of life, the SpO_2 decreases and oxygen concentration is increased again.

are balanced by the benefit of successful resuscitation in an infant who might not otherwise survive.

If the infant has not responded to all the prior measures, a trial of increasing intravascular volume should be considered, which involves administering crystalloid or blood. Situations associated with fetal blood loss are also frequently associated with the need for resuscitation. These situation include placental abruption, cord prolapse, and fetal maternal transfusion. Some of these clinical circumstances will have an obvious history associated with blood loss, whereas others might not be readily evident at the time of birth. Signs of hypovolemia in the newborn infant are nonspecific, but include pallor and weak pulses. Volume replacement requires intravenous access, for which emergent placement of an umbilical venous catheter is essential. Any infant who has signs of hypovolemia and has not responded quickly to other resuscitative measures should have an umbilical venous line placed and a volume infusion administered. The most common, and currently recommended, fluid for volume replacement is isotonic saline. A trial volume of 10 mL/kg is given initially and repeated if necessary. If a substantial blood loss has occurred, the infant may require infusion of red blood cells to provide adequate oxygen-carrying capacity. This infusion can be accomplished emergently with noncrossmatched, O-negative blood, with blood collected from the placenta or with blood drawn from the mother, who will have a compatible antibody profile with her infant at the time of birth. Because not all blood loss is obvious and resuscitation algorithms usually discuss volume replacement as a last resort of a difficult resuscitation, the clinician needs to keep a high index of suspicion for significant hypovolemia so that action can be taken to correct the problem as promptly as possible. Therefore in situations where the possibility for hypovolemia is known before birth, it would be wise to prepare an umbilical catheter and an initial syringe of isotonic saline and discuss with the blood bank and the delivering physicians the possibility that non-crossmatched blood may be required.

SPECIFIC PROBLEMS ENCOUNTERED DURING RESUSCITATION

NEONATAL RESPONSE TO MATERNAL ANESTHESIA AND ANALGESIA

Medications administered to the mother during labor can affect the fetus by transfer across the placenta and direct action on the fetus or by adversely affecting the mother's condition, and therefore altering uteroplacental circulation and fetal oxygen delivery. The most commonly discussed complication of intrapartum medication exposure is perinatal respiratory depression after maternal opiate administration. The fetus can develop respiratory depression from the direct effect of the drug. Naloxone has been used during neonatal resuscitation as an opiate receptor antagonist to reverse the effects of fetal opiate exposure. Naloxone chloride (0.1 mg/kg per dose, intravenously, intramuscularly, or endotracheally) can be considered if the newly born infant does not develop spontaneous respirations after adequate resuscitation and the mother has received an opiate analgesic during labor, provided

the opiate exposure is not chronic. Infants of mothers who have a chronic opiate exposure can potentially have a sudden withdrawal syndrome, including seizures if they receive a narcotic antagonist. It is also critical that assisted ventilation be provided as long as spontaneous respirations are inadequate. It should be noted that the administration of a narcotic antagonist is never an acutely required intervention during neonatal resuscitation, because these infants can be treated with assisted ventilation.

CONDITIONS COMPLICATING RESUSCITATION

When resuscitation has proceeded through the described steps without improvement in the infant's clinical condition, other problems should be considered. Some of these problems may be modifiable with interventions that could improve the course of the resuscitation. For example, an unrecognized pneumothorax could prevent adequate pulmonary inflation and if under tension could impair cardiac function. If the pneumothorax is recognized and drained, gas exchange and circulation can be improved. Some congenital anomalies that were not diagnosed antenatally make resuscitation more difficult. Congenital diaphragmatic hernia is difficult to recognize on initial inspection of the infant, but can cause significant problems with resuscitation. The abdominal organs are displaced into one hemithorax, and the lungs are unable to develop normally; this will cause ventilation to be difficult. If the intestines are displaced into the thorax and mask ventilation is provided, the intestines will become inflated, making ventilation more difficult. If the congenital diaphragmatic hernia is known before delivery or a presumptive diagnosis is made in the delivery room, the baby should be intubated early to prevent intestinal inflation. An orogastric suction tube should also be placed to decompress the inflated intestines.

Many other congenital anomalies that can lead to a difficult resuscitation will be more visibly obvious when the baby is born. For example, hydrops fetalis occurring for any reason can be associated with difficult resuscitation. Although most cases are diagnosed on fetal ultrasound examination before delivery, severe hydrops would be visible on examination with skin edema and abdominal distention. Frequently peritoneal and pleural fluid will need to be drained to achieve adequate ventilation. Abdominal wall defects such as gastroschisis require special attention in the delivery room to ensure that the exposed bowel is covered in plastic, to prevent excessive fluid loss, and is protected from twisting or trauma. An orogastric suction tube is also important to decompress the stomach and limit the chances of further vomiting. If assisted ventilation is necessary, early intubation as opposed to mask ventilation should be considered to prevent gastric distention. Infants with neural tube defects should also have any exposed tissues protected with a covering. In addition, all efforts should be made to avoid pressure on the defect.

Fetal congenital high airway obstruction can cause particularly difficult resuscitation. If a significant airway obstruction is diagnosed antenatally, an ex utero intrapartum treatment (i.e., EXIT) procedure can be planned. This procedure allows for establishing a stable airway before clamping the umbilical cord, which maintains placental function until the airway is secure. An airway obstruction may not necessarily be diagnosed before delivery and can cause difficult resuscitation. The therapy will vary depending on the cause of obstruction. An alternate airway (oral or nasopharyngeal) can be helpful if endotracheal intubation is not possible, as can occur with micrognathia. Tracheal suctioning can be attempted if a tracheal plug is suspected. In extreme situations of airway obstruction, an emergency cricothyroidotomy may be attempted.

Birth trauma of any kind has been documented to occur in approximately 2.6% of all deliveries in the United States (Moczygemba et al, 2010). The most serious injuries are the variety of head injuries that can occur, including subgaleal hemorrhage and intracranial hemorrhage. Subgaleal hemorrhage is more often associated with vacuum-assisted delivery; it and is important to recognize because of the rapid blood loss that can occur into this soft tissue space. Intracranial hemorrhages such as subdural hematomas can occur, although many such injuries are mild and can be found incidentally after uncomplicated vaginal delivery. Spinal cord injuries after birth are extremely rare, but can be severe with long-lasting functional limitations. Brachial plexus and other peripheral nerve injuries may be noticed in the delivery room and evaluated shortly after birth, but they should not interfere with the resuscitation efforts. Pressure injuries from forceps-assisted deliveries can be noted on examination and evaluated as necessary in accordance with the location of the injury. Fractures and lacerations can occur and need to be evaluated after the newborn infant has transitioned adequately.

LIMITS OF VIABILITY

Neonatal intensive care has increased survival at lower gestational ages, resulting in changes in the definition of viability over time. There is a variety of opinion among practitioners regarding the lower limit of gestational age when intensive care should be offered. The NRP states that not providing intensive care is appropriate at less than 23 weeks' gestation or 400 g birthweight. When the outcome is uncertain, parents of the infant are frequently included in the decision-making process. Making an informed decision about providing intensive care should be done with the best information available. One of the most useful resources to determine the likelihood of survival without severe disabilities has been provided by Tyson et al (2008) using the National Institute of Child Health and Human Development Neonatal Research Network data. Using information regarding the gestational age, birthweight, sex, number of fetuses, and antenatal steroid exposure, a calculation of the risk of mortality and neurodevelopmental impairment can be made. These predictive data that were compiled from the participating centers of the Neonatal Research Network, a group of mostly academic centers, may currently be the best national data available for predicting outcome, but they do not necessarily represent the outcome at any single unit or of any individual baby. When there is the possibility of delivery at a very preterm gestational age at a small, inexperienced center, all efforts should be made to transport the mother to an experienced inborn center.

CARE AFTER RESUSCITATION

Infants who survive a significant resuscitation require special attention in the hours to days that follow. Frequent complications immediately following resuscitation include hypoglycemia, hypotension, and persistent metabolic acidosis. In addition, infants with evidence of hypoxic ischemic encephalopathy may benefit from mild therapeutic hypothermia (Azzopardi et al, 2009; Jacobs et al, 2007; Shankaran et al, 2005). Mild therapeutic hypothermia, in which the core body temperature is kept at 33.5° C, has been extensively evaluated and has been effective at reducing death or impairment in infants with moderate to severe hypoxic ischemic encephalopathy. The decreased temperature is thought to decrease the secondary injury that occurs after an hypoxic-ischemic insult. Hypothermia can be accomplished with both whole-body and head cooling, although clinical trials of whole-body cooling more effectively achieved a reduction in adverse outcomes. The therapy is most beneficial when initiated as quickly as possible after an insult, with beneficial effects noted when treatment was initiated within 6 hours of birth. The timing of insult in relation to the time of birth is not always obvious, making it difficult to know the actual timing of initiating therapy after the insult.

Mild hypothermia therapy should be considered when an infant has required a significant resuscitation after birth, Apgar scores are low (especially a 5-minute score less than 5), fetal or neonatal acidosis are documented on cord or newborn blood gases, and signs of encephalopathy are apparent. In addition, the history of a significant event likely to cause a hypoxic-ischemic insult should trigger a thorough evaluation of the newborn to determine whether hypothermia therapy is indicated. Hypothermia therapy is not currently available at all institutions; however, all delivery services must be able to recognize the indications for therapy, so that a transfer can be initiated as quickly as possible, if necessary.

In infants born without a heart rate or any respiratory effort, if resuscitation is performed to the full extent without any response, discontinuation is recommended after 10 minutes. From a review of 13 years of data from a database including 81,603 deliveries, Haddad et al (2000) found that survival with an Apgar score of 0 at 1 minute occurred in 1.26 of 1000 delivered infants without major malformations. Of 33 infants assigned Apgar scores of 0 at both 1 and 5 minutes, 67% died before hospital discharge (Haddad et al, 2000). A recent review of the available literature for infants with Apgar scores of 0 at 10 minutes found that 94% of infants either died or were severely handicapped, whereas 3% were mild or moderately handicapped (Harrington et al, 2007).

The transition from fetal to neonatal life is a critical time in an individual's life and is an opportunity for care providers to have significant effect on the outcome of infants who need assistance. The need for neonatal resuscitation, even when no signs of encephalopathy are recognized, increases the risk that children will have lower scores on intelligence quotient tests at school age (Odd et al, 2009). This risk arises most likely because resuscitation is a marker for a prior insult. However, a well-performed resuscitation could be critical for a successful recovery. Neonatal care providers have an obligation to ensure that this process is performed as well as possible and that the techniques of resuscitation are evaluated in an objective manner to promote continued improvement.

PART VIII

Care of the High-Risk Infant

CHAPTER 29

Stabilization and Transport of the High-Risk Infant

George A. Woodward, Roxanne Kirsch, Michael Stone Trautman, Monica E. Kleinman, Gil Wernovsky, and Bradley S. Marino

NEONATAL TRANSPORT MEDICINE

INTRODUCTION

Regionalization of medical care has improved the ability to centralize resources and improve patient outcomes. For optimal coordinated care, however, adequate medical transport needs to be developed and continually refined to enable delivery of patients to regional centers, and for specialized care to be available for and delivered to patients in distress. For centers that serve as a basic or specialized service, there will be times when subspecialty care is required. For those who deliver subspecialty care, there will also be times for most organizations when transfer to a similar level organization may be required for reasons such as capacity or extraordinary care. For hospitals that do not have birthing centers as part of their facility, the patient population, the acuity of the arriving patients, and potentially the ultimate morbidity and mortality of those patients depend on skilled, efficient, and quality neonatal transport. Although transfers to neonatal centers in the 1960s and early 1970s often occurred in an ad hoc manner, such as in a police car or an ambulance (i.e., a converted hearse) with variably skilled providers, transfer programs today offer a more sophisticated level of care. This level of care, however, is not consistent throughout cities, nationwide, and internationally. Many transport services and centers have grown around individual center needs, without clear attention to coordination and regionalization of services. Competitive systems, often located in similar areas or vying for similar patient populations, have resulted in the duplication of services at the ground and air levels, and at times increased risk and cost to patients and providers as part of the efforts to increase patient volume and revenue.

When considering transport of neonatal patients, several situations can occur. Intrafacility transport may be required for specialty services within a particular institution. Interfacility transport between lower and higher levels of service capability can also occur, as well as between relatively equivalent levels of service because of capacity or other issues. Transported patients may be of high acuity, relatively stable, or in various stages of convalescent care. Each type of transport requires anticipatory planning, appropriate staffing, adequate modalities (e.g., transport vehicles), and strong relationships between referring and receiving providers, in addition to skilled, qualified, and certified transport personnel. As noted in the next section, transfer agreements can help to minimize inefficiencies and enable rapid approval and eventually transport of patients.

This chapter will review considerations and requirements for neonatal transport; discuss issues involved in transport team operation, including equipment, personnel, mode of transport, and medical-legal issues; and present general and specific topics, including quality improvement opportunities, that might be encountered in a neonatal transport system (American Academy of Pediatrics et al, 2007; Cornette, 2004; Woodward et al, 2007).

REGIONALIZATION OF NEONATAL CARE, TRANSFER AGREEMENTS, AND BACK TRANSPORT

The concept of regionalization of neonatal care and transport developed from the formation of neonatal stations in the 1920s and 1940s (Oppenheimer, 1996). These stations were located within certain area hospitals, where additional resources were allocated to provide care for premature infants. One consequence of the formation of these stations was the development of equipment and protocols to transport premature infants from other area hospitals to those specialized areas to receive care.

In the 1960s and 1970s, as interest in neonatal care grew, so did the number of hospitals offering services for premature infants. To help optimize the care being delivered, the March of Dimes produced *Toward Improving the Outcome of Pregnancy* in a 1976 report (Committee on Perinatal Health, 1976). The report stratified maternal and neonatal care into levels based on their complexity, and it proposed the referral of high-risk patients to centers with sufficient personnel and resources to provide care. The goal was to create standard definitions so that comparisons of health outcomes, resource utilization, and costs among regional institutions could be made. High-risk maternity patients would be able to actively participate in selecting a delivery service, and businesses would be able to select appropriate health care resources for their employees. The subsequent March of Dimes publication in 1993 *Toward Improving the Outcome of Pregnancy: The 90s and Beyond* reiterated the importance of regionalized care and further delineated care levels (Committee on Perinatal Health, 1993). The concepts of regional care were adopted and incorporated into the Guidelines for Perinatal Care (American Academy

of Pediatrics Committee on Fetus and Newborn and Bell, 2007; Woodward et al, 2007). Whereas the original driving forces for regionalization in the 1970s were the shortage of trained personnel to care for low birthweight (LBW) infants and the economic expense to maintain these skills, during the late 1980s and 1990s, technology and clinical expertise disseminated outside the regional tertiary centers, resulting in proliferation of the number of intermediate care neonatal intensive care units (NICUs). This proliferation has blurred many of the original distinctions between various care systems. Whether driven by third party payers or other factors, with various interpretations and applications of what "regional care" means, the results have been the creation of a variety of care options (Lainwala et al, 2007).

Limited space and cooperative longitudinal care planning in some tertiary care units have created the necessity for patient transport back to a unit with less acuity or fewer resources once their critical condition has resolved or stabilized (Attar et al, 2005; Donovan and Schmitt, 1991; Lynch et al, 1988). Regionalization guidelines should support the return to the community for patients who no longer need the highest care level. Patient selection for back transport (transport back to referring service, hospital, or a hospital closer to the patient's home) and care in another facility should match the capabilities and expertise of the community hospital (Stark and American Academy of Pediatrics Committee on Fetus and Newborn, 2004).

Although third-party payers often drive decision making, transport relationships develop between various institutions either by formalized transfer and preferred provider agreements or by historical and personal relationships (Attar et al, 2005). Transfer agreements can help to define the roles, understanding, and expectations between institutions and the transport service; they also help frequently to detail reimbursement issues. These agreements set the expectations for participating facilities, with the ultimate goal of the timely movement of patients from one facility to another 2007; Woodward et al, 2007). Whether optimal care can be provided in some smaller NICUs or outside of a tertiary unit is frequently debated. Nonetheless, there is a trend in the United States and elsewhere toward the centralization of perinatal care (Howell et al, 2002; Wall et al, 2004).

Several investigators have shown that mortality was lowest for deliveries of infants with very LBW that occurred in hospitals with tertiary care NICUs (Chien et al, 2001; Phibbs et al, 2007; Rautava et al, 2007; Robertson et al, 1994). Cifuentes et al (2003) supported the idea that whenever possible, women in early preterm labor should be moved to the regional hospital rather than transferring the infant after birth. The study was insufficiently powered, however, to make a recommendation regarding the difference between regional and large community NICUs (Cifuentes et al, 2003). In trying to discern which LBW infant might be better cared for in tertiary regional care centers, Vieux et al (2006) showed that the risk factors for requiring high levels of intensive care were low gestational age, twin pregnancy, maternal hypertension, antepartum hemorrhage, infection, and male gender, whereas antenatal steroid therapy and premature rupture of membranes were protective factors against requiring intensive care. Regional care concerns can apply to the neonates with extremely LBW and to the late preterm population (Khashu et al, 2009). Investigators trying to describe the optimal neonatal unit caring for very preterm infants in Europe were unable to produce a consensus as to what the ideal neonatal unit size and patient volume should be (Van Reempts et al, 2007). Given the wide variability in levels of neonatal care and the inability to predict premature delivery, neonatal transport will continue to be a dynamic process.

TRANSPORT COMMUNICATIONS

When developing and maximizing transport capabilities, a key concept is the centralization of communication. Although a telephone call from a referring provider to a receiving provider might be the most efficient way to receive advice or notify a receiving provider of a potential transport, there are more centralized and effective means of communication. First, a centralized, easily recalled, advertised, and monitored (24 hours per day, 7 days per week) communication system should be available. Identifying and publishing a centralized access number for immediate access to the transport system or receiving center personnel are imperative for optimal communication and efficiency (Southard et al, 2005). Anyone who has transported or referred patients to systems without centralized access understands the challenges in working through operators, unit clerks, multiple providers, and often multiple services to enable a singular transport. This process is time consuming and often frustrating for the referring provider, and it is often time that could be better spent in direct assessment and care of the patient, rather than on the telephone with repetitive informational transfer. Ideally a centralized transport communication center would enable a referring provider to make a single call to a single number and immediately receive all the services that they might require. Those services include appreciation and recognition of the need for transfer, identification of appropriate hospital and facility, review of medical issues, and determination of required services (i.e., personnel, equipment, time of response) needed for transport. Also included would be simultaneous awareness of need for transport by the personnel responsible for arrangement of particular modes of transport, verification of bed capacity, and any other logistic items that may need to take place prior to the transport. A telephone call made to an individual provider requesting transport requires a sequential process from data gathering through acceptance for admission and eventual transport service or modality identification and dispatch. Centralized access to a communication center allows all those functions to occur simultaneously, enabling more rapid transport response and appropriate involvement of all those required for the management of the particular patient (American Academy of Pediatrics Committee on Fetus and Newborn and Bell, 2007; Woodward et al, 2007).

MEDICAL SUPERVISION

A key requirement for any system is to have appropriately skilled and immediately available medical command physicians (American Academy of Pediatrics Committee on Fetus and Newborn and Bell, 2007; Woodward et al, 2007). A medical command physician should be literate

and expert in the medical area of concern. In most cases involving neonatal transport, this provider should be a neonatologist. There may be instances, however, when the referring or receiving physicians may request or desire additional medical expertise. For example, a cyanotic newborn with congenital heart disease may be temporarily improved or stabilized well by the referring neonatologist and have additional stabilization direction provided by the receiving medical command physician; however, invaluable additional management and planning might be added by a partnering cardiac intensive care physician. A communication or transfer center can allow for multiple providers to be linked together during an initial referral call to allow the highest level advice to be presented and discussed among the providers. These telephone calls should also include the transport personnel so that the providers have the background information and care plans delivered directly.

MODE OF TRANSPORT

Once the transport referral has been made, ideally through a communication center, and discussions have been started with the medical command physician, the transport can take place. Decision on mode of transport is an important component to consider at this juncture. In general, ground transport allows door-to-door service between facilities, enables a well-lighted environment, provides space for several providers as well as the patient and a family member, and is efficient in urban and short-range transfers. As the distance for transfer increases, and the need for decreased out-of-hospital time becomes more important, consideration of air transport becomes important depending on acuity and patient disease process. In general, air transport is most expeditious over approximately 50 miles, with helicopter being favored between 50 and 150 miles and airplane being effective for transports greater than 150 miles. The decision regarding mode of transport is influenced by several issues, which include available modes of transport, staffing and medical expertise of the providers involved in those particular modes, current and projected patient condition (which includes preliminary identification of the underlying disease process), consideration of stability or illness progression during the projected transport timeframe, capabilities of the referring facility and personnel, and the urgency of intervention and definitive placement of the patient. Other issues that influence the process include geographic and weather constraints, distance and duration of transport, and provider perception about the transport process. In addition to the potential risks of ground transport, which include traffic accidents, vibration, noise, and other issues, air transport creates concerns for accident, vibration, gravitational forces during acceleration and deceleration, excessive noise, temperature variations, and decreased humidity with altitude. Air transport also includes issues related to altitude physiology that can affect patients with respiratory issues or air trapping and their air-containing equipment (e.g., endotracheal tube cuffs, laryngeal mask airways; Wilson et al, 2008; Woodward et al, 2002, 2006). Dalton's Law recognizes that ambient oxygen decreases as altitude increases; therefore there may be a need for pressurization and augmentation with increased FiO_2. Boyle's Law states that as altitude increases, the volume of a gas also increases, and the barometric pressure is inversely related to the volume of the gas. This law is potentially a serious issue for patients with an enclosed gas collection, such as a simple or developing pneumothorax.

TRANSPORT PERSONNEL, EDUCATION, AND TEAM COMPOSITION

Awareness of the capabilities of the transport system and of the personnel involved in transport is imperative in decisions regarding mode of transport. Although it is ultimately the responsibility of the referring physician to identify the appropriate mode and personnel for transport, per Emergency medical Treatment and Active Labor Act (EMTALA), opportunities exist for tertiary care and referral centers to help to educate the referral providers regarding optimal transport planning and usage (Bolte, 1995; Woodward, 1995). In general, issues influencing transport decisions include current level of care, urgency for a different level of medical capability or equipment, current providers of care, stability of the patient, options available to the provider and patient, and efficiency and quality of the transport process. Ideally, these issues are the determinants of appropriate transfer; however, referring providers are often overwhelmed by the severity or acuity of the patient and their primary desire may be to have the patient removed from their facility as quickly as possible. The providers may decide on a transport or transfer process based solely on speed of transport process rather than quality of care. It is imperative for the receiving and tertiary care centers to educate the referring population on the importance of stabilization, initiation and quality of initial response, transport options, and definitive care to maximize potential patient outcome. When examining the transfer of patients, providers should ask a simple question: "Are we trying to deliver the patient to tertiary care, or are we trying to deliver tertiary care to the patient?" In most high-functioning transport and referral centers, the latter is true. The referring physician should expect to have tertiary care advice and direction delivered at the moment of the referral telephone call and continued throughout the transport process (American Academy of Pediatrics Committee on Fetus and Newborn and Bell, 2007; Woodward, 1995; Woodward et al, 2007). At no time should the care delivered to the patient decrease in sophistication after a referral call is made. If a transfer places the infant in a suboptimal environment or with providers who are not competent to address the infant's current or potential medical needs, the patient might receive suboptimal care and the referring provider is liable for arranging and providing inappropriate care.

When considering the team composition of the transport providers, it is important to consider the quality of the personnel, their expertise and experience, and their ability to work in the transport environment (King and Woodward, 2002a; King et al, 2001, 2007). There are many variations of transport teams in the United States and abroad. These teams can be composed of physicians, nurse practitioners, nurses, respiratory therapists, paramedics, and other health care providers. In the United States, medical (pediatric or specialty) trainees are often

used as primary providers in the transport environment. Regardless of the formal educational background of an individual, there are several criteria that must be met to be optimally effective in the transport environment. First, the provider must have adequate certification, be licensed for the care they deliver, and be able to provide the assessments and interventions that the patient currently or potentially requires during the transport process. For example, a neonatal retrieval service must be able to manage acute and critical airways in the neonatal population, both at a referring hospital and during the transport. It is interesting that those same providers might not be credentialed to provide those skills within their home hospital; however, they have been certified to provide them in the ambulance environment. In general, this must be done under the auspices of a physician's care, which may be from an accompanying physician or via online medical control (real-time medical advice during the transport process). Transport care also often involves offline medical control, which involves the use of protocols developed by medical personnel. It is important to recognize that the transport timeframe is somewhat limited; therefore the personnel might not need to have the longitudinal or differential diagnosis expertise of a fully trained neonatologist. However, these personnel must have the acute care assessment abilities and intervention skills of an experienced neonatal expert. In addition to training the onsite personnel, it is imperative to have medical command physicians understand the opportunities and limitations of the transport services and environment and to understand the risks and challenges that referring personnel can potentially encounter with situations and patients who exceed their own personal or their facility's management abilities. The physicians must have significant awareness of the transport environment to understand the limitations of potential interventions. It is also imperative that medical command positions have superb communication skills, not only at the referring physician level but also within the transport team. Medical command physicians will need to be able to effectively and efficiently communicate with providers from different disciplines.

QUALITY IMPROVEMENT

Transport medicine offers an opportunity to identify areas for potential improvement within the inpatient arena, in the transport system, and at the referring facilities (Browning Carmo et al, 2008; Chen et al, 2005; Lim and Ratnavel, 2008; McPherson et al, 2008; Ramnarayan, 2009). This glimpse into medical sophistication and capability is one that is privileged and should be used to identify educational opportunities rather than prompt judgmental and critical review. Education by referring physicians and transport teams can have a significant effect on the quality and outcome of patient care and the volume of future referrals. Ideally, once a referral call is made, a receiving physician or medical command physician will direct the care so that the job of the transport team is to verify that an appropriate working diagnosis has been made and that adequate stabilization procedures have been performed. The team can verify that the interventions are secure and then transport the patient in a stable fashion. Systems that do not gather adequate information or offer appropriate advice, or in which the referring facilities do not follow that advice or choose not to perform needed interventions, put the patient at risk by having a delay in care of initial interventions, prolonging the transport, and delaying delivery of definitive care. The transport team that has invested several hours at a bedside, stabilizing a newborn with medical or surgical issues, may be spending time in a facility that is not ideal, has a limited number of skilled personnel, and has minimal backup, thus prolonging the transport process and potentially putting that individual patient at risk (Chen et al, 2005; Haji-Michael, 2005). However, the patient and the system are at risk because the valuable resource of specialized neonatal transport personnel is not available for another patient.

Ideally, care delivery would be the same at referral and receiving centers; the development of practice guidelines can be helpful in that regard. Guidelines that are evidence based, developed by regional and local experts, and disseminated to referring locations and transport teams will help to standardize and enable consistent care across variable locations. It is necessary, however, to assess and reassess the quality of the guidelines and the competency of their use to ensure optimal results from this process. Even in the best of hands, near-miss or realized adverse events may happen. It is clear that identification of those events, discussion with families (where appropriate), and root cause analysis are imperative. Several studies have examined adverse events in transported patients. Ligtenberg et al (2005) noted that one third of patients had an adverse event, and 50% of those resulted from not following the advice of the medical command physician. Of that group, 70% of events were avoidable and 30% were logistical. In a review of the London Neonatal Transfer Service, Lim and Ratnavel (2008) noted that 36% of their patients had greater than or equal to one adverse event, and two thirds of those were due to human error; half of those occurred before the team arrived at the referral center, and their major etiologies included preparation and communication.

A neonatal transport service must determine if maternal transport is part of their purview. It is clear that preterm infants who are born at outside hospitals and require transfer to tertiary care centers or who are born at one tertiary care center and require transfer to another have worse outcomes that include increased mortality and morbidities such as intraventricular hemorrhage (IVH) and other medical issues (Baskett and O'Connell, 2009; Janse-Marec and Mairovitz, 2004; Jony and Baskett, 2007; O'Brien et al, 2004; Ohara et al, 2008). Developing appropriate criteria for transporting women in preterm labor may help to direct the optimal use of resources required with maternal transfer. Identifying the appropriate time to transport women in preterm labor, as well as those with other preterm medical issues, will help in developing appropriate criteria and limit resource utilization for maternal transfers. It is important to note that significant work regarding neonatal and maternal transport and regionalization of care in the United States, United Kingdom, Australia, Europe, and other areas has already been accomplished. There are, however, multiple opportunities to improve transport on an individual and regional basis in these developed countries and in other developing countries.

TRANSPORT ADMINISTRATION

As a hospital develops and optimizes a neonatal transport program, experts in transport medicine are integral to the success of this program (American Academy of Pediatrics Committee on Fetus and Newborn and Bell, 2007; Woodward et al, 2007). A quality medical director and program director, often a nurse or respiratory therapist, are essential to understand the potentially complicated and challenging environment of transport medicine. These leaders should be instrumental in identifying expectations, roles, and responsibilities for the process; this includes access through a communication center and developing and disseminating referral center expectations. These expectations include stabilization and preparation of the patient before transport, making an appropriate decision to transfer, choosing the appropriate transport process and destination, obtaining consent from the family for transport, discussing plans for stabilization and intervention with the medical command physician, and initiating that plan as able. Referral centers must be able to be direct when they believe that the suggested interventions are inappropriate or beyond their scope. The referring team also needs to be available to participate in transition care to the transport team and the receiving service. The receiving and transport team responsibilities include being immediately available for case discussion, having the ability to rapidly accept the patient if capacity is available, offering clear and concise expert recommendations, ensuring preparation of the environment and the staff both for the transport and arrival of the patient, organizing additional diagnostics and interventions, and providing available and accessible neonatal advice throughout the process. Most important, the team needs to ensure that appropriate skills and therapy are available and delivered throughout the process, from referral call through definitive placement, and ensure seamless transition at each point of care. The team needs to communicate well with referring and the patient's physicians and document their advice, interventions and activities in a clear, concise fashion to enable appropriate patient and provide protection for the transport service.

TRANSPORT EXPERTISE

As transport medicine has developed over the past 30 to 40 years, there has been an increase in the quality and volume of transport research, as well as organizations that are discipline and process specific. Multiple disciplines have organizations with transport focus and expertise, including the American Academy of Pediatrics Section on Transport Medicine, which includes executive committee representation from neonatology, pediatric critical care, and emergency medicine physicians, as well as a broad membership from other subspecialties and disciplines. The American Academy of Pediatrics Transport Section published its most recent Guidelines for Neonatal and Pediatric Transport in 2007; they also host a listserv at transmedaap@listserve.aap.org, which is a national repository of information and a conduit to others in the transport arena for transport-related issues.

There are many keys to success in transport medicine. These keys include integrity, professionalism, preparation, anticipation, education, competency, critical evaluation of current and new practices, the ability to critically assess the quality of care being delivered at every point along the way, and looking for opportunities to improve access, efficiency, and delivery of care. An area that is vital for appropriate transport care is the assurance of competency of the providers (American Academy of Pediatric Committee on Fetus and Newborn and Bell, 2007). As noted, providers can come from many different backgrounds and bring different skills from their clinical and training experience. It is imperative for the transport system and leadership to ensure that the skills required are present in their personnel. This responsibility includes initial education, continuing education, and competency assessment. A team may decide to have individuals who are experts in defined areas of care, such as a physician who manages airways and the pneumothorax, a nurse who manages intravenous access and medication delivery, and a respiratory therapist who is responsible for airway and ventilatory support, whereas another team may choose to have all team members competent in all skills. Specific procedures may be useful or needed in transport that are not as common in the hospital environment or to the hospital-based providers (e.g., laryngeal mask airway; Trevisanuto et al, 2005). However the team is structured, there must be clear and concise guidelines for ongoing training and assessment of the personnel. High-fidelity simulation models offer additional opportunities to assess and potentially improve technical and cognitive capabilities (LeFlore and Anderson, 2008). The American Academy of Pediatrics Guidelines for Air and Ground Transport of Neonatal and Pediatric Patients (available at www.aap.org) is an invaluable resource that outlines required education and competencies for each level and discipline.

The true quality of a transport service is sometimes difficult to determine, because many teams and services have been developed independently and are not part of larger regional systems. It is difficult to compare and contrast systems in different areas for which different patient populations are transported (Berge et al, 2005; Cornette and Miall, 2006; Craig, 2005; Doyle and Orr, 2002; Khilnani and Chhabra, 2008; Van Reempts et al, 2007).

One avenue for potential standardization of the transport environment is by assessment and accreditation by the Commission on Accreditation of Medical Transport Systems, which was initiated in 1990 as a direct response to the number of air medical accidents in the 1980s. This certification is voluntary in some areas and required in others, and it serves to assure providers, stakeholders, and the public of adherence to quality of care and transport safety standards. The Commission on Accreditation of Medical Transport Systems is an independent organization, supported by 16 member organizations, which publishes standards and arranges reviews of interested air and ground transport programs. Further information can be found at http:www.camts.org.

TRANSPORT SAFETY

Safety of the transport system and for its providers is paramount and must be assessed and ensured before transporting any patient. Vehicles must be safe and meet the standards for air or ground transport, the personnel must be appropriate, licensed, and competent, and the patients

must be managed in the most appropriate and professional fashion. In addition, the logistics of travel must include a safe environment, including helmets and fire-retardant suits for those who fly in helicopters, three-point restraints, and appropriate ambulance seating arrangements. There should not be an occasion when providers put themselves at risk by being unrestrained or being in an area where unsecured debris or inappropriately placed equipment may damage a provider or a patient. Adherence to rules and regulations of air and ground transport is imperative as well (Clawson, 2002; Greene, 2009; King and Woodward, 2002b; Levick et al, 2006; National Highway Traffic Safety Administration, 2009).

It is imperative to recognize that there is risk with both air and ground transport. The air transport industry has seen an acute spike in tragic and fatal air accidents (Greene, 2009; National Transportation Safety Board Accident Database, 2009). This increase has caused the industry, and the U.S. government, to critically investigate these issues and offer suggestions to improve transport safety (Federal Aviation Administration Helicopter Safety Initiative, 2011; 10.5-year U.S. HEMS Safety, 2008). Requirements such as duty hours for pilots, weather restrictions, flight under instrument, flight rules with terrain avoidance equipment, and night vision goggles can to help minimize the risk for these transports. Although ground ambulances are used much more frequently, and the risk of injury and death is evident, the fatality rate is lower in ambulance accidents than it is in aircraft accidents (Becker, 2003; Becker et al, 2003; King and Woodward, 2002b). It is necessary, however, that the vehicles be maintained and operated in a safe manner. Many systems do not allow ambulances to exceed posted speed limits and use lights and sirens only as a way to identify an emergency response, not to enable the vehicle to circumvent or ignore standard traffic laws (Clawson, 2002). Appropriate equipment for ambulances is required as well, and the July 2009 statement by the American College of Surgeons Committee on Trauma regarding appropriate equipment for ambulances (also published as an American Academy of Pediatrics' policy statement) should be reviewed by all transport systems (American College of Surgeons Committee on Trauma, 2009; American College of Surgeons Committee on Trauma et al, 2009).

It is evident from the transport and pediatric literature that patient outcomes are improved with specialty providers. There have been multiple studies to examine this particular issue (Belway et al, 2006; Mullane et al, 2004). Perhaps the most compelling is the study by Orr et al (2009), which examined transports provided by variable providers within the same system. This study compared outcomes in patients whose care was delivered by specialized pediatric critical care teams with those whose care was delivered by general providers. Both teams had the same medical command oversight, equipment, and modalities. Patient outcomes were worse for those whose care was not delivered by specialty teams, and much improved for those who were. One challenge, however, with transport teams is that differentiation of medical resources, such as a neonatal specialty team, likely means that there may be a scarcity and potential need for rationing of those resources. It is possible to develop teams with a variety of personnel with complementary cognitive and procedural skill sets and work toward appropriate triage of transport requests to ensure the proper level of onsite skill provision. There have been multiple attempts to develop triage tools for pediatric and neonatal care providers, including the Mortality Index for Neonatal Transport, the Modified Clinical Risk Index for Babies, and the Risk Score for Transported Patients, which are noted in the bibliography (Broughton et al, 2004a, 2004b; Markakis et al, 2006).

FAMILY-CENTERED CARE

Transport team research has shown that family-oriented care, as in other areas of the medical systems, is an important component of transport (Woodward and Fleegler, 2000, 2001). Families who have been formally surveyed appreciate the opportunity to participate in the care of their child. In neonatal transport, however, there are times when there are two patients who may require care in two disparate locations. A mother who has had a cesarean section and has delivered an acutely ill child in need of care in a higher facility is one such example. It is required that the mother be in one facility and the child be in another. The father may be conflicted regarding accompanying his new child on the transport or staying with the child's mother. Transport teams need to be sensitive to the challenges and opportunities for the family and include them in the process when possible. It is evident that when parents attend or accompany transport team members on critical care transports, they are not there to assess the medical skill set of the provider, but to provide support to their child. It is also a great opportunity for the transport team to demonstrate to the family that their patient is in focused, professional, caring, and capable hands.

MEDICAL LEGAL ISSUES

There are many medical legal issues in transport medicine, as elsewhere in the medical system (Hedges et al, 2006; Williams, 2001; Woodward, 2003). The Health Insurance Portability and Accountability Act (HIPAA) is a required component of transport planning and delivery. Discussion of patients should not take place in a public area or via public communication airways where non–patient-related personnel or bystanders could overhear information about a specific patient. As noted earlier, a requirement of EMTALA is that the referring physician chooses the appropriate mode of transport and ensures that the transport process and receiving hospital are appropriate for the particular patient. Patients cannot be transferred if they are unstable and the ability to further stabilize them is available at the initial site of care. If a patient must be transferred for care while in an unstable condition—a frequent scenario for critically ill patients who need care not available at the referring institution—consent must be obtained from the family, which acknowledges their understanding of the potential risks and benefits of the process. In practice, there are often patients in unstable condition who are transferred from lower to higher levels of care, because the level of care that can be provided at the referring or initial center is not optimal for the child. This reason is appropriate for transfer as compared with transferring patients because of financial or other economic drivers. The medical liability for transport

is a shared process. Before the referring center calls regarding the patient and the center of referral has accepted care, the entire medical responsibility lies with the referring provider. Once the receiving team has accepted the patient and offered advice, medical liability is a shared process. The referring physician maintains the majority of the liability, as well as medical control of the patient, throughout the process until the transport team has left the referring hospital. It is important to recognize that most transport teams and personnel do not have privileges at referring hospitals and are working under the guidance and supervision of the referring physician team. Transport teams that act independently, or referring physicians who are not available when the transport team arrives, put both the referring provider and the transport team at risk if there is disagreement or inappropriate care delivered to the patient. There will be times, however, when there is disagreement regarding the optimal care to be delivered. For example, a child with a hypoplastic left heart syndrome and an open ductus arteriosus may be given a low-dose prostaglandin infusion and be in stable condition. A transport team can insist on intubation before a long air transport, whereas the referral physician might believe that intubation is not required and that it poses a risk to that particular patient. This situation can be challenging, and it must be handled appropriately. It is never appropriate to have obvious provider conflict occur at a patient's bedside, especially in front of family members. The appropriate way to handle a situation that cannot be easily mitigated is to involve the medical command physician with a telephone call to the referring physician in a discussion at a peer-to-peer level. Transport teams have been known to comply with the wishes of the referring providers to not perform advanced procedures at the referring hospital, only to perform those procedures in the ambulance, which is a much less desirable location. Ideally, all disagreements and considerations of different therapies are discussed in a collegial fashion in the appropriate environment to enable the safe care and transport of the child to the receiving center. As noted previously, documentation of all information received and advice offered is imperative. If there is future review or challenge to the care delivered during transport, as with any other care delivered in the hospital, clear and appropriate documentation should stand alone as an excellent defense. In addition, many centers use recorded (i.e., digital, tape, other retrievable recording process) for their intake and advice lines; this is another way to review, educate, and ensure that appropriate information is delivered in an effective communication style. The use of recorded lines with frequent review, for educational and quality assurance purposes, can be invaluable. Review with legal advisors can help to define the length of time the recorded materials should be maintained for quality improvement or patient record addendum.

PATIENT CARE DURING TRANSPORT

EXTREME PREMATURITY

The most effective method of transporting premature infants is within the mother as a maternal transport. By delivering at a referral hospital, the premature infant is exposed to all the variability of the extrauterine environment, with the added complexity of having to be transported to a facility capable of providing the level of care the infant needs. Most neonatal transport teams are regarded as extensions of the NICU. The team initiates and provides much of the same level of complex neonatal care as the receiving hospital, but in a changing environment. It is this changing environment that poses unique challenges for both patient and caregiver. These issues would be amplified in the case of a disaster with care and transfer required for premature infants (Gershanik, 2006).

Limit of Viability

The incidence of premature births has been increasing in the United States. Of the approximate 4.1 million live births occurring annually, 520,000 (12.7%) infants are born premature (Ananth et al, 2009; Martin et al, 2008). Although some premature infants require minimal care to survive, infants with very LBW often test the resources and skills of the most experienced care provider. The long-term outcome for many of these small infants is often unknown for months to years after leaving the hospital. In some instances, the long-term results have not been ideal (Donohue et al, 2009; Tyson and Saigal, 2005). Several studies of extremely premature infants born outside of tertiary care centers show increases in morbidity and mortality (Cifuentes et al, 2002; EXPRESS Group et al, 2009; Phibbs et al, 2007; Rautava et al, 2007). Human viability is currently limited by the physiology of pulmonary development and its ability to exchange gases. Currently this limit appears to be at approximately 22 to 24 weeks' gestation (Pignotti and Donzelli, 2008). Unfortunately, for transport teams and the care givers at referring hospitals, it is difficult to determine which infants born at the margins of viability should be resuscitated and provided with aggressive neonatal care and which should be allowed to die (American Academy of Pediatrics Committee on Fetus and Newborn and Bell, 2007; Buchanan, 2009). These decisions are best made collaboratively with the family, transport team members, and the referring and receiving physicians (Ahluwalia et al, 2008; Gunderman and Engle, 2005; Tyson et al, 1996) and may ultimately result in a patient transport, even when the likelihood for survival is minimal.

Thermoregulation

Problems in neonatal thermoregulation continue to be a major contributor to neonatal morbidity and mortality worldwide and can be especially problematic in neonatal transport (World Health Organization, 1996). During transport, neonates often cross into and out of multiple different environments with wide temperature and humidity variations. Although a normal term infant is capable of a significant homoeothermic response by using their sympathetic nervous system to vasoconstrict peripherally, thus placing their normal layer of insulating white fat between the body's core and the exposed skin, preterm infants lack the subcutaneous white fat insulation to protect their core temperature. Moreover, term infants use brown fat as a source for nonshivering thermogenesis. Preterm infants, although as sensitive to temperature as term infants, lack sufficient brown fat to sustain a response when exposed to a cold environment (Baumgart, 2008). The consequences

of hypothermia can include hypoglycemia, metabolic acidosis, intraventricular hemorrhage, persistent pulmonary hypertension, and hypoxemia (Bartels et al, 2005). Silverman et al (1958) demonstrated that using a higher incubator temperature, even without additional humidity resulted in improved premature survival rates.

Additional measures such as chemical gel packs and polyethylene occlusive skin wrapping help in maintaining the temperature of an infant with very LBW (Vohra et al, 2004). For all newborns, an equally important condition to avoid is hyperthermia.

Although elevated temperatures in neonates occur with increased metabolic rates, prolonged seizures, dehydration, or infection, the most common cause of neonatal hyperthermia is high ambient air temperature and humidity (Baumgart, 2008). In a review of a subset of patients referred for a trial of hypothermia for hypoxic ischemic encephalopathy, patients with an elevated body temperature had poorer neurologic outcomes than those with normal body temperatures (Laptook et al, 2008; Yager et al, 2004). Humidity also has an extremely important role in temperature control of LBW infants, especially those receiving mechanical ventilator support. The importance of delivering humidified gas to neonates receiving mechanical ventilation is widely acknowledged (Sousulski et al, 1983). Ventilation with dry gases affects the airway epithelium in very LBW infants, and it can result in hypothermia secondary to their large surface area–to–body mass ratio and their relatively large respiratory minute volume (Fassassi et al, 2007). There is a linear correlation between incubator temperature and the humidity generated by heated humidity systems (Fassassi et al, 2007). Whereas ventilator complications can be reduced and thermoregulation can be improved by providing exogenous heat and humidity to the gases, active heated humidification systems are used infrequently during neonatal transport. Passive hygroscopic heat and moisture exchangers have been used for short-term conventional mechanical ventilation and with some types of high-frequency ventilation (Fassassi et al, 2007; Schiffmann, 1997; Schiffmann et al, 1999). Humidifying the incubator and the ventilator system helps in thermoregulation while transporting very LBW neonates.

Surfactant

Surfactant replacement has had a significant effect on newborn intensive care. Numerous systematic reviews have demonstrated the benefit of surfactant administration in reducing oxygen needs and ventilation requirements, as well as ventilator complications such as pneumothorax and pulmonary interstitial emphysema (Horbar et al, 1993; Liechty et al, 1991; Schwartz et al, 1994). Extremely LBW infants benefit from both prophylactic (defined as within 10 to 30 minutes of birth) and rescue surfactant administration (within 12 hours of birth) (Kendig et al, 1991; Soll, 2000). Infants given prophylactic surfactant appear to have fewer complications, including death, pneumothorax, and bronchopulmonary dysplasia (Soll and Morley, 2001), supporting its use during transport (Riek, 2004). Surfactant administration can be complicated by airway obstruction and right mainstem bronchus or esophageal instillation, justifying the American Academy of Pediatrics Committee on Fetus and Newborn recommendations that "preterm and term neonates who are receiving surfactant should be managed by nursery and transport personnel with the technical and clinical expertise to administer surfactant safely and deal with multisystem illness" (Engle, 2008). While investigations are still ongoing as to the optimal manner of surfactant administration, future technology might eventually allow for surfactant to be delivered without airway intubation. Currently, aerosolized surfactant has yet to be shown to be superior to endotracheal tube administration (Berggren et al, 2000; Mazela et al, 2007). Although there are concerns about the composition variability of animal-derived surfactants, use of a synthetic surfactant such as Lucinactant creates other concerns. Lucinactant requires a special warming cradle to convert it from a gel to a liquid before administration, adding a level of difficulty to its administration during neonatal transport (Kattwinkel, 2005; Moya et al, 2005). Smaller community hospitals might not stock surfactant in their pharmacies, making it necessary for the transport team to carry it as part of their medical supplies. Earlier forms of surfactant came as lyophilized powder and could be reconstituted when needed. Currently, the most frequently used surfactant preparations in the United States are derived from either bovine or porcine lung extracts. These surfactants require refrigeration and are usually carried by transport teams in small containers cooled by gel packs. The same precautions used in the delivery room or the NICU apply to its use in transport. Checklists should be used to avoid inadvertently leaving this lifesaving therapy behind when the transport team is dispatched.

Before surfactant administration, proper endotracheal tube position must be confirmed either clinically or radiographically. Surfactant administration is generally done using transport team protocols, which usually mirror the package inserts. After administering surfactant, monitoring pulmonary compliance and adjusting the patient's ventilator support will occasionally extend the time of a transport to avoid clinical complications, such as pneumothorax or endotracheal tube occlusion, during the transfer process. Often by the time the transport team arrives at the receiving hospital, significant clinical improvement has occurred.

Surfactant has a role in other disease processes, such as meconium aspiration, sepsis, and pulmonary hemorrhage, during which a patient's endogenous surfactant is depleted or inactivated, thus creating a condition of secondary surfactant deficiency (Chinese Collaborative Study Group for Neonatal Respiratory Diseases, 2005; Finer, 2004; Wiswell et al, 2002).

HYPOXIC RESPIRATORY FAILURE

Meconium Aspiration Syndrome, Persistent Pulmonary Hypertension of the Newborn, Inhaled Nitric Oxide on Transport, and Extracorporeal Membrane Oxygenation Referrals

Hypoxic respiratory failure describes a heterogeneous group of neonatal disorders that have in common impaired oxygenation and the need for assisted ventilation. The most frequently observed conditions are respiratory

distress syndrome, meconium aspiration syndrome, and persistent pulmonary hypertension of the newborn (PPHN), which can occur individually or in combination. Interfacility transport of the newborn with hypoxic respiratory failure is potentially hazardous, with a high risk for patient deterioration and complications of therapy, such as pneumothorax.

Assisted ventilation during neonatal transport can be accomplished with a variety of devices, although not all modes of mechanical ventilators have been modified for use in a mobile setting. Newborns with milder degrees of illness may be managed successfully with continuous positive airway pressure (Murray and Stewart, 2008). Infant transport ventilators range from simple time-cycled, pressure-limited machines to more sophisticated devices with flow sensitivity and the ability to synchronize. Certain high-frequency ventilators have been successfully adapted for the transport environment (see later).

Inhaled nitric oxide (iNO) is approved for use in term and near-term newborns with hypoxic respiratory failure with clinical or echocardiographic evidence of pulmonary hypertension. Persistent PPHN can exist in isolation or be secondary to another insult, such as sepsis or meconium aspiration syndrome. Administration of iNO to newborns with PPHN reduces the need for extracorporeal membrane oxygenation (ECMO; Clark et al, 2000; Lowe and Trautwein, 2007). With its availability to community NICUs, iNO is often initiated before transport to a tertiary care center. Once iNO is administered, abrupt cessation of therapy can result in rapid clinical deterioration from rebound pulmonary hypertension, so it is essential to continue iNO if already initiated (Kinsella et al, 1995). Transport teams may also consider initiation of iNO therapy for term and near-term newborns with hypoxic respiratory failure. If the referring facility does not have the capability to perform echocardiography, transport staff should carefully consider the possibility of congenital heart lesions that could be worsened by the use of iNO, including total anomalous venous return and lesions dependent on right-to-left ductal flow such as critical aortic stenosis.

The rationale for initiating iNO during transport is to reduce pulmonary vasoreactivity and improve stability during transport. However, there have been no prospective studies to determine whether this practice affects patient outcome. INO during transport has been delivered by a number of different systems, such as the aeroNOX (Aeronox Technology Corporation, Quezon City, Philippines) iNOvent, and INOmax DS (INO Therapeutics, New Jersey) transport systems (Kinsella et al, 1995, 2002; Lutman and Petros, 2008; Tung, 2001). The use of iNO in combination with high-frequency ventilation in non-ECMO centers can complicate the transfer process. If the transport team does not have the capability to provide mobile high-frequency ventilation, it is recommended that the referring hospital perform a trial of conventional mechanical ventilation before the arrival of the transport team to establish that the infant can tolerate the transition.

Both high-frequency jet ventilation (Bunnell ventilators [Bunnell Inc., Utah]) and high-frequency flow interrupter ventilation (Bird ventilators [Viasys, California]) have been configured and used with nitric oxide during transport (Honey et al, 2007; Mainilli et al, 2007). The high-frequency oscillator (SensorMedics 3100A [Viasys, California]) that is commonly used in many NICUs is impractical for ground transport and is not configured for helicopter or fixed wing transport. However, even with these technologies, 30% to 40% of critically ill neonates improve only temporarily with iNO therapy and will ultimately require higher care levels (Fakioglu et al, 2005; Kinsella et al, 2002).

In patients with pulmonary or cardiac failure that is unresponsive to maximal medical therapy, conventional ECMO is often used as a bridge therapy to allow either the lungs and heart to recover. Ideally, centers without ECMO capability have prospective criteria to guide the transfer of newborns before the need for ECMO cannulation. In some cases, the patient's condition is so unstable that conventional transport cannot be conducted safely. Selected programs have the capability to provide mobile ECMO, during which patients are cannulated for ECMO before transport to the referring institution. Mobile ECMO can also benefit patients already receiving ECMO at a tertiary facility who are in need of advanced quaternary therapies, such as heart or heart-lung transplants (Wagner et al, 2008; Wilson et al, 2002). The resources and skill set necessary to safely and consistently perform ECMO in the transport environment have, by their complexity, restricted the number of transport programs with mobile ECMO capabilities (Coppola et al, 2008).

NEUROLOGIC ISSUES

Perinatal Depression and Therapeutic Hypothermia

Hypoxic ischemic encephalopathy affects approximately 1 to 2 in 1000 term neonates (du Plessis and Volpe, 2002). Several early studies from the 1950s and 1960s suggested that hypothermia might be an effective therapy for the asphyxiated neonates, but there was no systemic long-term follow-up for these patients to confirm its effectiveness until a series of animal studies suggested that hypothermia was an effective neuroprotective therapy (Gunn et al, 1997, 1998). Several randomized trials of therapeutic hypothermia for term human infants have demonstrated a reduction in the combined outcome of death and neurodevelopmental disability when cooled, compared with a control population (Gluckman et al, 2005; Shankaran et al, 2005). However, the efficacy of hypothermia may diminish as the time from insult to cooling increases. Although clinical trials and current guidelines suggest that cooling should be initiated within 6 hours of insult, animal studies demonstrated that hypothermia is most effective if it is started as soon as possible (Gunn et al, 1997, 1998). For patients with a delay in referral or who are being transported from a distant center, waiting to start hypothermic therapy until arrival at the receiving center potentially places the patient at a significant disadvantage. The initial larger clinical trials did not address these issues in regard to critical care transport, but several case (Anderson et al, 2007), pilot (Eicher et al, 2005), and single-center studies have demonstrated the feasibility of controlled hypothermia during transport to significantly shorten the time to therapy initiation (Zanelli et al, 2008). Several new

large-scale hypothermia trials that have been recently completed or are nearing completion include initiation of hypothermia before arrival at the referral center. The Total Body Hypothermia for Neonatal Encephalopathy Trial (the Toby Trial) compared standard intensive care plus total body cooling with standard intensive care for 72 hours. Recruited patients from referring hospital were assessed by the transport team, who performed amplitude integrated electroencephalograms and obtained consent if the patient was eligible and less than 6 hours of age. The patients randomized to cooling had gel packs applied if needed to cool the body to rectal temperature between 33° and 34° C (Azzopardi et al, 2009). The Australian Cooling Trial for Hypoxic-Ischemic Encephalopathy achieves the temperature range for referral study patients by turning off the normal heating systems and applying gel packs (at 10° C) around the infant's head and chest, until the rectal temperature is reduced to 33° to 34° C (Jacob et al, 2008). While hypothermia is still being evaluated as a therapeutic tool to manage hypoxic ischemic encephalopathy, the current management trend for term and near-term infants being considered for hypothermia is to delay actively warming the patient at a referral hospital until there is a consultation with a receiving hospital that offers therapeutic hypothermia. If criteria are met, further cooling could be achieved by placing wrapped disposable cooling packs next to the trunk and head with continuous monitoring of rectal temperature. Once the rectal temperature stabilizes, the infant is transferred to a transport incubator with the heater turned off, and the transport team applies cooling packs or a blanket as needed to maintain a rectal temperature of 33° to 34° C during transport. Just as careful temperature monitoring during hypothermia is necessary for the safe transport of these patients, observational studies suggest that the avoidance of hyperthermia is critically important. In an observational study, Laptook et al (2008) noted an increase in mortality or disability in asphyxiated neonates who had elevated skin or esophageal temperatures. As additional studies are completed, therapeutic hypothermia may enter common clinical and transport practices. When combined with other therapeutic interventions, hopefully therapeutic hypothermia will have a greater effect on the consequences of perinatal asphyxia.

Neonatal Seizures

The highest rate for seizures in pediatrics occurs during the neonatal period, with an incidence of 2 to 3.5 in 1000 live births (Cowan, 2002); however, there is considerable variability in treatment regimens among pediatric hospitals in the United States (Blume et al, 2009). Phenobarbital, phenytoin, or midazolam have not been shown to significantly improve seizure management or reduce morbidity and mortality (Booth and Evanse, 2004; Carmo and Barr, 2005; Painter et al, 1999). Despite the evidence of limited efficacy, phenobarbital remains the first line of therapy to treat neonatal seizures (Painter et al, 1999; Sankar and Painter, 2005). Before initiating therapy, the transport team needs to consider the diverse causes for neonatal seizures. Metabolic disorders such as hypoglycemia, hypocalcemia, and inborn errors of metabolism, cerebral vascular events including intraventricular hemorrhage and stroke, bacterial and viral meningitis, infectious and developmental abnormalities can all manifest as or with neonatal seizures (Silverstein and Jensen, 2007). Having initiated treatment, the transport team needs to remain vigilant for potential changes in the patient's clinical status either as a response to therapy or from the primary disease process. Attention to the basics of airway, breathing, and circulation should continue throughout the transport, because the major anticonvulsants used to treat neonatal seizure all have potential side effects, most commonly respiratory depression and hypotension. Controversy remains as to whether to treat all forms of neonatal seizures, although treatment seems prudent in the transport environment (Bartha et al, 2007). In animal models, seizures create neural, biochemical, and structural changes that have long-term cognitive and behavioral consequences (Thibeault-Eybalin et al, 2009). Similar neurologic findings have been suggested in human neonates. Both of the large-scale clinical hypothermia trials for hypoxic ischemic encephalopathy noted poorer prognosis for children with hypoxic ischemic encephalopathy with seizures (Gluckman et al, 2005; Shankaran et al, 2005). Glass et al (2009) compared magnetic resonance imaging findings and the presence of seizures in a group of newborns with suggested hypoxic ischemic encephalopathy. Adjusting for the magnetic resonance imaging results, patients with seizures were more likely to have long-term neurologic issues than those without seizures (Glass et al, 2009). The ideal anticonvulsant agent would reliably stop clinical and electrographic seizures with minimal adverse effects (Thibeault-Eybalin et al, 2009). Several trials of new antiepileptic medications are underway. Topirmante, levetiracetam, bumetanide, and zonisamide have all been used to treat neonatal seizures, but there have been no randomized trial to demonstrate their effectiveness compared with current therapies. Trials with levetiracetam and bumetanide are reportedly ongoing. Further work is necessary to develop more effective and safer antiepileptic drugs so that, along with potentially neuroprotective strategies, the vulnerable and immature brain can be protected. Several trials and studies have been proposed to hopefully elucidate a better treatment strategy (Clancy, 2006).

STABILIZATION AND TRANSPORT OF THE NEONATE WITH CONGENITAL HEART DISEASE

Transport of the neonate with congenital heart disease (CHD) follows the general guidelines for the transport of any critically ill neonate. However, neonates with complex CHD often need therapeutic intervention, requiring the support of multiple subspecialty consultants, including the pediatric cardiothoracic surgeon and pediatric cardiologist (Allen et al, 2003; Stark et al, 2000). The care of the neonate with CHD generally necessitates transport to a specialized center (Castaneda et al, 1989; Penny and Shekerdemian, 2001). The preoperative care of the patient affects postoperative outcomes and mortality (Mahle and Wernovsky, 2000; Mahle et al, 2000; Robertson et al, 2004; Simsic et al, 2007; Wernovsky et al, 1995, 2000). With the increasing use of fetal ultrasound examination to diagnose CHD antenatally, the ability to intervene immediately at delivery

has become increasingly expected. In a single tertiary care center, 53% of neonates with CHD had a prenatal diagnosis (Dorfman et al, 2008), with an additional 38% obtaining a diagnosis before discharge from the newborn nursery. The aspects of stabilization of the neonate with CHD either diagnosed by prenatal ultrasound or suggested by postnatal clinical examination include initial resuscitation, airway management, vascular access, a judicious use of supplemental oxygen, prostaglandin E1 (PGE1) therapy, inotropic support, and communication with cardiac specialty services for timely transport and intervention.

Neonates with Prenatally Diagnosed Congenital Heart Disease

Significant advances in the diagnosis and treatment of neonates with critical CHD across the last decade have altered the timing of intervention, the types of interventions available, and the way in which CHD is diagnosed. With increasing numbers of patients with prenatal diagnosis (Berkley et al, 2009; Friedman et al, 2002; Jone and Schowengerdt, 2009; Khoshnood et al, 2005), fewer neonates may have their initial presentation of CHD in the emergency department. In a single-center review, prenatal diagnosis accounted for 53% of presentations of CHD (Dorfman et al, 2008). Another European center reported that 51% of transports with CHD had a prenatal diagnosis (Bouchut, 2008). In addition, a single-center cohort of critical CHD showed 44.3% to have had a prenatal diagnosis (Schultz et al, 2008). Clearly, prenatal diagnosis of CHD has increased across the past decade.

Neonates with Suspected Congenital Heart Disease

In a single tertiary care center, Dorfman et al (2008) found that 38% of neonates received a diagnosis with CHD in the newborn nursery before discharge, and 8% of patients presented with CHD after initial hospital discharge at 4 to 27 days of life. The most common nursery findings prompting diagnosis of heart disease in the nursery were an isolated murmur, cyanosis, or both (Berkley et al, 2009; Table 29-1). In a single emergency department review of patients younger than 5 months with undiagnosed cardiac disease, the most common presentation was congestive heart failure, shock, and cyanosis; if restricting the findings to a neonatal population, shock and profound cyanosis were the presenting symptoms (Savitsky et al, 2003). Another study showed that 45% of critical CHD cases (CHD with signs of shock, end organ dysfunction, or in cardiac arrest) were diagnosed postnatally, particularly left-sided obstructive lesions (Schultz et al, 2008). This finding is consistent with other centers showing a preponderance of left-sided obstructive lesions (excluding hypoplastic left heart syndrome) in those diagnosed postnatally (Friedberg et al, 2009).

TABLE 29-1 Presenting Symptoms of Patients Diagnosed Postnatally

	Diagnosis in Nursery, n = 73 (%)	Diagnosis After Discharge, n = 16 (%)
Murmur	38	25
Cyanosis	32	0
Respiratory distress	7	19
Shock	4	38
Arrhythmia	3	0
Other	3	6
Multiple symptoms	14	13

Modified from Dorfman AT, Marino BS, Wernovsky G, et al: Critical heart disease in the neonate: presentation and outcome at a tertiary care center, *Pediatr Crit Care Med* 9:193-202, 2008.

The cyanotic neonate who fails the hyperoxia test without an obvious pulmonary etiology, who has an equivocal result on the hyperoxia test but has other signs or symptoms of CHD, or who is in shock within the first 3 weeks of life is highly likely to have complex CHD. Furthermore, pulse oximeter measurement of the postductal (probe on the foot) oxygen saturation has been found to be specific for the detection of CHD, particularly when combined with findings on the clinical examination (de-Wahl Granelli et al, 2009; Meberg et al, 2008, 2009; Reich et al, 2008; Sendelbach et al, 2008; Thangaratinam et al, 2007; Valmari, 2007). Although debate is ongoing as to the appropriateness of routine pulse oximetry as a screening tool (Sendelbach et al, 2008), the detection of saturations of less than 95% has a sensitivity of 72% to 77%, specificity rates over 99%, and false-positive rates of 0.2% to 0.6% in large-volume studies (Meberg et al, 2008; Valmari, 2007). These neonates are likely to have heart lesions that depend on blood flow through a patent ductus arteriosus to contribute to either systemic or pulmonary blood flow, or improvement of intercirculatory mixing. PGE1 given as continuous infusion will reopen the ductus arteriosus. In babies with ductal-dependent pulmonary blood flow, hypoxemia is lessened as the ductus opens, and the resultant metabolic acidosis will resolve. Babies with systemic flow that is dependent on the ductal connection to provide flow to the descending aorta will have congestive heart failure, low cardiac output, or shock, which is unlikely to be treatable by standard measures without reopening the ductus arteriosus. Patients with transposition of the great arteries will have improved intercirculatory mixing with a patent ductus arteriosus (Wernovsky, 2008; Wernovsky and Jonas, 1998). Interventions such as supplemental oxygen, airway management, volume resuscitation, inotropic therapy, and prostaglandin infusion require careful thought and consideration in the child with CHD.

Considerations of Therapies in the Neonate with Congenital Heart Disease

The neonatal resuscitation algorithm is still applicable in the presence of CHD (Johnson and Ades, 2005), but should be modified in certain circumstances. In presentations with hypoxemia that is unresponsive to supplemental oxygen, congestive heart failure, or shock, simultaneous attention is devoted to the basics of neonatal advanced life support and to assurance of a patent ductus arteriosus.

A stable airway must be maintained, allowing for adequate alveolar oxygenation and ventilation. In critically ill neonates with CHD presenting with severe cyanosis or circulatory collapse, intubation should be performed if

possible after premedication with sedation and neuromuscular blockade (discussed subsequently). Reliable venous access is important, and arterial monitoring is helpful for ongoing assessment of blood pressure, acid-base status, and gas exchange. Volume resuscitation, inotropic support, and correction of metabolic acidosis may be required to maximize cardiac output and tissue perfusion. Blood glucose and ionized calcium should be checked and treated to achieve normal range for age. An evaluation for sepsis is typically performed simultaneously, and empiric antibiotic therapy is initiated while evaluation continues.

Supplemental Oxygen

Supplemental oxygen is a potent pulmonary vasodilator and systemic vasoconstrictor, and it can adversely affect the physiology in neonates with a single ventricle, as well as those with two ventricles with an unrestrictive ventricular septal defect or great vessel communication (see Chapter 55, Congenital Heart Disease). In these babies, the ratio of pulmonary vascular resistance to systemic vascular resistance will determine the proportion of blood flow to each vascular bed. The oxygen-induced pulmonary vasodilation can decrease pulmonary vascular resistance and increase pulmonary blood flow at the expense of systemic blood flow, thus reducing systemic output. Titrating oxygen via nasal cannula or face mask to a target peripheral saturation of 75% to 85% usually corresponds to adequate blood flow in both the pulmonary and systemic systems. In the setting of normal hemoglobin, cardiac output, and oxygen consumption, these oximetry values will provide adequate oxygen delivery. Higher oxygen saturations are typically not necessary and importantly may in fact ultimately result in decreased oxygen delivery to the peripheral tissues. Considerations for intubation and mechanical ventilation are discussed Intubation and Ventilation, later.

Prostaglandin E1 Therapy

In the instance of antenatally diagnosed CHD, ductal dependency (either for systemic or pulmonary blood flow) is often already determined. Whenever possible, PGE1 infusions should be prepared ahead of delivery and started promptly in a peripheral intravenous catheter. The dose of PGE1 varies according to the timing of the diagnosis and the degree of ductal closure that is present upon discovery (or suspicion) of the cardiac lesion. In most cases, PGE1 at 0.01 to 0.025 μg/kg/min via intravenous infusion is adequate for stabilization. PGE1 may be given via a central venous catheter or peripheral intravenous catheter, or in situations where intravenous access cannot be obtained, via an umbilical arterial catheter or intraosseous line. The dose is usually titrated down once the patent ductus arteriosus has been demonstrated echocardiographically. However, doses as high as 0.1 μg/kg/min may be required in the newborn with significant ductal constriction or in the neonate who at 1 to 2 weeks of life presents with a closing, closed, or severely restrictive ductus arteriosus. As in the prenatally diagnosed neonate, once therapeutic effect is achieved, the dose can generally be decreased without loss of therapeutic effect. Prostaglandin response is often immediate if ductal patency is important to the hemodynamics of the infant. Failure to respond may mean that the initial diagnosis of ductal dependent CHD is incorrect, the ductus is unresponsive to PGE1 (which may occur in older infants), or that there is no ductus arteriosus present.

On rare occasion, the neonate may have progressive instability after initiating PGE1 therapy. This important diagnostic finding strongly suggests a congenital heart defect with obstructed blood flow out of the pulmonary veins or the left atrium. These lesions include (1) hypoplastic left heart syndrome with restrictive foramen ovale or intact atrial septum, (2) other variants of mitral atresia with a restrictive foramen ovale, (3) transposition of the great arteries with intact ventricular septum and restrictive foramen ovale, and (4) total anomalous pulmonary venous return with obstruction of the common pulmonary vein.

If the neonate clinically deteriorates despite PGE1 therapy, urgent echocardiography with plans for potential interventional cardiac catheterization or cardiac surgery need to be made. Early recognition of this deterioration despite PGE1 requires prompt transfer to a cardiac unit (Penny and Shekerdemian, 2001). Controversy exists as to whether PGE1 should be continued in these rare instances; it has generally been the authors' practice to continue the infusion at the usual dose. More important than the decision to continue or discontinue PGE1 is that the lack of response to PGE1 in a child with suspected CHD is a marker for rare forms of CHD that do not respond to medical management and require urgent surgical or catheter intervention.

Although PGE1 is critical in the management of most neonates with CHD, there are a number of potential adverse effects associated with PGE1 continuous infusion that must be anticipated, particularly in the premature or LBW infant, in which they occur more commonly. The most common adverse effects include hypotension (caused by vasodilation), apnea, rash, and fever (Kramer et al, 1995; Lewis et al, 1981). Other less common side effects include seizures, gastric outlet obstruction, cortical hyperostosis, and leukocytosis (Arav-Boger et al, 2001; Teixeira et al, 1984).

Although high-dose PGE1 infusions may occasionally be required, most often neonates are in stable condition receiving a low-dose infusion. The resultant vasodilation and hypotension is less common and usually treatable with fluid resuscitation rather than inotropic support (Kramer et al, 1995). A separate intravenous catheter is typically necessary for the purpose of volume administration and should be considered prior to transport. A 5 to 10 mL/kg bolus of normal saline, lactated Ringer's solution, or 5% albumin will generally normalize the blood pressure in cases of hypotension related to PGE1. Serum ionized calcium levels should be checked and normalized if low. If hypotension is refractory to fluid administration, an alternative cause of hypotension should be considered (e.g., a restrictive ductus, pericardial effusion, myocardial dysfunction, sepsis), and dopamine (3 to 5 μg/kg/min) may be given to offset the vasodilatory effects of PGE1.

If apnea and hypotension occur, they will usually manifest during the first hours of administration, but may occur at any time during the infusion. This occurrence mandates the need for ongoing cardiorespiratory monitoring even after stabilization on PGE1 infusion. Furthermore it has

been shown that, although the side effect profile (particularly apnea) increases with increasing doses and lower weight, the clinical response is not dose dependent. In other words, infants can be maintained safely on a low-dose PGE1 infusion until definitive care is achieved and thereby potentially avoid the significant side effects of apnea and hypotension. Certainly, PGE1 therapy alone does not require mechanical ventilation without the presence of significant or recurrent apnea (Browning et al, 2007; Kramer et al, 1995) or other clinical states requiring mechanical ventilation. The use of low-dose PGE1 (<0.015 μg/kg/min) for duct-dependent lesions is unlikely to cause apnea requiring mechanical ventilation, and it is safe to transport the infant without establishing an artificial airway in most cases (Carmo and Barr, 2005).

When starting PGE1 infusion, it is prudent to remeasure arterial blood gases and reassess vital signs and perfusion within 15 to 30 minutes of initiation. Doing so allows effectiveness to be assessed and any adverse events to be addressed promptly.

Intubation and Ventilation

Although the initiation of PGE1 alone does not require the neonate to be intubated, the presence of profound hypoxemia, respiratory distress, or hemodynamic instability may demand airway intervention. In most cases, intubation should be performed after premedication with sedation (narcotic or benzodiazepine), preferably with neuromuscular blockade. Although intubation can be performed without sedation and neuromuscular blockade, there are physiologic reasons to use these agents for the intubation of a neonate with CHD. First, the catecholamine surge that will occur with a nonsedated intubation may result in significant dysrhythmias in the at-risk myocardium. Second, vagally mediated bradycardia from hypoxemia, hypercapnia, or laryngeal stimulation may lead to asystole in these neonates, who have little reserve. Finally, sedation and neuromuscular blockade will reduce total body oxygen consumption, raising the mixed venous oxygen saturation and improving oxygen delivery. Premedication with atropine (0.02 mg/kg) can blunt the vagal effects of laryngoscopy. Fentanyl (1 to 2 μg/kg) or midazolam (0.05 to 0.1 mg/kg) for sedation may be given, with titration of dose to effect. Chest wall rigidity may occur with low-dose fentanyl (more likely if given rapid push) and may require neuromuscular blockade for adequate ventilation.

In most cases, the neonate is preoxygenated with 100% FiO_2, which can be down-titrated to achieve an acceptable oxygen saturation given the underlying CHD after intubation. In an effort to maintain a balanced circulation, ventilation should attempt to achieve normocarbia (Pco_2, 35 to 40 mm Hg). In the single-ventricle patient (i.e., a patient in whom the systemic and pulmonary circulations are dependent on a single-ventricular pumping chamber) or the neonate with unrestrictive ventricular or great vessel communications, significant adjustments in ventilation will alter pulmonary vascular resistance, and therefore may have an effect on both pulmonary and systemic blood flow. Hyperventilation in the neonate decreases pulmonary vascular resistance, thereby increasing pulmonary blood flow potentially at the expense of systemic blood flow.

Although intubation and ventilation may be necessary interventions, it should be noted that preoperative mechanical ventilation is a risk factor for mortality or poor outcome after surgery for CHD in multiple studies (Gottlieb et al, 2008; Robertson et al, 2004; Simsic et al, 2007; Tabbutt et al, 2008).

Inotropic Therapy

The neonate with CHD discharged from the nursery before diagnosis may be experiencing congestive heart failure or circulatory collapse. These infants, while urgently requiring the opening of the ductus arteriosus to provide either systemic or pulmonary blood flow, may also require inotropic therapy to recover from the adverse effects of a myocardium that has decompensated in the face of high afterload (obstructive left-sided lesions requiring ductal patency for systemic blood flow) or hypoxemia (obstructive right-sided lesions requiring ductal patency for pulmonary blood flow). Appropriate volume status should be achieved in conjunction with the institution of inotropic therapy and secure access for its delivery. The choice of inotropic agent remains largely practitioner dependent.

Sympathomimetic amines are the most commonly used inotropic agents. They can be endogenous (dopamine and epinephrine) or synthetic (dobutamine and isoproterenol). Dopamine is a norepinephrine precursor and stimulates dopaminergic, β1-adrenergic, and α-adrenergic receptors in a dose-dependent manner. Dopamine improves myocardial contractility, which will increase stroke volume. This increase leads to improved cardiac output and higher mean arterial pressure, with resultant increased urine output. There is a low incidence of side effects at doses less than 10 μg/kg/min. Dobutamine is an analogue of dopamine; it stimulates β1-adrenergic receptors predominantly, with relatively weak β2-adrenergic receptor and α-adrenergic receptor activity. No definitive benefit has been found in the use of dopamine versus dobutamine, although dopamine is more likely to increase the systemic blood pressure in the short term. No differences in outcomes or mortality were found between the two inotropes (Subhedar and Shaw, 2003). Both drugs are generally initiated at 3 to 5 μg/kg/min. Epinephrine may also be used in neonates with hypotension and hemodynamic deterioration. Epinephrine has α1-, α2-, β1-, and β2-adrenergic effects. Few trials have been done to recommend epinephrine over other agents. A randomized controlled trial comparing epinephrine and dopamine in LBW infants found equal efficacy in treating hypotension (Valverde et al, 2006). The recommended starting dose is 0.03 to 0.05 μg/kg/min. Isoproterenol stimulates β1- and β2-adrenergic receptors. It has greater chronotropic effect and stronger vasodilatory effect because of the β2 stimulation. It needs to be started at low dose and titrated to effect, because of the strong chronotropic effect. Chronotropic effects will precede inotropic effects in a responsive heart and can produce tachyarrhythmias. Recommended starting dose is 0.01 to 0.05 μg/kg/min.

The adverse effects of the sympathomimetic amines include tachycardia, atrial and ventricular arrhythmias, and peripheral vasoconstriction causing increased afterload. Tachycardia will increase myocardial oxygen

consumption, whereas arrhythmias and vasoconstriction decrease cardiac output.

Vascular Access

Umbilical venous catheters (UVCs) and umbilical arterial catheters (UACs) are useful in the stabilization, transport, and preoperative and postoperative management of the neonate with CHD. However, the placement of these lines is not without risk. Beyond the infectious risks, newborns with CHD are at a higher risk for thromboembolic events because of their underdeveloped clotting mechanisms, small vessel lumens, and low flow states. There is also an ongoing risk of systemic embolization of air and particulate matter in babies with an intracardiac right-to-left shunt. There has been much controversy surrounding the optimal placement of a UAC in premature infants, although there are scant data regarding full-term infants with CHD. A Cochrane Database review suggested that "high" catheters were associated with a decreased risk of vascular complications with no significant increase in adverse sequelae (Barrington, 2000; Hermansen et al, 2005). Although there is variation in definition, in general "high" catheters are above the level of the diaphragm and below the level of the left subclavian artery (approximately T6 to T10); "low" catheters are below the renal arteries but above the aortic bifurcation (approximately L3 to L5). Levels between high or low are associated with increased risks of complications, as are placements below the L5 level (Hermansen et al, 2005). Although transient placement of a UAC in this area will generally be well tolerated, long-term placement should be avoided if possible. The UVC should be placed, if possible, at the inferior vena cava/right atrial junction or in the atria. It might not be necessary to obtain ideal placement of either the UAC or UVC for stabilization and transport, and manipulation of lines and reconfirmation can delay transport and stabilization to the tertiary care center. The risk-benefit relation for the use of umbilical lines in the neonate with ductal dependent circulation has not been well delineated. The need for central access should be judged based on the clinical status of the neonate and stability for transport.

Transport of the Neonate With Congenital Heart Disease

Once the neonate with suspected or known CHD has been sufficiently resuscitated and stabilized, they should be transferred to an institution that provides subspecialty care in pediatric cardiology and pediatric cardiothoracic surgery. In a single tertiary center study of neonates presenting with CHD, 157 of 190 patients required at least one surgical or catheter intervention with a median of 3 days of life at time of surgery (Dorfman et al, 2008). To optimize management, early communication with the specialist center is vital. Successful transport involves two phases: referring hospital staff to the transport team and subspecialists, and transport staff to the accepting hospital staff. The need for this precise and thorough communication between respective teams cannot be overemphasized. Whenever possible, the pediatric cardiologist, neonatologist, or intensivist at the accepting hospital should be included in formulating the transport management plan while the neonate is still at the referring hospital. This procedure will help to guide the timing and urgency of the transport, line placement, and recommendations for airway management and supplemental oxygen. Often the patient with a duct-dependent lesion will improve greatly with the institution of prostaglandin therapy and may not need to be rushed to the cardiac referral center as an emergent case.

Similar supports and treatments need to be put into place before transport of any critically ill neonate or infant. Secure vascular access should be obtained, with a port available for volume resuscitation that is not running the inotropic support or PGE1 infusion, to avoid interruption of this medication. Intubated patients should have the airway position recorded and secured and have a nasogastric or orogastric tube for decompression. The intubated infant should remain unfed, and medication administration and fluids should be given intravenously. Appropriate sedation should be used, as well as maintenance of normothermia and avoidance of hyperthermia, to minimize oxygen consumption.

Evaluation of acid-base status, oxygen delivery, temperature, serum glucose, and calcium should take place before transport and should be corrected when possible. Neonates with conotruncal anomalies are at particular risk for hypocalcemia, because they have an increased frequency of 22q11 deletion syndrome (Gallot et al, 1998), which may have associated thymic and parathyroid hypoplasia. Furthermore, the neonatal myocardium may be more dependent on calcium for inotropy than the adult. Ionized calcium levels less than 1 mg/dL may have a significant negative effect on contractility and should be considered for treatment with calcium gluconate (50 to 100 mg/kg) or calcium chloride (0.1 mEq/kg of elemental calcium or 0.01 g/kg) intravenously, via a central catheter if possible.

In patients with mixing lesions, single ventricle or in those with an unknown diagnosis, supplemental oxygen should be used and titrated to maintain pulse oximeter oxygen saturation of 75% to 85% for "balance" of circulation between pulmonary and systemic systems and to provide adequate oxygen delivery, because higher oxygen saturations may actually be deleterious, as noted previously. The accepting pediatric cardiologist can aid with lesion-specific advice and guidelines to optimize in-transport care.

Hypotension is a late finding of shock in neonates. Earlier, more sensitive signs, of impending decompensation include persistent tachycardia despite adequate intravascular volume and temperature control, poor tissue perfusion, and metabolic acidosis. Treatment of shock should occur before transport during the stabilization phase of management, although the patient in profound shock and with significant acidosis at presentation may require significant time for resolution of organ dysfunction and perfusion and clearance of acidosis. Finally, failure to respond to prostaglandin, assuming adequate dose and delivery, should promote prompt transfer to a cardiac unit able to care for lesions with obstruction to pulmonary venous outflow. Before leaving the referring hospital, hemodynamic status (capillary refill, heart rate, systemic blood pressure, and acid-base status) needs to be reassessed and communicated to the accepting hospital.

Summary of Cardiac Transport

Stabilization and transport of the neonate with known or suspected critical CHD affect their preoperative condition, potentially contributing to short-term mortality risk and long-term morbidity. One key to stabilization is the recognition of potential or confirmed CHD, appropriate resuscitation, airway management where indicated, stable vascular access, judicious oxygen utilization, PGE1, and inotropic support when necessary. Early consultation with a center specializing in pediatric cardiac care, for advice and timing of transport, will aid the initial care and stability of the infant on transport. Accurate, detailed information must be communicated among the referring hospital, the transport team, and the accepting hospital.

SURGICAL EMERGENCIES

Because most births occur in hospitals without an NICU or neonatal surgical abilities, the need for surgical evaluation or intervention is a common reason for interfacility transport. Whereas some surgical conditions are relatively not urgent in nature, there are several diagnoses that represent truly life-threatening conditions for which stabilization and transport require expertise and specialized resources.

Congenital Diaphragmatic Hernia

Advances in ultrasound technology have resulted in the prenatal diagnosis of up to 60% of fetuses affected by congenital diaphragmatic hernia (Gallot et al, 2007). A recent systematic review showed that outcome was improved for newborns with a prenatal diagnosis or born in a tertiary care center (Logan et al, 2007b). Newborns with undiagnosed CDH, especially those delivered at a community hospital, are at high risk for complications. Before transport, critically ill infants with suspected or known CDH should undergo tracheal intubation and placement of a large-bore nasogastric or orogastric tube to continuous suction, because many have received bag-mask ventilations and swallowed air can quickly travel beyond the pylorus and distend the intrathoracic intestinal contents (Grisaru-Granovsky et al, 2009; Logan et al, 2007b). Whenever possible, the same principles of management that are used in the tertiary care center should be used during transport: limitation of peak airway pressures and use of low tidal volumes to avoid ventilator-induced lung injury, judicious use of sedation, avoidance of chemical paralysis to permit spontaneous breathing, and maintenance of adequate systemic blood pressure with the use of fluid therapy and inotropes (Logan et al, 2007a). Although there is still controversy over the role of extracorporeal membrane oxygenation for newborns with CDH, transport to a high-volume center with ECMO capabilities should be strongly considered (Grushka et al, 2009; Morini et al, 2006).

Abdominal Wall Defects

The proper management of a newborn with gastroschisis or omphalocele is critical during the first several hours of life, and delivery in a tertiary care center has been associated with improved outcome (Quirk et al, 1996). In addition to the need for initial resuscitation and cardiorespiratory support, the correct treatment of the exposed bowel or sac may improve the infants' chances of a successful repair and long-term intestinal function.

The mean gestational age for newborns with gastroschisis is 36.6 weeks, and many affected infants are small for gestational age (Baerg et al, 2003; Lausman et al, 2007). As with other mildly premature and growth-restricted infants, patients with gastroschisis are at risk for hypothermia and hypoglycemia. Heat loss is exacerbated by the large surface area of the exposed intestines, which can also serve as a significant source of fluid loss. Prevention of heat and fluid losses can be accomplished by placing the lower part of the infant's body, including the intestines, into a transport bag (i.e., bowel bag or Lahey bag) before placement of the infant into the heated transport isolette. Significant fluid losses can occur through the exposed mucosa, and the patient may require aggressive fluid replacement (120 to 150 mL/kg/day). The use of antibiotics should be considered if risk factors for sepsis are present and reviewed with the pediatric surgeon.

Infants with gastroschisis are at risk for intestinal vascular compromise, because the vascular pedicle containing the arterial supply and venous drainage from the bowel must pass through the relatively small abdominal wall defect. Transport personnel must closely monitor the appearance of the bowel to detect signs of venous congestion or ischemia. Transporting the infant in the lateral position, with support of the exposed intestines to avoid tension or torque, is recommended. The use of intestinal pulse oximetry has been described for monitoring the bowel for ischemia through a transparent silo, but has not been studied as a tool during interfacility transport (Kim et al, 2006). Vascular compromise of the intestine is a surgical emergency, and communication with the receiving facility is essential to coordinate urgent intervention.

The transport of an infant with omphalocele has similar considerations, although unless the sac has ruptured there is significantly less risk of heat and fluid loss. Infants with an omphalocele are more likely than those with gastroschisis to have other birth defects (e.g., CHD). Furthermore, infants with giant omphaloceles often have respiratory insufficiency caused by diaphragmatic dysfunction, pulmonary hypoplasia, or both, and they may require ventilatory assistance.

All infants with gastroschisis or omphalocele require placement of a large-bore nasogastric or orogastric tube due to functional ileus or intestinal obstruction, as may occur with associated stenoses or atresias. In general, cannulation of the umbilical vessels is not recommended unless other methods for vascular access are not successful.

Esophageal Atresia and Tracheo Esophageal Fistula

Esophageal atresia, with or without tracheo esophageal fistula, is typically diagnosed within the first day of life because of increased secretions, poor feeding, and respiratory distress. General transport considerations include placement of a large-bore sump-type tube for continuous aspiration of the proximal esophageal pouch, positioning (prone with the head of bed elevated), and respiratory

support as indicated. Direct aspiration of secretions into the trachea may occur with either a proximal or distal tracheo esophageal fistula. Transport providers should be aware that infants with a distal tracheo esophageal fistula (type C), characterized by the presence of air in the intestinal tract, are at risk for gastric and intestinal insufflation via the fistula when receiving positive-pressure ventilation. Bag-mask ventilation and continuous positive airway pressure should be avoided. If the infant requires endotracheal intubation, the endotracheal tube should be positioned as close to the carina as tolerated in an effort to position the distal tip beyond the fistula and minimize direct inflation of the distal esophageal segment with pressurized gas. In extreme cases, gastric rupture with pneumoperitoneum has been reported, requiring emergency paracentesis, laparotomy, or both (Maoate et al, 1999).

Midgut Volvulus

Malrotation with midgut volvulus can be a catastrophic event resulting in intestinal ischemia and shock, and it represents a surgical emergency in the neonate. The most common clinical presentation of midgut volvulus is bilious vomiting, which is a nonspecific sign of intestinal obstruction. Expeditious evaluation of the newborn with bilious vomiting is essential to facilitate prompt surgical intervention in the event that midgut volvulus is identified, to prevent progression of vascular insufficiency to actual intestinal necrosis. An upper gastrointestinal series is the radiologic test of choice to diagnose malrotation and midgut volvulus, although some practitioners have reported success with the use of ultrasound examination to identify the relationship of the superior mesenteric vessels (Lampl et al, 2009; Shew, 2009).

An infant with suspected midgut volvulus should be rapidly transported to a facility with pediatric radiology and surgical capabilities. Care of the infant with suspected midgut volvulus during interfacility transport is primarily supportive and includes circulatory support with intravenous fluid repletion, correction of metabolic abnormalities, and gastric decompression with a large-bore nasogastric or orogastric tube.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is common in premature infants, and approximately 30% of newborns with NEC will require surgical intervention in the form of laparotomy or peritoneal drain placement (Guthrie et al, 2003). The clinical presentation of NEC is typically nonfocal and often mimics signs of systemic sepsis. Clinical and radiologic findings that are specific to NEC include abdominal distention and discoloration of the abdominal wall, dilated or thickened bowel loops, pneumatosis intestinalis, portal venous gas, and free intraperitoneal air.

Infants with suspected NEC should be transported to a facility with pediatric surgical capabilities. Care during transport is primarily supportive and includes intravenous fluids, administration of broad-spectrum antibiotics, correction of metabolic abnormalities, and gastric decompression. Respiratory failure is common because of disordered control of breathing and elevation of the diaphragm from abdominal distension.

Meningomyelocele

Although most newborns with neural tube defects are diagnosed prenatally because of an elevated AFP and are therefore delivered in a tertiary care center, the unexpected birth of an infant with a meningomyelocele may be an indication for neonatal transport. For purposes of transport, the infant should be placed in the prone position and the spinal defect should be covered with moist sterile dressings as well as some form of plastic wrap to maintain moisture. The lesion can be covered with a moistened Telfa dressing and then loosely encircled with a Kerlix "donut," with the entire defect covered with a sterile drape. This dressing can be moistened as indicated during the transport process (Jason and Mayock, 1999). Avoid the use of latex gloves during care of these patients. If the skin covering the defect is disrupted, there is an increased risk of infection, and empiric antibiotics should be considered. Infants with meningomyelocele may or may not have accompanying hydrocephalus at birth; approximately 25% of affected patients will require shunting in the immediate newborn period, with up to 85% eventually undergoing shunt placement (Bowman et al, 2001).

CHAPTER 30

Temperature Regulation of the Premature Neonate

Stephen Baumgart and Sudhish Chandra

The human neonate is a homeothermic mammal. Even the smallest premature infants respond adaptively to changes in their environment. Response, however, may be insufficient to maintain core body temperature and can render preterm babies functionally poikilothermic, even in moderately temperate environments. Morbidity (e.g., poor brain and somatic growth) and mortality rates increase when core body temperature is permitted to decline much below 36° C (96.8° F), and moderate to severe hypothermia below 31° C (88.7° F) results in precipitous declines in heart rate and blood pressure.

COLD STRESS

Evaporative heat loss is widely as regarded the most stressful cooling event upon birth. Severe nonevaporative heat loss is also problematic for several reasons. First, a baby's exposed body surface area is much larger than an adult's, relative to metabolically active body mass (Table 30-1). Especially for the extremely low birthweight infant, the heat-dissipating area is fivefold to sixfold greater proportionate to that of the adult. Second, the baby's small size presents a much smaller heat sink to store thermal reserve. Finally, the radius of curvature of the body is less than in the adult, resulting in a thinner protective boundary layer of warm, still air.

Aside from these geometric considerations, characteristics of the premature infant's skin contribute to the problem of excessive heat loss. The skin and subcutaneous fascia provide little insulation against the flow of heat from the core to the surface. Moreover, the lack of a keratinized epidermal barrier exposes infants to vastly increased evaporative heat loss.

Finally, premature infants may not induce effective thermogenesis in response to cold stress. Shivering and nonshivering thermogenesis are compromised by low brown fat stores. Furthermore, the presence of hypoxia (common with preterm birth) seriously reduces nonshivering thermogenesis by reducing mitochondrial oxidative capacity.

PHYSICAL ROUTES OF HEAT LOSS

CONVECTION

Convective heat loss in newborns occurs when ambient air temperature is less than the infant's skin temperature. Convective heat loss includes natural convection (passage of heat from the skin to the ambient still air) and forced convection, in which mass movement of air over the infant conveys heat away from the skin. The quantity of heat lost is proportional to the difference between air and skin temperatures, and to air speed. The effect of forced convection in disrupting the microenvironment of warm, humid air layered near an infant's skin usually is not appreciated in the nursery, where drafts, air turbulence, and consequently heat loss can occur within the relatively protective environment of an incubator.

EVAPORATION

Passive transcutaneous evaporation of water from a newborn's skin (insensible water loss) results in the dissipation of 0.58 Kcal/mL of latent heat. As shown in Figure 30-1, transcutaneous water loss increases exponentially with decreasing body size and gestation. The tiniest premature baby, who is least able to tolerate cold stress, can incur evaporative heat loss in excess of 4 Kcal/kg/hr (water loss of approximately 7 mL/kg/hr). Evaporation is enhanced by low vapor pressure (i.e., high air temperature and low relative humidity) and air turbulence. The highest evaporative losses occur on the first day of life. During the first week of life in infants born at 25 to 27 weeks' gestation, evaporative heat losses may be higher than radiant losses (Hammarlund et al, 1986).

RADIATION

Radiant heat loss constitutes the transfer of heat from an infant's warm skin, via infrared electromagnetic waves, to the cooler surrounding walls that absorb heat. Radiant heat loss is proportional to the temperature gradient between the skin and surrounding walls. An infant's posture may affect radiant heat loss by increasing or reducing the exposed radiating surface area. In a moderately humid environment (relative humidity approximately 50%), babies experience an ambient temperature (termed *operant temperature*) determined 60% by wall temperature and 40% by air temperature.

CONDUCTION

Conductive heat loss to cooler surfaces in contact with an infant's skin depends on the conductivity of the surface material and its temperature. Usually babies are nursed on insulating mattresses and blankets that minimize conductive heat loss.

PHYSIOLOGY OF COLD RESPONSE

AFFERENTS

Homeothermic response to a cold environment begins with the sensation of temperature. Traditional physiology identifies two temperature-sensitive sites: the hypothalamus and the skin. Sensation of cold by neonatal skin triggers a cold-adaptive response long before core sensors

TABLE 30-1 Body Surface Area-to-Body Mass Ratio

	Body Weight (kg)	Surface Area (m^2)	Ratio (cm^2/kg)
Adult	70	1.73	250
Premature infant	1.5	0.13	870
Very premature infant	0.5	0.07	1400

in the hypothalamus become chilled. Some investigators conjecture that neonatal cold reception resides primarily in the skin, whereas warm reception resides in the hypothalamus. Both sensors are probably integrated, because cold sensory response is inhibited by core sensor hyperthermia and vice versa. Peripheral skin cold sensation is teleologically important, because early detection of heat loss from the skin aids in the infant's timely response for maintaining core temperature.

CENTRAL REGULATION

Integration of multiple skin temperature inputs probably occurs in the hypothalamus; however, no single control temperature seems to exist. Under different environmental conditions, temperature of the skin can fluctuate 8° to 10° C, and temperature of the hypothalamus may vary ±0.5° C. There are also diurnal temperature fluctuations, variations with general sympathetic tone, and blunted regulation with asphyxia, hypoxemia, and other central nervous system defects. Premature infants can regulate core temperature near 37.5° C (99.5° F), whereas term infants may respond by maintaining 36.5° C (97.7° F). Because important thermoregulatory processes are triggered by deviations of as little as 0.5° C at any temperature-sensitive site, environmental temperature homeothermy is important.

EFFERENTS

The effector limb of the neonatal thermal response is mediated primarily by the sympathetic nervous system, although infant behavior may also be involved. The earliest maturing response is vasoconstriction in deep dermal arterioles, resulting in reduced flow of warm blood from the infant's core into the exposed periphery. In addition, reducing blood flow effectively places a layer of insulating fat between the warm core tissue compartment and the cooler exposed skin surface in the term infant. Reduced fat content in babies with low birthweight diminishes this effective insulating property. Vasoconstriction nevertheless remains the newborn's first line of thermally insulating defense, and the response is present even in the most premature infant.

Brown fat constitutes a second sympathetic effector organ that provides a metabolic source of nonshivering thermogenesis. (Babies do not shiver like adults to generate heat, because muscle constriction-relaxation fibers are not yet myelinated.) Brown fat located in axillary, mediastinal, perinephric, and other regions of the newborn is particularly enervated and equipped with an abundance of mitochondria to hydrolyze and reesterify triglycerides

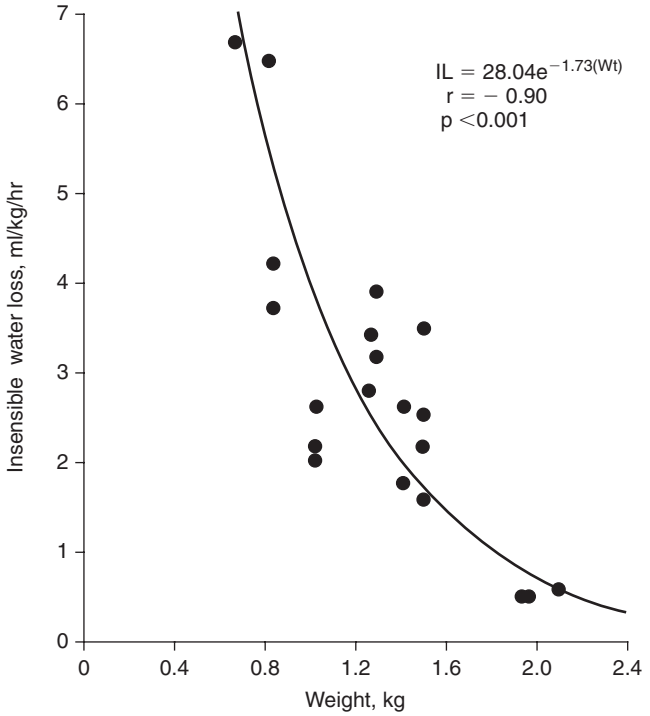

FIGURE 30-1 Exponential increase in evaporative water loss from skin of infants with very low birthweight who were nurtured under radiant warmers. (*Adapted from Baumgart S, et al: Fluid, electrolyte and glucose maintenance in the very low birthweight infant*, Clin Pediatr *21:199-206, 1982.*)

and to oxidize free fatty acids. In the term infant, these reactions are exothermic and may increase metabolic rate by twofold or more. Preterm babies, however, have little brown fat and may not be capable of more than a 25% increase in metabolic rate despite the most severe cold stress (Hull, 1966).

Finally, recent evidence suggests that control of voluntary muscle tone, posture, and increased motor activity with agitation may serve to augment heat production in skeletal muscle via glycogenolysis and glucose oxidation. Clinical observations of infant posture, behavior, and skin perfusion and measurements of skin and core temperature gradient may ultimately provide the most useful guidelines for assessing infant comfort during incubation.

MODERN INCUBATION: INCUBATORS AND RADIANT WARMERS

The lifesaving requirement of an appropriate thermal environment was demonstrated conclusively by Day et al (1964) and further defined by Silverman et al (1966). Minor changes in heat balance create an oxygen and energy cost, inducing an increased metabolic rate that can be met only by increased ventilation or increased inspired oxygen and appropriate cardiovascular response to provide oxygen delivery to activated tissues.

THERMAL NEUTRAL ZONE

The thermal neutral zone is a narrow range of environmental temperatures within which an infant's metabolic rate is minimal and normal body temperature is maintained.

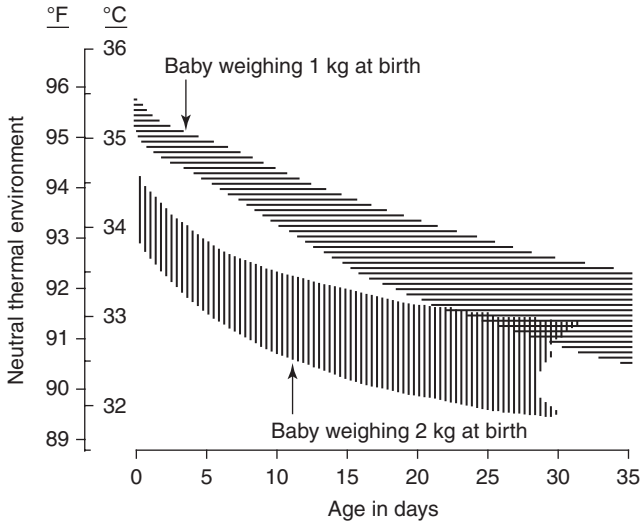

FIGURE 30-2 The range of temperature needed to provide neutral environmental conditions for a baby lying naked on a warm mattress in draft-free surroundings of moderate humidity (50% saturation) when mean radiant temperature is the same as air temperature. The *hatched areas* show the average neutral temperature range for a healthy baby weighing 1 or 2 kg at birth. Optimal temperature probably approximates the lower limit of neutral range as defined here. Approximately 1° C should be added to these operative temperatures to derive the appropriate neutral air temperature for a single-walled incubator when room temperature is less than 27° C (80° F), and more should be added if room temperature is significantly less. (*Adapted from Hey EN, Katz G: The optimum thermal environment for naked babies*, Arch Dis Child *45:328-334, 1970.*)

TABLE 30-2 Mean Temperature Needed to Provide Thermal Neutrality for a Healthy Baby Nursed Naked in Draft-Free Surroundings of Uniform Temperature and Moderate Humidity during the Days or Weeks after Birth

	Operative Environmental Temperature*			
Birth-weight (kg)	**35° C**	**34° C**	**33° C**	**32° C**
1.0	For 10 days	After 10 days	After 3 weeks	After 5 weeks
1.5		For 10 days	After 10 days	After 4 weeks
2.0		For 2 days	After 2 days	After 3 weeks
>2.5			For 2 days	After 2 days
