Data from Hey E: Thermal neutrality, *Br Med Bull* 31:72, 1975.
*To estimate operative temperature in a single-walled incubator, subtract 1° C from incubator air temperature for every 7° C by which this temperature exceeds room temperature.

When thermally neutral, infants regulate temperature through vasomotor tone alone without regulatory changes in metabolic heat production. A range of critical environmental temperatures relevant to modern incubators was clearly articulated by Hey and Katz (1970; Figure 30-2, Table 30-2). Below this range, an increase in the infant's minimal metabolic rate was observed; therefore the thermal neutral temperature range was defined as the optimal incubator operating (operant) temperature. Several important considerations in regulating incubator temperature were included in these studies: (1) incubator wall temperature was maintained identical to air temperature, (2) relative humidity was controlled near 50%, and (3) the environment was maintained in a steady state, uninterrupted by turbulence or invasion of the incubator's enclosed perimeter.

Rigid application of older air temperature recommendations should be modified. Many modern incubators incorporate a double-walled design that results in lower radiant heat loss to colder incubator walls encountered in single-walled designs. As a result, slightly cooler air temperature may be required. In addition, many nurseries do not humidify incubators artificially, fearing the occurrence of condensation ("rain-out") resulting in bacterial colonization, particularly around door openings. Finally, it is important to recognize that the incubator's steady state temperature control is frequently interrupted for nursing and medical procedures that require opening doors to care for the infant. More than 1 hour may be required to recover prior steady state conditions after such procedures; therefore the thermal neutral zone must be redefined in practical terms. Silverman et al (1966) used a modified concept of the thermal neutral zone to simplify clinical application. Reasoning that infants sense environmental temperature first on the skin, electronic negative-feedback (servo-controlled) regulation of the incubator heater in response to skin temperature was introduced. These authors demonstrated minimum metabolic expenditure near 36.5° C (97.7° F) abdominal skin temperature as measured by a shielded thermistor in a less rigidly defined incubator environment. The importance of frequently checking core temperatures (axillary or rectal) must be emphasized before delegating the infant's environment to thermostatic control. In addition, Chessex et al (1988) have demonstrated that incubator temperature can vary by more than 2° C when skin temperature servo control rather than air temperature control is used, obviating homeothermic environmental conditions.

Finally, with the modern use of open radiant warmer beds (improving access to the critically ill premature infant without interrupting heat delivery) skin temperature servo control is the only practical method for approximating the thermal neutral zone (Malin and Baumgart, 1987). The extension of infant warming to include extremely low birthweight, critically ill premature babies have generated new problems for determining a universally accepted optimal environment.

PARTITIONING INFANT HEAT LOSSES AND HEAT GAINS

Wheldon and Rutter (1982) demonstrated the special problems encountered in incubating infants with very low birthweight in a convection-warmed, closed-hood incubator environment (Figure 30-3). Figure 30-3, *A*, demonstrates the thermal balance achieved by a series of 12 infants (mean weight, 1.58 kg). Heat losses to radiation (R), convection (C), and evaporation (E) are modest, and their sum (Σ) is balanced by the infant's metabolic heat production (M). Used in this fashion, the incubator reduces physical heat losses such that the infant's minimal metabolism (larger than any single avenue of heat loss)

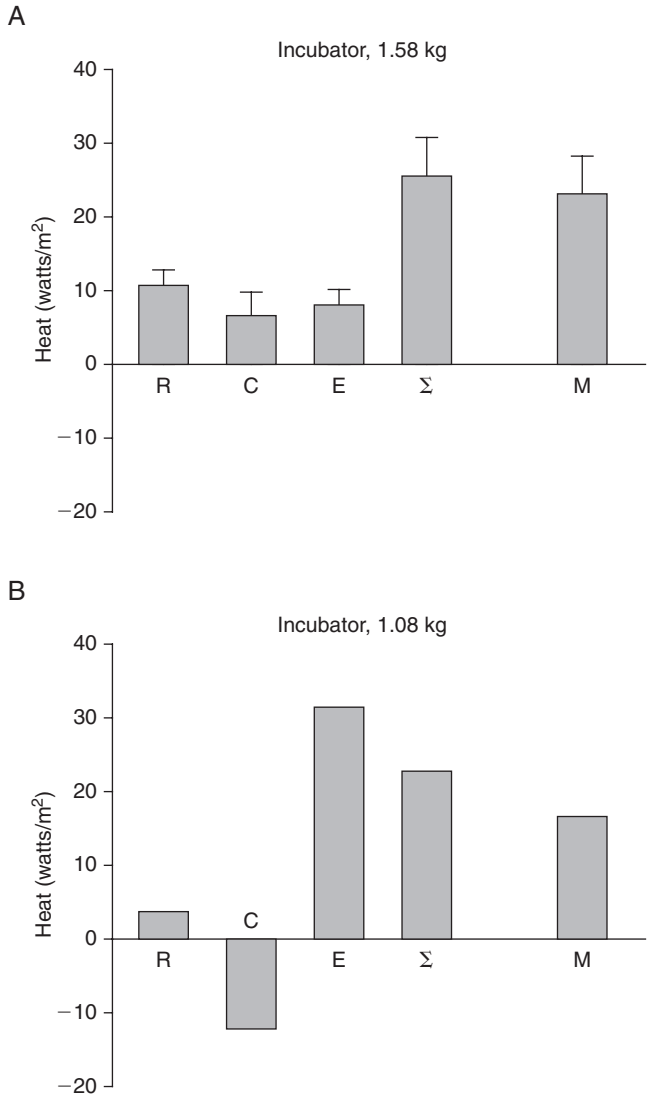

FIGURE 30-3 **A**, Partition of heat losses and gains in 12 premature infants nursed within incubators. **B,** Partition in an infant weighing 1.08 kg at birth. Heat losses to radiation (*R*), convection (*C*), and evaporation (*E*) are modest, and their sum (*Σ*) is balanced by the infant's metabolic heat production (*M*). (*Adapted from Wheldon AE, Rutter N: The heat balance of small babies nursed in incubators and under radiant warmers*, Early Hum Dev *6:131-143, 1982.*)

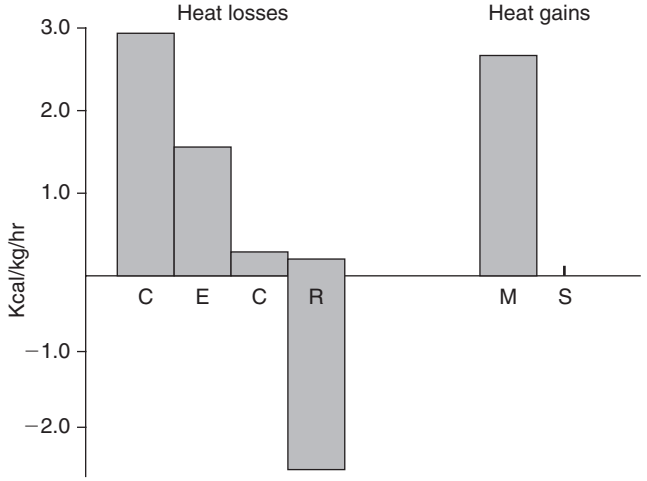

FIGURE 30-4 Partitional calorimetry in 10 critically ill premature newborns with low birthweight who were nursed under open radiant warmers. *C*, Convection; *E*, evaporation; *M*, infant's metabolic heat production; *R*, radiation. (*Adapted from Baumgart S: Radiant heat loss vs. radiant heat gain in premature neonates under radiant warmers*, Biol Neonate *57:10-20, 1990.*)

delicately balances minimal physical heat losses within the controlled thermal environment.

In contrast, a subject with very low birthweight (1.08 kg) is evaluated in Figure 30-3, *B*. As the incubator servo control increases warming power to accommodate massive evaporative heat loss, convective loss becomes a net gain (negative histogram bar). Radiant loss is diminished by warm walls inside the incubator. These conditions differ strikingly from those discussed previously: the incubator truly warms the infant rather than modestly attenuating convective heat loss, and evaporative heat loss vastly exceeds the infant's metabolism. The small infant's body temperature is balanced, therefore, between opposing physical parameters of evaporative and convective heat transfer. Metabolism plays a secondary role.

The modern use of radiant warmers that are servo controlled to maintain infant abdominal skin temperature between 36.5° and 37° C (97.7° to 98.6° F) also demonstrates the opposition of physical forces described earlier. Figure 30-4 demonstrates the heat balance partition for 10 critically ill premature infants (mean weight, 1.39 kg) nursed on open radiant warmer beds (Baumgart, 1990). Because ambient room air temperature is 5° to 10° C cooler than air inside an incubator, convective heat loss is nearly double the infant's metabolic heat production. Evaporation adds to the net physical heat loss. In addition, small amounts of heat are lost to conduction and radiation (to cooler room walls). The infant's metabolism provides only one third of the energy required to maintain body temperature, with the majority of heat supplied by the servo-controlled radiant heat source injecting heat transdermally through skin blood flow. In this instance, radiant warming (not convection as in the incubator discussed earlier) delicately balances the infant's physical temperature environment. Wheldon and Rutter (1982) demonstrated similar results in their studies.

HYBRID INCUBATOR-RADIANT WARMER TECHNOLOGY

A more promising new development in commercially available incubators is a hybrid design, combining these two separate warming modes in one device. Manufacturers in the United States and Germany (Air-Shields [Hatboro, Pennsylvania], Hill-Rom [Batesville, Indiana], Drager [Lubeck, Germany], and General Electric, Ohmeda [Laurel, Maryland]) have launched such products. In the incubator mode, movable plastic walls enclose the tiny premature infant, providing servo-controlled air warming, while the overhead radiant warmer is incorporated into the roof of this design but remains off. In the radiant warmer mode, the plastic walls are dropped down, and the radiant warmer rises overhead on a motorized pylon and rapidly turns on to maintain servo-controlled skin temperature during infant care procedures. The infant is not moved, and no plastic barrier is placed between the infant and the radiant heat source when turned on in this mode. The

servo control algorithms, and the integrity of the plastic enclosure in incubator mode, are critical to the performance of such devices, and the utility of these products (e.g., survival, quality of life) is still unproved. Published data are reviewed in the following sections.

VERSALET INCUWARMER

Greenspan et al (2001) tested nine premature lambs, randomized at delivery, to receive incubation from a conventional radiant warming bed (Resuscitaire) with subsequent transfer into an incubator C550 Isolette or from the hybrid Versalet 7700 Care System (Air-Shields, Hatboro, Pennsylvania) in both the warmer bed and the incubator modes. Deep central and surface temperatures, heart rate, blood pressure, and blood gas determinations were measured during warming in the radiant warmer bed mode (Versalet) or on the radiant warmer bed Resuscitaire and then during transition to the incubator mode (Versalet or Isolette), and then back to the warmer bed, and bed mode. The animals conditions all remained clinically stable throughout the entire transfer protocol on both arms of the study. Despite careful planning, loss of temperature probe data occurred when probes became unattached in the control group during transfers from one device to the other. There were no significant differences in recorded temperatures or in pH and blood gasses in either group. Compared with the standard warming techniques currently used in neonatal intensive care units (NICUs; separate warmer bed for resuscitation and stabilization with transfer as soon as possible into an incubator device), the Versalet provided similar thermal and cardiovascular stability without adverse physiologic events during transition to different modes of warming. The authors state that the contribution of this hybrid device to the ease of management and improved outcomes in humans needs to be evaluated in a clinical trial (Greenspan et al, 2001; Sherman et al, 2006). No such trial has yet been conducted, and the Versalet is currently not in production (Jay Greenspan, personal communication).

GIRAFFE OMNIBED

As a radiant warmer, the Giraffe OmniBed (General Electric, Ohmeda Division, Laurel, Maryland) evenly heats the infant's mattress with a curved reflector surface designed to distribute heat to the baby and its bed surface without overwarming bedside caregivers. Babies are warmed uniformly, regardless of their position on the bed platform surface, which can be rotated 360 degrees, accommodating intravenous and ventilator tubing and attached wire leads. The same platform tilts up to 12 degrees in Trendelenburg or reverse Trendelenburg positions. Three-sided access from drop-down walls in the radiant warmer mode facilitates procedures such as diaper and bedding changes, blood sampling, starting intravenous lines, performing tracheal intubation, administering medications, creating radiographs, and conducting ultrasound examinations without interrupting warming. A stable thermal environment in either the incubator or radiant warmer mode eliminates the stress of moving premature babies, such as when performing chest tube insertion or other surgical procedures performed in the NICU and outside the operating room. In one of several industry sponsored studies, Leef et al (2001) reported that infants were handled significantly less with the Giraffe OmniBed, especially when converted to incubator mode (from 6.9 handling events per hour maximum on a standard radiant warmer bed device to 1.6 times per hour on an OmniBed-closed). These authors concluded that the OmniBed is conducive to providing developmentally appropriate care—that is, medically fragile newborns are not exposed to a variety of visual, auditory, and tactile stimuli that would not occur otherwise within the mother's womb. Consequences of such stimulation are unknown, although it seems reasonable to avoid excessive handling and inappropriate touches because of documented physiologic effects of procedural handling (Gressens et al, 2002).

In a second industry-sponsored study (Gaylord et al, 2001), there were no differences found in mean skin temperature among the four tested conditions in premature neonates (R = radiant warmer configuration of OmniBed; transition R to C = convection-warmed closed OmniBed and transition C to R). Mean heart rate, respiratory rate, blood pressure, and oxygen saturation were not statistically different among the four test conditions. These authors conclude that the Giraffe OmniBed provided thermal and physiologic stability across bed states, eliminating the risk of infant mishap as a result of bed transfer.

When transforming the Giraffe OmniBed from incubator to warmer bed and back, the closed-convection heat partition adapts to form a uniform open-radiant heating configuration with sequential alterations of air warming temperature, fan power, and radiant heat delivered while displaying all equipment and baby parameters in one control panel. For example, when returning to the closed-convection mode, the retracting radiant warmer pylon immediately disconnects electrical power to the warming element and opens a mechanical air vent to cool the reflector hood, avoiding overheating the infant upon descent. In closed-convection configuration, bidirectional airflow through a double wall construction provides a stably enclosed thermal environment. When either door port is opened, an air curtain minimizes infant heat loss.

Light and sound levels are carefully controlled within the OmniBed to promote infant health and development (Lynam, 2003). An alarm light easily visible to caregivers remains out of infant's view. The WhisperQuiet mode limits sound to create the most quiet and soothing environment possible. Alarm speakers are deflected to minimize any noise experienced by the baby. An in-bed scale further reduces infant handling.

In addition, servo-regulated humidification is supplied within the closed-incubator condition and can be set to a determined relative humidity between 70% and 80%, which is optimal to avoid excessive insensible water loss and electrolyte disturbances often experienced by premature neonates with extremely low birthweight in the first week of life when incubated dry. One recent non–industry-sponsored report of a clinical series compared the use of initial stabilization of babies with extremely low birthweight (<1000 g) under a radiant warmer followed by conventional incubation—dry versus use of humidity control in OmniBeds. The authors demonstrated that humidification improved care by decreasing fluid intake, with more stable electrolyte

balance, and growth velocity (Kim et al, 2010). The authors did not address the risk-benefit issue of humidification and infection.

The Giraffe Humidifier immerses a heating element in a reservoir of sterile, distilled water. Water temperature at equilibrium ranges 52° to 58° C, which is bactericidal to most organisms thriving at temperatures of 20 to 45° C (most human pathogens). As an added safety measure against reservoir contamination, water is boiled off the immersion element as the humidified air is passed inside the infant's compartment. Sterile humidity is created in a vapor state, with no airborne droplets. In a third industry-sponsored study by Lynam and Biagotti (2002), humidified OmniBeds (in vitro, air control mode at 35° C, and humidified to 65% relative humidity) were cultured after investigator inoculation with reservoir contamination with four waterborne pathogens over a 4-week incubating period. No infant environment culture revealed growth of any pathogen. The authors concluded that there is no concern for an increased risk of infection to an infant when the reservoir is filled daily with sterile distilled water and the bed is routinely cleaned, according to their protocol.

LESS CONVENTIONAL TECHNIQUES

PLASTIC HOODS

Plastic hoods comprise rigid body shields sometimes used as miniature incubator hoods placed over infants on open radiant beds. Hoods are usually made of plastic (1 to 3 mm thick) and can obstruct the delivery of radiant heat to the baby's skin when placed between an infant and the radiant warming element. The plastic can form a heat sink, warming to 42° to 44° C, but disrupts the radiant warmer's servo control mechanism and is a poor strategy. In addition, such devices might not diminish insensible water loss, especially when used without humidity. Use with humidity—a technique often referred to as *swamping*, which has never been validated—encourages bacterial colonization with water born pathogens.

PLASTIC BLANKETS

Alternatively, a thin, flexible plastic wrap or polyethelene plastic "blanket" was introduced in 1968 for covering premature infants under radiant warmers (Baumgart, 1984; Baumgart et al, 1981, 1982a, 1982b). The blanket prevents convective heat loss and is thin enough to transmit almost completely radiant heat from the warmer. The flexible plastic molds closely around the infant's body (with care taken to avoid skin adhesion), conserves evaporation, and forms a microenvironment near the baby's body. The plastic acts as a mechanical barrier to prevent convective turbulence from disrupting this microenvironment. A two-thirds reduction in insensible water (and evaporative heat) loss under radiant warmers is prevented, resulting in less servo-controlled radiant heat delivery required to maintain body temperature in even the smallest infants. By moderating heat losses, oxygen consumption is reduced by approximately 10%. This reduction exactly matches the oxygen consumption cost of using radiant warmers reported by LeBlanc (1982). Risks of plastic blankets include sticking to immature skin, causing masceration and accidental airway obstruction in patients without intubation. In rare cases, partial detachment of the skin thermistor probe can result in life-threatening hyperthermia. Diligence is required to avoid these complications. The risk for abnormal bacterial colonization has not been evaluated.

A polyethylene plastic bag was evaluated by Vohra et al (1999) to promote temperature maintenance during delivery room resuscitation under radiant warmers and during subsequent transport of infants to the NICU. A significantly higher admission rectal temperature and survival was reported for infants at less than 28 weeks' gestation. A larger, randomized trial of this technique was performed, confirming the prevention of heat loss with a polyethylene bag but not the improvement in mortality (Vohra et al, 2004). Recently another large, randomized trial was performed to compare polyethylene caps with polyethylene bags; it found that both methods were more effective than conventional treatment in improving NICU admission temperature for infants at less than 29 weeks' gestation (Trevisanuto et al, 2010).

SEMIPERMEABLE POLYURETHANE SKIN

A semipermeable, semiocclusive polyurethane dressing (Tegederm [3m Corporation, Maplewood, Minnesota] or Opsite [Smith & Nephew, London, United Kingdom]) can be applied like an artificial skin to shield premature infants with very low birthweight. These breathing polyurethane plastics do not cause skin breakdown and are often used to dress central venous catheter sites. Temperature probe detachment is less likely to occur because of skin adherence. These dressings can also be tailored to avoid airway obstruction. Insensible water loss may be reduced more than 30% with these dressings, and after carefully removing them the skin's naturally developing keratin moisture barrier may be preserved. Porat and Brodsky (1993) and Bhandari et al (2005) demonstrated that an adherent polyurethane layer over the torso and extremities of infants with very low birthweight improved fluid and electrolyte balance, reduced the occurrences of patent ductus arteriosus and intraventricular hemorrhage, and improved survival. Further study is required to demonstrate the safety of this technique.

PETROLEUM OINTMENTS

Another occlusive dressing for the skin of preterm infants with low birthweight during the first week of life is the application of Aquaphor (Biersdorf Co, Hamburg, Germany). Although early results were encouraging for preserving skin integrity and perhaps controlling excessive dehydration in dry incubators, the findings of a multicenter randomized trial were not so laudable (Edwards et al, 2004). Anecdotal reports suggest that bacterial infections may actually be more common with use of this technique. Clinicians should exercise critical judgment before adopting this practice.

KANGAROO CARE

Kangaroo care connotes warming by skin-to-skin contact with the mother or father, where premature infants are held naked between the axilla or the breasts, mimicking a kangaroo's pouch. First implemented in Bogota,

Columbia, this method was popularized for nonintubated premature infants in Scandinavian and European countries in the 1980s. Early studies suggested a significant reduction in early mortality and morbidity in premature infants weighing less than 1.5 kg and who are nursed by kangaroo care. Behavioral studies demonstrated more stable sleep patterns, less irritability at 6 months of age, and more eye contact with caregivers in infants nursed with kangaroo care. Kangaroo care has been shown to promote a thermal-neutral metabolic response and temperature stability in stably growing premature babies. Moreover during kangaroo care, infants with bronchopulmonary dysplasia have better oxygenation, and other infants show less periodic breathing and reduced apnea. In the modern nursery, kangaroo care be initiated during mechanical ventilation in uncomplicated patients. The infant should be placed between breasts with maximum skin contact and should be covered with a blanket to avoid outward convective and evaporative heat losses. After initial sessions of 30 minutes to 1 hour with careful intermittent temperature monitoring, periods up to 4 hours may be achieved successively. Kangaroo care integrates the family into the neonatal intensive care team. No adverse reports have been published, and use in many nurseries is on the rise.

SPECIAL CASES

EXTREMELY LOW-BIRTHWEIGHT INFANTS

Case Presentation

A baby boy (23⅐ weeks' gestation, weighing 510 g) was born limp, cyanotic, with no respiratory effort, and a heart rate less than 100 beats/min. The baby was resuscitated under a radiant warmer and dried, and a stocking cap was placed over the head. The warmer's temperature probe recorded a low skin temperature because it did not attach well to skin. The radiant warmer was on full power to compensate for this low probe reading. After resuscitation, the baby was transported to the NICU in an incubator preheated to a temperature of 35° C. On arrival, the baby was weighed quickly and placed onto a preheated radiant warmer bed. Skin probe (servo control) temperature registered 33° C, with a rectal temperature of 35° C and axillary temperature of 34° C. The radiant warmer set point was targeted at 37° C, and temperatures were monitored every 15 minutes. A plastic blanket was used to minimize heat loss. Heated and 100% humidified air from a respiratory pack was run underneath the blanket. next, the baby was prepared with iodine solution and draped completely for umbilical catheterization (a 30-minute procedure). Over the first 2 hours of life, rectal temperature increased only to 34.5° C. The baby was transferred into a preheated and humidified incubator regulated by a skin probe set at 37° C. Two light bulbs (250 W) were positioned over the incubator hood for supplemental heat and for warming during any procedure requiring opening the incubator (e.g., serial weight determinations). Over the next 12 hours the baby had difficulty maintaining temperature despite incubator air temperature running near a set temperature of 37° C, and sometimes greater than 38.5° C.

Discussion

Temperature maintenance of an extremely premature infant should be part of resuscitation from the time of delivery. Despite radiant warming in the delivery room and convective incubation during transport, this baby had hypothermia on admission to the NICU. Low admission temperature correlates with increased mortality rates in these infants. They are born wet and prone to excessive transepidermal evaporative and convective heat losses. In addition, heat loss can be exacerbated by suboptimal radiant heating; blowing noncontrolled warm, humidified air under plastic blankets, which is probably not as effective as the still air envelope conserved by the blanket; and the pressure for performing procedures with surgical drapes that block radiant heat delivery.

Quick drying, proper placement directly under the radiant heater at birth, and covering the head are small but important steps of temperature resuscitation. Other techniques might be considered from birth, such a use of a plastic bag described by Vohra et al (1999) or a plastic blanket or polyurethane drape during umbilical catheterization. Finally, transferring infants into incubators before adequately rewarming them under a radiant warmer can prolong thermal recovery in hypoxic subjects who are incapable of generating enough metabolic heat to recover. The use of light bulbs to provide supplemental radiant heat in incubators attests to the incubator's intrinsic operating power deficiency (i.e., seeking to reduce heat loss, rather than rewarm cold babies). Moreover, such supplemental radiant heat sources are not controlled, produce more radiation in the visible light range, and are inefficient and potentially dangerous for promoting burns if placed too close to the infant's skin.

There are few data describing the best rate of rewarming. Cold-stressed babies should probably be nursed under a servo-controlled radiant heat source, and heat loss should be minimized. During rewarming the infants should be closely monitored, and heat delivery should be servo controlled. A rate of approximately 0.5° to 1° C per hour seems reasonable, but it might not be achievable. Profound cardiovascular and electrolyte disturbances characterize rewarming. Alternatively, a preheated and humidified incubator can be used to rewarm infants, although the rate may be slower. The incubator air or skin servo control temperature can be set 1° C higher than the baby's temperature and gradually increased until a normal core temperature is achieved. Hybrid incubators that can also be used as radiant warmer beds are available and are helpful in rewarming scenarios.

NEONATAL FEVER

Problem of Temperature Elevation

There is no universally accepted definition of neonatal fever. Craig (1963) defined *neonatal pyrexia* as a rectal (core body) temperature greater than 37.4° C; however, other investigators accept temperatures up to 37.8°C as normal. Between 1% and 2.5% of all newborns admitted to the nursery develop fever, judged by rectal or axillary temperatures and depending on the limits chosen. Fever is an inconsistent and infrequent sign of sepsis (fewer than 10%

of febrile neonates have culture-proven sepsis), and temperature elevation may be seen with several other clinical entities.

Mechanisms Producing Neonatal Fever

Mechanisms producing neonatal fever are understood incompletely and result from disturbances in the complex interactions between heat conservation and heat dissipation mechanisms. Fever can occur when immunogenic pyrogens (commonly prostagladin [PG E2]) leads to upward displacement of the normal thermal set-point in the hypothalamus, leading to activation of heat conservation and physiologic heat-generating responses. Generally heat conservation starts with peripheral vasoconstriction and is followed by thermogenesis (generally nonshivering in neonates) while the new set-point is achieved. It is important to note that newborn infants of different animal species react in peculiar ways to different known pyrogens. Human newborns can have severe bacterial infections without increased body temperature.

In addition to pyogenic mechanisms of febrile response in newborns, other phenomena can lead to elevated of body temperature. Newborn infants have poor heat dissipation mechanisms (absence of sweating); therefore exposure to excess heat or insulation (e.g., excessive swaddling) can quickly increase their core temperature. Such overheating commonly occurs when term babies are nursed in uncontrolled incubators or under radiant warmers. Temperature elevation can also occur with increased infant metabolic rate such as that seen with skeletal muscle rigidity and status epilepticus. Another cause of temperature elevation is occasionally observed in healthy, breast-feeding newborn infants on the third to fourth day of life, and it is believed to result from dehydration caused by insufficient milk production. Finally, there are more recent reports of an increased incidence of neonatal fever in infants of mothers receiving epidural analgesia. The mechanisms for temperature elevation in these latter instances are unknown.

Determining the Cause of Fever

Sepsis is an uncommon cause of fever. Paradoxically, neonates with sepsis more frequently have hypothermia as well. However, sepsis is probably the most treatable life-threatening illness occurring in febrile newborn infants, especially those with temperature elevations to greater than 38° to 39° C, who are more likely to have bacteremia, purulant menigitis, and pnemonia. Most neonatal febrile episodes are noted in first day of life (54% in one series); however, any fever occurring on the third day of life and body temperature greater than 39° C have both been correlated with a significantly higher chance of bacterial disease. Severe temperature elevation is also associated with viral disease, particularly herpes simplex encephalitis; therefore work-ups for sepsis in these infants should include lumbar puncture.

Hyperthermia has been reported in tiny premature infants as a complication of improper use of shielding devices under either convection-warmed incubator or radiant warmer conditions. When incubated, babies should always have a strictly monitored and controlled source of heat. Fever secondary to overheating, particularly associated with incubators, is more common in equatorial and tropical countries.

Dehydration is an infrequently recognized cause of fever in the newborn period. Dehydration occurring in healthy term infants between the third and fourth day of life was noted previously, and it is probably the result of inadequate milk intake. Dehydration fever is commonly seen in large breastfed babies whose milk intake is poor and who may be exposed to high environmental temperatures during the summertime or in tropical areas. Body temperature can range between 37.8° and 40° C. Rehydration leads to resolution of fever and is key to the diagnosis of dehydration fever.

In two reports (Lieberman et al, 1997; Pleasure and Stahl, 1990), fever was more common in neonates born to mothers receiving epidural analgesia during labor when compared with those without analgesia (7.5% versus 2.5% and 14.5% versus 1%, respectively). One of these reports (Lieberman et al, 1977) observed more frequent sepsis evaluations and antibiotic use in the offspring of women receiving epidural analgesia. With the increasing use of epidural analgesia during labor, recognizing epidural neonatal fever is an important consideration when evaluating a febrile neonate.

Unusual and uncommon causes of neonatal fever include neonatal typhoid fever and congenital malaria, which should be considered in immigrant populations or in third-world countries. An increase in unexplained neonatal fevers was associated with the introduction of routine hepatitis B vaccination versus historical controls (Lewis et al, 2001), but this was not confirmed in a subsequent, large prospective clinical study (Lewis et al, 2001). In addition, temperature elevations may be seen with hypothalamic or other central nervous system malformations or masses. Subarachnoid or other intracranial hemorrhages may also be associated with temperature elevation. On rare occasions, neonatal spinal neurenteric cyst can manifest with long-lasting neonatal fever and should be considered in the differential diagnosis of acute myelopathy with persistent fever in infancy (greater than 3 weeks' duration). The presence of myelopathy will help to establish this diagnosis.

Management

The clinical problem is that fever may be the only indication of severe bacterial disease. The relevant perinatal history should be evaluated for risk factors mitigating a laboratory evaluation, presumptive treatment for infection, or both. Furthermore, signs that are suggestive of sepsis (e.g., diminished activity, irritability, seizures) should be considered. All neonates with fever should be evaluated for hydration, weight loss, and foci of infection (i.e., cellulitis, septic arthritis or osteomyelitis, omphalitis, and the presence of colonized foreign bodies, such as a central venous line).

However, febrile neonates without clinical history or any signs of infection present a challenge with insufficient data in the literature regarding appropriate management. An infant's environment should be examined for overheating. In breastfeeding, infants with fever at 3 to 4 days of age and excessive weight loss, dehydration fever should be considered and treated to establish this diagnosis. Mothers

receiving epidural analgesia often manifest shivering with their temperature rise, and they experience a rapid defervescence after discontinuing the epidural infusion. Recognition of this pattern may avoid unnecessary sepsis evaluations in neonates with early fever.

THERAPEUTIC HYPOTHERMIA FOR BRAIN PROTECTION FOLLOWING NEONATAL ASPHYXIA

Since 2005, therapeutic hypothermia has been considered the standard of care for a highly selected population of near-term and term infants suffering hypoxic-ischemic events after birth, or after medically witnessed cardiopulmonary arrest and resuscitation. Two randomized studies suggest that cerebral cooling with either whole body cooling to a core temperature of 33.5° C (considered moderate hypothermia) or selective head cooling to approxmately 10° C (with mild whole-body cooling to 34° C) reduces the risk for death or moderate to severe neurologic injury from approxiately two thirds, to less than half (Gluckman et al, 2005; Shankaran et al, 2005). In the United States, the National Institutes of Health Institute of Child Health and Human Development Experts Panel Workshop held in May 2005 emphasized using standardized protocols adapted from these randomized trials for hypothermia treatment, and it recommended continual follow-up until school age to develop and better refine therapy for treating moderate to severe clinical neonatal encephalopathy observed in term or near-term neonates (Higgins et al, 2006).

The Children's National Medical Center (CNMC) has adapted the Neonatal Network's whole-body hypothermia protocol (Shankaran et al, 2005). In addition, CNMC provides continuous electroencephalogram (EEG) neurologic monitoring as part of a protocol, without consideration of the EEG as a criteria for initiating cooling. A full montage video-EEG (using a modified International 10-20 system accepted for neonates) is recorded by computer for 120 hours after birth to include cooling and rewarming recovery. EEG data are displayed on a centralized monitoring station and reviewed at least daily for every patient treated for hypothermia. Amplitude-integrated EEG is also reviewed for characterization of background pattern and for detection of seizures that can contribute to evolving brain injury and are treated aggressively. Automated seizure detection software is confirmed on raw EEG signals by an electrophysiology neonatal neurologist who is integrated into the program. To receive cooling therapy, infants must be at 34 weeks' gestation or greater, arrive for treatment within 6 hours of birth, and have experienced a hypoxic-ischemic event. Evidence of hypoxic-ischemic injury includes: resuscitation being required at delivery, an umbilical vessel blood gas pH of 7.00 or less, or having a significant base deficit of at least –16. Also qualifying for therapy are blood gas disturbances within the first hour of life, with a pH of 7.01 to 7.15 and a base deficit of –10 to –15.9, along with an ominous perinatal history (e.g., fetal heart rate decelerations, umbilical cord prolapse or rupture, uterine rupture, severe maternal trauma preceding birth, abruption of the placenta, maternal life-threatening event requiring cardiopulmonary resuscitation). Signs of moderate to severe neonatal encephalopathy must also be present to qualify for hypothermia intervention: lethargy, complete stupor, diminished or completely absent spontaneous activity and/or aberrant muscle tone, weak or absent sucking and Moro reflexes with pupils fixed and constricted or unresponsive and dilated, fixed flexion or extension posturing of extremities, or a clinically observed seizure. Infants with such symptoms persisting for several days have an approximately 60% risk for death before hospital discharge, whereas a majority of survivors experience moderate to severe life-long neurodevelopmental disabilities (e.g., cerebral palsy, deafness, blindness, mental retardation, or recurrent seizures as in epilepsy).

Infants meeting these criteria are quickly examined at admission and then placed supine onto a water-filled cooling blanket that is precooled to 5° C (41° F). CNMC uses a Blanketrol II device (Cincinnati Sub-Zero, Cincinnati, Ohio) that is used commonly in the emergency department to reduce high fevers and in the operating room to promote hypothermia before and during reconstructive heart surgery. An esophageal temperature probe is placed into the distal third of the esophagus to monitor the infant's core temperature, and the thermostatic controller in the water mattress' cooling unit is set to 33.5° C. A second, larger pediatric-size blanket is also attached in parallel to the cooling system and is suspended at the bedside as a "sail" heat capacitor. Water circulates through both blankets exposed to both the baby and the room air temperature to diminish continuously monitored temperature fluctuations in esophageal temperature (less than ±0.5° C). Although CNMC uses a warmer bed platform as a crib, the overhead warmer is not turned on during the cooling period. Abdominal wall skin temperature is monitored with a surface probe that is available with the warmer bed (in monitor-only mode). Temperatures of the esophagus, skin, and axilla are thus monitored and recorded every 15 minutes for the first 4 hours of cooling, every hour for the next 8 hours, and every 4 hours during the remaining 72-hour period of hypothermia. CNMC's electronic medical record (Cerner) provides hourly esophageal temperature recording. After 72 hours, the set-point of the controller on the cooling system is increased by 0.5° C increments per hour to promote gradual rewarming. The Neonatal Network reported febrile rebound and seizures during rewarming (Shankaran et al, 2005); however, CNMC has not experienced this with continuous EEG monitoring over 24 to 48 hours throughout rewarming and a subsequent recovery period. After 6 hours, the esophageal probe and cooling blankets are removed, and anterior abdominal wall skin temperature is then regulated using the radiant warmer's servomechanism set at 36° to 36.5° C (i.e., warmer is turned on). The purpose of rewarming slowly is to avoid rapid shifts in electrolytes (calcium and potassium in particular), cardiac arrhythmias, and in rewarming hyperthermia, because fever promotes further brain injury. Infants otherwise receive routine neonatal intensive care, with continuous monitoring of vital signs. Mild sinus bradycardia (80 to 90 beats/min) and small decreases in mean arterial blood pressure (less than 20 mm Hg) are commonly observed and treated easily with volume and pressor infusions, according to CNMC's standard institutional guidelines for babies developmentally.

Frequent blood samples are monitored for glucose regulation (infants are restricted to 4 to 6 mg/kg/min of dextrose infusion), coagulopathy (in particular treating fibrinogen levels less than 150 mg/dL and platelet levels less than 80,000 per millimeter), and major organ failure (e.g., electrolytes, blood urea nitrogen, creatinine, liver enzymes).

CNMC's clinical experience over the past 3 years in more than 98 babies meeting strict criteria for therapeutic hypothermia has been commensurate with that reported from the Neonatal Network (Shankaran et al, 2005). Target esophageal temperature was achieved at 33.5 ± 0.5° C (range 33° to 34° C) in 30 to 60 minutes without a major circulatory mishap at CNMC. Continuous EEG monitoring has been instructive for intervening seizure activity (observed on EEG in approximately one quarter of infants shortly after admission). CNMC electrophysiologists observed general improvements in background voltages and patterns on EEG recordings during and after hypothermia. Specifically, improvement of background activity, appearance of sleep wake cycling, and disappearance of seizures has been observed at the time of rewarming (El-Dib et al, 2007). The Neonatal Network observed seizures emerging frequently during rewarming, hence the precaution in re-warming more slowly. CNMC is presently acquiring and reviewing infant neurologic and neuron-developmental follow-up data on a 6-month schedule through the first 2 years of life. CNMC has also made the clinical observation that the water mattress felt warm to the touch (i.e., warmer than the examiner's hand) during most of the cooling period (Baumgart et al, 2007). Median ambient temperature in CNMC's NICU during October 2007 (23.1° C; range, 20.9° to 25.4° C) was usually less than both the blanket water and baby temperatures. No infant had acidemia during cooling. Temperature gradients suggest that whole-body cooling is achieved through surface cooling from skin exposed to the ambient environment, and not actually by heat loss into the water-blanket. CNMC observers believe that the water matress simply incubates infants at a lower temperature. Except during the first 30 minutes, the blanket more often provided warmth to maintain esophageal temperature at 33.5° C. Whole-body cooling might also be provided by regulating an incubator air temperature or a radiant heater to maintain esophageal temperature. It has been important to CNMC's outreach education program to emphasize that referring (i.e., resuscitating) institutions should perform cardio pulmonary resuscitation under warm conditions to facilitate cardiac response according to Neonatal Resuscitation Program guidelines. Cold resuscitation is not advocated until after careful clinical evaluation of a stabilized patient has been performed at CNMC to meet therapeutic cooling criteria.

SUMMARY

The premature newborn with very low birthweight is extremely vulnerable to harsh fluctuations in physical environment. These infants require frequent assessments of skin, core, and air temperature and relative humidity to design an optimal strategy for thermal regulation. In caring for smaller babies, heat replacement is often required, and refinement of techniques to accomplish replacement without inducing hyperthermia is needed. The use of therapeutic hypothermia in highly selective cases at risk for brain injury is no longer considered novel.

CHAPTER 31

Acid-Base, Fluid, and Electrolyte Management

Michael A. Posencheg and Jacquelyn R. Evans

FLUID AND ELECTROLYTE BALANCE

Maintenance of fluid and electrolyte balance is essential for normal cell and organ function during intrauterine development and throughout extrauterine life. Pathologic conditions in the newborn often lead to disruption of the complex regulatory mechanisms of fluid and electrolyte homeostasis. Therefore a thorough understanding of the physiologic changes in neonatal fluid and electrolyte homeostasis and the provision of appropriate fluid and electrolyte therapy based on the principles of developmental fluid and electrolyte physiology are among the cornerstones of modern neonatal intensive care.

DEVELOPMENTAL CHANGES AFFECTING FLUID AND ELECTROLYTE BALANCE IN THE FETUS AND NEONATE

Developmental Changes in Body Composition and Fluid Compartments

Dynamic changes occur in body composition and fluid distribution during intrauterine life, labor and delivery, and the early postnatal period. Thereafter the rate of change in body composition and fluid distribution gradually decreases, with more subtle changes taking place especially after the first year of life (Friis-Hansen, 1961).

Changes during Intrauterine Development

In early gestation, body composition is characterized by a high proportion of total body water (TBW) and a large extracellular compartment (Brans, 1986; Friis-Hansen, 1983). As gestation advances, rapid cellular growth, accretion of body solids, and fat deposition result in gradual reductions in TBW content and extracellular fluid volume while the intracellular fluid compartment increases (Figure 31-1) (Friis-Hansen, 1983). In the 16-week-old fetus, TBW represents approximately 94% of total body weight, and approximately two thirds of the TBW is distributed in the extracellular and one third in the intracellular compartment. By term, TBW contributes only 75% of body weight, and almost half of this volume is located in the intracellular compartment. Therefore infants born prematurely have TBW excess and extracellular volume expansion compared with their term counterparts, with the majority of the expanded extracellular volume being distributed in the interstitium (Brace, 1992).

Changes during Labor and Delivery

Additional and more acute changes in TBW and its distribution occur during labor and delivery. Arterial blood pressure rises several days before delivery in response to increases in catecholamine, vasopressin, and cortisol plasma concentrations and translocation of blood from the placenta into the fetus. This rise in arterial blood pressure, along with changes in the fetal hormonal milieu and an intrapartum hypoxia-induced increase in capillary permeability, results in a shift of fluid from the intravascular to the interstitial compartment. This fluid shift results in an approximately 25% reduction in circulating plasma volume in the human fetus during labor and delivery (Brace, 1992). The postnatal increase in oxygenation and changes in vasoactive hormone production then restore capillary membrane integrity and favor absorption of interstitial fluid into the intravascular compartment. The ensuing gradual movement of fluid from the expanded interstitial space into the bloodstream aids in maintaining intravascular volume during the first 24 to 48 hours postnatally, when oral fluid intake may be limited. However, prematurity, pathologic conditions, or both can disrupt this delicate process and interfere with the physiologic contraction of the extracellular fluid (ECF) compartment in the immediate postnatal period.

In the fetus, body composition and fluid balance depend on the electrolyte and water exchange between mother, fetus, and amniotic space (Brace, 1986). Antenatal events can have significant effects on postnatal fluid balance. Maternal indomethacin treatment or excessive administration of intravenous fluids during labor can result in neonatal hyponatremia with expanded extracellular water content (Rojas et al, 1984; vd Heijden et al, 1988). Placental insufficiency or maternal diuretic therapy can impair fetal hydration, leading to decreases in extracellular volume, urine output, and amniotic fluid volume (Van Otterlo et al, 1977). The timing of cord clamping after delivery is another important factor significantly affecting total circulating blood volume and extracellular volume in the neonate. Immediate cord clamping does not allow for placental transfusion, but if the cord clamping is delayed only 3 to 4 minutes after delivery with the newborn positioned at or below the level of the placenta, up to 25 to 50 mL/kg of blood is transfused into the neonate, representing an approximately 25% to 50% increase in the total blood volume (Linderkamp, 1982; Yao and Lind, 1974). The onset of infant respiratory effort after birth also increases placental transfusion regardless of the infant's position (Philip and Teng, 1977).

Changes in the Postnatal Period

In the first few days and weeks after birth, the most important effects on the pace of further changes in body composition, TBW content, and its distribution are exerted by gestational and postnatal ages, the presence or absence of pathologic conditions, the immediate environment, and the type of nutrition. In normal conditions in the first few

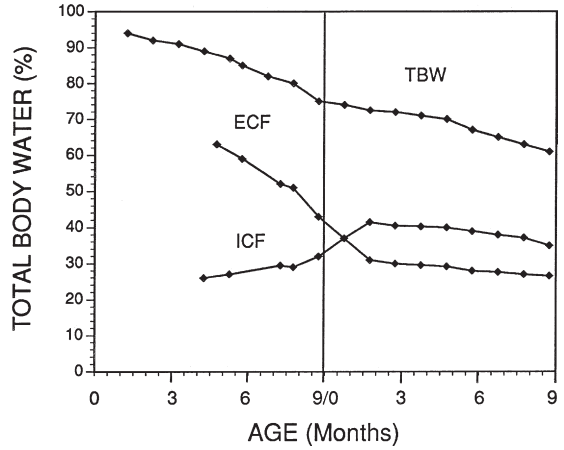

FIGURE 31-1 Total body water *(TBW)* content and its distribution between the extracellular fluid *(ECF)* and intracellular fluid *(ICF)* compartments in the human fetus, newborn, and infant from conception until 9 months of age. (*Data represent average values from Friis-Hansen B: Body water compartments in children: changes during growth and related changes in body composition*, Pediatrics *28:169-181, 1961.*)

days after birth, the postnatal increase in capillary membrane integrity favors absorption of the interstitial fluid into the intravascular compartment. The ensuing rise in circulating blood volume stimulates the release of atrial natriuretic peptide from the heart, which in turn enhances renal sodium and water excretion (Sagnella and MacGregor, 1984) resulting in an abrupt decrease in TBW and attendant weight loss. Although it is generally accepted that this postnatal weight loss is primarily due to the contraction of the expanded ECF compartment (Cheek et al, 1961), some water loss from the intracellular compartment can also occur, particularly in infants with extremely low birthweight (ELBW) and increased transepidermal water losses (Costarino and Baumgart, 1991; Sedin, 1995).

Healthy term newborns lose an average of 5% to 10% of their birthweight during the first 4 to 7 days of life (Brace, 1992); thereafter they establish a pattern of steady weight gain. Because preterm infants have an increased TBW content and extracellular volume, they lose an average of 15% of their birthweight during transition (Shaffer and Meade, 1989) and, depending on the degree of prematurity and associated pathologic conditions, these neonates only regain their birthweight by 10 to 20 days after birth (Figure 31-2).

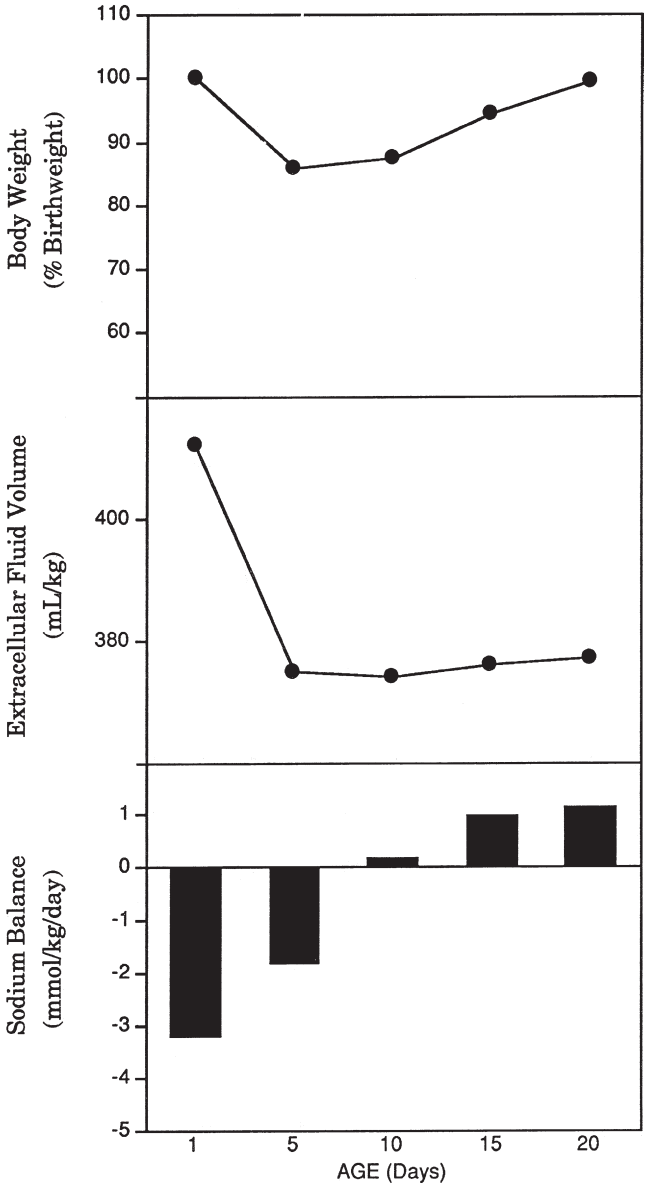

FIGURE 31-2 Postnatal changes in body weight (expressed in percent of birthweight), extracellular fluid volume (estimated by the bromide dilution method), and sodium balance (defined as the difference between sodium intake and urinary sodium excretion). (*From Shaffer SG, Weismann DN: Fluid requirements in the preterm infant*, Clin Perinatol *19:233-250, 1992.*)

Physiology of the Regulation of Body Composition and Fluid Compartments

Although human cells have the ability to adjust their intracellular composition, ultimate regulation of the intracellular volume and osmolality relies on the control of the extracellular compartment. Therefore the human body must be able to monitor the volume and osmolality of the extracellular compartment and to correct the changes resulting from its interaction with the environment.

Regulation of the Intracellular Solute and Water Compartment

The major intracellular solutes are the cellular proteins necessary for cell function, the organic phosphates associated with cellular energy production and storage, and the equivalent cations balancing the phosphate and protein anions (MacKnight and Leaf, 1977). Potassium is the major intracellular cation, and sodium is the major extracellular cation. The energy derived from the concentration differences for sodium and potassium between the intracellular and extracellular compartments is used for cellular work. Because changes in osmolality of the extracellular compartment are reflected as net movements of water in or out of the cell, regulation of ECF concentration ultimately controls the osmolality and size of the intracellular compartment (MacKnight and Leaf, 1977). This physiologic principle must be kept in mind by the neonatologist managing sick term and preterm neonates with disturbances of sodium homeostasis. Rapid changes in serum sodium concentration and thus in extracellular osmolality directly

affect the osmolality and size of the intracellular compartment and can lead to irreversible cell damage, especially in the central nervous system.

Regulation of the Intracellular-Extracellular Interface: The Interstitial Compartment

In the healthy term neonate, hydrostatic and oncotic pressures are well balanced, with both being approximately half those in the adult (Sola and Gregory, 1981). In normal physiologic conditions, movement of fluid across the capillary is determined by the direction of the net driving pressure ($[P_C - P_T] - [\pi_P - \pi_T]$) and the water and protein permeability characteristics of the capillary wall (Figure 31-3). At the arterial end of the capillary, intracapillary hydrostatic pressure (P_C) is high, and plasma oncotic pressure (π_P) is relatively low, resulting in a net movement of fluid out of the capillary. As filtration of relatively protein-poor fluid continues along the capillary, plasma oncotic pressure rises and intracapillary hydrostatic pressure drops; therefore on the venous side, fluid moves from the interstitium into the capillary, so that much of the filtered fluid is reabsorbed at the end of the capillary bed. The fluid remaining in the interstitium (arterial-venous side of the capillary) is drained by the lymphatic system. Interstitial hydrostatic (P_T) and oncotic (π_T) pressures remain virtually unchanged along the capillary bed. However, pathologic conditions readily disturb the delicate balance between the hydrostatic and oncotic forces, leading to an expansion of the interstitial compartment at the expense of the intravascular compartment. The increased interstitial fluid volume (edema) then further affects tissue perfusion by altering the normal function of the extracellular-intracellular interface. Box 31-1 summarizes the mechanisms for conditions resulting in interstitial edema formation in the neonate. There are also some important developmentally regulated differences between the newborn and adult relating to the pathogenesis of edema formation. Capillary permeability to proteins is increased during the early stages of development (Brace, 1992; Gold and Brace, 1988). Because neonatal capillary permeability is further increased under pathologic conditions (see Box 31-1), protein concentration in the interstitial compartment may approach that of the intravascular space, favoring further intravascular volume depletion and interstitial volume expansion. When sick neonates are treated with frequent albumin boluses, much of the infused albumin leaks into the interstitium, creating a vicious cycle of intravascular volume depletion and edema formation. If the cycle is not interrupted, it can result in the formation of anasarca, which has an extremely poor prognosis. In summary, the sick neonate has a limited capacity to maintain appropriate intravascular volume and to regulate the volume and composition of the interstitium. The ensuing intravascular hypovolemia and edema formation result in vasoconstriction and disturbances in tissue perfusion and cellular function with further impairments in the regulation of extracellular volume distribution.

Regulation of the Extracellular Solute and Water Compartment

The regulation of the volume and osmolality of the extracellular compartment ensures the integrity of the circulation and maintains the osmolality of the extracellular

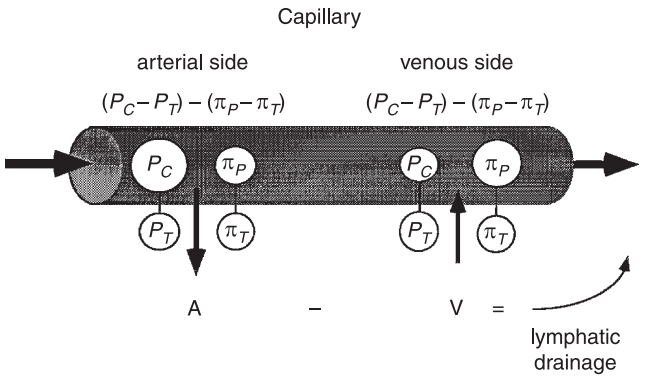

FIGURE 31-3 Filtration and reabsorption of fluid along the capillary under physiologic conditions.

BOX 31-1 Mechanisms for Conditions Causing Interstitial Edema in the Neonate

CONDTIONS FAVORING FLUID ACCUMULATION IN THE INTERSTITIAL SPACE BY CAUSING A DYSEQUILIBRIUM BETWEEN FILTRATION AND REABSORPTION OF FLUID BY THE CAPILLARIES

- Increased hydrostatic pressure
  - Elevated capillary hydrostatic pressure
    - Increased cardiac output
    - Venous obstruction
  - Decreased tissue hydrostatic pressure
  - Conditions associated with changes in the properties of the interstitial gel (edematous states, effects of hormones including prolactin)
- Decreased oncotic pressure gradient
  - Decreased capillary oncotic pressure
    - Prematurity, hyaline membrane disease
    - Malnutrition, liver dysfunction
    - Nephrotic syndrome
- Increased interstitial oncotic pressure is usually the result of increased capillary permeability
- Elevation of the filtration coefficient
  - Increased capillary permeability
    - Organs with large-pore capillary endothelium (liver, spleen)
    - State of maturity (preterm infants > term newborns > adults)
    - Production of pro-inflammatory cytokines (sepsis, anaphylaxis, hypoxic tissue injury, tissue ischemia, ischemia-reperfusion, soft tissue trauma, extracorporeal membrane oxygenation)
  - Increased capillary surface area
  - Vasodilation

CONDITIONS ASSOCIATED WITH DECREASED LYMPHATIC DRAINAGE

- Decreased muscle movement
  - Neuromuscular blockade and/or heavy sedation
  - Central and/or peripheral nervous system disease
- Obstruction of lymphatic flow
  - Increased central venous pressure
  - Scar tissue formation (bronchopulmonary dysplasia)
  - Mechanical obstruction (dressings, high mean airway pressure in mechanically ventilated newborns)

Modified from Costarino AT, Baumgard S: Neonatal water metabolism. In Cowett RM, editor: *Principles of perinatal/neonatal metabolism,* New York, 1991, Springer Verlag, pp 623-649.

compartment within 2% of the osmolar set point between 275 and 290 mOsm (Robertson and Berl, 1986). Blood pressure and serum sodium concentration (i.e., osmolality) are monitored by baroreceptors and osmoreceptors, respectively. The effector limb of the regulatory system consists of the heart, vascular bed, kidneys, and intake of fluid in response to thirst. The latter part of the effector system is inactive in critically ill term and preterm neonates whose fluid intake is completely controlled by caregivers. By regulating the function of the effector organs, several hormones have a role in the control of the extracellular compartment, including the renin-angiotensin-aldosterone system, vasopressin, atrial natriuretic peptide, brain (B-type) natriuretic peptide, bradykinin, prostaglandins, and catecholamines. Because volume changes in the extracellular compartment must be reflected by similar changes in the intravascular volume for effective operation of the regulatory mechanisms, regulation of the extracellular compartment relies on intact cardiovascular function and on the integrity of the capillary endothelium (Robertson and Berl, 1986). For example, under physiologic conditions, an increase in the extracellular volume is reflected by an increase in the circulating plasma volume, leading to rises in blood pressure and renal blood flow. The ensuing increase in glomerular filtration and urine output returns the extracellular volume to normal. In critically ill neonates, however, the capillary leak and reduced myocardial responsiveness resulting from immaturity and underlying pathologic conditions limit the increase in the circulating blood volume when extracellular volume expands. Thus, especially in sick preterm infants, blood pressure may rise only transiently, and renal blood flow may remain low after volume boluses as fluid rapidly leaks into the interstitium. Inappropriate central regulation of vascular tone results in vasodilatation, further decreasing effective circulating blood volume and compromising tissue perfusion; this leads to impaired gas exchange in the lungs, resulting in hypoxia with further increases in capillary leak. Unless interrupted by appropriate therapeutic measures, a vicious cycle with further deterioration readily occurs in the sick neonate.

Maturation of Organs Regulating Body Composition and Fluid Compartments

The heart, kidneys, skin, and endocrine system play the most important roles in the regulation of extracellular (and thus intracellular) fluid and electrolyte balance in the neonate. Immaturity of these organ systems, especially in infants with very low birthweight (VLBW), results in a compromised regulatory capacity, which must be noted when estimating daily fluid and electrolyte requirements in these patients.

Maturation of the Cardiovascular System

There is a direct relationship between gestational maturity and the ability of the neonatal heart to respond to acute volume loading (Baylen et al, 1986). The blunted Starling response of the immature myocardium results from its lower content of contractile elements and incomplete sympathetic innervations (Mahony, 1995). Because central vasoregulation and endothelial integrity are also developmentally regulated (Brace, 1992; Gold and Brace, 1988), an appropriate effective intravascular volume is seldom maintained in a critically ill preterm infant. Since regulation of the extracellular volume requires the maintenance of an adequate effective circulating blood volume, the immaturity of the cardiovascular system contributes to the limited capacity of sick preterm infants to effectively regulate the total volume of their extracellular compartment.

Maturation of Renal Function

The kidney has a crucial role in the physiologic control of fluid and electrolyte balance. It regulates extracellular volume and osmolality through the selective reabsorption of sodium and water, respectively. Immaturity of renal function renders preterm infants susceptible to both excessive sodium and bicarbonate losses (El-Dahr and Chevalier, 1990). In addition, the inability of the preterm infant to respond promptly to a sodium or volume load results in a tendency toward extracellular volume expansion with edema formation. Because prenatal steroid administration accelerates maturation of renal function (van den Anker et al, 1994), preterm infants treated with steroids in utero have a better capacity to regulate their postnatal ECF contractions. During the first few weeks of life, hemodynamically stable but extremely immature infants produce dilute urine and may develop polyuria because of their renal tubular immaturity. As tubular functions mature, their concentrating capacity gradually improves from the 2nd to 4th week of life. However, it takes years for the developing kidney to reach the concentrating capacity of the adult kidney.

Maturation of the Skin

Although term infants have a well-developed cornified layer of the epidermis, extremely immature neonates have only two or three cell layers in the epidermis (Cartridge-Patrick and Rutter, 1992). Because of the lack of an effective barrier to diffusion of water through the immature skin, transepidermal free water losses in the immature infant may be extremely high during the first few days postnatally. Gestational age, postnatal age, the pattern of intrauterine growth, and environmental factors have crucial roles in the magnitude of transepidermal free water losses (Figure 31-4). Although skin cornification rapidly increases, even in the extremely immature infant during the first few days after birth, full maturation of the epidermis does not occur for more than 28 days of age (Sedin, 1995). Chronic intrauterine stress (Hammarlund et al, 1983) and prenatal steroid treatment (Aszterbaum et al, 1993) also enhance maturation of the skin.

Increases in free water losses through the immature skin of the VLBW infant can result in early postnatal hypertonic dehydration with rapid changes in intracellular volume and osmolality. In many organs, especially the brain, these abrupt changes in intracellular volume and osmolality can lead to cellular dysfunction and ultimately cell death.

Maturation of End-Organ Responsiveness to Hormones Involved in the Regulation of Fluid and Electrolyte Balance

Several hormones, including but not limited to the renin-angiotensin-aldosterone system, vasopressin, atrial natriuretic peptide, and brain (B-type) natriuretic peptide, directly regulate the volume or composition of the extracellular compartment. These hormones exert their effects

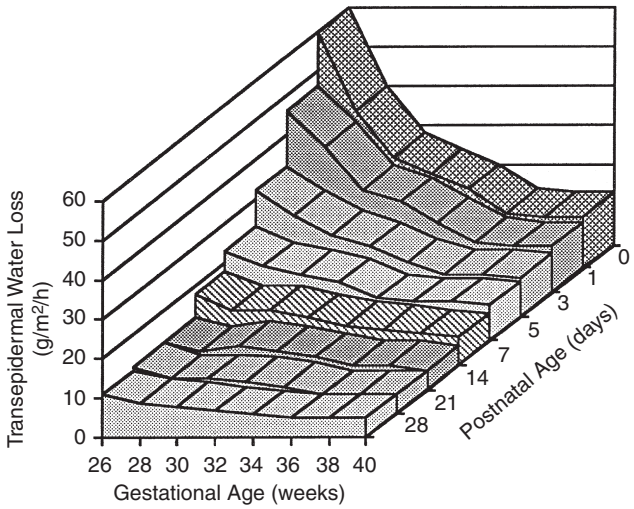

FIGURE 31-4 Transepidermal water loss in relation to gestational age during the first 28 postnatal days in infants who are appropriate for gestational age. There is an exponential relationship between transepidermal water loss and gestational age, the water loss being higher in preterm infants than in term infants. Transepidermal water loss is also significantly affected by postnatal age, especially in the immature preterm infant. The measurements were performed at an ambient air humidity of 50% and with the infants calm and quiet. (*From Hammarlund K, Sedin G, Stromberg B: Transepidermal water loss in newborn infants. VIII: Relation to gestational age and postnatal age in appropriate and small for gestational age infants*, Acta Paediatr Scand *72:721-728, 1983.*)

mainly by altering renal sodium and water excretion and by inducing changes in systemic vascular resistance and myocardial contractility. Other hormones, including the prostaglandins, bradykinin, and prolactin, modulate the actions of many of the regulatory hormones.

Renin-Angiotensin-Aldosterone System

Decreases in renal capillary blood flow stimulate renin secretion, which in turn initiates the production of angiotensin. Angiotensin induces vasoconstriction, increased tubular sodium and water reabsorption, and the release of aldosterone (Riordan, 1995). Aldosterone increases potassium secretion and further enhances sodium reabsorption in the distal tubule; therefore the primary function of this system is to protect the volume of the extracellular compartment and maintain adequate tissue perfusion (Bailie, 1992). However, its effectiveness in the neonate is somewhat limited by the decreased responsiveness of the immature kidney to the sodium- and water-retaining effects of these hormones (Sulyok et al, 1985). Vasodilatory and natriuretic prostaglandins generated in the kidney (Gleason, 1987) are the main counterregulatory hormones balancing the renal actions of the renin-angiotensin-aldosterone system. Therefore, when prostaglandin production is inhibited by indomethacin, the unopposed vasoconstrictive and sodium-retentive actions of the activated renin-angiotensin-aldosterone system contribute to the development of the drug-induced renal failure in the preterm infant (Gleason, 1987; Seri, 1995; Seri et al, 2002).

Vasopressin (Antidiuretic Hormone)

Vasopressin has its major effect in maintaining the osmolality of the extracellular compartment. Vasopressin selectively raises free water reabsorption in the kidneys and results in blood pressure elevation (Elliot et al, 1996). Plasma levels of vasopressin are markedly elevated in the neonate, especially after vaginal delivery, and its cardiovascular actions facilitate neonatal adaptation (Pohjavuori and Raivio, 1985). The high vasopressin levels are in part also responsible for the diminished urine output of the healthy term neonate during the first day of life. Under certain pathologic conditions, the dysregulated release of, or the end-organ unresponsiveness to, vasopressin significantly affects renal and cardiovascular functions and electrolyte and fluid status in the sick preterm and term infant. In the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), an uncontrolled release of vasopressin occurs in sick preterm and term infants, with resulting water retention, hyponatremia, and oliguria. In the syndrome of diabetes insipidus (DI), the lack of pituitary production of vasopressin or renal unresponsiveness to vasopressin results in polyuria, with increased thirst and hypernatremia.

Atrial Natriuretic Peptide

Via its direct vasodilatory and renal natriuretic actions, atrial natriuretic peptide (ANP) regulates the volume of the extracellular compartment in the fetus and neonate in a fashion opposite to that of the renin-angiotensin-aldosterone system (Iwamoto, 1992; Needleman and Greenwald, 1986; Seymour, 1985). ANP has a direct inhibitory effect on renin production and aldosterone release (Christensen, 1993).

The stretch of the atrial wall caused by an increase in the circulating blood volume is the most potent stimulus for the release of this hormone. Plasma levels of this hormone are high in the fetus (Claycomb, 1988). There are a few specific conditions in which the actions of atrial natriuretic peptide are directly relevant for the neonatologist. For example, the hormone is involved in the regulation of both the fluid shifts during labor (Brace, 1992) and the extracellular volume contraction during postnatal transition (Kojima et al, 1987; Ronconi et al, 1995; Rozycki and Baumgart, 1991; Tulassay et al, 1987). Furthermore, the oliguric effects of positive end-expiratory pressure ventilation are due in part to a decrease in atrial natriuretic peptide secretion (Christensen, 1993) along with the enhanced release of vasopressin (El-Dahr and Chevalier, 1990).

Brain (or B-type) Natriuretic Peptide

Similar to ANP, brain natriuretic peptide (BNP) is a hormone secreted by cardiac myocytes. Specifically, BNP is thought to be secreted by cardiac ventricular myocytes in response to increases in wall tension. Both of these peptides cause natriuresis, diuresis, and vasodilation while inhibiting the renin-angiotensin-aldosterone system (Gemelli et al, 1991; Holmes et al, 1993; Kojima et al, 1989). BNP levels increase rapidly after birth, with levels on the first day of life up to 20-fold higher than those at birth (Mir et al, 2003; Yoshibayashi et al, 1995), and correlate with the downward trend in pulmonary arterial pressure in the days after birth, unlike ANP (Ikemoto et al, 1996). BNP levels continue to fall during the first week of life (Koch and Singer, 2003; Mir et al, 2003). Infants and children with congestive heart failure have an elevated

BNP level, which is associated with decreased ejection fraction and increased heart failure score (Mir et al, 2002). In this way, BNP can be used as a surrogate for changes in ventricular volume from either pulmonary hypertension or ventricular overload. Clinical researchers have begun to investigate the utility of this peptide in diagnosing and managing cardiac disorders in neonates. The best-studied association to date is the relationship between BNP and a patent ductus arteriosus (PDA). Multiple studies have described a positive correlation between BNP level and a hemodynamically significant PDA (Choi et al, 2005; Czernik et al, 2008; Flynn et al, 2005; Sanjeev et al, 2005). BNP levels were associated with larger ductal size and degree of shunting, especially in infants older than 2 days (Flynn et al, 2005). Furthermore, significant correlations have been seen between BNP level and left atrial to aortic root diameter (Choi et al, 2005; Czernik et al, 2008) and diastolic flow velocity in the left pulmonary artery (Choi et al, 2005). BNP levels decline significantly with either medical or surgical therapy of a hemodynamically significant PDA (Choi et al, 2005; Sanjeev et al, 2005). The biologically inactive fragment N-terminal pro-B-type natriuretic peptide (NT-proBNP) has also been studied regarding its association with PDA with similar results (Farombi et al, 2008). NT-proBNP has a longer half-life (60 versus 20 minutes) than BNP and has also been associated with sepsis (Farombi et al, 2008). BNP has also been associated with other forms of cardiac dysfunction in neonates. Increases in BNP levels have been described in infants with persistent pulmonary hypertension of the newborn over the first 4 days of life, correlating with the degree of tricuspid regurgitation on an echocardiogram (Reynolds et al, 2004). BNP measurements can also be useful in differentiating infants in respiratory distress who have a cardiac etiology for their disease from those who do not (Ko et al, 2008; Reynolds et al, 2004). The usefulness of this test is limited by the variability of levels in the first few days of life as well as the variety of assays available to measure BNP levels. Its utility may ultimately lie in repeated measures in the same patient over time using the same assay and following trends.

Prostaglandins

Prostaglandins have a well-documented, counterregulatory role for the renal vascular and tubular effects of renin-angiotensin-aldosterone and vasopressin (Bonvalet et al, 1987). The inhibition of these actions of prostaglandins by indomethacin results in clinically important and sometimes detrimental renal vascular and tubular effects in the preterm infant. The actions of prostaglandins modulating the effects of the other regulatory hormones of neonatal fluid and electrolyte homeostasis are less well studied.

Prolactin

Prolactin plays a permissive role in the regulation of fetal and neonatal water homeostasis (Coulter, 1983; Pullano et al, 1989). High fetal plasma prolactin levels contribute to the increased tissue water content of the fetus. Interestingly, postnatal prolactin levels remain high in the preterm neonate until approximately the 40th postconceptional week (Perlman et al, 1978).

MANAGEMENT OF FLUID AND ELECTROLYTE HOMEOSTASIS

General Principles of Fluid and Electrolyte Management

Fluid and electrolyte management is the cornerstone of neonatal intensive care, and appropriate management requires an understanding of the previously outlined physiologic principles and careful monitoring of key clinical data. Requirements vary substantially from infant to infant and in the same infant over time; therefore intakes must be individualized and frequently reassessed. The primary goals are to maintain the appropriate ECF volume, ECF and intracellular fluid osmolality, and ionic concentrations.

Assessment of Fluid and Electrolyte Status

Maternal conditions during pregnancy, drugs and fluids administered to the mother during labor and delivery, and specific fetal and neonatal conditions all affect early fluid and electrolyte balance. Excessive administration of free water or oxytocin use in the mother can result in hyponatremia in the neonate. Maternal therapy with indomethacin, angiotensin-converting enzyme inhibitors, furosemide, and aminoglycosides can all adversely affect neonatal renal function. A newborn's history of oligohydramnios or birth asphyxia may also alert the clinician to the possibility of abnormal renal function. In young infants, altered skin turgor, sunken anterior fontanel, and dry mucous membrane are not sensitive indicators of dehydration, but tachycardia, hypotension, and metabolic acidosis may be seen when intravascular volume is moderately to severely affected. In addition, edema usually occurs early when there is volume overload. Serial measurements of body weight, intake and output, and serum electrolytes will usually provide the most precise and accurate information regarding overall fluid status. Appropriate fluid balance in the first few days after birth is associated with a urine output of 1 to 3 mL/kg per hour and a weight loss of 5% to 10% in term infants and 10% to 15% in preterm infants. In critically ill infants and in situations of altered homeostasis, additional clinical data that may help in diagnosis and management include blood urea nitrogen, serum and urine osmolarity or specific gravity, urine electrolytes and serum bicarbonate, along with close monitoring of blood pressure and heart rate. The frequency of monitoring depends on the extent of immaturity and the severity of the fluid and electrolyte disturbance and of the underlying pathologic condition.

Water Homeostasis and Management

Water Losses

Free water losses occurring through the skin and the respiratory tract are considered insensible losses, whereas the sensible water losses are composed of the amounts lost through urine and feces. Urine output is the most important source of sensible water loss. Extremely preterm infants without systemic hypotension or renal failure usually lose 30 to 40 mL/kg/day of water in the urine on the first postnatal day and approximately 120 mL/kg/day by the third day. In stable, more mature preterm infants born after the 28 weeks' gestation, urinary water

loss is approximately 90 mL/kg/day on the first postnatal day and 150 mL/kg/day by the third day (Coulthard and Hey, 1985). Because of their renal immaturity, preterm neonates have a tendency to produce dilute urine, thereby increasing their obligatory free water losses.

Normal water losses in the stool are less significant, amounting to approximately 10 mL/kg/day in term infants and 7 mL/kg/day in preterm infants during the first postnatal week (Sedin, 1995). Water losses in the stool increase thereafter and are influenced by the type of feeding and the frequency of stooling.

Gestational age, postnatal age, and environmental factors determine the amount of daily insensible water losses through the skin (see Figure 31-4). During the first few postnatal days, transepidermal water losses may be 15-fold higher in extremely premature infants born at 23 to 26 weeks' gestation than in term neonates (Sedin, 1995). Although the skin matures rapidly after birth, even in extremely immature infants, insensible losses are still somewhat higher at the end of the first month than in the term counterparts. Prenatal steroid exposure is associated with substantially less insensible water loss (IWL) in premature infants (Aszterbaum et al, 1993; Omar et al, 1999; Sedin, 1995).

Among environmental factors, ambient humidity has the greatest effect on transepidermal water loss. In extremely immature neonates, a rise in the ambient humidity of the incubator from 20% to 80% decreases the transepidermal water loss by approximately 75% (Sedin, 1995). However, the use of an open radiant warmer more than doubles transepidermal water losses (Flenady and Woodgate, 2003). Applying a plastic heat shield while the infant is under the warmer can decrease transepidermal water loss by 30% to 50% (Costarino et al, 1992). At low ambient humidity, phototherapy increases transepidermal water losses by approximately 30%. However, one study showed that if the ambient humidity is at least 50% in the incubator, regular phototherapy lamps will not increase the transepidermal water loss in infants older than 28 weeks' gestation (Sedin, 1995). On the other hand, halogen spotlight phototherapy increases transepidermal water loss in premature infants by 20% despite constant skin temperature and relative humidity (Grunhagen et al, 2002). Newer light-emitting diode phototherapy devices are not associated with significant transepidermal water loss or changes in cerebral hemodynamics (Bertini et al, 2008). Other factors that increase IWL include activity, airflow, elevated body, and environmental temperature as well as skin breakdown and skin or mucosal defects (e.g., gastroschisis, epidermolysis bullosa).

Insensible water losses from the respiratory tract depend mainly on the temperature and humidity of the inspired gas mixture and on the respiratory rate, tidal volume, and dead space ventilation. In a healthy term newborn, the water loss through the respiratory tract is approximately half the total IWL if the ambient air temperature is 32.5°C and the humidity is 50% (Sedin, 1995). However, in infants undergoing mechanical ventilation there will be no insensible losses through the respiratory tract if the ventilator gas mixture is humidified at body temperature.

Extraordinary losses are also seen in the neonate requiring intensive care. The most commonly encountered extraordinary water losses occur when a nasogastric tube is placed under continuous suction (to be discussed later in this chapter). Large losses may also occur in association with chest tubes, other drains, ostomies, and fistulas as well as with emesis or diarrhea.

Management of Water Requirements

Appropriate management requires estimating any existing deficits or surpluses, calculating ongoing maintenance needs because of usual sensible and insensible losses and growth and additional needs as a result of extraordinary losses. The infant's prenatal history, birthweight, gestational age, and need for mechanical ventilation and the environment in which the infant is to be cared for should be considered when determining initial fluid and electrolyte needs. Frequent reevaluations are necessary. The most useful parameter for monitoring fluid balance is the weight of the baby, as rapid changes in weight will reflect changes in water balance. Serial weights can be used to estimate the IWL using the following formula:

$$\text{IWL} = \text{Fluid intake} - \text{Urine output} + \text{Weight loss } \textit{or}$$

$$\text{IWL} = \text{Fluid intake} - \text{Urine output} - \text{Weight gain}$$

It is reasonable to initiate fluid volume based on the sum of an allowance for sensible water loss of 30 to 60 mL/kg/day and the estimated IWL. Figure 31-4 shows usual IWL ranges by gestational and postnatal age. Factors previously outlined that predictably affect IWL should be considered when prescribing fluids. Prevention of excessive IWL rather than replacement of increased IWL is associated with fewer complications in the preterm neonate and usually can be achieved by modifying the infant's environment. See Table 31-1 for usual maintenance fluid administration based on birthweight. These numbers are guidelines for initial management only; the approach must subsequently be individualized based on laboratory values and other clinical data.

It is important to remember that the TBW excess and extracellular volume expansion of preterm infants implies that their negative water and sodium balance during the first 5 to 10 postnatal days (see Figure 31-2; Shaffer and Meade, 1989) represents an appropriate adaptation to extrauterine life and should not be compensated for by increased fluid administration and sodium supplementation. If this principle is not followed and a positive fluid balance (i.e., weight gain) is achieved during the transitional period, preterm infants are at higher risk of a more severe course of respiratory distress syndrome (Shaffer and Weismann, 1992) and a higher incidence of patent ductus arteriosus (Bell et al, 1980), congestive heart failure (Bell et al, 1980),

TABLE 31-1 Estimated Maintenance Fluid Requirements

	Fluid Requirements (mL/kg/day)			
Birthweight (g)	**Day 1**	**Day 2**	**Day 3-6**	**≥ Day 7**
<750	100-140	120-160	140-200	140-160
750-1000	100-120	100-140	130-180	140-160
1000-1500	80-100	100-120	120-160	150
>1500	60-80	80-120	120-160	150

pulmonary edema (Shaffer and Weismann, 1992), necrotizing enterocolitis (Bell et al, 1979), and bronchopulmonary dysplasia (Oh et al, 2005; Van Marter et al, 1990).

Infants with ELBW and others with anticipated fluid problems should be weighed daily or twice daily. Serum sodium levels should be measured every 4 to 8 hours untilstabilized, usually by 3 to 4 days after birth, and urine output should be recorded and reviewed every 6 to 8 hours. Once data are available, fluids should be increased if weight loss is greater than 1% to 2% per day in term infants and 2% to 3% per day in preterm infants, if urine output is low, if urine specific gravity is rising, or if serum sodium concentration is rising. Overall, expected and appropriate weight loss in the first week of life is up to 10% in term infants and up to 20% in preterm infants. Conversely, fluids should be decreased if weight is not falling appropriately and serum sodium is decreasing. The goal is to reach 140 to 160 mL/kg/day of fluids by 7 to 10 days to allow for adequate caloric intake.

Treatment of Fluid Overload

Fluid overload commonly occurs in sick neonates, often because of the use of fluid bolus administration for hypotension. The diagnosis is based on weight gain, edema, and often hyponatremia. Overhydration can sometimes be prevented by the use of blood transfusions or dopamine instead of colloid or crystalloid, if appropriate, for blood pressure support. In addition to reducing the need for volume boluses, dopamine may facilitate the process of extracellular volume contraction via its renal and hormonal effects (Seri, 1995). Once overhydration has occurred, management is usually effected by 10% to 20% decrements of total daily fluid intake while carefully monitoring clinical and laboratory signs to ensure maintenance of adequate intravascular volume as well as normal glucose and electrolyte status while the ECF contraction occurs.

Treatment of Dehydration

Dehydration may be suspected based on clinical signs. The total water deficit may be estimated by using weight changes, calculating total inputs and outputs, and following serial sodium levels. Free water deficit (or excess) can be calculated as:

$$H_2O \text{ deficit (or excess) (L)} = [0.7 \times BW\,(kg)] \times \left\{ \frac{[Na\,(mEq/L)]_{current}}{[Na\,(mEq/L)]_{desired}} - 1 \right\}$$

In this formula, 0.7 × BW is the estimation of TBW.

When dehydration is diagnosed, correction should generally occur over 24 hours, with half correction over 8 hours and the remainder over the next 16 hours. Longer correction times are indicated when dehydration is accompanied by moderate to severe hypernatremia. Treatment is best approached by considering separately the fluid resuscitation requirements, fluid to replace current deficits and ongoing losses, and maintenance requirements, because the volume of the fluid, the composition, and the rate of replacement differ for each. Resuscitation of the intravascular volume to restore blood pressure and perfusion should be provided with boluses of isotonic saline (0.9% saline), and this volume is included in the initial half correction. The remaining deficit replacement volume should be with fluid of appropriate sodium content based on the serum sodium (see Sodium and Potassium Homeostasis and Management, later), usually 0.2% or 0.45% saline. Free water contents of the common intravenous fluids are listed in Table 31-2. Usual maintenance fluids and electrolytes must also be provided. Ongoing urine losses should be replaced volume for volume every 4 to 6 hours with a solution tailored to the urine's electrolyte concentration (usually 0.45% normal saline). Extraordinary losses caused by tubes, drains, emesis, diarrhea, and ostomies should always be sought in the dehydrated infant and also accounted for in fluid management. The composition of this latter replacement solution depends on the electrolyte concentration of the fluid loss. The most common extraordinary loss, gastric fluid, contains significant sodium and chloride. See Table 31-3 for approximate electrolyte compositions of body fluids.

Potassium replacement (usually by adding 20 to 40 mEq potassium per liter of replacement fluid) should not begin until adequate urine output is established. For additional details of fluid correction and sodium management, see the discussion under Management of Hypernatremia later in this chapter.

TABLE 31-2 Free Water Content (as Volume %) of Common Intravenous Solutions at Normal and High Serum Sodium Concentrations*

	Serum Sodium Concentration			
	145 mEq/L		195 mEq/L	
Intravenous Fluid	Isotonic (%)	Water (%)	Isotonic (%)	Water (%)
D_5W	0	100	0	100
0.2% saline	22	78	17	83
0.45% saline	50	50	39	61
0.9% saline	100	0	79	21
Lactated Ringer's solution	86	14	68	32

Modified from Molteni KH: Initial management of hypernatremic dehydration in the breastfed infant, *Clin Pediatr* 33:731-740, 1994.
*Note that isotonic saline provides 21% free water when given to a patient with a serum sodium concentration of 195 mEq/L and therefore will induce undesirable decreases in serum sodium concentration when used for volume resuscitation in the severely dehydrated hypernatremic neonate.

TABLE 31-3 Approximate Electrolyte Composition of Body Fluids (mEq/L)

Body Fluid	Sodium	Potassium	Chloride
Gastric	20-80	5-20	100-150
Small intestine	100-140	5-15	90-130
Bile	120-140	5-15	80-120
Ileostomy	45-135	3-15	20-115
Diarrhea	10-90	10-80	10-110

Sodium and Potassium Homeostasis and Management

Serum sodium values should be kept between 135 and 145 mEq/L. Sodium chloride supplementation at 1 to 2 mEq/kg/day should be started in preterm and sick term neonates

only after completion of the postnatal extracellular volume contraction, usually after the first few days of life or after more than 5% of birthweight is lost (Hartnoll et al, 2001). In general, as long as the infant's fluid balance is stable, maintenance sodium requirements do not exceed 3 to 4 mEq/kg/day, and providing this amount usually ensures the positive sodium balance necessary for adequate growth. Extreme prematurity and pathologic conditions associated with delayed transition or disturbance of fluid and electrolyte balance may significantly alter the infant's daily sodium requirement. For example, although the preterm infant has a limited ability to excrete a sodium load (Hartnoll, 2003), some of the most immature infants may have sodium requirements of as much as 6 to 8 mEq/kg/day because of the decreased capacity of their kidneys to retain sodium. Neonates recovering from an acute renal insult and preterm infants with immature proximal tubule functions who are in a state of extracellular volume expansion (Ramiro-Tolentino et al, 1996) may need daily sodium bicarbonate supplementation to compensate for their greater renal bicarbonate losses.

Hyponatremia

Hyponatremia (serum sodium <130 mEq/L) represents a deficit of sodium in relation to body water content and may be caused by either total body sodium deficit or free water excess. In both situations, total body water may be decreased (hyponatremia with volume contraction), normal, or increased (hyponatremia with volume expansion). Hyponatremia may be hypotonic, isotonic, or hypertonic. To initiate effective treatment, it is important to attempt to determine the primary cause of the hyponatremia and whether there is associated volume expansion or contraction. The most common cause of hyponatremia in the sick neonate is excessive administration or retention of free water. In these situations the total body sodium content is normal, and the appropriate treatment is restriction of free water intake and not administration of sodium. In situations of true sodium deficit, the deficits can be estimated by assuming 70% of total body weight as the distribution space of sodium. The formula for calculating sodium deficit is:

$$Na^+ \text{deficit (or excess) (mEq)} \approx 0.7 \times \text{kg} \times [(Na^+)_{\text{desired}} - [(Na^+)_{\text{actual}}]$$

In most situations of depletional hyponatremia, the sodium deficit should be replaced on a schedule that provides two thirds replacement in the first 24 hours and the remainder in the next 24 hours. Frequent measurements of serum electrolytes are needed to ensure that the correction is occurring appropriately. If the serum sodium concentration is less than 120 mEq/L, regardless of whether the hyponatremia is due to free water overload or total body sodium deficit, then correction of the serum sodium concentration up to 120 mEq/L is recommended with administration of 3% saline solution (513 mEq of sodium per liter). This correction should be done over 4 to 6 hours, depending on the severity of hyponatremia (Avner, 1995) and using the above formula. Although rapid intravenous bolus administration of 4 to 6 mL/kg of 3% saline solution has been effective in children with seizures or coma (Sarnaik et al, 1991), rapid and complete correction of low serum sodium concentration in adults with chronic hyponatremia has been shown to be associated with pontine and extrapontine myelinolysis. Once the risk of acute central nervous system symptoms has been minimized and serum sodium concentration has reached 120 mEq/L, complete correction of hyponatremia should be performed more slowly over the next 48 hours. In patients with asymptomatic hyponatremia whose serum sodium concentration exceeds 120 mEq/L, hypertonic infusions are not indicated. Additional therapy should be directed at fluid restriction if the hyponatremia is dilutional or sodium repletion if the hyponatremia is depletional. The use of 5% dextrose in water with 0.45% to 0.9% saline is a reasonable replacement fluid for depletional hyponatremia once the sodium is above 120 mEq/L. More stable infants with chronic sodium losses can also be corrected with enteral sodium chloride. Figure 31-5 summarizes the clinical evaluation and therapy of neonates with hyponatremia.

Hypernatremia

Hypernatremia (serum sodium >145 mEq/L) reflects a deficiency of water relative to total body sodium and is most often a disorder of water rather than sodium homeostasis. Hypernatremia does not reflect the total body sodium content, which can be high, normal, or low depending on the cause of the condition. Hypernatremia can also be associated with hypovolemia, normovolemia, or hypervolemia (Box 31-2). If hypernatremia is primarily due to changes in sodium balance, it can result from pure sodium gain or, more commonly, sodium gain coupled with a lesser degree of water accumulation or, rarely, water loss. The hypernatremia-induced hypertonicity causes water to shift from the intracellular to the extracellular compartment, resulting in intracellular dehydration and the relative preservation of the extracellular compartment. This shift is the main reason that neonates with chronic hypernatremic dehydration often do not demonstrate overt clinical signs of intravascular depletion and dehydration until late in the course of the condition.

Compared with other organs, the central nervous system has a unique adaptive capacity to respond to the hypernatremia-induced hypertonicity, leading to a relative preservation of neuronal cell volume. The shrinkage of the brain stimulates the uptake of electrolytes such as sodium, potassium, and chloride (immediate effect) as well as the synthesis of osmoprotective amino acids and organic solutes (more delayed response). These idiogenic osmols aid in maintaining normal brain cell volume during longer periods of hyperosmolar stress (Trachtman, 1991). As long as hypernatremia develops rapidly (within hours), as in accidental sodium loading, a relatively rapid correction of the condition improves the prognosis without raising the risk of cerebral edema formation. Intracellular fluid accumulation does not occur because the accumulated electrolytes (sodium, potassium, and chloride) are rapidly extruded from the brain cells, and cerebral edema is unlikely. In these cases, reducing serum sodium concentration by 1 mEq/L per hour (24 mEq/L per day) is appropriate (Adrogue and Madias, 2000).

However, because of the slow dissipation of idiogenic osmols over a period of several days (Adrogue and Madias,

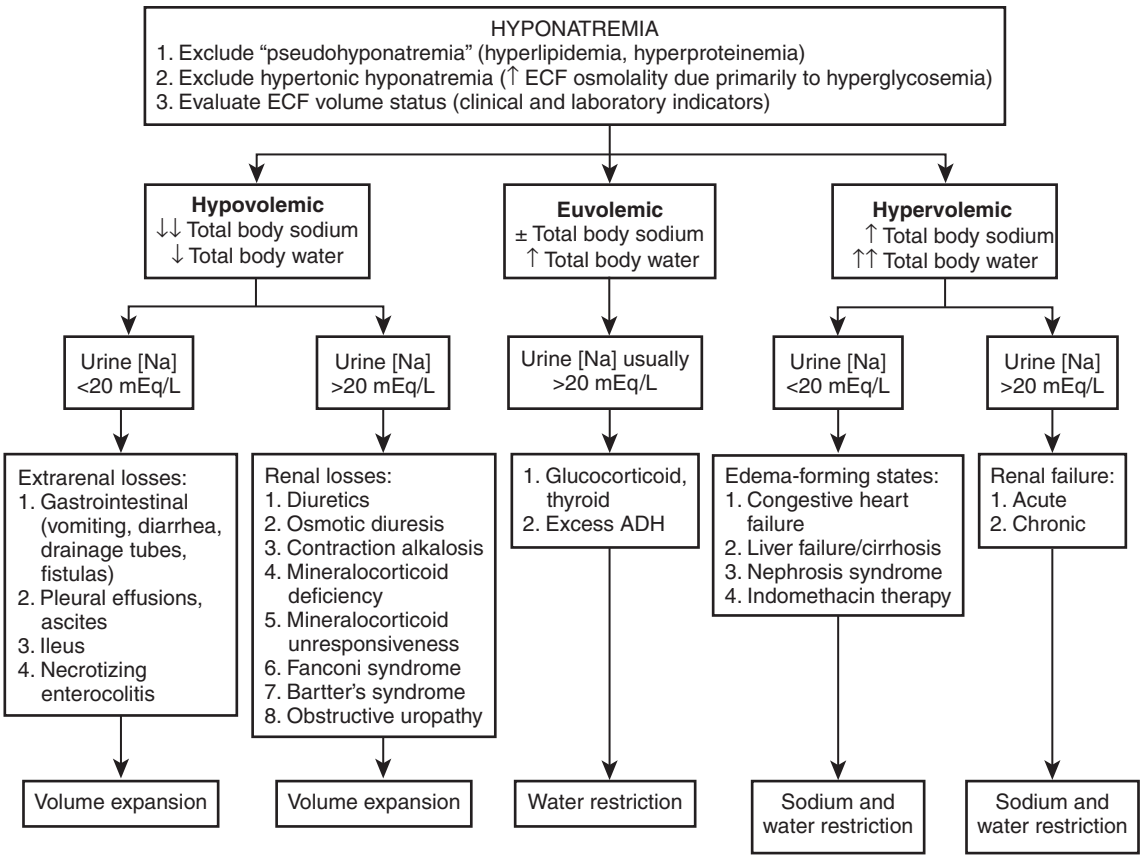

FIGURE 31-5 Flow diagram for the clinical evaluation and therapy of neonates with hyponatremia. *ADH*, Antidiuretic hormone; *ECF*, extracellular fluid. (*Modified from Avner ED: Clinical disorders of water metabolism: hyponatremia and hypernatremia*, Pediatr Ann *24:23-30, 1995*.)

2000), in cases of chronic hypernatremia or in cases in which the time frame is unknown, the hypernatremia should be corrected more slowly, at a maximum rate of 0.5 mEq/L per hour (12 mEq/L per day). If correction is performed more rapidly in these cases, the abrupt fall in the extracellular tonicity results in the movement of water into the brain cells, which have a relatively fixed hypertonicity because of the presence of the osmoprotective molecules. The result is the development of brain edema with deleterious consequences (Adrogue and Madias, 2000; Molteni, 1994).

In the breastfed term neonate, hypernatremia most commonly develops because of dehydration caused by inadequate breast milk intake (Molteni, 1994), but may also be caused by high sodium levels in maternal breast milk. Reduction in breastfeeding frequency has been shown to be associated with a marked rise in the sodium concentration of breast milk (Neville et al, 1991). A vicious cycle can ensue in which the infant sucks poorly, breast milk production drops, sodium concentration rises, and the infant becomes increasingly dehydrated, hypernatremic, and lethargic. Recognition may be delayed because these infants may appear quiet and content initially. Because this process is chronic, usually occurring over 7 to 14 days, signs of extracellular volume contraction are less prominent until the development of the full clinical presentation consisting of lethargy, irritability, abnormal muscle tone with or without seizures, and cardiovascular collapse

BOX 31-2 Conditions Causing Hypernatremia

HYPOVOLEMIC HYPERNATREMIA

Inadequate breast milk intake
Diarrhea
Radiant warmers
Excessive sweating
Renal dysplasia
Osmotic diuresis

EUVOLEMIC HYPERNATREMIA

Decreased Production of Antidiuretic Hormone

Central diabetes insipidus, head trauma, central nervous system tumors (craniopharyngioma), meningitis, or encephalitis

Decrease or Absence of Renal Responsiveness

Nephrogenic diabetes insipidus, extreme immaturity, renal insult, and medications such as amphotericin, hydantoin, aminoglycosides

HYPERVOLEMIC HYPERNATREMIA

Improperly mixed formula
$NaHCO_3$ administration
NaCl administration
Primary hyperaldosteronism

with renal failure. This presentation can be associated with serious central nervous system morbidity from both the hypertonicity (sagital or other venous sinus thrombosis, subdural capillary hemorrhage, white matter injury) and inappropriately rapid rehydration therapy (brain edema, myelinolysis).

In the extremely immature neonate, hypernatremia most commonly occurs from excessive transepidermal free water losses. The condition usually develops rapidly, within 24 to 48 hours after birth. The diagnosis is based on the attendant decrease in body weight and clinical signs of extracellular volume contraction. Prevention of this condition has been successful in the majority of immature neonates by frequent monitoring of serum electrolyte levels, appropriate adjustments of free water intake, and the use of humidified incubators (Modi, 2004).

The central and nephrogenic forms of diabetes insipidus are much less commonly encountered and result in hypernatremia because of the lack of production of and renal responsiveness to ADH, respectively. Hypernatremia can also develop in response to excessive sodium supplementation, mainly in the sick neonate receiving repeated volume boluses for cardiovascular support. In these cases, clinical signs of edema, increased body weight, and the history of volume boluses help to establish the diagnosis.

Treatment of Hypernatremia

Thorough analysis of the medical history and the changes in clinical signs, laboratory findings, and body weight usually aid in determining the major etiologic factor in hypernatremia and thus the appropriate treatment. In the critically ill infant, the cause of the serum sodium abnormality may be multifactorial however, and the treatment less straightforward. Although some cases of hypernatremia are a result of sodium excess with normal or high TBW, most cases in neonates are due to hypernatremic dehydration. Treatment of this condition is generally divided into two phases: the emergent phase where the intravascular volume is restored, usually by administration of 10 to 20 mL/kg of isotonic saline, and the rehydration phase, where the sum of the remaining free water deficit and usual maintenance needs are administered evenly over at least 48 hours.

The free water deficit can be calculated as:

$$H_2O \text{ deficit (or excess) (L)} = [0.7 \times BW \text{ (kg)}] \times \left\{1 - [NA^+ \text{ (mEq/L)}]_{\text{current}} / [NA^+ \text{ (mEq/L)}]_{\text{desired}}\right\}$$

In this formula, (0.7 × BW) is the estimation of TBW.

It is important to note that the amount of free water required to decrease the serum sodium by 1 mEq/L is 4 mL/kg with moderate hypernatremia, but only 3 mL/kg when the hypernatremia is as high as 195 mEq/L (Molteni, 1994). Therefore the amount of free water required to decrease serum sodium by 12 mEq/L over a 24-hour period when hypernatremia is moderate is calculated as:

$$\text{Free water required} = \text{Current weight (kg)} \times 4\text{mL/kg} \times 12\text{mEq/L} \textit{ or}$$
$$\text{Free water required} = \text{Current weight} \times 48 \text{ mL/kg/day}$$

And the amount of free water required to decrease serum sodium by 12 mEq/L over a 24-hour period when hypernatremia is severe is calculated as:

$$\text{Free water required} = \text{Current weight} \times 36 \text{ mL/kg/day}$$

The free water contents of the common intravenous fluids are listed in Table 31-2. In most mild to moderate hypernatremic states, during the rehydration phase, replacement fluids of 5% dextrose in 0.2% normal saline (31 mEq/L) or 0.45% normal saline (77 mEq/L) are appropriate. Infants with serum sodium levels greater than 165 mEq/L should initially be given 0.9% saline to avoid sudden drops in serum sodium concentration. When the serum sodium is greater than 175 mEq/L, however, normal saline will be hypotonic compared with the patient's serum. In these instances of severe hypernatremia, an appropriate amount of 3% saline (513 mEq/L) should be added to the intravenous (IV) fluid so that the sodium concentration is approximately 10 to 15 mEq/L less than the serum sodium level (Rand and Kolberg, 2001). The relative free water content of an IV solution for a specific patient with sodium perturbations can be calculated using the formula:

$$\text{Percentage of free water content} = 1 - (\text{IV fluid sodium} / \text{Serum sodium})$$

Serum electrolytes should be monitored every 2 to 4 hours until the desired rate of decline in serum sodium concentration is established. At this point, the frequency of the laboratory measurements can be relaxed to every 4 to 6 hours until the serum sodium concentration is less than 150 mEq/L. The speed of correction of hypernatremia depends on the rate of its development. This approach provides a reasonable chance that the serum sodium concentration will gradually decrease to the normal range over 2 to 4 days. Except in cases of acute massive sodium overload, the goal should be to drop the serum sodium concentration at a rate no greater than 1 mEq/L/h. A slower pace of correction of 0.5 mEq/L/h is prudent in patients with hypernatremia of chronic or unknown duration to avoid iatrogenic central nervous system sequelae.

Once serum sodium concentration, urine output, and renal function are normal, the patient should receive standard maintenance fluids, either intravenously or orally, depending on his or her condition. At this time, electrolyte status must still be monitored for an additional 24 hours to ensure that complete recovery has occurred. Hyperglycemia and hypocalcemia commonly accompany hypernatremia. The use of insulin to treat the hyperglycemia is not recommended, because it can increase brain idiogenic osmol content. Hypocalcemia should be corrected with appropriate calcium supplementation.

Potassium Homeostasis and Management

Serum potassium should be kept between 3.5 and 5 mEq/L. In the early postnatal period, neonates, especially immature preterm infants, have higher serum potassium concentrations than older persons. The etiology of the relative hyperkalemia of the newborn is multifactorial and

involves developmentally regulated differences in renal function, Na^+,K^+-ATPase activity (Vasarhelyi et al, 2000), and hormonal milieu. Exposure to prenatal steroids in premature infants is associated with a decreased incidence of hyperkalemia, believed to be due to improved renal function (Omar et al, 2000).

In general, potassium supplementation should be started only after urine output has been well established, usually by the third postnatal day. Supplementation should be started at 1 to 2 mEq/kg/day and increased over 1 to 2 days to the usual maintenance requirement of 2 to 3 mEq/kg/day. Some preterm infants may need more potassium supplementation after the completion of their postnatal volume contraction, because of their increased plasma aldosterone concentrations, prostaglandin excretion, and disproportionately high urine flow rates. Most term and preterm neonates will require potassium supplementation if they are receiving diuretics.

Hypokalemia

Hypokalemia in the neonate is usually defined as a serum potassium level of less than 3.5 mEq/L. Hypokalemia can occur from potassium loss due to diuretics, diarrhea, renal dysfunction, or nasogastric drainage from inadequate potassium intake or from intracellular movement of potassium in the presence of alkalosis. Except in patients receiving digoxin, hypokalemia is rarely symptomatic until the serum potassium concentration is less than 2.5 mEq/L. Electrocardiogram (ECG) manifestations of hypokalemia include flattened T waves, prolongation of the QT interval, or the appearance of U waves. Severe hypokalemia can result in cardiac arrhythmias, ileus, and lethargy.

Treatment of Hypokalemia

Hypokalemia is treated by slowly replacing potassium either intravenously or orally, usually in the daily fluids. Rapid administration of potassium chloride is not recommended, because it is associated with life-threatening cardiac dysfunction. In extreme emergencies, potassium can be given as an infusion over 30 to 60 minutes of not more than 0.3 mEq/kg potassium chloride. If hypokalemia is secondary to alkalosis, the alkalosis should be corrected before considering increasing the potassium intake.

Hyperkalemia

Hyperkalemia in the neonate is defined as a serum potassium level greater than 6 mEq/L in a nonhemolyzed specimen. It is important to understand that most of the body's potassium is contained within cells; therefore serum potassium levels do not accurately reflect total body stores. However, a serum potassium greater than 6.5 to 7 mEq/L can be life threatening, even if stores are normal or low, because of its effect on cardiac rhythm. ECG manifestations of hyperkalemia include peaked T waves (the earliest sign), a widened QRS configuration, bradycardia, tachycardia, supraventricular tachycardia, ventricular tachycardia, and ventricular fibrillation. Because pH affects the distribution of potassium between the intracellular and the extracellular space, serum potassium levels rise during acidosis, which may occur acutely. The clinician should be aware of the potential for life-threatening arrhythmias to occur in infants with chronic lung disease on diuretics and potassium supplements who develop a sudden respiratory deterioration with acidosis. Another common cause of hyperkalemia is renal dysfunction, of particular concern in very preterm and asphyxiated infants. In addition, infants who have suffered intraventricular hemorrhage or tissue trauma and those with intravascular hemolysis often have hyperkalemia caused by the release of potassium during breakdown of red blood cells. Finally, hyperkalemia may be one of the earliest manifestations of congenital adrenal hyperplasia.

Treatment of Hyperkalemia

When hyperkalemia is diagnosed, all potassium intake should be discontinued and the ECG should be monitored. Table 31-4 presents medications used in management of significant hyperkalemia. Calcium gluconate stabilizes cardiac membranes and alkali therapy, insulin, and inhaled albuterol (Singh et al, 2002) all rapidly enhance cellular uptake of potassium and can acutely drop serum potassium levels, but not decrease total body potassium. Intravenous furosemide and rectally administered sodium polystyrene sulfonate (Kayexalate) enhance potassium excretion and will lower total body stores, but they require several hours to take effect. Dialysis or exchange transfusion may be used when the hyperkalemia is life threatening and these measures do not result in improvement.

CLINICAL CONDITIONS ASSOCIATED WITH FLUID AND ELECTROLYTE DISTURBANCES

Extreme Prematurity

Infants born between 23 and 27 weeks' gestation, or with a birthweight of <1000 g (i.e., ELBW), are at particular risk for acute abnormalities of both fluid and electrolyte status in the immediate postnatal period. Their transepidermal water loss is much higher than that in more mature preterm neonates (see Figure 31-4), and it is difficult for their water balance to be maintained unless the excessive losses are prevented. It should be kept in mind that such an infant, when cared for in an open warmer without the use of a plastic heat shield, may lose up to 150 to 300 mL/kg/day of free water through the skin during the first 3 to 5 days of life. Infants whose mothers received antenatal glucocorticoids often have fewer problems because prenatal glucocorticoids enhance maturation of the epidermis and result in increases in urine output and fractional excretion of sodium (Ali et al, 2000; Omar et al, 1999).

Although the IWL primarily affects the extracellular volume, the intracellular compartment ultimately shares the loss of free water as osmotic pressure in the extracellular compartment rises. As water leaves the cells, intracellular osmolality rises and cell volume diminishes. In the central nervous system, as described earlier, these changes stimulate the generation of idiogenic osmols, resulting in selective increases in intracellular osmolality and a tendency toward normalization of neuronal cell volumes. This protective mechanism has significant clinical implications for the rate at which hypernatremia should be corrected, and the decrease in serum sodium concentration should not exceed 12 mEq/L/day, especially in the infant in whom the hypernatremia has been chronic (>12 hours).

TABLE 31-4 Medications Used for Treatment of Hyperkalemia

Medication	Dosage	Onset	Length of Effects	Mechanism of Action	Comments and Cautions
Calcium gluconate	100 mg/kg IV over 2-5 min	Immediate	30 min	Protects the myocardium from toxic effects of potassium; no effect on total body potassium	Can worsen digoxin toxicity
Sodium bicarbonate	1-2 mEq/kg	Immediate	Variable	Shifts potassium intracellularly; no effect on total body potassium	Maximum infusion: mEq/min in emergency situations
Tromethamine	3-5 mL/kg	Immediate	Variable	Shifts potassium intracellularly; no effect on total body potassium	—
Insulin plus dextrose	Insulin 0.1-0.15 U/kg IV plus dextrose 0.5 g/kg IV	15 to 30 min	2 to 6 h	Shifts potassium intracellularly; no effect on total body potassium	Monitor for hypoglycemia
Albuterol*	0.15 mg/kg every 20 min for three doses then 0.15-0.3 mg/kg	15 to 30 min	2 to 3 h	Shifts potassium intracellularly; no effect on total body potassium	Minimum dose, 2.5 mg
Furosemide	PO: 1-4 mg/kg/dose 1-2 times/day IV: 1-2 mg/kg/dose given every 12-24 hours	15 min to 1 h	4 h	Increases renal excretion of potassium	—
Kayexalate	1 g/kg PR every 6 hours	1 to 2 h (rectal route faster)	4 to 6 h	Removes potassium from the gut in exchange for sodium	Use with extreme caution in neonates, especialy preterm; contains sorbital; may be associated with bowel necrosis and sodium retention

IV, Intravenous; *PO*, by mouth or gastric tube; *PR*, per rectum.
*From Singh BS, Sadiq HF, Noguchi A, et al: Efficacy of albuterol inhalation in treatment of hyperkalemia in premature neonates, *J Pediatr* 141:16, 2002.

Because serum sodium concentration is a reliable clinical indicator of extracellular tonicity, monitoring of this parameter every 6 to 12 hours during the first 2 to 3 postnatal days coupled with daily (or twice daily) measurements of body weight provide valuable information and appropriate guidance for the fluid and electrolyte management of the extremely immature preterm neonate. This is especially true in the absence of prenatal steroid exposure and if the infant is not cared for in a humidified incubator. Serum osmolality should be directly measured in patients in whom calculated serum osmolality is more than 300 to 320 mOsm/L.

Table 31-1 shows suggested maintenance fluid requirements by birthweight and postnatal day of life. Because immature neonates in an incubator with an ambient air humidity of 50% to 80% require significantly less free water and less frequent measurements of serum electrolyte and osmolality (Sedin, 1995), open radiant warmers should be used only for critically ill, extremely labile preterm infants requiring frequent hands-on medical management. In these cases, the use of a protective plastic heat shield can help decrease excessive evaporative losses, and total daily fluid intake, similar to that used for infants in incubators, may be started at approximately 100 mL/kg/day containing 5% to 10% dextrose in water with close monitoring for dehydration. Daily fluid intake is then increased by 10 to 30 mL/kg/day every 6 to 12 hours if the serum sodium concentration rises from the baseline, the goal being to keep serum sodium concentration below 145 to 150 mEq/L. As skin integrity improves during the course of the 2nd to 3rd days, serum sodium concentration starts to fall. At this time, a significant stepwise limitation of total fluid intake is obligatory to allow a complete contraction of the extracellular volume to occur and to minimize the possibility of free water overload with its attendant risks for the development of ductal patency, pulmonary edema, and worsening lung disease.

Potassium chloride supplementation may be started as soon as urine output has been established and the serum potassium concentration is less than 5 mEq/L. Extremely premature infants are at risk for the development of both oliguric and nonoliguric hyperkalemia, so the serum potassium concentration should be monitored closely, and supplementation should be discontinued if warranted by changes in serum potassium values or in renal function. Critically ill, extremely immature neonates often receive excess sodium with volume boluses, medications, and the maintenance infusion of their arterial lines (Costarino et al, 1992). Therefore extra sodium supplementation usually should not be started during the first few postnatal days, to prevent a rise in total body sodium concentration and thus in extracellular volume, which will hinder the appropriate postnatal diuresis.

Many critically ill preterm infants retain their originally high extracellular volumes, even when sodium and water intakes are restricted, and such neonates also tend to lose more bicarbonate in the urine. Interestingly, proximal tubular bicarbonate reabsorption may be appropriate even in the VLBW infant despite the immaturity of their renal functions, as long as extracellular volume contraction

takes place (Ramiro-Tolentino et al, 1996). Therefore the presence of the extracellular volume expansion appears to be an important factor in the renal bicarbonate wasting in these infants. The diagnosis of functional proximal tubular acidosis in such cases should not rely solely on the finding of an alkaline urine pH, because the distal tubular function is usually mature enough to acidify the urine once serum bicarbonate has decreased to its new threshold. Provided that liver function is normal, daily supplementation of bicarbonate in the form of sodium acetate, potassium acetate, or both normalizes blood pH and serum bicarbonate in these infants and also increases urine pH, aiding in the diagnosis. Once extracellular volume contraction occurs, these neonates generally achieve a positive bicarbonate balance (Ramiro-Tolentino et al, 1996), and supplementation becomes unnecessary.

Other general guidelines in the fluid and electrolyte management of the immature preterm infant during the 1st week of life are (1) daily calculation of fluid balance and estimation of sodium balance; (2) daily measurements of body weight, serum electrolytes, blood urea nitrogen, creatinine, and plasma glucose; and (3) testing of urine samples for glucose, and osmolality or specific gravity. The frequency of testing and the addition of other tests, including the measurement of serum albumin concentration and osmolality, depend on the clinical status, severity of underlying disease, and fluid and electrolyte disturbance of the individual patient.

Respiratory Distress Syndrome

There is a well-established relationship between fluid and electrolyte imbalance and respiratory distress syndrome. Surfactant deficiency results in pulmonary atelectasis, elevated pulmonary vascular resistance, poor lung compliance, and decreased lymphatic drainage. In addition, preterm infants have low plasma oncotic and critical pulmonary capillary pressures and suffer pulmonary capillary endothelial injury from mechanical ventilation, oxygen administration, and perinatal hypoxia (Dudek and Garcia, 2001; Sola and Gregory, 1981). These abnormalities alter the balance of the Starling forces in the pulmonary microcirculation, leading to interstitial edema formation with further impairment in pulmonary functions.

In the presurfactant era, an improvement in pulmonary function occurred only during the 3rd to 4th postnatal day. This improvement was usually preceded by a period of brisk diuresis characterized by small increases in glomerular filtration rate and sodium clearance and a larger rise in free water clearance (Costarino and Baumgart, 1991). Although the exact mechanism for this diuresis is not known, it is likely that improving endogenous surfactant production and capillary integrity promoted the recovery of the pulmonary capillary endothelium and lymphatic drainage. The ensuing changes in Starling forces then favored reabsorption of the hypotonic interstitial lung fluid into the circulation, and a delayed physiologic diuresis took place.

Currently, with the routine use of surfactant and antenatal steroids, the pulmonary compromise and its consequences are less severe. However, because significant improvements in lung function take place only after the majority of the excess free water is excreted (Costarino and Baumgart, 1991), daily fluid intake should still be restricted to allow the extracellular volume contraction to take place. If this principle is not followed and a positive fluid balance occurs, preterm infants with respiratory distress syndrome are at higher risk for a more severe course of acute lung disease and have a higher incidence of patent ductus arteriosus, congestive heart failure, and necrotizing enterocolitis as well as a greater severity of the ensuing bronchopulmonary dysplasia.

Antenatal administration of steroids and postnatal use of surfactants have clearly altered the course and clinical presentation of respiratory distress syndrome (Ballard and Ballard, 1995; Kari et al, 1994). Antenatal steroid administration accelerates maturation of organs including those involved in the regulation of fluid and electrolyte balance (Ballard and Ballard, 1995), whereas the use of exogenous surfactant decreases pulmonary capillary leak and edema formation (Carlton et al, 1995). Furthermore, surfactant administration does not alter the rate and timing of ductal closure (Reller et al, 1993), although it may affect the pattern of shunting through the ductus arteriosus in the acute period (Kaapa et al, 1993; Kluckow and Evans, 2000). Thus, these interventions generally enhance extracellular volume contraction and aid in the stabilization of fluid and electrolyte homeostasis in preterm neonates with respiratory distress syndrome. However, maintenance of a negative water and sodium balance during the first few days of life remains the cornerstone of fluid and electrolyte management in these infants (Tammela, 1995; Van Marter et al, 1990).

On the basis of the events in the pathophysiology of pulmonary edema formation in these infants, the use of furosemide has long been suggested to promote a negative fluid balance and to directly inhibit pulmonary epithelial transport processes involved in edema formation in the lungs (Green et al, 1988; Yeh et al, 1984). However, furosemide induces only short-term improvements in pulmonary function in these patients, and no beneficial effects on long-term morbidity or mortality have been documented. Moreover, prophylactic use of the drug during the first postnatal days can lead to intravascular volume depletion with hypotension, tachycardia, and decreased peripheral perfusion as well as to acute and chronic disturbances in serum electrolytes and thus osmolality (Green et al, 1988; Shaffer and Weismann, 1992; Yeh et al, 1984). Furthermore, continued administration may be associated with an increased incidence of patent ductus arteriosus (Green et al, 1983). Therefore the use of furosemide during this period should be restricted to patients with oliguria of renal origin whose intravascular volume appears to be adequate.

Chronic Lung Disease or Bronchopulmonary Dysplasia

Low gestational age and birthweight, lack of antenatal steroid administration, severe respiratory distress syndrome with oxygen toxicity, volutrauma and barotrauma, air leak, inflammation, patent ductus arteriosus, and insufficient nutrition are among the known etiologic factors for the development of bronchopulmonary dysplasia. In addition, a high fluid and salt intake during the first weeks

of life has been shown to increase the incidence and severity of chronic lung disease. Specifically, higher fluid intake and lack of appropriate weight loss in the first 10 days of life are associated with significantly higher risk for bronchopulmonary dysplasia, even after controlling for other known risk factors such as those listed previously (Oh et al, 2005). Therefore careful fluid and electrolyte management during the first weeks of life, allowing for the appropriate degree of weight loss, is of great importance in decreasing the incidence and severity of this condition (see Chapter 48).

Patent Ductus Arteriosus

A PDA has been associated with an increase in morbidity and mortality in epidemiological studies, especially in the infant with ELBW. However, trials aimed at prophylactic or therapeutic closure of the ductus have not demonstrated improvements in these outcomes. Several conditions, including hypoxemia, unstable cardiovascular status, metabolic acidosis, increases in extracellular volume, inflammatory mediators, and ductal prostaglandin synthesis, have been recognized to prolong patency of the ductus arteriosus (Hammerman, 1995; see Chapter 54). Accordingly, clinical management aimed at preventing the occurrence of ductal patency involves interventions that keep the cardiovascular status and oxygenation stable, minimize inflammation, restrict fluid intake, and maintain low levels of local prostaglandin synthesis by the administration of indomethacin (Clyman, 1996). Pharmacologic ductal closure with indomethacin is normally indicated during the first 2 postnatal weeks, because ductal sensitivity to prostaglandins rapidly diminishes thereafter (Clyman, 1996; Van Overmeire et al, 2000). Ibuprofen has been offered as an alternative inhibitor of cyclooxygenase, the enzyme responsible for prostaglandin synthesis, because of its equivalent efficacy in closing the symptomatic PDA with fewer adverse effects (Ohlsson et al, 2008). Specifically, ibuprofen may cause less renal dysfunction (Van Overmeire et al, 2000) and cerebral vasoconstriction (Mosca et al, 1997; Patel et al, 2000) when used in this manner. However, ibuprofen is not recommended for prophylactic use because it has an adverse effect on renal function in this setting and does not reduce grade III and IV IVH as indomethacin has been proven to do (Shah and Ohlssen, 2006). For more details, see Chapter 61.

Under physiologic circumstances in the immediate postnatal period, renal prostaglandin production is increased to counterbalance the renal actions of vasoconstrictor and sodium- and water-retaining hormones released during labor and delivery (Bonvalet et al, 1987; Gleason, 1987). Compared with the renal function of the adult kidney in euvolemia, the neonatal kidney is more dependent on the increased production of vasodilatory and natriuretic prostaglandins, rendering it more sensitive to the vasoconstrictive and sodium- and water-retaining actions of cyclooxygenase inhibition. In the preterm infant, indomethacin administration has been shown to have clinically significant, although mostly transient, renal side effects because of decreased prostaglandin production through inhibition of cyclooxygenase. In the indomethacin-treated neonate, the unopposed renal vasoconstriction and sodium and water reabsorption leads to decreases in renal blood flow and glomerular filtration rate and to increases in sodium and free water reabsorption. These side effects occur despite the diminishing left-to-right shunt through the closing ductus. Characteristic clinical findings include a rise in serum creatinine level, oliguria, and hyponatremia (Cifuentes et al, 1979). Hyponatremia occurs because the free water retention caused by the unopposed renal actions of high plasma vasopressin levels is out of proportion to the sodium retention induced by angiotensin and noradrenaline. This pattern of renal response can most likely be explained by the fact that in a preterm infant, the function of the distal tubule is more mature than that of the proximal tubule (Lumbers et al, 1988), leading to an expanded but somewhat hypotonic extracellular space. Therefore fluid management of the preterm infant receiving indomethacin must focus on maintaining an appropriately restricted fluid intake and avoiding extra sodium supplementation. As the prostaglandin inhibitory effects of indomethacin diminish following the last dose, renal prostaglandin production returns to normal, and the retained sodium and excess free water are usually rapidly excreted, especially with the improvement in the cardiovascular status as the ductal shunt decreases.

Because furosemide increases prostaglandin production, the drug has been hypothesized to attenuate the renal side effects of indomethacin if the intravascular volume is judged to be adequate (Yeh et al, 1982). However, furosemide administration can increase the incidence of ductal patency (Green et al, 1983), so routine use of the drug might not be prudent in preterm infants treated with indomethacin, because of the theoretical risk of reopening the ductus arteriosus (Seri, 1995). Furthermore, the concomitant use of furosemide and indomethacin has been shown to worsen renal function, as evidenced by increases in serum creatinine and worsening hyponatremia without increasing overall urine output (Andriessen et al, 2009). As a result, furosemide should not be used early in life when the PDA is also being actively managed. In cases of hemodynamic instability or to avoid the potential effect of furosemide on ductal closure, dopamine infusion can be used to support the cardiovascular status and attenuate the indomethacin-induced oliguria (Cochran et al, 1989; Seri et al, 1984, 1993). However, there is controversy regarding the efficacy and clinical significance of this intervention (Baenziger et al, 1999; Fajardo et al, 1992; Seri, 1995).

Growing Premature Infant With Negative Sodium Balance

The 2- to 6-week-old growing preterm neonate who does not have significant chronic lung disease and is not undergoing diuretic treatment may have hyponatremia (serum sodium concentration 125 to 129 mEq/L) because of a relative sodium deficiency (Sulyok et al, 1979, 1985). Despite the low total body sodium and high activity of sodium retaining hormones, these infants continue to lose sodium in the urine mainly because of immature renal function. Although the infant is usually in a positive sodium balance, it is insufficient to compete with the increased sodium demand because of growth. The treatment of this condition is to provide extra sodium supplementation in the

form of sodium chloride (usually 2 to 4 mEq/kg/day) to keep serum sodium values greater than 130 mEq/L.

Shock and Edema

In the uncompensated phase of shock, blood pressure is low; cardiac output may be low, normal, or high; effective circulating blood volume is usually decreased; transcapillary hydrostatic pressure is elevated; and capillary integrity and lymphatic drainage are impaired, resulting in edema formation and increased interstitial compliance. The latter condition further enhances fluid accumulation in the interstitium. The changes in the effective circulating blood volume also trigger the release of antidiuretic hormones, including catecholamines, renin-angiotensin-aldosterone, and vasopressin, resulting in the retention of sodium and free water. The specific cause of shock (e.g., infection, asphyxia, myocardial insufficiency, hypovolemia) may independently contribute to this chain of events, further compromising fluid and electrolyte balance. In affected infants, treatment is directed at normalizing tissue perfusion and oxygen delivery by restoring effective intravascular volume, cardiac output, and renal function with the use of vasopressor and inotropic support, as well as with the judicious use of volume expanders while monitoring blood pressure, cardiac output, and changes in organ blood flow (see Chapter 51). In shock refractory to these therapies, early initiation of low-dose glucocorticoid and mineralocorticoid replacement may help to break the vicious cycle by improving capillary integrity and thus effective circulating blood volume, and by potentiating the cardiovascular response to vasopressors and inotropic agents (Seri et al, 2000).

Syndrome of Inappropriate Anti-Diuretic Hormone Secretion

SIADH may be associated with birth asphyxia, intracerebral hemorrhage, respiratory distress syndrome, pneumothorax, and the use of continuous positive-pressure ventilation (El-Dahr and Chevalier, 1990; Leake, 1992). The syndrome is characterized by oliguria, free water retention, decreased serum sodium concentration and serum osmolality, increased urine concentration, and weight gain caused by edema formation. However, because the urinary concentrating capacity of the newborn is limited, a less than maximally diluted urine satisfies the diagnosis of SIADH in the presence of the other symptoms. The treatment is based on fluid and sodium restriction despite the oliguria and hyponatremia, as well as on appropriate circulatory and ventilatory support. The clinician must remember that total body sodium is normal, but TBW is elevated in such an infant, and that it is particularly dangerous to treat the hyponatremia caused by free water retention with large amounts of sodium. Because of their more immature renal functions, infants with extreme LBW during the first few weeks of life usually do not exhibit the full-blown syndrome despite their sometimes excessively high plasma vasopressin levels (Aperia et al, 1983).

Diminished vasopressin secretion or complete unresponsiveness of the renal tubules to vasopressin results in polyuria, dilute urine production, and increased serum osmolality (Leake, 1992), otherwise known as diabetes insipidus (DI). This condition is not common in neonates, but can occur in association with central nervous system injury or disease, such as in meningitis or cerebral hemorrhage affecting the pituitary gland (central DI) or in an inherited form (nephrogenic DI). The treatment of neonates with this condition consists of allowing for adequate free water intake and the use of desmopressin.

Surgical Conditions

Surgery has a major effect on metabolism, fluid balance, and electrolyte balance in the newborn. Preterm infants with acute or chronic lung disease are especially sensitive and respond to the procedure with significant catabolic responses, increases in capillary permeability with the attendant shift of fluid into the interstitial space, and retention of sodium and free water (John et al, 1989). The retention of sodium and free water is secondary to the decrease in effective circulating blood volume and to the increased plasma levels of sodium- and water-retaining hormones, including catecholamines, renin-angiotensin-aldosterone, and vasopressin.

Preoperative management has a significant effect on outcome and should be aimed at maintaining adequate effective circulating blood volume as well as cardiovascular and renal function. In preterm infants who have evidence of absolute or relative adrenal insufficiency (Watterberg, 2002), the provision of stress doses of steroids may be necessary. In the postoperative period, maintenance of the integrity of the cardiovascular system through the judicious use of volume expanders and pressor support, meticulous replacement of ongoing surgical and nonsurgical fluid and electrolyte losses, close monitoring, and intense and effective communication between the neonatal and surgical teams are essential to ensure a successful outcome. As capillary integrity improves, reabsorption and excretion of the expanded interstitial fluid volume occurs, with normalization in the secretion of hormones regulating fluid and electrolyte balance. At this time, the provision of maximized nutritional support becomes essential to restore the anabolic state and growth of the infant.

The most commonly encountered surgical water losses occur when a nasogastric tube is placed under continuous suction to provide relief for the gastrointestinal tract in conditions such as necrotizing enterocolitis and postoperative management after abdominal surgery. Because these losses may be substantial, they should be monitored and a portion of it should be replaced every 6 to 12 hours to maintain appropriate water and electrolyte balance. However, free water retention often develops after surgery; therefore full replacement of the nasogastric free water loss is not usually recommended. The composition of the replacement solution depends on the electrolyte concentration of the fluid loss. Gastric fluid usually contains 50 to 60 mEq/L of sodium chloride, and therefore, 0.45% sodium chloride with potassium is normally used as the fluid of choice for replacement. See Table 31-3 for estimated electrolyte compositions of body fluids.

ACID-BASE BALANCE

PHYSIOLOGY OF ACID-BASE BALANCE REGULATION

Like adults, newborns must maintain their extracellular pH, or hydrogen ion concentration, within a narrow range. A normal pH is essential for intact functioning of all enzymatic processes and, therefore, the intact functioning of all organ systems of the body. Newborns are subjected to many stresses that can affect their acid-base balance. In addition, neonates, especially if they are premature, have a limited ability to compensate for acid-base alterations; therefore acid-base disturbances are common in the neonatal period. An understanding of the principles of acid-base regulation is essential for proper diagnosis and treatment of these disturbances.

In healthy humans, the normal range of ECF hydrogen ion concentration is 35 to 45 mEq/L. Because pH is defined as the negative logarithm of hydrogen ion concentration (pH = $-log[H^+]$), these values of hydrogen ion concentration correspond to a pH range of 7.35 to 7.45. Acidosis is a downward shift in pH to less than 7.35, and alkalosis is an upward shift in pH to more than 7.45. Alterations in normal pH are resisted by complex physiologic regulatory mechanisms. The main systems that maintain pH are the body's buffer systems, the respiratory system, and the kidneys. Some of these systems respond immediately to sudden alterations in hydrogen ion concentration, whereas others respond more slowly to changes but maintain the overall balance between acid and base production, intake, metabolism, and excretion over the long term.

The physiologic regulatory systems that respond immediately to changes in acid-base balance include the various intracellular and extracellular buffers as well as the lungs. A buffer is a substance that can minimize changes in pH when acid or base is added to the system. The extracellular buffers, which include the bicarbonate-carbonic acid system, phosphates, and plasma proteins, act rapidly to return the extracellular pH toward normal. The intracellular buffers, which include hemoglobin, organic phosphates, and bone apatite, act more slowly and require several hours to reach maximal capacity.

The most important extracellular buffer is the plasma bicarbonate–carbonic acid buffer system, in which the acid component (carbonic acid [H_2CO_3]) is regulated by the lungs, and the base component (bicarbonate [HCO_3^-]) is regulated by the kidneys. The buffer equation is:

$$H^+ + HCO_3^- \leftrightarrow H_2CO_3 \leftrightarrow H_2O + (CO_2)_d$$

where $(CO_2)_d$ represents the dissolved carbon dioxide. At equilibrium, the amount of $(CO_2)_d$ exceeds that of H_2CO_3 by a factor of 800:1; therefore for practical purposes, $(CO_2)_d$ and H_2CO_3 can be treated interchangeably. The fact that CO_2 excretion can be controlled by the respiratory system markedly improves the efficiency of this buffer system at physiologic pH. The enzyme carbonic anhydrase allows rapid interconversion of H_2CO_3 to H_2O and CO_2. If the hydrogen ion (H^+) concentration increases for any reason, hydrogen combines with HCO_3^-, driving the buffer reaction toward greater production of H_2CO_3 and CO_2. Carbon dioxide crosses the blood-brain barrier and stimulates central nervous system chemoreceptors, leading to increased alveolar ventilation and decreased concentration of extracellular CO_2. This respiratory compensation begins within minutes after a pH change and is complete within 12 to 24 hours. A similar compensation occurs in response to a decrease in H^+ concentration, leading to decreased alveolar ventilation and a resultant increase in extracellular CO_2.

The relationship of the two components of the bicarbonate–carbonic acid buffer system to pH is expressed by the Henderson-Hasselbalch equation:

$$pH = pK + log\frac{[HCO_3^-]}{[H_2CO_3]}$$

Because H_2CO_3 is in equilibrium with the dissolved CO_2 in the plasma, and because the amount of dissolved CO_2 depends on the partial pressure of CO_2, the equation can be modified as:

$$pH = pK + log\frac{[HCO_3^-]}{0.03} \times Pa_{CO_2}$$

Both the original equation and the modified equation are clinically difficult to use; therefore the modified Henderson-Hasselbalch equation can be rewritten as the Henderson equation without logarithms for easier clinical use.

$$[H^+] = 24 \times \frac{Pa_{CO_2}}{[HCO_3^-]}$$

This last equation clearly indicates the clinically most important aspect of acid-base regulation by the bicarbonate-carbonic acid buffer system, that the change in the ratio of $Paco_2$ to HCO_3^- concentration, and not in their absolute values, determines the direction of change in H^+ concentration and thus in pH. The status of the plasma bicarbonate-carbonic acid buffer system can be monitored easily by serial blood gas measurements, making understanding of this buffer system important in clinical care.

The physiologic regulation system that responds more slowly to changes in acid-base balance is the renal system. There must be a long-term balance between net acid increase caused by intake and production and net acid decrease caused by excretion and metabolism. Although infant formula and protein-containing intravenous fluids have small amounts of preformed acid, most of the daily acid load is derived from metabolism. A large amount of the acid produced is in the form of the volatile H_2CO_3 that can be excreted in the lungs. Nonvolatile or fixed acids are also produced, which must be excreted through the kidneys. Nonvolatile acids normally are sulfuric acid produced in the metabolism of the amino acids methionine and cysteine as well as smaller contributions from phosphoric acid, lactic acid, hydrochloric acid, and incompletely oxidized organic acids. In addition to the excretion of nonvolatile acids, however, the kidneys have a role in long-term acid-base regulation by controlling renal HCO_3^- excretion.

Two regions of the kidney act to achieve urinary acidification—the proximal tubule and the collecting tubule. The proximal tubule acidifies the urine by two mechanisms. The first mechanism is by the reabsorption of any HCO_3^- already present in the blood that is being constantly filtered through the glomeruli. The proximal tubule reabsorbs 60% to 80% of all filtered HCO_3^- and performs this role through an exchange of Na^+ for H^+ across the luminal membrane of the proximal tubular cells via the Na^+/H^+ exchanger. The excreted H^+ combines with filtered HCO_3^-, producing H_2CO_3 through the activity of carbonic anhydrase in the cellular brush border. The H_2CO_3 is then quickly converted to CO_2, which crosses into the tubular cell, where HCO_3^- is regenerated and reabsorbed back into the blood stream, probably in exchange for chloride (Cl^-). The regenerated H^+ ion reenters the cycle at the Na^+/H^+ exchanger.

The second mechanism by which the proximal tubule acidifies urine is by the production of ammonia (NH_3). Inside the tubular cell, NH_3 is produced by the deamination of glutamine. The NH_3 is secreted into the tubular lumen, where it combines with and traps free H^+ to form ammonium (NH_4^+).

The remaining urinary acidification occurs mostly in the collecting tubule. H^+ secretion in this region of the kidney is sufficient to combine with or titrate any remaining filtered HCO_3^- or any filtered anions, such as phosphate and sulfate. Hydrogenated phosphate and sulfate anions produce the titratable acid of the urine. The collecting tubule also takes up NH_3 from the medullary interstitium and secretes it into the urine, where again it can combine with and trap H^+ as NH_4^+. This urinary NH_4^+ can act as a cation and be excreted with urinary anions such as Cl^-, PO_4^-, and SO_4^-, thereby preventing loss of cations such as Na^+, Ca^{++}, and K^+. Total acid secretion in the kidney can be represented by

$$\text{Titratable acid} + NH_4^+ - HCO_3^-$$

and under normal conditions should equal the net production of acid from diet and metabolism that is not excreted in the form of CO_2 through the lungs.

In adults, the steady state for renal compensation for respiratory alkalosis is reached within 1 to 2 days and for respiratory acidosis within 3 to 5 days. Newborns are able to compensate for acidemia through the previously described renal mechanisms, although the renal response to acid loads is limited, especially in premature infants born before 34 weeks' gestation. Reabsorption of HCO_3^- in the proximal tubule and distal tubular acidification are also decreased, with a fairly rapid gestational age-dependent maturation of these functions after birth (Jones and Chesney, 1992).

To accomplish the tight regulation of pH necessary for survival, H^+ ions generated in the form of the volatile acid H_2CO_3 are excreted by the lungs as CO_2. H^+ ions generated in the form of nonvolatile acids are buffered rapidly by extracellular HCO_3^- and more slowly by intracellular buffers. HCO_3^- is then replenished by the kidneys via the reabsorption of much of the filtered HCO_3^- and by the excretion of H^+ in the urine as NH_4^+ and titratable acids.

DISTURBANCES OF ACID-BASE BALANCE IN THE NEWBORN

General Principles

The evaluation of the acid-base status in a newborn is one of the most common laboratory assessments made in the neonatal intensive care unit. The status of this system can be monitored with blood gas measurements and should be the starting point for the evaluation of any acid-base disorder. In the blood gas measurement, the pH and $Paco_2$ levels are directly measured; from these, the HCO_3^- level and base excess or deficit are calculated.

The whole blood buffer base, defined as the sum of the HCO_3^- and non-HCO_3^- buffer systems, is another important blood gas value used in evaluating acid-base disturbances. The difference between the observed whole blood buffer base of any blood gas sample and the expected normal buffer base of that sample is called the base excess or base deficit. The base excess and base deficit give an accurate measure of the amount of strong acid or base, respectively, that would be needed to titrate the pH back to normal once the respiratory contribution of the acid-base disturbance is also corrected. For example, a base excess of 10 mEq/L indicates that there is an additional 10 mEq of base per liter (or loss of 10 mEq of H^+ per liter) that is contributing to the acid-base abnormality. Conversely, a base deficit of 10 mEq/L indicates there is relatively more acid (or less base) in the ECF than expected after accounting for the effect of Pco_2 on pH.

Acid-base disorders are classified according to their cause as being either metabolic or respiratory. Metabolic acidosis occurs as a result of the accumulation of increased amounts of nonvolatile acid or decreased amounts of HCO_3^- in the ECF. Metabolic alkalosis occurs as a result of increased amounts of HCO_3^- in the ECF. Respiratory acidosis is caused by hypoventilation and decreased excretion of volatile acid (CO_2), whereas respiratory alkalosis is caused by hyperventilation and increased excretion of volatile acid (CO_2).

Acid-base disorders are also classified according to the number of conditions causing the disorder. When only one primary acid-base abnormality and its compensatory mechanisms occur, the disorder is classified as a *simple acid-base disorder*. When a combination of simple acid-base disturbances occurs, the patient has a mixed (or complex) acid-base disorder. Because secondary physiologic regulatory mechanisms often compensate for the alteration in pH caused by primary disturbances, it is sometimes difficult to differentiate simple from mixed disorders or even a simple disorder from its resulting compensation. One important principle that allows the determination of primary acid-base disturbance is that the compensatory regulatory mechanisms do not completely normalize the pH.

Nomograms, such as the one shown in Figure 31-6, can help in the diagnosis of the primary disturbance. The nomogram describes the 95% confidence limits of the expected compensatory response to a primary abnormality in either $Paco_2$ or HCO_3^-. Table 31-5 summarizes the expected respiratory and metabolic compensatory mechanisms for primary acid-base disorders (Brewer, 1990). If the compensation in a given patient differs from

that predicted in Figure 31-6 or Table 31-5, the patient either has not had enough time to compensate for a simple acid-base disturbance or has a mixed acid-base disorder. Furthermore, the complete correction of an acid-base disturbance occurs only when the underlying process responsible for the abnormality has been treated effectively.

For identification of the primary disturbance, the analysis of blood gas values must be considered in light of the patient's history and physical findings and with an understanding of expected compensatory responses. Further laboratory evaluation is indicated if the problem is not immediately obvious or if the response to therapy is not as expected. The evaluation of the acid-base disturbance should always involve efforts to determine the underlying cause of the disturbance, because adequate treatment requires correction of the underlying disorder, if possible.

Transitional Physiology after Birth

As part of a discussion of normal physiology, it is important to understand the in utero environment just before delivery of the newborn and its effects on neonatal acid-base analysis shortly after birth. Hyperventilation of pregnancy is a known phenomenon with corresponding maternal PCO_2 levels of approximately 31 to 34 mm Hg (Thorp and Rushing, 1999). This relative respiratory alkalosis in the mother is compensated for by a corresponding metabolic acidosis in the mother and, therefore, fetus. As a result, umbilical arterial blood gases have a normal pH range of 7.20 to 7.28 with a corresponding base deficit ranging from 2.7 ± 2.8 mEq/L (SD) to 8.3 ± 4.0 mEq/L (SD) (Riley and Johnson, 1993; Sykes et al, 1982). In other words, a mild metabolic acidosis in the newborn shortly after birth can be expected and explained by normal physiology.

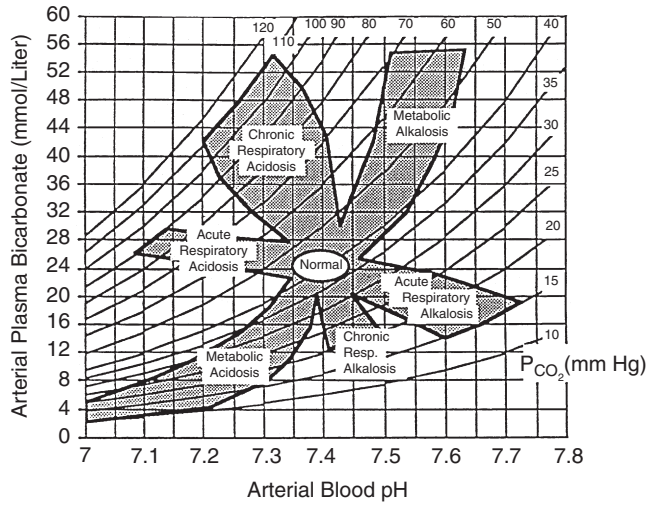

FIGURE 31-6 Acid-base nomogram illustrating the 95% confidence limits for compensatory responses to primary acid-base disorders. *(From Cogan MG, Rector FC Jr: Acid-base disorders. In Brenner BM, Rector FC Jr, editors:* The kidney, *Philadelphia, 1986, WB Saunders.)*

Metabolic Acidosis

Metabolic acidosis is a common problem, particularly in the critically ill newborn. Metabolic acidosis occurs when the drop in pH is caused by the accumulation of acid other than H_2CO_3 by the ECF, resulting in loss of available HCO_3^-, or by the direct loss of HCO_3^- from body fluids. Patients who have metabolic acidosis are divided into those with an elevated anion gap and those with a normal anion gap.

The anion gap reflects the unaccounted acidic anions and certain cations in the ECF. The unmeasured anions normally include the serum proteins, phosphates, sulfates, and organic acids, whereas the unaccounted cations are the serum potassium, calcium, and magnesium. Thus, in clinical practice, the anion gap is estimated using the formula

$$\text{Anion gap} = [Na^+]_{serum} - ([Cl^-]_{serum} + [HCO_3^-]_{serum})$$

The normal range of the serum anion gap in newborns is 8 to 16 mEq/L, with slightly higher values in very premature newborns. Accumulation of strong acids because of increased intake, increased production, or decreased excretion results in an increased anion gap acidosis, whereas loss of HCO_3^- or accumulation of H^+ results in a normal anion gap acidosis. A decrease in serum potassium, calcium, and magnesium concentrations, an increase in serum protein concentration, or a falsely elevated serum sodium concentration can also result in an increased anion gap in the absence of metabolic acidosis. In clinical practice, although

TABLE 31-5 Expected Compensatory Mechanisms Operating in Primary Acid-Base Disorders

Acid-Base Disorder	Primary Event	Compensation	Rate of Compensation
Metabolic acidosis			
Normal anion gap	↓ $[HCO_3^-]$	↓ Pco_2	For 1 mEq/L ↓ $[HCO_3^-]$, Pco_2 ↓ by 1-1.5 mm Hg
Increased anion gap	↑ Acid production ↑ Acid intake	↓ Pco_2	For 1 mEq/L ↓ $[HCO_3^-]$, Pco_2 ↓ by 1-1.5 mm Hg
Metabolic alkalosis	↑ $[HCO_3^-]$	↑ Pco_2	For 1 mEq/L ↑ $[HCO_3^-]$, Pco_2 ↑ by 0.5-1 mm Hg
Respiratory acidosis Acute (<12-24 h) Chronic (3-5 days)	↑ Pco_2 ↑ Pco_2	↑ $[HCO_3^-]$ ↑ $[HCO_3^-]$	For 10 mm Hg ↑ Pco_2, $[HCO_3^-]$ ↑ by 1 mEq/L For 10 mm Hg ↑ Pco_2, $[HCO_3^-]$ ↑ by 4 mEq/L
Respiratory alkalosis Acute (<12 h) Chronic (1-2 days)	↓ Pco_2 ↓ Pco_2	↓ $[HCO_3^-]$ ↓ $[HCO_3^-]$	For 10 mm Hg ↑ Pco_2, $[HCO_3^-]$ ↑ by 1-3 mEq/L For 10 mm Hg ↓ Pco_2, $[HCO_3^-]$ ↓ by 2-5 mEq/L

BOX 31-3 Common Causes of Metabolic Acidosis

INCREASED ANION GAP

- Lactic acidosis caused by tissue hypoxia
  - Asphyxia, hypothermia, shock
  - Sepsis, respiratory distress syndrome
- Inborn errors of metabolism
  - Congenital lactic acidosis
  - Organic acidosis
- Renal failure
- Late metabolic acidosis
- Toxins (e.g., benzyl alcohol)

NORMAL ANION GAP

- Renal bicarbonate loss
  - Bicarbonate wasting caused by immaturity
  - Renal tubular acidosis
  - Carbonic anhydrase inhibitors
- Gastrointestinal bicarbonate loss
  - Small bowel drainage: ileostomy, fistula
  - Diarrhea
- Extracellular volume expansion with bicarbonate dilution
- Aldosterone deficiency
- Excessive chloride in intravenous fluids

BOX 31-4 Inborn Errors of Metabolism Associated With Metabolic Acidosis

- Primary lactic acidosis
- Organic acidemias
- Pyruvate carboxylase deficiency
- Pyruvate hydroxylase deficiency
- Galactosemia
- Hereditary fructose intolerance
- Type I glycogen storage disease

a serum anion gap value greater than 16 mEq/L is highly predictive of the presence of lactic acidosis and a value less than 8 mEq/L is highly predictive of the absence of lactic acidosis, an anion gap value between 8 and 16 mEq/L cannot be used to differentiate between lactic and nonlactic acidosis in the critically ill newborn (Lorenz et al, 1999). Therefore if the anion gap is within this high normal range and lactic acidosis is suggested, measuring serum lactate is indicated.

An increased anion gap metabolic acidosis in the newborn is most commonly caused by lactic acidosis secondary to tissue hypoxia, as seen in asphyxia, hypothermia, severe respiratory distress, sepsis, and other severe neonatal illnesses. Other important but much less common causes of an increased anion gap metabolic acidosis in the neonatal period are inborn errors of metabolism, renal failure, and intake of toxins (Box 31-3). Box 31-4 lists inborn errors of metabolism that can manifest as increased anion gap metabolic acidosis in the newborn period.

In the syndrome of late metabolic acidosis of prematurity, first described in the 1960s, otherwise healthy premature infants at several weeks of age demonstrated mild to moderate increased anion gap acidosis and decreased growth. All the infants were receiving high-protein cow's milk formula, and they demonstrated higher net acid excretion compared with controls. This type of late metabolic acidosis is rarely seen, probably because of the use of special premature infant formulas and changes in regular formulas with decreased casein-to-whey ratios and lower fixed acid loads.

A normal anion gap metabolic acidosis most commonly occurs in the newborn as a result of HCO_3^- loss from the extracellular space through the kidneys or the gastrointestinal tract. Hyperchloremia develops with the HCO_3^- loss because a proportionate rise in serum chloride concentration must occur to maintain the ionic balance or to correct the volume depletion in the extracellular compartment. The most common cause of normal anion gap metabolic acidosis in the preterm newborn is a mild, developmentally regulated, proximal renal tubular acidosis with renal HCO_3^- wasting. In infants with this disorder, the serum HCO_3^- usually stabilizes at 14 to 18 mEq/L in the early postnatal period. The urinary pH is normal once the serum HCO_3^- falls to this level, because the impairment in proximal tubular HCO_3^- reabsorption is not associated with an impaired distal tubular acidification of similar magnitude (Jones and Chesney, 1992). The diagnosis of this temporary cause of acidosis can be established by the recurrence of a urinary alkaline pH when serum HCO_3^- is raised above the threshold after HCO_3^- or acetate supplementation. Even term newborns have a lower renal threshold for HCO_3^-, with normal plasma HCO_3^- levels in the range of 17 to 21 mEq/L. In most infants, plasma HCO_3^- increases to adult levels over the first year as the proximal tubule matures. Other common causes of normal anion gap metabolic acidosis seen in neonatal intensive care units are gastrointestinal HCO_3^- losses, often caused by increased ileostomy drainage, diuretic treatment with carbonic anhydrase inhibitors, and dilutional acidosis with rapid expansion of the extracellular space through the use of non-HCO_3^- solutions in the hypovolemic newborn.

The presence of metabolic acidosis in the newborn should be suggested by the clinical presentation and the history of predisposing conditions, including perinatal depression, respiratory distress, blood or volume loss, sepsis, and congenital heart disease associated with poor systemic perfusion or cyanosis. Metabolic acidosis is confirmed by blood gas measurements. The cause of metabolic acidosis is often readily discernible from the history and physical examination. Specific laboratory evaluation of electrolytes, renal function, lactate, and serum and urine amino acids may be undertaken, depending on the diagnosis that is suggested clinically. Figure 31-7 shows a simple flow diagram outlining an approach to diagnosis of metabolic acidosis in the newborn. It is important to remember that infants might not manifest an increased anion gap in the setting of lactic acidosis and thus require the direct measurement of lactate when a lactic acidosis is suspected (Lorenz et al, 1999).

The morbidity and mortality of metabolic acidosis depend on the underlying pathologic process, the severity of the acidosis, and the responsiveness of the process to clinical management. By far, the most important intervention for an infant with a metabolic acidosis is to identify the pathologic process contributing to the acidosis and to take measures to correct it. The administration of base, such as sodium bicarbonate, as supportive therapy for metabolic acidosis is unproven in its efficacy (Aschner and Poland, 2008).

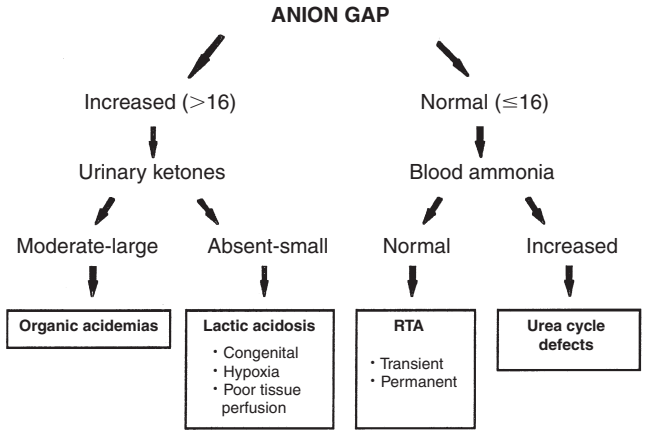

FIGURE 31-7 Diagnostic approach of increased anion gap and normal anion gap metabolic acidosis in the newborn. Infants with lactic acidosis may not have an increased anion gap and lactate should be measured directly if suspected by the history and physical examination. *RTA*, Renal tubular acidosis. (*Adapted from Lorenz JM, Kleinman LI, Markarian K, et al: Serum anion gap in the differential diagnosis of metabolic acidosis in critically ill newborns*, J Pediatr *135:751-755, 1999.*)

The use of base administration is supported by findings on the beneficial cardiovascular effects of sodium bicarbonate in preterm newborns with an arterial pH of less than 7.25 and term newborns with an arterial pH of less than 7.30 (Fanconi et al, 1993). The use of sodium bicarbonate in this study was associated with an increase in myocardial contractility and a reduction in afterload, albeit transient. However, there is concern for harm associated with the administration of base, including increased mortality and intraventricular hemorrhage (Papile et al, 1978; Simmons et al, 1974; Usher, 1967), increased cerebral blood volume regardless of rate of administration (van Alfen-van der Velden et al, 2006), and decreased intracellular pH with cellular injury (Lipshultz et al, 2003).

If therapy with base is warranted, the clinician has three options: sodium bicarbonate, sodium (or potassium) acetate, and tromethamine. Sodium bicarbonate is the most widely used buffer in the treatment of metabolic acidosis in the neonatal period. Bicarbonate should not be given if ventilation is inadequate, because its administration results in an increase in P_aco_2 with no improvement in pH and an increase in intracellular acidosis. Therefore sodium bicarbonate should be administered slowly and in diluted form only to newborns with documented metabolic acidosis and adequate alveolar ventilation. Once a blood gas measurement has been obtained, the dose of sodium bicarbonate required to fully correct the pH can be estimated with the use of the following formula:

$$\text{Dose of } NaHCO_3 \text{ (mEq)} = \text{Base deficit (mEq/L)} \times \text{Body weight (kg)} \times 0.3$$

Sodium bicarbonate is thought to be confined mostly to the ECF compartment. Although there are controversies regarding the actual bicarbonate space in humans, the 30% of total body weight in the formula represents its estimated volume of distribution in the neonate. Most clinicians would use half of the calculated total correction dose for initial therapy to avoid overcorrection of metabolic acidosis. Subsequent doses of sodium bicarbonate are then based on the results of additional blood gas measurements.

When clinicians are faced with a chronic metabolic acidosis caused by a prematurity-related proximal renal tubular acidosis with bicarbonate wasting, many choose to replace these losses over time. In this instance, either sodium or potassium acetate can be used as an alternative to sodium bicarbonate. Sodium acetate is a conjugate base of a weak acid (acetic acid) with a pKb of 9.25. pKb is a measure of the strength of a base, which depends on its base dissociation constant. It has been shown in one study to be an effective alternative to sodium bicarbonate in correcting this type of acid-base abnormality when added to parenteral nutrition (Peters et al, 1997). The median doses of acetate used in this randomized controlled trial were 2.6 mmol/kg/day on day 4 of life and 4.1 mmol/kg/day on day 8 of life. Infants randomized to acetate had an increased base excess and pH and increased Pco_2, and they received less bicarbonate boluses compared with control infants.

In certain clinical situations, tromethamine can be used as an alternative buffer to sodium bicarbonate. The theoretical advantages of tromethamine over sodium bicarbonate in the treatment of metabolic acidosis of the newborn include its more rapid intracellular buffering capability, its ability to lower $Paco_2$ levels directly, and the lack of an increase in the sodium load (Schneiderman et al, 1993). Tromethamine lowers P_aco_2 by covalently binding H^+ and thus shifting the equilibrium of the reaction

$$H^+ + HCO_3^- \leftrightarrow H_2CO_3 \leftrightarrow H_2O + CO_2$$

to the left, resulting in a decrease in CO_2 and an increase in HCO_3^-. Because the end-product (chelated tromethamine) is a cation that is excreted by the kidneys, oliguria is a relative contraindication to the repeated use of this buffer. Tromethamine administration also has been associated with the development of acute respiratory depression, most likely secondary to an abrupt decrease in P_aco_2 levels as well as from rapid intracellular correction of acidosis in the cells of the respiratory center (Robertson, 1970). Furthermore, because hypocapnia is associated with decreases in brain blood flow and a higher incidence of white matter damage, especially in the immature preterm neonate, close monitoring of $Paco_2$ is of paramount importance when tromethamine is being used. Finally, when large doses of tromethamine are administered, hyponatremia (Seri et al, 1998b), hypoglycemia, hyperkalemia, an increase in hemoglobin oxygen affinity, and diuresis followed by oliguria can occur. Because the tromethamine solution is hyperosmolar, and because rapid infusion of tromethamine can also lower blood pressure and intracranial pressure (Duthie et al, 1994), slow infusion is recommended. The suggested initial dose is 1 to 2 mEq/kg or 3.5 to 6 mL/kg given intravenously using the 0.3 M solution, with the rate of administration not exceeding 1 mL/kg/min. Once a blood gas measurement has been obtained, the dose of tromethamine required to raise the pH can be estimated using the formula

$$\text{Dose of tromethamine (mL)} = \text{Base deficit (mEq/L)} \times \text{Body weight (kg)}$$

Finally, during the correction of metabolic acidosis, particular attention should be paid to ensuring an appropriate potassium balance. Because potassium moves from the intracellular to the extracellular space in exchange for H^+ when acidosis occurs, the presence of a total body potassium deficit might not be appreciated during metabolic acidosis. Hypokalemia may become evident only as the pH increases and potassium returns to the intracellular space. Furthermore, intracellular acidosis cannot be completely corrected until the potassium stores are restored. Therefore close monitoring of serum electrolytes and potassium supplementation are important during the correction of metabolic acidosis in the sick newborn.

Respiratory Acidosis

Respiratory acidosis occurs when a primary increase in $Paco_2$ develops secondary to impairments in alveolar ventilation that result in an arterial pH of less than 7.35. Primary respiratory acidosis is a common problem in newborns, and causes include hyaline membrane disease, pneumonia owing to infection or aspiration, patent ductus arteriosus with pulmonary edema, chronic lung disease, pleural effusion, pneumothorax, and pulmonary hypoplasia. The initial increase in P_aco_2 is buffered by the non-HCO_3^- intracellular buffers without noticeable renal compensation for at least 12 to 24 hours (see Table 31-5). Renal metabolic compensation reaches its maximum levels within 3 to 5 days, and its effectiveness in the newborn is influenced mainly by the functional maturity of proximal tubular HCO_3^- transport.

Management of respiratory acidosis is directed toward improving alveolar ventilation and treating the underlying disorder. For sick newborns, adequate ventilation must often be provided by mechanical ventilation. In severe respiratory acidosis, tromethamine can be used to raise pH, because it lowers CO_2 levels. Tromethamine, however, produces only a transient decrease in P_aco_2, and toxic doses would quickly be reached if it were used to buffer all the CO_2 produced by metabolism over a sustained period. Therefore tromethamine should be used only as a temporizing measure in severe respiratory acidosis until alveolar ventilation can be improved.

Metabolic Alkalosis

Metabolic alkalosis is characterized by a primary increase in the extracellular HCO_3^- concentration sufficient to raise the arterial pH above 7.45. In the newborn, metabolic alkalosis occurs when there is a loss of H^+, a gain of HCO_3^-, or a depletion of the extracellular volume with the loss of more chloride than HCO_3^-. It is important to understand that metabolic alkalosis generated by any of these mechanisms can be maintained only when factors limiting the renal excretion of HCO_3^- are also present.

Metabolic alkalosis can result from a loss of H^+ from the body, from either the gastrointestinal tract or the kidneys, that induces an equivalent rise in the extracellular HCO_3^- concentration. The most common causes of this type of metabolic alkalosis in the newborn period are continuous nasogastric aspiration, persistent vomiting, and diuretic treatment. Less common causes of H^+ losses are congenital chloride-wasting diarrhea, certain forms of congenital adrenal hyperplasia, hyperaldosteronism, posthypercapnia, and Bartter syndrome.

Metabolic alkalosis can also result from a gain of HCO_3^-, such as occurs during the administration of buffer solutions to the newborn. In the past, a metabolic alkalosis was intentionally created when sodium bicarbonate or tromethamine was used to maintain an alkaline pH to decrease pulmonary vasoreactivity in infants with persistent pulmonary hypertension, a practice not recommended anymore. Currently, iatrogenically produced metabolic alkalosis is primarily unintentional and due to chronic excessive administration of HCO_3^-, lactate, citrate, or acetate in intravenous fluids and blood products. Because excretion of HCO_3^- is normally not limited in the newborn, metabolic alkalosis resulting from HCO_3^- gain alone should rapidly resolve after administration of HCO_3^- is discontinued. However, if the alkalosis is severe and urine output is limited, inhibition of the carbonic anhydrase enzyme by the administration of acetazolamide may enhance elimination of HCO_3^-.

Metabolic alkalosis can also result from a loss of ECF containing disproportionately more chloride than HCO_3^-—the so-called contraction alkalosis. During the diuretic phase of normal postnatal adaptation, preterm and term newborns retain relatively more HCO_3^- than chloride (Ramiro-Tolentino et al, 1996). The obvious clinical benefits of allowing this physiologic extracellular volume contraction to occur, especially in the critically ill newborn, clearly outweigh the clinical importance of a mild contraction alkalosis that develops after recovery. No specific treatment is needed in such cases, because with the stabilization of the extracellular volume and renal function after recovery, acid-base balance rapidly returns to normal. Contraction alkalosis due to other causes, however, may require treatment.

For metabolic alkalosis to persist, factors limiting the renal excretion of HCO_3^- must be present. The kidneys are usually effective in excreting excess HCO_3^-, but this ability can be limited under certain conditions, such as decreased glomerular filtration rate, increased aldosterone production, and the more common clinical situation of volume contraction–triggered metabolic alkalosis with potassium deficiency. In the last condition, there is a direct stimulation of Na^+ reabsorption coupled with H^+ loss in the proximal tubule, and an indirect stimulation of H^+ loss in the distal nephron by the increased activity of the renin-angiotensin-aldosterone system. Contraction alkalosis responds to administration of saline to replace the intravascular volume in conjunction with additional potassium supplementation to account for renal potassium wasting. In the other disorders, however, the primary problem of reduced glomerular filtration rate or elevated aldosterone must be treated for the alkalosis to resolve.

One of the most commonly encountered clinical scenarios of chronic metabolic alkalosis actually occurs in the form of a mixed acid-base disorder in a preterm infant with chronic lung disease on long-term diuretic treatment. Such a newborn initially has a chronic respiratory acidosis that is partially compensated for by renal HCO_3^- retention. Prolonged or aggressive use of diuretics

can lead to total-body potassium depletion and contraction of the extracellular volume, thus exacerbating the metabolic alkalosis. By stimulating proximal tubular Na^+ reabsorption and thus H^+ loss, distal tubular H^+ secretion, and renal ammonium production, the diuretic-induced hypokalemia contributes to the severity and maintenance of the metabolic alkalosis. Furthermore, metabolic alkalosis per se worsens hypokalemia, because potassium moves intracellularly to replace hydrogen as the latter shifts into the extracellular space. Although the serum potassium concentration may be decreased, the serum levels in the newborn do not accurately reflect the extent of total-body potassium deficit because potassium is primarily an intracellular ion, with approximately 98% of the total body potassium being in the intracellular compartment. In addition, the condition is often accompanied by marked hypochloremia and hyponatremia. Hyponatremia occurs in part because sodium shifts into the intracellular space to compensate for the depleted intracellular potassium. If the alkalosis is severe, alkalemia (pH >7.45) can supervene and result in hypoventilation. In this situation, potassium chloride, and not sodium chloride supplementation, reverses hyponatremia and hypochloremia, corrects hypokalemia and metabolic alkalosis, and increases the effectiveness of diuretic therapy. Because chloride deficiency is the predominant cause of the increased pH, ammonium chloride or arginine chloride also corrects the alkalosis. These agents do not affect the other electrolyte imbalances such as the hypokalemia, so they should not be the only therapy given.

It is important to keep ahead of the potassium losses in infants receiving long-term diuretic therapy, rather than to attempt to replace potassium after intracellular depletion has occurred. Because the rate of potassium repletion is limited by the rate at which potassium moves intracellularly, correction of total body potassium deficits can require days to weeks. In addition, there is also a risk of acute hyperkalemia if serum potassium levels are driven too high during repletion, particularly in newborns in whom an acute respiratory deterioration may occur, with worsened respiratory acidosis and the subsequent movement of potassium from the intracellular to the extracellular space. The routine use of potassium chloride supplementation and close monitoring of serum sodium, chloride, and potassium levels are therefore recommended during long-term diuretic therapy to prevent these common iatrogenic problems.

Respiratory Alkalosis

When a primary decrease in $Paco_2$ results in an increase in the arterial pH beyond 7.45, respiratory alkalosis develops. The initial hypocapnia is acutely titrated by the intracellular buffers, and metabolic compensation by the kidneys returns pH toward normal within 1 to 2 days (see Table 31-5). Interestingly, respiratory alkalosis is the only simple acid-base disorder in which, at least in adults, the pH can completely be normalized by the compensatory mechanisms (Brewer, 1990). The cause of respiratory alkalosis is hyperventilation, which in the spontaneously breathing newborn is most often caused by fever, sepsis, retained fetal lung fluid, mild aspiration pneumonia, or central nervous system disorders. In the neonatal intensive care unit, the most common cause of respiratory alkalosis is iatrogenic secondary to hyperventilation of the intubated newborn. Because findings suggest an association between hypocapnia and the development of periventricular leukomalacia (Okumura et al, 2001; Wiswell et al, 1996) and chronic lung disease (Garland et al, 1995) in ventilated preterm infants, avoidance of hyperventilation during resuscitation and mechanical ventilation is of utmost importance in the management of sick preterm newborns. The treatment of neonatal respiratory alkalosis consists of the specific management of the underlying process causing hyperventilation.

CHAPTER 32

Care of the Extremely Low-Birthweight Infant

Eric C. Eichenwald

In the past two decades, the field of neonatology has experienced significant progress in medical care and improvement in overall patient survival. Advancement in technology, greater use of prenatal glucocorticoids and neonatal surfactant replacement therapy, better regionalization of perinatal and high-risk neonatal care, and a more comprehensive understanding of the physiology of the immature infant have all contributed to dramatic increases in survival of very preterm infants. Care of premature infants with birthweights between 1000 and 1500 g has become almost routine in most neonatal intensive care units (NICUs) in the United States.

The most recent challenge in neonatology is the care of extremely low-birthweight (ELBW) infants (birthweight <1000 g), sometimes referred to colloquially as *micropremies*. These infants present one of the greatest medical and ethical challenges to the field. Although they represent a small percentage of overall births and NICU admissions, ELBW infants are often the most critically ill and at the highest risk for mortality and long-term morbidity of any NICU patient. They also contribute disproportionately to overall hospital days and consume a large percentage of NICU personnel time, effort, and costs of care. Care of these infants is in constant evolution, as a result of new discoveries in both basic and clinical research as well as to growing clinical experience. This chapter will review some of the special challenges in and practical aspects of the management of the ELBW infant. The reader is referred to specific chapters throughout the text for a more comprehensive review of specific problems and conditions.

EPIDEMIOLOGY

The percentage of babies born preterm in the United States has risen slowly over the past two decades (Behrman and Stith Butler, 2007). In the year 2007, preterm births (<37 weeks' gestation) accounted for 12.7% of all births, with approximately 1% of births occurring before 28 weeks' gestation. There is a significant racial disparity in the incidence of extreme preterm birth, with the African American ELBW birth rate being nearly double that of the Hispanic and non-Hispanic white populations. Associated with this increase in frequency of preterm births is the greater availability of assisted reproductive technologies. These technologies result in a higher incidence of LBW infants, because of the higher frequency of multiple gestations (Schieve et al, 2002). Twins, triplets, and higher-order multiple gestations currently represent almost a quarter all LBW deliveries in the United States (Martin et al, 2002) and contribute to the ELBW population. Multiple gestations add to the potential morbidity of extremely premature birth because of a higher frequency of intrauterine growth restriction and other medical complications of pregnancy.

Several studies have shown increased survival in the smallest and most premature infants over the past decade (Figures 32-1 and 32-2) (Fanaroff et al, 2007; Horbar et al, 2002; Lemons et al, 2001). See Chapter 1 for a complete discussion of these changes.

Improved survival has not been accompanied by a change in the incidence of several major morbidities among survivors (Tables 32-1 and 32-2). Little to no change in the frequency of severe intracranial hemorrhage, periventricular white matter injury, necrotizing enterocolitis, or bronchopulmonary dysplasia was observed in the Eunice Kennedy Shriver National Institute of Child Health and Human Development cohort of infants born in institutions participating in the Neonatal Research Network in 1995-1996 compared with and 1997-2002 (Fanaroff et al, 2007). Although the Vermont–Oxford NICUs reported a reduction in the incidence of severe intracranial hemorrhage in the early part of the 1990s, the incidence has remained static into the late 1990s (Horbar et al, 2002). With the current trends in survival and in hospital morbidity, the absolute number of extremely premature infants who survive to NICU discharge and are diagnosed with a major morbidity in the neonatal period is increasing. A significant percentage of these infants continues to suffer from neurodevelopmental and neurosensory disability into childhood (Hack et al, 2005; Marlow et al, 2005; Wood et al, 2000).

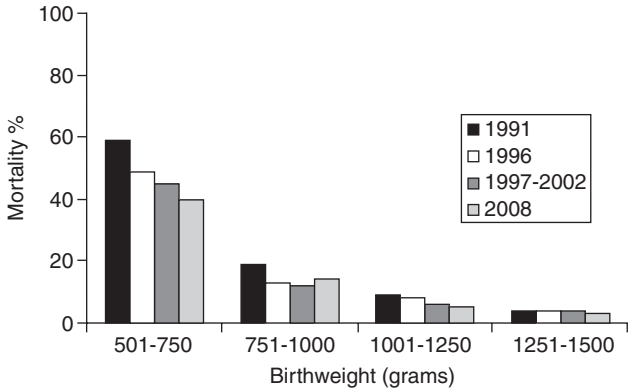

FIGURE 32-1 Mortality in very low birthweight infants receiving care in the National Institute of Child Health and Human Development Eunice Kennedy Shriver Neonatal Research Network Centers from 1991 to 2002 and the Vermont-Oxford Network in 2008. *(From Eichenwald EC, Stark AR: Management and outcomes of very low birth weight,* N Engl J Med *358:1700-1711, 2008. PERINATAL MANAGEMENT

Extremely premature infants born in perinatal centers for high-risk infants, especially those with a high volume of such infants, have better short-term outcomes than infants transferred to such centers after birth (Arad et al, 1999; Bartels et al, 2006; Chien et al, 2001; Cifuentes et al, 2002; Phibbs et al, 2007; Shah et al, 2005; Towers et al, 2000). Therefore, if clinically feasible, the pregnant woman who seems likely to deliver an extremely premature infant should be transferred to a high-risk perinatal center for the expertise in both obstetric and neonatal management. Upon arrival, the expectant mother should be evaluated for factors that may have predisposed to preterm labor and assessed for the status of the fetal membranes and the presence or absence of chorioamnionitis. In addition, best obstetric estimate of gestational age (by date of last menstrual period and early ultrasonographic dating, if available), ultrasonographic assessment of fetal size and position, and the presence of other medical or obstetric complications (preeclampsia, placenta previa, abruptio placentae) should be documented. Specimens for rectovaginal cultures to detect the presence of group B streptococci should also be obtained on admission (Schrag et al, 2002), and treatment with penicillin or ampicillin (or vancomycin for the patient with a severe penicillin allergy) should be initiated until culture results are available. There is widespread agreement that prenatal glucocorticoids should be offered to any woman in whom delivery at 24 to 34 weeks' gestation threatens; treatment at earlier gestational ages is controversial and of unclear benefit. Although unlikely to arrest labor for an extended period, tocolytic agents should be considered for women with preterm uterine contractions without evidence of chorioamnionitis.

Premature rupture of the fetal membranes (PROM) occurs in 30% to 40% of women who deliver prematurely (Mazor et al, 1998). If PROM is diagnosed without evidence of chorioamnionitis, consideration should be given

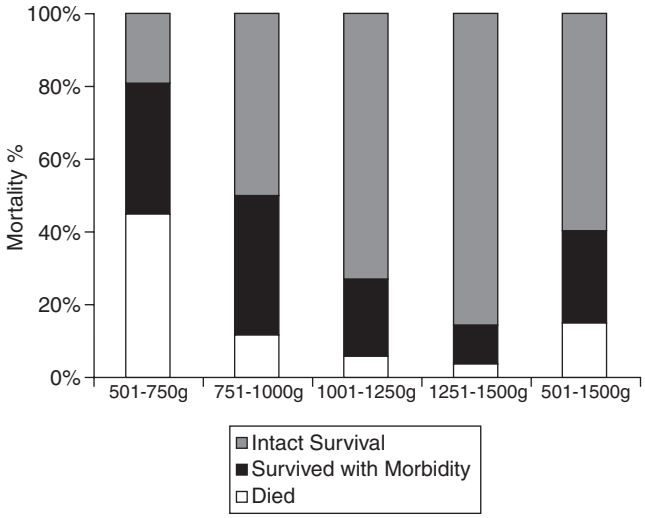

FIGURE 32-2 Proportion of very low birthweight infants who died, and the proportion who survived with short-term complications (bronchopulmonary dysplasia, severe intraventricular hemorrhage, necrotizing enterocolitis, or a combination of these disorders, or with no complications from 1997 to 2002 at the Eunice Kennedy Shriver National Institute of Child Health and Human Development Neonatal Research Network sites. *(From Eichenwald EC, Stark AR: Management and outcomes of very low birth weight*, N Engl J Med *358:1700-1711, 2008. to the use of prophylactic antibiotic therapy (ampicillin or erythromycin) for the mother. Several studies have shown that such therapy prolongs the latency period, reduces the incidence of chorioamnionitis and endometritis, and improves neonatal outcome (Gibbs and Eschenbach, 1997; Mazor et al, 1998; Mercer et al, 1997). Tocolytic and antibiotic therapy in the setting of PROM may prolong latency by 48 to 72 hours in many extremely preterm pregnancies in which delivery threatens, allowing the administration of a complete course of glucocorticoids to the mother.

PRENATAL CONSULTATION

If possible, all parents who are at risk for delivery of an extremely premature infant should meet in consultation with a neonatologist before the infant's birth, preferably jointly with a perinatologist caring for the mother (Finer and Barrington, 1998). There are several goals of this consultation. First, the neonatologist and perinatologist should inform the parents about the proposed management of the pregnancy and delivery of the infant, including a discussion of the advantages of administration of glucocorticoids to the mother, the possible need for cesarean delivery, and delivery room care and resuscitation of the baby. Second, the parents should be informed about the potential risks of both the extent of prematurity and the proposed therapeutic interventions (Tables 32-3 and 32-4). Third, the neonatologist should investigate the parents' beliefs and attitudes about delivery of an extremely premature infant and the potential for long-term morbidity. This outline for prenatal consultation is especially important if delivery is expected at the borderline of viability (23 to 24 weeks' gestation).

Data are sparse about the process and results of prenatal consultation with parents of an extremely preterm infant. Some studies suggest that significant incongruity exists among the attitudes of obstetricians, nurses, neonatologists, and parents about active delivery room resuscitation and treatment of extremely premature infants (Streiner et al, 2001; Zupancic et al, 2002). Reuss and Gordon (1995) have shown that the obstetric judgment of fetal viability was associated with an 18-fold increase in survival for infants with a birthweight less than 750 g, indicating that obstetric attitudes and decisions influence outcome. Obstetricians and nurses tend to overestimate, and parents tend to underestimate, mortality and morbidity in premature infants

TABLE 32-3 Major Problems of Extremely Low Birthweight Infants

System	Short-Term Problems	Long-Term Problems
Respiratory	Respiratory distress syndrome Air leaks Bronchopulmonary dysplasia Apnea of prematurity	Chronic lung disease Reactive airway disease
Gastrointestinal, nutritional	Feeding intolerance Necrotizing enterocolitis Growth failure	Growth failure Failure to thrive Inguinal hernias
Immunologic, infection	Immune deficiency Perinatal infection Nosocomial infection	Respiratory syncytial virus

(Doron et al, 1998; Haywood et al, 1994). Parents report being more in favor of intervening regardless of gestational age or condition at birth compared with health care professionals (Streiner et al, 2001). In a survey by Ballard et al (2002), the majority of neonatologists responded that they would respect parents' wishes about resuscitation of a borderline viable infant. In practice, when parental preferences about active resuscitation are known before delivery of an extremely preterm infant, neonatologists report that they would alter their management of the infant in the delivery room accordingly after assessment of the baby after birth (Doron et al, 1998), indicating the important role for prenatal consultation. However, parental attitudes likely are strongly influenced by physician recommendations about aggressive resuscitation conveyed during the prenatal consultation. This consultation is further complicated by significant variability in physician's opinions about the benefits and burdens of providing intensive care at the borders of viability (De Leeuw et al, 2000). Physician attitudes may be influenced by fear of litigation for not actively resuscitating an extremely premature infant even if parental choices are made clear, as well as local, regional, and national norms (Partridge et al, 2009).

The earliest gestational age at which resuscitation should be initiated remains controversial among neonatologists (Finer et al, 1999), making firm recommendations for the actual content of prenatal consultation difficult (Kaempf et al, 2006). Most studies that describe the outcome of premature infants are based on birthweight rather than gestational age and thus confound the effects of extremely preterm birth with those of intrauterine growth restriction, but both parents and physicians are usually faced with making decisions based on the anticipated gestational age at delivery. However, the likelihood of survival without serious sequelae may be influenced by factors other than gestational age. Using prospectively collected data from the Eunice Kennedy Shriver National Institute of Child Health and Human Development Neonatal Research Network on infants born at 22 to 25 weeks' gestation between 1998 and 2003, Tyson et al (2008) presented an analysis of some of these factors. In a multivariate analysis, exposure to antenatal glucocorticoids, female sex, singleton gestation, and higher birthweight (in 100-g increments) were each associated with a decrease in the risk of death or of survival with neurodevelopmental impairment. The reduced risk was similar to the risk for infants with an additional week of gestational age. Other data from several studies suggest that in terms of survival and potential for long-term disability, encouragement of active management is appropriate for pregnancies expected to deliver at 25 weeks' gestation or later (Piecuch et al, 1997; Wood et al, 2000). The risk of death and severe morbidity is significantly higher before 25 weeks' gestation (El-Metwally et al, 2002). Mortality approaches 80% for infants delivered at 23 weeks' gestation, with the majority of survivors suffering from neurodevelopmental sequelae (Vohr et al, 2000; Wood et al, 2000). These data should be shared with parents during prenatal consultation, and appropriate guidance should be given for decision making about the pregnancy, delivery, and resuscitation of the infant. Some have argued that, because of the risk of long-term disability associated with extreme preterm birth and the difficulty of making an informed decision immediately before delivery, parents should be given the opportunity to have these issues discussed during routine prenatal care (Harrison, 2008).

GENERAL PRINCIPLES OF CARE SPECIFIC TO EXTREMELY LOW-BIRTHWEIGHT INFANTS

FIRST HOURS

The first few hours after admission to the NICU are critical for the ELBW infant, although there are significant variations in practice among hospitals and practitioners. Careful adherence to details in the delivery room and during the first few hours after birth is essential to help avoid some of the immediate and long-term complications of the ELBW infant. All NICUs should have a consistent approach to the initial care of these fragile infants in the delivery room and upon admission to the NICU. A suggested treatment guideline for the first few hours after birth is presented in Table 32-5, and screening guidelines for common complications are shown in Table 32-6.

DELIVERY ROOM

At delivery, strict attention to maintenance of body temperature by means of rapid, gentle drying of the infant and the use of adequate heat sources is paramount to avoid cold stress. Use of a polyethylene occlusive skin wrap or bag immediately after delivery may also help to prevent initial evaporative heat losses (Vohra et al, 1999). Many ELBW infants need some form of assisted ventilation immediately after birth. If positive-pressure ventilation is required, it should be provided with low inspiratory pressure to prevent overdistention of the lungs, which can result in air leak and other lung injury, and adequate positive end-expiratory pressure (PEEP) to maintain lung volume by use of a flow-inflating bag, or optimally, a T-piece resuscitator that allows for more consistent delivery of inspiratory pressure and PEEP. Hyperventilation and hyperoxia also should be avoided; many units use continuous oxygen saturation monitoring in the delivery room, with supplemental oxygen titrated to maintain oxygen saturations in the range of 85% to 93%. The use of room air for resuscitation of these infants has been proposed to protect them from hyperoxia and damage to the lungs by oxygen free radicals. This issue is under active investigation (Lefkowitz, 2002), but most centers use blended oxygen for initial resuscitation, with an initial starting F_{IO_2} between 0.4 and 0.6 (see also Chapter 28.)

Considerable practice variation exists in the use and type of ventilatory support and timing of surfactant administration for the ELBW infant after birth. Some centers routinely intubate all ELBW infants in the delivery room for respiratory support and prophylactic surfactant administration (Egberts et al, 1997; Kendig et al, 1998). Soll (2009) has reported on a metaanalysis of eight randomized trials of the use of natural surfactant as prophylaxis versus as a rescue strategy for established respiratory distress syndrome (RDS) in the ELBW infant. Administration of exogenous surfactant before 15 minutes of age resulted in a reduction in the rates of neonatal mortality, air leak, and

TABLE 32-5 Treatment Guidelines for Initial Management of Extremely Low-Birthweight Infants

Time after Birth	Guideline
Delivery room	Ensure good thermoregulation "Gentle" ventilation as required Avoid hyperventilation and hyperoxia Administer surfactant (if prophylaxis approach) Initiate NCPAP (if early CPAP approach)
NICU admission	Obtain weight measurement Administer surfactant within first hour (if rescue approach) Establish vascular access: Peripheral intravenous catheter Umbilical arterial catheter Umbilical venous catheter (central, double-lumen) Start intravenous fluids as soon as possible with dextrose and amino acid solution Limit evaporative water losses (humidified incubator) Minimize stimulation Avoid hyperventilation and hyperoxia Maintain target oxygen saturations between 88% and 93% Obtain specimens for complete blood count with differential, blood culture, blood glucose measurement Give antibiotics as indicated Give parents information about their child
First 24 to 48 Hours	
Cardiovascular	Monitor blood pressure, give vasopressors as required Maintain vigilance for presence of patent ductus arteriosus Obtain echocardiogram as indicated
Respiratory	Give additional surfactant doses as indicated Maintain low tidal volume ventilation Avoid hyperventilation and hyperoxia Extubate infant and start on continuous positive airway pressure when possible
Fluid management	Obtain weight every 12 to 24 hours Monitor serum electrolyte, blood glucose, and calcium concentrations every 4 to 8 hours Limit evaporative water losses Administer skin care
Hematologic	Obtain second blood count Administer transfusion support as indicated Monitor bilirubin, give phototherapy as indicated
Infection	Consider discontinuing antibiotics if blood culture results are negative at 48 hours
Nutrition	Start amino acid solution, parenteral nutrition
Neurologic	Minimize stimulation Perform screening head ultrasonography
Social	Arrange to meet with family

CPAP, Continuous positive airway pressure; *NCPAP*, nasal continuous positive airway pressure; *NICU*, neonatal intensive care unit.

the combined outcome of bronchopulmonary dysplasia (BPD) or death compared with a selective rescue approach. However, no trials comparing prophylactic administration with early rescue administration of exogenous surfactant (within the first 30 to 60 minutes) have been performed (see Chapter 46). In some centers, ELBW infants are observed briefly after birth, and if respiratory distress develops, they are intubated and ventilated for transfer to the NICU. Exogenous surfactant is given within 1 hour of birth, after endotracheal tube position and the presence of RDS are confirmed on chest radiograph. This strategy assures uniform distribution of surfactant to both lungs and allows initial stabilization and more intensive monitoring of the infant during its administration. Recent data suggest that many spontaneously breathing, extremely premature infants can be managed successfully with continuous positive airway pressure (CPAP) started in the delivery room (Aly et al, 2005b; Lindner et al, 1999; Morley et al, 2008; SUPPORT Study Group, 2010). Routine use of CPAP immediately after delivery may obviate the need for intubation in infants with a gestational age of 24 weeks or more, and increasing experience with this approach has been shown to improve its success (Aly et al, 2005b; Finer, 2006). According to one report, mechanical ventilation was avoided in approximately one third of infants with a gestational age of 25 weeks or less, and in nearly 80% of infants with a gestational age of 28 weeks or more using this approach (Aly et al, 2005b). Whereas aggressive use of early CPAP in the delivery room avoids intubation in some ELBW infants, it remains unclear whether it improves longer term respiratory outcomes (Morley et al, 2008; SUPPORT Study Group, 2010).

If intubation is required, both oral and nasal routes for endotracheal tube placement are equally effective and have similar complication rates (Spence and Barr, 2002). Preference is usually institution specific, although successful placement of a nasal endotracheal tube requires more time.

ADMISSION TO THE NEONATAL INTENSIVE CARE UNIT

All infants should be weighed upon admission; frequent determination of subsequent weights is a valuable tool in managing fluid and electrolyte balance. In many centers, ELBW infants are initially placed under a radiant warmer for easier access (i.e., for surfactant administration and catheter placement). Because of the high transepidermal fluid losses in these infants, intravenous solutions containing 5% to 10% dextrose should be started as quickly as possible after admission, and efforts should be made to ameliorate evaporative water losses by increasing the relative humidity surrounding the infant. A plastic heat shield used in concert with the radiant warmer may decrease transepidermal water losses; alternatively, a polyethylene tent with an infusion of warmed humidified air may be used. Several studies suggest that fluid management is improved by using a humidified incubator instead of a radiant warmer, because of lower water losses (Gaylord et al, 2001;

TABLE 32-6 Recommended Screening for Common Complications of Extremely Low-Birthweight Infants

Complication	Screening
IVH	HUS on days 1-3; repeat on days 7-10
Germinal matrix hemorrhage	Repeat HUS weekly until findings normal
Intraventricular hemorrhage	Repeat HUS every 3 to 7 days until stable or resolved
IVH with ventricular dilation or intraparenchymal bleeding	Repeat HUS every 3 to 7 days until stable or resolved Consider measurement of resistive indices for progressive ventricular dilatation
Periventricular white matter disease	HUS at day 30; repeat at 36 weeks of postmenstrual age or at discharge Consider magnetic resonance imaging if HUS findings are equivocal
ROP	Perform OE examination at 4 to 6 weeks of postnatal age Repeat every 2 weeks if no ROP Repeat weekly if ROP present Repeat twice weekly for prethreshold disease or rapidly progressive ROP
Audiology screening	Hearing screen no earlier than 34 weeks of postmenstrual age, but before discharge home

HUS, Head ultrasonography; *IVH*, intraventricular hemorrhage; *OE*, ophthalmologic examination; *ROP*, retinopathy of prematurity.

Meyer et al, 2001). Exposure to high humidity may raise the rate of skin colonization with gram-negative organisms, although no increase in the rate of nosocomial infections was observed in several randomized trials comparing incubators with radiant warmers (Flenady and Woodgate, 2002). However, temperature regulation for the smallest infants in the first few days may be more difficult in an incubator than in a servo-controlled radiant warmer, because of rapid drops in air temperature as the incubator doors are opened to care for the infant (Meyer et al, 2001; see also Chapter 30).

VASCULAR ACCESS

Close monitoring of blood pressure, arterial blood gases, and serum chemistries during the first few days after birth is required in most sick ELBW infants; therefore it is advantageous to insert an umbilical arterial catheter for reliable access in infants who require assisted ventilation. Infusion of half-normal saline with 0.5 unit of heparin per milliliter at a low rate (0.5 to 1 mL/h) is usually enough to maintain catheter patency. Although using a saline solution rather than a dextrose-water solution in the umbilical arterial line may complicate fluid and electrolyte management, this disadvantage is offset by the advantage of reliable measurement of blood glucose levels, which are frequently required, without disturbing the infant. Placement of a central umbilical venous catheter (tip at the inferior vena cava–right atrial junction) at the same time the umbilical arterial catheter is placed also provides the clinician with reliable venous access for infusion of fluids, medications, and blood products. Use of a double-lumen umbilical venous catheter often obviates insertion of a peripheral intravenous line over the first few days after birth and helps to preserve intravenous sites and skin integrity.

The length of time that umbilical catheters are left in place varies by hospital. In most centers, umbilical lines are generally discontinued after 7 to 10 days because of the potential for catheter-related infection and vascular complications, although it is unusual for arterial access to be needed beyond a few days after birth. Before the umbilical venous catheter is removed, it is advisable to insert a percutaneous central venous catheter with its tip at the junction of the superior or inferior vena cava and the right atrium, dedicated to infusion of parenteral nutrition (see Nutritional Management, later). This catheter helps to maintain intravenous access for nutritional purposes without raising the risk of catheter-related infections and reduces the need to establish and maintain peripheral intravenous lines (Janes et al, 2000; Parellada et al, 1999). The incidence of complications of percutaneous central catheters, including catheter-related infections, is lower if a limited number of NICU personnel insert and maintain the lines.

SKIN CARE

The skin of an infant born at 23 to 26 weeks' gestation is extremely immature and is ineffective as an epidermal barrier. Poor epidermal barrier function in the extremely preterm infant leads to disturbances in temperature regulation and water balance as well as breakdown in skin integrity, which can increase the risk of infection. The stratum corneum, which is responsible for epidermal barrier function, does not become functionally mature in the fetus until approximately 32 weeks' gestation (Rutter, 2000). However, acceleration of the maturation process occurs after birth, so most extremely premature infants have a mature epidermal barrier by approximately 2 weeks of postnatal age. Until that time, full-thickness skin injury can occur in the ELBW infant from seemingly innocuous causes, such as local pressure from body positioning, removal of adhesives, and prolonged exposure to products containing alcohol or iodine. Such injury can lead to larger transepidermal water losses, an even greater risk of nosocomial infection, and significant scarring.

Because of these risks, preservation of skin integrity should be incorporated into the care of the extremely preterm infant (Table 32-7). Limited use of adhesives and extreme care upon their removal, frequent repositioning of the infant to avoid pressure points on the skin, and use of soft bedding or a water mattress are the minimum requirements. Hydrocolloids (e.g., DuoDerm, ConvaTech, U.S.) applied to the baby in areas where adhesive tape may come in prolonged contact with the skin (i.e., umbilical catheter or endotracheal tube fixation) to prevent the direct application of tape to the baby may be useful, because it is more easily removed than standard adhesive tape. Polyurethane adhesive dressings (Tegaderm 3m, St. Paul, Minnesota) or hydrogels (Vigilon, Bard Medical, Covington, Georgia) may also be used to protect areas of skin friction and superficial wounds.

Prophylactic application of preservative-free emollient ointments (Aquaphor, Beiersdorf AG, Hamburg, Germany) to protect the skin of the ELBW infant has been studied

TABLE 32-7 Practical Guidelines for Skin Care of Extremely Low-Birthweight Infants

Interventions	Guidelines
Adhesive application	Increase adhesive tack by applying to dry, clean skin surface Avoid alcohol for skin cleansing Use smallest amount of tape possible Use a hydrocolloid or pectin-based layer on the skin, before application of heavy adhesive Avoid using adhesive over areas of skin breakdown Avoid adhesive bonding agents (e.g., benzoin) Use hydrophilic gel or pectin-based adhesives preferentially
Adhesive removal	Avoid adhesive removers and solvents Use a warm, wet cotton ball to periodically saturate hydrogel adhesives (avoid overdrying and oversaturation) Facilitate removal of adhesive with mineral oil, petrolatum, and emollients if reapplication is not necessary
Emollient application	Infants born at <27 weeks' gestation may benefit from emollient use Avoid multidose containers (e.g., large jars) Use nonperfumed, nonirritating hydrophilic emollients Recognize potential for emollients to interfere with adhesive and conductive properties of monitoring devices
Emollient removal	Wipe off gently with a soft cloth or gauze if site is contaminated Avoid repeated attempts to thoroughly cleanse the skin (undesired friction effect) Remove emollients before attaching thermistors or other monitoring devices

Data from Hoath S, Narendran V: Adhesives and emollients in the preterm infant, *Semin Neonataol* 5:289-296, 2000.

(Edwards et al, 2004; Lane and Drost, 1993; Nopper et al, 1996). Several small studies demonstrated smaller transepidermal water losses, improved skin condition, and lower risk of suspected or proven nosocomial infection with prophylactic application of emollient ointments. However, one report documented an increase in the rate of systemic yeast infections in a single NICU coincident with a change to use of prophylactic emollients in ELBW infants, who returned to baseline after such use was discontinued (Campbell et al, 2000). In the largest study to date, infants randomized to prophylactic emollient had better skin integrity during the first month after birth, but had a higher rate of nosocomial bacterial infection compared with a control group with no emollient use (Edwards et al, 2004). Given these concerns, routine use of prophylactic emollients is not recommended; however, selective use in ELBW infants at risk for significant skin breakdown may be effective as an adjunct to other types of local skin care already described.

MECHANICAL VENTILATION AND NASAL CONTINUOUS AIRWAY PRESSURE

A high percentage of ELBW infants require some level of assisted ventilation to survive. Data from animal models of RDS indicate that positive-pressure ventilation with large tidal volumes damages pulmonary capillary endothelium, alveolar and airway epithelium, and basement membranes. This mechanical damage results in leakage of fluid, protein, and blood into the airways, alveoli, and interstitial spaces, leading to inhibition of surfactant activity and further damage to the lungs. These data suggest that a ventilator strategy that avoids large changes in tidal volume may reduce ventilator-induced lung injury in ELBW infants, an important management goal. The optimal mode, timing, and application of ventilatory support used in the initial management of the ELBW infant to meet this goal remain controversial. However, the objectives of all strategies of assisted ventilation in the ELBW infant should be similar—(1) to provide the lowest level of ventilatory support possible that will both support adequate oxygenation and ventilation and prevent atelectasis and (2) to try to reduce acute and chronic lung injury secondary to barotrauma, volutrauma, and oxygen toxicity (Clark et al, 2000). Data also suggest that targeting oxygen saturations (88% to 93%) lower than those used historically in ELBW infants who are receiving supplemental oxygen may protect the lung from oxidative injury and result in better outcomes (Askie et al, 2003).

CONTINUOUS POSITIVE AIRWAY PRESSURE

In a classic study comparing the incidence of BPD between NICUs, Avery et al (1987) reported that the NICU with the lowest incidence used CPAP more frequently and more aggressively than the other units. Van Marter et al (2000) confirmed these observations.

Theoretically, early CPAP protects the immature lung from injury caused by positive-pressure tidal breaths, by preserving surfactant function, increasing alveolar volume and functional residual capacity, enhancing alveolar stability, and improving ventilation-perfusion matching. It also may stimulate the growth of the immature lung. Some NICUs now use CPAP (delivered via nasal prongs or nasopharyngeal tube at 5 to 7 cm H_2O) as the initial mode of assisted ventilation for ELBW infants, starting almost immediately in the delivery room (Lindner et al, 1999). CPAP used this way has been reported in retrospective studies to decrease the need for mechanical ventilation (Gittermann et al, 1997; Poets and Sens, 1996), the need for surfactant treatment, and the incidence of BPD (Aly, 2001; Aly et al, 2005b; de Klerk and de Klerk, 2001; Lindner et al, 1999). In one prospective study (Morley et al, 2008), infants with a gestational age of 25 to 28 weeks who were breathing spontaneously, but required ventilatory assistance at 5 minutes after birth, were randomly assigned to treatment with nasal CPAP or intubation and mechanical ventilation. In the infants assigned to CPAP, 56% did not require intubation, and surfactant use was halved. Although respiratory outcomes at 36 weeks postmenstrual age were equivalent in the two study groups, a greater number of infants who were assigned to initial treatment with CPAP had pneumothorax (9% versus 3%). Alternatively, CPAP may be used after prophylactic or rescue surfactant therapy is given during a brief period of intubation and positive-pressure ventilation (Booth et al, 2006; Verder et al, 1999). Observational studies of this approach show that approximately one fourth of infants born before

27 weeks' gestation do not require a subsequent course of mechanical ventilation and are less likely to develop BPD (Booth et al, 2006; Dani et al, 2004).

CPAP can be delivered by a conventional mechanical ventilator with continuous flow, a variable flow device that adjusts flow through the respiratory cycle, or via "bubble" CPAP, in which a tube is immersed in water to the desired depth to generate CPAP with continuous gas flow bubbling through the immersed tube. Animal data suggest that bubble CPAP improves lung volume and gas exchange compared with conventional CPAP (Pillow et al, 2007), perhaps secondary to effects of the higher intranasal pressures generated by the bubbling water (Kahn et al, 2008). Other data suggest that work of breathing and thoracoabdominal asynchrony may be lessened with variable flow devices (Liptsen et al, 2005). Whether these differences are clinically relevant remains to be elucidated.

CONVENTIONAL MECHANICAL VENTILATION

Most NICUs continue to use pressure-limited, time-cycled conventional ventilators for the initial respiratory management of the ELBW infant requiring mechanical ventilation. Synchronized intermittent mandatory ventilation (SIMV) remains the preferred mode of conventional ventilation for the ELBW infant. In the premature infant, SIMV, in which the inspiratory cycle is synchronized with the patient's own effort, is better than conventional IMV in terms of oxygenation, ventilation, work of breathing, and blood pressure variability (Cleary et al, 1995; Hummler et al, 1996; Jarreau et al, 1996). Technologic limitations in the ability of some ventilators to synchronize breaths with very weak inspiratory efforts may prevent use of SIMV in the smallest infants. With further advancement in ventilator design, other modes of patient-triggered ventilation, including volume guarantee, assist control, and pressure support, have become available to clinicians. These designs generally allow ventilation at lower pressures than conventional SIMV. These modes of ventilation are under investigation but have not been proved to produce better pulmonary outcomes than SIMV in ELBW infants (Donn and Sinha, 1998; Herrera et al, 2002), although one report suggested a shorter time to extubation in infants babies managed with pressure-support ventilation (Reyes et al, 2006).

Currently accepted conventional ventilatory strategies in the ELBW infant stress the avoidance of excessive tidal volumes by limiting peak inspiratory pressures and provision of adequate PEEP to maintain lung volume (Thome et al, 1998). This strategy helps to prevent repeated cycles of atelectasis and lung overdistention, a risk factor for ventilator-induced lung injury (Dreyfuss and Saumon, 1998). Hyperventilation ($Paco_2$ <35 mm Hg) has been associated with a higher risk for the development of BPD (Garland et al, 1995; Van Marter et al, 2000) and neurodevelopmental sequelae in ELBW infants (Wiswell et al, 1996).

In response to this suggestion of worse pulmonary outcome in hyperventilated infants, a strategy of minimal ventilation, or permissive hypercapnia, has been proposed for conventional ventilation in ELBW infants. In the largest study to date of this ventilatory strategy, Carlo et al (2002) randomly assigned 220 infants with birthweights between 501 and 1000 g to receive either minimal ventilation (target $Paco_2$ >52 mm Hg) or routine ventilation (target $Paco_2$ <48 mm Hg). No difference in the rate of BPD, death, or other major short-term morbidities was seen between the two groups. Potential risks of a high $Paco_2$ include increases in both cerebral perfusion and pulmonary vascular resistance and lower pH. Without clear data to support the benefit and safety of higher levels of hypercapnia, most centers target their conventional ventilatory strategy to maintain $Paco_2$ between 45 and 55 mm Hg in the first several days of mechanical ventilation in the ELBW infant.

In infants whose lung disease prevents extubation in the first several days after birth, changes in lung dynamics over the first 1 to 2 weeks often necessitate a change in ventilatory strategy. In the early stages of chronic lung disease, increased airway resistance and decreased lung compliance may require higher values for mean airway pressure, peak inspiratory pressure, PEEP, and inspiratory time than are usually used in initial ventilatory management. Once the need for more prolonged mechanical ventilation is established, many centers tolerate higher target $Paco_2$ values in an attempt to limit further ventilator-induced lung injury.

HIGH-FREQUENCY VENTILATION

Considerable interest has been generated over the past 15 years in the application of high-frequency ventilation (HFV) in newborns who have respiratory failure, because this technique allows ventilation with small tidal volumes. Results of studies using HFV in animal models of RDS have been promising in the prevention of lung injury, but results of clinical studies of this ventilatory technique have not. Despite many clinical trials, controversy continues to surround the indications for HFV in ELBW infants, whether HFV is more effective than other modes of ventilation for RDS, whether HFV reduces adverse outcomes (specifically BPD), and whether HFV is more likely to have significant long-term complications than conventional mechanical ventilation.

Early trials of HFV before surfactant replacement therapy demonstrated no pulmonary advantage of HFV over conventional mechanical ventilation and suggested an increase in rates of air leak and intracranial abnormalities in the HFV-treated infants (HIFI Study Group, 1989). Later trials in ELBW infants who were treated with surfactant also failed to demonstrate any reduction in the incidence of BPD in the HFV-treated infants (Johnson et al, 2002; Rettitz-Volk et al, 1998; Thome et al, 1999).

A rigorously controlled trial of HFV as the primary mode of assisted ventilation compared with conventional mechanical ventilation was the first to suggest a small advantage to the early use of HFV in reduction of BPD or death without an increase in the incidence of short-term complications in ELBW infants. Courtney et al (2002) compared high-frequency oscillatory ventilation (HFOV) with synchronized IMV in a randomized trial that enrolled 500 ELBW infants. These investigators found a small but

significant decrease in the incidence of BPD in survivors, requirement of fewer doses of exogenous surfactant, and shorter time to successful extubation in the HFOV-treated group. No differences in other complications of prematurity were observed between the two groups.

These results suggest that, when used in experienced hands according to strict protocol, HFV confers some protection from lung injury in ELBW infants. It remains unclear whether this same advantage is gained when HFV is used in usual clinical circumstances in less experienced centers and whether the incidence of other complications may be affected by mode of ventilation. Some NICUs with the most experience with HFV use it routinely as the initial mode of ventilation for ELBW infants. Most centers continue to use conventional ventilation with low tidal volumes and reasonable ventilation goals as the initial mode of ventilation for ELBW infants, reserving HFV for infants in whom conventional ventilation and surfactant fail. This latter practice seems advisable, given the potential risks of HFV, including inadvertent lung overdistention, impaired cardiac output, and increased central venous pressure that may lead to intracranial hemorrhage.

POST-EXTUBATION CPAP FOR RESPIRATORY DISTRESS SYNDROME AND APNEA

CPAP is commonly used in ELBW infants after extubation to stabilize functional residual capacity and reduce the frequency of apneic spells after the lung disease has improved. All ELBW infants should be extubated as soon as they have recovered from acute RDS and should be given a trial of CPAP to protect them from further ventilator induced lung injury. When used in combination with methylxanthine therapy, CPAP decreases the need for reintubation because of progressive respiratory distress or apnea (Davis et al, 2003). Methylxanthine (aminophylline or caffeine) treatment before extubation has also been shown to lower the incidence of apnea and the need for reintubation in premature infants. Many ELBW infants benefit from prolonged use of CPAP by nasal prongs after extubation, especially those with frequent or severe episodes of apnea and bradycardia resistant to methylxanthine. Some centers currently provide assisted ventilation through nasal prongs (nasal intermittent positive pressure ventilation) to avoid intubation (Khalaf et al, 2001); this method may be more successful than conventional CPAP in avoiding postextubation failure in some infants (Bhandari et al, 2009). However, the smallest and least mature infants may need prolonged mechanical ventilation because of frequent, severe apneic spells that are unresponsive to other therapies.

ADJUNCTIVE THERAPIES TO PREVENT BRONCHOPULMONARY DYSPLASIA

Vitamin A Supplementation

ELBW infants have low stores of vitamin A. Because of the role of vitamin A in promoting lung healing, its deficiency has been linked to a higher risk for development of BPD. In a large multicenter trial, vitamin A supplementation (5000 IU given intramuscularly three times per week for 4 weeks) reduced biochemical evidence of vitamin A deficiency and decreased the incidence of BPD by 12% without adverse effects in ELBW infants who required mechanical ventilation or supplemental oxygen at 24 hours of age (Tyson et al, 1999). Given these efficacy data and apparent safety, many NICUs choose to administer vitamin A supplementation as described previously to all ELBW infants starting at 24 hours after birth. However, widespread acceptance of this therapy has been limited by concerns over the need for thrice weekly intramuscular injections and its associated pain and stress to the infant.

Caffeine

In a prospective, masked, randomized trial involving infants with a birthweight of 500 to 1250 grams, the initiation of treatment with caffeine citrate (20 mg/kg loading dose, followed by 5 mg/kg/day) in the first 10 days after birth decreased the rate of BPD (a secondary outcome), as compared with placebo (36% versus 47%) without adverse effects (Schmidt et al, 2006). The composite primary outcome of death, cerebral palsy, cognitive delay, deafness or blindness at 18 to 22 months of age was also reduced in the subjects randomized to caffeine (Schmidt et al, 2007). The effect of caffeine on the incidence of bronchopulmonary dysplasia may be secondary to less ventilator-induced lung injury in the caffeine-treated infants, because shorter duration of positive pressure ventilation and supplemental oxygen therapy was associated with its use (Schmidt et al, 2006). These results suggest that caffeine should be administered routinely in ELBW infants in the first 10 days after birth, even if they continue to require mechanical ventilation.

Inhaled Nitric Oxide

Inhaled nitric oxide (iNO) may improve the pulmonary outcome in some VLBW infants, through mechanisms that are thought to involve decreased pulmonary vascular resistance or improved ventilation-perfusion matching, bronchodilatation, antiinflammatory effects, promotion of lung remodeling in response to injury, or normalized surfactant function. iNO used as rescue therapy for ELBW infants with severe hypoxic respiratory failure does not improve the pulmonary outcome or survival, and it may be associated with increased mortality or an increased incidence of intraventricular hemorrhage (Van Meurs et al, 2005). Results of trials of iNO involving premature infants with less severe lung disease who were at risk for BPD are mixed. In the Nitric Oxide for the Prevention of Chronic Lung Disease Trial (NO-CLD) study, a multicenter trial involving ventilator-dependent infants with a birthweight of 500 to 1250 g, treatment with iNO started at 7 to 14 days and continued for an average of 23 days of increased survival without BPD as compared with placebo (Ballard et al, 2006). In contrast, in a multicenter trial of iNO, treatment started before 48 hours of age and continued for 21 days (20 ppm for 3 to 4 days, then weaned to 10 ppm, 5 ppm, and 2 ppm for 7 days each) in infants with a birthweight of 500 to 1250 g who continued to require mechanical ventilation, only iNO-treated infants

with a birthweight greater than 1000 g had a pulmonary benefit (Kinsella et al, 2006). Treated infants in this latter study were also less likely to have ultrasonic evidence of brain injury than were control infants. Long-term follow-up from the latter two studies suggests that iNO is safe and may improve long term pulmonary outcomes (Hibbs et al, 2008; Watson et al, 2009). iNO use for the prevention of BPD is not currently approved by the United States Food and Drug Administration. Routine use of iNO for the prevention of BPD should be discouraged until additional studies are available to define dosing and duration of therapy.

Systemic Corticosteroids

Inflammation also plays an important role in the pathogenesis of BPD; therefore pharmacologic doses of systemic corticosteroids have been widely used for prevention and treatment of BPD in ELBW infants. Several studies have examined early (<96 hours of age) administration of corticosteroids, usually dexamethasone, to prevent the development of BPD in infants at risk (Garland et al, 1999; Rastogi et al, 1996; Stark et al, 2001). A meta-analysis of studies in which corticosteroids were used to prevent rather than treat established BPD suggested that early corticosteroid treatment in ELBW infants results in more rapid extubation and a lower incidence of BPD (Halliday et al, 2002), although no effect on mortality was observed. However, a higher incidence of short-term complications, including hyperglycemia, hypertension, poor growth, and intestinal perforations and bleeding, was observed in the corticosteroid-treated infants (Garland et al, 1999; Stark et al, 2001; Watterberg et al, 2004). More importantly, long-term follow-up data suggest that exposure to corticosteroid for prevention or treatment of BPD raises the risk of neurological sequelae in treated infants, including poor head growth, cerebral palsy, and developmental impairment (American Academy of Pediatrics, 2010).

The apparently higher risk of long-term sequelae without an effect on overall mortality has tempered enthusiasm for systemic corticosteroid treatment to prevent or treat BPD in ELBW infants. The possible role of postnatal corticosteroids in the prevention of BPD in selected infants, such as those exposed to chorioamnionitis, was suggested by a trial of early treatment with hydrocortisone (Watterberg et al, 2004). The risk of impaired neurodevelopment may be lower with hydrocortisone than dexamethasone (Rademaker et al, 2007; Watterberg et al, 2007), and some centers are substituting hydrocortisone for dexamethasone if postnatal corticosteroids are used. However, it seems prudent to avoid routine use of systemic corticosteroids in ELBW infants for the prevention or treatment of BPD until further data are available (American Academy of Pediatrics, 2010).

NUTRITIONAL MANAGEMENT

Provision of adequate nutrition is central to effective care of ELBW infants (see Chapters 66 and 67). These infants are born with limited nutrient reserves, immature pathways for nutrient absorption and metabolism, and higher nutrient demands. In addition, medical conditions associated with extreme prematurity both alter requirements for and complicate the adequate delivery of nutrients. The goals of nutritional management of the ELBW infant are preservation of endogenous body stores, achievement of postnatal growth similar to intrauterine weight accretion and body composition, and maintenance of normal physiologic and metabolic processes concomitant with minimizing complications and side effects. However, few ELBW infants are able to meet these goals despite the use of central parenteral nutrition and caloric supplementation of enteral feedings. As a result, significant growth failure is commonplace (Berry et al, 1997; Ehrenkranz et al, 1999; Martin et al, 2009).

Enteral Nutrition

Medical problems of ELBW infants sometimes preclude initiation of enteral feedings for several days to weeks. However, the structural and functional integrity of the gastrointestinal tract depends on the provision of enteral feedings. Withholding enteral feedings at birth imposes risks for all the complications of luminal starvation, including mucosal thinning, flattening of the villi, and bacterial translocation. Early initiation (within the first few days after birth) of low volumes of milk (10 to 20 mL/kg/day, preferably with expressed breast milk; trophic feedings, or "gut priming") has been studied in several small trials in premature infants (McClure and Newell, 2000; Schanler et al, 1999a). Trophic feedings are not meant to give the infant significant nutrition, rather to promote continued functional maturation of the gastrointestinal tract. Documented benefits of trophic feedings include higher plasma concentrations of gastrointestinal hormones, a more mature gut motility pattern, lower incidence of cholestasis, increased calcium and phosphorus absorption, and improved and earlier tolerance of enteral feedings. Trophic feedings have not been associated with a higher risk of necrotizing enterocolitis or other adverse outcomes; therefore there is no clinical advantage to delaying initiation of feedings in the medically stable ELBW infant. (See also Chapter 66.)

Feeding intolerance, indicated by gastric residuals that exceed 25% to 50% of the volume fed, abdominal distention, or microscopic blood in the stool, is common in ELBW infants and may be difficult to differentiate from early stages of necrotizing enterocolitis. Feeding intolerance may preclude the advance of enteral nutrition for days to weeks, complicating nutritional management and prolonging the need for parenteral nutrition. Numerous feeding strategies to avoid episodes of feeding intolerance have been used in ELBW infants, including slow increase in enteral volume (<10 mL/kg/day), use of dilute rather than full-strength milk, continuous versus bolus tube-feeding, and use of prokinetic agents. None of these feeding strategies has been found to be clearly superior, although bolus feedings may decrease episodes of gastric residuals compared with continuous tube feedings and may allow a more rapid advance to full enteral volumes as well as promote better growth.

Episodes of feeding intolerance also are reduced in ELBW infants fed human milk rather than specialized

formulas for premature infants (Schanler et al, 1999b). Other benefits of giving human milk in ELBW infants are a more rapid advance to full enteral volumes and its positive immunologic effects, with an associated reduction in the risk of necrotizing enterocolitis and late-onset sepsis. Data also suggest that neurodevelopmental outcome may be improved in ELBW infants fed expressed breast milk (Vohr et al, 2006). Human milk must be fortified with calcium, phosphorus, sodium, protein, and other minerals to provide adequate nutrition in the ELBW infant. In addition to commercially available human milk fortifiers, which increase the caloric density to approximately 24 calories per ounce, human milk can be fortified further to higher caloric densities with medium chain triglycerides, glucose polymers, and added protein.

Premature infants who are fed fortified human milk may grow more slowly than infants fed premature formulas (Schanler et al, 1999b), perhaps because of the variability in fat and caloric content of pumped breast milk or changes in the nutrient composition of human milk with fortification that affect fat absorption. Despite the potential for slower growth in infants fed human milk, its use should be strongly encouraged in ELBW infants because of the immunologic and other nutritional benefits. Further research on how best to fortify human milk is necessary to promote the best rate of growth in ELBW infants. (See also Chapters 65 and 66.) In addition, even after recommended enteral dietary intakes are reached, many ELBW infants continue to have a cumulative energy and protein deficit, which in part explains their later growth failure (Ehrenkranz et al, 1999; Embleton et al, 2001; Martin et al, 2009).

Early Parenteral Nutrition

Protein losses in ELBW infants receiving a glucose infusion alone begin immediately after birth and can approach 1.5 g/kg/day in the first 24 to 72 hours. Fortunately, these losses can be offset by early administration of an amino acid solution, even at low caloric intakes. Several studies have demonstrated the safety of early administration (within 24 hours after birth) of an amino acid solution, with no abnormal elevations of ammonia or blood urea nitrogen even in the most immature infants (Rivera et al, 1993; Van Goudoever et al, 1995). To prevent early protein deficit, ELBW infants should be given a source of parenteral protein as soon as possible after birth (see also Chapter 67). In one study, ELBW infants who received 3 g or more of protein per day at 5 days of age or less were less likely to have a weight below the 10th percentile at 36 weeks postmenstrual age and suboptimal head growth at 18 months of age when compared with ELBW infants who received less protein supplementation after birth (Poindexter et al, 2006).

In most centers, parenteral nutrition is used exclusively during the first few days after birth and then gradually reduced as enteral feedings are introduced. Longer duration of parenteral nutrition is associated with the development of a number of complications, including cholestasis, osteopenia, and sepsis. For example, the risk of an episode of late-onset sepsis in premature infants is 22-fold higher if parenteral nutrition is continued for more than 3 weeks compared with 1 week or less (Stoll et al, 2002b).

MANAGEMENT AND PREVENTION OF INFECTION

Bacterial and fungal infections are an important cause of illness and death among ELBW infants. In addition to the immediate morbidity and mortality, local and systemic inflammation caused by infections may increase the risk for development of other complications of prematurity, including BPD and brain injury. ELBW infants are frequently exposed to perinatal and delivery complications that raise their risk of early-onset (<72 hours) infections. The need for prolonged intravenous access, exposure to parenteral nutrition, and mechanical ventilation also subject the ELBW infant to a high risk of late-onset (>72 hours) nosocomial infections. The frequent infections seen in the ELBW population are related to immaturity of both humoral and cellular immunity (see Chapter 36). In addition to the judicious use of antimicrobial therapy, environmental controls, nursery surveillance, and modulation of the immature immune response have been proposed as possible interventions to prevent infections in extremely premature infants.

Early-Onset Infections

The incidence of early-onset bacterial infections in very LBW (VLBW) infants is approximately 1% to 2%, with a mortality of approximately 40% to 50% (Stoll et al, 2002a; see also Chapter 39). The major risk factor for the development of perinatally acquired bacterial infections is PROM with chorioamnionitis, which frequently complicates premature deliveries. However, a significant percentage of extremely premature births may be associated with intrauterine infection before membrane rupture (Goldenberg et al, 2000). In one study, 41% of premature infants with early-onset sepsis were born less than 6 hours after membrane rupture (Stoll et al, 2002a).

Because the clinical signs of perinatally acquired infection are nonspecific, the index of suspicion and the concern about the possibility of intrauterine infection should always be high in the presence of premature birth. All ELBW infants, except for those delivered for maternal indications with no labor, should be evaluated for infection at birth by means of a complete blood count with differential and blood culture, and empiric antibiotic therapy with ampicillin and an aminoglycoside should be initiated. A white blood cell count less than 5000 cells/μL, a ratio of immature to total neutrophils ratio greater than 0.2 to 0.3, and neutropenia (absolute neutrophil count less than 1000 cells/μL) are all suggestive of infection, but may also be seen in infants with other conditions, including maternal preeclampsia and hypertension. The duration of initial antibiotic therapy depends on the results of the blood culture, blood counts, the clinical course, and the perinatal history. If the blood culture is negative for bacterial growth at 48 hours and the infant has improved clinically, consideration should be given to discontinuing antibiotics. Prolonged exposure to antibiotic therapy increases the likelihood of colonization with multiple antibiotic-resistant

organisms, the development of fungemia, and necrotizing enterocolitis (Cotten et al, 2009); therefore it should be reserved for infants with documented infection or a very high index of suspicion of infection based on clinical or historical factors.

The distribution of pathogens causing early-onset sepsis in VLBW infants has changed, likely because of increased use of intrapartum antibiotics for prevention of group B streptococcal infections and treatment of preterm PROM (Puopolo and Eichenwald, 2010). As the rate of infections from group B streptococci has diminished with intrapartum antibiotic prophylaxis, the proportion of documented infections from gram-negative organisms has risen (Table 32-8; Stoll et al, 2002a). In an additional change of the epidemiology of early-onset infections in premature infants, possibly related to increased use of intrapartum antibiotics, the frequency of infections owing to ampicillin-resistant *Escherichia coli* strains has increased in some centers (Bizzarro et al, 2008; Joseph et al, 1998; Stoll et al, 2002a). Current recommendations for empiric antibiotic therapy for ELBW infants at risk of early-onset sepsis have not changed, but continued surveillance of the epidemiology and antibiotic resistance patterns of isolates within individual units is warranted. In infants with severe illness that may be caused by sepsis, broadening initial antibiotic coverage to include a third-generation cephalosporin should be considered.

TABLE 32-8 Distribution of Pathogens among 84 Cases of Early-Onset Sepsis*

Organism	No.	%
Gram-negative:	51	60.7
Escherichia coli	37	44.0

LATE-ONSET INFECTIONS

Nosocomial infection is a common though preventable complication of intensive care of the ELBW infant. The incidence of late-onset sepsis in ELBW infants who survive beyond 3 days of age is 25% to 50%, depending on gestational age and birthweight, with the median age at onset of the first episode approximately 2 weeks (Fanaroff et al, 1998; Stoll et al, 2002b). The overall mortality rate is approximately 20% but may be as high as 80%, depending on the organism causing sepsis. The risk of neurodevelopmental impairment is increased by approximately 1.5-fold in ELBW survivors of nosocomial bloodstream infections (Stoll et al, 2004). Risk factors for the development of late-onset sepsis include prolonged hyperalimentation and lipid use, the presence of a central venous catheter, longer duration of mechanical ventilation, and delay in initiation of enteral feedings (Stoll et al, 2002b). These practices and procedures are common events that may be unavoidable in the care of ELBW infants. However, large variations have been observed among NICUs in the rate of late-onset infections in premature infants (Brodie et al, 2000; Stoll et al, 2002b), suggesting that individual NICU practices may affect the incidence of nosocomial infections.

The most common cause of late-onset infections in ELBW infants is coagulase-negative *Staphylococcus* (CoNS). The most significant risk factor for the development of CoNS infection is the use of a fat emulsion (e.g., Intralipid) infusion (Freeman et al, 1990). Infection with CoNS is almost never fatal but is associated with significant morbidity, such as prolonged ventilator use and hospital stay (Gray et al, 1995). Other organisms that cause late-onset infections in ELBW infants are associated with a much higher morbidity and mortality. The distribution of pathogens associated with the first episode of late-onset sepsis among 1313 infants in a cohort of VLBW babies over a 2-year period is shown in Table 32-9.

Presenting features of late-onset sepsis include increased apnea, feeding intolerance, abdominal distention, guaiac-positive stools, increased respiratory support, and lethargy and hypotonia (Fanaroff et al, 1998). Because these

symptoms are nonspecific, ELBW infants are frequently evaluated for infection and treated with empiric antibiotic therapy. In one study, use of both vancomycin and antifungal therapy was inversely related to birthweight; approximately three fourth of infants with a birthweight less than 750 g was treated with vancomycin during their hospital stay, and approximately one third was treated with antifungals (Stoll et al, 2002b). Central catheters should be removed immediately to ensure adequate treatment of infants in whom sepsis is diagnosed, except for that caused by CoNS (Benjamin et al, 2001).

Endotracheal tube colonization with multiple organisms is common in infants who require prolonged mechanical ventilation. In general, such colonization should not be treated with antibiotics unless there is evidence of pneumonia or significant inflammation indicative of tracheitis. Prospective surveillance of common isolates and antimicrobial resistance patterns within individual NICUs can help to guide empiric antibiotic therapy in ELBW infants being evaluated and treated for presumed sepsis. However, indiscriminate use of broad-spectrum antibiotics in the absence of true infection can alter antimicrobial resistance patterns (Goldmann et al, 1996), raising the risk of late-onset infections and complicating therapy.

Prevention of Nosocomial Infection

Because of the frequency and potential severity of late-onset sepsis in ELBW infants, several strategies to prevent infection have been proposed. Using these practices as a guideline, Horbar et al (2001) observed a decrease in the CoNS infection rate from 22% to 16.6% over a 2-year period in VLBW infants in six study NICUs. Other investigators have confirmed that changes in practice, primarily surrounding the use and care of central venous catheters, can reduce the overall burden of late onset infections in individual units (Aly et al, 2005a; Kilbride et al, 2003). Some NICUs routinely screen ELBW infants by stool or respiratory secretion cultures for the presence of multiple antibiotic-resistant organisms, which would necessitate isolation (Gregory et al, 2009). Clusters of infections with unusual organisms should prompt surveillance cultures of infants, potential NICU environmental sources, and NICU staff (Foca et al, 2000). Restriction of broad-spectrum antibiotic use by hospital policy or treatment guidelines may limit the local spread of resistant organisms (Goldmann et al, 1996). Strict adherence to hand hygiene before and after every patient contact and avoidance of overcrowding within NICUs also help to decrease the incidence of infection. The use of alcohol-based hand gels at the bedside may improve compliance with hand hygiene (Harbarth et al, 2002).

In addition to practice and environmental controls, prophylactic use of antibiotics and modulation of the immune response of ELBW infants have been studied as methods to reduce the incidence of late-onset sepsis. Low-dose vancomycin given continuously via hyperalimentation solutions (Baier et al, 1998; Spafford et al, 1994), intermittently via peripheral vein (Cooke et al, 1997), or vancomycin lock of the central venous catheter (Garland et al, 2005) has been shown to reduce the incidence of CoNS in premature infants at risk. Concern about the emergence of vancomycin-resistant organisms and the low mortality associated with CoNS infections has prevented widespread use of this approach. Prophylactic fluconazole given for 6 weeks lowered the incidence of fungal colonization and invasive disease in ELBW infants without associated complications or the emergence of resistant organisms (Kaufman et al, 2001, 2005; Manzoni et al, 2007). Such an approach might be advisable for NICUs with a high incidence of fungal infections in their ELBW population, but more study is needed to define any potential short- and long-term risks. Approaches that have been used with success in immunocompromised adult patients, such as antiseptic-impregnated central catheters, are promising but have not yet been studied adequately in premature infants.

Prophylactic intravenous administration of polyclonal immunoglobulin (IVIG) to prevent late-onset sepsis has been studied extensively in premature infants. Several trials have shown a decrease in the incidence of documented sepsis by a small but significant amount in premature infants treated with prophylactic IVIG and no effect on mortality or other complications of prematurity (Lacy and Ohlsson, 1995). The costs associated with this therapy to achieve the small decrease in infection rates, as well as the increased exposure to blood products, have limited its use; it is unclear whether selective prophylactic IVIG treatment of ELBW infants at highest risk for sepsis is warranted. However, IVIG therapy in addition to antibiotic therapy may be of benefit in reducing mortality in infants with established sepsis (Jenson and Pollock, 1997). Development of more targeted polyclonal or monoclonal γ-globulin preparations for specific organisms that cause sepsis in premature newborns may alter the use of IVIG in the future (Lamari et al, 2000; Weisman et al, 2009).

Another promising strategy under investigation for modulation of the immature immune response to help prevent infections in premature infants is treatment with hemopoietic colony-stimulating factors, including granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor (Modi and Carr, 2000). Most studies of these factors have been conducted in neutropenic, small-for-gestational-age infants or infants delivered to women with preeclampsia. Treatment with granulocyte colony-stimulating factor in neutropenic infants resulted in an increase in neutrophil counts and reduced the incidence of sepsis (Kocherlakota and La Gamma, 1998). Prophylactic treatment with granulocyte-macrophage colony-stimulating factor in premature infants with normal neutrophil counts prevented the development of neutropenia in episodes of sepsis, but it remains unclear whether this type of therapy to address cellular immune deficiency in ELBW infants will reduce the incidence of infection without additional complications (Miura et al, 2001; Modi and Carr, 2000).

NEUROSENSORY COMPLICATIONS

The major neurosensory complications associated with extreme premature birth are intraventricular hemorrhage, periventricular white matter injury, and retinopathy of prematurity. Although the incidence of severe intraventricular hemorrhage has fallen with improvements in management and increased antenatal steroid use, it remains a major cause of brain injury with consequent abnormal

neurodevelopment. Pharmacologic approaches to its prevention after birth have been generally unsuccessful. Prophylactic indomethacin reduces the incidence of severe intraventricular hemorrhage, but does not improve long-term neurodevelopment (Schmidt et al, 2001).

Periventricular white matter injury is the predominant form of brain injury in extremely preterm infants and correlates strongly with the development of cerebral palsy. Its pathogenesis is poorly understood, and no specific neuroprotective strategy is known. In some infants, cerebral blood flow and oxygen delivery measured with near infrared spectroscopy varies during variations of blood pressure considered to be in the normal range, and this lack of autoregulation of cerebral blood flow may lead to ischemic white matter injury (Evans, 2006). Whether aggressive treatment of hypotension in ELBW infants prevents or may lead to subsequent brain injury is uncertain, probably because blood pressure, which is easily measured, does not correlate well with systemic or cerebral blood flow (Fanaroff et al, 2006; Limperopoulos et al, 2007). A higher rate of white matter injury occurs in the setting of maternal or neonatal infection, or with elevated proinflammatory cytokines in amniotic fluid or cord blood, suggesting that inflammation has a role in the pathogenesis (Viscardi et al, 2004). Advanced magnetic resonance imaging techniques in infants with white matter injury show disturbances in cerebral growth, with reduced volume of both gray and white matter (Inder et al, 2005). These observations might serve to explain the motor and cognitive dysfunction often seen in infants with white matter injury.

Retinopathy of prematurity, a vascular proliferative disorder that affects the incompletely vascularized retina of preterm infants, is a major cause of blindness in these children. Severe retinopathy is 18-fold more likely to develop in infants delivered at less than 25 weeks' gestation compared with 28 weeks' gestation (Fanaroff et al, 2007). Periods of hyperoxia owing to exposure to excessive inspired oxygen concentration contribute to the development of retinopathy (Saugstad, 2006); however, the optimal target range of oxygen saturation is not known. Because fetal hemoglobin shifts the hemoglobin oxygen saturation curve to the left, oxygen saturations greater than 95% may be associated with arterial oxygen tension greater than 80 mm Hg, possibly excessive for the ELBW infant. Conversely, oxygen saturation that is too low can increase the risk of injury to the brain or other end organs (Deulofuet et al, 2006).

Adjusting inspired oxygen concentration to target lower oxygen saturations in extremely preterm infants may decrease the rate of severe retinopathy. In a prospective observational study, ELBW infants treated in centers with a restrictive approach to oxygen delivery (i.e., saturation alarm limits of 70% to 90%) had less retinopathy requiring cryotherapy (6.3 versus 27.7 %) than did those in units with a liberal approach (i.e., alarm limits of 88% to 98%), and neurodevelopmental outcome at 1 year of age was similar (Tin et al, 2001). In two other studies with historical controls, the incidence of severe retinopathy decreased after oxygen saturation alarm limits were lowered from 87%-97% to 85%-93% for infants born at 28 weeks' gestation and less until they reached 32 weeks postmenstrual age (Chow et al, 2003; Vanderveen et al, 2006). In a masked randomized trial comparing two different target oxygen saturation ranges (85% to 89% compared with 91% to 95%) in infants born between 24 and 27 weeks, ROP occurred less frequently in survivors assigned to the lower oxygen saturation group. However, death before discharge occurred more frequently in the lower oxygen saturation group, suggesting that the best target range for oxygen saturation remains unclear (SUPPORT Study Group, 2010).

DEVELOPMENTAL AND PARENTAL CARE

ELBW infants are particularly vulnerable to the potentially noxious stimuli of the NICU environment, including light, noise, frequent disturbances, and painful procedures. The ELBW infant reacts to the noisy and well-lit environment of many NICUs with greater variability of blood pressure, ventilatory requirements, and oxygen saturation as well as behavioral disorganization, which may have both short- and long-term effects on outcome (Jacobs et al, 2002). Modification of the NICU environment to limit exposure of ELBW infants to such stresses—by lowering ambient light and reducing noise, clustering caregiving periods and procedures to allow periods of uninterrupted sleep, and using positioning aids to promote containment—is an intuitive part of their care. Newer NICU designs, transitioning from open common rooms to private room settings, may also facilitate a better environment for vulnerable infants and enhance parental involvement. These environmental and developmental interventions in the NICU can improve physiologic stability and some short-term outcomes in preterm infants, including decreased severity of BPD and shorter length of hospital stay. It remains unclear whether individualized, developmentally supportive care or other developmental interventions started in the NICU improve long-term outcome in ELBW infants (Symington et al, 2009).

In addition to environmental modifications, NICUs should promote parental involvement with infants, even when they are critically ill. Open family presence guidelines and encouragement of parental caregiving when appropriate may help parents to bond with their baby. Many NICUs have embraced a philosophy of family-centered care, in which a stronger bond is forged with the families of NICU patients by encouraging collaboration among family members and care providers in policy and program development, professional education, and aspects of the delivery of care (Dunn et al, 2006). Skin-to-skin (kangaroo) care, in which the infant is placed unclothed on the mother or father's bare chest, was originally developed in nonindustrialized countries to maintain temperature regulation in premature infants. It is now used in many NICUs to promote parental attachment. Skin-to-skin care may have a positive effect on infant state organization and respiratory patterns, increase the rate of infant weight gain, improve maternal milk production, and have long-term benefits in infant development and parents' perceptions of their babies (Feldman et al, 2002). Skin-to-skin care can be initiated in ELBW infants within the first 2 weeks after birth, when they are more medically stable.

FUTURE DIRECTIONS

This chapter presents some of the special needs of the ELBW infant. The medical care of the ELBW infant is a complex combination of knowledge of developmental physiology, evidenced-based interventions, and clinical experience. Wide variability in approaches to care of these infants exists among practitioners and NICUs, as does variability in outcomes. Nevertheless, NICUs involved in treating ELBW infants should develop a coherent approach to the medical and ethical aspects of their care. Future research should focus on identifying best practices to narrow the variability in approach to care and with the goal to prevent long-term disability. As more of these tiny infants survive, it is the responsibility of neonatologists to stay abreast of clinical improvements and the short- and long-term consequences of established and newly proposed medical interventions to provide the best care for these vulnerable infants and to keep parents informed and involved.

CHAPTER 33

Care of the Late Preterm Infant

Sowmya S. Mohan and Lucky Jain

Had he been alive today, Patrick Bouvier Kennedy would have been hailed as a triumph of neonatal care—after all, he was the son of the former United States President, John F. Kennedy and former First Lady Jacqueline B. Kennedy. Born prematurely at 34 weeks gestation, he would have been aptly labeled as a late preterm neonate; however, based on his birth weight (2.1 kg) and gestational age, few would have predicted the outcome he had then, were he born in 2009. But then, in 1963, little was available to the clinician for the management of hyaline membrane disease—no routine use of neonatal ventilators, no device to provide airway positive pressure, no surfactant, and no antenatal steroids. He died two days after his birth; the New York Times obituary said that "the battle for the Kennedy baby was lost because medical science has not advanced far enough."

(Jain and Carlton, 2009)

With more than 4 million live births per year (Martin et al, 2007), the United States has one of the highest birth rates among industrialized countries; it also has the stigma of having a disproportionately high prematurity rate. Decades of efforts to reduce preterm births have not affected this formidable problem. In recent years the problem has been highlighted by the rise in births between 34 and 36⁶⁄₇ weeks' gestation, a group referred to as *late preterm infants* (Figure 33-1). Late preterm infants have a checkered history, having been passed off as nothing more than "near term" infants, yet being feared as the "quick to spiral down group" when they develop respiratory distress syndrome or other complications. As the number of late preterm infants has grown, so has the awareness of their unique set of problems, such as delayed neonatal transition, wet lung syndrome, hypothermia, hypoglycemia, and hyperbilirubinemia (Figure 33-2). Although not unique to this population, these complications have sufficient differences in their manifestations and management, prompting the editors to add an entirely new chapter to this textbook devoted to the health issues of late preterm infants. In Chapter 14, the obstetric issues and epidemiology related to prematurity are addressed. This chapter focuses on the special considerations applicable to the clinical course and management of late preterm infants.

There has been a shift in the distribution of births away from term and post term and toward earlier gestational ages (Davidoff et al, 2006). This shift has resulted in a disproportionately high rate of premature births with estimates of up to 12.7% of live births being premature (Martin et al, 2007)—defined as <37 completed weeks' gestation or <260 days, counting from the first day of the last menstrual period (Raju, 2006). Within this group of premature babies, up to 75% are classified as late preterm infants (Adamkin, 2009). Although the reasons for such a high number of late preterm births are multifactorial, higher rates of induced deliveries, cesarean births, and efforts to reduce stillbirths may have contributed to the increase.

Late preterm babies currently account for up to one third of all neonatal intensive care unit (NICU) admissions in the United States (Angus et al, 2001), adding strain to the overburdened system of health care delivery, particularly in community hospitals and rural areas. These admissions range from short stays, for problems such as transient tachypnea of the newborn (TTNB), to more complicated or extended NICU stays for problems such as persistent pulmonary hypertension of the newborn (PPHN). With the average NICU stay costing up to $3500 per day, the economic impact of caring for the late preterm baby can be significant. For example, in 1996 the State of California alone could have saved $49.9 million in health care costs by preventing non–medically indicated deliveries between 34 and 37 weeks' gestation (Gilbert et al, 2003). In addition to the expense of the initial hospitalization, the cost of caring for a late preterm baby can also be compounded by the increased incidence of hospital readmissions and the long-term care issues related to persistent problems. The effects of the increasing number of late preterm births create a societal burden in lost productivity, as parents take extended leave from work to be with their fragile newborns. More importantly, there may be lasting effects with neurodevelopmental delays extending into early school age. Because a significant proportion of brain growth occurs during the last 6 weeks of gestation (Adams-Chapman, 2006), late preterm infants are vulnerable to neuronal injury and disruption of normal brain development. Whereas more longitudinal studies are needed, preliminary studies show that late preterm infants are more likely to have a diagnosis of developmental delay within the first 3 years of life, require special needs preschool resources, and have more problems with school readiness (Morse et al, 2009).

Given their large numbers, the overall socioeconomic effects of the late preterm births can be significant. Strategies are required that can reduce the preventable fraction of late preterm births and work toward reducing the morbidity in others, when continuation of the pregnancy is deemed harmful to the fetus or the mother. This chapter explores the pathophysiology of the major morbidities that affect late preterm infants and discusses the unique challenges faced by clinicians in the management of these conditions.

DEFINITION

Late preterm birth is an accepted term used for infants born between 34 and 36⁶⁄₇ weeks' gestation (see Figure 33-1) (Raju et al, 2006). This group of infants was initially referred to as *near term*, but the misleading implication of

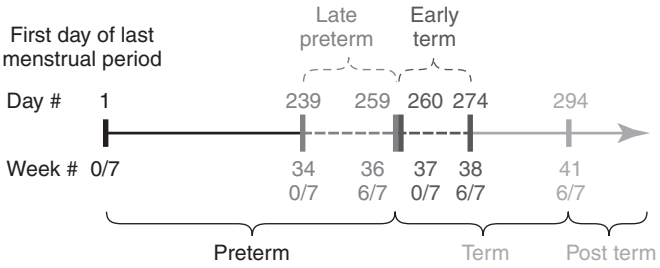

FIGURE 33-1 Definitions of late preterm and early term. *(Adapted from Engle WA, Kominiarek MA: Late preterm infants, early term infants, and timing of elective deliveries,* Clin Perinatol *35:325-341, 2008.)*

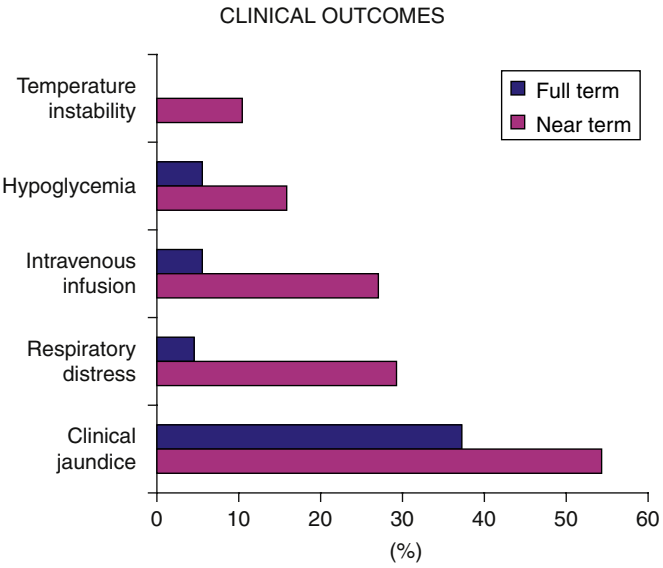

FIGURE 33-2 Graph of clinical outcomes in near-term (35 to 36⁶⁄₇ weeks) and full-term infants as percentage of patients studied. *(Adapted from Wang ML, Dorer DJ, Fleming MP, et al: Clinical outcomes of near-term infants,* Pediatrics *114:372-376, 2004.)*

maturity has prompted the name change to *late preterm* (Box 33-1). This notion is further validated by recent studies showing that term infants born at 37 to 38 weeks' gestation have higher morbidity and mortality than those born at 39 weeks' gestation (Hansen et al, 2008; Madar et al, 1999; McIntire and Leveno, 2008; Shapiro-Mendoza et al, 2008); this has prompted the use of *early term* to describe births at 37 to 38 weeks' gestation.

The term *late preterm* and the gestational age limits were established by a panel of experts convened by the National Institutes of Health and the National Institute of Child Health and Human Development in 2005. While developing these criteria, the group considered many factors, including the obstetric guidelines that consider 34 weeks to be a maturational milestone. Beyond 34 weeks' gestation, surfactant is generally considered to be adequate and antenatal steroids are not offered to mothers with anticipated delivery (Raju et al, 2006). Unlike the smaller, more typical premature infant, late preterm infants appear mature because of their larger size, but have a higher incidence of transient tachypnea of the newborn (McIntire and Leveno, 2008; Wang et al, 2004), respiratory distress syndrome (RDS) (Clark, 2005; Wang et al, 2004), PPHN (Roth-Kleiner et al, 2003), respiratory failure, prolonged

BOX 33-1 Characteristics of Late Preterm Infants

- Late preterm infants—defined as born at 34 to 36⁶⁄₇ weeks' gestation
- Physiologically immature with limited compensatory responses to extrauterine environment compared to term infants
- Greater risk than term infants for mortality and morbidities such as:
  - Temperature instability
  - Hypoglycemia
  - Respiratory distress
  - Apnea
  - Jaundice
  - Feeding difficulties
  - Dehydration
  - Suspected sepsis

Adapted from Engle WA, Tomashek KM, Wallman C: "Late preterm" infants: a population at risk, *Pediatrics* 120:1390-1401, 2007.

physiological jaundice, late neonatal sepsis (Raju, 2006), thermoregulation issues, hypoglycemia, feeding difficulties (Dudell and Jain, 2006; Escobar et al, 2006; Fuchs and Wapner, 2006), and risk of injury to the developing brain, which can lead to neurodevelopmental problems. These problems account for a substantially higher number of NICU admissions (see Figures 33-2 and 33-3).

PATHOPHYSIOLOGY AND CLINICAL COURSE

Although many of the diseases discussed in this section are not specific or unique to late preterm infants and are being covered in other chapters in this book, it is important to understand and recognize them as part of the unique challenge of caring for late preterm newborns.

RESPIRATORY

Several studies have consistently shown that late preterm infants have higher respiratory morbidity and mortality compared with full-term infants. Many late preterm infants develop respiratory distress soon after birth (sustained distress for more than 2 hours after birth accompanied by grunting, flaring, tachypnea, retractions, or supplemental oxygen requirement), which studies show occurs more often in late preterm infants than in term newborns (28.9% versus 4.2%, respectively) (Wang et al, 2004). In addition, within the early term and late preterm groups, infants born at 37 weeks' gestation are fivefold more likely, and babies born at 35 weeks' gestation are ninefold more likely, to have respiratory distress compared with babies born at 38 to 40 weeks' gestation (Escobar et al, 2006). For each gestational week of age, infants delivered by elective cesarean section tend to do worse (Figure 33-4). In fact, Madar et al (1999) found that the incidence of respiratory distress was significantly increased with every week of gestation less than 39 weeks: 30 in 1000 infants born at 34 weeks' gestation developed respiratory distress, 14 in 1000 born at 35 weeks' gestation, and 7.1 in 1000 born at 36 weeks' gestation. The etiology of respiratory distress is diverse and includes transient tachypnea of the newborn, RDS, persistent pulmonary hypertension, and apnea. Not surprisingly, of the affected babies, the incidence of respiratory

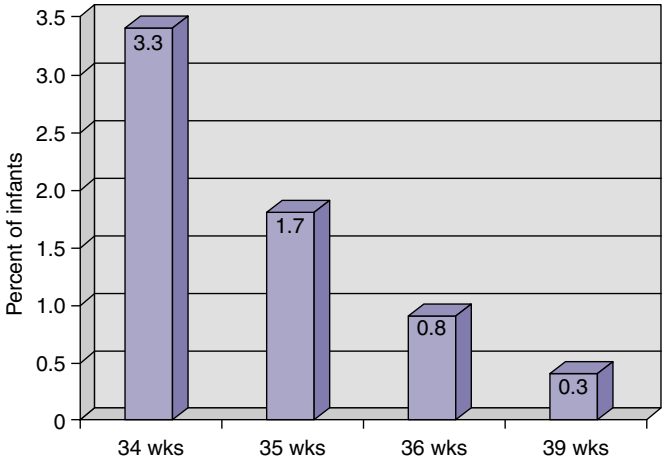

FIGURE 33-5 Percentage of infants born at late preterm gestations who require mechanical ventilation. *(Adapted from McIntire DD, Leveno KJ: Neonatal mortality and morbidity rates in late preterm births compared with births at term*, Obstet Gynecol *111:35-41, 2008.)*

distress requiring mechanical ventilation corresponded to the degree of prematurity: 3.3% of late preterm infants born at 34 weeks' gestation, 1.7% at 35 weeks' gestation, and 0.8% at 36 weeks' gestation (Figure 33-5) (McIntire and Leveno, 2008).

Whereas respiratory issues often tend to be transient in a vast majority of these neonates, some develop into PPHN or severe hypoxic respiratory failure requiring additional therapies such as nitric oxide, high frequency ventilation, and extracorporeal membrane oxygenation (ECMO; Heritage and Cunningham, 1985; Keszler et al, 1992). Studies have shown that pulmonary hypertension is more likely in preterm infants (born at 34 to 37 weeks' gestation) who develop RDS than in similar infants born at 32 weeks' gestation. Such predisposition is attributed to a developmental increase in smooth muscle in the walls of pulmonary blood vessels. PPHN is associated with increased pulmonary vascular resistance that eventually leads to right-to-left shunting by means of fetal pathways and ventilation-perfusion mismatching (Dudell and Jain, 2006). Management of neonates who develop significant pulmonary hypertension can be challenging, given the self propagated nature of hypoxia-induced pulmonary vasoconstriction. Treatment options include exogenous surfactant (shown to be effective if used earlier in the disease course; Dudell and Jain, 2006), inhaled nitric oxide (selectively lowers pulmonary vascular resistance and decreases extrapulmonary right-to-left shunting) (Kinsella et al, 1992, 1993), high-frequency ventilation, and ECMO.

A review of the Extracorporeal Life Support Organization Neonatal Registry from 1989 to 2006 by Dudell and Jain (2006) found that 14.5% of the ECMO patients during that time period were late preterm infants and had a mean gestational age of 35.3 weeks. Interestingly, affected

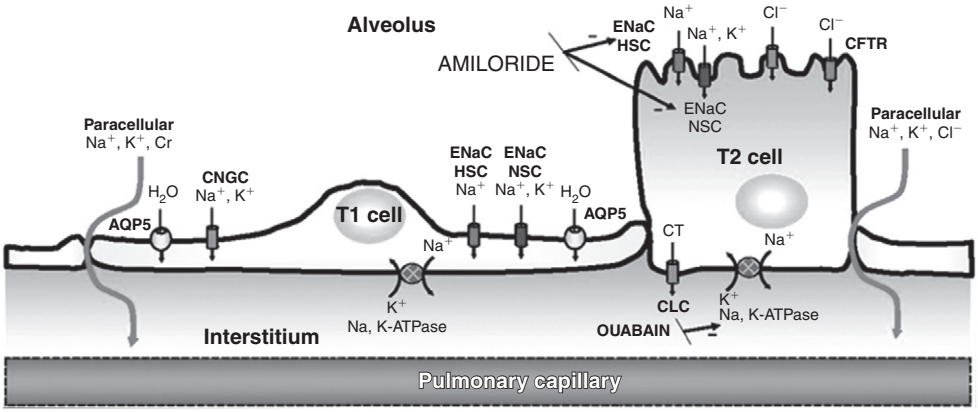

FIGURE 33-6 Epithelial sodium (Na) absorption in the fetal lung near birth. Na enters the cell through the apical surface of both ATI and ATII cells via amiloride-sensitive epithelial Na channels *(ENaC)*, both highly selective channels *(HSC)* and nonselective channels *(NSC)*, and cyclic nucleotide gated channels (seen only in ATI cells). Electroneutrality is conserved with chloride movement through cystic fibrosis transmembrane conductance regulator *(CFTR)* or through chloride channels *(CLC)* in ATI and ATII cells, and/or paracellularly through tight junctions. The increase in cell Na stimulates Na-K-ATPase activity on the basolateral aspect of the cell membrane, which drives out three Na ions in exchange for two K ions, a process that can be blocked by the cardiac glycoside ouabain. If the net ion movement is from the apical surface to the interstitium, an osmotic gradient would be created, which would in turn direct water transport in the same direction, either through aquaporins or by diffusion. *(From Jain L: Respiratory morbidity in late-preterm infants: prevention is better than cure!* Am J Perinatol *25:75-78, 2008.)*

infants were more likely to require ECMO secondary to hypoxic respiratory failure or RDS instead of aspiration syndromes, which is the primary insult for term infants requiring ECMO (Dudell and Jain, 2006). In addition, late preterm infants were older at cannulation (likely because most of these infants are asymptomatic at birth, but gradually develop an increasing oxygen requirement with subsequent development of PPHN), had a longer duration of ECMO support, and were more likely to have intraventricular hemorrhage and other neurologic complications than term infants. Overall survival rate was significantly lower (74%) for late preterm infants compared with term infants (87%) (Dudell and Jain, 2006).

Why is it that, even in situations in which amniotic fluid testing shows a mature surfactant profile, late preterm infants are at risk for developing respiratory distress? Part of the answer lies in the delay in clearing fetal lung fluid. Throughout much of gestation, fetal lungs actively secrete fluid into alveolar spaces via a chloride secretory mechanism. This process can be blocked by inhibitors of Na-K-2Cl co-transport. The fluid that accumulates in the developing lung plays a critical role by providing a structural template that prevents the collapse of the developing lung and promotes its growth. At the time of delivery, the lung epithelium becomes integral in the process of switching from placental to pulmonary gas exchange (Bland, 2001; Jain, 1999). For effective gas exchange to occur in the lungs, alveolar spaces must be cleared of excess fluid, and pulmonary blood flow must be increased to match ventilation with the perfusion that is taking place. If either the ventilation or perfusion is inadequate, the infant will have a difficult time transitioning and will develop respiratory distress. In addition, during fetal development, many abnormalities can occur and interfere with the normal production of this lung fluid. Some problems during development include pulmonary artery occlusion, diaphragmatic hernia, and uterine compression of the fetal thorax from chronic leak of amniotic fluid. All these conditions inhibit normal lung development and growth (Jain and Eaton, 2006).

Although a small role in the clearance of this fluid can be attributed to Starling forces and "vaginal squeeze" (Bland, 2001; Jain, 1999), amiloride-sensitive sodium transport by lung epithelial cells through epithelial sodium channels (ENaCs) has emerged as a key event in the transepithelial movement of alveolar fluid (Figure 33-6) (Bland, 2001; Jain et al, 2001). Research has shown that these ENaCs orchestrate the clearing of fluid from the fetal lungs, and disruption of their function has been implicated in several disease processes affecting the newborn, including transient tachypnea of the newborn and hyaline membrane disease. The late preterm infant is more susceptible to these problems, in part because ENaC expression is developmentally regulated and peak expression in the alveolar epithelium is achieved only at term gestation, which leaves the preterm infant with lower expression of these channels, thus reducing their ability to clear fetal lung fluid after birth (Smith et al, 2000).

High doses of glucocorticoids have been shown to stimulate transcription of ENaCs in several sodium transporting epithelia and in the lung (Tomashek et al, 2007). In the alveolar epithelia, glucocorticoids were found to induce lung sodium reabsorption in the late gestation fetal lung (Tomashek et al, 2007). In addition to increasing transcription of sodium channel subunits, steroids increase the number of available channels, by decreasing the rate at which membrane-associated channels are degraded, and increase the activity of existing channels. Glucocorticoids have also been shown to enhance the responsiveness of lungs to β-adrenergic agents and thyroid hormones (Venkatesh and Katzberg, 1997).

In addition to problems with lung fluid clearance, several other factors may contribute to the overall burden of respiratory morbidity (Hansen et al, 2008; Kolas et al, 2006; Levine et al, 2001; Morrison et al, 1995; Roth-Kleiner et al, 2003; Villar et al, 2007). Given the shortcomings clinicians face in accurate estimation of gestational age, elective induction and cesarean section may have increased the burden of iatrogenic

prematurity. In an attempt to minimize the occurrence of iatrogenic RDS in light of the increasing frequency of elective cesarean sections—commonly performed between 37 and 40 weeks' gestation (Hales et al, 1993)—fetal lung maturity testing was recommended before elective cesarean sections. Because of the risks and complications associated with amniocentesis, this testing is done infrequently (Dudell and Jain, 2006), especially in light of recent studies showing that even late preterm infants and some early term infants born by cesarean section before the onset of labor have respiratory distress despite having mature surfactant profiles. This finding prompted the American College of Obstetrics and Gynecologists (2002) to recommend scheduling elective cesarean section at 39 weeks or later or waiting for the onset of spontaneous labor, but unfortunately factors related to the convenience of scheduled elective cesarean section deliveries for both families and providers will continue to influence the timing of elective cesarean section (Dudell and Jain, 2006).

GASTROINTESTINAL

Nutrition

Feeding problems are one of the primary reasons for delay in the discharge of late preterm infants (Adamkin, 2006). Late preterm infants often have poor coordination of sucking and swallowing because of neuronal immaturity, decreased oromotor tone, and inability to generate adequate intraoral pressures during sucking (Engle et al, 2007; Kinney, 2006; Polin et al, 2003; Raju et al, 2006). Breastfeeding has also been shown to be more difficult for early term or late preterm infants compared with term infants (Raju, 2006). These problems can lead to poor caloric intake and dehydration.

These problems are compounded by the variations in practice and nutritional management of these infants, given the paucity of published studies in this regard. Recent studies have shown that issues such as hypoglycemia and poor feeding contributed to 27% of all late preterm babies requiring intravenous fluids, compared with only 5% of their term counterparts (Wang et al, 2004). In the face of poor enteral intake, TPN is indicated and can become an important therapy in the care of the late preterm infant, but is often delayed in anticipation of a quick recovery (Adamkin, 2006). The challenge then becomes providing adequate nutrition to support growth and equate the energy expenditure that can occur when the infant faces issues such as hypothermia, sepsis, and respiratory distress, which are often seen in late preterm infants. Studies show that the energy expenditure of nongrowing low-birthweight infants (birthweight less than 2500 g) is 45 to 55 cal/kg/day (Adamkin, 2006). These calories come from several sources in the TPN including amino acids and lipids.

Late preterm infants are more adept at handling amino acids, allowing the protein content in TPN to be started at 2 g/kg/day. With a protein intake of 2.5 to 3 g/kg/day (with adequate caloric intake), a late preterm infant can achieve weight gain similar to a term infant fed human milk (Adamkin, 2006). More controversial is the use of intravenous lipids in late preterm infants. Of the late preterm infants with respiratory distress or disease, there are two subgroups: infants with parenchymal lung disease without increased pulmonary vascular resistance (PVR) and those with signs of PPHN or increased PVR (Adamkin, 2006). The concern over the use of lipids in the late preterm infant with lung disease stems from adult studies showing that failure to clear infused lipids has an adverse effect on gas exchange in the lungs (Greene et al, 1976). Contrary to those findings, preterm neonates randomized to different lipid infusion rates did not demonstrate any effect on alveolar-arterial oxygen gradient, arterial blood pH, or oxygenation when randomly assigned to modest doses of lipids (0.6 to 1.4 g/kg/day) over the first week of life (Adamkin, 2006). The other argument for restricted use of lipids in late preterm infants specifically addresses the infants with increased PVR and respiratory disease. The concern is that the high polyunsaturated fatty acid content of lipid emulsions (with excess omega 6-linoleic acid) feeds into the arachidonic acid pathways, leading to synthesis of prostaglandins and leukotrienes, which can increase vasomotor tone and result in hypoxemia (Adamkin, 2006). Despite the lack of firm evidence for the effects of lipid emulsions in infants with severe respiratory failure with or without pulmonary hypertension, the recommendation is that infants with respiratory disease, but not increased PVR, should receive adequate lipids to prevent essential fatty acid deficiency; in infants with elements of PPHN, lipids should be avoided during the critical stages of their illness (Adamkin, 2006). Because of these issues and other concerns about parenteral nutrition (e.g., difficult in optimizing nutrition, the need for intravenous access and the potential for infiltrates or infection, risk of cholestatic jaundice with prolonged use of parenteral nutrition) enteral feeds should be started as soon as clinically possible while the infant is slowly weaned from the parenteral nutrition.

In general, nutritional experts recommend that 34- and 35-week late preterm infants receive nutrient-enriched (22 kcal/oz) milk, whereas older 36- and 37-week late preterm infants with an uncomplicated neonatal course be fed unfortified milk after discharge (Adamkin, 2006). These nutrient-enriched formulas have a higher protein content (1.9 versus 1.4 g/dL), increased energy (22 versus 20 kcal/oz), additional calcium, phosphorous, zinc, trace elements, and vitamins compared with standard formulas (Adamkin, 2006). This enrichment becomes essential to the late preterm infant who was born at 34 to 35 weeks' gestation or the older group of late preterm infants who had a difficult NICU course, where the goal is to compensate for earlier deprivation of adequate nutrition and allow for somatic and brain growth during the first year of life. These issues notwithstanding, these nutritional guidelines are not always followed, leading to variability in nutritional practices by providers. One study showed that, although nearly 46% of late preterm infants were discharged home with recommendations to use formula that contained more than 20 kcal/oz, this practice recommendation had a broad range of followers (4% to 72%) (Adamkin, 2006). The issue becomes more pressing in the late preterm infant with chronic conditions, such as bronchopulmonary dysplasia, that are often associated with growth failure caused by inadequate nutrient intake.

BOX 33-2 Causes of Hypoglycemia in the Late Preterm Infant

TRANSIENT HYPOGLYCEMIA IN THE LATE PRETERM INFANT

Maternal Conditions

- Glucose infusion in the mother
- Preeclampsia
- Drugs: tocolytic therapy, sympathomimetics
- Infant of diabetic mother

Neonatal Conditions

- Prematurity
- Respiratory distress syndrome
- Twin gestation
- Neonatal sepsis
- Perinatal hypoxia-ischemia
- Temperature instability: hypothermia
- Polycythemia
- Specific glucose transporter deficiency
- Isoimmune thrombocytopenia, Rh incompatibility

PERSISTENT HYPOGLYCEMIA IN THE LATE PRETERM INFANT

Endocrine Disorders

- Pituitary insufficiency
- Cortisol deficiency
- Congenital glucagon deficiency

Inborn Errors of Metabolism

- Carbohydrate metabolism: glycogen storage disease, galactosemia, fructose-1,6-diphoshatase deficiency
- Amino acid metabolism: maple syrup urine disease, propionic academia, methylmalonic academia hereditary tyrosinemia
- Fatty acid metabolism: acyl-coenzyme dehydrogenase defect, defects in carnitine metabolism, beta-oxidation defects
- Defective glucose transport

From Garg M, Devaskar SU: Glucose metabolism in the late preterm infant, *Clin Perinatol* 33:853-870, 2006. Reprinted with permission.

For mothers who choose to breastfeed their late preterm infant, it can often be more challenging compared with nursing a full-term infant. The challenge often lies in initiating and establishing breastfeeding because these infants are sleepier; have less stamina; have more difficulty maintaining body temperature; have problems with latching, sucking, and swallowing; and have more respiratory instability than full-term infants (Adamkin, 2006). Despite these obstacles, mothers should still be encouraged to provide breast milk given the numerous proven benefits of breast milk. In fact, recent studies have shown that the advantages of breast milk feeding for premature infants might be even greater than those for term infants (Adamkin, 2006).

Hypoglycemia

Hypoglycemia is defined as low circulating glucose concentrations, but the actual neonatal threshold value is still debated. A physiologic definition was established, based on abnormal electroencephalograms at glucose levels that were lower, with a glucose level less than 45 mg/dL being considered hypoglycemia (Koh et al, 1988). Hypoglycemia is often missed in late preterm infants, mainly because of the early transition of these infants to the well baby nursery or the mother's room in an effort to triage the limited number of acute care beds in the NICU and to allow the mother to bond with her new baby (Garg and Devaskar, 2006). However, developmental immaturity is associated with multiple problems, including decreased glycogen stores and feeding difficulties, both of which can lead to hypoglycemia (Box 33-2). Not surprisingly, the incidence of hypoglycemia in preterm infants is threefold greater than in full-term infants (Wang et al, 2004). In addition, severe hypoglycemia is a well-known risk factor for neuronal cell death and adverse neurodevelopmental outcomes (Garg and Devaskar, 2006). Therefore, if the hypoglycemia is not recognized and treated in a timely manner with intravenous fluids or feedings, the infant can develop neurodevelopmental abnormalities because the compensatory mechanisms for protecting the brain from hypoglycemia are not fully developed (Cornblath and Ichord, 2000; Cornblath et al, 2000; Rozance and Hay, 2006; Vannucci and Vannucci, 2001). Therefore early recognition, diagnosis, and treatment of hypoglycemia are crucial to the late preterm infant's long-term outcome. It is recommended that institutions develop protocols for routine testing of blood sugars in late preterm infants. One can use existing serum glucose screening protocols for infants at high risk for hypoglycemia (i.e., small for gestational age, large for gestational age, infant of a diabetic mother). If none are available, the following is recommended: glucose checks between 1 and 2 hours after birth, followed by testing before the next three consecutive feeds and then before alternate feedings for the remainder of the first 24 hours. If the blood sugar is less than 40 to 45 mg/dL, the hypoglycemia protocol should be followed for management.

Hypoglycemia is not a problem in utero, because the fetus receives a steady supply of glucose primarily by maternal transfer through the placenta. Once the baby is delivered, this constant supply of glucose is abruptly stopped and the infant has to rely on glucose production primarily via hepatic glycogenolysis and gluconeogenesis (Halamek et al, 1997). After birth, the baby experiences a surge in catecholamines, glucagon, and corticosteroids, which play a key role in maintaining a euglycemic state. The increase in catecholamines leads to a surge in glucagon concentration and a decline in circulating insulin concentrations, which both contribute to maintaining a normal serum glucose level. Glucose levels are also affected by the unregulated insulin production by the immature pancreatic β cells (Garg and Devaskar, 2006). As a result, the late preterm newborn can experience significant hypoglycemia secondary to developmentally immature hepatic enzyme systems for gluconeogenesis, glycogenolysis, and hormonal dysregulation (Engle et al, 2007; Garg and Devaskar, 2006; Raju et al, 2006).

The neonatal glucose requirement is 6 to 8 mg/kg/min, which is a higher value than that observed in adults (3 mg/kg/min) (Bier et al, 1977). This demand for glucose increases if the late preterm infant has coexisting conditions such as sepsis, birth asphyxia, or cold stress (Greisen and Pryds, 1989; Halamek et al, 1997; Halamek and

Stevenson, 1998). Treatment options for hypoglycemia in the late preterm infant include establishing early feeds (supplementing with formula if quantity of breast milk is insufficient), glucose infusion through intravenous fluids, hydrocortisone, glucagon, epinephrine, diazoxide, and octreotide (Garg and Devaskar, 2006). The treatment choice for the late preterm infant is based on the underlying cause of the hypoglycemia. Regardless of the etiology of the hypoglycemia, it is important to have constant monitoring of the glucose levels until they stabilize and the baby is tolerating adequate nutrition.

Hyperbilirubinemia

Hyperbilirubinemia is the most common clinical condition requiring evaluation and treatment in the late preterm newborn and the most common cause for readmission during the first postnatal week of life (Bhutani et al, 2004; Brown et al, 1999; Escobar et al, 2005; Maisels and Kring, 1998). Studies show that late preterm infants are more likely than term infants to be rehospitalized for jaundice (4.5% versus 1.2% in term infants) (Escobar et al, 2005).

In general, neonatal hyperbilirubinemia in late preterm infants is more prevalent, more pronounced, and more protracted than in their term counterparts. Important risk factors for severe jaundice are summarized in Figure 33-7, *A*. A study by Newman et al (1999) showed that infants born at 36 weeks' gestation have an eightfold increase in the risk of developing a total serum bilirubin concentration greater than 20 mg/dL (343 μmol/L) when compared with those born at 41 weeks' gestation or later. Part of the reason for this increased risk is the immature hepatic metabolic pathways for bilirubin and the overall immaturity of gastrointestinal function and motility. The decreased ability for hepatic uptake and conjugation puts the late preterm infant at increased risk of elevated serum bilirubin levels, and the jaundice then becomes more prolonged, prevalent, and severe (Bhutani and Johnson, 2006). In addition, late preterm infants are at increased risk of kernicterus at bilirubin levels equal to or lower than that of term infants (Bhutani and Johnson, 2006). Kernicterus is a devastating, chronic, and disabling condition characterized by the tetrad of choreoathetoid cerebral palsy, neural hearing loss, palsy of vertical gaze, and dental enamel hypoplasia (Watchko, 2006).

Whereas the need for universal predischarge bilirubin testing in neonates is debated, it is generally accepted that late preterm infants are at higher risk and should not be included with term infants. The current recommendation from the American Academy of Pediatrics from 2004 for the management of hyperbilirubinemia recommends that all newborns be assessed for their risk of developing hyperbilirubinemia by using predischarge total serum bilirubin or transcutaneous bilirubin measurements (Kuzniewicz et al, 2009). The effectiveness of this policy was studied by Kuzniewicz et al (2009), and they concluded that universal bilirubin screening, whether using transcutaneous bilirubin or total serum bilirubin for measurements, was associated with increased identification of newborns needing phototherapy and a significantly lower incidence of severe hyperbilirubinemia (see Figure 33-7, *B* and *C*).

This finding underscores the need for close monitoring of late preterm infants, particularly breastfed infants whose mothers may not have a proper milk supply before being discharge home. Early discharges should be avoided until proper feeding has been established, and early follow-up should be arranged.

INFECTIOUS DISEASES

Late preterm infants are also more susceptible to infections because of their immunologic immaturity. The timing of the infection categorizes them as congenital (acquired before delivery), early onset (usually acquired during delivery and presenting within the first 72 hours), or late onset (often acquired in the hospital and presents after 72 hours of life). Congenital infections are commonly attributed to rubella, cytomegalovirus, herpes simplex virus, and HIV (Benjamin and Stoll, 2006). The severity of the infection and its effect on the late preterm infant depends on the stage of pregnancy at which the maternal infection occurred. With both herpes simplex virus and HIV, maternal-infant transmission is more frequent if a mother has a primary infection at the time of delivery, whereas maternal viral load is the main risk factor for HIV transmission from mother to newborn (Benjamin and Stoll, 2006).

Early-onset sepsis is almost always caused by perinatally acquired infections. In most cases, the late preterm infant is initially colonized by exposure to various organisms in the maternal genital tract including group B *Streptococcus* (GBS), *Escherichia coli*, and *Candida* spp. Additional risk factors for developing sepsis are prolonged rupture of membranes (greater than 18 hours), maternal fever, and chorioamnionitis (Centers for Disease Control and Prevention, 2002).

The third group—the late-onset sepsis—may be caused by perinatally or postnatally acquired organisms, but usually is a consequence of nosocomial transmission. The most common organisms are gram-negative rods, but sepsis could be caused by *Staphylococcus aureus*, *Enterobacter* spp., or *Candida* spp. Although the mortality rate is low for late preterm infants, infections increase the risk of complications and often involve longer hospital stays (Benjamin and Stoll, 2006).

In addition, research shows that late preterm infants undergo testing for sepsis more often than term infants (36.7% versus 12.6%; odds ratio, 3.97; 95% confidence interval, 1.82 to 9.21; $p = 0.00015$) and receive antibiotics more often and for a longer duration (7-day course 30% versus 17% in term infants) (Wang et al, 2004). Other studies show that the need for a sepsis evaluation increases with decreasing gestational age; 33% were evaluated for possible sepsis at 34 weeks' gestation compared with 12% at 39 weeks' gestation ($p < 0.01$), of which only 0.4% of infants had culture-proven sepsis (McIntire and Leveno, 2008). This higher frequency of screening late preterm newborns for sepsis compared with term infants may be multifactorial. First, records show that one third of all preterm deliveries occur after prolonged premature rupture of membranes, which can put the newborn at a significantly higher risk of infection. In addition, this higher rate of sepsis workups in the late preterm baby may be

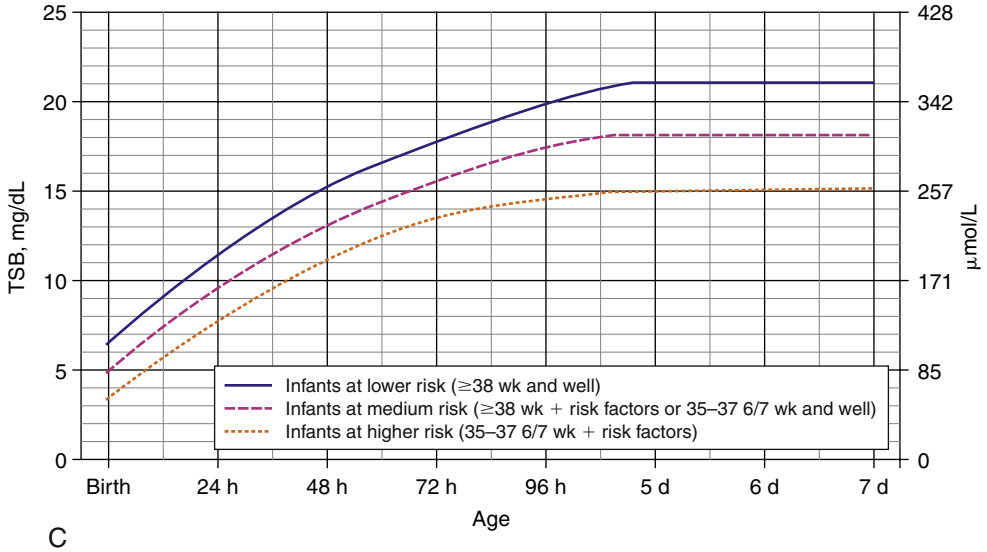
A

IMPORTANT RISK FACTORS FOR SEVERE HYPERBILIRUBINEMIA

- Predischarge total serum bilirubin (TSB) or transcutaneous bilirubin (TcB) measurement in the high-risk or high-intermediate-risk zone
- Lower gestational age
- Exclusive breastfeeding, particularly if nursing is not going well and weight loss is excessive
- Jaundice observed in the first 24 h
- Isoimmune or other hemolytic disease (e.g., G6PD deficiency)
- Previous sibling with jaundice
- Cephalohematoma or significant bruising
- East Asian race

B

HOURLY PROGRESSION OF TOTAL SERUM BILIRUBIN (TSB) LEVELS: RISK CATEGORIES



C

GUIDELINES FOR PHOTOTHERAPY IN HOSPITALIZED INFANTS ≥35 WEEKS' GESTATION

Note that these guidelines are based on limited evidence and that the levels shown are approximations. The guidelines refer to the use of intensive phototherapy, which should be used when the TSB level exceeds the line indicated for each category.

- Use total bilirubin. Do not subtract direct-reacting or conjugated bilirubin.
- Risk factors are isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or an albumin level of <3.0 g/dL (if measured).
- For well infants at 35 to 37 6/7 weeks' gestation, on can adjust TSB levels for intervention around the medium-risk line. It is an option to intervene at lower TSB levels for infants closer to 35 weeks' gestation and at higher TSB levels for those closer to 37 6/7 weeks' gestation.
- It is an option to provide conventional phototherapy in the hospital or at home at TSB levels of 2 to 3 mg/dL (35–50 μmol/L) below those shown, but home phototherapy should not be used in any infant with risk factors.

FIGURE 33-7 Hyperbilirubinemia. A, Risk factors. **B,** Hourly progression of total serum bilirubin levels. **C,** Management guidelines. *(Adapted from Maisels MJ, Bhutani VK, Bogen D et al: Hyperbilirubinemia in the newborn infant > or = 35 weeks' gestation: an update with clarifications*, Pediatrics *124:1193-1198, 2009.)*

a reflection of a standard protocol used for admissions to the NICU or due to their clinical presentation (e.g., respiratory distress, hypothermia, hypoglycemia), which could be a sign of sepsis or a reflection of the infants' immaturity.

THERMOREGULATION

Because of their relatively smaller size, the late preterm infant is susceptible to periods of hypothermia or cold stress. Unfortunately, as for other problems discussed earlier, this may be difficult to assess if the late preterm newborn has

been sent to the mother's room or is not closely observed. Usually cold stress will manifest as tachypnea or apnea, poor feeding, poor color caused by peripheral vasoconstriction, and metabolic acidosis. Hypothermia and its related consequences can delay the respiratory transition and exacerbate hypoglycemia; these signs and symptoms may also be misinterpreted as possible sepsis, which then leads to unnecessary interventions and workups.

The reason that late preterm infants are particularly more susceptible to temperature instability is because of their physiologic immaturity of thermoregulation, which in turn is dependent on three main things: the amount of brown adipose tissue, white adipose tissue, and body surface area (Engle et al, 2007; Martin et al, 2006; Polin et al, 2003). Nonshivering thermogenesis is controlled by the hypothalamic ventromedial nucleus through the sympathetic nervous system, which releases the neurotransmitter norepinephrine. The norepinephrine then causes the brown adipose tissue to liberate free fatty acids, which are eventually oxidized and produce heat (Engle et al, 2007; Martin et al, 2006; Polin et al, 2003). Late preterm infants have decreased stores of brown adipose tissue and the hormones responsible for brown fat metabolism (i.e., prolactin, norepinephrine, triiodothyronine, and cortisol). These hormones peak at term gestation and the late preterm infant misses those last few weeks of in utero development (Engle et al, 2007; Polin et al, 2003). In addition to the decreased stores of hormones leading to thermogenesis, late preterm infants also have problems with hypothermia because of a decreased amount of white adipose tissue, which leads to less insulation, and their smaller size. The late preterm infant's relatively smaller size, compared with term infants, leads to an increased ratio of surface area to body weight, which allows for greater heat loss to the environment (Engle et al, 2007; Martin et al, 2006; Polin et al, 2003). Appropriate monitoring and triaging of the late preterm infant who is susceptible to temperature instability can avoid unnecessary morbidity, workups, interventions, and prolonged hospitalizations.

NEURODEVELOPMENTAL

During pregnancy, the infant's lungs and brain are among the last organs to mature and are therefore more prone to injury. Not surprisingly, research has shown that even healthy near-term or late preterm infants are at risk for developmental delays through the first 5 years of life (Raju, 2006). During the final few weeks of gestation, many aspects of brain maturity are still in progress. These aspects include maturing oligodendroglia, increasing neuronal arborization and connectivity, maturation of neurotransmitter systems, and continued brain growth that accounts for a 30% increase in brain size during the last few weeks of gestation (Figure 33-8) (Jain and Raju, 2006). At 34 weeks' gestation, the brain weighs only 65% of the weight of a 40-week term infant (Billiards et al, 2006; Kinney, 2006). Researchers have shown that the brain of a late preterm infant is still immature and continues to grow until 2 years of age, when it reaches 80% of adult brain volume. In addition, the cerebral cortex is still smooth and the gyri and sulci are not fully formed, and myelination and interneuronal connectivity is still

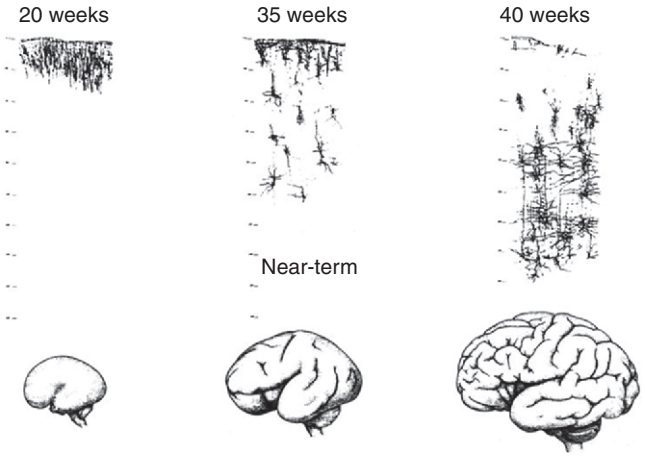


FIGURE 33-8 The immaturity of the laminar position and dendritic arborization of neurons, as demonstrated by Golgi drawings, in the cerebral cortex in the late preterm infant at 35 weeks' gestation is striking in comparison with neurons at mid-gestation (20 weeks) and at term (40 weeks). *(From Kinney HC, Armstrong DD: Perinatal neuropathology. In Graham DI, Lantos PE, editors:* Greenfield's neuropathology, *ed 7, London, 2002, Arnold, pp 557-559.)*

incomplete. Multiple insults during this critical phase of neuronal and glial maturation cause white and grey matter injury, especially in the thalamic region and the periventricular white matter (Kinney, 2006). These events can be correlated subsequently to delayed development and special education needs; therefore it is important to start early developmental follow-up, anticipatory guidance, and interventions for infants born at 32 to 36 weeks' gestation (Chyi et al, 2008).

HOSPITALIZATION OF THE LATE PRETERM INFANT

Based on the need for close monitoring and management of the various medical problems identified in late preterm infants, they are more likely than a full-term infant to require admission to an intensive care unit. Despite this finding, individual hospitals and nurseries follow different criteria regarding which infants to admit to the NICU, an intermediate care unit, or an observation area. Some routinely admit all infants <35 weeks, gestation to the NICU, whereas others do so on an individual basis. The most common reasons for admission include temperature instability, jaundice, respiratory distress, dehydration, poor feeding, and hypoglycemia (Vachharajani and Dawson, 2009; Wang et al, 2004). Studies have shown that 88% of infants born at 34 weeks' gestation, 12% born at 37 weeks' gestation, and 2.6% born at 38 to 40 weeks' gestation were admitted to the NICU (Engle and Kominiarek, 2008). Other studies have shown similar rates, and the overall trend was that the late preterm infant had significantly higher rates of NICU admission than the 39-week infants (McIntire and Leveno, 2008). In addition, the duration of hospitalization for the late preterm infant is inversely proportional to the baby's gestational age, which means that late preterm infants require longer hospitalization after birth than their term counterparts. On average, infants are hospitalized for 6 to 11 days at 34 weeks', 4 to 6 days at 35 weeks', and 3 to 4 days at 36 weeks' gestation (Escobar

TABLE 33-1 Mortality (rate per 1000 live births) in Infants Born at Late Preterm and Early Term Gestations

	Early Neonatal Mortality (1-7 days)		Infant Mortality (1-365 days)

et al, 2005; Gilbert et al, 2003; Khashu et al, 2009; McIntire and Leveno, 2008; Phibbs and Schmitt, 2006; Vachharajani and Dawson, 2009).

MORTALITY

Preterm birth is consistently recognized as the most pressing public health problem in perinatology by both clinicians and researchers, given its overall contribution to infant mortality. It also contributes substantially to neurocognitive, pulmonary, and ophthalmologic morbidity (Kramer et al, 2000). On review of infant birth and death files from 1995 to 2002 in the United States, Tomashek et al (2007) compared the overall and cause-specific mortality rates between singleton late preterm infants and term infants. They found that, despite significant declines since 1995 in mortality rates for late preterm and term infants, the infant mortality rate in 2002 was threefold higher in late preterm infants than in term infants (7.9 versus 2.4 deaths per 1000 live births); early, late, and postneonatal mortality rates were sixfold, threefold, and twofold higher, respectively. Another study by Young et al (2007) found that in a large cohort from Utah, the relative risk of death increased for every decreasing week in gestational age less than 40 weeks (Table 33-1). In addition, a large study involving 133,022 infants born at 34 to 40 weeks' gestation found that neonatal mortality rates were significantly higher for late preterm infants (1.1, 1.5, and 0.5 per 1000 live births at 34, 35, and 36 weeks, respectively, compared with 0.2 per 1000 live births at 39 weeks' gestation p <0.001) (McIntire and Leveno, 2008). In 2005, the U.S. infant mortality rate for late preterm infants was 7.3 versus 2.43 per 1000 live births in term neonates. Surprisingly, the mortality rate is 30% higher even for infants born between 37 and 39 weeks' gestation (early term) (Mathews and MacDorman, 2008). These studies and statistics again emphasize the fact that infants born just a few weeks early are at a much greater risk of morbidity and mortality than those born at term gestation. However, perinatal data collected over similar periods also reveal a remarkable decline in stillbirth rate (Figure 33-9). Perinatologists argue that this reduction in fetal demise is directly related to close monitoring of the fetus and early intervention (delivery) when needed.

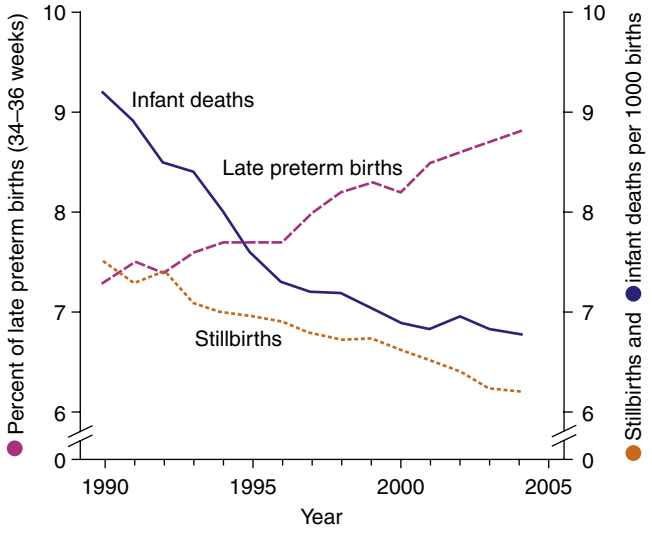

FIGURE 33-9 Trends in late preterm birth, stillbirth, and infant mortality in the United States, 1990 to 2004. The left axis shows trends in stillbirth and infant mortality rates; the right axis shows trends in late preterm births (34 to 36 weeks). Late preterm birth rates are shown per 100 live births; stillbirth rates per 1000 total births, and infant death rates per 1000 live births. *(Adapted from Ananth CV, Gyamfi C, Jain L: Characterizing risk profiles of infants who are delivered at late preterm gestations: does it matter?* Am J Obstet Gynecol *199:329-331, 2008.)*

RECOMMENDATIONS

ADMISSION CRITERIA

With more than 80% of all deliveries occurring in community hospitals (Jain and Raju, 2006), many of which have a relatively small number of deliveries, and health care teams that might not always be equipped to assess and manage the needs of a late preterm infant, it becomes increasingly important to establish safeguards for the screening, identification, and appropriate triage of these patients. A subcommittee on the American Academy of Pediatrics Committee on the Fetus and Newborn (Engle et al, 2007) outlined recommendations for the care of the late preterm newborn. Based on these guidelines and the potential complications associated with late preterm infants, we recommend that all infants born before 35 weeks' gestation weighing less than 2300 g should be admitted to a transitional nursery where the infant can be monitored closely until there has been adequate time to assess the baby's vital signs, feeding abilities, and thermoregulation, among other issues, before sending the baby to the mother's room. Sicker neonates who require intensive care obviously will need to be admitted to higher levels of care. In addition, each nursery should establish guidelines for frequency of monitoring vital signs, assessment for sepsis and use of antibiotics, and the use of supplemental oxygen. It is also important to determine a threshold (based on comfort level, staff training, and available resources) for transferring the newborn to a tertiary care center when the disease process associated with the late preterm infant continues to progress or worsen. Box 33-3 shows the recommendations for admission, management, and discharge of the late preterm infant. This list is not all-inclusive and was designed to be used as a guideline, and not as a replacement for good clinical judgment.

BOX 33-3 Admission and Discharge Criteria and Management of Late Preterm Infants

ADMISSION CRITERIA

- Admit all infants born before 35 weeks' gestation or weighing less than 2300 g at birth
- They should not to be sent to their mother's rooms in the first 24 hours until stable, unless arrangements can be made to provide transitional care and close monitoring in the mother's room.

HOSPITAL MANAGEMENT

- Physical examination on admission and discharge
- Determination of accurate gestation age on admission examination
- Vital signs and pulse oximeter check on admission, followed by vital signs every 3 to 4 hours in the first 24 hours, and every shift thereafter
- Caution against use of oxyhoods with high F_{IO_2}; consider transfer to NICU or tertiary care center if F_{IO_2} exceeds 0.4
- A feeding plan should be developed. Formal evaluation of breastfeeding and documentation in the record by care givers trained in breastfeeding at least twice daily after birth
- Serum glucose screening per existing protocols for infants at high risk of hypoglycemia

DISCHARGE CRITERIA

- Discharge should not be considered before 48 hours after birth
- Vital signs should be within normal range for the 12 hours preceding discharge
  - Respiratory rate less than 60 breaths/min
  - Heart rate of 100 to 160 beats/min
  - Axillary temperature of 36.5° to 37.4° C measured in an open crib with appropriate clothing
- Passage of one stool spontaneously
- Adequate urine output
- Twenty-four hours of successful feeding: ability to coordinate sucking, swallowing, and breathing while feeding
- If weight loss is greater than 7% in 48 hours, consider further assessment before discharge
- Risk assessment plan for jaundice for infants discharged within 72 hours of birth
- No evidence of active bleeding at circumcision site for at least 2 hours
- Initial hepatitis B vaccine has been given or an appointment scheduled for its administration
- Metabolic and genetic screening tests have been performed in accordance with local or hospital requirements
- The late preterm infant has passed a car seat safety test
- Hearing assessment is performed and results documented in the medical record; follow-up if necessary has been arranged
- Parents have been trained and demonstrate competency in caring for the infant
- Family, environmental, and social risk factors have been assessed; when risk factors are present, discharge should be delayed until a plan for future care has been generated
- Identification of a physician with a follow-up visit arranged for 24 to 48 hours after discharge with a possibility of additional visits initially until the infant can demonstrate a consistent pattern of weight gain

F_{IO_2}, Fractional concentration of oxygen in inspired gas; *NICU*, neonatal intensive care unit.

DISCHARGE CRITERIA

Because of the morbidities and risk factors associated with late preterm babies, they should not be discharged before 48 hours after birth. Before discharge, while the baby is still in the NICU, the following are recommended:

1. Vital signs should be within normal range for at least 12 hours preceding discharge; this includes respiratory rate less than 60 breaths/min, heart rate of 100 to 160 beats/min, and axillary temperature 36.5 to 37.5° C in an open crib with appropriate clothing.
2. There should be documentation of passage of at least one stool spontaneously.
3. Adequate urine output should be accompanied by educating the parents about ways to assess the adequacy of output and appropriate interventions if the urine output appears to decrease, with at least 24 hours of successful feeding with adequate coordination of sucking, swallowing, and breathing during feedings.
4. Weight loss should not exceed 7% of birthweight in the first 48 hours of life.
5. Serum or transcutaneous bilirubin check—a transcutaneous bilirubin higher than 12 mg/dL should warrant a serum bilirubin check, which will then be stratified into risk category by using a bilirubin nomogram. Parents should also be educated on what to look for and what to do if their baby appears jaundiced.
6. Hearing screen, a car seat test, and metabolic and genetic screening tests should have been performed in accordance with state, local, and hospital protocols; if the baby is circumcised, there should be no bleeding at the site for at least 2 hours.
7. Hepatitis B vaccine should be given or an appointment should be made for its administration.
8. Parents should be educated about umbilical cord and skin care, identification of common signs and symptoms of illness, sleeping patterns and positions, instructions on using the thermometer and parameters for normal measurements, and instructions regarding responses to an emergency (i.e., CPR training before discharge).

If these guidelines (or other criteria outlined as standard of care) are not met, we recommend considering postponing discharge until the baby has been observed for a longer period of time and the issues have been resolved.

When additional risk factors are present (e.g., twin or multiple gestation, teenage mother), discharge should be delayed until an appropriate care plan has been generated. In addition, when indicated, it may be appropriate to arrange a nursing home health visit for closer monitoring, but this should not be used to replace the due diligence that must be done while the baby is in the hospital and the appropriate and timely follow-up with a pediatrician.

Follow-up after Discharge

After discharge from the hospital, the majority of the medical care a newborn baby receives occurs in two main settings: the primary care physician's office and the emergency department. To avoid fragmented care by multiple emergency department visits and to allow for an early assessment of the baby, it is recommended that the late preterm baby should be brought for a checkup by their pediatrician within 24 to 48 hours after discharge from the hospital.

In addition, because of their increased risk for developmental delays, these infants should be monitored closely to ensure that all milestones are achieved appropriately and that early intervention (e.g., physical therapy, occupational therapy, speech therapy) is in place if needed. Early developmental testing can also be useful in determining any cognitive delays, which can then be addressed with individualized educational programs.

Readmission to the Hospital

The late preterm infant is susceptible to many of the problems of smaller preterm infants. Because of the multiple factors discussed throughout this chapter, the close observation and intensity of management provided to smaller premature infants is often lacking. In addition, there are often more lenient criteria for discharge, which sets them (and their parents) up for failure and eventual readmission to the hospital. Tomashek et al (2007) looked at late preterm infants who were discharged early (<2 days after birth) from the hospital and found that 4.3% of late preterm and 2.7% of term infants were either readmitted or had an observational hospital stay.

Recent data suggest that the most frequent causes of emergency department visits by this subgroup of premature infants after being discharged home are dehydration, feeding problems, respiratory distress, apnea, fever, infection, and jaundice (Jain and Cheng, 2006). Whether they are evaluated in the emergency department or a pediatrician's office, it is important to have a lower threshold for readmitting these infants because of their vulnerability to serious complications. Their fragility is evidenced by their higher rate (4.4%) of rehospitalization than term infants (2%; Escobar et al, 2005). In addition, studies show that 34- to 36-week infants who were never admitted to the NICU (or if admitted, their NICU stay lasted less than 24 hours) had nearly a threefold and 1.3-fold higher risk of readmission compared with term infants, respectively (Escobar et al, 1999, 2005, 2006). Because late preterm infants are at a much higher risk for rehospitalization, they need close follow-up after discharge to assess breastfeeding and nutrition and to monitor for jaundice.

FUTURE RESEARCH

Since 1981, the number of premature births in the United States has increased by 30%. The majority of this increase is attributable to the increased number of late preterm infants (Pulver et al, 2009)—a unique and high-risk subgroup of premature infants. The identification and care of this group and their unique challenges have only recently been recognized as a high-priority area of research in the field of neonatology. There are many questions still to be answered regarding the care and outcomes associated with late preterm infants (Box 33-4). Topping this list of priorities is the need to know which babies are better off being delivered early, and for the rest, what can be done to take pregnancy as close to term as possible. Because answers to many issues related to preterm birth still remain elusive, clinicians have, rightly so, focused on ways to improve the postnatal management of these premature babies. New studies, albeit mostly retrospective, have added to the understanding of the spectrum of morbidities in late preterm infants; they have also formed the basis for current strategies to standardize management and optimize outcomes.

BOX 33-4 Unanswered Questions and Future Directions

EPIDEMIOLOGY, TRENDS, ETIOLOGY, AND PREVENTION OF LATE PRETERM BIRTHS

- Is there a subset of preventable late preterm births?
- What is the effect of continuing such pregnancies (preterm rupture of membranes, preterm labor, medically indicated birth) on perinatal outcomes?
- Is there a role for antenatal steroids in late preterm gestation pregnancies threatened with preterm delivery?
- Should singleton and multiple gestation late preterm deliveries be treated differently?

CLINICAL MANAGEMENT AND OUTCOMES OF LATE PRETERM INFANTS

- Can standardized "care paths" for late preterm infants improve outcomes?
- Optimal discharge strategies that minimize readmissions and other problems after discharge
- Strategies for management of rapidly progressive and/or severe morbidities in late preterm infants
- Standardized approach to central nervous system imaging and post-discharge follow-up.

LONGTERM OUTCOMES

- Prospective studies of long-term outcomes of symptomatic and asymptomatic late preterm births to determine which infants should have long-term follow-up

CHAPTER 34

Pharmacokinetics, Pharmacodynamics, and Pharmacogenetics

Robert M. Ward, Steven E. Kern, and Ralph A. Lugo

Dynamic changes in growth and physiologic maturation in newborns create unique complexities in drug therapy that affect absorption, distribution, metabolism, and elimination. Pharmacologic studies during this period of rapid growth and physiologic maturation reveal different patterns of change in kinetics, some related to postnatal age and others to postmenstrual age. These differences also provide information about varied patterns of maturation in drug metabolizing enzymes and pathways of elimination during early infancy. Therapeutic drug monitoring is used for a few drugs in neonatology, such as phenobarbital and gentamicin, when concentrations correlate with desired effects as well as adverse effects. Dosage adjustments to reach desired concentrations can be estimated at the bedside using simple calculations. Pharmacogenetics and pharmacogenomics of enzymes and receptors explain many variations among individuals in their responses to drugs. The immature, preterm newborn adds another level of complexity to drug metabolism, because of variability in the timing of the expression of these enzymes.

PRINCIPLES OF NEONATAL THERAPEUTICS

A thorough understanding of factors that affect drug concentrations helps to provide accurate, effective drug therapy and to identify the causes of therapeutic failure in neonates. Many important factors are not chosen consciously in a therapeutic plan, but have tremendous impact on its effectiveness. Because pharmacokinetics and pharmacodynamics in newborns follow the same general principles that govern drug actions in patients of any age, the diagnosis, drug selection, and administration needed to achieve a therapeutic goal must consider the effects of absorption, distribution, metabolism, and excretion on the dose-exposure relationship. When applied to the newborn, these principles should adjust for several unique physiologic and pharmacologic features of these immature patients, as outlined in Box 34-1 and discussed in detail here.

DIAGNOSIS

Effective treatment begins with an accurate diagnosis and assessment of clinical signs and symptoms. Although this principle applies to all areas of therapeutics, treatment in newborns presents special diagnostic challenges because the small size and fragility of such nonverbal patients may preclude useful, but inordinately invasive, diagnostic procedures. For example, many small immature newborns with chronic lung disease are treated for bronchospasm based on the findings of decreased air entry associated with desaturation and abnormal breath sounds. Relief of these symptoms with aerosolized bronchodilators may be interpreted as confirmation of the diagnosis. Although this interpretation may be correct, increased humidity or movement of the endotracheal tube bevel away from a pliable tracheal wall during an aerosol treatment may also produce the improvement. Therefore evaluation of any ineffective therapy should include reconsideration of the original diagnosis, just as conclusions about why a therapy succeeded should be made with a degree of skepticism.

ABSORPTION

Although most drug therapy for acute problems in the intensive care setting involves intravenous administration to ensure drug delivery to the site of action, this route is not always reliable in newborns (Gould and Roberts, 1979; Roberts, 1984). In a critical care setting, drugs should be infused toward the patient as close as possible to the site of vascular access. If a drug is injected away from the infant into a catheter with a slow infusion rate, the drug may reach the patient too slowly to achieve effective concentrations. Infusion solution filters may also prevent effective drug delivery by blocking large molecules, such as amphotericin, by direct adsorption of the drug to the filter, or by allowing a heavier drug to settle in the filtration chamber and mix slowly with the infusion solution. For drug therapy in which the driving force for tissue penetration is a concentration gradient between the circulation and the tissue (e.g., in meningitis), sustained low drug concentrations might be therapeutically suboptimal.

Intramuscular administration of drugs to newborns is generally suboptimal, but might be used when there is difficulty establishing intravenous access. Absorption of drugs from an intramuscular injection site is directly related to muscle blood flow, which is usually reduced in patients experiencing hypothermia or shock, when intravenous access can be difficult, but intramuscular doses are unlikely to be absorbed effectively. Furthermore, intramuscular administration of drugs can sclerose tissue and cause sterile abscesses or create large intramuscular collections of the drugs, which are then absorbed slowly, producing a "depot effect" in which serum concentrations rise slowly over a prolonged period. Intramuscular administration of drugs, especially for multiple doses, should be avoided in newborns. Although oral administration of drugs is preferred for treatment of chronic illnesses in newborns, this route is not well studied, particularly in acutely ill premature infants. Studies in adults show that less drug is usually absorbed from the stomach than from the intestinal tract because of the smaller surface area and differences in pH. Many newborns experience gastroesophageal reflux associated with delayed gastric emptying, which might also alter drug bioavailability. Delayed gastric emptying postpones

BOX 34-1 Pharmacologic Principles and Pitfalls in Management of the Very Low-Birthweight Infant

- **I.** Diagnosis
  - **A.** Limited diagnostic procedures
- **II.** Absorption
  - **A.** Intravenous
    - **1.** Drug injection away from patient
    - **2.** Uneven mixing of drugs and intravenous fluids
    - **3.** Delayed administration because of low flow
    - **4.** Part of the dose discarded with tubing changes
  - **B.** Intramuscular
    - **1.** Poor perfusion limits absorption
    - **2.** Danger of sclerosis or abscess formation
    - **3.** Depot effect
  - **C.** Oral
    - **1.** Poorly studied
    - **2.** Affected by delayed gastric emptying
    - **3.** Potentially affected by reflux
    - **4.** Passive venous congestion may occur with chronic lung disease, decreasing absorption
- **III.** Distribution, affected by
  - **A.** Higher (85%) total body water (versus 65% in adults)
  - **B.** Lower body fat—that is, approximately 1% body weight (versus 15% in term infants)
  - **C.** Low protein concentration
  - **D.** Decreased protein affinity for drugs
- **IV.** Metabolism
  - **A.** Half-life prolonged and unpredictable
  - **B.** Total body clearance decreased
  - **C.** Affected by nutrition, illness, and drug interaction
  - **D.** Affected by maturational changes
- **V.** Excretion: decreased renal function, both glomerular filtration rate and tubular secretion

reaching peak serum drug concentrations and prolongs the absorption phase, which reduces the peak concentration. If the total absorbed dose is reduced, the area under the concentration time curve (AUC) will decrease along with drug exposure. Passive venous congestion of the intestinal tract from elevated right atrial pressures decreases drug absorption in adults and may do so in premature infants with severe bronchopulmonary dysplasia complicated by cor pulmonale (Peterson et al, 1980). The administration of medications to newborns in small volumes of formula or during continuous gastric feedings may also alter drug absorption by binding to proteins, lipids, carbohydrates, or minerals in the feeding. When enteral drug therapy fails, possible effects of feeding patterns on drug absorption and action should be considered.

DISTRIBUTION

In pharmacokinetics, distribution is the partitioning of drugs among various body fluids, organs, and tissues. The distribution of a drug within the body is determined by several factors, including organ blood flow, pH and composition of body fluids and tissues, physical and chemical properties of the drug (e.g., lipid solubility, molecular weight, ionization constant), and the extent of drug binding to plasma proteins and other macromolecules (Plonait and Nau, 2004; Ward and Lugo, 2005).

Important differences among premature infants, children, and adults affect the distribution of drugs. Total body water varies from 85% in premature newborns to 75% in term newborns to 65% in adults (Friis-Hansen, 1961, 1971). Conversely, body fat content varies from 0.7% or less in extremely premature newborns to approximately 12% in term newborns (Friis-Hansen, 1971; Ziegler et al, 1976). These differences change the distribution of many drugs, especially polar, water-soluble drugs such as the aminoglycosides. Protein binding of drugs in the circulation is decreased in the premature newborn because of a smaller total amount of circulating protein and lower binding affinity of the protein itself (Aranda et al, 1976). With rare exceptions, only the free (not bound to protein) drug molecules cross membranes, exert pharmacologic actions, and undergo metabolism and excretion. Clinical measurements of serum or plasma drug concentrations usually reflect total circulating drug concentrations, which consist of both free and protein-bound drug. Thus, even when total circulating drug concentrations in the newborn may be low by adult standards, the free drug concentrations may be equivalent or even higher than those in the adult because of decreased protein binding in the newborn.

METABOLISM

Many drugs require metabolic conversion before elimination from the body. Biotransformation of a drug usually produces a more polar, less lipid-soluble molecule that can then be eliminated rapidly by renal, biliary, or other routes of excretion. Drug biotransformation is classified into two broad categories: nonsynthetic (phase I) reactions, which include oxidation, reduction, and hydrolysis; and synthetic or conjugation (phase II) reactions, which include glucuronidation, sulfation, and acetylation. Multiple forms of phase I and phase II enzymes exist to perform these metabolic functions. Although the liver is considered the major organ responsible for drug biotransformation, many other organs also contribute to drug metabolism.

For many drugs in the newborn, the half-life is prolonged and total body clearance is decreased compared with older children and adults. Important variations occur, however, among drug classes and among individuals that prevent broad generalizations. Glucuronide conjugation of bilirubin by uridine 5′-diphospho-glucuronosyltransferase (UGT) 1A1 is usually low at birth unless this enzyme has been induced in utero through maternal exposure to drugs, cigarette smoke, or other inducing agents (Maurer et al, 1968). In contrast, conjugation through sulfation is usually active at birth. Various factors after birth, such as nutrition, illness, and drug interactions, may hasten or retard the maturation of enzymes and organs responsible for drug metabolism in the newborn. Maturational changes in hepatic blood flow, drug transport into hepatocytes, synthesis of serum proteins, protein binding of drugs, and biliary secretion—alone and in combination—confound accurate predictions about drug metabolism after birth, leading to empiric dose adjustments (Morselli et al, 1980). Because smaller and more immature newborns are now surviving, many of these factors that were studied in larger, more mature neonates must be reassessed in this less mature population.

The primary types of enzymes involved in phase I reactions are cytochromes P450 (CYPs). CYPs are microsomal, mixed-function oxidases that catalyze chemical changes within a molecule, such as hydroxylation, methylation, demethylation, addition of oxygen, or removal of hydrogen (Leeder and Kearns, 1997). There are thousands of different CYP450 enzymes found in plants and animals on land and in water. CYPs with more than 40% of the same amino acid sequence are grouped as a numbered family (e.g., CYP3). Those with greater than 67% polypeptide homology belong to the same subfamily (e.g., CYP3A), and specific genes are denoted with a number (e.g., CYP3A5). The amino acid sequence of these enzymes determines the tertiary structure that creates a hydrophobic pocket with selective binding for chemicals and drugs. This substrate specificity creates groups of drugs, often with similar structure and function that are metabolized by the same CYP. In the preterm newborn, CYPs develop at different rates and in different patterns. Maturation correlates best with postmenstrual age for some CYPs and with postnatal age for others. Some CYPs do not reach adult activity until several years of age, whereas others develop activities twice that of the adult during childhood; therefore generalizations about patterns of maturation for CYPs are seldom valid. In addition, single nucleotide polymorphisms (SNPs) or substitutions in the DNA sequence for a CYP may reduce its metabolizing activity or completely eliminate it if the polypeptide cannot be formed.

The phase II conjugation enzymes, such as the UGTs, have several forms with different substrate specificity (e.g., UGT1A1 for bilirubin, UGT2B7 for morphine), although they are not as absolutely selective as the CYPs (Leeder and Kearns, 1997). Some phase II enzymes complement each other at birth for conjugation of specific drugs, such as acetaminophen that is conjugated primarily by sulfotransferases at birth and less so by UGT. Moreover, by adolescence, UGT has become the predominant conjugation pathway for acetaminophen.

EXCRETION

Drug elimination from the body can occur through several mechanisms, including renal excretion, biliary excretion, transcutaneous loss, gastrointestinal loss, and pulmonary exhalation. Renal excretion is one of the most important pathways for elimination of metabolized and unchanged drug. Neonatal renal function is diminished in absolute terms and when normalized to body weight or surface area. The neonatal glomerular filtration rate averages 30% of the adult rate per unit surface area. Glomerular function rises steadily after birth, whereas tubular function matures more slowly, causing a glomerular and tubular imbalance (Aperia et al, 1981). The postnatal increase in glomerular function reflects greater cardiac output, reduced renal vascular resistance, redistribution of intrarenal blood flow, and changes in intrinsic glomerular basement membrane permeability (Morselli et al, 1980). The dynamics of neonatal renal function markedly influence drug excretion. The rate of change of renal function and its susceptibility to hypoxemia, nephrotoxic drugs, and underperfusion prevent accurate predictions of drug elimination rates in newborns, which often must be measured empirically. Some drugs, such as nafcillin and spironolactone, have metabolites that must be eliminated through biliary excretion. Drugs that are conjugated within the liver may also be excreted through bile, enter the intestinal tract, and undergo deconjugation and enterohepatic recirculation, similar to bilirubin. Although biliary excretion is not well studied in newborns, clinical conditions such as parenteral nutrition– associated cholestasis suggest that it may be highly variable among specific patients and conditions.

Transporters play important roles in removing drugs and preventing drug absorption. Organic anion transporter polypeptides provide facilitated transport of anions in many tissues, including the kidney and liver. Permeability glycoprotein is an efflux transporter that belongs to the adenosine triphosphate–binding cassette–multiple drug resistance family of transporters. Permeability glycoprotein prevents the absorption of many compounds across the intestinal wall or into the brain, where it functions as a significant portion of the blood brain barrier.

PHARMACOGENETICS AND PHARMACOGENOMICS

The human genome project described the protein structures of many enzymes involved in drug metabolism and identified genetic variants in the proteins that alter activity, many of which are produced by a change in a single nucleotide to create SNPs. As discussed in the previous sections, genetic variation in drug metabolizing enzymes and in drug transporters can have a significant influence on the relative activity of these systems within a particular individual. Knowledge of pharmacogenetic and pharmacogenomic factors that can effect pharmacokinetics, particularly with a relationship to drug metabolism and elimination, has been important for understanding ways to avoid unanticipated drug effects in adults and to some extent older children. In neonates, however, this knowledge is only beginning to develop. Moreover, because many of these drug-metabolizing systems that are subject to pharmacogenetic variation continue to mature during the first few years of life, it can be difficult to determine whether genetic variability or physiologic maturation are contributing to differences in drug metabolism by neonates. What should be appreciated from this limited knowledge, however, is that drug metabolism is often reduced in neonates, and scaling of drug dosage by simple body weight or allometrically with an exponent will not fully compensate for differences in clearance that exist in this newborn population. Clearance often varies several-fold among adults, and the same degree of variation is emerging among neonates whether caused by maturation of the expression of these enzymes by gestational age or induction of protein synthesis after birth.

One of the most prominent phase 1 metabolizing enzymes, CYP3A4, illustrates several important aspects of CYPs. CYP3A4 exists as a fetal form at birth (CYP3A7) that decreases over the first months of life as it is replaced by the adult form, CYP3A4, by 1 year of age (Lacroix et al, 1997). However, these changes are not linear, which confounds making accurate dosing adjustments by age. The maturation of metabolic activity of phase I enzymes to adult activity varies among the specific enzymes, requiring

months for some and years for others (Kearns et al, 2003). During the fetal–neonatal period some CYPs increase in activity, but the most rapid increase in activity usually occurs after birth, regardless of the gestational age at birth (Koukouritaki et al, 2004). Drug-drug interactions influence activity of CYPs as well. Macrolide antibiotics, such as erythromycin and clarithromycin, and the azole antifungal drugs, such as fluconazole, inhibit the activity of CYP3A4 (Leeder and Kearns, 1997). These drugs can reduce clearance for drugs that are a substrate for CYP3A4, such as fentanyl or midazolam, and lead to toxicity without dosage adjustments. Conversely, inducers of CYP3A4 activity, such as rifampin and phenobarbital, can increase clearance of drugs that are substrates and reduce the concentration and effectiveness.

Large interindividual variation occurs for most of these enzymes and is complicated by inherited differences in activity. An SNP in the DNA for one of these enzymes is designated with an asterisk, such as CYP2C9*1, and can alter the protein structure enough to reduce or even inactivate its enzymatic activity. SNPs have been identified for most CYPs, especially CYP2D6, one of the first recognized inherited variations in activity for debrisoquine (Leeder and Kearns, 1997). Ethnic variations in these SNPs help to predict when activity is likely to be reduced or increased. For example, several inactivating SNPs of CYP2D6 have been recognized, indicating that 50% or more of Asians lack enough active CYP2D6 to metabolize codeine to morphine for a more potent analgesic effect (Ingelman-Sundberg, 2005). Study of the maturational changes in the pharmacokinetics of drugs metabolized by specific CYPs expands current knowledge of how these enzymes mature. A better understanding of the rates and patterns of maturation of different CYPs will help to guide appropriate dosage adjustments to improve drug therapy for newborns.

PHARMACOKINETIC PRINCIPLES

Pharmacokinetics describes the time course of changes in drug concentrations within the body. Although rates of change are often described with differential equations, useful concepts at the bedside are emphasized in this section. More detailed mathematical discussions of pharmacokinetics can be found elsewhere (Buxton, 2006; Rowland and Tozer, 2010).

COMPARTMENT

In pharmacokinetics, *compartment* refers to fluid and tissue spaces into which drugs penetrate. These compartments may or may not be equivalent to anatomic or physiologic fluid volumes. In the simplest case, the compartment may correspond to the vascular space and equal the volume of a real body fluid (i.e., blood). Large or highly polar molecules can be confined to this central compartment until they are eliminated by excretion or metabolism. Many drugs, however, diffuse reversibly out of the central compartment into tissues or other fluid spaces, generically referred to as *peripheral* or *tissue compartments*. Such compartments are seldom sampled directly, but their involvement in kinetic processes may be recognized from the graphic or mathematical description of the kinetics of a drug. The number of exponential terms necessary to adequately describe the kinetic profile of a drug designates the number of compartments involved, recognizing that many more compartments may exist. For appropriate clinical application, rarely are more than three compartments required to describe a drug's pharmacokinetics.

APPARENT VOLUME OF DISTRIBUTION

The apparent volume of distribution might be better termed *volume of dilution*, because it is a mathematical description of the volume (L or L/kg) that dilutes a dose (mg or mg/kg) to produce the observed circulating drug concentration (mg/L or μg/mL). (To simplify cancellation of units, concentrations are expressed as mg/L, which is the same as μg/mL, the more conventional unit for drug concentrations.)

$$\text{Concentration (mg/L)} = \frac{\text{Dose (mg/kg)}}{\text{Apparent volume of distribution (L/kg)}}$$

For many drugs, the volume of distribution does not correspond to a specific physiologic body fluid or tissue—hence the term *apparent*. In fact, the volume of distribution for drugs that are bound extensively in tissues may exceed 1.0 L/kg, a physiologic impossibility that emphasizes the arithmetic, nonphysiologic nature of the apparent volume of distribution. The determination of distribution volume is described later.

FIRST-ORDER KINETICS

Removal of most drugs from the body can be described by first-order (exponential or proportional) kinetics, in which a constant proportion or percentage of a drug is removed per unit of time (e.g., 50% in one half-life interval), rather than a constant amount per unit of time. For drugs exhibiting first-order kinetics, the higher the concentration, the greater the amount removed during an interval of time. The following equations describe the concentration (C) of a drug whose first-order kinetics have a constant rate k (hour^{-1}), at time t, and an initial concentration of C_0 achieved after administration of a dose.

In differential equation form, the change in C with time is

$$\frac{dC}{dt} = -kC$$

The solution to this differential equation gives the exponential form, which describes C at time t:

$$C_t = C_0 e^{-kt}$$

If this equation is transformed using the natural logarithm (ln), it results in:

$$\ln\ C_t = \ln\ C_0 - kt$$

The last equation fits the equation of a straight line, so that a graph that plots $ln\ C_t$ versus t has an intercept of $ln\ C_0$ at $t = 0$ and a slope of $-k$, the rate constant for the change in concentration; this can be used to calculate the half-life and to estimate appropriate dosages. Multiple rate constants in

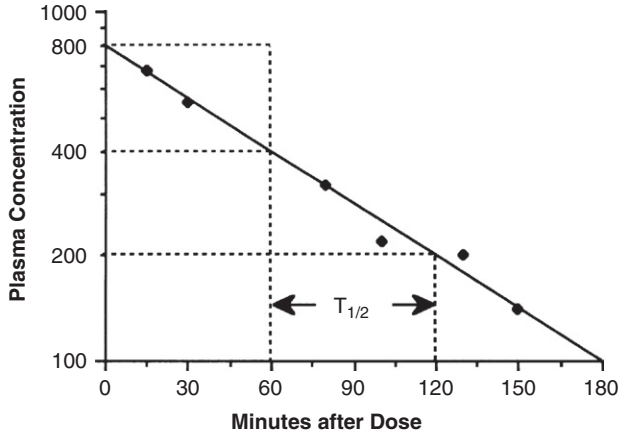

FIGURE 34-1 Apparent single-compartment, first-order plasma drug disappearance curve illustrating graphic determination of half-life from best-fit line of serial plasma concentrations.

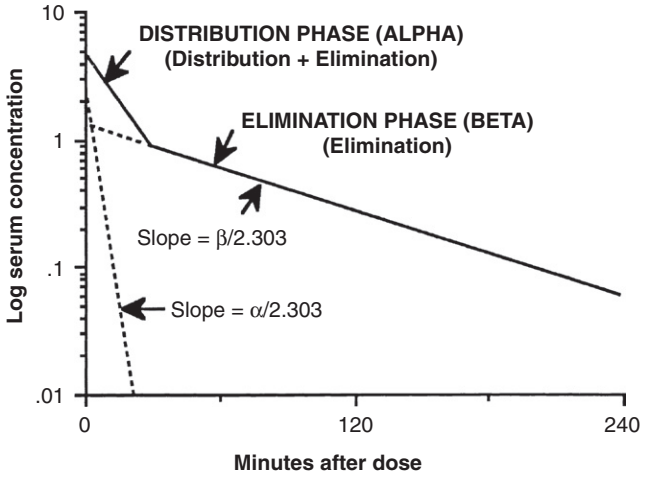

FIGURE 34-2 Multicompartment serum drug disappearance curve.

more complex equations are distinguished with the letter *k* and numbered subscripts or with Greek letters.

HALF-LIFE

The drug half-life ($t_{1/2}$) is the time required for a drug concentration to decrease by 50%. Half-life is a first-order kinetic process because the same proportion, 50%, of the drug is removed during equal periods. Half-life can be determined mathematically from the elimination rate constant *k* as:

$$t_{1/2} = \frac{\text{Natural logarithm } 2}{\text{k}} = \frac{0.693}{\text{k}}$$

Figure 34-1 illustrates a graphical method for determination of half-life. Drug concentrations measured serially are graphed on semilogarithmic axes, and the best-fit line is determined either visually or by linear regression analysis. In this illustration of first-order kinetics, the concentration decreases 50% (from 800 to 400) during the first hour and decreases another 50% (from 400 to 200) during the second hour. Thus the half-life is 1 hour. More drug is removed during one half-life at higher concentrations, although the proportion removed remains constant. The exponential equation for this graph is:

$$\text{C} = 800e^{-0.693\text{t}}$$

where k = 0.693/h and C_0 = 800, allowing a mathematical calculation of half-life using the equation described previously:

$$t_{1/2} = \frac{0.693}{\text{k (hour}^{-1})} = \frac{0.693}{0.693/\text{h}} = 1 \text{ hour}$$

MULTICOMPARTMENT, FIRST-ORDER KINETICS

The rate of removal of many drugs from the circulation is often biphasic. An initial rapid decrease in concentration is the distribution (α) phase, often lasting 15 to 45 minutes, which is followed by a sustained slower rate of removal, the elimination (β) phase. Such biphasic processes are best visualized from semilogarithmic graphs of concentration versus time. When such semilogarithmic graphs show kinetics that best fit two straight lines, the kinetics are described as *biexponential*, or reflective of a drug that shows two-compartment first order pharmacokinetics (Figure 34-2). Two exponential terms are needed to describe the change in concentration over time, as:

$$\text{C} = \text{A}e^{-\alpha\text{t}} + \text{B}e^{-\beta\text{t}}$$

In this equation, the rate constant for distribution is designated α to discriminate it from the rate constant for terminal elimination (β), where *A* and *B* are the *time* = 0 intercepts for the lines describing distribution and elimination, respectively. Division by 2.303 converts logarithms to natural logarithms.

After an intravenous dose, drug loss from the vascular space during the distribution phase occurs through both distribution and elimination (see Figure 34-2). The rate constant of distribution (α) can be determined by plotting the difference between the total amount of drug lost initially and the amount of drug lost through elimination (Greenblatt and Koch-Weser, 1975). This determination produces the line with the steeper slope (equal to α/2.303) below the serum concentration graph in Figure 34-2. The single slope of the distribution phase and of the terminal elimination phase does not imply that distribution or elimination occurs through a single process. The observed rates usually represent the summation of several simultaneous processes, each with differing rates, occurring in various tissues.

When the time course of drug elimination is observed for prolonged periods, a third rate of elimination, or γ phase, may also be observed and is usually attributed to elimination of drug that has reequilibrated from deep tissue compartments back into the plasma. Such kinetics are designated *three-compartment first-order pharmacokinetics*. The kinetics of a drug are expressed with the smallest number of compartments that accurately describe its concentration changes over time.

APPARENT SINGLE-COMPARTMENT, FIRST-ORDER KINETICS

When a semilogarithmic graph of concentration versus time reveals a single slope with no distribution phase, the kinetics are characterized as *apparent one-compartment*,

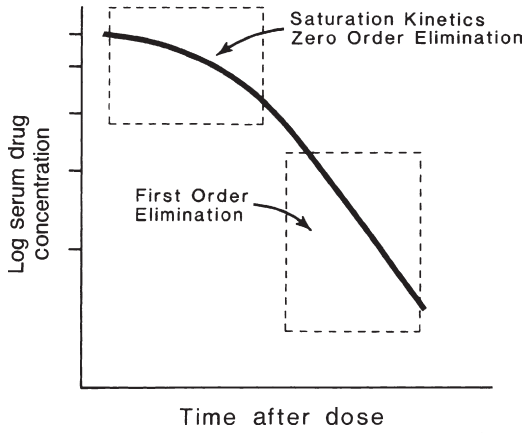

FIGURE 34-3 Representation of saturation, or zero-order (serum concentration–dependent), and first-order (serum concentration–independent) pharmacokinetics.

first-order (see Figure 34-1). Such kinetics can occur when a drug remains entirely within the vascular space or central compartment or when a drug passes rapidly back and forth between the circulation and peripheral sites until it is metabolized or excreted by first-order kinetics. The adjective *apparent* is used because careful study often shows that distribution occurs even though the kinetic curve has only a single slope. Single-compartment kinetics implies that the drug rapidly and completely distributes homogeneously throughout the body, which rarely occurs clinically.

In many pharmacokinetic studies in newborns, blood samples are not obtained early enough to allow calculation of the distribution phase, and the kinetics are described as single-compartment. If sampling begins after the distribution phase, the concentration time points may fit a single-compartment, first-order model, which determines the elimination rate constant (β). The kinetics cannot be assumed, however, to fit a single-compartment model from such a limited study. The more clinically limited but accurate approach to kinetic analysis, noncompartmental analysis, makes no assumptions about the number of compartments (Rowland and Tozer, 2010).

ZERO-ORDER KINETICS

Some drugs demonstrate zero-order kinetics, in which a constant amount of drug, rather than a constant proportion or percentage, is removed per unit of time. This relationship can be expressed as:

$$\frac{dC}{dt} = -k$$

It is important to understand when zero-order kinetics occurs, how to recognize it, and how it affects drug concentrations. Zero-order kinetics is sometimes referred to as *saturation kinetics*, because it can occur when excess amounts of drug completely saturate enzymes or transport systems so that they metabolize or transport only a constant amount of drug over time. Zero-order processes produce a curvilinear shape in a semilogarithmic graph of concentrations versus time (Figure 34-3). When drug concentrations are high from a drug overdose or the pathway for elimination is impaired as in renal dysfunction, kinetics may become zero-order initially and be followed by first-order kinetics at lower concentrations. For drugs exhibiting zero-order kinetics, small increments in dose can cause disproportionately large increments in serum concentration. Certain drugs administered to newborns exhibit zero-order kinetics at therapeutic doses, and concentrations and must be recognized for their potential accumulation (Box 34-2).

BOX 34-2 Drugs That Demonstrate Saturation Kinetics With Therapeutic Doses in Newborns

- Caffeine
- Heparin
- Theophylline
- Furosemide
- Indomethacin
- Phenytoin

NONCOMPARTMENTAL ANALYSIS

Noncompartmental analysis is based on describing drug exposure measured by the AUC without any assumptions about the pattern of elimination or number of compartments. Central to this analysis is the determination of drug clearance from the dose and the AUC:

$$Cl = Dose / AUC$$

If the dose is administered intravenously, then noncompartmental analysis allows the direct determination of drug clearance using this relationship. Estimation of the elimination half-life is generally done using the slope of the log transformed concentration measurements made during the end of a pharmacokinetic study. With an estimation of clearance and elimination rate, the apparent distribution volume can also be estimated from:

$$Cl = V \times K$$

Thus noncompartmental pharmacokinetics provides a simple means to assess fundamental pharmacokinetic parameters, which may be useful for dosing patients when detailed knowledge of the complete pharmacokinetic profile is not needed.

POPULATION PHARMACOKINETICS

Most pharmacokinetic studies in newborns are limited by the amount of blood that can be removed safely for sampling. To determine the kinetics safely, population pharmacokinetic approaches are valuable, particularly because they can accommodate unbalanced study designs for drug sampling. The population approach describes the concentration-versus-time profile for all the patients enrolled in a given study simultaneously, estimating population parameters that describe the general pharmacokinetic profile of the complete study group and patient specific parameters that define the individual patients in the study. The population approach can use fewer samples taken from each patient, if the samples are taken at different specified times over the complete time profile of

interest for the study analysis. For example, one group of 28- to 32-week premature infants might have samples drawn at 1, 4, and 12 hours, whereas another group of 28- to 32-week premature infants might be sampled at 0.5, 2, and 8 hours. The concentrations from these two groups of similar patients are then analyzed in aggregate to provide information during both distribution and elimination phases, thus describing the kinetics with a limited volume of blood sampled from each patient.

Furthermore, the population approach allows for the investigation of patient covariates of interest that might explain differences seen within the population of patients enrolled in the trial. Typical covariates such as gestational age, gender, and disease conditions can also be assessed for their contribution to differences seen between subjects in a clinical study. These covariates can be helpful for gaining a better understanding of factors that may alter the pharmacokinetics of infants that might otherwise be considered similar.

TARGET DRUG CONCENTRATION STRATEGY

Drug treatment of newborns commonly uses the target drug concentration strategy (Box 34-3), in which drug therapy corrects a specific problem by producing an effective concentration of free drug at a specific site of action (Rowland and Tozer, 2010). The target site of drug action is usually inaccessible for monitoring concentrations. A specific concentration or range of circulating concentrations is correlated with the effective concentration at the site of action, which provides a "therapeutic" concentration range.

The requirements for effective and accurate application of the target drug concentration treatment strategy in adults have been discussed by Spector et al (1988). When applied to newborns, these requirements highlight the special problems of drug therapy in these patients and the special circumstances in which clinical drug concentration monitoring is appropriate. Some of these requirements are as follows:

- An available analytic procedure for accurate measurement of drug concentrations in small volumes of blood
- A wide variation in pharmacokinetics among individuals with the knowledge that population-based kinetics do not accurately predict individual kinetics
- Drug effects are proportional to plasma drug concentrations
- A narrow concentration range between efficacy and toxicity (narrow therapeutic index)
- Constant pharmacologic effect over time, in which tolerance does not develop
- Clinical studies that have determined the therapeutic and toxic drug concentration ranges

THERAPEUTIC DRUG MONITORING

Box 34-3 illustrates the basic assumptions of therapeutic drug monitoring—that total plasma drug concentrations correlate with dose, circulating unbound drug concentrations, unbound drug concentration at the site of action. Clinical measurements of drug concentrations usually include both bound and unbound drug, and the active portion is the portion that is unbound (see Distribution, earlier). The two broad indications for monitoring drug concentrations are attainment of effective concentrations and avoidance of toxic concentrations. As Kauffman (1981) has indicated, drug concentration ranges are not absolute reflections of effective therapy. Patient response, not a specific drug concentration range, is the endpoint of therapy.

BOX 34-3 Target Drug Concentration Strategy

Drug dose	↔	Plasma total drug concentration	↔	Plasma unbound drug concentration	↔	Target site unbound drug concentration	↔	Desired pharmacologic effect

Data from Shenier LB, Tozer TN: Clinical pharmacokinetics: the use of plasma concentrations of drugs. In Melmon KL, Morrelli HF, editors: *Clinical pharmacology: basic principles in therapeutics,* ed 2, New York, 1978, Macmillan, p 71.

Although concentrations of aminoglycoside antibiotics, such as gentamicin, are monitored frequently in newborns, toxicity is rare (McCracken, 1986). Because of the limited evidence of toxicity in newborns, it is more important to measure aminoglycoside concentrations to achieve effective concentrations for treatment of culture-proven infections than to avoid toxicity. In newborns with serious therapeutic problems, measurement of serum drug concentrations should be used to achieve effective concentrations and to avoid toxicity. When the desired concentration range and kinetic parameters are known, doses may be estimated to reach that concentration with single bolus doses or bolus doses followed by continuous infusions.

PHARMACOKINETIC-BASED DOSING

The following equations can be used both to guide dosing and to derive kinetic parameters for individual patients.

$$\text{Dose} = \Delta C \times Vd = (C_{desired} - C_{initial}) \times Vd$$
$$\text{mg/kg} = (\text{mg/L}) \times (\text{L/kg}) = (\text{mg/L}) \times (\text{L/kg})$$

where C = concentration, and Vd = volume of distribution.

This equation may be used to estimate dosage changes needed to increase or decrease concentration. For the first dose, the starting concentration is zero; afterward, the calculation of distribution volume should use the change (Δ) in concentration from the preceding trough to the peak associated with that dose. To reach a desired concentration rapidly, a loading dose can be administered followed by a sustaining infusion. The equation for calculation of infusion doses to maintain a constant concentration is shown:

$$\text{Infusion rate} = k \times Vd \times C$$
$$(\text{mg/kg}) \quad (\text{min}^{-1}) = \text{min}^{-1} \times (\text{L/kg}) \times (\text{mg/L})$$

where C = concentration, Vd = volume of distribution, and k = rate constant of elimination.

Steady state is reached when tissue concentrations are in equilibrium and the amount of drug removed equals the amount of drug infused. The time needed to reach a steady state depends on the elimination half-life. Whereas the time is not shortened by the administration of a loading dose, a loading dose can allow the patient to achieve

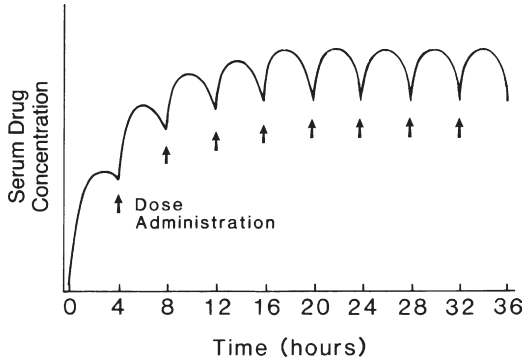

FIGURE 34-4 Representation of multiple dosing with accumulation of serum drug levels to steady-state concentration.

therapeutic concentrations rapidly that can be maintained with an infusion during steady state.

It is important to consider that if drug clearance decreases, the steady state concentration during an infusion will increase proportionally. In addition, the half-life increases and the rate constant decreases. Because concentrations are not measured for most of the drugs administered by continuous infusion in the neonatal intensive care unit (NICU), it is important to adjust dosages for factors that reduce clearance, such as kidney or liver dysfunction or reduced kidney or liver blood flow, to avoid high and toxic concentrations.

REPETITIVE DOSING AND THE "PLATEAU PRINCIPLE"

During the typical course of drug therapy, drug doses are administered before complete elimination of previous doses, and the drug accumulates in the body (Rowland and Tozer, 2010). During repeated administration, the peak and trough levels after each dose increase for a time. Steady-state, or plateau, concentrations are reached when the amount of drug eliminated equals the amount of drug administered during each dosing interval. During repetitive dosing, the steady-state concentrations achieved are related to the half-life, dose, and dosing interval relative to the half-life (Buxton, 2006; Rowland and Tozer, 2010). Figure 34-4 illustrates a hypothetical concentration-time curve for a drug with a half-life of 4 hours administered orally every 4 hours, so that the dosing interval corresponds to one half-life. Several important principles of pharmacokinetics are illustrated in this figure; the mathematics are described in detail elsewhere (Buxton, 2006). Drug concentrations rise and fall with drug administration (absorption) and elimination. For dosing intervals of one half-life, accumulation is 88% complete after the third dose, 94% complete after the fourth dose, and 97% complete after the fifth dose. At steady state, the peak and trough concentrations between doses are the same after each dose. If a drug is administered with a dosing interval equal to one half-life, the steady-state peak and trough concentrations are twofold those reached after the first dose. If the dosing interval is shortened to half of a half-life, the concentration decreases less before the next dose, more total drug is administered per day, and the steady-state peak and trough concentrations are considerably higher (3.4-fold the peak and trough concentrations after the first dose); therefore the shorter the dosing interval–to–half-life ratio, the higher the drug accumulation. As noted during infusions, the length of time required to reach steady-state concentrations depends primarily on the elimination half-life, not the dosing interval.

CLEARANCE

Clearance of drugs, as for creatinine, describes the volume of blood from which all the drug is removed per unit of time. Clearance is proportional to organ blood flow and the intrinsic capacity of organs to metabolize or remove drug from the circulation. In its simplest form, clearance is proportional to the flow to a single organ (Q) and to the arterial-venous difference in drug concentrations compared with the amount of drug in the arterial circulation, expressed as

$$CL = Q \times \frac{C_{arterial} - C_{venous}}{C_{arterial}}$$

Total body clearance usually reflects the combined clearance of multiple organs with different enzyme activities and different rates of blood flow. Clearance can be measured by the rate of appearance of drug outside the body (similar to urinary creatinine clearance) or by the rate of disappearance of drug from the circulation compared with the circulating concentration. For calculations, clearance (CL) is defined as the dose divided by the area under the plasmaconcentration versus AUC and by the rate of drug input per Css average, where rate of input is the dosing interval (τ) and Css is the steady-state concentration. For a drug administered by continuous infusion, this is simply the infusion rate (mg/kg)hr^{-1} divided by *Css* as follows:

$$CL = \frac{Dose}{AUC} = \frac{Dose/\tau}{Css} = \frac{Infusion\ rate}{Css}$$

Once clearance is known, this equation can be rearranged to solve for the dose necessary to achieve any desired steady state concentration:

$$Infusion\ rate = Css \times CL$$
$$(mg/kg)\,h^{-1} = (mg/L) \times (mL/kg)\,h^{-1}$$

Clearance changes significantly for some drugs during fetal and infant development because the activity of metabolic enzymes increases with advancing gestational and postnatal age. Values for clearance and volume of distribution at different stages of preterm development are available for a few drugs and can be used to estimate the doses needed to achieve and maintain therapeutic concentrations associated with desired clinical responses.

Studies of the analgesic fentanyl illustrate the developmental changes in its kinetics and how they can be used to calculate dosages to reach and maintain concentrations associated with effective analgesia. Analgesia has been associated with a serum fentanyl concentration of 1 to 2 ng/mL (Santeiro et al, 1997). If analgesic treatment is initiated with a continuous infusion of fentanyl, five half-lives are needed to reach a steady state. The fentanyl half-life ranges from 3 hours in term newborns to 12.7 hours in premature newborns (Koehntop et al, 1986; Santeiro et al, 1997). Because of this prolonged half-life, the patient may be inadequately

TABLE 34-1 Fentanyl Development Kinetics

Gestational Age (wk)	Clearance at 0-47 Hours after Birth (mL/[min·kg])
29	9.6
33	11.4
37	13.2
41	15.0

Data from Saarenmaa E, Neuvonen PJ, Fellman V: Gestational age and birth weight defects of plasma clearance of fentanyl in newborn infants, *J Pediatr* 136:767-770, 2000.

treated for a long time, unless a loading dose is administered to reach an effective concentration more rapidly. In general, the initiation of analgesic treatment and increases in infusion doses of analgesics should begin with a loading dose based on the estimated volume of distribution in the central compartment (circulation) and desired concentration. The use of a loading dose shortens the time to reach higher effective analgesic concentrations, but also increases the likelihood of toxicity, as has been reported with digoxin.

Limited data are available regarding the gestational age–related changes in fentanyl clearance, but two studies show that it increases with advancing gestational age (Koehntop et al, 1986; Santeiro et al, 1997) and with increasing age after birth (Gauntlett et al, 1988; Santeiro et al, 1997). The linear graph of clearance versus gestational age from 38 neonates who began treatment within 47 hours after birth was used to derive mean rates of clearance at different gestational ages, as shown in Table 34-1.

Other investigators studied single-dose fentanyl kinetics during anesthesia and found an apparent central volume of distribution of fentanyl in neonates of 1.45 L/kg (Koehntop et al, 1986). Note that this distribution volume is smaller than the steady-state volume of distribution of 5.1 L/kg, also calculated after a single dose of fentanyl (Koehntop et al, 1986). In turn, the apparent steady-state volume of distribution after a single bolus dose of a lipophilic drug is usually smaller than that associated with continuous drug infusions, during which tissues throughout the body become saturated with drug. The steady-state distribution volume for fentanyl during continuous infusions was calculated as 17 L/kg (Santeiro et al, 1997). It should be noted that because fentanyl is highly lipid soluble, it distributes rapidly from the central compartment into the peripheral tissue compartment. This large distribution volume likely reflects the period during the infusion when the drug is leaving the circulation to penetrate peripheral tissues, such as fat. Because it may take 15 to 60 hours to achieve a steady-state concentration (five half-lives) after a fentanyl infusion is begun or the infusion rate is increased, a patient may need repeated bolus doses to maintain effective plasma concentrations in the central compartment. The best approach is to repeat the calculated loading dose until the desired clinical effect is achieved. This also illustrates why, for sedation specifically, dosing should be adjusted to achieve the desired clinical effect. Clearance calculations, however, can guide the starting doses to achieve effective sedation, as illustrated later.

The kinetic parameters for fentanyl in premature infants reported by Koehntop et al (1986) can be used to calculate a loading and infusion dose to reach a fentanyl concentration of 2 ng/mL, which is considered an analgesic concentration (Saarenmaa et al, 2000). Fentanyl analgesic concentration is estimated for a premature newborn at a gestational age of 33 weeks (note that ng/mL is equivalent to μg/L) as follows:

$$C\ (\mu g/L) = \frac{\text{Loading dose}\ (\mu g/kg)}{Vd_{central}\ (L/kg)} \quad [1]$$

$$\begin{aligned}\text{Loading dose} &= 2\ \mu g/L \times 1.45\ L/kg \\ &= 2.9\ \mu g/kg\end{aligned} \quad [2]$$

$$\begin{aligned}\text{Infusion rate}\ (\mu g/kg \times h) &= C\ (\mu g/L) \times CL\ (mL/kg \times h) \\ &= 2\ \mu g/L \times 11.4\ mL/kg/min \times \\ &\quad 1\ L/1000\ mL \times 60\ min/h \\ &= 1.4\ \mu g/kg \times h\end{aligned} \quad [3]$$

Two studies have observed rises in fentanyl clearance with increasing postnatal age (Gauntlett et al, 1988; Santeiro et al, 1997). This postnatal rise in clearance of fentanyl likely relates either to maturation of cytochrome P450 3A4 (the enzyme responsible for fentanyl metabolism) activity or to increased hepatic blood flow after birth, because fentanyl has a high hepatic extraction rate. For drugs like fentanyl with a high hepatic extraction ratio, the rate-limiting factor in clearance is the flow of blood to the liver (Saarenmaa et al, 2000). Some researchers have observed that increased intraabdominal pressure reduces fentanyl clearance, which is likely caused by reduced hepatic blood flow (Gauntlett et al, 1988; Koehntop et al, 1986). Clinical changes known to increase or decrease fentanyl clearance should be used to adjust starting dosages, but dosing should be adjusted primarily for the desired clinical effect.

MODELING AND SIMULATIONS

Pharmacokinetic modeling and simulations can be used to evaluate the effects of important developmental changes and disease processes upon pharmacokinetic parameters for distribution volume, elimination rate, and clearance. These models can identify clinical situations and conditions when doses are likely to require modification. Mathematical simulations create theoretical pharmacokinetic profiles for patients after a dose using the range of pharmacokinetic parameters determined from a patient population. These can then be calculated for 100 to 1000 hypothetical patients to define the expected range of concentrations that are likely after a dose. For drugs, such as antiinfectives with which serum concentrations have been correlated with effectiveness, this provides estimates of how large a dose is needed to reach effective concentrations. A recent study of fluconazole kinetics in newborns illustrates the application of this process (Wade et al, 2008).

PHARMACOKINETIC PRACTICAL EXAMPLES

ESTIMATED DOSE ADJUSTMENTS

Gentamicin and phenobarbital can be used to illustrate the practical application of the principles of pharmacokinetics and therapeutic drug monitoring already discussed.

The calculations can be performed with standard arithmetic calculators and provide close enough estimates of the kinetics for drugs with a long half-life to adjust dosages at the bedside.

GENTAMICIN

Assume that optimal gentamicin concentrations are

$$\text{Peak} = 6 \text{ to } 10 \text{ } \mu\text{g/mL}$$
$$\text{Trough} = 0.5 \text{ to } 2 \text{ } \mu\text{g/mL}$$

After the fourth dose (2.5 mg/kg) of gentamicin to an edematous premature newborn, the peak concentration was 5.0 μg/mL; 18 hours later, the trough was 2.5 μg/mL. It appears that the distribution volume is greater than anticipated, because the peak concentration is lower than expected, and the half-life is longer than anticipated because the trough is higher than expected. The time of drug administration and blood sampling were confirmed (an important step), so the half-life is 18 hours, because the concentration decreases 50% from 5.0 to 2.5 μg/mL in 18 hours, assuming that the kinetics are linear and first-order.

$$\text{Vd (mL/kg)} = \frac{\text{Dose (mg/kg)}}{\Delta \text{C } (\mu\text{g/mL}) \times 1 \text{ mg/1000 } \mu\text{g}}$$
$$= \frac{2.5 \text{ mg/kg} \times 1000 \text{ } \mu\text{g/mg}}{(5.0 - 2.5) \text{ } (\mu\text{g/mL})}$$
$$= 1000 \text{ mL/kg}$$

To ensure a trough concentration of 2.0 μg/mL or less, doses are administered every two half-lives or every 36 hours. When two half-lives have passed after the fourth dose, the gentamicin concentration should be approximately 1.25 μg/mL (50% of 2.5 μg/mL). Increasing the concentration from the 1.25 μg/mL (trough) to greater than 6 μg/mL (peak) requires a concentration difference of 4.75 μg/mL or greater. With a distribution volume of 1000 mL/kg, a dose of 4.75 mg/kg should raise the concentration from a trough of 1.25 μg/mL to a peak of 6.00 μg/mL. In one half-life, this concentration will decrease to 3.0 μg/mL, and in two half-lives or 36 hours to 1.5 μg/mL. An additional 4.75-mg/kg dose will raise the peak concentration to 6.25 μg/mL, which will fall to 3.12 μg/mL in one half-life and to 1.6 μg/mL in two half-lives. The variation between the peak and trough concentrations after the last dose is within the measurement error for gentamicin and should achieve the optimum concentrations defined previously.

PHENOBARBITAL

Seizures that were difficult to control developed in a 3.6-kg asphyxiated newborn. Seizures continued after two 20-mg/kg phenobarbital doses until an additional 10-mg/kg dose was administered. A maintenance dose of 7 mg/kg per day was started 24 hours after the loading doses were administered. At 10 days, the child was increasingly somnolent. The phenobarbital level measured in a blood specimen taken 2 hours after administration of the oral maintenance dose was 50 μg/mL. Additional doses were withheld, and the phenobarbital concentration was checked daily. The results were as follows:

- 24 hours: 40 μg/mL
- 48 hours: 31 μg/mL
- 72 hours: 25 μg/mL
- 96 hours: 21 μg/mL

The maintenance dose (7 mg/kg) was resumed immediately after the 21 μg/mL concentration was measured and produced a peak concentration of 30 μg/mL after administration of the dose. These concentrations and doses can be used to calculate the volume of distribution and a dose to maintain the phenobarbital concentration between 20 and 30 μg/mL as follows:

$$\text{Vd (L/kg)} = \frac{\text{Dose (mg/kg)}}{\Delta \text{C } (\mu\text{g/mL} = \text{mg/L})}$$
$$= \frac{7.0 \text{ (mg/kg)}}{(30 - 21) \text{ (mg/L)}}$$
$$= \frac{7 \text{ mg/kg}}{9 \text{ mg/L}}$$
$$= 0.78 \text{ L/kg}$$

Half-life can be determined from inspection, because the concentration decreased from 50 to 25 μg/mL in 72 hours; therefore it should take 72 hours for the concentration to decrease by one half-life from 30 to 15 μg/mL. The concentration will decrease approximately 5 μg/mL every 24 hours, or one third of a half-life. Dividing the half-life into fractions is an approximation because it estimates the change in concentration as linear rather than exponential. To be more accurate, the concentration decreases 59% in half of one half-life. Although this approximation violates certain principles of pharmacokinetics, it allows estimation of the change in concentration for each one third of a half-life as one third of the change during one half-life. Therefore the concentration decreases approximately 5 μg/mL in 24 hours. The following approach can be used to estimate the daily phenobarbital dose needed to return the concentration to 30 μg/mL, a change in concentration of 5 μg/mL:

$$\Delta \text{C (mg/L)} = \frac{\text{Dose (mg/kg)}}{\text{Vd (L/kg)}}$$
$$5 \text{ mg/L} = \frac{\text{Dose (mg/kg)}}{0.78 \text{ L/kg}}$$
$$3.6 \text{ mg/kg} = \text{Dose (mg/kg)}$$

DRUG-INDUCED ILLNESS

The extensive exposure of newborns to drugs in the NICU is not benign. Neonates in the NICU have higher rates of medication errors and potential adverse error rates (91 in 100 admissions) than do neonates in other areas of the hospital, and physician orders are responsible for 74% of errors and 79% of potential errors (Kaushal et al, 2001). Physician reviewers judged more than 90% of these errors to be preventable, and 16% were potentially life-threatening or fatal (e.g., heparin and digoxin overdoses).

Similar problems have been observed worldwide (Kunac et al, 2009). The causes of this drug-related morbidity and mortality are complex. Pharmacologic studies in pediatric patients are difficult because of a variety of problems ranging from ethics to study design (Ward and Green, 1988). The difficulty of studying therapeutics in the newborn has created a situation in which a plethora of drugs is administered with a paucity of pharmacologic data. For the smaller and more immature newborns who are now surviving, gestational age–appropriate pharmacologic data for efficacy, dose-response, and kinetics for most drugs remain limited and need further study (Ward and Kern, 2009).

Furthermore, drug-induced illness is seldom considered in newborns. Failure to recognize drug-induced illness in the newborn often leads to further pharmacologic treatment as the first approach to correct unrecognized drug-induced problems. This fact may reflect an expectation that drug therapy is usually effective and safe. Prudent management of newborns must recognize and weigh the potential benefits of unstudied drug therapy against potential drug-induced adverse effects, morbidity, and mortality. Some examples from the history of drug-induced mortality and morbidity in newborns should serve as a reminder of how more harm than good may accrue from uncontrolled or unstudied drug therapy in the NICU.

LESSONS FROM CHLORAMPHENICOL

Chloramphenicol was released for use in the 1940s, and reports of its efficacy for treatment of *Salmonella* spp. infections included pediatric patients. The manufacturer recommended doses of 50 to 100 mg/kg per day for patients weighing 15 kg or less. When Sutherland (1959) reported three cases of sudden death in newborns treated with high doses of chloramphenicol (up to 230 mg/kg per day), the drug was considered "well tolerated and nontoxic." Later the same year, Burns et al (1959) reported the disturbing results of a controlled trial of the following four prophylactic treatment regimens for newborn sepsis: (1) no treatment, (2) chloramphenicol alone, (3) penicillin and streptomycin, and (4) penicillin, streptomycin, and chloramphenicol. The groups that received chloramphenicol (100 to 165 mg/kg per day), in regimens 2 and 4, had overall mortality rates of 60% and 68%, respectively, whereas groups receiving regimens 1 and 3 had mortality rates of 19% and 18%, respectively. The deaths of these newborns demonstrated the stereotyped sequence of symptoms and signs caused by chloramphenicol, designated the *gray syndrome*, which consisted of abdominal distention with or without emesis, poor peripheral perfusion and cyanosis, vasomotor collapse, irregular respirations, and death within hours of the onset of these symptoms. Weiss et al (1960) attributed the gray syndrome in newborns to high concentrations of chloramphenicol secondary to its prolonged half-life in newborns who received dosages of more than 100 mg/kg per day, which are usually used in older children. They recommended maximum doses of 50 mg/kg per day in term infants younger than 1 month, half that dose for premature infants, and careful monitoring of chloramphenicol blood concentrations.

The discovery and explanation of chloramphenicol toxicity in newborns illustrate several important aspects of neonatal pharmacology. Because chloramphenicol was considered well tolerated in older children and adults, it was regarded as nontoxic for newborns. Chloramphenicol was so effective in newborns that higher doses were used without pharmacokinetic study. Higher doses were administered to newborns despite recognition that its clearance required glucuronide conjugation, which was known to be immature in newborns. The unexpected finding that chloramphenicol in doses of 100 to 165 mg/kg per day could be lethal to newborns was demonstrated because the study conducted by Burns et al (1959) included appropriate control groups. Because the mortality rate from the most effective antibiotic treatment regimen was equivalent to that of no antibiotic treatment, these investigators discontinued prophylactic use of antibiotics in the nursery.

Similar pharmacologic comparisons are needed for other drugs used in newborns. Additional thoughtful consideration should be given to clinicians' response to therapeutic failure. Fewer drugs and lower doses may be safer and more effective than additional drugs in higher dosages.

REDUCTION AND PREVENTION OF MEDICATION ERRORS IN NEWBORN CARE

Drug treatment is one of the most common approaches used in the care of sick newborns. At Primary Children's Medical Center 35-bed NICU in Salt Lake City, Utah, with an average of 785 patient-days per month, patients receive an average of 8700 (range 6990 to 11,290) doses of medications, pharmacy-formulated intravenous solutions, and aerosols each month (unpublished observations, 1994). These doses are usually prepared by pharmacists and administered by nurses, respiratory therapists, and (rarely) physicians. In such a large and complex system that produces so many drug treatments per month, errors are virtually inevitable despite several levels of prospective and redundant reviews by nurses, pharmacists, and NICU unit secretaries involved in the drug treatment process. At Primary Children's NICU, the medication error rate averages 0.04% for nurses and pharmacists and 0.07% for physicians (unpublished observations, 1994). Many errors are inconsequential, whereas others have serious adverse effects. Medication errors incur significant costs, ranging from the obvious ones such as direct patient injury, prolonged hospital stays, and additional corrective treatments to the more subtle costs associated with monitoring and regulation of medication use within hospitals (ASHP, 1995).

In a study of 393 malpractice claims reported to the Physician Insurers Association of America, the second-most common cause of malpractice claims was drug errors (Physician Insurers Association of America, 1993). Among 16 medical specialties with two or more claims, pediatric practice ranked sixth in the number of claims, yet it had the third highest average cost per indemnity. The medications most frequently involved in all claims were antibiotics, glucocorticoids, narcotic or non-narcotic analgesics, and narcotic antagonists. In pediatric practice, the medications most frequently involved were vaccines (diphtheria-pertussis-tetanus) and bronchodilators (theophylline). In the Physician Insurers Association of America review

(Physician Insurers Association of America, 1993), the five most common causes of drug errors were as follows:

- Incorrect doses
- Medications that were inappropriate for the medical condition
- Failure to monitor for drug side effects
- Failure of communication between physician and patient
- Failure to monitor drug levels

The primary opportunity for prevention of these five most common errors rests with the prescribing physician. Additional information and time for communication and documentation may be needed.

Prescriptions and drug orders are a means of communicating, but clinicians often devote too little attention to making them legible, clear, and unambiguous (ASHP guidelines on preventing medication errors in hospitals, 1993). Physicians should keep the following recommendations in mind to ensure that their medication orders communicate more effectively:

- Write instructions in full rather than with abbreviations.
- Avoid vague instructions (e.g., "take as directed").
- Specify exact dose strengths.
- Avoid abbreviations of drug names (e.g., *MS* could mean morphine sulfate or magnesium sulfate).
- Avoid *U* as an abbreviation for units, because the *U* may be mistaken for a 0 (zero).
- Avoid trailing zeroes (e.g., 5.0 mg).
- Use leading zeroes (e.g., 0.5 mg).
- Minimize the use of verbal orders.
- Ensure that prescriptions and signatures are legible, even if it means printing the name that corresponds to the signature.

The process for ordering, preparing, dispensing, and administering medications in an ICU with acutely ill patients is often complicated and may contribute directly to errors. The frequency of those errors, however, may be reduced in almost every NICU. Although complex and expensive computerized systems may help reduce medication errors, caregivers can take steps that are completely within their control to reduce medication errors without waiting for changes in the entire pharmacy process within the hospital (ASHP guidelines on preventing medication errors in hospitals, 1993).

DRUG EXCRETION IN BREAST MILK

The excretion of drugs in breast milk remains a source of confusion and concern for many physicians and families. Newer analytic techniques and more thorough pharmacokinetic studies have improved the available data in this area of neonatal pharmacology. The available data regarding drug exposure of the newborn through human milk have been organized, in decreasing levels of concern, from drugs that are associated with adverse effects on the infant during nursing to those that are of concern pharmacologically to those that have not been associated with problems during nursing. The list of drugs clearly contraindicated during nursing is surprisingly short (American Academy of Pediatrics, Committee on Drugs, 2001). On average, the breastfeeding infant receives approximately 2% to 3% of a maternal dose through milk. Drugs that are organic bases or are lipid soluble may reach higher concentrations in milk than in maternal serum.

SUMMARY

The extensive drug exposure of the sick newborn in the NICU is dangerous because of the frequency of adverse, sometimes fatal, drug reactions. Unfortunately, in the rapidly changing fetus and newborn, drug therapy is often empiric because of a lack of gestational age–appropriate kinetic data. Methods appropriate for the study of therapeutics in newborns present unique difficulties, but a review by Ward and Green (1988) may provide assistance for investigators. Drug therapy of newborns requires practical application of the principles of pharmacokinetics and pharmacodynamics—which describe the processes of drug absorption, distribution, metabolism, and excretion—to the estimation and individualization of dosages.

CHAPTER 35

Neonatal Pain and Stress: Assessment and Management

Dennis E. Mayock and Christine A. Gleason

Relief of human suffering is one of the most important goals of all health care providers. Advances in neonatology have significantly improved neonatal morbidity and mortality, but pain, discomfort, and stress remain sad realities for babies in the neonatal intensive care unit (NICU). Assessing, managing, and trying to limit these clinical realities, particularly while caring for critically ill neonates, are challenging and increasingly controversial. Fortunately there has been considerable clinical and laboratory research and much clinical dialogue aimed at developing the best clinical practices in this problematic arena. This chapter describes the developmental biology, history, and public policies that have informed and shaped current clinical practices; it also summarizes relevant clinical and basic research regarding clinical assessment tools and both pharmacologic and nonpharmacologic management approaches. Finally, future directions in this field are discussed.

HISTORY AND DEVELOPMENT OF PUBLIC POLICIES

HISTORICAL TIMELINE: NEONATAL PAIN MANAGEMENT

Like all challenging medical issues, it is important to know the history and current practice of neonatal pain management to understand what direction research should take in the future. Management of neonatal pain and stress serves as an excellent example of this philosophy; therefore a brief history of neonatal pain management follows, beginning with the isolation of morphine from the opium poppy, which has been used to treat pain since approximately 3500 BC.

- 1806: Morphine (named for Morpheus, god of dreams) isolated from opium poppy by Friedrich Serturner (a pharmacist) and used to treat pain
- 1960s to 1980s: Infants believed to be too immature to feel pain; adverse effects of anesthetics feared; Liverpool method (pancuronium only, no anesthesia) used widely for patent ductus arteriosus (PDA) ligation in premature infants
- 1985: Landmark paper published by Anand et al (1985) describing adverse physiologic effects of Liverpool method and improved outcomes using anesthesia for PDA ligation; anesthesia and postoperative pain medication begin to become more widely used in neonatal care
- 1987: Joint statement issued by the American Academy of Pediatrics (AAP) and American Society of Anesthesiologists (ASA) regarding safety of (and necessity for) operative anesthesia and postoperative analgesia for neonates, regardless of their age or maturity
- 1990s: Use of morphine infusions in the NICU expands from operative and postoperative pain relief to include preemptive sedation, particularly during mechanical ventilation
- 1999: Pilot study (NOPAIN) suggesting that neurologic outcome is improved if preemptive morphine infusions are used in a neonate receiving mechanical ventilation 2000: AAP and Canadian Pediatric Society issue joint statement regarding neonatal pain management; primarily directed at surgical anesthesia and postoperative and procedural pain assessment and relief (American Academy of Pediatrics Committees on Fetus and Newborn and on Drugs, Sections on Anesthesiology and on Surgery et al, 2000)
- 2001: International evidence-based group develops consensus guidelines for prevention and management of neonatal pain, most of which are pharmacologically based
- 2003: The Joint Commission issues mandate regarding pain assessment and management in all hospitalized patients, including neonates
- 2004: Cochrane Review (Stevens et al, 2004) supports use of oral sucrose for procedural analgesia
- 2004: NEOPAIN trial results published *(Neurologic Outcomes and Pre-emptive Analgesia in Neonates)*, concluding that preemptive morphine infusion did not improve outcomes in neonates receiving ventilation and did not relieve procedural pain
- 2005: Cochrane Review (Bellù et al, 2005) states "There is insufficient evidence to recommend routine use of opioids in mechanically-ventilated newborns."
- 2005: Lee et al (2005) conclude that "fetal perception of pain is unlikely before the 3rd trimester" and "little or no evidence addresses the effectiveness of direct fetal anesthetic or analgesic techniques."
- 2006: Cochrane Review (Shah et al, 2006) recommends breastfeeding or oral breast milk for neonatal procedural pain
- 2009: More than 40 infant pain assessment tools available around the world; most were developed for research and have not been validated for clinical use
- 2009: First national practice guidelines developed in Italy for procedural pain management for NICU patients

DEVELOPMENT OF PUBLIC POLICY

Since the late 1980s, in response to a public outcry regarding the recognition and management of pain in hospitalized patients, mandates have been promulgated by the U.S. Department of Health and Human Services, The Joint Commission, and other professional organizations. The initial public policy statement regarding pain management for neonates undergoing surgical interventions was issued as a joint communication by the AAP and the ASA

(American Academy of Pediatrics Committees on Fetus and Newborn and on Drugs, Sections on Anesthesiology and on Surgery, 1987; American Society of Anesthesiologists, 1987). This statement made it clear that anesthesia and analgesia could be given relatively safely to neonates despite their age or cortical immaturity. A second influential document was issued by the Acute Pain Management Guideline Panel of the U.S. Agency for Health Care Policy and Research (Acute Pain Management Guideline Panel, 1992; Agency for Health Care Policy and Research Pain Management Guideline Panel, 1992). This statement unequivocally endorsed the need for pain management in neonates. The result of the publication of these two documents was the initiation of research studies into the prevention and amelioration of neonatal pain.

The most influential of these documents came from The Joint Commission. The 2003 accreditation standards required health care providers to look across the continuum of life, including the neonatal period, at the complex nature of the pain experience so as to create new foundations for care (Joint Commission International Accreditation Standards for the Care Continuum, 2003). However, these guidelines do not provide specific instructions for assessing or managing pain in neonates. Neonatal caregivers needed to assess and treat perceived neonatal pain and discomfort, but had little research-based evidence on which to base their assessment and therapy. Organizations have commissioned interdisciplinary teams to incorporate regulatory directives and results of scientific investigation into institutional practice guidelines and standards for care (Anand, 2001; Howard et al, 2008a, 2008b; Lago et al, 2009). These guidelines include a patient's right to regular and systematic assessments of pain, interventions to relieve pain, evaluation of effectiveness of interventions, attention to long-term pain management needs, deleterious effects of unmanaged pain, and educational needs of families and staff members who provide care (American Pain Society, 2006; Bell, 1994; Carrier and Walden, 2001; Howard et al, 2008a, 2008b; Joint Commission on Accreditation of Healthcare Organizations, 2004; Lago et al, 2009).

As a result of these public policy initiatives and regulations, new tools for pain assessment and innovative methods to treat pain have been developed and evaluated. However, many old questions remain unanswered and new concerns have been raised. Neonates can suffer both acute and chronic pain. Treatment protocols for acute pain may not be appropriate for chronic pain, because the origin and resultant physiologic status can be quite different. Long-term use of narcotics and other drugs leads to drug tolerance and the need to wean slowly to avoid drug withdrawal. The drugs themselves, as well as drug tolerance and drug withdrawal, may all contribute to adverse effects on brain development and neurodevelopmental outcomes.

RECENT SURVEYS OF CLINICAL PRACTICE

Surveys of clinical practice have shown that attention to neonatal pain management has improved over the last decade, but they also demonstrate that much more needs to be done. This concern is evidenced by three recent surveys from NICUs. Prestes et al (2005) surveyed four Brazilian units in October 2001 prospectively. They found that, of 91 neonates admitted to the NICU, there was documentation of systemic analgesia in only 25% of 1025 patient days. No specific drug was administered during arterial, venous, and capillary sticks, lumbar punctures, or intubation. Only 9 of 17 surgical patients received any postoperative analgesia (Prestes et al, 2005). Taylor et al (2006) surveyed 10 NICUs in North America to determine their use of postoperative analgesia. Data were collected for 25 consecutive postoperative admissions. Nurses documented pain assessments for 88% of the infants, whereas physicians documented pain assessments for only 9%. The study concluded that "documentation of postoperative pain assessment and management in neonates was extremely variable" and called for development of evidence-based guidelines for postoperative care and education of professional staff. Carbajal et al (2008) prospectively studied 430 infants admitted to tertiary NICUs in Paris between September 2005 and January 2006. Each neonate averaged 115 total procedures (75 of which were considered to be painful) and 16 procedures per day (10 of which were considered to be painful). Of a total of 42,413 painful procedures, 2.1% were performed with pharmacologic therapy; 18.2% with nonpharmacologic therapy; 20.8% with pharmacologic, nonpharmacologic, or both; and 79.2% without specific analgesia. All three of these recent survey studies found that despite current knowledge of pain assessment and treatment methods, most infants still are not provided any specific treatment to alleviate pain and discomfort

ONTOGENY AND DEVELOPMENT OF PAIN AND STRESS RESPONSES

The sensory system of the neonate, especially the preterm infant, is immature (Figure 35-1). Afferent input from both noxious and non-noxious stimuli terminate in the dorsal horn of the spinal cord in a diffuse manner on multiple cells; this results in the inability to distinguish between noxious and non-noxious stimuli and limits the care provider's ability to correctly interpret the infants' behavioral response. In the neonatal rat, separation of sensory input is not completed until 3 to 4 weeks after birth (approximately 1 to 2 years in humans; Beggs et al, 2002); this prevents the newborn from differentiating touch from painful sensory input. The responses of the infant are therefore nonspecific. With repeated painful exposures, infants may lose any discriminatory ability and develop hypersensitive states for long periods of time. This hypersensitivity persists even if non-noxious stimuli are introduced (Evans, 2001; Jennings and Fitzgerald, 1998). The responses are less synchronized in the immature central nervous system are also noted in the immature central nervous system because of underdeveloped myelination and slower synaptic transmission as manifested in longer and more variable latencies (Fitzgerald, 2005; Jennings and Fitzgerald, 1998).

Neuronal connections within the cortex appear to form at approximately 22 weeks' gestation (Kostovic and Jovanov-Milosevic, 2006), suggesting that higher cortical level pain processing may be limited despite the presence of a behavioral response (Fitzgerald and Walker, 2009). In addition, the neonate lacks sufficient descending modulatory control, thereby limiting their ability to benefit from endogenous control over noxious stimuli compared with adults (Fitzgerald and Koltzenburg, 1986; Hathway et al, 2006).

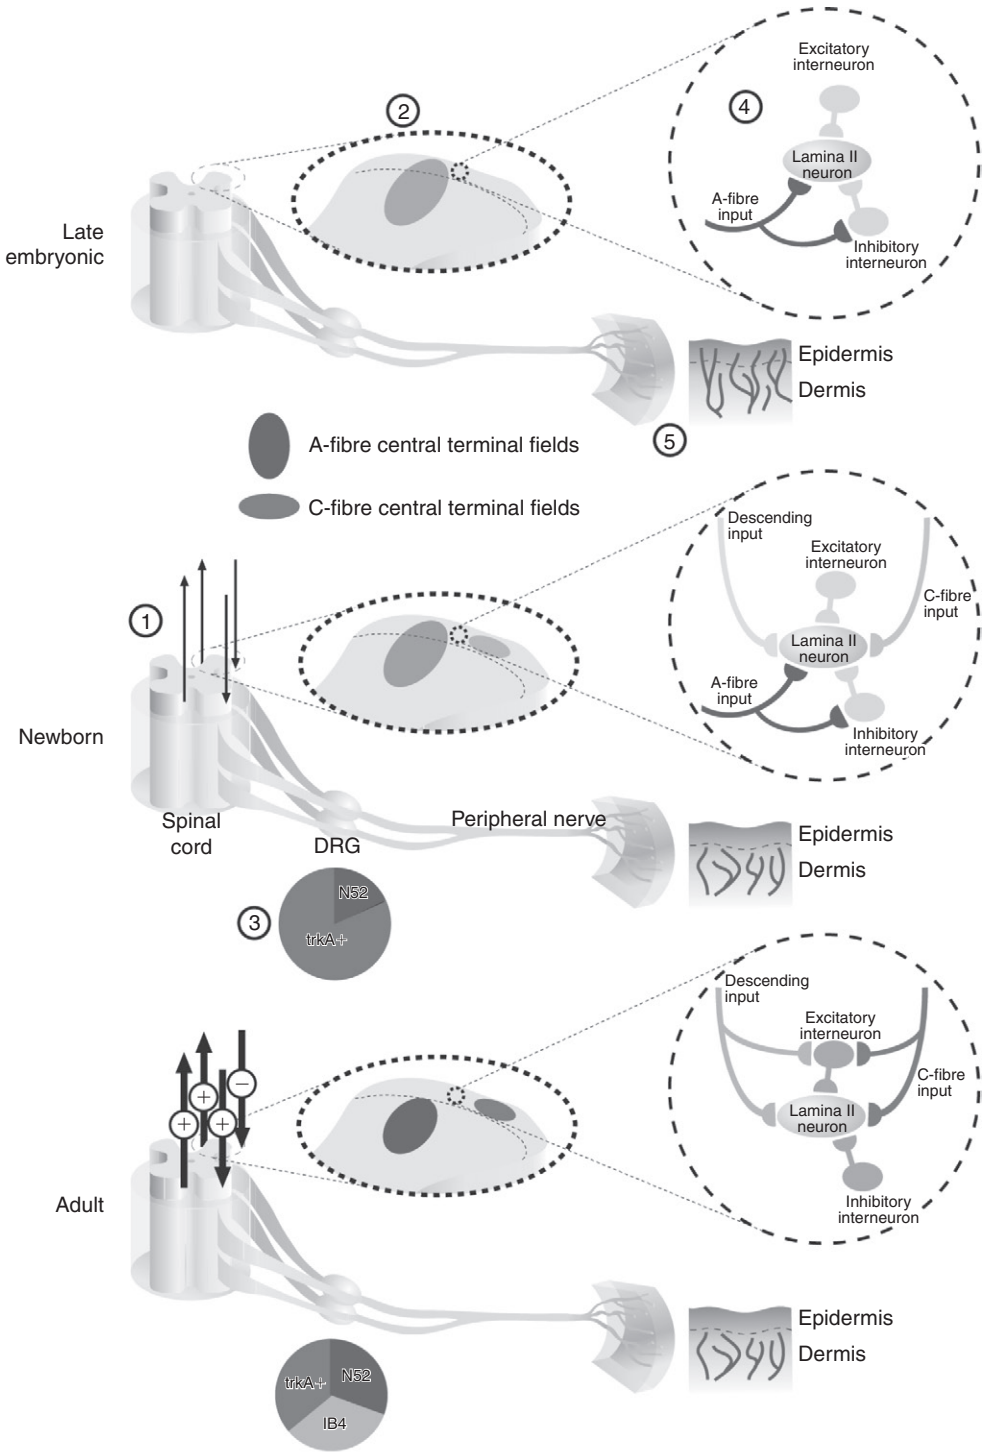

FIGURE 35-1 *1*, In early postnatal life, descending fibres are present, but inhibitory and excitatory influences are weak or absent. The connections gradually strengthen, becoming fully functional at the end of the third postnatal week. *2*, A-fibres are the first primary afferents to enter the dorsal horn gray matter and are present during the last few embryonic days. Their distribution is diffuse with exuberant, more superficial projections gradually retracting over the first 3 postnatal weeks. C-fibres are present in the dorsal horn during late embryonic stages, but only enter the gray matter 2 to 3 days before birth. Unlike A-fibres, they project to topographically appropriate regions in lamina II of the spinal cord as soon as they enter. C-fibre synaptic connectivity is present, although weak at the time of birth, with connections strengthening over the first 2 postnatal weeks. *3*, At birth the majority (approximately 80%) of dorsal root ganglion (DRG) neurons express the nerve growth factor (NGF) receptor trkA. Over the first postnatal week, this population reduces, with approximately half of these neurons losing their trkA expression and beginning to express receptors for glial cell line-derived neurotrophic factor (GDNF) (identifiable as the IB4-binding population). *4*, The balance of excitation and inhibition in the superficial dorsal horn develops postnatally, through changes in both local interneuron circuitry and descending fibres. A-fibre input is stronger in the neonate and weakens as the influence of C-fibre input increases. *5*, Primary afferent innervations of the skin occurs earlier than central projections. By late embryonic stages, primary afferents of all classes have reached the skin and innervate through the dermis into the epidermis. These projections die back during the immediate perinatal period to leave the full adult situation of dermal innervations present soon after birth. *(From Beggs S, Fitzgerald M: Development of peripheral and spinal nociceptive systems. In Anand KJ, Stevens BJ, McGrath PJ, editors:* Pain in neonates and infants, *ed 3, Philadelphia, 2007, Elsevier, p 15.)*

Noxious stimuli in adults result in the release of inflammatory and trophic factors that activate and sensitize nociceptors in the injured tissue. Such noxious stimuli lead to nociceptive afferent input to the central nervous system, exciting nociceptive circuits in the spinal cord, brainstem, thalamus, somatosensory cortex, cingulate cortex, and amygdale (Tracey and Mantyh, 2007; Woolf and Ma, 2007). However, noxious stimuli in infants do not evoke similar patterns of central nervous system activity as noted in adults (Fitzgerald, 2005). The response to noxious stimuli is more diffuse and less spatially focused in infants. Studies in rats have demonstrated major alterations in neuronal circuitry with maturation, appearing to mirror that seen in humans but in a compressed time period. These animal data may parallel developmental changes that have been noted in humans (Fitzgerald, 2005). Local tissue injury resulting from repeated heel sticks and invasive procedures triggers increased proliferation of nerve endings in surrounding tissues, particularly when this damage occurs early in gestation. As a result, scars (e.g., from heel sticks, old intravenous sites) and surrounding tissues can remain hypersensitive well beyond the neonatal period (Jennings and Fitzgerald, 1998; Reynolds and Fitzgerald, 1995). Pain assessment and management are thus most challenging in preterm infants who are exposed to the stressful NICU environment for long periods (Johnston and Stevens, 1996).

In summary, the immature nervous system in preterm infants lacks the ability to discriminate consistently between noxious and non-noxious stimuli, reacts often with similar behavior to a variety of stimuli, lacks the ability to modulate pain responses, and does not consistently manifest signs or symptoms that allow care providers to accurately assess the infant's level of pain and discomfort. Furthermore, infants cannot verbally report their level of pain. This later challenge remains a significant obstacle to accurate assessment of pain in the newborn and determination appropriate treatment.

ASSESSMENT OF NEONATAL PAIN AND STRESS

DEVELOPMENT OF BEHAVIORAL RESPONSES TO PAIN

Tools for assessment of neonatal pain and stress must be based on an understanding of the normal development of behavioral responses to pain and stress—an infant is not a small adult. Behavioral responses to noxious stimuli in infants are not always predictable because of immaturity of the central nervous system; therefore assessment of pain and response to therapeutic intervention can be similarly unpredictable. Significant structural and functional changes occur in pain pathways during development, many of which continue to take place after birth (see later discussion of ontogeny and development of pain and stress responses). When assessing pain and discomfort in infants, especially those born prematurely, it is important to remember that the patients are nonverbal and cannot say where and how badly they hurt. Indeed, even if they could verbalize such information, their ability to accurately localize and describe the pain would be limited as discrimination between inputs (tactile or nociceptive) is immature. Moreover, their behavioral response repertoire is also limited and is not always predictable. These limitations make the use of assessment tools problematic, especially when trying to determine whether there has been a response to a drug or other intervention.

INFANT PAIN SCORES

Over the past two decades, more than 40 infant pain scales have been developed (Ranger et al, 2007). Most of these scales were developed for use in clinical trials to assess efficacy of various pharmacologic therapies and have not been validated for general clinical use. However, the use of these scales in clinical practice has led to better health care provider recognition that procedural pain and stress are common. Moreover, it is assumed that this pain and distress can be ameliorated by appropriate use of pharmacologic and nonpharmacologic approaches. However, assessment and treatment of chronic pain and discomfort in infants remains problematic. The pain instruments developed for assessment of acute pain were not designed or validated for the chronic pain and discomfort associated with mechanical ventilatory support, or for use in paralyzed or neurologically compromised infants (Anand, 1998). Furthermore, painful stimuli may be processed at the cortical level in infants without producing detectable behavioral changes (Slater et al, 2008). Therefore the clinician is left to decide whether the touted benefits of opiate sedation during mechanical ventilation in newborns outweigh the possible adverse effects, both acute and long term. The importance of selecting a valid, reliable, and practical pain assessment tool is evident from the current literature. These tools assess the response to noxious stimuli by categorizing the behavioral or physiologic reactions of the infant, or a combination of both (Grunau and Craig, 1987). The behavioral responses can include limb movements, muscle tone, crying, and characteristic facial expressions. The physiologic measures can include heart rate, oxygen saturation, and respiratory rate. Of note, specific facial expression changes have been determined to be the most reliable indicators of pain (brow bulge, eye squeeze, nasolabial furrow, taut lips, and open mouth) whereas crying is the least reliable indicator (Grunau and Craig, 1987; Guinsburg et al, 1997; Stevens et al, 1993). Use of facial expression changes can be challenging when the infant's face is partially covered with adhesives to secure tubes and lines, or with a phototherapy mask in place.

A recent publication lists the current available pain assessment tools that can be used in neonates (Stevens et al, 2007). The most commonly used tools are listed in Table 35-1.

Many pain assessment tools are available; however, they have not been systematically reviewed, and there is no specific gold standard for comparison. Because each instrument requires training and practice for optimal use, care providers should choose one that best fits the infant population being assessed to allow for consistency. The optimal approach to pain management should include reducing the frequency of painful procedures, reducing environmental stressors, facilitating neurologic developmental, determining the best technique to minimize the pain and stress

TABLE 35-1 Infant Pain Scales

Measure	Age Level	Indicators	Pain Type	Psychometric Properties
Unidimensional Behavioral Measures of Infant Pain				
Baby facial action coding system (Rosenstein and Oster, 1988)	Term infants	Facial actions based on adaptation from adult work	Procedural	Interrater reliability (r = 0.65-0.85)
Infant body coding system (Craig et al, 1993)	Preterm infants (32 wk GA) to term infants	Movement of hand, foot, arm, leg, head, torso	Procedural	Interrater reliability (r = 0.83), face validity, content validity
Neonatal facial coding system (Grunau and Craig, 1987)	Preterm infants (>25 wk GA) to term infants	Brow bulge, eye squeeze, nasolabial furrow, open lips, horizontal mouth, vertical mouth, lips pursed, taut tongue, chin quiver, tongue protrusion	Procedural	Interrater reliability (r = 0.88), content validity, face validity, construct validity, convergent validity, feasibility
Multidimensional Pain Measures in Infants				
Children's and infants' postoperative pain scale (Büttner and Finke, 2000)	Birth to 4 years	Crying, facial expression, posture of the trunk, posture of the legs, motor restlessness	Prolonged (postoperative)	Interrater reliability (<3 yr old subsample; r = 0.64-0.77), internal consistency (<1 yr old subsample; r = 0.96), content validity, construct and concurrent validity demonstrated in older subsample
Modified behavioral pain scale (Taddio et al, 1995a)	2-6 months	Facial expression, cry, body movement	Procedural	Interrater reliability (ICC = 0.95), internal consistency (r = 0.55-0.66), test-rest reliability (r = 0.95), content validity, construct validity (p <0.01), concurrent validity (r = 0.68-0.74)
Composite Pain Measures in Infants				
Clinical scoring system (Barrieret al, 1989)	1-7 months	Infant sleep during the preceding hour, facial expression, cry, motor activity, excitability, flexion, sucking, tone, consolability	Prolonged (postoperative)	Interrater reliability (r = 0.79-0.88), content validity, discriminant validity (p <0.0001)
Modified postoperative comfort score (Guinsburg et al, 1998)	<32 wk GA (postnatal age of 12-48 h)	Sleep, facial expression, sucking, hyperreactivity, agitation, hypertonicity, toe or finger flexion, consolability	Prolonged (mechanical ventilation)	Convergent validity in bedside (p <0.0001) and laboratory video coding (p = 0.02), content validity, divergent validity shown between placebo and analgesic samples (p <0.05)
Echelle Douleur Inconfort Nouveau-né (Debillon et al, 2001)	26-36 wk GA	Facial expression, movement, sleep, consolability	Prolonged (postoperative)	Interrater reliability (r = 0.59-0.74), content validity, construct validity (p <0.000)
Modified postoperative comfort score (Guinsburg et al, 1998)	Preterm infants	Sleep, facial expression, activity, tone, consolability, cry, sociability	Prolonged (postoperative)	Content validity, discriminant validity (p <0.0001)
Neonatal pain, agitation and sedation scale (Hummel et al, 2008)	<28-35 wk GA (age correction for prematurity)	Crying, irritability, behavior state, facial expression, extremities, tone, vital signs (heart rate, respiratory rate, blood pressure, oxygen saturation)	Prolonged (mechanical ventilation or postoperative)	Preliminary reliability and validity testing in progress
Pain assessment tool (Hodgkinson et al, 1994)	27 wk GA to full term	Posture, tone, sleep pattern, expression, color, cry, respirations, heart rate, oxygen saturations, blood pressure, nurse perception	Prolonged (postoperative)	Interrater reliability (r = 0.85), content validity, convergent validity (r = 0.38), concurrent validity (r = 0.76)
Scale for use in newborns (Blauer and Gerstmann, 1998)	24-40 wk GA	Central nervous system state, breathing, movement, tone, face, heart rate, mean blood pressure	Procedural (excluded postoperative)	Beginning indications of reliability, content validity, discriminant validity (p <0.05-0.01)
Distress scale for ventilated newborn infants (Sparshott, 1996)	—	Facial expression, body movement, color, heart rate, blood pressure, oxygenation, temperature	—	Face validity, content validity (Duhn and Medves, 2004)
Crying, requires increased oxygen, increased vital signs, expression, sleeplessness (Krechel and Bildner, 1995)	Neonates 32-60 wk GA	Crying, requires increased oxygen, increased vital signs, expression, sleeplessness	Prolonged (postoperative)	Interrater reliability (r = 0.72), content validity, concurrent validity (r = 0.49-0.73), discriminant validity (p <0.0001), concurrent validity for first 24 h (ICC = 0.34-0.65; McNair et al, 2004)

Continued

TABLE 35-1 Infant Pain Scales—cont'd

Measure	Age Level	Indicators	Pain Type	Psychometric Properties
Neonatal infant pain scale (Lawrence et al, 1993)	Preterm and full term	Facial expression, cry, breathing patterns, arm movement, leg movement, state of arousal	Procedural	Interrater reliability (r = 0.92-0.97), internal consistency (0.87-0.95), content validity, concurrent validity (r = 0.53-0.83)
Pain assessment in neonates scale GA (Hudson-Barr et al, 2002)	26-47 wk GA	Facial expression, cry, breathing patterns, extremity movement, state of arousal, oxygen saturation, increased heart rate	Procedural	Content validity, concurrent validity (r = 0.93)
Modified infant pain scale (Bucholz et al, 1998)	4-30 wk old	Sleep during evaluation, facial expression, quality of cry, spontaneous motor activity, excitability and responsiveness to stimulation, finger and toe flexion, sucking, overall tone, consolability, sociability, change in heart rate, change in blood pressure, fall in oxygen saturation	Prolonged preceding hour	Interrater reliability (postoperative; r = 0.85), content validity, convergent validity in dichotomous rating (p <0.0001)
Premature infant pain profile (Stevens et al, 1996)	Term and preterm neonates	GA, behavioral state, heart rate, oxygen saturation, brow bulge, eye squeeze, nasolabial furrow	Procedural	Interrater reliability (ICC = 0.93-0.96), intrarater reliability (ICC = 0.94-0.98), internal consistency (alpha = 0.59-0.76), content validity, construct validity (in preterm neonates, p = 0.0001-0.02; in term neonates, p <0.02), construct validity in clinical setting (p <0.0001), interrater reliability (r = 0.94-0.98; Ballantyn et al 1999), concurrent validity with cry duration (Johnston et al, 1999)

Modified from Stevens BJ et al: Assessment of pain in neonates and infants. In Anand KJ, Stevens BJ, MaGrath PJ, editors: *Pain in neonates and infants*, ed 3, Philadelphia, 2007, Elsevier, pp 70-75.

associated with procedures, delegating responsibility for pain assessment and treatment to the bedside nurse staff, and using a balanced multimodal approach to pain control (Allegaert et al, 2009).

BEDSIDE NONINVASIVE NEUROIMAGING TO EVALUATE PAIN AND STRESS

Several new modalities are being evaluated for their capability to help health care providers recognize pain in neonates. Near infrared spectroscopy might be a helpful technology. In a study of 29 infants between 26 and 36 weeks' gestation at birth, cortical activation occurred over both somatosensory cortices during unilateral tactile and painful stimuli (Bartocci et al, 2006). Amplitude-integrated electroencephalography also can be used to detect cortical activation in neonates (Toet and Lemmers, 2009). These and other new technologies will be needed to first recognize and then continually assess and manage pain and discomfort in our fragile patients.

LONG-TERM CONSEQUENCES OF NEONATAL PAIN AND STRESS

Untreated pain and stress has been linked to adverse long-term outcomes. Acute effects include elevations of cortisol, catecholamines, and lactate, hypertension, tachycardia, respiratory instability, glucose instability, and changes in cerebral blood flow. Chronic pain can affect growth, immune function, recovery, and length of hospitalization. In addition, a growing body of evidence has drawn attention to the potential deleterious effects of repeated handling, stress, and pain on long-term memory, social and cognitive development, and neural plasticity (Anand, 1998; Anand et al, 1987, 1989; Evans, 2001; Jennings and Fitzgerald, 1998; Pokela, 1994; Porter et al, 1999; Taddio et al, 1995a). Extrapolation of information from older children and adults can be inappropriate for our most vulnerable infants (Berde et al, 2005; Howard, 2003; Walker, 2008).

Pain and stress may alter neurodevelopment (Abdulkader et al, 2008; Anand et al, 1987, 2000). Pain suffered during neonatal intensive care has been associated with adverse long-term outcomes, such as altered pain perception to subsequent immunizations after circumcisions without anesthesia (Taddio et al, 1997), abnormal cortisol responses to stress in later infancy (Grunau et al, 2007), and altered pain responses in childhood (Grunau et al, 1998). There is concern that such hormonal changes might lead to the development of cardiovascular disease and type 2 diabetes in adulthood (Kajantie et al, 2002; Rosmond and Björntorp, 2000). As a result, appropriate use of sedation and analgesia might be beneficial to infants requiring intensive care support; however, a clear delineation of the benefits still requires further study.

CLINICAL PAIN AND STRESS MANAGEMENT STRATEGIES

SURGICAL ANESTHESIA

The recognition that surgical intervention in infants results in dramatic physiologic and metabolic changes similar to those noted in adults with significant pain has changed current practice. It is well recognized that infants perceive pain, and surgical intervention without anesthesia and analgesia leads to increased morbidity and excess mortality; however, experience obtained in older children and adults cannot be extrapolated to immature patients. Providing general anesthesia in infants requires an intimate knowledge of the developmental status and function of each organ system. A complete review of this subject is beyond the scope of this chapter. Interested readers are referred to *A Practice of Anesthesia for Infants and Children* by Spaeth and Kurth (2009) or *Anesthesia for Infants and Children* by Brett et al (2006).

FETAL SURGERY

The fetus has increasingly become a candidate for surgical intervention to repair fetal anomalies such as congenital cystic adenomatoid malformation of the lung, sacrococcygeal teratoma, and myelomeningocele, and to treat fetal disorders such as severe anemia secondary to hemolytic diseases. Many fetal interventions are accomplished using general maternal anesthesia, and therefore fetal anesthesia, but certain procedures are attempted with maternal analgesia and local anesthesia. Thus, during such fetal surgical interventions, the fetus requires consideration for pain management to attenuate fetal physiologic and hormonal stress responses (Fisk et al, 2001; Giannakoulopoulos et al, 1999). Anand et al (1987) summarized the available evidence regarding fetal and neonatal nociceptive activity in 1987 and put all care providers on notice that late gestation fetuses and newborns have intact cortical and subcortical centers necessary for pain perception and demonstrate physiologic responses to painful stimuli similar to evidence in adult subjects. A recent review of the literature supports the contention that the fetus perceives pain (Lee et al, 2005). The International Association for the Study of Pain supported the view that the human fetus is capable of reacting to nociceptive stimuli during the second trimester (Anand, 2006).

NEONATAL SURGERY

Selection of anesthetic agents to be used in neonates must account for the developmental status and function of each organ system and the potential adverse and toxic effects of specific anesthetic agents. Animal models have demonstrated that anesthetic agents can be both neuroprotective and neurotoxic in the immature brain. Frequently used anesthetics act by two principal mechanisms, either by decreasing excitation via *N*-methyl-D-aspartate (NMDA) receptors (e.g., ketamine, nitrous oxide) or by increasing inhibition via gamma-aminobutyric acid receptors (e.g., benzodiazepines, barbiturates, propofol, etomidate, isoflurane, enflurane, halothane). In the immature rat brain, drugs that act by either of these two mechanisms can induce widespread neuronal apoptosis when given during the period of synaptogenesis (Ikonomidou et al, 1999; Ishimaru et al, 1999). The applicability of these findings to the human infant has been questioned (Soriano and Anand, 2005); however, recent data suggest that some toxicity may occur in human infants (Wilder et al, 2009).

Regional anesthesia for neonatal surgery is commonly used for minor interventions. As more experience with regional anesthesia for major surgical procedures is gained, such practice is expanding. Bösenberg (1998) presented results of the use of epidural analgesia for major neonatal surgical interventions in 240 infants weighing between 900 and 5800 g and reported that all infants had effective intraoperative analgesia with only two complications. Advantages of regional anesthesia may include less postoperative apnea, lees need for intubation, and better postoperative pain control. Sethna and Suresh (2007) reviewed this subject in depth recently.

POSTOPERATIVE PAIN MANAGEMENT STRATEGIES

Pain management after surgical intervention, like acute pain management, requires knowledge of the developmental status and function of each organ system and the potential adverse and toxic effects of specific analgesic agents. Many neonates remain intubated for mechanical ventilation after major surgery. Analgesia can be provided via intravenous administration of an analgesic agent, either by intermittent bolus dosing or by continuous infusion. Another option is continuation of regional analgesia (Bösenberg, 1998). Regional analgesia appears to be effective for pain control, but sedation may also be required in active or vigorous infants (Frumeinto et al, 2000). Regional anesthesia, when used alone, may also reduce the incidence of postoperative apnea in preterm infants (Craven et al, 2003).

Research-based evidence of appropriate postoperative pain management in neonates is limited. Taylor et al (2006) surveyed 10 NICUs regarding their postoperative pain assessment and management practices; they found that pain assessment documentation was extremely variable. Nursing documentation was done for most infants, whereas few physicians documented any assessment. Most infants were treated with opioids, benzodiazepines, or both, and some infants (7%) received no analgesia despite recent major surgery (Taylor et al, 2006). Van der Marel et al (2007) evaluated the use of rectal acetaminophen as an adjuvant treatment to continuous morphine infusion in postoperative neonates and could not demonstrate any additional analgesia effect. Recent evidence suggests that neonates require significantly less morphine to control pain and discomfort than older infants do, based on monitoring of pain scale data. Bouwmeester et al (2003a, 2003b) determined that neonates required less morphine for postoperative pain control and that the dose requirement increased with age. Both studies found that morphine, given by bolus or continuous infusion, was equally effective. The later study (2003b) found that mechanical ventilation decreased morphine metabolism and clearance.

The Association of Pediatric Anesthetists of Great Britain and Ireland commissioned guideline development for pain management after surgery and painful medical procedures (Howard et al, 2008a, 2008b). The level of evidence from the literature was determined and the recommendations were graded, allowing for better interpretation. These guidelines provided evidence-based recommendations and listed best clinical practice points when published evidence was insufficient to make formal recommendations.

MECHANICAL VENTILATION

The use of mechanical ventilation in neonates with respiratory failure is a fairly common practice in the United States, although decreasingly less than in the 1980s and 1990s. In older children and adults who require mechanical ventilation, sedation is routinely provided—most often with opiates (Gélinas et al, 2004). However, pharmacologic sedation is used less frequently in the adult intensive care unit because of concern regarding adverse cognitive outcomes and longer duration of ventilator support (Izurieta and Rabatin, 2002; Oderda et al, 2007). Extrapolation of evidence from past studies in adult patients led to the routine use of opiate sedation in neonates during mechanical ventilation (Kahn et al, 1998), with limited information regarding safety and efficacy (Anand et al, 2004; Simons et al, 2003b). As noted previously, the ability to assess and treat discomfort and pain is limited, and preemptive use of pharmacologic sedation during mechanical ventilation in newborns, especially preterm infants, remains controversial (Anand and Hall, 2007).

Mechanical ventilation in neonates is associated with an increase in hormonal stress responses, including increased cortisol and catecholamine levels (Guinsburg et al, 1998; Quinn et al, 1998). In the past, infants who appeared uncomfortable while receiving ventilatory support demonstrated asynchronous respiratory effort (i.e., "fighting" the ventilator), compromised gas exchange, and altered stress responses (Dyke et al, 1995). Furthermore, pain and stress in newborns receiving mechanical ventilation have been associated with decreased pulmonary compliance, atelectasis, and intrapulmonary shunting (Bolivar et al, 1995). More recently, with the introduction and use of surfactant replacement therapy and synchronized ventilatory technology, some of the problems with fighting the ventilator have been eliminated (Claure and Bancalari, 2009; Keszler, 2009).

Clinical studies from the 1990s demonstrated that opiate treatment prevented these adverse effects on neonatal ventilation and reversed the previously described hormonal stress changes (Quinn et al, 1993; Saarenmaa et al, 1999). Opiate sedation has been demonstrated to decrease stress scores in newborns who receive mechanical ventilation (Orsini et al, 1996; Quinn et al, 1993, 1998). In full-term infants receiving mechanical ventilation, the severity of respiratory failure as assessed by the oxygenation index directly correlated with the need for analgesia and sedation (Aretz et al, 2004).

A small randomized trial of routine morphine infusion in preterm infants receiving mechanical ventilation concluded that morphine lacked a "measurable analgesic effect" and there was "absence of a beneficial effect on poor neurological outcome" (Orsini et al, 1996). The larger clinical trial that followed (i.e., NEOPAIN) reported no beneficial effect of preemptive morphine infusions in ventilated preterm infants and an increased incidence of severe intraventricular hemorrhage in preterm infants born at 27 to 29 weeks' gestation and receiving morphine (Anand et al, 2004). Bhandari et al (2005) found that morphine infusions had no beneficial effects in preterm infants receiving mechanical ventilation. Additional bolus doses of morphine resulted in worse respiratory outcomes and longer requirement for ventilatory support. None of these controlled clinical trials provide evidence that routine narcotic sedation during mechanical ventilatory support in neonates is beneficial. In addition, the well-recognized and common adverse effects of narcotic exposure (e.g., hypotension, feeding intolerance, respiratory depression) are mentioned infrequently in sedation and pain treatment protocols in neonates receiving mechanical ventilation. Future trials have been deemed unethical if they involve withholding sedation from a group of infants. One approach to this dilemma would be to minimize the use of ventilatory support as much as possible.

A recent Cochrane Review evaluated the effects of opioid analgesics on pain, duration of mechanical ventilation, mortality, growth, and development in neonates requiring mechanical ventilation (Bellù et al, 2008). The authors found no differences in mortality, duration of mechanical ventilation, and short- and long-term neurodevelopmental outcomes. Preterm infants given morphine took longer to achieve full enteral feeding. If morphine sedation prolongs ventilatory support needs and time to full enteral feeds, then an increase in the risk of complications related to the use of venous lines (bloodstream infections) and parenteral nutrition (cholestasis) should be expected (Menon et al, 2008). Hällström et al (2003) studied risk factors for necrotizing enterocolitis in premature infants and found that the duration of morphine use was the strongest predictor for development of severe necrotizing enterocolitis. The Cochrane Review's overall conclusion regarding the use of sedation during mechanical ventilation was that "there is insufficient evidence to recommend routine use of opioids in mechanically ventilated newborns" (Bellù et al, 2008). Menon and McIntosh (2008) came to a similar conclusion in their recent review.

PROCEDURES

Infants undergoing intensive care suffer through many painful procedures, often several times each day. Although new pharmacologic and nonpharmacologic treatment strategies to decrease or eliminate some of this pain and stress have been developed, there is still a need to develop better management techniques. An article by D'Apolito (2006) reviews this issue in detail and outlines where knowledge remains limited.

BLOOD SAMPLING AND MONITORING

Heel sticks are routinely performed to obtain blood samples in neonates. The most appropriate method for relieving pain from a heel stick is yet to be determined. The heel

should be warmed to aid blood sampling. Eutectic mixture of local anesthetics (EMLA) cream does not relieve the pain of a heel lance (Stevens et al, 1999b; Taddio et al, 1998). Shah et al (1997) and Larsson et al (1998a, 1998b) demonstrated that neonates experiencing venipuncture had lower pain scores than those who underwent heel stick for blood sampling. In selected neonates, venipuncture should be used preferentially over heel stick.

The pain of arterial puncture can be decreased by infiltrating the site with 0.1 to 0.2 mL of 0.5% or 1% lidocaine using the smallest-gauge needle possible (Franck and Gregory, 1993). Buffering the lidocaine with sodium bicarbonate is recommended to decrease the burning caused by lidocaine. In addition, EMLA may reduce the pain of arterial puncture.

TRACHEAL INTUBATION

The use of premedication to minimize the pain and stress of intubation has been demonstrated to benefit neonates (Simons et al, 2003a). However, concerns about rapid medication availability, ability to maintain the airway, and the ability to provide ongoing ventilatory support continue to cause controversy (Carbajal et al, 2007). Premedications typically include atropine, narcotics for sedation, and muscle relaxants. Atropine abolishes vagal bradycardia. Narcotics attenuate the increases in arterial blood pressure. Muscle relaxants attenuate the increases in intracranial pressure. Combinations decrease the time and number of attempts needed to intubate the infant.

When considering the use of medications for intubation, several questions need to be asked:

- Does the infant have adequate vascular assess?
- What is the urgency of intubation need?
- Is the infant known to have a difficult airway?
- When was the last feeding?
- Can the infant be preoxygenated while avoiding gastric distension?

If the decision is made to use medications for intubation, typical doses include:

- Atropine 0.02 mg/kg fast intravenous (IV) push
- Fentanyl 2 μg/kg slow IV push
- Vecuronium 0.1 mg/kg IV push

Alternative medications may include succinylcholine (1 to 2 mg/kg IV push) or rocuronium (1 mg/kg IV push).

The investigational agent sugammadex can reverse rocuronium-induced neuromuscular blockade in less than under 2 minutes. Sugammadex forms a 1:1 complex with steroidal nondepolarizing neuromuscular blockers in the plasma. Although approved for use in Europe, sugammadex is not currently available in the United States; it might render succinylcholine unnecessary. Rocuronium could be administered and if intubation is unsuccessful, paralysis could be immediately reversed with sugammadex (de Boer et al, 2007).

Propofol has been used as a premedication for intubation. Being a single agent, it is easier and faster to prepare than three separate drugs. Propofol is a hypnotic agent without anesthetic properties. If combined with remifentanil, there is no need for paralysis in older children (Batra et al, 2004); however, propofol is painful when injected in small veins, and extremely painful if it extravasates. A major advantage is continued spontaneous breathing during the intubation procedure. The dose is 2.5 mg/kg IV; this dose might need to be repeated. Concerns over the use of propofol for intubation in neonates include minimal experience in neonates, uncertain pharmacokinetics and duration of action, and compatibility with precutaneously inserted central catheters lines.

Because intubation can raise both blood pressure and intracranial pressure, a short-acting benzodiazepine, such as midazolam, can be beneficial for infants with stable cardiovascular function. Fentanyl can be used as an alternative for infants with compromised cardiovascular function (McClain and Anand, 1996). Any infant who is pharmacologically paralyzed during mechanical ventilation should receive adequate sedation. In addition, the infant should receive pain medication if pain is suggested by the infant's condition or because of the procedures being performed.

CIRCUMCISION

The AAP Circumcision Policy Statement (American Academy of Pediatrics Task Force on Circumcision, 1999) states that analgesia must be provided to infants undergoing circumcisions. EMLA cream, dorsal penile nerve block, and subcutaneous ring block are all possible options. The AAP reports that subcutaneous ring block may provide the best analgesia (American Academy of Pediatrics Task Force on Circumcision, 1999). Subcutaneous ring block has been found to be more effective than EMLA or dorsal penile nerve block in other studies (Lander et al, 1997). Dorsal penile nerve block has been found to be more effective than EMLA, but this method is not always available (Lee and Forrester, 1992).

EMLA has been established as superior to placebo for pain relief during circumcision (Benini, 1993; Taddio et al, 1997). An effective method for applying EMLA in preparation for circumcision is to apply one third of the dose to the lower abdomen, extend the penis upward gently, pressing it against the abdomen, and then apply the remainder of the dose to an occlusive dressing placed over the penis. This dressing is then taped to the abdomen so that the cream surrounds the penis. Another method is to apply the cream and then place plastic wrap around the penis in a tubelike fashion to direct the urine stream out and away from the cream.

Acetaminophen is ineffective for the management of severe pain associated with the circumcision procedure, but it provides some analgesia in the postoperative period. Acetaminophen has been found to decrease pain 6 hours after circumcision (Howard et al, 1994).

OTHER INVASIVE PROCEDURES

Placement of a central venous catheter requires topical anesthesia with EMLA or infiltration of the skin with lidocaine. In addition, a parenteral opioid, such as morphine or fentanyl, is typically required. Consideration should also be given to regional blocks for central line placement.

The pain of a lumbar puncture is compounded by both the needle puncture and the distress caused by the body position required for the procedure. EMLA has been

shown to decrease the pain of lumbar puncture in children (Halperin et al, 1989). Chest tube insertion requires an intravenous opioid, adequate local analgesia (lidocaine), or both.

PHARMACOLOGIC ANALGESIA INTERVENTIONS

The severity of the pain, etiology, available administration routes, and consideration of potential side effects should all be evaluated during selection of an analgesic. Once medication administration has begun, careful monitoring for side effects can decrease potential adverse events related to administration of pain medications to infants. A key component of effective pain management is reassessment after a painful intervention, although this is difficult to do with limited pain assessment tools.

NONOPIOID ANALGESICS

Nonsteroidal Antiinflammatory Drugs (Indomethacin, Ibuprofen)

Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit prostaglandin synthesis by inhibiting the action of cyclooxygenase enzymes. Cyclooxygenase enzymes are responsible for the breakdown of arachidonic acid to prostaglandins. NSAIDs have many physiologic effects, including sleep cycle disruption, increased risk of pulmonary hypertension, cerebral blood flow alterations, decreased renal function by decreasing glomerular filtration rate, alteration in thermoregulatory control, and changes in platelet function. Moreover, development of the central nervous, cardiovascular, and renal systems is dependent on prostaglandins. These adverse effects are particularly worrisome for neonates and infants; however, these drugs are used frequently in the NICU for pharmacologic closure of the PDA. Aside from effects on renal and perhaps mesenteric circulation, which are difficult to separate from the PDA, no clear side effects have been reported.

Acetaminophen

Acetaminophen is the most widely administered analgesic in patients of all ages. Acetaminophen inhibits the activity of cyclooxygenase in the central nervous system, decreasing the production of prostaglandins, and peripherally blocks pain impulse generation (Arana et al, 2001). Neonates are able to form the metabolite that results in hepatocellular damage (Arana et al, 2001); however, it is inappropriate to withhold acetaminophen in newborns because of concerns of liver toxicity. The immaturity of the newborn's cytochrome P-450 system may actually decrease the potential for toxicity by reducing production of toxic metabolites (Collins, 1981).

Current recommendations are for less frequent oral dosing (every 8 to 12 hours in preterm and term neonates), because of slower clearance times, and higher rectal dosing because of decreased absorption (Arana et al, 2001; van Lingen et al, 1999). Typical oral doses for acetaminophen are 10 to 15 mg/kg every 6 to 8 hours for term neonates and 10 to 15 mg/kg every 4 to 6 hours for infants. Administering 10 mg/kg may be inadequate for pain control, because this dose is based on antipyretic dose-response studies. The maximum recommended daily dose is 75 to 90 mg/kg for infants, 45 to 60 mg/kg for term and preterm neonates more than 32 to 34 weeks of postconceptual age, and 25 to 40 mg/kg/day for preterm neonates 28 to 32 weeks of postconceptual age (Berde and Sethna, 2002; Morris et al, 2003).

Rectally administered acetaminophen has a longer half-life, but absorption is highly variable because it depends on the individual infant and placement of the suppository. It should also be noted that the suppository may contain all of the drug in its tip and should be divided lengthwise if a partial dose is desired. The analgesic effect of acetaminophen may be additive when the agent is administered with opioids. This coadministration may enable a decrease in the opioid dose and therefore in corresponding opioid side effects; however, demonstration of this potential benefit awaits further study (van der Marel et al, 2007).

OPIOID ANALGESICS

Opioids are believed to provide the most effective treatment for moderate to severe pain in patients of all ages. There is a wide range of interpatient pharmacokinetic variability. Opioid dosing depends on the severity of the pain as well as the age and clinical condition of the infant. Opioids should be used in infants younger than 2 months only in a monitored setting such as an intensive or intermediate care unit (Yaster et al, 2003). Some clinicians propose a more conservative recommendation, restricting the use of opioids to monitored settings for any infant younger than 6 months.

Morphine

Morphine remains the standard for pain management in neonates, although not necessarily because it has been shown to be the most effective analgesic. Morphine is metabolized in the liver by uridine diphosphate glucuronyltransferase into two active metabolites: (1) morphine-6-glucuronide (M6G), a potent opiate receptor agonist, and (2) morphine-3-glucuronide (M3G), a potent opiate receptor antagonist. Both metabolites and some unchanged morphine are excreted in the urine. The predominant metabolite in preterm and full-term neonates is M3G. Because of slow renal excretion, the metabolites can accumulate substantially over time (Bouwmeester et al, 2003a, 2003b; Saarenmaa et al, 2000). There is a potential for late respiratory depression because of a delayed release of morphine from less well-perfused tissues and the sedating properties of the M6G metabolite (Anand et al, 2000).

Because the predominant metabolite of morphine in infants is M3G, a potent opiate receptor antagonist, using the lowest dose possible to achieve the needed analgesia should be considered. Escalating morphine doses will also increase the levels of M3G in the infant, interfering with the goal of adequate analgesia. Doses as low as 1 to 5 μg/kg/h can provide adequate analgesia, minimizing the risk of accumulation of high M3G levels with

the metabolite's prolonged half-life (Bouwmeester et al, 2003a, 2003b).

Clearance or elimination of morphine and other opioids is prolonged in infants, because of the immaturity of the cytochrome P-450 system at birth. The rate of elimination and clearance of morphine in infants 6 months and older approaches that in adults. Chronologic age seems a better indicator than gestational age of how an infant metabolizes opioids (Scott et al, 1999; Yaster et al, 2003).

Infants are at greater risk for opioid-associated respiratory depression because of their immature responses to hypoxia and hypercarbia. There is an increase in unbound or free morphine and M6G available to reach the brain as a result of the reduced concentration of albumin and alpha$_1$ acid glycoproteins (Houck, 1998).

Hypotension, bradycardia, and flushing constitute the response to the histamine release and rapid intravenous administration of morphine. Histamine release may cause bronchospasm in infants with chronic lung disease, although this is not commonly seen (Anand et al, 2000). Morphine sedation may result in extended need for ventilatory support in neonates (Anand et al, 1999; Bhandari et al, 2005).

Dosing recommendations currently reflect the wide range of interpatient pharmacokinetic variability. In the past, 0.03 mg/kg of morphine IV was suggested as a starting dose in infants not receiving ventilation (Acute Pain Management Guideline Panel, 1992), whereas 0.05 to 0.1 mg/kg of morphine IV was recommended as an appropriate starting dose in infants receiving ventilation. Recently, much lower doses have been recommended (Anand et al, 2008; Bouwmeester et al, 2003b, 2004; Lynn et al, 2000; Saarenmaa et al, 2000). Titration to the desired clinical effect is required in adjusting both the dose and the frequency of administration. Furthermore, it is important to continually assess need and responses so that dosing can be adjusted both up and down (Allegaert et al, 2009). As the use of morphine for analgesia and sedation in neonates is explored further, it is becoming clear that some of the risks may outweigh the potential benefits (Allegaert et al, 2009; Anand et al, 2008; Black et al, 2008; Carbajal et al, 2005; Nandi et al, 2004; Ng et al, 2003; Ranger et al, 2007).

Fentanyl

Fentanyl is 80- to 100-fold more potent than morphine and causes less histamine release, making it a more appropriate choice for infants with hypovolemia, hemodynamic instability, or congenital heart disease. Another potential clinical advantage of fentanyl is its ability to reduce pulmonary vascular resistance, which can be of benefit for infants who have undergone cardiac surgery, have persistent pulmonary hypertension, or need extracorporeal membrane oxygenation (Anand et al, 2000). Bolus doses of fentanyl must be administered over a minimum of 3 to 5 minutes to avoid chest wall rigidity, a serious side effect observed after rapid infusion. Chest wall rigidity, which can result in difficulty or inability to ventilate, can be treated with naloxone or a muscle relaxant such as pancuronium or vecuronium.

Fentanyl is highly lipophilic. It has a quick onset and relatively short duration of action. Because of fentanyl's short duration of action, it is typically used as a continuous infusion for postoperative pain. In infants 3 to 12 months of age, total body clearance of fentanyl is greater than that of older children, and the elimination half-life is longer because of its increased volume of distribution (Singleton et al, 1987). Fentanyl has been demonstrated to have a prolonged elimination half-life in infants with increased abdominal pressure (Gauntlett et al, 1988; Koehntop et al, 1986). Because of tachyphylaxis, continuous infusions of fentanyl are often increased to maintain constant levels of sedation and pain management. Infusion dosing can reach substantial levels requiring prolonged withdrawal.

A rebound transient increase in plasma fentanyl levels is a phenomenon known to occur after discontinuation of therapy in neonates. It is a result of the accumulation of fentanyl in fatty tissues, which can prolong its effects after continued use; therefore caution must be exercised in the use of repeated doses or a continuous infusion.

Oral Opioids

Oral methadone can be used to wean infants from long-term opioid use. Methadone is widely used in neonates and children, although there are limited data regarding its efficacy and pharmacokinetics in this population (Chana and Anand, 2001; Suresh and Anand, 1998). The respiratory depressant effect of methadone is longer than its analgesic effect. Methadone is metabolized slowly, and it has a long half-life.

Codeine is prescribed at 0.5 mg to 1 mg/kg orally every 4 hours as needed. Scarce data are available to recommend use of codeine in neonates. Most pharmacies supply acetaminophen and codeine in a set formula, consisting of acetaminophen (120 mg) and codeine phosphate (12 mg per 5 mL) with alcohol (7%). The dose prescribed is limited by both the appropriate dose of codeine and the safe dose of acetaminophen. This combination is not recommended in neonates.

Oxycodone dosing is 0.05 mg/kg to 0.15 mg/kg orally every 4 to 6 hours as needed. No data are available to recommend oxycodone in neonates. The liquid form is not universally available.

MIXED OPIOID AGONIST-ANTAGONIST DRUGS

Nalbuphine is a mixed agonist-antagonist opioid receptor drug; therefore its administration in infants of opioid-addicted mothers may precipitate withdrawal. This agent is equianalgesic with morphine. Nalbuphine has a ceiling effect for analgesia. Additional studies are needed regarding the safety and efficacy of nalbuphine use in infants. It is not recommended for use in neonates, although it may be useful during opioid drug withdrawal (Jang et al, 2006).

LONG-TERM CONSEQUENCES OF NEONATAL OPIOID EXPOSURE

Experimental Animal Studies

Perinatal and neonatal opioid exposure in experimental animals is associated with both short- and long-term adverse neurologic effects that should make clinicians ask

whether the use of such medications with questionable benefits should be used at all. Data from previous studies suggested that perinatal narcotic exposure restricts brain growth, induces neuronal apoptosis, and alters behavioral pain responses later in life (Handelmann and Dow-Edwards, 1985; Hu et al, 2002; Kirby et al, 1982; Seatriz and Hammer, 1993). One area of particular concern to clinicians is the developing cerebral circulation, which is extremely vulnerable to physiologic perturbations and the effects of drugs (Volpe, 1998). Cerebrovascular effects of drug exposure early in development can have lifelong consequences, including increased risk for stroke (Barker, 2000; Craft et al, 2006; Hanson et al, 2004). The acute effects of exogenous narcotics, including morphine, on the developing cerebral circulation have been described in piglets and include modulation of prostaglandin-induced pial artery dilation during hypoxia, alteration in endothelin production, and increases in endothelin A receptor mRNA expression (Armstead et al, 1990, 1996; Van Woerkom et al, 2004). Endogenous opioids are important regulators of cerebrovascular tone and angiogenesis (Blebea et al, 2000; Gupta et al, 2002; Pasi et al, 1991; Poonawala et al, 2005). Exposure to morphine in fetal sheep and neonatal rats permanently alters cerebrovascular control mechanisms (Mayock et al, 2005, 2006). We have also shown permanent neurobehavioral and neuropathologic changes in a rodent model of neonatal stress and morphine exposure (Boasen et al, 2009; McPherson et al, 2007; Vien et al, 2009). These and other animal studies demonstrate short- and long-term effects of neonatal morphine exposure, which is not surprising because opioid receptor-mediated signaling likely has a role in several aspects of early brain development (Durrmeyer et al, 2010). However, the clinical relevance of these animal studies regarding the long-term effects of neonatal opioids is difficult because of species differences in the timing of brain development, the development of opiate receptors and major neurotransmitter systems, and the pharmacokinetics of administered opioids. Overall, it is difficult but necessary to simulate the premature infant's NICU experience in an animal model (Durrmeyer et al, 2010).

Clinical Studies

Clinical studies addressing the short- and long-term effects of prolonged opiate use in neonates are limited. The few that exist are contradictory and confounded by illness severity. Bergman et al (1991) described reversible encephalopathic changes in neonates receiving long-term sedative and narcotic infusions. MacGregor et al (1998) demonstrated no adverse neurodevelopmental outcomes in a small group of newborns who received morphine for a median of 5 days. Roźe et al (2008) presented 5-year neurodevelopmental outcomes in very low-birthweight (VLBW) infants exposed to prolonged sedation or analgesia (defined as greater than 7 days of sedative or opioid drugs). They found that exposed VLBW infants had more severe or moderate disability at 5 years (42%) compared with those not exposed (26%), but after adjusting for gestational age and propensity score (as a way to ensure that treatment effects are only compared between infants who are equally likely to receive that treatment), the association was no longer significant. Preterm infants (23 to 32 weeks' gestation at birth) evaluated at 36 weeks postconceptual age in the NEOPAIN study already demonstrated neurobehavioral abnormalities if exposed to morphine during ventilatory support (Rao et al, 2007).

TOPICAL AND LOCAL ANESTHETICS

Lidocaine reduces the pain and stress of venipuncture and IV catheter placement (Larsson et al, 1998a, 1998b; Long et al, 2003). EMLA cream has been demonstrated to reduce the pain of circumcision. Place the cream on the area where anesthesia is desired and then cover it with an occlusive dressing for 1 hour before the procedure. Longer application times provide deeper local anesthetic penetration, but can lead to toxicity. There is a slight risk of methemoglobinemia with the use of EMLA cream in infants and patients who are G6PD deficient. A rare occurrence, methemoglobinemia can occur when hemoglobin is oxidized by exposure to prilocaine. EMLA should not be used in patients with methemoglobinemia or in infants younger than 12 months who are also receiving methemoglobinemia-inducing drugs, such as acetaminophen, sulfonamides, nitrates, phenytoin, and class I antiarrhythmics. (Refer to Table 35-2 for recommended maximum doses of EMLA cream by age and weight.) A study of 30 preterm infants found that a single 0.5-g dose of EMLA applied for 1 hour did not lead to a measurable change in methemoglobin levels (Taddio et al, 1995b). A systematic review concluded that EMLA diminishes the pain during circumcision. Limited efficacy was noted with pain from venipuncture, arterial puncture, and percutaneous venous line placement. EMLA was not found to diminish pain from heel lancing (Taddio et al, 1998). Oral sucrose or glucose may be as effective as EMLA for venipuncture (Abad et al, 2001; Gradin et al, 2002).

SEDATIVES

Benzodiazepines

Benzodiazepines such as lorazepam and midazolam are sedatives which activate gamma-aminobutyric acid receptors and should not be used in place of an appropriate

TABLE 35-2 EMLA Cream: Recommended Maximum Dose by Age and Weight

Age	Body Weight (kg)	Maximum Total EMLA Dose (g)	Maximum Application Area (cm^2)	Maximum Application Time (h)
Birth to 3 mo	or <5	1	10	1
3-12 mo	and >5 kg	2	20	4

EMLA, Eutectic mixture of local anesthetics.

pain medication, because this class of medication has no analgesic effect. For painful procedures, an analgesic must be used in conjunction with the benzodiazepine. Benzodiazepines are administered to decrease irritability and agitation in infants and to provide sedation for procedures. In ventilated infants, benzodiazepines can help to avoid hypoxia and hypercarbia from breathing out of sync with the ventilator although, as noted for opioids, new synchronized infant ventilators make this clinical problem less likely. When given as continuous infusions, dosing often escalates rapidly to maintain apparent sedation resulting in need for prolonged weaning. Use of such medications has been associated with abnormal neurologic movements in both preterm (Lee et al, 1994) and term infants (Chess and D'Angio, 1998). In rats, prenatal exposure to diazepam results in long-term functional deficits and atypical behaviors (Kellogg et al, 1985); exposure of 7-day-old mice to diazepam induces widespread cortical and subcortical apoptosis (Bittigau et al, 2002); and midazolam potentiates pain behavior, sensitizes cutaneous reflexes, and has no sedative effect in newborn rats (Koch et al, 2008). Whether these data can be extrapolated to human infants is unknown, but clinicians have reason to be concerned and should use these drugs with caution in the NICU.

Dexmedetomidine

Dexmedetomidine is a potent and relatively selective α_2 adrenergic receptor agonist indicated for the short-term sedation of patients in intensive care settings, especially those receiving mechanical ventilatory support. The drug is administered by either bolus doses for short procedural sedation (1 to 3 μg/kg) or continuous intravenous infusion (0.25 to 0.6 μg/kg/h). Because dexmedetomidine does not produce significant respiratory depression, it has been used for procedural interventions in spontaneously breathing infants (Barton et al, 2008; Chrysostomou et al, 2009). As neonatologists become more familiar with dexmedetomidine, its use may increase (O'Mara et al, 2009); however, short- and long-term safety and effectiveness information needs to be assessed in infants, as has been initiated in adults (Pandharipande et al, 2007; Riker et al, 2009).

NONPHARMACOLOGIC ANALGESIC INTERVENTIONS

Nonpharmacologic interventions for prevention or relief of neonatal pain and stress are numerous and widely publicized in the medical literature. These interventions have been used either as the sole method of pain control or in combination with pharmacologic interventions. No one would argue with the statement that neonatal intensive care is associated with stress, pain, and discomfort. Because opioid analgesia and sedation have not been proved to be efficacious and may possibly be harmful, alternative methods of pain and stress relief need to be evaluated for efficacy and safety. A variety of approaches have been investigated. As stated clearly by Golianu et al (2007), "These therapies may optimize the homeostatic mechanisms of the infant, thereby mitigating some of the adverse consequences of untreated pain, as well as facilitating healthy physiologic adaptions to stress." However, widespread adoption of specific techniques is not consistent.

Nonnutritive sucking with pacifiers reduces pain responses to heel prick, injections, venipuncture, and circumcision procedures (Sexton and Natale, 2009; Shiao et al, 1997; South et al, 2005). Infant massage has been demonstrated to decrease plasma cortisol and catecholamine levels in preterm infants (Acolet et al, 1993; Kuhn et al, 1991).

Maternal skin-to-skin contact (also termed *kangaroo care*) is associated with greater physiologic stability and reduced responses to acute pain (Bergman et al, 2004; Fohe et al, 2000; Gray et al, 2000; Johnston et al, 2003; Ludington-Hoe and Swinth, 1996). Kangaroo care can decrease Neonatal Infant Pain Scale scores after vitamin K injections (Kashaninia et al, 2008). Maternal rocking has been shown to diminish neonatal distress (Jahromi et al, 2004). Breastfeeding reduces the physiologic and behavioral responses to acute pain and stress in neonates and has been recommended as the first line of treatment (Osinaike et al, 2007; Shah et al, 2006).

The Neonatal Individualized Developmental Care and Assessment Program (NIDCAP) systematically changes a protocol-based model of nursing care to a relationship-based approach (Als et al, 1994). There is a significant body of empiric evidence that use of the NIDCAP approach improves the clinical and neurodevelopmental outcomes of preterm infants (Als and Gilkerson, 1997; Brown and Heermann, 1997; Kleberg et al, 2002; Westrup et al, 2000; Wielenga et al, 2007), but recent metaanalyses of published studies could not demonstrate any improvement in long-term outcomes (Jacobs et al, 2002; Symington and Pinelli, 2006).

Another approach is multisensory stimulation of preterm infants undergoing painful procedures. This approach entails simultaneous gentle massage, soothing vocalizations, eye contact, smelling a perfume, and sucking on a pacifier. This technique was associated with analgesia and calming of the infants in several reports from one unit (Bellieni et al, 2001, 2002, 2007).

Music therapy may reduce the behavioral and physiologic responses to acute procedural pain (Hartling et al, 2009).

Oral sucrose (versus intragastric) reduces pain behavior in preterm and term infants and is used widely (Stevens et al, 1997, 2004). The mechanism of oral sucrose analgesia is believed to be the sweet taste stimulation of endogenous opioid release (Shide and Blass, 1989). Of all methods and techniques discussed, oral sucrose has been the most widely used. As more data regarding the limitations of pharmacologic treatment are published, consideration of nonpharmacologic interventions will likely become more important and commonplace.

IATROGENIC DRUG DEPENDENCE, TOLERANCE, WITHDRAWAL

A clear distinction must be made between opioid or benzodiazepine dependence, tolerance, and addiction. Physical dependence is demonstrated by the need to continue

the administration of the drug to prevent signs or symptoms of physical withdrawal. Tolerance is a reduction in the drug effects after repeated administration, or the need to increase the dose to achieve the same clinical effect. Addiction is compulsive drug-taking behavior (Gutstein and Akil, 2001). Infants are not capable of becoming psychologically addicted, but they clearly develop tolerance and dependence.

DRUG WEANING CONSIDERATIONS

Baseline pain and withdrawal scores should be obtained before beginning the drug weaning process, and infants should be reassessed every 2 to 4 hours for signs of withdrawal. In addition, when an opioid dosage is being tapered, the infant should be assessed for the presence of pain a minimum of every 4 hours. If an infant is receiving both an opioid and a benzodiazepine, it is prudent to taper and stop only one class of medication at a time. Typically, a weaning schedule is 10% of the total initial dose every other day. Many patients can tolerate a relatively large initial decrease in dose, but subsequent decreases may need to be smaller. Environmental stressors should be eliminated or reduced whenever possible. It should be noted that the potential onset of withdrawal symptoms varies according to the half-life of the opioid or benzodiazepine and the half-life of active metabolites, which may be much longer than that of the parent compound (Tobias, 2000).

PALLIATIVE CARE

Palliation, as defined in the *New Oxford American Dictionary*, is "making a disease (or its symptoms) less severe or unpleasant without removing the cause." Most deaths in neonatal intensive care units occur after withdrawal of supportive measures, when the burden of care is extreme and the likelihood of recovery is remote (Cook and Watchko, 1996; Wall and Partridge, 1997). Traditionally, initiation of palliative care occurs when further medical interventions are no longer curative and death of the infant is expected. However, the AAP and the World Health Organization both support palliative care that starts early in the course of an illness and works with other therapies to prolong life. "The goal of palliative care is the achievement of the best quality of life for the patients and their families, consistent with their values, regardless of the location of the patient" (World Health Organization, 1998). Both the AAP (American Academy of Pediatrics Committee of Bioethics and Committee on Hospital Care, 2000) and the World Health Organization (1998) have provided guidelines for palliative care for infants that emphasize optimizing quality of life until death occurs and eliminating of the notion of euthanasia. Such care is an active process that includes family-centered care with attention to physical, emotional, and spiritual issues (Papadatou, 1997). Several good reviews of neonatal end-of-life care have been published (De Lisle-Porter and Podruchny, 2009; Institute of Medicine of the National Academies, 2003; Moro et al, 2006). Box 35-1 provides a comprehensive listing of the many aspects of end-of-life care that should be considered for the dying neonate.

Parents and other family members should be actively involved in palliative care. Palliative treatments focus on relief from clinical symptoms such as dyspnea, pain, agitation, vomiting, and seizures, in addition to maintaining dignity and providing warmth. Palliative care should also include attention relieving psychological stress in caregivers such as loneliness, depression, anxiety, grief, and separation from family and loved ones. Family members should be prepared for the end of life. They need to be provided with a description of the dying process that includes mention of the potential for gasping respiratory efforts and an estimate of the length of the dying process. Opportunities to create memories for the family should be offered, such as pictures, footprints, locks of hair, hats, or blankets.

Consideration of to the place of death is important. Should it occur in the hospital or at home with hospice care? Unfortunately, many deaths occur in busy NICUs with little privacy. Placement of the infant and the family on a postpartum ward with other parents and their healthy infants is also suboptimal. Ideally, for deaths likely to occur in the hospital, the infant and family should be placed in a private room with enough space for all family members to be present to support the parents in their grieving process.

Bereavement and follow-up discussions should be planned with the family. Care providers should discuss autopsy, discuss follow-up discussion times, and provide ongoing bereavement support to the family for as long as needed.

SUMMARY

Recognition and treatment of pain and discomfort in the neonate remain challenging issues. Despite significant progress in the understanding of human neurodevelopment, pharmacology, and more careful attention to the care of sick infants, there is still have much to learn. Because protecting and comforting these patients are important, and because external regulatory forces have required intervention to minimize distress, what is known about adult patients must be applied to infants. Some good has come from these endeavors, but errors have been made along the way.

It is important to minimize pain and distress in these patients to avoid more aggressive interventions. Such care will minimize the risks of adverse effects on neurodevelopment. Learning to provide good care without doing harm should be the goal. Nonpharmacologic methods of pain and distress control should be explored further. When pharmacologic intervention is necessary for pain control, use the least amount of drug that controls the pain. Escalation of drug doses may, in fact, be adding to the problem.

As newer techniques and medications are introduced to clinical practice, it must be demonstrates that such additions achieve the goal of pain control. It must also be demonstrates that neonatal interventions are safe over the lives of the patients. Better tools are needed to help optimize the outcomes for infants.

BOX 35-1 Guideline for End-of-Life Care of the Neonate

I. Patient population
Any infant in the NICU diagnosed with a medical condition incompatible with life.

II. Purpose
The guideline is for use by the bedside nurse in the NICU when faced with caring for an infant at the end of life. It provides the bedside nurse with alternative ways to encourage parents to perform normal parenting activities, such as bathing, holding, and picture taking with their infant, in the time surrounding his death. These activities may be the only, and sometimes last, opportunity the mother and father will have to parent their infant.

III. Background and rationale
Many NICUs have policies in place relating to bereavement and postmortem care of the neonate, but few have policies or guidelines on palliative care (Sudia-Robinson, 2003). Many nurses have not received sufficient training to support families or themselves through this bereavement process. Many nursing programs lack or have only recently added curricula regarding end-of-life care (Romesberg, 2004). This lack of protocols, along with the limited education available to professionals, serves to decrease the chance that infants and their families will receive the end-of-life care they deserve. Palliative care consists of three components: (1) pain and comfort management, (2) assistance with end-of-life decision making, and (3) bereavement support (March of Dimes, 2010).

IV. Procedure

A. Inclusion criteria: any infant in the NICU with a diagnosis of nonviability or a fatal condition should be considered for inclusion in this guideline. These medical conditions may fall into three categories: (1) newborns born at the edge of viability with extremely low birthweight (<500 g) and <24 weeks' gestational, (2) newborns with complex or multiple congenital anomalies, and (3) newborns not responding to intensive care interventions and experiencing deterioration despite medical efforts to save them (Catlin and Carter, 2002). For these infants, the focus of care should change from curative to palliative.

B. Predeath: any intervention should focus on supporting the parents during their infant's end-of-life care. Some nurses may be uncomfortable with their own feelings and have trouble communicating with parents at this time. Communication, however, is vital, and the words spoken should serve to validate the infant's life and death (Capitulo, 2005). Communication also helps the parents understand their infant's condition and offers them the opportunity to make choices concerning the extent of their participation in his end-of-life care (Workman, 2001).

1. Communication
- **a.** The following are suggestions for successful communication techniques to use with parents:
  - **(1)** Active listening
  - **(2)** Open communication
  - **(3)** Total presence
  - **(4)** Uninterrupted time for parents to express their wishes
  - **(5)** Nonverbal gestures such as touch
- **b.** Refer to the infant by name
- **c.** Inform parents of what to expect while their infant is dying (see, hear, smell, feel)
- **d.** Inform parents of their options for disposition of their infant's remains
  - **(1)** Transfer to morgue
  - **(2)** Pick up by mortuary
- **e.** Use language that does not confuse the parents.
  - **(1)** Use definite words such as *death, die,* and *dying* instead of euphemisms such as *not doing well* or *passing away*
  - **(2)** Words such as *good, stable,* or *better* could be misinterpreted to mean the infant could improve or survive

2. Environment
- **a.** Do not restrict the number of visitors
- **b.** Provide privacy and comfort
  - **(1)** Low lights
  - **(2)** Decreased noise and activity

3. Religion
- **a.** Ask parents about any religious preference
- **b.** Notify clergy of the parents' choice
- **c.** Offer baptism, blessing, anointing, or prayer

4. Parental activity
- **a.** Provide a stuffed animal
- **b.** Keep the family involved
  - **(1)** Decisions (medical and physical care)
  - **(2)** Handprints, footprints
  - **(3)** Kangaroo care, holding
  - **(4)** Bathing
  - **(5)** Dressing
  - **(6)** Changing diaper
  - **(7)** Any other parenting acts
  - **(8)** Taking pictures of the infant and family members at any time during this process

C. Active dying: the time period when the infant is dying offers special challenges for both the nurse caring for the dying infant and his family members. Pain management for the infant during the extubation and dying process is of extreme importance. Parents must be informed of what they may see, hear, and experience during this time. The family and infant should be offered a comfortable, private area for this process.

1. Pain management
- **a.** Maintain intravenous access
- **b.** Medicate the infant appropriately
- **c.** Assess pain routinely and frequently after the withdrawal of life support

2. Communication
- **a.** Inform the parents what to expect (see, hear, smell, feel)
- **b.** Inform the parents that their baby may not die immediately after removal of the endotracheal tube
- **c.** Be available for any questions or concerns the parents may have

3. Environment
- **a.** Do not restrict the number of visitors
- **b.** Provide privacy and comfort
  - **(1)** Low lights
  - **(2)** Decreased noise and activity

4. Religion
- **a.** If ceremonies or rituals have not been performed before now, offer any of the following:
  - **(1)** Clergy of choice
  - **(2)** Blessing, baptism, anointing, orprayer
- **b.** Parental activity
  - **(1)** Offer the opportunity to hold the baby during extubation
  - **(2)** Encourage the parents to notify the nurse if they believe their baby is in pain and needs assistance

Continued

BOX 35-1 Guideline for End-of-Life Care of the Neonate—cont'd

D. After death: once the infant has died, creating lasting memories is integral to the healing of the family. Regardless of whether the family participates in their infant's death care, no steps should be eliminated. When an infant dies, there are few, if any, memories of their time together, and parents will cherish any memento of their infant's life (Jansen, 2003). It is the nurse's responsibility to help ensure that as many memories as possible are created (Capitulo, 2005).

1. Communication
- **a.** Offer the parents opportunities to be involved with all aspects of after-death care.
- **b.** If parents decline, respect their decision, but gently remind them that this will be their only chance to perform these tasks.
- **c.** If parents decline, offer them the opportunity to help the nurse with the infant's care.
- **d.** Reassure the family that the nurse is available at any moment if assistance is required.

2. Environment
- **a.** A room with a bed and chairs for family and friends to be alone with their infant should be provided.
- **b.** Complimentary snacks and beverages should be made available.
- **c.** Family time with the infant should be unrushed and unlimited.

3. Parental activities
- **a.** Encourage the parents to hold and dress their infant.
- **b.** Offer the parents the opportunity to bathe their infant if this has not already been done.
- **c.** Offer the parents the opportunity to have family pictures taken at this time.

4. Memory makers: memory boxes should contain items that have meaning and have been a part of the infant's hospitalization. Objects that seem trivial to others will have profound significance for the family. They will be the only concrete evidence to the parents and family that their infant was alive. The nurse needs to be creative. There is no second chance to create memories for the family (Catlin and Carter, 2002).
- **a.** Identification band
- **b.** Name card
- **c.** Blood pressure cuff
- **d.** Oxygen saturation probe
- **e.** Thermometer
- **f.** Respiratory paraphernalia
- **g.** Measuring tape with infant's length marked and name and date written on it
- **h.** Polaroid or digital photographs pictures
- **i.** Stuffed animal
- **j.** Pacifier
- **k.** Diaper
- **l.** Lock of hair
- **m.** Handprints, footprints
- **n.** Swaddling blanket (do not discard blanket if soiled)
- **o.** Clothing (include postmortem gown, hat, socks, T-shirt; do not wash if soiled)
- **p.** Ring
- **q.** Mold of hand, foot, or both
- **r.** Cord clamp
- **s.** Phototherapy mask
- **t.** Dried washcloth and soap from bath, placed in a small plastic bag to preserve soap fragrance
- **u.** Black mourning (remembrance) pin

5. Final departure of parents: ensure that the parents do not leave with "empty arms"
- **a.** Memory box
- **b.** Stuffed animal
- **c.** Baby's blanket
- **d.** Pictures
- **e.** Baby's belongings

V. Nursing responsibilities
- **A.** Prepare the infant's body for transportation to the hospital morgue per hospital protocol.
- **B.** Complete the necessary paperwork.
- **C.** Ensure that all tasks are completed per hospital policy.

PART IX

Immunology and Infections

CHAPTER 36

Immunology of the Fetus and Newborn

Calvin B. Williams, Eli M. Eisenstein, and F. Sessions Cole

Understanding the contribution of the newborn infant's immunologic response to neonatal disease requires a review of the complex immunologic environment of pregnancy and the developmentally regulated changes in fetal and neonatal immunity. The contrasting functions of the fetal, neonatal, and maternal immunologic responses (i.e., preservation of fetal well-being as an allogenic graft versus adequate immunologic protection in a nonsterile extrauterine environment) are regulated by a host of incompletely understood developmental and genetic mechanisms. The diversity and importance of these mechanisms are suggested by the heterogeneity and frequency of the infectious problems encountered in newborns. Differences in immunologic responsiveness between adults and newborns should not be considered defects or abnormalities. Just as the ductus arteriosus, a cardiopulmonary necessity in the intrauterine environment, closes at different rates in different infants, human fetal and newborn infant immunologic response mechanisms are developmentally and genetically programmed to change from graft preservation to identification and destruction of invading pathogens at different rates.

MATERNAL AND PLACENTAL IMMUNOLOGY

Although pregnancy is a natural process that is essential for the propagation of all mammalian species, from an immunologic perspective it poses a great dilemma. The fetus represents a hemiallogenic graft that expresses paternal antigens, which under ordinary circumstances would be rejected as foreign tissue. The fact that such rejection ordinarily does not occur cannot be explained by systemic suppression of the maternal immune system. Most studies of maternal immune function during pregnancy have not shown significant abnormalities (Aagaard-Tillery et al, 2006) and are consistent with the clinical observation that pregnant women are not at increased risk for opportunistic infection. Furthermore, maternal acceptance of the fetus does not occur exclusively as a result of physical separation between immunogenic fetal and maternal tissues. Trophoblastic tissue expressing paternal antigens comes into direct contact with maternal immune cells, and fetal cells can readily be detected in maternal peripheral blood (Price et al, 1991). Conversely, maternal leukocytes and somatic cells are present in significant numbers in the fetus and may persist into adult life in a phenomenon known as *microchimerism* (Bianchi et al, 1996; Lo et al, 1996; Maloney et al, 1999). As a result, mechanisms must exist whereby antigen-specific responses against paternal antigens either are not initiated or are specifically suppressed. Beginning with the seminal studies of Peter Medawar more than 50 years ago, significant progress has been made in unraveling the immunologic mechanisms underlying maternal-fetal tolerance (Seavey and Mosmann, 2008; Trowsdale and Betz, 2006). Currently it appears that no single factor can explain the commensal immunologic relationship that exists between mother and fetus throughout pregnancy. Rather, several distinct but complementary innate and adaptive immune mechanisms contribute to this process.

Before fertilization, both systemic and local immunologic changes occur in the endometrium to favor acceptance of the fetal allograft. For example, progesterone induced by ovulation can reduce the proliferation of T cells and inhibit antigen-presenting cells (Ehring et al, 1998; Miyaura and Iwata, 2002). In addition, as discussed later, T cells with immunosuppressive properties accumulate cyclically in the endometrium during normal menses.

Semen has contrasting immunomodulatory effects on the female reproductive tract and immune system, respectively; however, seminal plasma induces expression of proinflammatory cytokines, including granulocyte-monocyte colony-stimulating factor (GM-CSF), interleukin (IL) 6, IL-8, and the chemokine monocyte chemotactic protein 1 by the uterine endometrium (Sharkey et al, 2007). These molecules help to induce a local inflammatory cell infiltrate containing macrophages, neutrophils, and dendritic cells, which may help to break down endometrial mucin and thereby facilitate adherence of the blastocyst to the endometrium (Dekel et al, 2010). GM-CSF also has embryotrophic effects that promote fetal growth and viability. Knockout mice lacking GM-CSF have normal implantation rates, but have 15% to 25% smaller litters (Robertson et al, 1999). However, semen contains immunosuppressive factors that teleologically are necessary to inhibit initiation of an immunologic reaction against sperm antigens. Therefore seminal plasma can induce secretion of the immunosuppressive cytokine IL-10 by monocytic cell lines (Denison et al, 1999) and is rich in transforming growth factor (TGF) β-family cytokines (Tremellen et al, 1998). TGF-β1 is essential for inducing local differentiation of certain forms of immunoregulatory T cells (Chen et al, 2003; Keskin et al, 2007).

Inflammatory mediators and cytokines produced by uterine tissues have a key role in embryonic implantation. Prostacyclin is expressed by uterine tissues by day 5 of gestation and is required for blastocyst adherence and subsequent placental decidualization (Lim et al, 1999). The IL-6 family of cytokines, which includes leukemia inhibitory factor (LIF), IL-11, and IL-6 itself, is also essential for placental implantation. This family of cytokines is defined by their receptors, which share a common signaling component, GP130, in addition to a cytokine-specific alpha chain. LIF is expressed by uterine endometrium, beginning during the mid-secretory phase of the menstrual cycle (Cullinan et al, 1996), probably in response to progesterone (Eijkemans et al, 2005). Implantation does not occur in LIF-deficient mice (Stewart, 1992). Interleukin-11, a cytokine that possesses hematopotic and antiinflammatory properties, has also been shown to be essential for implantation, albeit at a later stage than LIF. Placenta of mice deficient in the alpha chain of the IL-11 receptor fail to undergo decidualization, resulting in infertility (Robb et al, 1998). IL-6 itself is expressed by endometrial epithelial and stromal cells, mainly during the secretory phase of menses (Perrier d'Hauterive et al, 2004). Reduced expression of IL-6 mRNA has been noted in secretory-phase endometrium of women with recurrent miscarriages (Jasper et al, 2007). This finding was attributed to a possible role of IL-6 in facilitating placental decidualization and trophoblast development. In summary, an orchestrated series of specific proinflammatory and tolerogenic mechanisms support implantation and early fetal allograft survival.

TABLE 36-1 Selected Molecules of Immunologic Significance at the Fetal-Maternal Interface

Molecule	Expression Pattern	Functional Consequence
MHC class II	Not expressed by trophoblast, either constitutively or inducibly	Impaired $CD4^+$ T cell activiation
MHC Class I Molecules		
HLA-A, HLA-B	Not expressed by trophoblast	Impaired $CD8^+$ T cell activation
HLA-C	Expressed by trophoblast during 1st trimester	Modulation of NK cell function
HLA-G	Expressed by trophoblast	Inhibition of T cell and dendritic cell function; modulation of T cell and dendritic cell function
Fas ligand (CD178)	Expressed by placental decidual and glandular epithelium and by fetal trophoblast	Induces leukocyte apoptosis
PDL-1	Expressed on placental deciduas basalis	Immune inhibition Cofactor for induction of regulatory T cells
Galectins	Expressed by trophoblast early in pregnancy	Induction of T cell apoptosis

HLA, Histocompatibility leukocyte antigen; *MHC*, major histocompatibility complex; *NK*, natural killer; *PDL*, programmed cell death ligand.

STRATEGIES FOR IMMUNOLOGIC EVASION AT THE MATERNAL-FETAL INTERFACE

One possible way in which the hemiallogeneic fetus might avoid rejection is to evade detection by the maternal immune system. This approach clearly is not the entire explanation for tolerance of the fetal allograft. Indeed, fetal antigenic maturity in eliciting a maternal immunologic response has been well documented (Beer and Billingham, 1976; Billington, 1987). The view that maternal tolerance is an active process is further supported by observations that, at least in mice, maternal T lymphocytes specific for paternal antigens in particular are activated during pregnancy. In addition, the fact that paternally derived tumor cells are not rejected by pregnant female mice supports a central role for antigen-specific systemic immune inhibition (Tefuri et al, 1995); therefore, tolerance appears to be at least in part a metabolically active process. Nevertheless, several unique features of the maternal-fetal interface undoubtedly contribute to attenuation of antifetal immunity (Table 36-1).

One such mechanism is altered expression of major histocompatibility complex (MHC) proteins. MHC class II molecules are necessary for $CD4^+$ T cell responses, which contribute both effector and regulatory functions needed for graft rejection. MHC class II molecules are not ordinarily constitutively expressed, except by certain antigen-presenting cells; however, proinflammatory stimuli such as interferon (IFN)-γ are capable of inducing MHC class II expression on most cell types. In contrast, fetal trophoblastic tissues do not express MHC class II proteins, either in the resting state or in response to IFN-γ (Peyman et al, 1992). MHC class II gene silencing in trophoblasts is at least partially the result of the transcriptional repression of class II transactivator, a necessary transcription factor for class II gene expression (Murphy and Tomasi, 1998; Peyman et al, 1992).

More importantly, human trophoblasts also do not express conventional MHC class I human leukocyte antigen (HLA) A or HLA-B molecules. This fact undoubtedly contributes to reduced alloantigenic recognition at the fetal-maternal interface. Human trophoblasts express HLA-C, principally during the first trimester of pregnancy (King et al, 1996) and two nonclassic HLA molecules—HLA-E and HLA-G. The role of the latter in pregnancy has been studied extensively. HLA-G is a nonpolymorphic molecule encoded by a single gene that encodes seven alternatively spliced transcripts and exists as a protein in both membrane-bound and soluble forms. Its expression is primarily limited to fetal tissue, but it can be detected on some adult tissues, and its expression can be induced on other cells in response to infection, inflammation, or malignant transformation (Carosella et al, 2008). Unlike classical MHC molecules, HLA-G does not have a significant role in stimulating $CD8^+$ T cells via the T cell receptor complex. Rather, the principal function of HLA-G molecules expressed by the trophoblast appears to be modulating the activity of natural killer (NK) cells. HLA-G has also been shown to have other immunomodulatory properties, including inhibition of cytotoxic T cell activity, inhibition of alloproliferative responses by $CD4^+$ T cells,

and modulation of dendritic cell maturation and function (Carosella et al, 2008). These data reveal that the unique MHC class I molecule expression pattern on fetal trophoblast constitutes an intricate mechanism for orchestrating the activity of immune cells.

Several additional interesting molecules expressed at the maternal-fetal interface confer unique immunologic properties to this environment. Fas ligand (FasL) is expressed in both maternal and fetal components of the uteroplacental unit throughout gestation. Activated T cells express the Fas receptor, which delivers an apoptotic (death) signal when bound by FasL. Implicit in these observations is the hypothesis that expression of FasL limits the reciprocal migration of activated fetal and maternal T cells. This idea is strengthened further by experiments examining the homozygous matings between generalized lymphoproliferative disease (gld) mice, which make a nonfunctional FasL. Pregnant generalized lymphoproliferative disease (gld) mice demonstrate leukocyte infiltration and necrosis at the decidual-placental border, with many resorption sites and small litters (Hunt et al, 1997). Progesterone-induced blocking factor is an immunomodulatory molecule released in response to progesterone by trophoblastic cells (Anderle et al, 2008). Its properties include indirectly suppressing NK cell function and inducing bias of $CD4^+$ T cells toward Th2-type cytokine secretion (Szekeres-Bartho and Wegmann, 1996). The galectins represent a family of molecules expressed at the maternal-fetal interface with immunoregulatory properties. These glycoproteins regulate the immune response by recognition of cell surface glycans on immune cells. Galectins are expressed in human placenta primarily by the syntrophoblast early in pregnancy (Than et al, 2009). Upon cell surface contact, galectins downregulate the cellular immune response, in part by inducing programmed cell death (apoptosis) of T lymphocytes (Liu and Rabinovich, 2010).

A series of murine investigations points to a role for local metabolic factors in suppressing maternal T cell alloresponses in preventing spontaneous fetal loss. When monocytes are induced to differentiate into macrophages in vitro using macrophage colony-stimulating factor, they become inhibitors of T cell proliferation rather than activators. This inhibition was shown to be the result of selective degradation of tryptophan by the inducible enzyme indoleamine 2,3-dioxygenase (IDO). Serum tryptophan levels fall during pregnancy, possibly in response to IDO expression by syncytiotrophoblast cells, which make the enzyme as early as 7.5 days after coitus. Given the localization of IDO to the maternal-fetal interface and the immunosuppressive effects of tryptophan depletion, it seemed plausible to investigators that this pathway had a role in survival of the fetal allograft. This hypothesis was supported by experime nts with either normal or recombinase activating gene knockout mice, which lack T and B cells, together with the IDO inhibitor 1-methyl tryptophan. Normal mice carrying allogenic fetuses lose all their concepti by 11.5 days after coitus when they are treated with the inhibitor. In contrast, the delivery of healthy litters in RAG-deficient mice treated with 1-methyl-tryptophan demonstrates an immunologic basis for the observation (Munn et al, 1998). More recently, an additional tolerogenic mechanism influenced by tryptophan metabolism has been suggested by studies of the indirect influence of the IDO pathway on differentiation and activation of regulatory T lymphocytes (Baban et al, 2009; Chen et al, 2008). However, the lack of fetal rejection observed in female, genetically deficient IDO mice suggests that IDO may be necessary, but not sufficient, in maintaining tolerance during pregnancy (Baban et al, 2004).

Another possible mechanism through which the maternal immune system might be rendered relatively indifferent to the presence of fetal alloantigens concerns antigen presentation within the uterine environment. Dendritic cells (DCs) are a type of antigen-presenting cell that is critical for cellular and humoral immune responses. Collins et al (2009) recently reported that the migration of DCs from decidual tissue to draining uterine lymph nodes is impaired compared with myometrial DCs. Therefore placental entrapment of DCs might represent a way by which presentation of fetal antigens to the maternal immune system is retarded, thereby potentially inhibiting initiation of allogenic immune responses.

NK cells found in the placental decidua are referred to as *decidual NK cells* (dNK cells) to distinguish them from NK cells found in maternal blood and those found in the nonpregnant uterine endometrium (Yagel, 2009). These cells comprise 70% of decidual lymphocytes, express a $CD56^+CD16^-$ phenotype (Manaster et al, 2008), and have a unique gene expression profile which indicates that dNK cells are a unique cell population (Koopman et al, 2003). Furthermore, despite expressing high amounts of granzyme and other molecules necessary for mounting a cytotoxic response, these cells exhibit reduced cytotoxicity compared with peripheral blood NK cells (Kopcow et al, 2005) and were noncytotoxic to trophoblastic cells. In contrast to NK cells found in peripheral blood and tissues that have important innate immune functions, including surveillance against infection and tumor cells, it is not certain whether dNK cells have any role in immunity during pregnancy. Rather, they have been shown to have an essential role in promoting trophoblast invasion into the decidua and placental vascularization. These cells accomplish these tasks by secreting cytokines with effects on the placental vasculature including IFN-γ, chemokines that affect trophoblastic growth, and angiogenic factors including vascular endothelial growth factor, placental growth factor, angiopoietin-2, and NKG5 (Hanna et al, 2006).

To facilitate activation of dNK cells to perform their essential tissue remodeling functions, while at the same time avoiding overactivation that could possibly lead to cytotoxic damage to the trophoblast, their activity must be tightly modulated by a series of interactions between several activating and inhibitory receptors and their respective ligands (Manaster and Mandelboim, 2010). The nonclassic class I MHC molecules are among these dNK cell receptor ligands. For example, a principal physiologic ligand of β2-microglobulin–associated HLA-G is the inhibitory receptor leukocyte immunoglobulin (Ig)-like receptor 1 (Ponte et al, 1999). Free heavy chain HLA-G also binds to this receptor in a noninhibitory fashion, and this interaction could represent a feedback mechanism to avoid overinhibition (Gonen-Gross, 2010).

HLA-C is a major ligand for the different killer immunoglobulin-like receptors (KIRs), some of which are activating and others which are inhibitory. Amino acid allotypes at position 80 of HLA-C confer preferential binding to different forms of KIR, which in turn may result in clinically significant differences in dNK cell activation. Various combinations of maternal KIR and fetal HLA-C genes have been shown to confer differential risk for preeclampsia, as a result of differences in dNK cell-mediated placental vascular changes (Hiby et al, 2004).

A final innate immune condition necessary for successful completion of pregnancy is the absence of placental activation of complement. Fetal death occurs in mice that are genetically deficient in the complement regulatory protein Crry, accompanied by placental complement deposition and inflammation (Xu et al, 2000). Although there is no direct homolog of Crry in humans, complement inhibition has been shown to be essential for normal pregnancy in a murine model of the antiphospholipid syndrome, an autoimmune condition characterized by thrombosis, thrombocytopenia, and recurrent fetal loss. In this model, fetal injury occurs as a result of placental inflammation initiated by local dysregulation of complement proteins. Both complement activation and fetal loss can be prevented administering anticoagulants with complement-inhibitory properties such as heparin, but not by anticoagulants lacking complement-binding properties (Girardi et al, 2003, 2004). Some but not all human clinical interventional studies using anticoagulants with complement-binding properties to prevent fetal loss in the antiphospholipid syndrome have shown positive results (Di Nisio et al, 2005).

CYTOKINE SECRETION BY T CELLS DURING PREGNANCY

Bias in T cell cytokine secretion toward Th2-type cytokines and away from Th1-type cytokines has been proposed as an immunologic condition necessary for maintaining healthy pregnancy. Excessive exposure to Th1-type cytokines is clearly detrimental to the fetus. The Th1 cytokines IFN-γ and tumor necrosis factor-α have been shown to inhibit the growth of trophoblasts and to inhibit embryonic and fetal development (Haimovici et al, 1991). Th1 cytokines terminate normal pregnancy when injected into pregnant mice (Chaouat et al, 1990). Th2-type cytokines contribute to implantation as discussed previously, and to maintenance of pregnancy as suggested by LIF expression throughout pregnancy by placental leukocytes, decidua, and chorionic villous cells (Sharkey et al, 1999). LIF production by maternal T cells from healthy pregnancies is also positively associated with IL-4 production and inversely with IFN-γ (Piccinni et al, 1998). These studies have been interpreted to support the notion that the balance between Th1 and Th2 cytokines is important in maintaining pregnancy. However, it has been indicated that mice lacking all Th2-type cytokines (deleted by multiple genetic mutations) undergo normal allogenic pregnancies with normal litter sizes (Fallon et al, 2002). Based on this result, some investigators have concluded that Th1/Th2 cytokine shifts is an epiphenomenon that is irrelevant to maternal-fetal tolerance (Trowsdale and Betz, 2006).

ROLE OF REGULATORY T CELLS IN PREGNANCY

The mechanism whereby adaptive allogenic responses against paternal antigens are actively suppressed during pregnancy was largely unexplained until the discovery of a distinct lineage of T lymphocytes with dominant immunosuppressive properties (Brunkow et al, 2001). This type of regulatory T (Treg) cell is characterized by expression of a lineage-specific transcription factor, Foxp3. Upon activation via their antigen-specific T cell receptor, Treg cells are capable of suppressing immune effector cells, including dendritic cells and T effector cells through a variety of mechanisms (Tang and Bluestone, 2008), thereby preventing a fatal form of autoimmune disease throughout life (Kim et al, 2007). The ontogeny of Treg cells is discussed more fully in the section on adaptive immunity.

The possible role of Treg cells during pregnancy was first investigated in mice. These experiments disclosed that Treg cell numbers are expanded in peripheral lymphoid tissues, and this expansion is not dependent on the presence of alloantigen. Particularly high numbers of Treg cells are found at the maternal-fetal interface, where they comprise 30% of all $CD4^+$ T cells. Treg cells are not required for pregnancy in syngeneic mice, in which the fetus does not display any foreign paternal antigens. In contrast, in allogenic pregnancy in which the fetus expresses paternal antigens, Treg cell depletion resulted in pregnancy failure (Aluvihare et al, 2004). In another series of experiments examining an abortion-prone strain of mice, allogeneic pregnancy loss could be prevented by adoptive transfer of Treg cells from healthy mice (Zenclussen et al, 2005). These data provide a plausible mechanism whereby the adaptive immune system can actively suppress cellular immune responses directed against paternal alloantigens.

Another line of evidence from studies performed in mice provides additional indirect support for an essential role of Treg cells in maintaining fetal tolerance in mice. Programmed death-1 (PD-1) is an inhibitory receptor expressed on activated lymphocytes. There are two programmed death ligands (PDLs) for the PD-1 receptor, PDL-1 and PDL-2. PDL-1 is expressed on the decidua basalis, the portion of the placenta abutting the fetal trophoblast, and by Treg cells. Blockade of PDL-1 using antibodies in allogenic pregnancy results in T cell–mediated fetal loss, indicating an essential role for this molecule in preventing rejection of the fetal allograft (Wang et al, 2008). This effect of anti–PDL-1 antibody is abrogated when Treg cells are depleted. Furthermore, in PDL-1–deficient mice, suppressive activity of Treg cells was found to be impaired (Habicht et al, 2007). Finally, an independent series of experiments has demonstrated an important role for PD-1–PDL-1 interaction in Treg cells (Krupnick et al, 2005). These data support a critical role for PD-1–PDL-1 interactions in generating functional Treg cell populations necessary for successful allogenic pregnancy.

Studies of Treg cells in humans further support an essential role for this cell type in initiating and maintaining healthy pregnancy. Treg cells are increased in the peripheral blood of women during the late follicular and luteal phases of the menstrual cycle. This increase is believed to occur in response to estradiol (Polanczyk et al, 2004; Tai et al, 2008). Soluble factors in seminal fluid may contribute to further

local expansion of these cells at the time of copulation (Robertson et al, 2009). Human Treg cells selectively migrate to the placental decidua under the influence of soluble factors including human chorionic gonadotropin (Schumacher et al, 2009). Most but not all studies have shown that Treg cell numbers are increased in peripheral blood throughout pregnancy (Mjosberg et al, 2009; Somerset et al, 2004).

Alterations in Treg cells have been associated with certain pathologic conditions during pregnancy. Although preeclampsia does not appear to be associated with reduced numbers of Treg cells in peripheral blood, the ratio of Treg cells relative to $CD4^+$ T cells bearing proinflammatory phenotypic markers, such as Th17 cells, is abnormal in preeclamptic women (Santner-Nanan et al, 2009). In addition, toxoplasma infection in pregnant mice is associated with reduced numbers of Treg cells in peripheral lymphoid tissues (Ge et al, 2008). This observation raises the possibility that embryopathy associated with prenatal infection is caused in part by the maternal immune system, because of the breakdown of maternal-fetal tolerance as a result of altered Treg cell differentiation.

A fascinating permutation of the role of Treg cells during pregnancy concerns the effects of these cells on the developing fetal immune system. As already noted, fetal lymphoid tissues are microchimeric—that is, they contain small but significant numbers of maternally derived cells. Because not all maternal antigens are inherited, it would be expected that the fetal immune system would reject these cells. Recently it was demonstrated that maternal cells expressing noninherited maternal antigens (NIMAs) are tolerated by the fetal immune system as a result of active suppression by fetal Treg cells (Mold et al, 2008). In this study, Treg cell numbers were not found to be increased in the fetal thymus, but were markedly increased in number in fetal lymphoid tissues. It is therefore likely that these cells represent an induced rather than a natural Treg cell population, which differentiates in peripheral lymphoid tissues under the influence of TGF-β. It was also shown in this study that small numbers of these NIMA-specific Treg cells persist into childhood, but can be reactivated using appropriate stimuli.

This property of Treg cells has important clinical implications in the transplantation setting. Bone marrow and solid organ transplants are known to be more successful when either the donor or recipient expresses NIMA (Burlingham, 2009; Dutta et al, 2009; van Rood et al, 2009). This finding is explained by restimulation of dormant, NIMA-specific T_{reg} cells by transplanted cells expressing these antigens, thereby contributing to active tolerance of the graft. In addition to their potential relevance for developing future clinical strategies for improving transplantation outcomes while reducing the need for pharmacologic immune suppression (Burlingham, 2009), these findings also show that some of what is learned by the fetal immune system in utero is retained into childhood, and perhaps throughout life.

DEVELOPMENTAL FETAL-NEONATAL IMMUNOLOGY

The newborn infant, especially the preterm infant, is at increased risk for developing a considerable spectrum of opportunistic infections, including *Candida* spp., herpes simplex, and cytomegalovirus. Developmental and genetic differences between adults and infants in immunologic responsiveness account for much of this enhanced susceptibility (Adkins et al, 2004; Levy, 2007), although under certain circumstances neonates can mount adult-level responses (Marchant et al, 2003; Sarzotti et al, 1996). Research has focused on the molecular, cellular, and functional definitions of these differences. This discussion focuses on those developmental aspects of innate and adaptive immunity known to be important for fetal or neonatal responsiveness to infection.

INNATE IMMUNITY

During fetal adaptation from the sterile intrauterine environment to neonatal colonization of mucosal surfaces, the innate immune system shields the newborn from infection while helping to orchestrate the acquisition of protective adaptive immune responses (Levy, 2007). These innate mechanisms include protective barriers like the vernix caseoa, which contains antimicrobial peptides and fatty acids (Tollin et al, 2005), developmentally controlled regulation of toll-like receptor signaling (Fusunyan et al, 2001; Lotz et al, 2006), expression of acute phase reactants (Jokic et al, 2000; Levy 2007) and complement proteins, and alterations in neutrophil and monocyte function (Forster-Waldl et al, 2005; Levy et al, 2004, 2006a, 2006b). Importantly, functional maturation of innate immunity allows for colonization with commensal organisms while reducing potentially dangerous inflammatory responses.

Complement

The complement system, a principal component of the innate immune response, consists of more than 40 plasma, cell surface, and regulatory proteins that interact dynamically to regulate multiple physiologic functions, including resistance to pyogenic infections, interaction between adaptive and innate immunity, and elimination of immune complexes, products of inflammatory injury, and apoptotic self cells (Carroll, 2004; Walport, 2001a; Zipfel and Skerka, 2009). Components of the complement system recognize and lyse bacteria, opsonize microorganisms nonspecifically, release anaphylatoxins, solubilize immune complexes, and induce B-cell proliferation and differentiation.

Activation of the complement cascade can occur via three pathways—classic, lectin, or alternative. The activation steps in these pathways have been reviewed recently (Thiel, 2007; Zipfel and Skerka, 2009). Several characteristics of the complement cascade are important for the fetal–neonatal immunologic response. First, whereas the specificity of classic pathway activation results from interaction of antigens with antibodies of several isotypes, activation of the alternative and lectin pathways is antibody-independent and can be initiated by structures such as endotoxin and polysaccharides frequently expressed by pathogenic organisms. For the fetus or infant who has not yet produced antigen-specific IgG for immunologic recognition, the alternative and lectin pathways may be critical for triggering the effector functions of the complement cascade (Kielgast et al, 2003; Simister, 2003; Stossel et al, 1973; Zilow et al, 1997). Second, the enzymatic activation

of the complement cascade permits rapid amplification of its functions: deposition of a single immunoglobulin molecule or C3b fragment can generate enzymatic cleavage of thousands of later-acting components and thus multiple complement activities (Carroll, 2004; Walport, 2001a, 2001b; Zipfel and Skerka, 2009). In addition, the alternative pathway can be amplified via a positive feedback activation mechanism, because C3b, an activation product of the alternative pathway C3 convertase, is a component of this convertase (Janssen et al, 2006). Because of the importance of antibody-independent recognition for the immunologic responsiveness of the fetus and infant, the positive amplification loop of the alternative pathway is critical for rapid generation of complement effector functions without specific immunologic recognition. Third, the continuous activation of the alternative pathway requires rigorous regulation in the fetus to avoid tissue damage during organ remodeling (Zipfel et al, 2007). Finally, the contributions of the lectin pathway to fetal–neonatal complement activation and fetal well-being are still under investigation.

Complement activation via any of the three pathways occurs in four main steps: initiation of complement activation, C3 convertase activation and amplification, C5 convertase activation, and terminal pathway activity or the assembly of the membrane attack complex (Zipfel and Skerka, 2009) (Figure 36-1). Although the classic and lectin pathways may be triggered by recognition of ligands via complement activating soluble pattern recognition molecules (e.g., IgG or IgM antibodies, mannan-binding lectin [MBL], or the ficolins), the alternative pathway is spontaneously and constantly activated on biological surfaces in plasma and in most or all other body fluids (Pangburn and Muller-Ederhard, 1984). The spontaneous activation of the alternative pathway readily initiates amplification and requires rigorous regulation (Zipfel et al, 2007). Complement activation results in assembly of the first enzyme in the cascade, C3 convertase, via early-acting components of the classical (C1, C4, and C2), alternative (factor B, factor D, and C3), or lectin (MBL, L-ficolin, M-ficolin, H-ficolin, MBL-associated serine proteases [MASP-1, -2, -3]), and a smaller MBL-associated protein (MAp19) pathway. C3 convertase is assembled via highly specific and limited proteolysis. Proteolytically activated components form specific enzymatic complexes composed of classical (C2b and C4b), alternative (C3bBb), or lectin (C2b and C4b) pathway components, which proteolytically cleave C3 into C3a and C3b (see Figure 36-1). These two endopeptidases (C3bBb and C4bC2b) have identical substrate specificities; each cleaves the single peptide bond $Argine_{77}$–$Serine_{78}$ of the alpha chain of C3 (Janssen et al, 2006). The rates of formation and dissociation of both C3 convertases are regulated by multiple soluble (e.g., factor H, factor I, C4b-binding protein) and membrane-associated proteins (e.g., membrane cofactor protein, delay accelerating factor) (Zipfel and Skerka, 2009). During the first phase of complement activation, small (8 to 10 kD) peptides are released by proteolytic cleavage from the second (C2a), third (C3a), and fourth (C4a) components of complement. These fragments have anaphylatoxin and antimicrobial activities and can establish chemotactic gradients for effector cells (Nordahl et al, 2004). If C3b is deposited close to the site of generation and surface-bound convertases are formed, complement cascade activation can be amplified (Gros et al, 2008). If C3b fragments coat microbial or apoptotic surfaces, they opsonize the particles for phagocytosis. Although C3b deposition on the surface membrane of intact self cells can be prevented by regulators that block further complement activation, C3b deposition on microbial surfaces or on modified self cells that lack such regulators amplifies complement activation (Zipfel and Skerka, 2009). The role of non–inflammation-inducing, C3b-mediated removal of

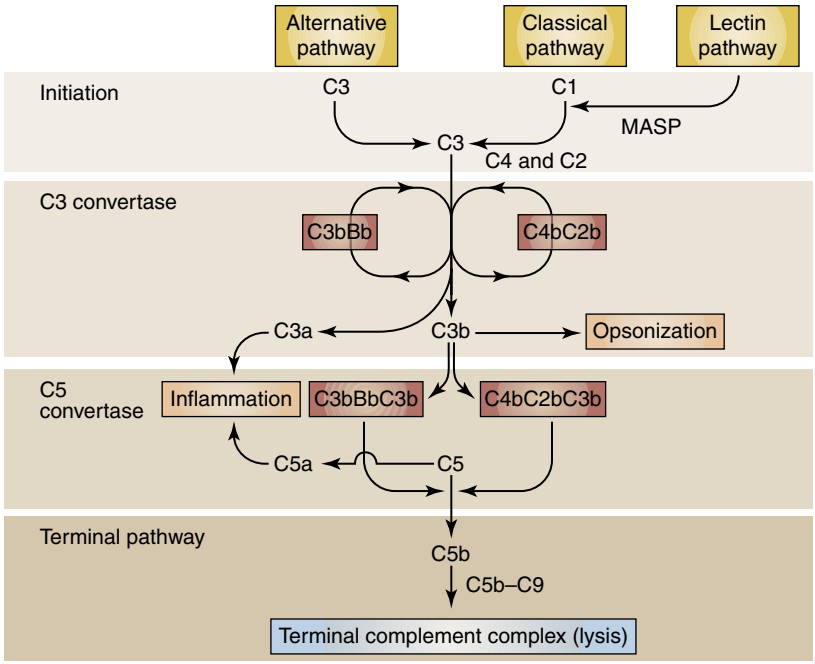

FIGURE 36-1 Summary of complement activation via the classic, alternative, and lectin pathways. *(From Zipfel PF, Skerka C: Complement regulators and inhibitory proteins*, Nat Rev Immunol *9:729-740, 2009.)*

cells during fetal organ remodeling has not been explored in detail.

If complement pathway activation continues beyond C3 cleavage, the binding of a second C3b molecule to either C3 convertase generates the alternative (C3bBbC3b) or classical or lectin (C4bC2bC3b) C5 convertases (see Figure 36-1). Both enzymes proteolytically cleave C5 to C5a and C5b. C5a is a powerful anaphylatoxin, and the C5b fragment can initiate activation of the terminal pathway (Ward, 2009). The C5a-induced inflammation and the C5b-initiated terminal pathway seem to be separately regulated (Zipfel and Skerka, 2009).

Binding of C5b to either of the active C5 convertases initiates directed, nonenzymatic assembly of the terminal pathway components C5, C6, C7, C8, and C9 to form the membrane attack complex (see Figure 36-1). The assembly and conformational changes of these soluble, hydrophilic proteins generate pores composed of lipophilic, membrane-inserting complexes (the membrane attack complex) that ultimately cause cell lysis by disrupting the osmotic gradient between the intracellular and extracellular environments (Morgan, 1999).

Studies of fetal and neonatal complement have focused on quantification of serum concentrations of individual components, examining maternal–fetal transport of these proteins, assessing specific effector functions of the classical and alternative pathways, and investigating contributions of complement activation to common neonatal diseases. In humans, Gitlin and Biasucci (1969) reported detectable concentrations of C3 (1% of adult levels) and C1 inhibitor (20% of adult levels) by immunochemical methods as early as 5 to 6 weeks' gestation. By 26 to 28 weeks' gestation, both C3 and C1 inhibitor concentrations increased to 66% of adult levels. Since these studies, multiple investigators have demonstrated that functionally and immunochemically measured classical and alternative pathway protein concentrations in cord blood increase with advancing gestational age and that they are only 50% to 75% of adult concentrations at full-term gestation (Sonntag et al, 1998; Wolach et al, 1997). Although cord blood lectin pathway component concentrations are lower than those in older children and adults, the correlation between MBL and gestational age has not been consistently observed (Hilgendorff et al, 2005; Kielgast et al, 2003; Kilpatrick et al, 1996; Lau et al, 1995; Swierzko et al, 2009; Thiel et al, 1995). The important roles of complement regulatory proteins, decay-accelerating factor, membrane cofactor protein, and CD59 have also prompted examination of the ontogeny of these proteins in the human fetus (Simpson et al, 1993).

On the basis of studies of genetically determined, structurally distinct complement variants in maternal and cord serum, no transplacental passage from mother to fetus of C3, C4, factor B, or C6 has been observed (Colten et al, 1981; Propp and Alper, 1968). The presence of detectable amounts of C2 and C1 inhibitor in cord blood, but not in the sera of mothers with genetic deficiencies of these proteins, suggests that fetal–maternal transport of these components does not occur.

Regulation of complement effector functions in the fetus and newborn infant has not been as extensively examined. Opsonization of invading microorganisms without specific immunoglobulin recognition requires activation of the alternative or lectin pathways. For infants born prematurely or without organism-specific maternal IgG, alternative or lectin pathway activation provides a critical mechanism for triggering complement effector functions (Maruvada et al, 2008; Super et al, 1989; Swierzko et al, 2009). For example, Stossel et al (1973) demonstrated opsonic deficiency in 6 of 40 cord sera examined because of decreased factor B concentrations, despite normal C3 and IgG levels. The functional contribution of the classic pathway to neonatal effector functions has been assessed through the use of cord blood–mediated opsonophagocytosis by adult polymorphonuclear leukocytes of group B streptococci type Ia (Edwards et al, 1983). This serotype may be opsonized by classical pathway components in the absence of specific antibodies and thus permits evaluation of the function of classical pathway activation. In 8 of 20 neonatal sera examined, decreased bactericidal activity was detected and correlated with significantly lower functional activity of C1q and C4. These studies did not determine whether this decrease was mediated by an inhibitor of function or by an intrinsic change in functional activity of these components in neonatal sera. The contribution of the lectin pathway to immunosusceptibility of the newborn infant has been suggested by studies of both MBL concentrations and pathway activity (Kielgast et al, 2003; Kilpatrick et al, 1996; Sumiya et al, 1991; Super et al, 1989; Swierzko et al, 2009; Thiel et al, 1995). Complement regulatory proteins (e.g., C4b-binding protein and factor H) also contribute to neonatal immunosusceptibility as suggested by the failure of neonatal serum to stop invasion by group B streptococci and *Escherichia coli* into human brain microvascular endothelial cells (Maruvada et al, 2008). The importance of the terminal complement component C9 for cytolysis of multiple isolates of *E. coli* was suggested by in vitro experiments in which killing of *E. coli* by neonatal serum samples was limited by C9, but not by other classical pathway components (Lassiter et al, 1992, 1994).

Although lower serum concentrations of classical, alternative, and lectin pathway complement proteins can contribute to enhanced susceptibility of infants to systemic infection, other complement functions important for fetal and neonatal well-being, but not related to antimicrobial response, can contribute to reduced capacity to activate the classical and alternative pathways. For example, reduced serum concentration of C4b-binding protein (8% to 35% of pooled adult plasma levels), which is a critical regulator of classical pathway C3 convertase activity, has been noted in fetal and neonatal sera (Fernandez et al, 1989; Malm et al, 1988; Melissari et al, 1988; Moalic et al, 1988). Lower C4b-binding protein concentration increases the functional anticoagulant activity of protein S, with which it complexes and thereby contributes to decreased coagulation function of the fetus and newborn. Consideration of functions besides immunologic effector functions may be important in furthering the current understanding of the developmental regulation of complement component production.

The contribution of complement activation to tissue injury has been investigated in several common neonatal diseases, including neonatal hypoxic ischemic encephalopathy, necrotizing enterocolitis, meconium aspiration

syndrome, and intrauterine growth restriction and fetal loss (Girardi and Salmon, 2003; Girardi et al, 2006; Lassiter, 2004; Mollnes et al, 2008; Schlapbach et al, 2008; Schultz et al, 2005). Concern has also been raised that unregulated complement activation can occur in selected infants who undergo extracorporeal membrane oxygenation therapy (Johnson, 1994; Kozik and Tweddell, 2006).

Complement activation is an important regulator of multiple functions of the host immunologic response. Further study of the fetus and newborn infant will be aimed at understanding the developmental and genetic regulation of immunologic and nonimmunologic functions of this important group of plasma and cell surface proteins.

Natural Killer Cells

NK cells are a component of the innate immune response and represent approximately 10% to 15% of all peripheral blood lymphocytes. NK cells are present in the spleen, lungs, and liver, but rarely are found in lymph nodes and thoracic duct lymph (Cerwenka and Lanier, 2001). Interestingly, NK cells are the major type of lymphocyte found in the maternal decidual tissue, where they represent up to 70% of all lymphocytes (King et al, 1996). NK cells are distinguished from other lymphocytes by their morphology, function, and expression of distinct surface molecules. Expression of the cell surface markers CD16 (FγRIII) and CD56 (nerve cell adhesion molecule-1) can be used to identify the NK population by analytical flow cytometry. Mature NK cells appear larger and more granular than T or B cells (Cooper et al, 2001) Mature NK cells are also distinguished by the presence of both activating and inhibitory receptors that are used to selectively identify and kill virally infected cells and tumors (Biassoni et al, 2001). NK receptors recognize MHC class I molecules on target cells, resulting in signals that suppress NK cell function. Target cells that are deficient in or lack MHC class I activate NK cell function, resulting in the release of lysosomal granules. These granules contain serine proteases, perforin, and TGF-β, which disrupt the target cell membrane and induce an inflammatory response. Studies show significantly lower NK cell activity in fetuses and neonates compared with adults (Georgeson et al, 2001; Kadowaki et al, 2001).

NK cells are derived from a common hematopoietic progenitor that retains T and B cell developmental potential (Boos et al, 2008). NK cells first make their appearance in fetal liver as early as 6 weeks' gestation. Committed $CD34^{+}CD56^{-}$ NK progenitors have been identified in the fetal thymus, bone marrow, and liver. In humans, there are several subsets of NK cells with distinct cell surface markers and function. For example, the $CD56^{high}$ $CD16^{-}$ subset is activated by IL-2 and also expresses CCR7 and CD62L, which allows these cells to traffic through lymph nodes (Di Santo, 2006). This subset is similar to NK cells that develop in the mouse thymus through an IL-7- and GATA3-dependent pathway and, in both species, is characterized by low cytotoxicity and enhanced cytokine production (Boos et al, 2008; Vosshenrich et al, 2006). In the human neonate, the NK population is immature; only half of all NK cells express CD56, and the NK cytolytic activity is lower (Dominguez et al, 1993). This functional reduction in NK activity has been proposed as a factor that contributes to the severity of neonatal herpes simplex virus infections. Profound defects in NK cell activity result in familial hemophagocytic lymphohistiocytosis, a disease characterized by fever, hepatosplenomegaly, cytopenia, hyperferritinemia, and hemophagocytosis. Familial hemophagocytic lymphohistiocytosis arises from mutations in genes that encode proteins involved in the granule-exocytosis pathway and is a fatal disorder without bone marrow transplantation (Jordan and Filipovich, 2008; Orange, 2006).

NK cell receptors are fundamentally different from the T cell receptor (TCR) and B cell receptor (BCR). NK receptor gene expression does not require gene segment rearrangement, and the receptors are not clonally distributed. Instead, NK cells use an array of stimulatory and inhibitory receptors to regulate their cytolytic functions (Lanier, 2008). A cluster of 10 or more genes encoding KIRs was located on human chromosome 19q13.4 (Biassoni et al, 2001; Lanier, 1998). Each of these type I glycoproteins recognizes a different allelic group of HLA-A–, HLA-B–, HLA-C–, or HLA-G– encoded proteins, and each KIR is expressed by only a subset of NK cells. Another family of immunoglobulin-like receptor genes termed *ILT* is present near the KIR locus at 19q13.3. These receptors are not as restricted as the KIRs and bind multiple HLA class I molecules. A third inhibitory receptor gene locus has been identified on chromosome 12p12-p13. These genes encode a C-type lectin inhibitory heterodimeric receptor called CD94/NKG2 that binds HLA-E. Importantly, those KIRs, ILT receptors, and CD94/NGK2 molecules with long cytoplasmic tails and two immunoreceptor tyrosine-based inhibitory motifs (ITIMs) function as inhibitory receptors. Upon phosphorylation, the two ITIMs recruit and activate the Src homology domain 2 (SH2)-containing phosphatases, which turn off the kinase-driven activation cascade (Ravetch and Lanier, 2000). The KIR family member KIR2DL4 is distinct from other KIRs in structure and distribution. KIR2DL4 binds HLA-G, has a single ITIM in the cytoplasmic tail and a lysine in the transmembrane region, which allows association with adaptor proteins. This inhibitory receptor was found on all dNK cells in the placenta at term, but not on circulating maternal NK cells. This observation suggests that expression of KIR2DL4 is induced during pregnancy (Rajagopalan and Long, 1999).

Other KIR or members of the C-type lectin superfamily serve as activating receptors (Moretta et al, 2001). These receptors lack the long cytoplasmic tail of the inhibitory receptors and therefore do not contain ITIMs. Instead, they have a charged amino acid in the transmembrane region that allows the receptor to associate with the adaptor molecule DAP12 (Lanier et al, 1998). This adaptor contains an immunoreceptor tyrosine-based activation motif (ITAM) that allows these receptors to activate NK cells. The physiologic role of these HLA class I–specific activating receptors remains unknown. Another group of NK cell–activating receptors has been identified and termed *natural cytotoxicity receptors* (Moretta et al, 2001). These proteins (NKp46, NKp30, NKp44) are immunoglobulin superfamily members with little similarity to one another or to other NK receptors. They are highly specific for NK cells and appear to interact with non-HLA molecules.

CD244 (2B4) is a member of the signaling lymphocyte activation molecule family of receptors expressed on all human NK cells (Ma, 2007). Upon interaction with the ligand CD48 on target cells, NK signaling proceeds via interactions between the ITSM (switch motif) in the cytoplasmic tail of CD244 and one of two SH2 domain-containing adaptor proteins, SAP and EAT-2. SAP interactions result in activation, as evidenced in humans with X-linked lymphoproliferative disease, which is caused by loss-of-function mutations in the SAP linker. In the absence of SAP, interactions with EAT-2 may be inhibitory (Lanier, 2008).

Polymorphonuclear Neutrophils

As observed for T and B lymphocytes, neonatal polymorphonuclear neutrophils (PMNs) are present at early stages of gestation, but their functional capacities are different from those of adult PMNs. Progenitor cells that are committed to maturation along granulocyte or macrophage cell lineages (granulocyte-macrophage colony-forming units) are detectable in the human fetal liver between 6 and 12 weeks' gestation in proportions comparable to those observed in adult bone marrow (Christensen, 1989). Human fetal blood has detectable granulocyte-macrophage colony-forming units from 12 weeks' gestation to term (Christensen, 1989; Liang et al, 1988). Although these progenitor cells are detectable in the fetus and newborn infant, developmental differences between adult and mature neonatal PMNs have been demonstrated—in signal transduction, cell surface protein expression, cytoskeletal rigidity, rolling adhesion, microfilament contraction, transmigration oxygen metabolism, intracellular antioxidant mechanisms, and extracellular trap formation (Carr, 2000; Henneke and Berner, 2006; Hill, 1987; Levy, 2007; Ricevuti and Mazzone, 1987; Yost et al, 2009). The severity of functional differences correlates with the maturity of the infant and begins to decrease within the first few weeks after birth (Carr, 2000).

Besides intrinsic differences in PMN function, induction of specific functions and maturation of these cells are developmentally regulated by the availability in the microenvironment of specific inflammatory mediators and growth factors (Christensen, 1989; Vercellotti et al, 1987). For example, an activation product of the fifth component of complement, C5a, is a chemoattractant at sites of inflammation. Low concentrations of C5 in neonatal sera might not permit establishment of chemoattractant gradients at sites of inflammation in newborns comparable to those in adults. Differences between adult and fetal–neonatal PMN functions may thus reflect intrinsic cellular differences required for fetal well-being and differences in the availability or activity of substances that regulate PMN function.

The recognition that systemic bacterial infection in newborns is frequently accompanied by profound neutropenia prompted the investigation of neutrophil kinetics in infected infants (Christensen et al, 1980, 1982; Santos, 1980). These studies have suggested diverse, developmentally specific regulatory mechanisms required for mobilization of the neutrophil response to infection. The lack of neutrophil precursors in bone marrow aspirates of infected infants and systemic neutropenia motivated several investigators to give neutrophil replacement therapy to neutropenic, infected infants (Christensen et al, 1980). Although this approach has been successful in some cases, the results have not been uniformly beneficial (Cairo, 1987; Cairo et al, 1984; Menitove and Abrams, 1987; Stegagno et al, 1985). Similarly, the use of granulocyte CSF or GM-CSF to treat infants with suspected infection has generally not shown a reduction in mortality (Carr et al, 2003). This heterogeneity emphasizes the importance of individualizing immunologic interventions for the developmental stage of the infant and the invading microorganism being treated.

Monocytes and Macrophages

Cells committed to phagocyte maturation (granulocyte or monocyte-macrophage) are detectable in the human fetal liver by 6 weeks' gestation and in peripheral fetal blood by 15 weeks' gestation. Unlike granulocytes, whose tissue half-life is hours to days, macrophages migrate into tissues and reside for weeks to months. In a tissue-specific fashion, these cells regulate availability of multiple factors, including proteases, antiproteases, prostaglandins, growth factors, reactive oxygen intermediates, and a considerable repertoire of cytokines.

The importance of macrophages in the neonatal response to infectious agents has been documented in multiple studies. For example, increased antibody response and protection from lethal doses of *Listeria monocytogenes* were induced in newborn mice by administration of adult macrophages (Lu et al, 1979). Functional differences in chemotaxis, phagocytosis, and toll-like receptor signaling between adult and neonatal cells have been observed and most likely result from both intrinsic fetal–neonatal monocyte-macrophage characteristics, such as reduced IL-12p70 production, and from nonmacrophage factors (e.g., decreased production of the lymphokine IFN-γ) (English et al, 1988; Kollmann et al, 2009; Levy, 2007; Stiehm et al, 1984; van Tol et al, 1984). Inducible expression of individual complement proteins by lipopolysaccharide (LPS), a constituent of gram-negative cell walls, has also been shown to differ between adult and neonatal monocyte–macrophages (Strunk et al, 1994; Sutton et al, 1986). This difference suggests that, although signal transduction mediated by LPS, LPS-induced transcription, and accumulation of mRNAs, which direct the synthesis of the third component of complement and factor B, are comparable in adult and neonatal cells, a translational regulatory mechanism does not permit these important inflammatory proteins to be synthesized by LPS-induced neonatal cells. This observation emphasizes the fact that fetal–neonatal monocytes–macrophages can have functions developmentally distinct from those of adult cells. For example, in utero production of growth factors and removal of senescent cells during tissue remodeling may be critical to fetal development (Kannourakis et al, 1988). Concurrent induction of these functions and immunologic effector functions in fetal monocyte–macrophages would potentially elicit nonspecific inflammation in actively remodeling tissues.

Besides having antibacterial functions, neonatal monocyte–macrophages contribute to tissue-specific regulation of the microenvironment in individual organs. For

example, considerable attention has focused on the contributions of these cells to antioxidant defenses and to regulation of protease-antiprotease balance. Because of the importance in tissue injury and repair, tissue and injury-specific treatment by appropriately targeted and primed monocyte–macrophages may provide therapeutic options for treating a spectrum of problems, from oxygen toxicity in the lung to hemorrhage in the brain.

ADAPTIVE IMMUNITY

Lymphocytes play multiple critical roles in the adaptive immune responses. Major lymphocyte lineages identified by cell surface and functional criteria include T, B, and NK cells (Kawamoto and Katsura, 2009). All three types develop from $CD34^{+}CD38^{dim}$ hematopoietic stem cells found in the fetal liver and bone marrow (see Figure 36-1). CD34 is also expressed on early committed progenitors, which differentially express other markers usefully in lineage determination. Some early T cell progenitors retain myeloid potential, suggesting a revision of the classic model base on the presence of a common lymphoid progenitor (Bell and Bhandoola, 2008; Wada et al, 2008). The process of lymphocyte differentiation is best viewed as a progressive narrowing of differentiation potential based on the sequential expression of specific transcriptional regulators (Mansson et al, 2010).

T Lymphocytes

T lymphocytes or T cells develop in the thymus, which is formed from the third branchial cleft and the third or fourth brachial pouch. Thymic lobes are generated when tissue from these sites moves caudally to fuse in the midline. Each lobe can be divided into three regions based on structure and function: the cortex, the corticomedullary junction, and the medulla. The thymic cortex is composed of specialized epithelial cells that express MHC class I and class II molecules and mediate the early stages of T cell maturation. This complex developmental process (Figure 36-2) begins when multipotent $CD1a^{-}$, $CD5^{-}$, $CD34^{+}$, and $CD38^{low}$ stem cells enter the thymus at the corticomedullary junction and migrate into the outer cortex (Awong et al, 2009; Res et al, 1996). Maturation continues as cells migrate back through the cortex toward the corticomedullary junction. The first committed T cells express low levels of CD4 and show DNA rearrangement at the TCR δ gene locus. These events are followed by low levels of CD8 expression and by rearrangement at the TCR-β locus, which generates a pre-TCR on the cell surface (Spits et al, 1998). The pre-TCR is composed of several polypeptides, including a TCR-β chain and the invariant pre-Tα chain. Expression of the pre-TCR serves as an important developmental checkpoint (beta selection; von Boehmer and Fehling, 1997). Cells that do not successfully rearrange their TCR-β chain cannot express the pre-TCR and die by apoptosis (Falk et al, 2001). The remaining cells generate antigen-specific receptors when the TCR-α chain replaces pre-Tα. These intermediate- to late-stage progenitors also express both the CD4 and CD8 coreceptors and are called *double positives*. The minor population of δγT cells follows a similar developmental pattern.

Small double-positive cells ($CD4^{+}$, $CD8^{+}$, TCR^{low}) constitute approximately three fourths of all thymocytes, reflecting the critical and rate-limiting developmental stage that follows. Further maturation requires that the unique TCR on each thymocyte interact with self-peptide–MHC complexes expressed on the surface of thymic epithelial cells. Several factors control the outcome of this interaction, including the strength and timing of the TCR signal generated and the nature of the antigen-presenting cell (Hogquist et al, 2005). The TCR and associated CD3 signaling complex translate subtle differences in the affinity of ligand binding into cell fate decisions through induced conformational changes in the CD3 signaling complex (Dave, 2009; Gil et al, 2005; Hayes, 2005), differential utilization of mitogen-activated protein kinase signaling pathways (Sohn et al, 2008; Sugawara et al, 1998), and subcellular compartmentalization of mitogen-activated protein kinase proteins (Daniels et al, 2006). Heterogeneity among thymic epithelial cells and the peptides that they

present also contributes to the complexity of the selection process (Klein et al, 2009).

In the affinity-based model of thymic selection (see Figure 36-2), thymocytes that are unable to interact with thymic cortical epithelial cells fail to generate a survival signal and die by apoptosis, the default pathway for most developing cells. Weak interactions generate survival signals and continued development of positive selection. Studies in mice show that the result of positive selection is a thymocyte population containing a high frequency of cells that are broadly cross-reactive for multiple MHC alleles (alloreactivity) and for multiple peptides (Huseby et al, 2005). For many positively selected cells, subsequent high-avidity interactions with bone marrow–derived antigen-presenting cells in the thymic medulla result in activation-induced apoptosis or negative selection (Gong et al, 2001). Negative selection effectively culls from the positively selected pool of cells with cross-reactive TCR and is the primary mechanism for the elimination of self-reactive T cells (Huseby et al, 2003). For a small subset of thymocytes, high-affinity interactions with an agonist ligand can also induce a transcription factor, Foxp3, that is associated with regulatory T cell development rather than cell death (Jordan et al, 2001; Relland et al, 2009). Following avidity-based selection, mature T cells that express either the CD4 or CD8 coreceptor and a single TCR heterodimer are found in the thymic medulla just before the egress into the peripheral circulation. In the human embryo, the first naive, mature T cells appear at approximately 11 to 12 weeks of embryonic development. Thymopoiesis continues for many years thereafter, and integrity of this process is essential for a healthy immune system. Thymectomy early in life results in a substantial loss of naive T cells and in an oligoclonal memory T cell compartment (Prelog et al, 2009; Sauce et al, 2009). The decay process is accelerated by chronic CMV infection, resulting in an immunosenescent T cell phenotype similar to that seen in elderly individuals and associated with increased morbidity and mortality (Wikby et al, 2006).

The final phase of T cell development is independent of the thymus and involves peripheral (lymph nodes, spleen- and gut-associated lymphoid tissue) homeostatic mechanisms. These poorly understood events control the expansion of clones recognizing specific antigens and the development of T cell memory. Peripheral repertoire selection begins with migration of lymphocytes from the blood into lymphatic tissue. Naive T cells express the adhesion molecule L-selectin (CD62L) that interacts with peripheral-node addressins, a group of sialomucins present on high endothelial venules. Lymphocyte attachment, coupled with the shear forces produced by blood flow, results in rolling of the lymphocytes along the endothelial cell surface. Signals mediated by CC-chemokine receptor 7 (CCR7) molecules on the surface of rolling lymphocytes result in their tight binding to endothelial cells via integrins and in transendothelial migration (Forster et al, 2008). After entering the lymph nodes, movement of lymphocytes is also controlled by chemokines and their receptors (Worbs et al, 2007). CCR7 signaling directs cells to the T cell areas, whereas CXCR5-mediated signaling controls movement to B cell follicles (Reif et al, 2002). After activation, changes in chemokine receptor expression control the mobilization and function of lymphocytes within the lymph nodes.

T cell activation requires a complex molecular cascade that results in reorganization of signaling molecules in the membrane into an "immunological synapse" and in signal transduction (Bromley et al, 2001). Many of the important biochemical events in this process have been described. TCR engagement by an appropriate MHC–peptide ligand results in phosphorylation of components of the CD3 complex. The CD3 complex is composed of the αβTCR and γ, δ, ε and ζ chains. These later molecules all contain specific amino acid sequences called *ITAMs*, which serve as molecular targets for the tyrosine kinases fyn and lck. The ζ chain is thought to be the most critical component and is found as a homodimer. Each ζ chain contains three ITAMs, which will bind the tyrosine kinase Zap-70 when sequentially phosphorylated. Appropriate phosphorylation of ζ results in a downstream cascade that involves the tyrosine phosphorylation of multiple cellular substrates including phospholipase Cγ1, the guanine nucleotide exchange factor Vav, and the adaptor protein Shc. Ultimately the genetic program of the cells is altered, leading to the transcription of genes for cytokines, cytokine receptors, and transcription factors (Cantrell, 2002).

After activation, $CD4^+$ T cells differentiate into Th1, Th2, or Th17 effector cells or become induced Treg cells (Figure 36-3) (Murphy and Reiner, 2002; Zhu et al, 2010). Each of these $CD4^+$ T cell types is defined by prototypical transcription factors and by secretion of a characteristic profile of cytokines in response to antigenic stimulation. The cytokine milieu in the local environment during antigen presentation is a primary factor influencing the developmental fate of a naive T cell following activation. IL-12 promotes Th1 cell development by a signal transducer and activator of transcription 4–dependent mechanism and

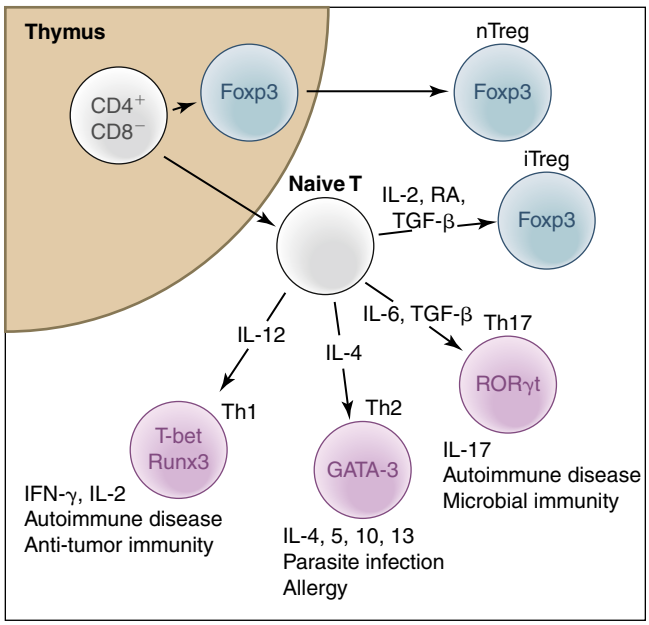

FIGURE 36-3 Cytokines and transcription factors associated with T cell differentiation. *IFN*, Interferon; *IL*, interleukin; *iTreg*, inducible regulatory T cell; *nTreg*, natural regulatory T cell; *TGF*, transforming growth factor. *(From Sakaguchi S, Yamaguchi T, Nomura T, et al: Regulatory T cells and immune tolerance,* Cell *133:775-787, 2008.)*

results in expression of the transcription factor T-bet. Th1 cells secrete IL-2, IFN-γ, lymphotoxin alpha, and tumor necrosis factor-α. Th1 responses are generally proinflammatory. Th1 cytokines act synergistically to lyse virally infected cells and activate antigen-presenting cells as well as granulocytes. In addition to being the signature cytokine of Th1 cells, IFN-γ also promotes the development of the Th1 phenotype and inhibits the development of Th2 cells (Lighvani et al, 2001). Human neonatal T cells are biased against Th1 polarization relative to adult T cells (Levy, 2007). This bias has been linked to reduced IL-12(p35) gene expression by dendritic cells (Goriely et al, 2001, 2004) and IL-4–dependent apoptosis of Th1 cells after reexposure to antigen (Li et al, 2004). Poor Th1 function is associated with impaired killing of intracellular pathogens and a reduction in vaccine responsiveness (Levy, 2007).

IL-4–mediated activation of the transcription factor STAT6 is required for Th2 cell development (Kaplan et al, 1996). STAT6 activation drives expression of another transcription factor, GATA3, which promotes Th2 cell differentiation. Th2 cells produce IL-4, IL-5, IL-10, and IL-13. IL-4 induces immunoglobulin heavy-chain class switching to the IgE isotype and promotes the development of the Th2 phenotype. IL-5 is an eosinophil growth factor. Thus, Th2 cells are thought to promote antibody production and the allergic response by multiple mechanisms (Ouyang et al, 2001). Human fetal T cells are biased toward Th2 polarization (Prescott et al, 1998), and their abundant representation in the neonate contributes to the Th2 skewing of neonatal responses (Adkins et al, 2004).

The cytokines TGF-β and IL-6 activate STAT3, which induces the expression of the transcription factor RORγt and Th17 cell differentiation (Littman and Rudensky, 2010). Th17 cells, which are named for their secretion of the cytokine IL-17A and related family members, are proinflammatory cells associated with the clearance of intracellular pathogens and protection from infection by a number of bacterial and fungal species (Weaver et al, 2007). Abnormalities in Th17 cell development and function are also linked to immunodeficiency and autoimmunity. For example, humans with mutations in molecules affecting Th17 cell differentiation have the hyper-IgE syndrome (Al Khatib et al, 2009; de Beaucoudrey et al, 2008), and genes associated with Th17 cell differentiation are associated with increased susceptibility to Crohn's disease (Brand, 2009).

Activation of naive T cells requires a second signal, and the most potent costimulatory molecule is CD28. The ligands for CD28 are B7-1 and B7-2, which are present on the surface of antigen-presenting cells. Cytotoxic T-lymphocyte antigen 4 (CTLA-4), a molecule expressed only on activated T cells, also binds B7-1 and B7-2 and functions as a negative regulator of T cell activation. Experiments with knockout mice demonstrate that CD28 is the major costimulatory receptor and that signaling through CTLA-4 attenuates CD28-dependent responses (Alegre and Thompson, 2001; Subudhi et al, 2005). A maturational delay in the development of costimulatory function that contributes to reduced T cell responses in the neonatal period has been suggested (Orlikowsky et al, 2003), and the expression of costimulatory molecules is further suppressed by treatment with dexamethasone (Orlikowsky et al, 2005).

Control of the clonal proliferation seen in a primary immune response involves a number of inhibitory mechanisms, including Fas/FasL–mediated cell death, ligation of the cell surface molecule PD-1, and regulatory T cell–mediated suppression (Haribhai et al, 2007; Lettau et al, 2009; Riley, 2009; Sakaguchi et al, 2008). These mechanisms reset the peripheral immune system and thereby maintain adequate clonal diversity. A small number of activated T cells survives, and these cells differentiate into memory cells (Wakim and Bevan, 2010). Memory cells are defined by function (i.e., more rapid response) and by expression of certain cell surface markers. The transcription factors T-bet and eomesodermin influence memory development, probably by controlling expression of IL-7R and IL-15R (Intlekofer et al, 2005; Pearce et al, 2003). These receptors are linked to cell survival. Early memory T cells are L-selectin^{low}, CD45RO^{high}, and CD44^{high}. Late memory cells can become L-selectin^{high}, which is a surface marker seen in naive T cells. The ultimate number of memory cells has been shown in mice to reflect the initial antigenic load and clonal burst size. Memory T cells allow the secondary response to be more rapid and more potent, characteristics that form the basis for vaccinations. The memory phenotype is not seen early in life, but increases with age. The precise mechanisms that generate and maintain memory T cells have not been determined, although it is known that the persistence of CD8$^+$ memory T cells in mice does not depend on the persistence of specific antigen (Surh and Sprent, 2002; Williams and Brady, 2001). In one study, preterm and term infants developed comparable memory T cell responses after vaccination (Klein et al, 2010).

Immunocompetent T cells capable of responding to foreign lymphocytes in the mixed lymphocyte reaction are found in the fetal liver at 5 weeks' gestation. Before 8 weeks' gestation, lymphocytes are not detectable in the fetal thymus. After 8 weeks, lymphoid follicles, T lymphocytes, and Hassall's corpuscles can be identified. By 12 to 14 weeks' gestation, T lymphocytes can be found in the fetal spleen (Timens et al, 1987). By 15 to 20 weeks' gestation, the fetus has readily detectable numbers of peripheral T lymphocytes. The first T cell proliferative responses that occur are to mitogens and can be measured at approximately 12 weeks' gestation. By 15 to 20 weeks' gestation, antigen-specific responses can be detected (Adkins, 1999; Garcia et al, 2001). Fetal growth has been shown to influence T, B, and NK lymphocyte counts by 3% to 6% per week increase of gestational age (Duijts et al, 2009). Maturation of immune responses continues throughout the first year of life, a fact that affects vaccination schedules (Gans et al, 1998). A low level of thymopoiesis has been shown to continue into adulthood (Kennedy et al, 2001).

Regulatory T Cells

Natural regulatory T cells develop as a distinct lineage in the thymus dedicated to maintaining self tolerance (Sakaguchi et al, 2008). Induced Treg cells arise in the periphery from conventional CD4$^+$ T cells activated in the presence of TGF-β (Curotto de Lafaille and Lafaille,

2009). Expression of the forkhead-winged helix transcription factor Foxp3 ultimately identifies these cell types and is essential for the acquisition of suppressive effector function (Zheng and Rudensky, 2007). Treg cells are required for the maintenance of immunologic tolerance, as illustrated by the autoimmunity that arises after neonatal thymectomy and by the fatal autoimmune lymphoproliferative disease that develops shortly after birth in mice and humans deficient in Foxp3 (Bennett et al, 2001; Brunkow et al, 2001; Chatila et al, 2000; Sakaguchi et al, 1995; Wildin et al, 2001).

Treg cells have risen to the forefront of research in immunology because of their essential role in maintaining immunologic tolerance. Preclinical animal models have demonstrated that adoptive transfer of Treg cells can prevent or cure diabetes, experimental allergic encephalomyelitis (multiple sclerosis), inflammatory bowel disease, lupus, arthritis, and graft-versus-host disease (Hori et al, 2002; Kohm et al, 2002; Morgan et al, 2005; Mottet et al, 2003; Scalapino et al, 2006; Tang et al, 2004; Tarbell et al, 2004; Taylor et al, 2002). In humans, removal of Treg cells in vitro enhances the proliferation of T cells in response to self-antigens (Danke et al, 2004). Defects in Treg cell function and number have been described in a number of different human autoimmune diseases, including diabetes, multiple sclerosis, rheumatoid arthritis, and juvenile idiopathic arthritis (Baecher-Allan and Hafler, 2006). Clinical trials using the adoptive transfer of Treg cells after allogenic hematopoietic stem cell transplantation as therapy for graft-versus-host disease have begun in Germany and are planned in the United States (Roncarolo and Battaglia, 2007).

B Lymphocytes

B cells are lymphocytes that upon activation give rise to terminally differentiated, immunoglobulin-secreting plasma cells. Immunoglobulins form the humoral arm of the immune system and provide the main form of protection against many pathogens. B cell development can be divided into embryonic and adult phases. The embryonic phase begins in the fetal liver at the same gestational age as T cell development, follows a similar time course, and uses similar developmental strategies. The adult phase occurs in the bone marrow and continues throughout life. In both phases, B cell progenitors are selected at key developmental checkpoints for the presence of a functional BCR rearrangement and for the absence of BCR self-reactivity. Those progenitors with self-reactive receptors are either eliminated or generate new antigen receptors by continued gene segment rearrangements that are not self-reactive. Both B cell development and peripheral B cell homeostasis require signal transduction through the BCR. Although the B cell compartment is well formed before birth, diversification of the antibody repertoire and several important antibody responses are not developed until long after the neonatal period (Hardy and Hayakawa, 2001; Rohrer et al, 2000; Rolink et al, 2001; Yankee and Clark, 2000).

B cell development begins before 7 weeks' gestation in the human fetal liver, and pre-B cells in various stages of maturation are seen by 8 weeks' gestation. By 8 to 10 weeks' gestation, $CD34^+$ hematopoietic stem cells are also found in the bone marrow. The early phase of B cell development, like T cell development, is antigen independent. The first committed progenitors (pro/pre-B-I) express CD34, terminal deoxynucleotidyl transferase (TdT), recombinase-activating genes (RAG) and CD19 (Li et al, 1993). They lack immunoglobulin gene rearrangement (Allman et al, 1999). The next lineage is marked by heavy chain (H) diversity to joining (D_H to J_H) gene segment rearrangements followed by variable to diversity/joining segment rearrangement. Terminal deoxynucleotidyl transferase is used during this process to insert nucleotides between the segments to create additional diversity at a region that encodes the V_H portion of the antibody-binding site. Late cells in this stage express an invariant surrogate light chain (Kitamura et al, 1992). The normal light chain genes remain in germline configuration.

The first developmental checkpoint in B cell development requires expression of surrogate light chain together with Ig-α and Ig-β on the cell surface as the pre-BCR, marking the transition to the pre–BII stage. Expression of the pre-BCR is essential for positive selection of cells that have a functional μH chain rearrangement and for expansion of the pre–B cell lineage (Gong and Nussenzweig, 1996). Cells with a nonfunctional H chain rearrangement or with H chains that assemble poorly with surrogate light chain are unable to progress. V_L to J_L rearrangement takes place next, and the newly expressed polymorphic L chain protein replaces the surrogate light chain. The completed BCR is antigen-specific and contains the mIgM molecule. A second developmental checkpoint occurs here, and those B cells with self-reactive receptors are eliminated or edited (Hartley et al, 1991). Only 10% to 20% of the immature B cells survive this negative selection and migrate to the spleen, which they enter through the terminal branches of the central arterioles. Once in the spleen, they rapidly differentiate into $mIgM^+$, $mIgD^+$, $B220^+$ mature B cells that enter the recirculating pool of B lymphocytes (Hardy and Hayakawa, 2001).

When mature B cells contact antigen through the BCR, a signal is transduced that promotes further growth and differentiation into surface Ig^+ memory cells and plasma cells (Calame, 2001). BCR signaling involves activation of the tyrosine kinases Syk and Btk, which are also involved in pre-BCR signal transduction. Certain mutations in Btk result in a failure of pre-BCR signaling and lead to X-linked agammaglobulinemia. Many B cell responses use the ability of B cells to capture antigen at vanishingly low concentrations, process the antigen into small peptide fragments, and then present the antigen to Th cells in the context of MHC class II molecules. Antigen-specific T cells then form conjugates with antigen-presenting B cells. The T cell membrane protein gp39 interacts with CD40 on B cells and triggers B clonal expansion, cytokine responsiveness, and isotype switching.

B lymphocytes with surface IgM are first found in the human fetal liver at 9 weeks' gestation and in the fetal spleen at 11 weeks' gestation (Owen et al, 1977; Timens et al, 1987). Antigen-specific antibody production can be detected in the human fetus by 20 weeks' gestation. Fetal spleen cells can synthesize in vitro IgM and IgG by 11 and 13 weeks' gestation, respectively.

TABLE 36-2 Characteristics and Functions of Immunoglobulins

	Molecular Weight (kD)	Serum Concentration (g/L)	Serum Half-life (Days)	Neutralization	Opsonization
IgG1	150	10	21	++	+++
IgG2	150	5	21	++	(+)
IgG3	170	1	7	++	++
IgG4	150	0.5	21	++	+
IgA1	160	3	7	++	+
IgA2	160	0.5	7	++	+
IgM	900	2	5	+	+
IgD	180	0.03	3	–	–
IgE	190	0.00003	3	–	–

Immunoglobulins

Immunoglobulins are a heterogeneous group of proteins that are detectable in plasma and body fluids and on the surfaces of mucosal barriers and B lymphocytes. Although these proteins have multiple, diverse functions, they are classified as a family of proteins because of their capacity to act as antibodies—that is, to recognize and bind specifically to antigens. The rapid advances in understanding molecular structure and regulation, genetic diversity, and differences in functions of immunoglobulins have been reviewed recently (Bengten et al, 2000; Mix et al, 2006). The functions of immunoglobulins relevant to fetal and neonatal immunity are summarized in Table 36-2.

There are five known classes of immunoglobulins: IgG, IgM, IgA, IgE, and IgD. Human IgM circulates as a pentamer or hexamer and IgA as a dimer. Multimers are formed in association with an additional J-chain (or joinchain). Functions of individual immunoglobulin classes are different but overlapping (see Table 36-2) (Mix et al, 2006). The prototype immunoglobulin molecule consists of a pair of identical heavy (H) chains that determine the immunoglobulin class in combination with a pair of identical light (L) chains (Figure 36-4). Disulfide bonds and electrostatic forces link the chains. Each immunoglobulin molecule contains two N-terminal, identical domains with antigen-binding activity (Fab). The Fab fragment consists of variable (V_H and V_L) and constant (C_H and C_L) regions on both the H and L chains. The Fab domains function to bind antigenic epitopes via complementarity determining regions. A third fragment (i.e., F crystalline [Fc]) is devoid of antibody activity, but mediates immunoglobulin effector functions (Table 36-3). The principal functions of the Fc fragment include: receptor-mediated phagocytosis (IgG1/3 and IgA), cytotoxicity (IgG1/3), release of inflammatory mediators (IgE), receptor-mediated transport through mucosa (IgA and IgM) and placenta (IgG1/3), and complement activation (IgG1/3 and IgM). The five different isotype classes of human immunoglobulins (IgG, IgM, IgA, IgD, and IgE) are defined structurally by differences in the Fc fragments. Within isotypes, there are four IgG subclasses (IgG1, IgG2, IgG3, and IgG4) and two IgA subclasses (IgA1 and IgA2).

Immunoglobulin G

IgG is the most abundant immunoglobulin class in human serum and accounts for more than 75% of all antibody activity in this compartment. Its monomeric form circulates in plasma, has a molecular mass of approximately 155 kD, and in adults constitutes approximately 45% of total body IgG in the extravascular compartment. The human conceptus is able to produce IgG by 11 weeks' gestation (Gitlin and Biasucci, 1969; Martensson and Fudenberg, 1965). The importance of the contribution of IgG to immunologic function is illustrated by the clinical problems encountered in individuals with genetically disrupted IgG production (hypogammaglobulinemia). These patients have recurrent infections if they do not receive treatment with immunoglobulin replacement therapy (Yong et al, 2008).

Several investigators have observed that infants in whom group B streptococcal sepsis develops have low concentrations of type-specific IgG, which has prompted attempts at acute or prophylactic treatment with immunoglobulin replacement therapy (Stiehm et al, 1987). Although successful in some trials, replacement therapy in newborns has not proved as efficacious as in individuals with genetically determined hypogammaglobulinemia (Cohen-Wolkowiez et al, 2009; Noya and Baker, 1989). This difference might be caused in part by fetal and neonatal IgG synthesis being regulated by both developmental and genetic mechanisms (Cates et al, 1988; Lewis et al, 2006).

The kinetics of IgG placental transport suggest both passive and active transport mechanisms (Saji et al, 1999; Simister, 2003). Because IgG transport begins at approximately 20 weeks' gestation, preterm infants are born with lower IgG concentrations than are their mothers or infants born at term. The full-term infant has a complete repertoire of adult, maternal IgG antibodies. Thus, provided that relevant maternal IgG has been transported to the fetus, newborns are generally immune to many viral and bacterial infections (e.g., measles, rubella, varicella, group B streptococcus, and *E. coli*) until transplacentally acquired antibody titers decrease to biologically nonprotective concentrations at 3 to 6 months of age (Pentsuk and van der Laan, 2009). The regulation of IgG production in

preterm infants has been a topic of study for more than 60 years (Ballow et al, 1986; Bauer et al, 2002; Bonhoeffer et al, 2006; Dancis et al, 1953; Meffre and Salmon, 2007; Schroeder et al, 1995). Although adults with antibody deficiency syndromes have a higher rate of infections when IgG concentrations are less than 300 mg/dL, the serum IgG concentrations of many preterm infants decrease to less than 100 mg/dL apparently without consequences. These observations suggest that preterm infants have additional immunologic protective mechanisms or that the protective capacity of humoral immunity is not accurately assessed by serum IgG concentrations alone in preterm infants. Studies also suggest that reduced endogenous secretion of IgG by newborns may result from reduced ability of neonatal B cells to undergo immunoglobulin isotype switching, because of decreased or ineffective expression of the ligand for the B cell surface protein CD40 on activated cord blood T cells (Brugnoni et al, 1994; Fuleihan et al, 1994).

TABLE 36-3 Severe Combined Immunodeficiency Classification

Mechanisms	Mutated Genes	Inheritance	Affected Cells
Premature cell death	*ADA*	AR	T, B, NK
Defective cytokine-dependent survival signaling	*γc*	X-L	T, NK
	JAK3	AR	T, NK
	IL7RA	AR	T
Defective VDJ rearrangement	*RAG1* or *RAG2*	AR	T, B
	Artemis	AR	T, B
Defective pre-TCR and TCR signaling	*CD3* δ, ξ, ε	AR	T
	CD45	AR	T

AR, Autosomal recessive; *NK*, natural killer; *TCR*, T cell receptor; *X-L*, X-linked.

IgG functions in host defenses in several ways. It can neutralize a variety of toxins in plasma by direct binding. As described previously in the section on complement, after antigen binding IgG can activate the complement cascade via interaction with early-acting, classical pathway complement components. The Fc portion of IgG can interact with cell surface receptors on mononuclear phagocytes and polymorphonuclear leukocytes and thereby promote clearance of immune complexes and phagocytosis of particles or microorganisms—a process known as *opsonization*. Finally, the presence of IgG on specific target cell antigens (e.g., tumors or allogeneic transplant tissues) can mediate antibody-dependent cellular cytotoxicity, a mechanism through which lymphocyte subpopulations bearing Fc receptors can acquire the capacity to recognize non–self-antigens.

Immunoglobulin M

IgM represents approximately 15% of normal adult immunoglobulin. IgM circulates in serum as a pentamer of disulfide-linked immunoglobulin molecules joined by a single cross-linking peptide (J-chain). The size of IgM (molecular mass >900 kD) restricts its distribution to the vascular compartment. Although the antibody-binding affinity of monomeric IgM is low, the multivalent structure of the molecule provides high pentameric antibody avidity. IgM synthesis has been detected in the human conceptus at 10.5 weeks' gestation (Rosen and Janeway, 1964). Because maternal-fetal transport of IgM does not occur, elevated (>20 mg/dL) concentrations of IgM in the fetus or newborn may be suggestive of intrauterine infection or immunologic stimulation (Alford et al, 1969; Stiehm et al, 1966). However, because it is technically difficult to distinguish IgM molecules with specificity for individual organisms, diagnosis of infections by analysis for specific IgM antibody remains of limited usefulness.

IgM is important for fetal and neonatal host defenses for several reasons. First, the IgM molecule is the most efficient of any immunoglobulin isotype in activation of the classical pathway of complement. As a result, it can trigger multiple effector functions of this cascade. Second, its pentameric structure provides conformational flexibility to accommodate multivalent ligand binding. Third, because of its localization in the vascular compartment and its high efficiency in complement activation, IgM has a prominent role in clearance from serum of invading microorganisms.

Immunoglobulin A

Although IgA accounts for approximately 10% of serum immunoglobulins, it is detectable in abundance in all external secretions (Brandtzaeg, 2010). In serum, IgA is present as a monomer (molecular weight, 160 kD), whereas in secretions it exists as a dimer (molecular weight, 500 kD) attached to a J chain identical to that found in IgM. In addition to this structural difference, mucosal IgA is attached to an additional protein called the *secretory component*. This protein is a proteolytic cleavage fragment of the receptor involved in the secretion of polymeric IgA onto mucosal surfaces and into bile. Secretory IgA produced locally on mucosal surfaces by plasma cells is thus readily distinguishable from serum IgA. Although the amount of IgA produced daily is not rigorously quantified, it is estimated to exceed immunoglobulin production of all isotypes combined. Despite its relative abundance, unlike IgM and IgG, IgA cannot activate the classical pathway of complement nor effectively opsonize for phagocytosis particles or microorganisms.

Although IgA is detectable on the surface of human fetal B cells at 12 weeks' gestation, adult concentrations of serum and secretory IgA are not achieved until approximately 10 years of age. Because serum IgA is not transplacentally transferred in significant amounts, IgA is almost undetectable in cord blood. Colostrum-derived secretory IgA can provide a source of IgA in both gastrointestinal tract and other secretions for the newborn infant (Brandtzaeg, 2010). Unlike other immunoglobulin isotypes, amino acid sequences of the hinge region of the IgA-2 subclass confer partial resistance to bacterial proteases. IgA is thus more resistant than other immunoglobulin isotypes to proteolytic effects of gastric acidity. Although considerable investigation suggests that passive immunization with IgA occurs with breastfeeding in humans, the overall importance of IgA in host defenses is currently not well characterized (Bailey et al, 2005).

Immunoglobulin E

The serum concentration of IgE is undetectable by standard immunochemical techniques and accounts for approximately 1/10,000 of the immunoglobulin in adult serum. It circulates in the monomeric form (molecular weight, 190 kD). Structurally, IgE lacks a hinge region. It is produced by most lymphoid tissues in the body, but in greatest amounts in the lung and gastrointestinal tract. It is not secreted, and its appearance in body fluids generally occurs only with induction of inflammation. IgE cannot activate complement or act as an effective opsonin. Its best-known role is as a mediator of immediate hypersensitivity reactions. Specifically, antigen-specific IgE triggers mast cell degranulation with resultant bronchoconstriction, tissue edema, and urticaria via interactions with IgE receptors on the mast cell surface. Because of the presence of IgE in lung secretions and its potential importance in mediating

allergic pulmonary and gastrointestinal reactions, considerable interest has been recently focused on the use of serum IgE concentrations to identify premature infants at risk for developing reactive airways disease or in the diagnosis of gastrointestinal hypersensitivity reactions (Bazaral et al, 1971; Herz, 2008; Jarrett, 1984; Kagan, 2003).

Immunoglobulin D

Although IgD is found in trace quantities in adult human serum and has neither complement-activating activity nor the capacity to opsonize particles or microorganisms, approximately 50% of cord blood lymphocytes exhibit IgD on their cell surface (Colten and Gitlin, 1995; Haraldsson et al, 2000; Preud'homme et al, 2000). These pre–B lymphocytes express surface IgM and IgD simultaneously. Because of its wide distribution on B cells, IgD may have an important role in primary antigen recognition for the fetus and newborn infant.

Immunoglobulin Therapy

Because of low serum immunoglobulin concentrations, a concurrent greater susceptibility to infection in preterm infants, and successful use of immunoglobulin replacement in patients with genetically based hypogammaglobulinemia, several investigators have proposed prophylactic, intravenous administration of immunoglobulin (IVIG) to prevent antibody deficiency and nosocomial infection (Baker et al, 1992; Clapp et al, 1989; Cohen-Wolkowiez et al, 2009; Fanaroff et al, 1994; Kinney et al, 1991; Lewis et al, 2006; Magny et al, 1991; Weisman et al, 1994). Immunoglobulin therapy in very low-birthweight neutropenic infants with bacterial sepsis and shock has been tried with some success, when the potential benefits might outweigh the immunomodulatory properties of IVIG (Christensen et al, 2006). However, well-designed, placebo-controlled studies have failed to show consistent benefit of this strategy using different preparations of immunoglobulin, different treatment groups, and different dosage regimens (Ohlsson and Lacy, 2004a). These results suggest that serum immunoglobulin concentrations do not predict immunoglobulin function and immunologic response as accurately in the newborn infant as in the older child or adult.

In infants with sepsis, the results of immunoglobulin therapy have been difficult to interpret because of the complexities in study design associated with enrolling acutely ill infants and the small numbers of enrolled infants (Ohlsson and Lacy, 2004b). A recent metaanalysis of randomized, controlled studies that examined the effects of polyvalent immunoglobulin for treatment of sepsis or septic shock in newborn infants (12 trials, 710 newborn infants) suggested a reduction in mortality (Kreymann et al, 2007). However, heterogeneous study quality led the Cochrane reviews to suggest that there is still insufficient evidence to recommend routine use of this strategy. The availability of results from the large cohort recruited for the International Neonatal Immunotherapy Study (www.npeu.ox.ac.uk/inis) should provide a more definitive recommendation (INIS Study Collaborative Group, 2008). Other interventions including administration of colony-stimulating factors, antistaphylococcal antibodies, probiotics, glutamine supplementation, recombinant human protein C, and lactoferrin have been reviewed recently (Cohen-Wolkowiez et al, 2009).

Besides prophylactic or acute treatment of systemic bacterial infection, the therapeutic scope of monoclonal and polyclonal immunoglobulin therapy has expanded over the last 10 years. For example, although controversy still exists concerning specific populations of infants for whom prophylaxis is appropriate, administration of anti–respiratory syncytial virus monoclonal antibody has become standard of care for prevention of respiratory syncytial virus (RSV) infection in high-risk infants and for management of nosocomial outbreaks of RSV (Fitzgerald, 2009; Halasa et al, 2005; Kurz et al, 2008; Wu et al, 2004). In addition, administration of intravenous IgG is a safe and effective immunomodulatory strategy for reducing the need for exchange transfusion in hemolytic disease of the newborn if the total serum bilirubin is rising despite intensive phototherapy (American Academy of Pediatrics Subcommittee on Hyperbilirubinemia, 2004; Smits-Wintjens et al, 2008; Walsh and Molloy, 2009). Intravenous immunoglobulin is also indicated for treatment of immune thrombocytopenia (Bussel and Sola-Visner, 2009). The administration directly into the ocular vitreous of antibody against vascular endothelial growth factor to bind and inactivate vascular endothelial growth factor has been shown in early studies to reduce the need for laser therapy for retinopathy of prematurity (Mintz-Hittner and Best, 2009). The historically promising use of oral immunoglobulin for preventing necrotizing enterocolitis has not proved effective in a recent Cochrane review of three trials (n = 2095 infants) (Foster and Cole, 2004). In view of the continued expansion of neonatal diseases that are potentially treatable with immunoglobulin, the use of immunoglobulin therapy must continue to be evaluated not only in terms of immediate benefits, but also in terms of long-term effects on immunologic function.

SPECIFIC IMMUNOLOGIC DEFICIENCIES

The most common reason for increased immunologic susceptibility to infection in newborns, besides prematurity, is iatrogenic immunosuppression caused by administration of corticosteroids for treatment or prevention of bronchopulmonary dysplasia. Although pulmonary and neurodevelopmental benefits have been attributed to this therapy (Abman and Groothius, 1994; Cummings et al, 1989), caution has developed concerning possible long-term, adverse neurodevelopmental effects of steroid administration (Bancalari, 2001; Barrington, 2002; Committee on the Fetus and Newborn, 2002). Although the mechanisms that lead to steroid-induced amelioration of pulmonary disease have not been elucidated completely, the pulmonary inflammatory response as measured by the concentrations of the anaphylatoxin C5a, leukotriene B4, IL-1, elastase-α1-proteinase inhibitor, and the number of neutrophils has been shown to be attenuated in infants receiving steroid treatment (Groneck et al, 1993). Whereas shorter courses of steroids can reduce side effects, including immunosusceptibility, the availability of nebulized steroids may provide effective antiinflammatory therapy with minimum toxicity (Cole et al, 1999).

There are more than 130 recognized primary immunodeficiency diseases (Notarangelo, 2010). The physician should attempt to differentiate infants with specific genetically regulated immunologic deficiencies from those with developmentally regulated, environmentally induced, or infection-related susceptibility to microbial invasion (Rosen, 1986; Rosen et al, 1984). Documenting a full family history during an antenatal visit can be helpful in identifying relatives removed by as many as two to four generations with histories suggestive of primary immunodeficiency disease, as most arise from single-gene defects. Genetic testing is widely available for many primary immunodeficiency diseases, although de novo mutations are common (Notarangelo, 2010). Several single-gene defects resulting in blocks in T and B cell development are shown in Figure 36-5. Several disorders arising from these defects can manifest in the first months of life.

SEVERE COMBINED IMMUNODEFICIENCY

Severe combined immunodeficiencyt (SCID) is a rare category of diseases that affect development of both B cells and T cells. The estimated frequency is between 1 per 70,000 and 1 per 100,000 live births (Buckley et al, 1997; Stephan et al, 1993). Before identifying the genes involved in producing the SCID phenotype, investigators classified patients with the disorder by analyzing the number, cell surface proteins, and function of circulating lymphocytes. The most common subgroups are T^-B^- SCID, T^-B^+SCID, and adenosine deaminase deficiency.

T^-B^+ SCID accounts for more than half of all SCID cases, and both X-linked and autosomal recessive forms exist (Fischer, 2000). Approximately 80% of T^-B^+ SCID cases involve males with the X-linked form, which results from deleterious mutations in the common gamma chain (γ_c) shared by the IL-2, IL-4, IL-7, IL-9, and IL-15 cytokine receptors (see Figure 36-5) (Noguhi et al, 1993). Defects in the γ_c protein abrogate the development of T cells and NK cells and lead to B cell dysfunction despite normal B cell numbers. IL-7 receptor signaling is essential for T cell development within the thymus, and the deficiency of this cytokine accounts for the absence of T cells (Cao et al, 1995; DiSanto et al, 1995; Peschon et al, 1994). IL-15 is implicated in NK cell development, and reductions in IL-4 receptor signaling are thought to contribute to poor B cell function seen in γ_c deficient patients (Mrozek et al, 1996). Nevertheless, the precise mechanisms involved in the NK cell developmental defect and the B cell functional defect are largely unknown.

The less common autosomal recessive form of T^-B^+SCID is primarily due to mutations in the Janus-associated tyrosine kinase JAK3 (Macchi et al, 1995; Russell et al, 1995). This kinase is expressed in cells of hematopoietic lineage and associates with γ_c as part of the cytokine receptor signaling cascade. The $T^-B^+NK^-$ immunophenotype of these patients is identical to that seen in γ_c deficiency. Rarely, patients with autosomal recessive T^-B^+ SCID have NK cells. In two such patients, a defect was found in the IL-7Rα chain (Puel et al, 1998). This finding was predicted by the phenotype of the IL7R knockout mouse, and the data imply that the IL-7 receptor is not essential for NK cell development.

Clinically, the X-linked and autosomal recessive forms of T^-B^+ SCID are indistinguishable. Affected infants often appear healthy at birth. In the neonatal period a morbilliform rash, probably the result of attenuated

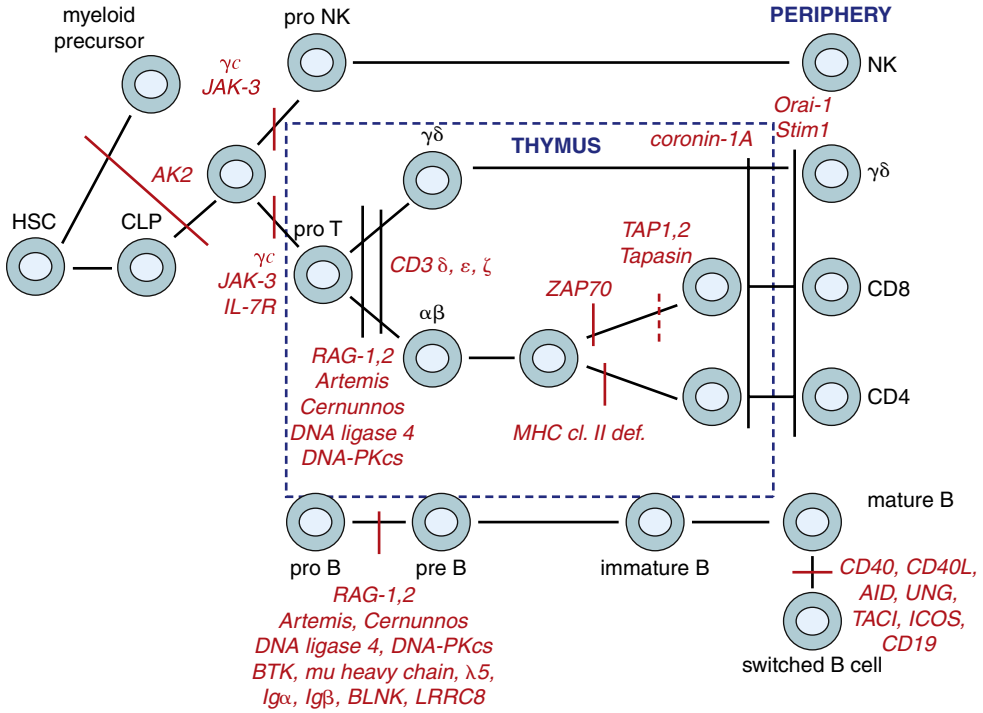

FIGURE 36-5 Blocks in T and B cell development associated with severe combined immunodeficiency and other primary immunodeficiencies. *NK*, Natural killer. *(From Notarangelo LD: Primary immunodeficiencies*, J Allergy Clin Immunol *125:S182-S194, 2010.)*

graft-versus-host disease from transplacental passage of maternal lymphocytes, may be the only symptom of SCID (Rosen, 1986). Over the first several months of life, as acquired maternal antibody levels drop, failure to thrive and undue susceptibility to infection become universal features. Intractable diarrhea, pneumonia, and persistent thrush, especially oral thrush, constitute the triad of findings most frequently seen in infants with this disease (Stephan et al, 1993).

Mutations in the gene encoding adenosine deaminase (ADA), an enzyme in the purine salvage pathway, account for approximately 20% of all cases of SCID. Mutations in another enzyme in the purine salvage pathway, purine nucleoside phosphorylase, are found in approximately 4% of patients with SCID (Fischer, 2000; Fischer et al, 1997). The ADA-deficient phenotype is variable, and neonatal onset, delayed onset, and partial forms have been described (Santisteban et al, 1993). In neonatal-onset ADA deficiency, patients have a profound T, B, and NK cell lymphopenia, with a clinical presentation similar to T^-B^+ SCID (Hirschhorn, 1990). Although ADA is normally present in all mammalian cells, life-threatening disease in ADA deficiency is limited to the immune system. Less severe manifestations include flaring of the costochondral junction as seen on the lateral chest radiograph (termed *rachitic rosary*) and pelvic dysplasia. Other findings associated with ADA deficiency include hepatic and renal dysfunction, deafness, and cognitive problems (Fischer, 2000; Rogers et al, 2001). Patients who lack ADA accumulate deoxy-adenosine triphosphate in red blood cells and lymphocytes, and the concentration correlates with disease severity. The ADA substrates, adenosine and deoxyadenosine, are found at increased levels in the serum and urine. Studies in ADA-deficient mice suggest that developing thymocytes are particularly sensitive to these metabolic derangements and that the few T cells that mature have signaling defects (Blackburn et al, 2001). The precise mechanism by which the accumulation of ADA substrates results in the immunologic pathology seen in humans remains unclear (Yamashita et al, 1998).

The remaining 20% of SCID patients lack mature T and B cells, but have functional NK cells ($T^-B^-NK^+$). These patients exhibit an autosomal recessive pattern of inheritance and have defects in the VDJ recombination machinery (Schwarz et al, 1996). Somatic recombination of variable, diversity, and joining DNA segments is a critical step in the development of B and T cells. A rearranged IgM heavy chain and TCR-β chain form components of the pre–B and pre–T receptors, which provide essential survival signals for developing lymphocytes. In the absence of recombination, these lymphocyte precursors do not receive a survival signal, die, and produce the T-B- SCID phenotype. NK cells do not require somatic cell recombination and survive. In the recombination process, DNA cleavage is mediated by RAG1 and RAG2, which are the recombination-activating proteins that recognize specific sequences flanking V, D, and J segments. The two proteins act in concert to introduce a double-strand DNA break and leave hairpin-sealed coding ends. Recruitment of a DNA-dependent protein kinase and other components of the general DNA repair machinery completes the process.

Mutations in the genes encoding both RAG1 and RAG2 have been identified in patients with T-B-NK+ SCID (Cornero et al, 2000) and in some patients with Omenn's syndrome (Cornero et al, 2001). Omenn's syndrome is clinically characterized by failure to thrive, diarrhea, erythroderma, alopecia, hepatosplenomegaly, and lymphadenopathy. This concurrence of RAG mutations implies that factors other than RAG mutations also contribute to the Omenn's syndrome phenotype. Finally, a small subset of T-B-NK+ SCID patients also have increased sensitivity to ionizing radiation, which suggests mutations that affect the DNA repair mechanism (Fischer, 2000). This supposition is strengthened by murine and equine SCID in which specific defects in the DNA-dependent protein kinase involved in VDJ recombination and DNA repair have been identified.

The diagnosis of SCID is often suggested by an opportunistic or unusually severe infection in the setting of profound lymphopenia (<1000 lymphocytes per mm^3) (Gennery and Cant, 2001). Only 10% of patients with SCID have lymphocyte counts in the normal range. T cells detectable in peripheral blood of affected infants shortly after birth may be either maternal T cells or circulating thymocytes. The thymus gland is not seen on chest radiographs. Histologically, the gland is composed of islands of endodermal cells that have not become lymphoid and contain no identifiable Hassall's corpuscles. Lymphocyte subpopulation analysis using monoclonal antibodies to cell surface markers and analytical flow cytometry is the most important confirmatory test. As noted previously, each phenotypic pattern suggests a specific diagnosis and molecular defect. Other useful tests include measurements of ADA and purine nucleoside phosphorylase activity in red blood cells and isohemagglutinins as a marker of specific IgM production. Quantitative immunoglobulin levels are not particularly helpful in the diagnosis of neonatal SCID, because most IgG is maternal in origin and IgA and IgM levels are often low in the neonatal period. Once the immunophenotype has been established, a precise molecular diagnosis should be obtained and genetic counseling should be provided. Females carrying deleterious mutations in the *IL2RG* gene (X-linked SCID) can be identified by nonrandom inactivation of the X chromosome in lymphocytes. Prenatal diagnosis is available by gene identification from a chorionic villous biopsy. In the absence of definitive prenatal genetic testing, all newborn siblings of patients with known SCID, and infant male first cousins of patients with known or suspected X-linked SCID, should be considered at high risk for this disorder and investigated promptly after birth.

An effective strategy for detecting newborn infants with SCID with statewide newborn screening was first implemented in Wisconsin (Routes et al, 2009). The test is based on the detection of T cell recombination excision circles by PCR and also identifies patients with lymphopenia resulting from other causes (Baker et al, 2009; Chan and Puck, 2005). When a fetus at risk for a genetic form of SCID is identified, treatment should begin in the delivery room and should be coordinated with antenatal diagnostic interventions. Specifically, cord blood samples should be obtained for white blood cell count and differential, lymphocyte subset determinations, karyotype (if not

performed antenatally), mitogen stimulation studies, and immunoglobulin measurements. Because the majority of children with genetic SCID do not become ill within the 1st week of life, care in an incubator should be provided, and staff members should observe strict handwashing technique.

SCID is a pediatric emergency and is invariably fatal if untreated. Most untreated patients die in the 1st year of life. Treatment of SCID begins with aggressive antibiotic and antiviral therapy for infections, intravenous immunoglobulin replacement, and prophylaxis for *Pneumocystis carinii* infection. Besides greater susceptibility to opportunistic infections, these infants are also susceptible to development of graft-versus-host disease, either before birth as a result of engraftment of maternal T lymphocytes or after birth as a result of the engraftment of T lymphocytes present in transfused blood products (Pollack et al, 1982; Thompson et al, 1984). Therefore infants in whom SCID is suspected should receive only irradiated blood products and should not be given live viral vaccines.

Good and colleagues performed the first successful bone marrow transplantation (BMT) in a SCID patient (Gatti et al, 1968). Allogeneic BMT, preferably from an HLA-matched sibling, is now the standard treatment for most types of SCID (Buckley, 2000). In these transplants, conditioning regimens are not required for engraftment. Recipients usually become chimeric, with only T and NK cells of donor origin. B cell function is frequently deficient and many patients continue to require monthly therapy with IVIG. Survival rates for this type of BMT exceed 90%. When no HLA-identical donor is available, haploidentical transplants have been used successfully, although overall survival is lower with such transplants (Fischer, 2000). The rates of engraftment after haploidentical transplantation of $T^-B^-NK^+$ SCID patients are low; this is likely due to host NK cell function, and some form of preconditioning may be indicated in this subset of patients. In addition to BMT, ADA deficiency can be treated with enzyme replacement. This treatment involves weekly injections of ADA coupled to polyethylene glycol. Response, consisting of decreasing deoxyadenosine triphosphate levels and increasing T cell numbers, is seen in most patients within weeks. Finally, gene therapy based on vector-mediated transfer of therapeutic gene into autologous hematopoietic stem cells has been used to treat patients with ADA and γc SCID and patients with chronic granulomatous disease. Results in more than 30 patients showed engraftment and clinical benefit, but were limited by transient expression and by insertional mutagenesis (Aiuti and Roncarolo, 2009).

WISKOTT-ALDRICH SYNDROME

Wiskott-Aldrich syndrome (WAS), another form of primary immunodeficiency, is characterized by severe eczema, thrombocytopenia, increased risk of malignancy, and susceptibility to opportunistic infection. Other manifestations, which may be present in the newborn period, include petechiae and bruises, bloody diarrhea, and hemorrhage after procedures. In infants with any of these clinical findings, abnormal low mean platelet volume in a complete blood count report is an important clue to possible WAS. WAS is inherited as a sex-linked recessive trait (Rosen, 1986). In untreated cases, children survive longer than infants with SCID (median survival, 5.7 years). T lymphocytes in affected patients are decreased in number and diminished in function. Reductions in platelet size and thrombopoiesis are also noted. Affected children can be treated with BMT, and the 5-year survival rate after HLA-identical sibling BMT is approximately 90% (Filipovich et al, 2001). Although transplantation corrects the T cell defects, thrombocytopenia persists. As for children with SCID, all blood products given to children with WAS should be irradiated before administration to avoid T cell engraftment and graft-versus-host disease.

The gene responsible for the WAS was cloned in 1994 (Derry et al, 1994). It is composed of 12 exons and encodes a 502 amino acid cytoplasmic protein (WAS) expressed in all hematopoietic cells. Evaluation by flow cytometry for expression of this protein by lymphocytes can be used to diagnose WAS. Other mammalian WAS family members include a more widely expressed N-WAS and three WAVE/Scar isoforms. These proteins have multiple domains and are important regulators of actin polymerization (Symons et al, 1996); they have a common carboxy-terminal region through which they activate Arp2/3, an actin-nucleating complex involved in actin assembly and cytoskeletal structure. The amino termini are distinct and allow the proteins to couple Arp2/3 activation to a wide variety of different intracellular signals. More than 340 mutations in WAS have been described, which have profound effects on cell motility, signaling, and apoptosis (Rengan and Ochs, 2000).

DIGEORGE SYNDROME

The embryologic anlage of the thymus gland and the parathyroid gland is the endodermal epithelium of the third and fourth pharyngeal pouches. When normal development of these structures is disturbed, thymic and parathyroid hypoplasia can occur (Rosen, 1986). Infants with this disorder, DiGeorge syndrome, can exhibit abnormalities of calcium homeostasis during the neonatal period (hypocalcemia and tetany) and variable T cell deficits, which appear to depend on the presence and number of small, normal-appearing ectopic thymic lobes. In addition, these infants have congenital, conotruncal cardiac defects, low-set ears, midline facial clefts, hypomandibular abnormalities, and hypertelorism.

The availability of methodology for performing gene dosage studies and more refined cytogenetic techniques (fluorescence in situ hybridization) has permitted the description of a contiguous gene syndrome that includes the DiGeorge phenotype (Hall, 1993). The DiGeorge syndrome is known to result from varying sized deletions on chromosome 22q11 in more than 90% of patients (Markert, 1998; Shprintzen, 2008). This deletion has been linked to several other diagnostic labels, including velocardiofacial (Shprintzen) syndrome, Cayler syndrome, and Opitz G/BBB syndrome. Collectively, these are referred to as the *22q11 deletion syndromes*. The cardiac anomalies associated with the 22q11 deletion syndrome are variable, but usually involve the outflow tract and the derivatives of the branchial arch arteries. These defects include interrupted

aortic arch type B, truncus arteriosus, and tetralogy of Fallot (Carotti et al, 2008).

Children with the 22q11 deletion syndrome also exhibit a higher incidence of receptive-expressive language difficulties, cognitive impairment, and behavioral problems including psychotic illness (Jolin et al, 2009; Scambler, 2000). The cardiovascular defects have been shown to be the result of haploinsufficiency of TBX1 (Merscher et al, 2001).

In the nursery, identification of infants with congenital conotruncal abnormalities or unexplained, persistent hypocalcemia should prompt consideration of this syndrome. Thymic implants can partially correct the immunologic deficits (Markert et al, 2007).

IMMUNIZATION

MATERNAL IMMUNIZATION

Immunization before or during pregnancy has been effective in preventing several specific neonatal infections including diphtheria, pertussis, tetanus, hepatitis B, and rabies (ACOG Technical Bulletin Number 160, 1993; Hackley, 1999; Immunization Practices Advisory Committee, 1991; Stevenson, 1999). For example, in developing countries, immunization during pregnancy with tetanus toxoid is a cost-effective method for preventing neonatal tetanus and for providing up to 10 years of protection for infants (Gill, 1991; Schofield, 1986; Vandelaer, 2003). The benefits are substantial for both mother and infant from induction before or during pregnancy of maternal IgG antibody that can be transferred to the fetus and protect both the fetus and mother against postpartum morbidity and mortality (Healy and Baker, 2006; Insel et al, 1994; Linder and Ohel, 1994). However, immunization during pregnancy is biologically distinct from immunization of nonpregnant individuals. Vaccine epitopes can be shared with vital fetal or placental tissues; therefore vaccination can lead to unanticipated maternal or fetal morbidity. Maternal immunization can induce an antibody response in the fetus, as has been demonstrated with tetanus toxoid (Gill et al, 1983) and thereby induce potentially undesirable immunologic side effects (e.g., immunologic unresponsiveness or tolerance) in the infant.

Nevertheless, the increase in availability of potentially protective, transplacentally transferred IgG through active maternal vaccination prompted the Institute of Medicine to recommend the establishment of a program of active immunization to control early-onset and late-onset group B streptococcal disease in both infants and mothers (Institute of Medicine and National Academy of Sciences, 1985). Efforts to develop safe, effective vaccines for protection from group B streptococcal infections have encountered the same difficulties with immunogenicity and safety observed in the development of other vaccines that induce protection from polysaccharide-encapsulated organisms (Baker et al, 1988; Noya and Baker, 1992). The availability of conjugate vaccines, which include group B streptococcal polysaccharide antigens covalently linked either to tetanus toxoid or to a protein in the membrane of group B streptococci (beta C protein) (Madoff et al, 1994; Wessels et al, 1993; Yang et al, 2007) have shown some promise.

The indications for active vaccination during pregnancy rest on assessment of maternal risk of exposure, the maternal-fetal-neonatal risk of disease, and the risk from the immunizing agents. (ACOG Technical Bulletin Number 160, 1993; Hackley, 1999; Stevenson, 1999). In general, immunization with live viral vaccines during pregnancy is not recommended (Box 36-1). Preferably, immunizations with live viral vaccines are performed before pregnancy occurs. However, rare instances may occur in which live viral vaccine administration is indicated. For example, if a pregnant woman travels to an area of high risk for yellow fever, administration of that vaccine might be indicated because of the susceptibility of the mother and the fetus, the probability of exposure, and the risk of the mother and fetus from the disease. More common examples in the United States include influenza and polio virus vaccination. If a chronic maternal medical condition would be adversely affected by influenza, active immunization may be indicated during pregnancy. Similarly, if imminent exposure to live polio virus in an unprotected woman is anticipated, live oral polio virus vaccine may be used during pregnancy. If immunization can be completed before the anticipated exposure, inactivated polio virus vaccine can be given. A summary of recommendations for immunizations during pregnancy is provided in Box 36-1.

For the pediatrician, maternal immunization represents an important preventive intervention. Breastfeeding does not adversely affect immunization, and inactivated or killed vaccines pose no special risk for mothers who are breastfeeding or for their infants. Maternal immunizations with vaccines against polysaccharide-encapsulated

BOX 36-1 Summary of Recommendations for Immunization during Pregnancy

LIVE VIRUS VACCINES

- Influenza (LAIV)—contraindicated
- Measles—contraindicated
- Mumps—contraindicated
- Rubella—contraindicated
- Yellow fever—safety not established (travel to high-risk areas only)
- Varicella—contraindicated

INACTIVATED VIRUS VACCINES

- Hepatitis A—consider if high risk of exposure
- Influenza—recommended
- Rabies—consider if indicated

INACTIVATED AND RECOMBINANT BACTERIAL VACCINES

- Cholera—to meet international travel requirements
- Meningococcal polysaccharide vaccine—consider if indicated
- Plague—selective vaccination of exposed persons
- Typhoid—safety not established
- Pneumococcal polysaccharide vaccine—consider if indicated
- Tetanus-diphtheria—consider if indicated
- Hepatitis B—consider if indicated
- Meningococcal conjugate vaccine—safety not established

POOLED IMMUNE SERUM GLOBULINS

- Hepatitis A—postexposure prophylaxis
- Measles—postexposure prophylaxis

Adapted from Centers for Disease Control and Prevention: *Guidelines for Vaccinating Pregnant Women* (May, 2007). Available at www.cdc.gov/vaccines/pubs/preg-guide.htm.
LAIV, Live attenuated influenza vaccine.

organisms (e.g., *Haemophilus influenzae* type b and group B streptococci) can decrease morbidity and mortality from these diseases during the first 3 to 6 months of the infant's life (Amstey et al, 1985; Baker et al, 1988; Colbourn et al, 2007; Walsh and Hutchins, 1989). The benefit of decreasing the risks of development of hepatocellular carcinoma, cirrhosis, and chronic active hepatitis from perinatal transmission of hepatitis B through prenatal screening and active and passive immunization of the infant is substantial (Arevalo and Washington, 1998). The implications of maternal vaccination during pregnancy for preterm infants have not been studied.

The anthrax attacks of September 2001 have raised the possibility of the need for preexposure or postexposure immunization programs that may include pregnant women. Currently available data tend to suggest that the anthrax vaccine licensed since 1970 in the United States has no detrimental effects on pregnancy and does not increase adverse birth outcomes, although caution is advised when administering this vaccine during the first trimester (Inglesby, 2002; Ryan et al, 2008; Wiesen and Littell, 2002). A second infectious agent that might be used in a bioterrorist attack is variola virus (smallpox). Although eradicated in 1977, this virus remains a concern because of its lethality, especially in pregnancy (Enserink, 2002; Suarez and Hankins, 2002). Pregnancy is a contraindication to smallpox immunization (Wharton et al, 2003); however, if an intentional release of smallpox virus should occur, pregnant women should be immunized because of their high risk of mortality if unprotected (Suarez and Hankins, 2002).

INFANT IMMUNIZATION

Advances in understanding the developmental regulation of immunity have suggested that immunization during the neonatal period offers important advantages (Lawton, 1994). The recommendations of the American Academy of Pediatrics for immunization of infants can be found at http://aapredbook.aappublications.org/resources/IZSchedule0-6yrs.pdf (Anonymous, 2002; Committee on Infectious Diseases et al, 2002). Immunization against *H. influenzae* type b should be considered for infants who are discharged from intensive care nurseries at or after 2 months of age. For the preterm infant, different clinical approaches to immunization are used by practitioners, including decreasing the dose of immunogen, postponing the first immunization until a corrected age of 2 months, or waiting for an arbitrary weight to be achieved by the infant (e.g., 4.5 kg). However, the American Academy of Pediatrics recommends administering full-dose diphtheria, tetanus, and pertussis immunization beginning at 2 months of age. These recommendations (i.e., that no correction needs to be made for prematurity when initiating routine immunization in preterm infants) have been supported by longitudinal evaluation of serum antibody response in preterm infants (Bernbaum et al, 1989; Conway et al, 1993).

The Advisory Committee on Immunization Practices (ACIP) of the United States Public Health Service recommends universal immunization of infants to protect against perinatal transmission of the hepatitis B virus (HBV) and chronic HBV infection (Mast et al, 2005). This recommendation has been endorsed by the Committee on Infectious Diseases of the American Academy of Pediatrics. Chronic HBV infection occurs in approximately 90% of infected infants and is associated with hepatocellular carcinoma and cirrhosis leading to end-stage liver disease. All medically stable infants born to women with a negative test result for hepatitis B surface antigen (HBsAg) and weighing more than 2000 g at birth should begin a hepatitis immunization schedule in the newborn period before hospital discharge. Only single-antigen hepatitis B vaccines should be used for the birth dose (Mast et al, 2005).

All infants regardless of gestational age at the time of birth, and whose mothers have a positive test result for HBsAg, should receive passive immunization with hepatitis B immunoglobulin and active immunization with a single-antigen HBV vaccine within 12 hours of birth. Repeated vaccinations are given at 1 to 2 months and again at 6 months of age. For premature infants weighing less than 2000 g and born to HBsAg-positive mothers, the birth dose is not counted as part of the vaccine series. Special efforts should be made to complete the hepatitis B vaccination schedule within 6 to 9 months in populations of infants with high rates of childhood hepatitis B infection (Peter, 1994). For premature infants with birthweights of less than 2000 g born to HBsAg-negative women, vaccination can be delayed until just before discharge. These infants do not need routine serologic testing for anti-HBsAg after the third dose of vaccine. The infant whose mother has a negative test result for HBsAg, but has received active or passive immunization during pregnancy because of exposure to hepatitis B, should receive no treatment as long as the mother was HBsAg-negative at the time of birth. For current HBV vaccinations recommendations, the reader is directed to the Centers for Disease Control and Prevention Web site: www.cdc.gov/hepatitis/HBV/VaccChildren.htm.

In 1999, the U.S. Agency for Toxic Substances and Disease Registry raised concern about the possibility that administration of thimerosal-containing vaccines, including the hepatitis B vaccines, might lead to exposure to mercury that exceeded federal guidelines (Clark et al, 2001). Since March 2000, HBV vaccines used in the United States have not contained thimerosal. These yeast-derived recombinant HBV vaccines contain 10 to 40 μg/mL of HBsAg protein, have excellent safety records, induce minimum adverse reactions, and are highly immunogenic (Greenberg, 1993). Multivalent vaccines are available, but are not recommended for the birth dose. Guidelines for hepatitis immunization of infants have been developed for implementation for term and preterm infants. However, vaccine responses in the extremely preterm infant whose mother is HBsAg-positive, a population seen with increasing frequency because of the coincidence of intravenous drug abuse and carriage of HBsAg, have not been studied.

Short-term and long-term neonatal immunologic protection after fetal exposure to maternally administered vaccines against anthrax or smallpox, the mass use of which might be prompted by a bioterrorist attack, has not been studied. Similarly, guidelines for neonatal immunization against these agents are not currently available. Before the eradication of smallpox, smallpox vaccine was routinely administered to older infants and children. No data

or experience is available on immunization of newborn infants with anthrax vaccine. For postexposure prophylaxis in newborn infants, both chemotherapy (amoxicillin, ciprofloxacin, or doxycycline) and immunization should be considered. Clinicians faced with decisions concerning immunization strategies for pregnant women and newborn infants after a bioterrorist attack should consult the Web site for the Centers for Disease Control and Prevention (www.cdc.gov).

CHAPTER 37

Viral Infections of the Fetus and Newborn and Human Immunodeficiency Virus Infection during Pregnancy*

Mark R. Schleiss and Janna C. Patterson

Viral Infections of the Fetus and Newborn

Viral infections of the fetus and newborn infant are common and underrecognized. Given the urgency of identifying invasive bacterial disease in the neonate, the identification of viral infections is often relegated to a matter of secondary importance. However, identifying viral infections can also be a matter of great urgency, because antiviral agents are available for many of the most common infections. Accordingly, an appropriately high index of clinical suspicion of a neonatal viral infection can be lifesaving. Moreover, identification of viral disease in the newborn period may be of great prognostic significance, particularly for neurodevelopmental issues. Making a diagnosis of a neonatal viral infection can help to direct and focus the anticipatory management of the child's pediatrician during the course of well-child care. This chapter reviews the epidemiology, pathogenesis, diagnosis, and short- and long-term clinical management of many of the more common viral infections encountered in neonates.

One of the great challenges in the evaluation of viral disease in the newborn is the ascertainment of the timing of acquisition of infection. Some infections can be acquired either in utero or in the early postnatal period. In this chapter, *congenital infection* is defined as any infection acquired in utero. *Perinatal infections* are defined as those acquired intrapartum, typically during the labor and delivery process. *Postnatal infections* are acquired in the post-partum period and are defined as infections acquired after delivery through the first month of life. In some situations, correctly identifying the timing of acquisition of infection can have substantial consequences, not only for the management of the infant, but for the long-term prognosis. Figure 37-1 outlines the most common timing of acquisition of neonatal viral infections with an emphasis on the relative importance of the many viruses that can be acquired congenitally, perinatally, or postnatally. There is considerable overlap across categories for some viral infections that can be transmitted at any of these time points, and this will be considered on a pathogen-by-pathogen basis.

GENERAL DIAGNOSTIC APPROACH

Clinicians caring for newborns have long recognized that there are some common clinical manifestations that suggest the presence of a congenital or perinatal viral infection. These manifestations include evidence of intrauterine growth restriction, hydrops fetalis, hepatomegaly, splenomegaly, pneumonitis, bone lesions, rashes, and hematologic abnormalities (Box 37-1). Because the incidence of congenital viral infections is high (Alpert and Plotkin, 1986), it is appropriate for clinicians to have a high index of suspicion in any newborn with signs or symptoms. However, caution should be taken in efforts to lump all neonatal viral infections into a single diagnostic category. An unfortunate example of this manner of thinking is the continued use of the terminology *TORCH titers* in the diagnostic approach to a symptomatic neonate. The *TORCH* acronym, first coined by Nahmias et al (1971), stands for toxoplasmosis, other infections, rubella, cytomegalovirus (CMV), and herpes simplex virus (HSV). Numerous variants of this acronym have been suggested over the past four decades (Ford-Jones and Kellner, 1995; Kinney and Kumar, 1988; Ronel et al, 1995; Tolan, 2008). Unfortunately numerous clinical laboratories continue to offer the "TORCH panel," typically consisting of serologic tests for toxoplasmosis, HSV, CMV, and rubella. This acronym has outlived its usefulness (Lim and Wong, 1994), and should be discarded from clinical parlance, based on the following considerations:

- Measurements of immunoglobulin G antibody titers virtually always simply reflect transplacental maternal antibody and provide little information of relevance to the infant's infection status. With the exception of the identification of antibodies to *Treponema pallidum*, which is always of interest and significance, antibodies against the other members of the TORCH panel are of little diagnostic significance.
- Congenital and perinatal infection can occur with HSV and CMV, even in the face of preconception maternal immunity. Thus the finding of antibody in a TORCH titer is neither diagnostic of infection nor reassuring in regard to protection against that infection.
- Highly sensitive virologic and molecular tools are available to identify virtually all pathogenic viruses. These tools include standard culture and nucleic acid identification techniques, typically based on polymerase chain reaction (PCR) amplification of viral nucleic acids. Such studies can facilitate rapid pathogen-specific diagnosis; therefore the diagnosis of neonatal viral disease should depend on diagnostic virology, not serology.
- Most importantly, the use of the TORCH acronym vastly underemphasizes the great diversity of viral pathogens that have been associated with infection in the newborn. A list of the myriad of viral pathogens that have been reported to cause congenital infection and disease is included in Box 37-2. A discussion of

*In writing this chapter, the authors excerpted portions of the chapters *Identification, Evaluation, and Care of the Human Immunodeficiency Virus–Exposed Neonate* by Karen P. Beckerman and *Viral Infections of the Fetus and Newborn* by Erica S. Pan, F. Sessions Cole, and Peggy Sue Weintrub from the previous edition of this book.

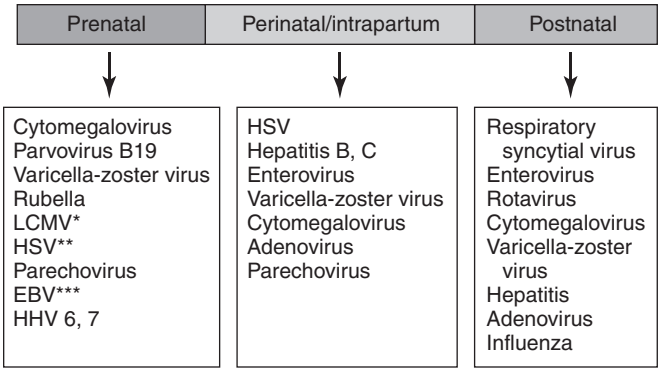

FIGURE 37-1 Relative importance of neonatal viral infections related to timing of acquisition of infection. Viruses listed in declining relative order of importance relative to prenatal, perinatal (intrapartum), and postnatal timing of typical infection. Some neonatal virus infections (e.g., cytomegalovirus) can be substantial causes of disease whether acquired during gestation or postpartum, whereas others (e.g., respiratory syncytial virus) are typically acquired in the postnatal period. *EBV*, Epsteinn–Barr virus; *HSV*, herpes simplex virus; *HHV*, human herpes virus; *LCMV*, Lymphocytic choriomeningitis virus

BOX 37-1 Clinical Features Commonly Associated With Congenital Viral Infections in Neonates

- Intrauterine growth restriction
- Nonimmune hydrops fetalis
- Echogenic bowel (prenatal ultrasound)
- Hepatosplenomegaly
- Jaundice (>20% direct-reacting bilirubin)
- Hemolytic anemia
- Purpura, ecchymoses and petechiae
- Skeletal defects ("celery-stalking")
- Microcephaly and hydrocephaly
- Intracranial calcification
- Neuronal migration defects
- Pneumonitis
- Myocarditis
- Cardiac abnormalities
- Chorioretinitis
- Keratoconjunctivitis
- Cataracts
- Glaucoma

BOX 37-2 Viral Pathogens Reported to Cause Congenital Infections

Adenoviridae
- Adenovirus serogroup 3

Arenaviridae
- Lymphocytic choriomeningitis virus
- Lassa fever virus

Bunyaviridae
- Bunyamwera serogroup (Cache Valley virus)
- La Crosse encephalitis virus

Flaviviridae
- Hepatitis C virus
- Japanese encephalitis virus
- West Nile virus
- St. Louis encephalitis virus
- Yellow fever virus
- Dengue virus

Hepadenoviridae
- Hepatitis B virus

Herpesvirinae
- Herpes simplex viruses 1 and 2
- Varicella zoster virus
- Cytomegalovirus
- Epstein–Barr virus
- Human herpesviruses 6 and 7

Orthomyxoviruses and paramyxoviruses
- Influenza
- Measles

Parvoviridae
- Human parvovirus B19

Picornaviridae
- Poliovirus
- Coxsackievirus
- Enteric cytopathic human orphan virus
- Parechovirus
- Hepatitis A virus

Retroviridae
- Human T-lymphotropic viruses 1 and 2
- HIV

Togavirinae
- Mumps
- Western equine encephalitis virus
- Venezuelan equine encephalitis virus

many of the more unusual viral causes of congenital infection is beyond the scope of this chapter, but this table underscores the diversity of agents associated with fetal infection. A recent travel history or recent emigration might suggest consideration of some of these more unusual agents.

Rather than rely on a large battery of serologic tests, the clinician can usually narrow the differential diagnosis of a suspect neonatal or congenital viral infection with the history and physical examination, followed by the use of focused, specific diagnostic studies. Important questions include: What was the overall health of the mother during her pregnancy? What is her age and marital status (e.g., young, unmarried women have a higher risk of acquiring primary genital HSV infection). What is her immunization history? Has she had chickenpox? Did she have other common childhood viral infections? What part of the world is she from? Are there potential animal exposures (e.g., exposure to cat litter or consumption of undercooked meat might suggest toxoplasmosis; exposure to rodents might suggest lymphocytic choriomeningitis virus)? Does she have other children and, if so, what are their ages, overall health status, and histories of group day care attendance? Have there been recent illnesses in the household? What time of year is it? (For example, respiratory syncytial virus and enterovirus infections have characteristic seasonality in temperate zones.) What are her occupational exposures? Did she have any symptomatic infectious illnesses during pregnancy? The answers to these types of questions, considered in the context of the infant's physical examination, can direct the next steps in establishing a definitive etiologic diagnosis.

TABLE 37-1 Clinical Findings in Selected Congenital and Perinatal Infections That Suggest a Specific Diagnosis

Congenital Infection	Findings
Rubella	Cataracts, cloudy cornea, pigmented retina; petechiae with "blueberry muffin" rash; bone defects with longitudinal bands of demineralization ("celery stalking"); cardiovascular malformations (patent ductus arteriosus, pulmonary artery stenosis); sensorineural hearing loss; hydrops
Cytomegalovirus	Microcephaly with periventricular calcifications; chorioretinitis; petechiae with thrombocytopenia; jaundice; sensorineural hearing loss; bone abnormalities; abnormal dentition, hypocalcified enamel
Herpes simplex virus	Skin vesicles, keratoconjunctivitis, acute central nervous system findings (seizures), hepatitis, pneumonitis
Parvovirus B19	Hydrops, ascites, hepatomegaly, ventriculomegaly, hypertrophic myocardiopathy, anemia
Varicella zoster virus	Limb hypoplasia, dermatomal scarring in cicatricial pattern, gastrointestinal tract atresia
Lymphocytic choriomeningitis virus	Hydrocephalus, chorioretinitis, intracranial calcifications

Some of the classic presentations of the more common perinatal viral infections are reviewed in Table 37-1. It should be noted that there can be considerable overlap of these clinical features across the different infectious categories listed; for example, the "blueberry muffin" rash of congenital rubella syndrome may be indistinguishable from that of congenital CMV, and both syndromes can include sensorineural deafness. The presence of brain calcifications is similarly nonspecific, and this finding should always suggest a differential diagnosis that includes CMV, toxoplasmosis, lymphocytic choriomeningitis virus, and the recently described parechoviruses. Because neuroradiologic studies cannot reliably distinguish these entities, definitive diagnostic virology is necessary. Specific viral pathogens, their basic virology, the clinical manifestations of diseases they cause in the newborn, management strategies, and prospects for prevention are considered on a pathogen-specific basis in the remainder of this chapter.

HERPESVIRIDAE

Currently there are eight recognized human herpesviruses, which are subdivided into three categories based on aspects of viral biology, pathogenesis, and clinical presentations. These categories are the α-herpesviruses, consisting of HSV-1, HSV-2, and varicella-zoster virus (VZV); the β-herpesviruses, which include CMV and the roseola viruses HHV-6 and HHV-7; and the γ-herpesviruses, which include Epstein–Barr virus (EBV) and Kaposi's sarcoma herpesvirus (KSHV), reviewed in Schleiss (2009). Remarkably, all of these agents have been implicated in varying degrees as causes of clinically important congenital and perinatal infections, although these associations are less well studied for the γ-herpesviruses.

HERPES SIMPLEX VIRUS INFECTIONS

HSV-1 and HSV-2 are highly related viruses. Although classically HSV-1 has been identified as a cause of oral infections (gingivostomatitis and pharyngitis), and HSV-2 has been implicated as the most common virus associated with genital herpes, in recent years these distinctions have become blurred. The greatest risk for the newborn is in the context of a first-time episode of maternal genital HSV infection occurring during pregnancy. The entity of neonatal herpes is reviewed in the following section, along with current management approaches for this infection.

VIROLOGY, EPIDEMIOLOGY, AND CLINICAL MANIFESTATIONS OF HSV DISEASE

HSV-1 and HSV-2 demonstrate a high degree of similarity, both at the molecular level and in their clinical manifestations. The degree of genetic relatedness of these two viruses is approximately 45%, and the genome structures and morphology of the virion (virus particle) are virtually identical (Kieff et al, 1972). HSV-1 and HSV-2 are both acquired predominantly at mucosal surfaces and require intimate contact for transmission. After primary infection in epithelial cells, intraaxonal trafficking of viral DNA to the dorsal route ganglia results in the establishment of latency. The latent state is characterized by the cessation of virtually all gene transcription, except for the latency-associated transcript (LAT), which is expressed in the dorsal route ganglia even as the virus maintains a quiescent state (Steiner et al, 2007; Taylor et al, 2002). The function of the latency-associated transcript is unknown, but it might involve a novel RNA-mediated mechanism, because there does not appear to be a protein product associated with the transcript (Umbach et al, 2008). After a number of triggers, including ultraviolet radiation, stress, and immunosuppression, the virus reactivates at the level of the dorsal route ganglia and initiates a cascade of viral transcription that leads to the production of infectious virus, which can traffic via the axon to the cutaneous surface or ocular surface, producing lesions (Toma et al, 2008). The recrudescence of HSV lesions, usually manifest as vesicular or ulcerative lesions at the site of primary infection, can in turn lead to person-to-person transmission, including maternal-fetal and maternal-infant transmission. Importantly, clinically evident lesions need not be present for person-to-person transmission of infection to susceptible individuals, because asymptomatic or subclinical shedding of virus is well documented, particularly in the setting of genital herpes.

A wide variety of disease syndromes are associated with primary and recurrent HSV infection. Classically HSV-1 has been described as causing disease "above the belt," whereas HSV-2 is associated with disease "below the belt." The finding of HSV-2 antibodies in seroprevalence studies is generally viewed as indicative of genital herpes, and in the pregnant patient it can be considered to be diagnostic of genital herpes. The most common disease associated with HSV infection is herpetic gingivostomatitis, characterized

typically by perioral and intraoral lesions involving the pharyngeal mucosa. HSV infection of the oropharynx may present in adolescence as herpetic pharyngitis (McMillan et al, 1993); it can be indistinguishable from other causes of pharyngitis. Other common manifestations of HSV infection include primary cutaneous infection, which can manifest as herpes gladiatorum or as a herpetic whitlow (Johnson, 2004; Wu and Schwartz, 2009). In children with atopic dermatitis, cutaneous HSV infection can be associated with eczema herpeticum, a serious illness that can be associated with systemic symptom (Bussman et al, 2008). All of these cutaneous manifestations of HSV could put a newborn at risk for acquisition of infection if care is not taken to protect the infant. HSV encephalitis is unlikely to be transmitted person-to-person; it is the most common sporadic cause of viral encephalitis in North America, and it can be associated with primary infection or reactivation of latent infection. It is most commonly associated with HSV-1 (Baringer, 2008).

The most important manifestation of HSV disease is maternal genital herpes. Genital herpes can be associated with either HSV-1 or HSV-2. HSV is the most common cause of genital ulcerative disease in the developed world, and the prevalence has increased steadily in recent year (Fleming et al, 1997). Genital herpes is characterized by blisters, ulcers, or crusts on the genital area, buttocks, or both. Typically, symptomatic disease manifests with a mixture of vesicles, ruptured vesicles with resulting ulcers, and crusted lesions. Systemic flulike symptoms such as headache, fever, and swollen glands can accompany an outbreak of genital herpes, particularly during primary infection. Other symptoms include dysuria, urinary retention, vaginal or penile discharge, genital itching, burning or tingling, and groin sensitivity. Genital lesions vary in number, are painful in nature, and if untreated persist for up to 21 days (Whitley et al, 1998). It has been recognized in recent years that many individuals with genital herpes are asymptomatic and unaware of their status (Wald et al, 2000). Therefore a negative maternal history of HSV should not dissuade the clinician from considering the possibility of neonatal herpes in an infant with compatible signs and symptoms. Patients with recurrent symptomatic episodes continue to shed virus in between episodes, even after lesions have healed and crusted over (Leone, 2005). This information has important implications for the continued evolution of the HSV epidemic in the United States. Because individuals with asymptomatic genital herpes shed virus frequently in the absence of lesions, all HSV-2 seropositive individuals are probably at risk for transmitting infection in setting of sexual activity, labor and delivery, and intimate contact.

NEONATAL HERPES

For the neonatologist, the most important category of HSV-associated disease is that of neonatal herpes. In the United States, the reported range of neonatal herpes ranges from 1 in 2500 births to 1 in 8000 births (Corey and Wald, 2009; Kimberlin, 2005; Whitley, 2004). Approximately 70% to 85% of neonatal herpes simplex infections are caused by HSV-2 (Kimberlin et al, 2001). The majority of cases occur in infants born to women who were recently infected, rather than to women with histories of recurrent genital herpes. Primary infection late in pregnancy poses a higher risk of transmission to the infant than do primary infections occurring before or early in pregnancy, suggesting that the evolution of a maternal antibody response confers some measure of protection for the infant (Brown et al, 2003; Caviness et al, 2008a). Primary genital herpes infection in a pregnant mother results in an attack rate of 33% to 50% for her infant, whereas recurrent maternal infection results in a 1% to 3% attack rate (Arvin, 1991; Brown et al, 1997; Prober et al, 1987). Overall, it is estimated that approximately 22% of pregnant women have genital herpes (HSV-2 seropositivity), and 2% of women will acquire HSV during pregnancy (Brown et al, 2005). Approximately 90% of these women are undiagnosed, because they are asymptomatic or have other subtle symptoms that are incorrectly attributed to other vulvovaginal disorders.

Strategies for preventing neonatal HSV infection can be optimized by identifying women with genital lesions at the time of labor for cesarean delivery, prescribing antiviral suppressive therapy as appropriate (see Treatment and Outcomes, later), and minimizing invasive intrapartum procedures for women in whom the diagnosis of genital herpes cannot be excluded. Rarely, cases of intrauterine infection have been described; these are often associated with overwhelming primary maternal infection and usually result in fetal demise. On occasion, placentitis is also observed (Baldwin and Whitley, 1989; Chatterjee et al, 2001; Florman et al, 1973; Hutto et al, 1987; Vasileiadis et al, 2003). Although intrauterine transmission is possible, the vast majority of HSV infections in newborns are acquired intrapartum, related to the presence of virus in the maternal genital track. Neonatal acquisition of HSV from an individual other than the mother, such as from a recurrent oropharyngeal lesion, is unusual (Light, 1979; Linnemann et al, 1978; Yeager et al, 1983). Neonatal HSV has been described as a complication of ritual circumcision (Rubin and Lanzkowsky, 2000). Approximately 85% of infants with neonatal HSV acquire infection from the maternal genital tract at the time of delivery, but only 15% to 30% of mothers who give birth to infants with neonatal HSV infection have a known history of genital HSV (Whitley, 1988). Intrapartum interventions that have the risk of penetrating fetal skin, such as scalp electrode monitoring, increase the risk of transmission to the infant (Golden et al, 1977; Parvey and Ch'ien, 1980).

Neonatal herpes can have devastating long-term consequences, making early recognition of paramount importance. Most infants with perinatal or postnatal HSV infection are normal at birth. Illness typically develops after 3 days of age; therefore the presence of skin lesions, oral ulcers, and other signs and symptoms in the first 72 hours of life should suggest diagnoses other than HSV. Premature infants appear to be at greater risk, possibly because of reduced transplacental transfer of protective antibody. Approximately 40% to 50% of affected infants are less than 36 weeks in gestational age (Whitley, 1988). Although a history of maternal cervical, vaginal, or labial lesions should be sought when neonatal HSV is being considered in the differential diagnosis, overt herpetic disease in the maternal genital tract is evident in approximately

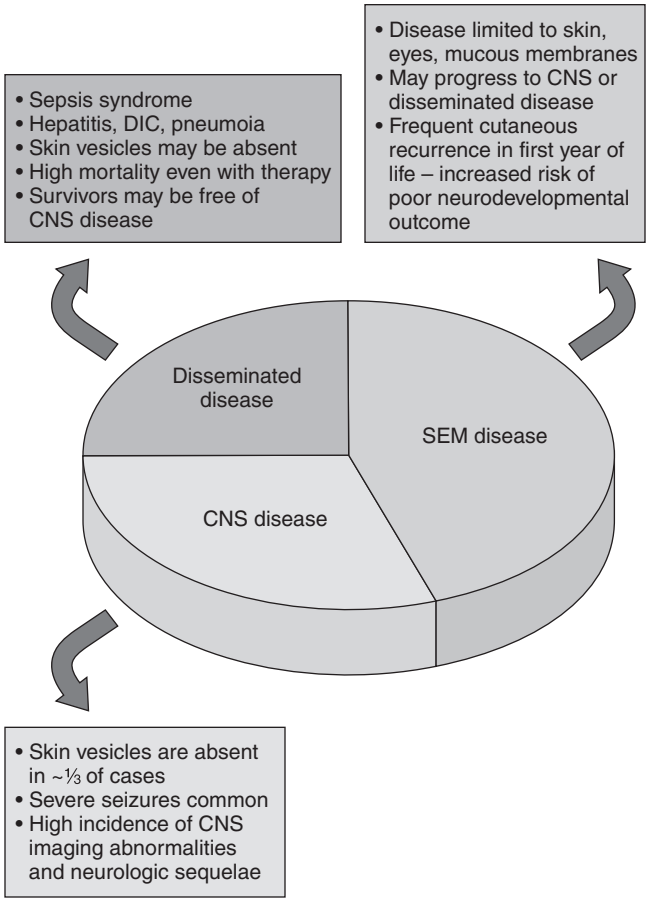

FIGURE 37-2 Characteristic presentations of neonatal herpes simplex virus (HSV) infection. Approximately 45% of neonatal HSV manifests as skin, eye, or mucous membrane disease (SEM disease); 25% as disseminated disease; and 30%, central nervous systems (CNS) disease. Characteristic features of each subtype of neonatal HSV are listed *(arrows)*. Disease may span categories; for example, infants with SEM disease may progress to disseminated or CNS disease, and infants with CNS disease may develop skin vesicles later in hospital course, although up to one-third of infants with CNS disease never have cutaneous manifestations.

one third of patients (Overall, 1994). In the remaining two thirds, infection is presumably via asymptomatic maternal genital tract shedding of virus.

Infection can manifest in newborns in one of three forms: disease limited to the skin, eye, or mucous membrane disease (SEM); disease involving the central nervous system (CNS); or disseminated HSV infection, frequently manifesting as a sepsislike syndrome, with pneumonia, hepatitis, and viremia (Figure 37-2) (Kimberlin, 2005; Whitley, 2004). There can be overlap in these syndromes; for example, an infant with disseminated disease may initially have only skin lesions. The relative proportion of infants with disseminated disease has been declining in recent years, probably because earlier recognition and treatment of SEM disease have resulted in more timely intervention with antiviral therapy. Disseminated disease usually begins toward the end of the 1st week of life. Skin vesicles may be an early sign, but they are entirely absent in almost half of patients. The scalp should be inspected carefully, particularly near the site of insertion of fetal scalp electrodes, because such lesions are easy to overlook. Systemic symptoms, although initially insidious in onset, progress rapidly. Poor feeding, lethargy, and fever may be accompanied by irritability or seizures if the CNS is involved. These symptoms are followed rapidly by jaundice, hypotension, disseminated intravascular coagulation, apnea, and shock. This form of disease is indistinguishable at its onset from both neonatal enterovirus infection and bacterial sepsis. HSV infection should be considered in the differential diagnosis of infants who have fever during the first 2 weeks of life, because fever can herald the onset of systemic disease. Localized disease may begin somewhat later, with most cases appearing in the 2nd to 3rd weeks of life. When the CNS is the primary site of infection, the skin or eyes may be involved: up to one third of infants with neonatal CNS disease will never have skin lesions during their clinical course. The infants are lethargic, irritable, and tremulous, and seizures are common and difficult to control.

Other less common but potentially localized or disseminated findings are keratoconjunctivitis, chorioretinitis, and pneumonitis, which can manifest as a focal infiltrate or as diffuse bilateral disease. Supraglottitis, intracranial hemorrhage, aseptic meningitis, and fulminant liver failure have been described (Abzug and Johnson, 2000; Erdem et al, 2002; Greenes et al, 1995; Kohl, 1994, 1999; Schlesinger and Storch, 1994). Less common presentations of neonatal herpes include hydrops fetalis (Anderson and Abzug, 1999) and laryngitis (Vitale et al, 1993).

Diagnosis

The cornerstone of the diagnosis of neonatal HSV is virologic detection; HSV serology is of little use. HSV-1 and HSV-2 are both easily recovered by culture of clinical samples. In disseminated disease, virus is present in blood, conjunctivae, respiratory secretions, and urine; it is also present in the central nervous system in approximately half of patients. In SEM disease, the virus can usually be found at the site of disease (i.e., within a vesicle). Definitive microbiologic diagnosis requires growth of the virus in tissue culture, or detection of viral nucleic acid by PCR. HSV can also be presumptively identified by immunofluorescence of infected cells using HSV-specific antibodies; such tests are commercially available and should be used in lieu of the outdated and insensitive Tzanck smear. Viral culture has the added advantage of allowing detection in the clinical virology laboratory of other agents that can mimic HSV disease in neonates, such as enteroviruses (see Enteroviruses later), because most diagnostic viral culture systems will support the growth of a variety of pathogens. When neonatal herpes is suggested, viral cultures of the throat, conjunctiva, blood, stool or rectum, and urine should be obtained, as should scrapings of vesicular, pustular, and ulcerative skin lesions. Of these sites, skin and conjunctival HSV cultures have the highest yield (Kimberlin et al, 2001).

All infants with presumed neonatal HSV disease should undergo lumbar puncture, even if SEM disease is the only observed clinical manifestation. In some infants, CNS infection may be present but subclinical, and the finding of HSV DNA in the cerebrospinal fluid (CSF) has important therapeutic and prognostic implications. Blood should be sent for viral blood culture or PCR, because viremia is

a common finding in neonatal HSV infection (Diamond et al, 1999; Stanberry et al, 1994). Usually if the CNS is involved in the setting of neonatal HSV disease, evaluation of the CSF reveals a lymphocytosis, red blood cells, normal or high protein level, and low or normal glucose level. In addition to viral culture, CSF, blood, skin lesions, and other specimens should be analyzed by PCR for the presence of HSV genome (Ryan and Kinghorn, 2006). Caution should be taken with interpretation of a negative CSF PCR result: many infants with neonatal HSV disease will not have CNS involvement, so a negative CSF PCR considered in isolation does not exclude the diagnosis of neonatal HSV. PCR of DNA extracted from the dried newborn blood spot has been reported as a way to retrospectively identify HSV infection in young infants (Lewensohn-Fuchs et al, 2003). Some experts recommend obtaining a second CSF specimen for evaluation at the end of antiviral therapy, and it has been reported that persistence of HSV DNA may be a poor prognostic factor and an indication for continuing antiviral therapy (Kimberlin et al, 1996b; Malm and Forsgren, 1999; Mejías et al, 2009). In disseminated disease, transaminase elevations consistent with hepatocellular injury are typically present; in severe disease, fulminant hepatitis with hepatic necrosis may be observed. Infants with CNS disease should undergo neuroradiographic imaging with computed tomography (CT) or magnetic resonance imaging (MRI). Early in the course of illness, imaging may demonstrate nonspecific lack of gray-white matter junction differentiation and general signs of encephalitis. Later CT findings include dilated ventricles, parenchymal echogenicity, cystic degeneration, and intracranial calcifications (O'Reilly et al, 1995), whereas MRI images demonstrate a variable appearance (Vossough et al, 2008). Neonatal HSV-2 encephalitis can be multifocal or limited to only the temporal lobes, brainstem, or cerebellum. Deep gray matter structures are involved and hemorrhage is observed in more than half of patients. In approximately 20% of patients, lesions are seen only by diffusion-weighted imaging. In 40% of patients, watershed distribution ischemic changes are also observed in addition to areas of presumed direct herpetic necrosis. In contrast to the classical description in older patients, neonatal HSV encephalitis is not usually confined to the temporal lobes. Electroencephalography should also be considered in all infants with CNS involvement or with disseminated disease, to evaluate for seizures. Electroencephalography findings will be abnormal in approximately 80% of such patients (Kimberlin et al, 2001).

Treatment and Outcomes

The cornerstone of the treatment of neonatal HSV disease is the nucleoside analog known as *acyclovir*. The development of acyclovir in the 1980s was a watershed event in the management of HSV infection. The use of acyclovir and other antivirals is summarized in Table 37-2. Although acyclovir had an efficacy similar to a previously used antiviral agent (vidarabine) in a controlled trial, acyclovir has emerged as the drug of choice because of its greater ease of administration and its highly favorable toxicity profile. The current recommendation of the American Academy of Pediatrics (AAP) Committee on Infectious Diseases is that neonatal HSV infections should be treated with high-dose acyclovir at a dose of 60 mg/kg/day intravenously, divided into three doses given every 8 hours, for either 14 days for infants with SEM disease or 21 days for infants with disseminated or CNS disease. Support for this recommendation was derived from a comparison of the results from an earlier study using standard-dose acyclovir (30 mg/kg/day) for 10 days (Kimberlin et al, 2001). There is no role for oral acyclovir in the management of neonatal HSV, and no role for topical acyclovir in neonatal SEM disease. Herpetic keratoconjunctivitis should receive topical ophthalmic antiviral therapy along with parenteral treatment. In addition to antiviral therapy, appropriate supportive care is essential, with anticipatory management targeting complications of neonatal HSV disease such as seizures, pneumonitis, and hepatic insufficiency. A beneficial role of intravenous immunoglobulin (IVIG) has been inferred from animal models of neonatal HSV disease, in which passive antibody is clearly beneficial (Bravo et al, 1996), but the absence of controlled studies precludes any recommendations in infants.

Even with timely institution of antiviral therapy, the prognosis following neonatal HSV infection is guarded. The mortality rates in infants with localized CNS disease range from 4% to 14% with antiviral therapy, and most survivors have long-term neurologic sequelae. Risk factors for increased morbidity and mortality from CNS infection include prematurity and seizures upon initiation of therapy (Kimberlin et al, 2001; Kohl, 1999). Infants with disseminated disease have a high mortality rate without antiviral therapy; 80% die, and most survivors have serious neurologic sequelae (Whitley, 1988). Intravenous antiviral therapy has decreased mortality of disseminated disease to approximately 30%, and approximately 80% of surviving infants have a normal neurologic outcome (Corey and Wald, 2009). Antiviral therapy has decreased the mortality of neonatal CNS infection from approximately 50% to 6%, but more than 70% of survivors have sequelae (Corey and Wald, 2009; Engman et al, 2008; Freij and Sever, 1988). Lethargy at initiation of therapy has been associated with a higher mortality rate in neonates with disseminated HSV infection (Kimberlin et al, 2001). Infants with skin involvement often have recurrent crops of skin vesicles for several years. In an infant younger than 6 months, readmission to the hospital for diagnostic evaluation and administration of intravenous acyclovir is appropriate when cutaneous recurrences are observed. It is postulated that recurrent cutaneous lesions may be associated with subclinical CNS reactivation, and it has been proposed that treatment of these recurrences with acyclovir will improve long-term outcome.

Management of asymptomatic neonates potentially exposed to HSV in the birth canal is controversial. This situation sometimes arises when a maternal perineal lesion is discovered after vaginal delivery. Some experts recommend neonatal surface cultures and administration of prophylactic antivirals, but there is little evidence to support this approach. The most important variable informing clinical management is probably the maternal history. Term infants exposed to HSV in the birth canal and born to women with long-standing histories of recurrent genital herpes are at low risk (<1%) of infection and, if the infant is

TABLE 37-2 Commonly Used Antiviral Agents in Neonatology Practice

Antiviral Agent	Indication	Dose, Route of Administration, Duration of Therapy	Comments
Acyclovir	Neonatal HSV	60 mg/kg/day, dosing every 8 h IV; 21 days for disseminated infection or CNS disease; 14 days for SEM disease	Monitor CBC twice weekly; adjust dosage for renal insufficiency
	Oral suppression following neonatal HSV	Efficacy for improving neurodevelopmental outcomes unproven; 10 to 20 mg/kg/dose twice daily; duration of therapy, 12 months	Neutropenia observed in ½ to ⅔ of infants; lesions while receiving suppressive therapy should suggest acyclovir-resistant strain
	VZV infection	15 mg/kg every 8 h for minimum of 5 to 7 days; longer courses may be needed for severe end-organ disease (pneumonia, hepatitis)	
	VZV postexposure prophylaxis	10 mg/kg PO four times per day; treat for at least 7 days (from 7 days after the earliest exposure until 14 days after the last exposure)	Use in conjunction with VariZIG
Trifluridine 1%	HSV ophthalmic disease	Apply as eye drops; 1 drop every 2 h to affected cornea while awake; maximum 9 drops per day	Manage in consultation with ophthalmologist
Ganciclovir	Congenital CMV; acquired CMV	12 mg/kg/day, dosing every 12 h IV; duration of therapy is 6 weeks for prevention of hearing loss; shorter courses of therapy (14 to 21 days) are reasonable for serious end-organ disease	Efficacy against CMV associated hearing loss in controlled trial; benefits of shorter courses of therapy unknown; neutropenia observed in 63% of patients in controlled trial; adjust dose for renal insufficiency; consider G-CSF if continued therapy desired in setting of neutropenia
Valganciclovir	Congenital CMV	32 mg/kg/day divided twice daily; no data available for duration or efficacy of oral formulation; CASG is currently performing a controlled clinical trial of 6 months oral suppression	Valine ester (prodrug) of ganciclovir; similar toxicity profile as GCV; long-term suppressive therapy not well studied in infants; theoretical concerns of carcinogenesis, gonadal toxicity
Lamivudine	Hepatitis B, HIV	For children 3 months to 16 years of age, recommended dose is 4 mg/kg, up to 150 mg per dose, twice daily	Chronic hepatitis B infection; also used for HIV therapy
Interferon α2b	Hepatitis B, hepatitis C	3 to 6 million international units/m^2 3 times weekly; up to 24 months duration; combined with oral ribavirin for hepatitis C	Chronic hepatitis B infection; no data in neonates; chronic hepatitis C infection when administered with ribavirin; systemic side effects (fever, flu-like symptoms, anorexia); leucopenia; thyroid autoantibodies
Pegylated interferon α2b	Hepatitis B, hepatitis C	1.5 μg/kg once per week; no information on dosing in children <2 yr old	Chronic hepatitis B; administer in conjunction with ribavirin for hepatitis C; systemic side effects (fever, flulike symptoms, anorexia); leucopenia; thyroid autoantibodies; side effects less common with pegylated formulations
Adefovir	Hepatitis B	Not recommended in children <10 years of age; 0.3 mg/kg once daily PO in children 2 to 6 yr old has favorable pharmacokinetics	Chronic hepatitis B infection; no safety or efficacy data in infants or young children
Ribavirin (oral)	Hepatitis C	15 mg/kg/day PO; no information on dosing in children <2 years of age	Hemolytic anemia; teratogenic in animal models
Ribavirin (aerosol)	Respiratory syncytial virus	Standard ribavirin aerosol therapy is 6 g per 300 mL water for 18 h daily; short-duration therapy, 6 g per 100 mL water given for a period of 2 h 3 times per day	Not indicated for use with mechanical ventilator; conjunctivitis; bronchospasm
Amantadine	Influenza A	FDA-approved dosage for children 1 to 9 yr old for treatment and prophylaxis is 4.4 to 8.8 mg/kg/day, not to exceed 150 mg/day in children <9 yr old	Not approved for use in children <1 yr old; influenza B resistant; influenza A; H1N1 resistant
Rimantidine	Influenza A	Administered in one or two divided doses at a dosage of 5 mg/kg/day, not to exceed 150 mg/day in children <9 yr old	Not approved for use in children <1 yr old; influenza B resistant; influenza A H1N1 resistant
Oseltamivir	Influenza A, influenza B	For children <15 kg, recommended dose is 30 mg PO twice daily for 5 days (treatment) or 10 days (prophylaxis)	Not typically recommended in children <1 yr old; FDA-approved guidelines for emergency use of oseltamivir in pediatric patients younger than 1 year in 2009 in response to H1N1 influenza pandemic
Zanamivir	Influenza A, influenza B	Recommended dose of zanamivir for treatment of influenza is two inhalations (one 5-mg blister per inhalation for a total dose of 10 mg) twice daily (approximately 12 h apart)	Not recommended in children <5 yr old

CASG, Collaborative Antiviral Study Group; *CBC*, complete blood cell count; *CNS*, central nervous system; *FDA*, U.S. Food and Drug Administration; *G-CSF*, granulocyte colony-stimulating factor; *HSV*, herpes simplex virus; *IV*, intravenous; *PO*, by mouth; *SEM*, skin, eye, or mucous membranes; *VariZIG*, varicella-zoster immunoglobulin; *VZV*, varicella-zoster virus.

asymptomatic, observation without antiviral therapy is sufficient. If the maternal HSV history is unclear, the infant is premature, or other obstetric complications or risk factors are present (e.g., prolonged rupture of membranes, maternal fever, signs or symptoms of chorioamnionitis, fetal scalp electrode monitoring), then empiric antiviral therapy is warranted. After the appropriate specimens are collected and sent for viral culture and PCR analysis, the infant should receive parenteral acyclovir (60 mg/kg/day) pending the results of diagnostic virology studies. There is no role for topical or oral formulations of acyclovir in this setting.

Similarly controversial is the question of whether empiric acyclovir therapy should be administered to neonates who are readmitted for evaluation of febrile illness in the first 30 days of life. Standard practice in most children's hospitals is to rule out sepsis in this setting by administering broad-spectrum antibiotics pending the result of diagnostic cultures of blood, urine, and spinal fluid. Some experts recommend the use of empiric acyclovir in this setting (Long, 2008), citing data that indicate that the prevalence of neonatal HSV infection is similar to that of invasive bacterial infection in this setting, and that infants may exhibit fever and sepsis-like syndrome as the only manifestations of HSV infection (Caviness et al, 2008b). Other experts recommend a more selective approach, based on analysis of history, risk factors, and laboratory and radiographic analyses, such as liver function tests and chest radiograph (Kimberlin, 2008). Additional studies will be required to ascertain whether acyclovir should be included in the empiric antimicrobial regimen of all neonates who are evaluated for fever in the first few weeks of life.

In addition to its critical role in the management of the acute clinical syndromes of neonatal HSV infection, acyclovir may be of benefit when administered as long-term suppressive therapy in the first 6 months of life. The Collaborative Antiviral Study Group (CASG) has reported results of controlled studies evaluating long-term oral suppressive acyclovir therapy after neonatal HSV aimed at both prevention of recurrent skin lesions and neurologic sequelae. The observation driving this study is that recurrent skin lesions (more than three episodes) within the first 6 months of life predict an adverse neurologic prognosis, possibly because recurrent skin lesions are a surrogate marker for subclinical reactivation events in the CNS (Whitley, 1991). Phase I and II trials demonstrated fewer cutaneous recurrences in the treatment group, but did not have enough subjects to analyze the effect on neurologic outcomes (Kimberlin et al, 1996a). Whether reducing cutaneous recurrences in the 1st year of life will result in improved neurodevelopmental outcome remains unknown (Gutierrez and Arvin, 2003). Given the favorable safety profile of acyclovir, the use of long-term suppression after an episode of neonatal herpes is probably an appropriate management strategy, and it is likely to reduce the need for repeat hospitalization when lesions reappear. Any theoretical benefit of acyclovir must be considered against the potential risk of neutropenia, which has been reported in 20% to 50% of neonates receiving long-term acyclovir therapy. Although readily reversible with discontinuation of drug, this concern necessitates frequent monitoring of the absolute neutrophil count. The emergence of acyclovir-resistant HSV strains is also a potential concern (Kimberlin et al, 1996a; Oram et al, 2000). That long-term oral suppressive therapy may be beneficial for improving long-term neurodevelopmental outcomes owing to neonatal HSV infection was suggested by a 2-year pilot study of oral suppressive therapy in a cohort of 16 infants (Tiffany et al, 2005). In this uncontrolled study, all children were independently mobile, free of seizures, and had normal vision and speech development at the time of final neurodevelopmental assessment.

Prospects for Prevention

Even with prompt recognition and therapy, the risk of long-term morbidity with neonatal HSV infection, particularly neurodevelopmental morbidity, remains significant. Ideally, prevention of neonatal HSV infection would be the best approach to solving the problem of HSV-induced long-term neurologic injury. Recent developments in the approach to HSV infections among women of childbearing age include consideration of maternal screening programs and the use of antiviral agents in women at risk for transmission of infection. The availability of reliable kits that allow specific serodiagnosis of HSV-1 and HSV-2 infections has enabled the identification of asymptomatic women with genital herpes who can be counseled appropriately during pregnancy (Sauerbrei and Wutzler, 2007). Although routine seroscreening of pregnant women is not currently considered a standard of care, screening in some instances, including situations where high maternal anxiety exists, seems justified. There is no evidence that routine administration of suppressive antivirals during pregnancy can improve outcomes or reduce disease in newborns (Sheffield et al, 2006), although this approach has become common in many obstetric practices (Hollier and Wendel, 2008). One benefit of suppressive antiviral therapy during pregnancy for a woman with a history of genital herpes may be a reduced likelihood of cesarean section, predicated on the assumption that suppressive therapy will prevent reactivation of HSV (Brown et al, 2003; Hollier and Wendel, 2008). Strategies for preventing neonatal herpes can also target prevention of intrapartum transmission by caesarean section. If a mother has active genital herpes simplex infection at the time of delivery, and if the membranes are either intact or have been ruptured for less than 4 hours, both the AAP and the American College of Obstetricians and Gynecologists (ACOG) recommend cesarean delivery. The role of intrapartum antivirals or immunoglobulin has not been studied in this setting.

Even with careful histories and meticulous physical examination during labor and delivery, many at-risk deliveries cannot be predicted or identified, because so many HSV-2–seropositive women are asymptomatic, do not know that they have genital herpes, and may unknowingly shed virus at the time of delivery. Infants in whom HSV infection is known or highly suspected should be put in isolation with contact precautions, and skin lesions should be covered. Finally, any health care provider with active herpetic whitlow or other skin lesions should not have direct patient care responsibilities for neonates.

Ultimately, prevention of neonatal HSV infection could be conferred by the development of a vaccine. Several

phase I, II, and III clinical trials are ongoing to investigate the utility of various HSV vaccines to prevent genital infections (Stanberry and Rosenthal, 2005). A double-blind, randomized trial of an HSV-2 glycoprotein-D-subunit vaccine given with alum adjuvant and 3-O-deacylated-monophosphoryl lipid A, was reported in a study of individuals whose regular sexual partners had a history of genital herpes. The primary end point was the occurrence of genital herpes disease. The vaccine was efficacious in women who were seronegative for both HSV-1 and HSV-2, but it was not efficacious in women who were seropositive for HSV-1 and seronegative for HSV-2 at base line. The vaccine had no efficacy in men, regardless of serostatus (Stanberry et al, 2002). The basis for this discrepancy remains unexplained, but may relate to anatomic differences in how primary infections are established in men and women, or sex-related differences in immune response. It remains to be studied what effect widespread HSV-2 vaccination might have on the incidence or severity of neonatal HSV infection.

VARICELLA-ZOSTER VIRUS

Varicella-zoster virus (VZV) is a member of the α-herpesvirus subfamily of the *Herpesviridae*. Like the related HSV-1 and HSV-2, VZV can infect neurons where it can establish latent infection. Primary varicella infection, commonly known as *chickenpox*, usually results in a fever and a characteristic vesicular exanthem. The illness often includes other systemic symptoms, such as headache and malaise. Reactivation from latency, which can occur decades after the primary VZV infection, is usually referred to as *zoster* or *shingles*. Zoster is characterized by a painful vesicular rash in a dermatomal distribution, and in older patients can lead to postherpetic neuralgia.

The neonatologist may encounter consequences of maternal VZV infection in two different clinical presentations. In congenital varicella, VZV is transmitted to the fetus in the first or second trimester of pregnancy, where it can produce a number of teratogenic consequences (Auriti et al, 2009; Laforet and Lynch, 1947; Smith and Arvin, 2009; Srabstein et al, 1974). In contrast, neonatal varicella occurs in the setting of primary maternal varicella acquired late in the third trimester, and the affected infant can exhibit symptoms and signs in the neonatal period. This section reviews both of these presentations of VZV-related disease in infants.

Epidemiology of Maternal and Perinatal Varicella-Zoster Virus

Before the advent of routine childhood vaccination against chickenpox, it was estimated that the VZV seroprevalence in women of childbearing age was greater than 95%, because of the formerly ubiquitous nature of this infection. In this era, primary VZV infections during pregnancy occurred with a frequency of 5 to 7 per 10,000 pregnancies in the United States (Balducci et al, 1992; Brunell, 1992). The major concern in the setting of primary maternal VZV infection is the risk for congenital varicella syndrome (CVS). It is not yet clear whether the risk for CVS has been ameliorated by the widespread use of VZV vaccine. For pregnant women with primary varicella infection, the transmission rate to the fetus is estimated to be approximately 25%. Only a subset of infected fetuses exhibit symptomatic disease. Approximately 100 cases of CVS have been reported in the literature (Sauerbrei and Wutzler, 2000). The risk of symptomatic intrauterine VZV infection after maternal varicella occurring during the first 20 weeks of pregnancy is approximately 1% to 2% (Enders et al, 1994; Paryani and Arvin, 1986; Pastuszak et al, 1994; Siegel, 1973). Symptomatic disease appears to be more common in female infants (Sauerbrei and Wutzler, 2000). CVS does not appear to occur in the setting of maternal zoster. A prospective study of infants born to 366 mothers with a clinical history of zoster during pregnancy found no infants with CVS (Enders et al, 1994).

Maternal infection in the third trimester is not associated with CVS, presumably because this falls outside the time frame when teratogenicity can occur. Maternal infection just before or after delivery poses a high risk for neonatal varicella. Before the advent of VZV vaccination, neonatal varicella was encountered much more commonly that CVS. For infants in which maternal illness begins 5 days or less before delivery or up to 2 days after delivery, the infant attack rate is 17% to 31% (Brunell, 1992; Feldman, 1986; Meyers, 1974). Because the incubation period for varicella is between 10 and 21 days, cases beginning in the first 10 days of life are considered to have been acquired in utero.

Pathogenesis and Clinical Manifestations

As noted, CVS is acquired from a maternal primary varicella infection that occurs during the first or second trimester. The virus is thought to be transmitted transplacentally during the viremia that precedes or accompanies the rash of chickenpox. Ascending infection from cervical infection has been proposed as a potential mechanism of transmission, but is probably much less common (Sauerbrei and Wutzler, 2000). Some of the congenital malformations associated with CVS may be a consequence of zosterlike virus reactivation events in the infected fetus rather than the direct effects of the primary viral infection. This explanation is supported by the common finding of unusual cicatricial rashes in dermatomal distributions in the newborn with CVS. Other clinical manifestations include asymmetric muscular atrophy with limb hypoplasia, low birthweight, neurologic abnormalities (cortical or spinal cord atrophy, seizures, microcephaly, encephalitis, Horner syndrome), and ophthalmologic abnormalities (chorioretinitis, microphthalmia, atrophy, and cataracts; Brunell, 1992; Feldman, 1986; Sauerbrei and Wutzler, 2000). Gastrointestinal abnormalities are reported in 15% to 23% of cases; findings include duodenal stenosis, dilated jejunum, small left colon, intestinal atresia or bands, and hepatic calcifications (Alkalay et al, 1987; Jones et al, 1994). Immature fetal cell–mediated immune response may explain the short latency period and the inadequate protection from the consequences of episodes of reactivation in utero (Higa et al, 1987; Kustermann et al, 1996). Pathology reports have noted destruction of neural tissue with residual dystrophic calcifications, chronic active inflammation in nonneural tissues surrounding viral inclusions, and evidence of

chronic placental villitis (Bruder et al, 2000; Petignat et al, 2001; Qureshi and Jacques, 1996).

Maternal varicella near term or immediately postpartum can lead to neonatal varicella. Neonatal varicella is usually caused by maternal chickenpox acquired during the last 3 weeks of pregnancy. Infection may be transmitted perinatally by transplacental viremia (most cases) or by ascending infection from the birth canal; it can also be treated postnatally by the aerosol route or direct contact with infectious lesions. Serious postnatal infection acquired from maternal varicella via breastfeeding has not been reported. Neonatal varicella may develop despite the administration of varicella-zoster immunoglobulin (VariZIG) to the infant at birth. Transplacentally transmitted infections occur in the first 10 to 12 days of life, whereas chickenpox after that time is most likely acquired by postnatal infection. The clinical presentation differs markedly for cases in which maternal rash began 5 days or more before delivery from those in which maternal illness occurred from 5 days before to 2 days after delivery. When maternal varicella is noted more than 5 days before delivery, neonatal disease usually begins within the first 4 days of life and is typically mild. In contrast, neonatal varicella in an infant whose mother develops varicella from 5 days before until 2 days after delivery has a high risk of morbidity and mortality (Isaacs, 2000; Tan and Koren, 2006). In this second group, neonatal disease typically begins between 5 and 10 days after delivery, and a fatal outcome has been reported in 23% to 30% of cases (Brunell, 1966; Sauerbrei and Wutzler, 2001). When the disease appears in this setting, it closely resembles varicella in the immunodeficient or immunosuppressed host. Recurrent crops of skin vesicles develop over a prolonged period. Typical presenting signs are fever, hemorrhagic rash, and visceral dissemination with involvement of the liver, lung, and brain. Secondary bacterial infection may occur.

Prospective studies of the long-term outcomes of CVS have not been performed, and there is probably a wide continuum of disease. Among the 96 infants reviewed by Sauerbrei and Wutzler (2000), 14 (15%) had clinical signs of zoster during early infancy; these infants had been exposed to varicella between 8 and 24 weeks' gestation. Some experts consider early zoster infections as one criterion for diagnosis of CVS. Between 1% and 2% of infants without clinical evidence of CVS, but whose mothers had chickenpox in the second and third trimesters, develop zoster in the first few weeks of life; if this occurs, consideration should be given to ophthalmologic evaluations to rule out the possibility of CVS (Enders et al, 2004; Sauerbrei and Wutzler, 2000). Overall mortality rates for CVS are estimated at 30%. Deaths occur in the first few months of life, usually secondary to severe pulmonary disease (Pastuszak et al, 1994; Sauerbrei and Wutzler, 2000).

Diagnostic Studies

Prenatal diagnosis—by means of quantification of varicella-specific IgM on fetal blood obtained by cordocentesis or through PCR analysis of chorionic villi, fetal blood, and amniotic fluid—has been attempted (Cuthbertson et al, 1987; Kustermann et al, 1996; Mouly et al, 1997). Although the yield of PCR on amniotic fluid or fetal blood is higher than that of serologic analysis of fetal IgM or viral cultures, large prospective studies of the correlation of such findings with clinical outcomes have not been performed. Reported prenatal ultrasonographic findings include polyhydramnios, hydrops, progressive intrauterine growth restriction, microcephaly, limb hypoplasia, and liver hyperechogenicities (Petignat, 2001; Pretorius et al, 1992). Abnormal ultrasonographic findings might not develop in a fetus for at least 5 weeks after maternal infection (Kerkering, 2001).

Serologic studies can be performed postnatally on infants (Paryani and Arvin, 1986). Suspected congenital infection with varicella can be confirmed by the finding of persistent VZV IgG beyond the presumed duration of passive transfer of maternal antibodies (at least 6 to 7 months). Detection of fetal IgM can also confirm infection, but it is less useful because approximately one fourth of infants reported with classic CVS have positive VZV IgM titer values (Enders et al, 1994; Sauerbrei and Wutzler, 2000). Scrapings of skin lesions, as with herpes simplex infections, can show large multinucleated cells when stained with Wright or Giemsa stain (Tzanck smears), but this procedure is no longer recommended, because highly sensitive direct fluorescent antibody (DFA) tests are readily available and are more sensitive and specific (Chan et al, 2001; Coffin and Hodinka, 1995). VZV can also be detected from skin lesions by PCR (Leung et al, 2010). Although VZV can be detected by DFA staining of cells or PCR of DNA extracted from skin and visceral lesions, these tests in infants with suspected congenital infection are often extremely low yield compared with infants and children who have acquired varicella infection. Neuroradiographic demonstration of intracranial calcifications has been reported with CVS, but this is not a common finding (Kerkering, 2001).

Treatment

No controlled studies examining the effect of antiviral therapy to prevent or treat congenital varicella syndrome have been conducted. Some experts have recommended oral acyclovir for pregnant women with varicella, especially during the second and third trimesters (AAP Committee on Infectious Diseases, 2010a). Intravenous treatment with acyclovir for the infected pregnant woman is recommended for patients with serious complications of varicella, particularly pneumonia. Anecdotal observations suggest a potential effect of acyclovir on the progression of eye disease in CVS (Sauerbrei and Wutzler, 2000). However, there are no recommendations for the use of acyclovir or immunoglobulin for treatment or prevention of CVS. For neonatal varicella, treatment with intravenous acyclovir, 60 mg/kg/day divided into doses every 8 hours, is recommended, particularly for infants at the highest risk of adverse outcomes (i.e., the infant born to a woman who develops varicella from 5 days before until 2 days after delivery; see Table 37-2).

Prevention

If a susceptible pregnant woman has a significant exposure to varicella, administration of VariZIG to her and her newborn infant should be considered seriously. These

BOX 37-3 Candidates for VariZIG* after Significant Exposure† to Varicella-Zoster Infection in Perinatology and Neonatology Practice

- Pregnant women without evidence of immunity
- Newborn infant whose mother developes chickenpox within 5 days before delivery or within 48 hours after delivery
- Hospitalized premature infant (≥28 weeks' gestational age) whose mother has no history for chickenpox or serologic evidence of prior infection
- Hospitalized preterm infants (<28 weeks' gestational age or birthweight ≤1000 g) regardless of the maternal history of varicella or varicella-zoster virus serostatus

*Varicella-zoster immunoglobulin (VariZIG) is given intramuscularly at a recommended dose of 125 units per 10 kg body weight, up to a maximum of 625 units. If VariZIG is unavailable, immunoglobulin (400 mg/kg, intravenously) can be substituted.

†Significant exposures include: household exposure; face-to-face indoor play; face-to-face contact in hospital setting with infectious staff member, patient, or visitor; intimate contact (hugging or touching) with patient with active zoster lesions.

recommendations are summarized in Box 37-3. Infants of mothers in whom varicella develops from 5 days before to 2 days after delivery should receive VZIG as soon as possible (AAP Committee on Infectious Diseases, 2010a). VariZIG is given intramuscularly at a recommended dose of 125 units per 10 kg bodyweight, up to a maximum of 625 units. If VariZIG is unavailable, IVIG (400 mg/kg) can be substituted. Passive immunoprophylaxis has been shown to prevent chickenpox in exposed older children (Brunell et al, 1969), but does not always prevent neonatal disease (Reynolds et al, 1999). Approximately 50% of exposed infants treated with immunoglobulin can still develop varicella, but the disease is often attenuated, and approximately 10% have severe disease (Hanngren et al, 1985). For healthy term infants exposed postnatally to varicella, including infants whose mother's rash began more than 48 hours after delivery, VariZIG is not generally indicated. VariZIG is not indicated for an infant whose mother has zoster. Breastfeeding is not contraindicated.

Follow-up of infants exposed to VZV and treated with VariZIG can include consideration of serologic testing (enzyme immunoassay, latex agglutination, or indirect fluorescent antibody staining for IgG) to determine whether asymptomatic infection has elicited immune protection. Some experts recommend repeated administration of VariZIG after a repeated exposure of an infant in whom varicella did not develop more than 3 weeks after administration of the initial dose of VariZIG, although the risk to these infants is less well defined. Infants receiving VariZIG should also be placed in respiratory isolation for 28 days or until discharge, because administration of VariZIG can prolong the incubation period.

In the event of a significant varicella exposure in a nursery situation, infants whose mothers have no history of chickenpox and who have undetectable antivaricella antibody titers should be considered candidates for VariZIG. All exposed infants less than 28 weeks of gestational age or birthweight less than 1000 g, regardless of maternal history, should receive VariZIG (see Box 37-3) (AAP Committee on Infectious Diseases, 2010a). The decision to use VariZIG in the premature infant greater than 28 weeks' gestation should be predicated on maternal history of chickenpox or serologic evidence of protection. As of late 2010, VariZIG is available under an investigational new drug protocol and can be obtained by calling FFF Enterprises (800-843-7477; www.fffenterprises.com/Products/VariZIG.aspx).

Acyclovir has also been recommended by some experts for postexposure prophylaxis in the setting of a nursery outbreak of VZV (Hayakawa et al, 2003; Shinjoh and Takahashi, 2009). A suggested dose is 10 mg/kg by mouth, four times per day for 7 days. All exposed health care professionals without evidence of immunity should be excused from patient contact from day 8 to 21 after exposure to an infectious patient, or to day 28 if the individual has received VariZIG (AAP Committee on Infectious Diseases, 2010a).

The best means of prevention is to follow current recommendations for universal varicella immunization of all children at 12 to 15 months of age, as well as vaccinating all susceptible adolescents and adults at high risk of exposure to varicella. VZV vaccine is available in three formulations: a monovalent formulation for children and young adults, a combination vaccine given with the measles-mumps-rubella vaccine in children and young adults, and a monovalent formulation for adults older than 60 years for prevention of herpes zoster (shingles). There is no evidence that CVS occurs after exposure to varicella vaccine during pregnancy. From March 17, 1995, through March 16, 2005, 981 women were enrolled in a pregnancy registry for women exposed to varicella vaccine (Shields et al, 2001; Wilson et al, 2008). Pregnancy outcomes were available for 629 prospectively enrolled women. Among the 131 live births to VZV-seronegative women, there was no evidence of congenital varicella syndrome. Nonetheless it is recommended that adolescents and women of childbearing age should avoid pregnancy for at least 1 month after immunization.

CYTOMEGALOVIRUS

CMV infection is ubiquitous in the general population and generally produces few if any symptoms in the immunocompetent infant, child, or adult. The mild nature of primary infection in most persons belies the severe nature of CMV-induced illness in those with impaired, suppressed, or immature immune systems, including infected newborns. Among the perinatally acquired viral infections in the developed world, CMV imposes the largest economic burden and produces the greatest long-term neurodevelopmental morbidity. This section focuses on the epidemiology, pathogenesis, diagnosis, and therapeutic management of maternal, congenital, and perinatal CMV infections.

Epidemiology

In retrospect, the first description of congenital CMV disease was in 1904, when Ribbert observed the large inclusion-bearing cells that represent the typical histopathologic finding of CMV end-organ disease in a stillborn infant. In 1920 a viral cause was proposed for the "cytomegaly" seen in tissue sections of these inclusion-bearing cells (Goodpasture and Talbot, 1921), and it would be several more decades before the ubiquitous nature of this virus

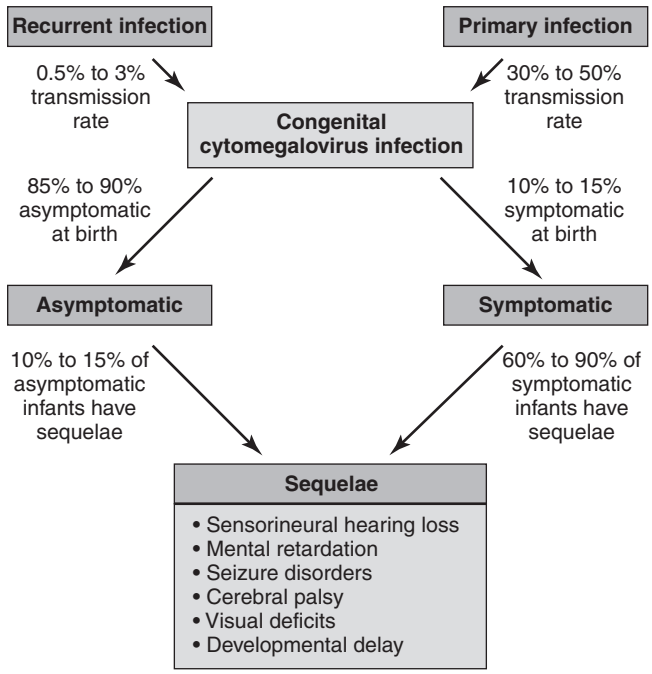

FIGURE 37-3 Profiles of congenital cytomegalovirus epidemiology, infection, and outcome. Transmission rates to the fetus are highest in the setting of primary maternal infection (up to 50%), although 0.5% to 3% of women with preconception immunity may nonetheless transmit cytomegalovirus (CMV) because of reinfection or reactivation of latent infection. Among all infants with congenital CMV infection, regardless of maternal immune status during pregnancy, approximately 10% to 15% have symptoms or signs at birth (e.g., microcephaly, chorioretinitis, hepatosplenomegaly, petechiae, purpura, thrombocytopenia, hepatitis, seizures, pneumonitis). Symptomatic infants have the highest risk of neurodevelopmental sequelae, although any infant with congenital CMV is potentially at risk for sequelae. Among asymptomatic congenitally infected infants with sequelae, the most common manifestation is sensorineural hearing loss, which may not be present at birth.

and the depth and breadth of the pathology it produces would be elucidated. In the developed world, CMV transmission occurs in 0.5% to 2% of all live births, making it the most common congenital viral infection (Demmler, 1991). Approximately 40,000 infants are born with CMV infection every year in the United States. Consequently, congenital CMV has a much greater impact than other more commonly recognized causes of birth defects in newborns. More than 8000 children per year will be permanently disabled by congenital CMV infection (Figure 37-3). This number is higher than those affected by other, better known childhood conditions such as Down syndrome, fetal alcohol syndrome, and spina bifida (Ross et al, 2006). Rates of congenital CMV infection tend to parallel those of maternal seropositivity and vary substantially across populations (Mustakangas et al, 2000). Although the lifetime risk of acquiring CMV infection is high, approaching 90% by the eighth decade of life (Staras et al, 2006), seroprevalence is substantially lower among women of childbearing age. Seronegative women are therefore at risk for acquiring primary infections during pregnancy. Primary infections pose an increased risk of transmission to the fetus, and possibly a higher risk of sequelae. Every year in the United States, approximately 27,000 seronegative women acquire a primary CMV infection (Colugnati et al, 2007).

Seroprevalence rates for CMV vary significantly globally and are generally inversely correlated with socioeconomic status. CMV seroprevalence is greater in childhood in developing countries. In developed countries, seroprevalence tends to be higher in blacks and Hispanics, low-income groups, and persons without higher education. Young maternal age, single marital status, and non-Caucasian race are associated with higher rates of congenital CMV infection. Women with increased occupational exposure to young children (including daycare providers) appear to be at elevated risk for primary CMV infections (Adler, 1989; Pass et al, 1986, 1990; Stagno and Britt, 2006; Stagno and Cloud, 1994). Health care providers in contrast are not at increased risk for acquisition of a primary CMV infection (Dworsky et al, 1983).

Pathogenesis

Morphologically and at the genome level, CMV is the largest pathogen (Schleiss, in press). There are approximately 160 known CMV genes; although based on its coding potential, CMV has the potential to encode more than 250 open reading frames. The mechanisms by which CMV injures the fetus are complex and involve a complex interplay of viral gene products, maternal immune response, and placental biology. CMV encodes genes modifying the cell cycle, cellular apoptosis mechanisms, inflammatory responses, and evasion of host immune responses. The pathogenesis of fetal injury in the setting of congenital CMV infection is incompletely understood. The pathogenesis of disease associated with acute CMV infection has been attributed to lytic virus replication, with end-organ damage occurring either secondary to virus-mediated cell death or from pathologic host immune responses targeting virus-infected cells (Britt, 2008; Schleiss, in press). Factors that contribute to fetal injury include the timing of infection relative to the gestational age of the fetus (Pass et al, 2006), the maternal immune status (Fowler et al, 1992), the extent of associated placental injury (Fisher et al, 2000), the magnitude of the viral load in the amniotic fluid (Lazzarotto et al, 2000), the induction of host genes occurring in response to infection (Challacombe et al, 2004), and possibly the genotype of the particular strain of CMV infecting the fetus (Arav-Boger et al, 2006). The relative contribution of maternal, placental, and fetal compartments in the pathogenesis of disease remains incompletely defined. Much of the injury that CMV produces in the newborn may be caused by placental insufficiency and not by viral infection of the fetus (Schleiss, 2006a). Delivery of oxygen, substrate, and nutritional factors to the fetus is impaired for a CMV-infected placenta. Moreover, CMV infection of the placenta might contribute to intrauterine growth restriction and fetal injury via induction of proinflammatory cytokines and modulation of normal trophoblast gene expression (Chan and Guilbert, 2005; Chou et al, 2006; La Torre et al, 2006; Maidji et al, 2007; Yamamoto-Tabata et al, 2004). Identified as a site for major pathogenic virus-induced injury, the placenta is increasingly considered to be a target for novel therapeutic interventions, such as CMV hyperimmune globulin for women with primary CMV infection during pregnancy (La Torre et al, 2006).

Congenital CMV infection appears to be pathologically more severe in the setting of primary maternal infection, which confers a 40% to 50% risk of intrauterine transmission during gestation, versus the 0.5% to 2% transmission risk in women with preconceptional immunity (Fowler et al, 2003). Congenital CMV infection in previously immune mothers appears to be related to reinfection with new strains of virus, with variations in epitopes of virally encoded proteins that may correlate with decreased maternal immune (Boppana et al, 1999, 2001). Many of the pathologic manifestations of congenital CMV infection that reflect visceral organ involvement (hepatitis and pneumonitis) are also observed in immunocompromised adults with disseminated CMV disease. The developing fetal brain is also highly susceptible to CMV-induced injury. CNS injury may be attributable to interference with important cellular functions of the stem and progenitor cells in the brain. The pathogenesis of CMV infection in the CNS seems to be strongly related to perturbations in neural migration, neural death, cellular compositions, and the immune system of the brain (Cheeran et al, 2009). In infants with severe symptomatic congenital CMV infection, histopathologic evidence of viral dissemination is commonly found in the brain, ear structures, retina, liver, lung, kidney, and endocrine glands (Bissinger et al, 2002). Distinctive features include large cells with large nuclei containing oval inclusions separated from the nuclear membrane by a clear zone, which gives them a characteristic "owl's eye" appearance. Inclusion-bearing epithelial cells have been described in the semicircular canals, vestibular membrane, cochlea, and other structures of the ear. In addition, temporal bone anomalies with cochlear, vestibular, and auditory canal defects have been noted in association with hearing loss in affected infants (Davis, 1969; Myers and Stool, 1968).

Clinical Presentation, Sequelae, and Prognosis

Prenatal ultrasonography provides clues to the possible diagnosis of fetal CMV infection. Findings include intrauterine growth restriction, microcephaly, ventriculomegaly, periventricular calcifications, echogenic bowel, polyhydramnios, pleural effusion, pericardial effusion, hepatosplenomegaly, intrahepatic calcifications, pseudomeconium ileus, and placental enlargement (Guerra et al, 2008; Nelson and Demmler, 1997). Fetal hydrops is also a common finding (Sampath et al, 2005). However, the sensitivity of ultrasound to detect congenital CMV infection is poor given that the majority of congenitally infected infants are asymptomatic. In a study of 600 pregnant women with primary CMV infection, abnormal ultrasound findings were detected in 51 of 600 (8.5%) pregnancies and in 23 of 154 (14.9%) fetuses in which congenital infection was documented. The positive predictive value of an abnormal ultrasound finding that predicted symptomatic congenital infection in women with primary CMV infection was only 35.3% when fetal infection status was unknown, compared with 78.3% when congenital CMV infection was confirmed (Guerra et al, 2000, 2008).

Signs and symptoms are apparent at birth in 10% to 15% of all children with congenital CMV infection. Table 37-1 outlines the clinical manifestations of symptomatic CMV infection. Each year in the United States, approximately 40,000 babies are born with congenital infection; of these, 4000 to 6000 have symptomatic disease (see Figure 37-3) (Sharon and Schleiss, 2007). Infection in the symptomatic infant can involve any organ and manifests along a spectrum from mild illness to severe disseminated multiorgan system disease. The mortality rate of symptomatic congenital CMV disease in the 1st year of life is estimated to be greater than 10% (Boppana et al, 1992). Clinical features include jaundice, hepatosplenomegaly, lethargy, respiratory distress, seizures, and petechial rash. Infants with symptomatic disease are often premature and small for gestational age. A wide spectrum of disease can be observed, including hemolysis, bone marrow suppression, hepatitis, pneumonitis, enteritis, and nephritis. Bone abnormalities have been described (Alessandri et al, 1995). Common laboratory abnormalities include thrombocytopenia, anemia, abnormal levels of liver enzymes (particularly elevated transaminases), and elevated conjugated bilirubin levels. End-organ involvement is often inferred on a clinical basis; it can be confirmed by isolation of the virus or viral DNA from tissue or by the histopathologic demonstration of characteristic inclusion bodies, positive in situ hybridization with CMV gene probes, or immunofluorescence using appropriate CMV-specific antibodies from tissue biopsies.

Of particular concern are the CNS pathologies observed with symptomatic congenital CMV infection. These pathologies include meningoencephalitis, calcifications, microcephaly, neuronal migration disturbances, germinal matrix cysts, ventriculomegaly, and cerebellar hypoplasia (Cheeran et al, 2009). CNS disease is usually characterized by at least one of the following signs and symptoms: lethargy, microcephaly, intracranial calcifications, hypotonia, seizures, hearing deficit, or an abnormal eye examination finding, such as chorioretinitis or optic atrophy. The clinical finding of microcephaly implicates the CNS as a site of infection with CMV, and abnormal findings on cranial imaging studies corroborate its involvement (Figure 37-4). Long-term neurodevelopmental disabilities are observed in 50% to 90% of children who are symptomatic at birth. In contrast, long-term neurodevelopment injury is strikingly less likely in congenitally infected infants who are asymptomatic at birth: when it does occur, it is typically limited to hearing deficits. If there is a control for sensorineural hearing loss (SNHL), the intellectual development of asymptomatic congenitally infected infants appears to be normal (Conboy et al, 1986, 1987; Stagno et al, 1982b). Among symptomatic congenitally infected infants, long-term sequelae can include microcephaly, hearing loss, motor deficits (paresis or paralysis), cerebral palsy, mental retardation, seizures, ocular abnormalities (chorioretinitis, optic atrophy), and learning disabilities (Cheeran et al, 2009; Sharon and Schleiss, 2007).

The incidence of hearing loss among children with congenital CMV infection ranges from 10% to 15% of those who are asymptomatic at birth to up to 60% of those who are symptomatic as newborns (Pass, 2005). SNHL can be progressive and fluctuating in both asymptomatic and symptomatically congenitally infected infants (Rosenthal et al, 2009). Among asymptomatic congenitally infected

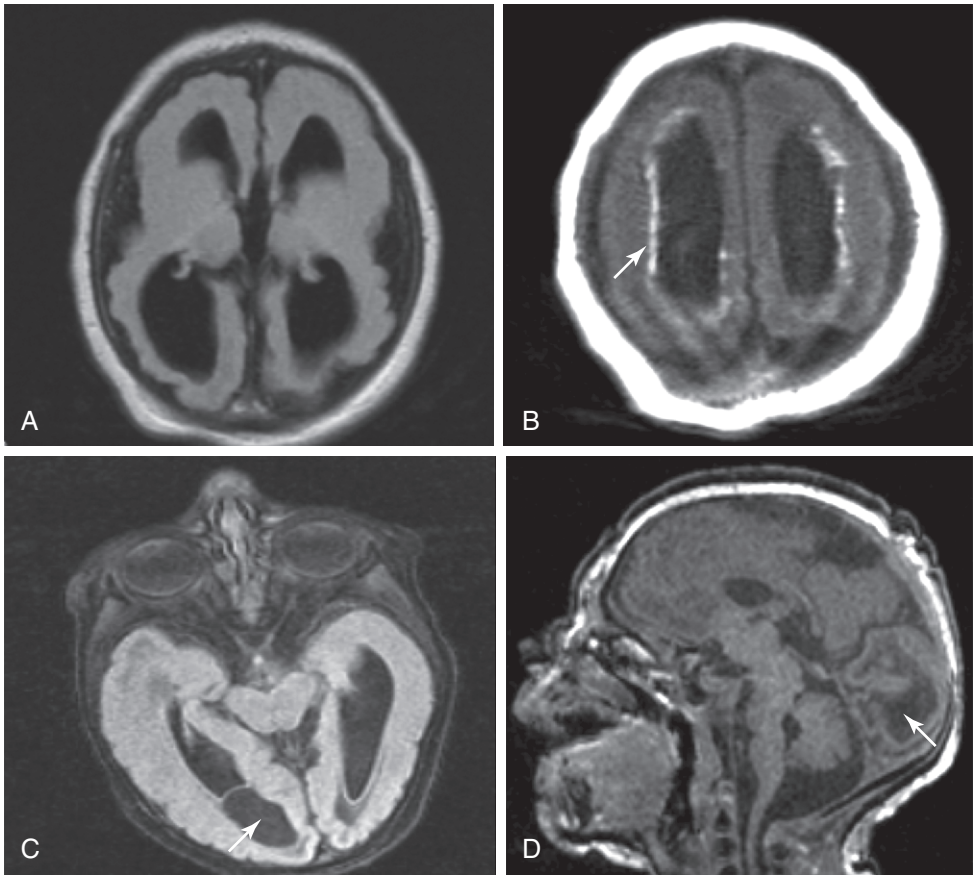

FIGURE 37-4 **Magnetic resonance image abnormalities in infants with congenital cytomegalovirus (CMV) infection with neurologic manifestations. A,** T1 axial flair image of neonate with congenital CMV diagnosed with CNS malformation in utero by prenatal ultrasound, demonstrating severe hydrocephalus and cortical dysplasia and polymicrogyria. **B,** Axial T1 image of infant with symptomatic congenital CMV infection demonstrating ventriculomegaly and periventricular enhancement *(arrow)*. **C** and **D,** T1 flash axial **(C)** and sagittal **(D)** images of a symptomatic, congenitally infected infant demonstrating ventriculomegaly, polymicrogyria, and porencephalic cyst *(arrow)*.

infants, SNHL tends to be high frequency in nature; it ranges in severity from a unilateral, mild hearing deficit to severe, bilateral, profound deafness. CMV-induced SNHL is a dynamic, evolving lesion; it may be present at birth or can appear later in childhood. Delayed-onset hearing loss usually occurs before 4 years of age (Dahle et al, 2000; Fowler et al, 1997; Rivera et al, 2002; Williamson et al, 1992), but has been reported to evolve and progress through 6 years of age and beyond. The pathogenesis of the SNHL is incompletely understood. SNHL appears to be related to an inflammatory labyrinthitis, possibly potentiated by the fact that the labyrinth is a site of immune privilege, allowing virus to persist in this compartment long after it has been cleared from the systemic compartment (Schleiss and Choo, 2006). Although some temporal bone and cochlear abnormalities have been described in a small case series of hearing-impaired infants with congenital CMV infection (Bauman et al, 1994), a more comprehensive analysis indicated that CMV-associated SNHL was not associated with structural abnormalities, such as enlarged vestibular aqueduct syndrome (Pryor et al, 2005). Logistic regression analysis of the clinical and laboratory parameters observed in 180 children with symptomatic congenital CMV infection showed that the presence of petechiae and intrauterine growth restriction were independently associated with the development of hearing loss (Rivera et al, 2002). A retrospective review of symptomatic congenitally infected infants identified neurologic and radiologic sequelae in 81% of affected patients. There was a significant correlation between the severity of the initial pure-tone audiometry and the development of progressive hearing loss, in addition to a significant correlation between a less severe final pure-tone audiometry and the presence of cerebral palsy (Madden et al, 2005). All congenitally infected infants, regardless of the results of functional hearing assessment at birth, should be monitored prospectively for SNHL by an audiologist using age-appropriate diagnostic tools. For severe SNHL, cochlear implantation has been used with success (Lee et al, 2005; Yoshida et al, 2009).

Diagnosis and Infant Assessment

Congenital CMV infection is best diagnosed by detection of virus, either through culture techniques or via PCR, in samples collected within the first 2 to 3 weeks of life. The timing of these samples is important because subsequent viral isolation may represent neonatal infection acquired in the birth canal or after exposure to breast milk (Schleiss, 2006b). Urine and saliva are the clinical samples of choice for viral culture. Specimens are typically inoculated onto a monolayer of human fibroblasts. The high viral titer in

these samples usually allows virus detection by cytopathic effect within 1 to 3 days; however, 2 to 4 weeks may be required (Revello and Gerna, 2002). Rapid virus isolation can be achieved using monoclonal antibodies to CMV-specific early protein with low-speed centrifugation of the clinical isolate onto the monolayer of fibroblasts growing on cover slips inside shell vials. This "shell vial" assay has a high sensitivity and specificity, and it allows the confirmation of diagnosis within 24 hours of inoculation (Gleaves et al, 1984; Rabella and Drew, 1990).

PCR can readily amplify CMV DNA from various clinical samples, including urine, cerebrospinal fluid, blood, plasma, saliva, and biopsy material (Revello and Gerna, 2002). If primer selection and amplification conditions are carefully chosen, PCR can yield results comparable to a standard tissue culture test. Obvious advantages of PCR over culture are the small sample requirement, the short time requirement for test results, and the ability to use frozen specimens for diagnosis. The magnitude of the systemic viral load in the congenitally infected infant can be a predictor of neurodevelopmental prognosis. In some studies, the magnitude of viral DNA in blood (DNAemia) assessed by quantitative PCR correlated with an increased risk of long-term sequelae, including SNHL (Lanari et al, 2006). Quantitative PCR assays, particularly of blood, should be ordered in the evaluation of congenitally infected infants and may be useful in making decisions about which infants to treat with antiviral therapy.

Serodiagnosis of congenital CMV is problematic. In congenital CMV infection, antibody production by the infected fetus begins in utero; however, serodiagnosis of congenital infection is complicated by the presence of maternal IgG antibodies that cross the placenta. Although a negative antibody titer in infant and maternal sera provides sufficient evidence to exclude the diagnosis of congenital CMV infection, positive titers in the newborn by no means confirm congenital infection. The presence of IgM antibodies to CMV in cord or neonatal blood is highly specific and in principle represents fetal antibody response, but many IgM commercial detection assays cross-react with IgG antibodies. Therefore a positive IgM titer has limited sensitivity in diagnosing congenital CMV infection and should not take the place of viral culture or PCR (Revello et al, 1999b).

A recent development in molecular diagnostics for congenital CMV infection has been the use of dried blood spots (DBSs) as a source of CMV DNA for PCR-based detection (Barbi et al, 2006; Scanga et al, 2006; Yamagishi et al, 2006). DBS screening is amenable to long-term storage, so diagnosis can be made retrospectively, even after several years. The test might be useful in the future for implementation of widespread population-based newborn screening for congenital CMV infection (Dollard et al, in press; Kharrazi et al, 2010). However, recent evidence from a large multicenter study suggests that DBS is not sufficiently sensitive for diagnosis of congenital CMV compared with detection in other bodily fluids such as saliva and urine (Boppana et al, 2010). An alternative approach would be to analyze the DBSs obtained from infants with failed newborn hearing screens, because congenital CMV infection can be identified in approximately 3% of such cases (Choi et al, 2009). This approach would allow early detection and more timely intervention; however, it would fail to identify those congenitally infected infants who pass the newborn hearing screening but later develop SNHL.

Cranial ultrasonography, head CT, and brain MRI are used to detect brain lesions associated with congenital CMV infection. CNS anomalies can be detected in some infants in utero. Fetal MRI can also detect abnormalities, including microcephaly and cortical anomalies, even when the ultrasound is normal; this appears to be the preferred modality for diagnosis of fetal CNS involvement (see Figure 37-4; Benoist et al, 2008; Doneda et al, 2010). Because the finding of CNS disease is a potential harbinger of permanent sequelae, diagnostic CNS imaging is warranted in all suspected cases of congenital infection (Ancora et al, 2007; Boesch et al, 1989; Boppana et al, 1997; Kylat et al, 2006). Any of the standard imaging modalities is valuable in assessing CNS involvement. Ultrasound, because of its convenience, is an appropriate initial study and is particularly valuable and sensitive in detecting periventricular calcifications and lenticulostriate vasculopathy associated with mild to moderate ventricular dilatation. MRI provides important additional information, particularly the presence of associated polymicrogyria, hippocampal dysplasia, and cerebellar hypoplasia (de Vries et al, 2004); therefore the staged sequential use of ultrasound and MRI is probably the preferred approach to CNS imaging in this setting.

Careful initial hearing evaluation and longitudinal monitoring for SNHL is required in all infants with documented congenital CMV infection, given that this complication is the most common late sequela of congenital CMV infection. Early recognition of SNHL and institution of appropriate interventions (speech–language therapy, centers for deafness education, and cochlear implants) can markedly improve the developmental, social, and language skills of a child with hearing impairment. Any child born with congenital CMV infection, whether symptomatic or not, deserves careful and recurring evaluation for cognitive delays, visual impairment, or motor disabilities. Follow-up evaluation should include a multidisciplinary team approach involving a pediatric infectious diseases specialist, pediatric otolaryngologist, and child behavioral-developmental specialist, in addition to a physical therapist, ophthalmologist, and neurologist as needed.

Treatment: Antiviral Intervention in the Newborn and the Pregnant Patient

Experience with the use of antiviral therapies against CMV in immunosuppressed patients, particularly solid organ and hematopoietic stem cell recipients and patients with HIV infection, is considerable (Boeckh and Ljungman, 2009; Razonable, 2005). Several studies in recent years have extended this experience to infants and children and have clearly indicated a benefit of antiviral therapy against CMV infection in several settings. In a phase 3, randomized, nonblinded controlled trial of ganciclovir for newborns with congenital CMV disease (Kimberlin et al, 2003), a group of infants with virologically confirmed congenital CMV received a 6-week course of ganciclovir (6 mg/kg every 12 hours). The primary endpoint was improved hearing or retention of normal hearing. Significant differences

between treated and untreated groups were noted, including a statistically higher likelihood of normal or improved hearing at 6 months of age in treated infants compared to controls. Although almost two thirds of the treated infants had neutropenia, it was reversible when antiviral therapy was halted. In a follow-up assessment, infants with symptomatic congenital CMV involving the CNS who received intravenous ganciclovir therapy had fewer developmental delays at 6 and 12 months, using the Denver Developmental Screening test, compared with untreated infants (Oliver et al, 2009). Because the use of ganciclovir can promote improved hearing and neurodevelopmental outcomes, antiviral therapy should be considered for all infants with congenital CMV infection with any evidence of CNS involvement (microcephaly, abnormal CNS imaging study, positive CSF for CMV DNA, chorioretinitis, or evidence of SNHL).

Ganciclovir should also be used in any infant with severe or life-threatening end-organ CMV disease, whether acquired via congenital infection or via a postnatal route (see Table 37-2) (Schleiss and McVoy, 2004). CMV retinitis in the congenitally infected infant can represent a particularly problematic management issue; it has been reported that up to 6 months of antiviral therapy may be required to control chorioretinitis in the symptomatic congenitally infected infant (Shoji et al, 2010). All infants with documented congenital infection should have an ophthalmologic evaluation. If chorioretinitis is present, it should be managed in consultation with an ophthalmologist and infectious diseases expert. Although ganciclovir improves neurodevelopmental outcomes for symptomatic infants, it is not clear whether ganciclovir holds the promise of improving outcomes in infants with asymptomatic congenital CMV infection. Because some of these infants are at risk to progress to SNHL, clinical trials are warranted to explore whether antiviral therapy could prevent development of hearing loss. Other investigational studies including the assessment of the therapeutic potential in infants of the prodrug of ganciclovir, valganciclovir, are needed. The potential role of valganciclovir in long-term (suppressive) therapy of CMV in congenitally infected infants is currently under investigation. The CASG is currently conducting a clinical trial of 6 weeks versus 6 months of valganciclovir (www.casg.uab.edu; Nassetta et al, 2009). A number of case reports and small case series have reported the safety, tolerability, and possibly efficacy of long-term oral therapy with valganciclovir in the setting of congenital CMV infection (Amir et al, 2010; Hilgendorff et al, 2009; Lombardi et al, 2009; Yilmaz Çiftdogan and Vardar, 2011), but the uncontrolled nature of these reports precludes any recommendations for oral therapy at this time.

The prospect of treating the pregnant patient to prevent transmission of CMV to the fetus is an area of active investigation. Ganciclovir has demonstrated teratogenic risk in some studies (Schleiss and McVoy, 2004); although this has never been demonstrated in humans, it has limited research in this area. A case report of the use of oral ganciclovir in a pregnant liver transplant patient did not show any evidence of teratogenicity (Pescovitz, 1999). Ganciclovir has been demonstrated to cross the placenta, and therefore could theoretically be used to treat CMV infection in utero (Brady et al, 2002). An observational study of 20 women with 21 fetuses, with confirmed congenital CMV infection treated with oral valacyclovir, demonstrated placental transfer of valacyclovir with measurable concentrations in the amniotic fluid and a subsequent reduced viral load in the fetal blood (Jacquemard et al, 2007). There have been several case reports of treatment of congenital CMV infection in utero with oral, parenteral, or intraamniotic ganciclovir with varying degrees of success (Miguelez et al, 1998; Puliyanda et al, 2005; Revello et al, 1993, 1999a). Although it is probably safe, prenatal treatment of fetal CMV infection with ganciclovir is currently not supported by the available data; further study with a randomized controlled trial is needed.

Passive immunization with CMV human immunoglobulin (HIG) has been studied for the in utero treatment and prevention of congenital CMV infection. CMV HIG is a pooled, high-titer immunoglobulin preparation derived from donors with high levels of CMV antibody. Nigro et al (2005) completed a prospective study of CMV HIG for the treatment of pregnant women with primary CMV infection, including some women with confirmed fetal CMV (Nigro et al, 2005). The women were enrolled in the therapy group if they had an amniocentesis and confirmed congenital CMV infection, as evidenced by a positive PCR in the amniotic fluid; they were enrolled in prevention group if they did not have an amniocentesis. In the therapy group, only 1 in 31 of the treated mothers delivered an infant with congenital CMV disease, compared to 7 in 14 mothers who were not treated with HIG. In the prevention group 6 of 37 mothers receiving HIG delivered infants with congenital CMV, compared to 19 of 7 mothers who did not receive treatment. Overall, there was a statistically significant reduction of risk for congenital CMV infection with HIG therapy. In a subsequent study, three fetuses treated with HIG had resolution of their ultrasonographically detected cerebral abnormalities; in contrast the two untreated fetuses had persistence of their cerebral abnormalities (Nigro et al, 2008). In addition to fetal effects, CMV HIG has been demonstrated to affect the placenta. In pregnancies treated with HIG, significant reductions in placental thickness have been demonstrated (La Torre et al, 2006). The reduction in placental thickness with HIG treatment suggests that at least part of the beneficial effect of treatment is mediated at the level of the placenta (Schleiss, 2006a). Randomized controlled trials of HIG for the treatment and prevention of congenital CMV infection are needed. Until such data are available, clinicians could consider treatment with CMV HIG in pregnant patients with confirmed fetal CMV infection.

Natal Acquisition of CMV Infection: Implications for the Premature Infant

In addition to congenital infection, CMV can produce disease in the newborn infant after natal acquisition; this can occur via one of three mechanisms: (1) transmission in the birth canal during vaginal delivery after exposure to infectious cervicovaginal secretions, (2) through ingestion of breast milk, and (3) via blood transfusion. Of these potential mechanisms, the most common is via breast milk (Schleiss, 2006c), with transmission in the birth canal occurring less commonly. It has long been recognized that

CMV is shed by the cervix (Montgomery et al, 1972) and excreted in the breast milk of seropositive women (Hayes et al, 1972; Stagno, 1982a). The risk of CMV transmission in infants who are breastfed by seropositive women shedding virus in their breast milk has been reported to be between 58% and 69% (Dworsky et al, 1983; Stagno et al, 1980). CMV infection acquired in the postnatal period in healthy term infants by this route typically is asymptomatic, only rarely producing any morbidity. There is no convincing evidence that acquisition of CMV via breast milk leads to any adverse neurodevelopmental sequelae (Kurath et al, 2010). In a study of CMV transmission through breastfeeding, all the infants who acquired CMV infection had normal neurodevelopment at a mean follow-up of 51 months of age (Vollmer et al, 2004).

Although the safety of breastfeeding has been established in term infants in CMV-seropositive women, controversy exists regarding the safety of breastfeeding low-birthweight, premature infants. Studies in low-birthweight and very low-birthweight (VLBW) preterm infants yield conflicting results regarding to the risk of developing symptomatic infection after breast milk acquisition of CMV (Schleiss, 2006c). In one study of VLBW premature infants (<32 weeks' gestation, <1500 g) exposed to CMV via breast milk, virus transmission occurred in 33 of the 87 exposed infants (Maschmann et al, 2001). Approximately half of these infants were ill and exhibited symptoms such as hepatopathy, neutropenia, thrombocytopenia, and sepsislike deterioration. Conflicting reports of early postnatal CMV infection in preterm infants in highly immune populations have suggested that symptomatic CMV infection acquired by breast milk is rare (Mussi-Pinhata et al, 2004; Kurath et al, 2010). Proposed efforts to reduce the infectivity of breast milk from seropositive mothers have included freezing breast milk at –20°C, Holder pasteurization, and short-term pasteurization (Hamprecht et al, 2004). Of these methods, freezing is the most studied and most likely to maintain the salutary immunologic properties of breast milk. Some experts recommend freeze-thawing all breast milk before feeding the VLBW premature infant if the mother is known to be CMV seropositive, or if her CMV serostatus is unknown. Although freezing breast milk may lower the incidence of postnatally acquired CMV infection, it does not entirely eliminate the risk (Maschmann et al, 2006). It is presumed that VLBW premature infants are at increased risk because they possess fewer transplacentally acquired antibodies against CMV than do term babies, and thus are more likely to develop disease upon infection. It has recently been shown that treating the VLBW infant with IVIG appeared to reduce the likelihood of transmission of CMV by breast milk (Capretti et al, 2009), although this is not currently considered to be an indication for the use of IVIG in the premature infant. Further evidence is necessary to make recommendations regarding what, if any, interventions are appropriate in low-birthweight, preterm infants receiving breast milk from CMV-seropositive mothers.

CMV can be transmitted through blood transfusion, and transfusion-associated infections were at one time a major problem in the neonatal intensive care setting (Adler, 1986; Adler et al, 1983, 1984; Prober et al, 1981). Two approaches are currently used to decrease the risks of transfusion-associated CMV, leukocyte reduction, and directed transfusion of CMV-negative blood products (Lamberson et al, 1988). Although leukocyte reduction has had a dramatic effect on the risk of transfusion-associated CMV, reports are conflicting in the literature regarding the question of whether this intervention is completely effective at eliminating the risk of transfusion-transmitted CMV (Allain et al, 2009; Fergusson et al, 2002; Vamvakas, 2005). A recent survey of the American Association of Blood Banks physician membership revealed that 65% of those responding believed that leukocyte-reduced and CMV-negative blood components were equivalent in their ability to prevent transfusion-associated transmission of CMV (Smith et al, 2010). Leukoreduction should be adequate for preventing the overwhelming majority of transfusion-associated CMV infections in the newborn intensive care unit. However, despite the American Association of Blood Banks survey results on attitudes toward leukocyte-reduced blood products, fetuses and neonates are more likely to receive CMV-negative products compared with other groups receiving transfusions, and additional studies are warranted to ascertain what risk may exist for premature infants receiving leukocyte-reduced products from CMV-seropositive donors.

Prevention

One important strategy for addressing the problem of congenital CMV is the education of women of childbearing age about the risks of transmission and strategies for prevention. Child care providers (including daycare workers, special education teachers, and therapists) appear to have a higher risk of occupational exposure to CMV, because of extensive contact with infants and young children (Adler, 1989; Pass et al, 1986, 1990). Education of the potential occupational risk in this group is essential. In contrast to these child care providers, health care workers who appropriately use routine infection control practices are not at increased risk of CMV acquisition. CMV infections in pregnant women are typically clinically "silent." Like most healthy individuals, more than 90% of pregnant women with primary CMV infections have no symptoms. When symptoms occur, they are nonspecific and vague, often described as a flulike syndrome. Potential manifestations include fever, fatigue, headache, myalgia, lymphadenitis, and pharyngitis, but these are the exception and not the rule. Because most maternal CMV infections are asymptomatic, a major goal is education of all women of childbearing age on hygienic practices (ACOG Practice Bulletin, 2002; Jeon et al, 2006; Ross et al, 2006). Hygienic strategies are important because the saliva and urine of infected children are significant sources of CMV infection among pregnant women. Strategies include washing hands whenever there is contact with a child's saliva or urine, not sharing food, utensils, or cups, and not kissing a child on the mouth or cheek (Anderson et al, 2007; Cannon and Davis, 2005). It is also essential that women become better educated on the importance of CMV infection. A survey of women in 2005 showed that only 14% of women knew what CMV was, but most believed that preventative measures for an infection that could harm an unborn baby would generally be acceptable (Ross et al, 2008). The

effectiveness of educating pregnant women on methods to prevent CMV transmission has been demonstrated (Adler et al, 1996). In a study in which seronegative mothers with a child in group day care were instructed on measures to prevent CMV transmission, pregnant mothers had a significantly lower rate of CMV infection when compared with nonpregnant mothers attempting conception (Adler et al, 2004). In addition, a study in France recently demonstrated a lower CMV seroconversion rate after counseling pregnant women on hygienic measures (Vauloup-Fellous et al, 2009).

Prenatal maternal screening for CMV antibodies is controversial. Because women who are CMV-immune can be reinfected with new strains that can then be transmitted to the fetus, with subsequent sequelae (Boppana et al, 1999, 2001), the finding of a positive preconception titer for CMV IgG antibody may provide a false sense of reassurance and decrease a pregnant patient's motivation to engage in careful hygienic practices. A recent study evaluated three screening strategies and suggested that universal maternal screening for CMV could be a cost-effective strategy if a treatment were available that could achieve a 47% reduction in disease (Cahill et al, 2009).

Ultimately the control of congenital CMV could be realized by the development of an effective vaccine. No CMV vaccines are currently licensed; however, because of the enormous economic impact of congenital CMV, the Institute of Medicine has identified a CMV vaccine as the highest-level priority for new vaccine development (excluding HIV vaccines) for the United States (Stratton et al, 2001). The CMV envelope glycoprotein B has been the most studied subunit vaccine candidate for this purpose, because it is a target of neutralizing antibody in all CMV-seropositive individuals. Results of a phase II, placebo-controlled, randomized, double-blind trial of the recombinant CMV envelope glycoprotein B with MF59 adjuvant were published recently (Pass et al, 2009). In this study, three doses of the CMV vaccine or placebo were administered at 0, 1, and 6 months to healthy women within 12 months postpartum. Women in the vaccine group were less likely than the placebo group to become infected with CMV (p = 0.02) with 18 of 225 women becoming infected with CMV in the vaccine group, compared to 31 o 216 in the placebo group. This report is the first to document efficacy of any CMV vaccine in a clinical trial and should help to accelerate the pace of future vaccine development and testing. Other clinical trials include evaluation of live, attenuated CMV vaccines and the testing of subunit vaccines targeting other key proteins involved in the humoral and cellular immune responses to CMV infection (Schleiss, 2008).

HUMAN HERPESVIRUS 6 AND 7

Human herpesvirus (HHV) 6 was isolated in tissue culture in 1986 from peripheral blood leukocytes of patients with both lymphoproliferative disorders and HIV infection (Bernstein and Schleiss, 1996; Schleiss, 2009). The virus was eventually shown to have a tropism for T cells, and molecular studies revealed homology with CMV. These findings suggested that the virus belonged to the family Herpesviridae. For several years after discovery, its role in disease was unclear, but it is now known to be the major etiologic agent of roseola infantum (exanthem subitum) and has been implicated in other clinical syndromes. HHV-6 is a prototypical β-herpesvirus, with a double-stranded DNA genome contained within an icosahedral capsid, surrounded by an outer envelope. HHV-6 is subclassified as either variant A or B, based on differences in nucleotide sequence, restriction enzyme profile, and reactivity with monoclonal antibodies. HHV-6B is the subtype typically associated with exanthem subitum (Yamanishi et al, 1988). HHV-6 and HHV-7 are ubiquitous in nature, and typically cause infection in the first 2 years of life.

HHV-7 is highly related to HHV-6 and, like HHV-6, is responsible for roseola infantum (Tanaka et al, 1994). HHV-7 is a β-herpesvirus, structurally and molecularly similar to CMV and HHV-6. It was first isolated from $CD4^+$ T cells of a healthy individual. The high degree of homology with HHV-6 creates difficulty in interpretation of serologic assays, which are largely investigational in nature and not generally useful for clinical practice, because there is considerable cross-reactivity of antibodies between HHV-6 and HHV-7 proteins. As with HHV-6, infection with HHV-7 appears to be ubiquitous, although infection appears to be acquired somewhat later in life than is HHV-6 (Caserta et al, 1998; Suga et al, 1997). Approximately 40% to 45% of children have antibodies to HHV-7 by 2 years of age, and 70% of children are seropositive by 6 years of age. Like other β-herpesviruses, HHV-7 can be found in the saliva, suggesting a route for person-to-person transmission. Based on its identification in cervical secretions, HHV-7 also has the potential for perinatal transmission (Okuno et al, 1995).

It is of interest to examine the evidence that suggests that HHV-6, like CMV, can cross the placenta and infect the fetus in utero, given the extensive molecular similarities between these two viruses. In one early study, HHV-6 DNA was detected by PCR in approximately 25% of pregnant seropositive women at the time of delivery, and in approximately 1% of cord blood samples, suggesting the possibility of congenital transmission (Dahl et al, 1999). Examination of 305 cord blood samples in another study identified HHV-6 DNA by PCR in 1.6% of infants (Adams et al, 1998). Interestingly, this potential vertical transmission rate of 1% to 2% is similar to congenital infection rates commonly reported for CMV. Congenital HHV-6 transmission was first definitively reported in a study of 5638 cord bloods; 57 samples (1%) had HHV-6 DNA by PCR, but none had HHV-7 (Hall et al, 2004). Of note, these infections were all asymptomatic, and the HHV-6 genome variant in one third of congenital infections was HHV6A, in contrast to the more common variant HHV6B, which is encountered in virtually all postnatal infections. Although the rate of congenital HHV-6 transmission at approximately 1% is highly similar to that observed for congenital CMV, the mechanisms of transmission are different. It has been shown that vertical transmission of HHV-6 most often occurs (90% of cases) because of the germline passage of chromosomally integrated HHV-6 (Hall et al, 2008). The mode of inheritance of HHV-6 genome in this form of vertical transmission appears to be exclusively maternal (Hall et al, 2010). HHV-6 is unique among the human Herpesviridae regarding its capacity to integrate into the host chromosome and mediate germline transmission of

viral genome from mother to fetus. Remarkably, HHV-6 is the first functional virus of any type reported to be passed through the human germline. The clinical consequences of such transmission, and the differences in germline transmission of viral genome and the more common postnatal acquisition of HHV-6 in early childhood, remain unknown. That HHV-6 genome appears to integrate into the telomere—a chromosomal component important in cellular aging and in cancer—suggests that there may be interesting long-term consequences associated with vertical germline transmission of this virus (Arbuckle et al, 2010; Nacheva et al, 2008) that remain to be elucidated.

HHV-6 and HHV-7 DNA has been found to be present in cervical secretions, placenta, and peripheral blood mononuclear cells of pregnant women (Caserta et al, 2007). Whether intrapartum transmission of these viruses can occur in the birth canal during delivery remains unknown. HHV-6 DNA can also be found in breast milk. Perinatal transmission via this mechanism has been postulated (Joshi et al, 2000), but has not been demonstrated.

KAPOSI'S SARCOMA HERPESVIRUS AND EPSTEIN–BARR VIRUS

In 1994 a novel herpesvirus, HHV-8 or KSHV, was identified in patients with AIDS-associated Kaposi's sarcoma (KS; Chang et al, 1994). This virus was assigned to the γ-herpesvirus family of the Herpesviridae, based on its molecular and sequence similarity to the other prototypical γ-herpesvirus, Epstein–Barr virus. Subsequent studies have linked KSHV to both AIDS-associated KS and the endemic forms of KS that are prevalent in elderly Mediterranean men. Little is known about routes of transmission of KSHV in nonpregnant patients, let alone whether it can be transmitted perinatally. The clinical significance of acquiring primary KSHV infection outside of the HIV setting is also unclear. Serologic evidence from sexually transmitted disease clinics suggests that sexual contact is a risk factor for acquiring KSHV. The epidemiology of primary HHV-8 infection appears to vary considerably worldwide. Indeed, the routes of acquisition of infection and mechanisms responsible for person-to-person transmission remain uncertain. After the virus was initially discovered, the unique role it seemed to play in inducing malignant disease in HIV-infected patients suggested that the primary route of transmission of HHV-8 was through sexual contact, particularly among gay men. However, more recent evidence suggests that other routes of infection exist, including transmission by saliva (Pica and Volpi, 2007).

A recent cross-sectional study of the seroprevalence of HHV-8 in children and adolescents in the United States indicated a prevalence of approximately 1% (Anderson et al, 2008). There appears to be considerable regional variation in prevalence in the United States. In a population of children in south Texas, the seroprevalence was 26%, strongly suggesting that nonsexual modes of transmission predominate (Baillargeon et al, 2002). In Sub-Saharan Africa, prevalence in children is even higher, approaching 60% in some studies (Sarmati, 2004). There are reports of infections in infants that suggest possible vertical transmission, but congenital infection has not been demonstrable by PCR techniques (Sarmati et al, 2004). HHV-8 can also be transmitted by blood transfusion (Hladik et al, 2006); this observation would suggest that transplacental transmission is at least theoretically feasible. In a study of 89 KSHV-seropositive women, 13 mothers (14.6%) had KSHV DNA detected in their peripheral blood mononuclear cells; 2 of 89 samples drawn at birth from infants born to these mothers had KSHV DNA detectable within their peripheral blood mononuclear cells. These findings suggest that KSHV can be transmitted perinatally, but infrequently (Mantina et al, 2001). As serologic and nucleic acid–based diagnostics tests become more widely available, a better assessment of the worldwide seroepidemiology of HHV-8 infection and an increased understanding of its modes of transmission will be achievable.

Most primary infections with HHV-8 are probably asymptomatic, although the clinical course of primary symptomatic HHV-8 infection in immunocompetent children has been described (Andreoni et al, 2002). In this study, fever and rash were noted with primary infection. The rash first appeared on the face and gradually spread to the trunk, arms, and legs. It initially consisted of discrete red macules that blanched with pressure and eventually became papular. An upper respiratory tract infection appeared as a secondary symptom in most children, and a lower respiratory tract infection appeared as a secondary symptom in one third of symptomatic children. Additional information on the epidemiology and modes of transmission of this pathogen, particularly in the prenatal and intrapartum period, is needed.

There is a minimal amount of information available about prenatal and perinatal modes of transmission of EBV. EBV is the causative agent of infectious mononucleosis and is associated with nasopharyngeal carcinoma, Burkitt's lymphoma, and lymphoproliferative disease in immunocompromised patients (Schleiss, 2009). Primary EBV infection during pregnancy appears to be rare. In a prospective study, susceptibility to EBV infection in 1729 pregnant women was evaluated by screening for EBV antibodies. Fifty-eight subjects (3.4%) had no detectable EBV antibody and were presumably susceptible. Of the 54 women who agreed to participate in this study, none acquired EBV antibody during pregnancy (Le et al, 1983). It is not clear whether transplacental passage of EBV in seropositive pregnant women occurs. Because EBV can be acquired by blood transfusion, such a mode of transmission is feasible. It has been postulated that high-titer antibodies cross the placenta and protect the fetus from hematogenous transmission of virus in women who reactivate EBV during pregnancy (Purtilo and Sakamoto, 1982). A solitary case report describes the occurrence of severe EBV disease in a premature infant, born at 28 weeks' gestation, who was examined on the 42nd day of life with hepatosplenomegaly, hemolytic anemia, thrombocytopenia, and atypical lymphocytosis (Andronikou et al, 1999). In another study, the potential for EBV vertical transmission from a seropositive mother to her child was evaluated in 67 pregnant women by nested PCR (Meyohas et al, 1996). Two of 67 neonates were positive for EBV DNA, suggesting that mother-to-child transmission of free EBV or of maternal EBV-infected cells can occur during pregnancy in the setting of latent EBV infection, but no clinical consequences

of these putative congenital infections were reported. In a study of six pregnant women with evidence of primary EBV infection, four pathologic births were observed: one spontaneous abortion, two premature babies, one of whom died, and one stillborn with multiple malformations (Icart et al, 1981). However, the assessment of primary infection was drawn solely from the serologic profile (including the presence of anti–early antigen antibodies) and the relationship of EBV infection to adverse pregnancy outcome was undefined, and it was unclear whether intrauterine EBV infection was present. In another study, placentas and some fetuses were studied in five cases of pregnancy interruption caused by maternal infectious mononucleosis in early gestation (Ornoy et al, 1982). Decidual lesions, consisting of perivasculitis and necrotizing deciduitis, were noted, and endovasculitis, perivasculitis, and occasional vascular obliteration were found in villi, as well as mononuclear and plasma cell infiltrates. Two fetal hearts exhibited evidence of myocarditis. These observations suggested a pathogenic role for placental and fetal EBV infection, but no direct virologic evidence of EBV was obtained, and these observations have not been duplicated. Accordingly a recent review concluded that maternal EBV infection did not impose a serious threat to pregnancy outcome (Avgil and Ornoy, 2006) and that no strong evidence for teratogenicity or fetal injury existed.

HUMAN PARVOVIRUS B19

Parvovirus B19, a small, single-stranded DNA virus, is the only member of the parvovirus family that causes human disease. The virus was identified in 1975 (Cossart et al, 1975) and was first linked to a disease in 1981—aplastic crisis in children with sickle cell anemia (Pattison et al, 1981). Primary infection with parvovirus B19 is commonly known as *fifth disease* or *erythema infectiosum;* it is classically described as a childhood exanthem with a "slapped cheek" appearance (Anderson et al, 1984). The agent is less ubiquitous than other common childhood exanthematous illnesses, such as HHV-6; therefore many individuals reach adulthood with no prior evidence of infection, placing women of childbearing age at potential risk. Considerable interest in the role of this virus in hydrops fetalis (nonimmune) and fetal aplastic crisis has evolved since the first cases of fetal death associated with maternal parvovirus B19 infection were reported in the 1980s (Brown et al, 1984; Kinney et al, 1988).

Epidemiology

Parvovirus B19 infection is global in nature. It is common in childhood and continues at a low rate throughout adult life. One study identified an annual seroconversion of 1.5% in women of childbearing age unrelated to their occupation (Koch and Adler, 1989). The peak incidence of erythema infectiosum is in the late winter and early spring. Periodic epidemics at intervals of a few years are typical. The virus is spread by respiratory droplet (Anderson and Cohen, 1987), by blood products (especially pooled clotting factor concentrates; Jordan et al, 1998), and transplacentally (Ergaz and Ornoy, 2006). Approximately 50% to 80% of adults in the United States are seropositive for human parvovirus B19 (Anderson, 1987; Vyse et al, 2007). A significant proportion of childbearing women are thus susceptible to infection (Markenson and Yancey, 1998; Yaegashi et al, 1998). Preconception seroprevalence to parvovirus B19 ranges from 24% to 84% (Ergaz and Ornoy, 2006). During pregnancy the risk of acquiring parvovirus B19 infection is low, ranging from 0% to 16.5% in different studies (Ergaz and Ornoy, 2006). The risk of primary maternal infection is higher during epidemics, with reported seroconversion rates ranging between 3% (Kerr et al, 1994) and 34% (Woernle et al, 1987).

It is estimated that one fourth to half of maternal parvovirus infections result in transmission of infection to the fetus (Alger, 1997; Gratacos et al, 1995; Koch et al, 1998). The vast majority of pregnancies are unaffected (Berry et al, 1992; Sheikh et al, 1992). The risk of adverse fetal outcome is increased if maternal infection occurs during the first two trimesters of pregnancy (Skjoldebrand-Sparre et al, 2000), particularly before 20 weeks' gestation. There are conflicting reports regarding the prognosis once fetal infection has been established. A longitudinal study of fetal morbidity and mortality in more than 1000 women with primary parvovirus B19 infection in pregnancy demonstrated a risk of fetal hydrops of 3.9% and a risk of fetal death of 6.3%; fetal death was observed only if maternal infection occurred before the 20th week of gestation (Enders et al, 2004). A recent retrospective analysis of intrauterine parvovirus B19 infection at a single site suggested that the rate of adverse fetal outcome is much higher than previously appreciated, with fetal hydrops and demise occurring in greater than 10% of pregnancies (Beigi et al, 2008), although the total number of cases reported in this series was low; this primarily represented a referral population to a tertiary care center.

Pathogenesis

The most common mode of transmission of parvovirus B19 is via a respiratory route. Typically, once the virus establishes infection, viremia occurs, followed by mild systemic symptoms such as fever and malaise. Viremia is short-lived, lasting only 1 to 3 days, and the characteristic immune-mediated rash develops 1 to 2 weeks later. Once the rash appears, an individual is no longer infectious. Arthropathy caused by parvovirus B19 is common; it is observed more frequently in adults with primary infection than in children. It typically manifests late in the course of illness with acute onset of arthralgias or frank arthritis involving the hands, knees, wrists, and ankles. The symptoms usually subside within 1 to 3 weeks, although approximately 20% of affected women have persistent or recurring arthropathy for months to years (Woolf et al, 1989).

Potential pathogenic mechanisms involve the recognized affinity of parvovirus B19 for progenitor erythroid cells of bone marrow. The blood group P antigen is a main cellular receptor for parvovirus B19, and it is found on red blood cells and on placental trophoblast cells (Jordan et al, 2001). The P antigen is also expressed on fetal cardiac myocytes, enabling parvovirus B19 to infect myocardial cells (Rouger et al, 1987) leading to myocarditis (von Kaisenberg et al, 2001). Myocarditis induced by parvovirus B19 can contribute to high-output cardiac failure, and the

myocardial inflammation and subendocardial fibroelastosis may also contribute to fetal hydrops (Morey et al, 1992). Fetal infection most likely occurs hematogenously via the placenta during maternal viremia. Parvovirus B19 infection in utero causes a pronormoblast arrest, which leads to fetal anemia, nonimmune hydrops, and sometimes progressive congestive heart failure (Ergaz and Ornoy, 2006; Kinney et al, 1988). The fetus is especially susceptible to adverse consequences of red blood cell infection, secondary to the intrinsic short fetal erythrocyte life span and rapidly expanding blood volume, especially during the second trimester. It has also been postulated that parvovirus B19 infection leads to cytotoxicity and subsequent anemia by inducing apoptosis of infected red blood cells (Yaegashi et al, 1999, 2000). The NS1 protein of parvovirus B19 induces cell death by apoptosis in erythroid-lineage cells by a pathway that involves caspase 3, whose activation may be a key event during parvovirus-induced cell death (Moffatt et al, 1998). The NS1 protein also has a key role in the arrest of infected cells at the G1 phase of the cell cycle prior to apoptosis induction (Chisaka et al, 2003). In addition to erythroid precursors and myocytes, other organs appear to be involved in fetal parvovirus B19 infection. Fetal brain infection has been reported. Neuropathologic findings in the infected hydropic fetus include perivascular calcifications, primarily in the cerebral white matter, as well as multinucleated giant cells. Viral DNA has been demonstrated in the brain and liver (Isumi et al, 1999). Data also suggest that the maternal cell–mediated immune response at the placental level contributes to the pathogenesis of congenital infection. In one study, placentas from women whose pregnancies were complicated by parvovirus B19 infection had increased infiltration of CD3 T cells and elevated levels of interleukin 2 (Jordan et al, 2001).

Clinical Spectrum

Parvovirus B19 infection causes erythema infectiosum, or fifth disease, in normal hosts, aplastic crisis in patients with hemolytic disorders, and chronic anemia in immunocompromised hosts. A substantial proportion of infected adult women may also have arthropathy in association with parvovirus B19 infection (Woolf et al, 1989). Maternal symptoms have been present in up to two thirds of documented cases of nonimmune hydrops fetalis associated with parvovirus B19 infection (Yaegashi et al, 1998).

The major clinical presentation of parvovirus B19 infection in the fetus is hydrops fetalis. Various estimates suggest that human parvovirus B19 infection contributes from 10% to 27% of cases of nonimmune hydrops fetalis (Essary et al, 1998; Markenson and Yancey, 1998; Yaegashi et al, 1994). Nonimmune hydrops fetalis was the main complication in 0.9% to 23% of pregnancies among proven maternal infections with parvovirus B19 (Ergaz and Ornoy, 2006). A risk of 7.1% for hydrops fetalis has been described for pregnant women who acquire parvovirus B19 infection between 13 and 20 weeks' gestation (Enders et al, 2004). Parvovirus B19 does not appear to have a major role in intrauterine fetal demise in the absence of hydrops fetalis (Riipinen et al, 2008). In addition to hydrops fetalis, in recent years there have been increasing numbers of case reports of neurologic and ophthalmologic anomalies associated with fetal parvovirus B19 infections. Although some studies undertaken to examine the association between fetal infection and congenital anomalies failed to reveal any associations (Kinney et al, 1988; Mortimer et al, 1985), parvovirus B19 has increasingly been recognized as a cause of neuronal migration defects (Pistorius et al, 2008). The role of parvovirus B19 in neurodevelopmental injury has not been fully explored. There have been at least three case reports of fetal encephalopathy associated with in utero infection with parvovirus B19 (Alger, 1997). Parvovirus B19 has recently been recognized as a cause of CNS injury in older children, including encephalitis, meningitis, stroke, and peripheral neuropathy (Douvoyiannis et al, 2009). Consideration should be given to performing brain imaging studies in infants with symptomatic in utero parvovirus B19 infection. Such infants need careful neurodevelopmental follow-up. Few data are available regarding long-term outcomes of infants infected in utero. Two prospective studies in the United Kingdom of approximately 300 congenitally exposed infants found the risk of major congenital or developmental abnormality to be less than 1% (Miller et al, 1998).

Parvovirus B19 has been implicated in some cases of congenital anemia (Heegaard and Brown, 2002). In one series of 11 children with a diagnosis of Diamond-Blackfan syndrome, 3 of 11 bone marrow aspirates revealed evidence of parvovirus B19 DNA. All three of these children, but none of the parvovirus B19 PCR-negative cases, underwent spontaneous remission (Heegaard et al, 1996). In light of these data, all infants undergoing evaluation for congenital anemias should be evaluated for the possibility of parvovirus B19 infection.

Laboratory Evaluation

In primary care, the diagnosis of human parvovirus B19 infection is most commonly made clinically through recognition of the characteristic rash. Serologic confirmation is necessary in high-risk situations, such as after a significant exposure of a pregnant woman to a child with erythema infectiosum. Both radioimmunoassays and enzyme-linked immunosorbent assays are available for detection of human parvovirus B19–specific IgG and IgM antibodies (Kinney and Kumar, 1988). Presence of anti–parvovirus B19 IgM in fetal blood or amniotic fluid may confirm fetal infection, but may be detected in only one fifth of infected fetuses (Torok et al, 1992). False-positive results of parvovirus B19 IgM testing have been reported, including cross-reactions with anti-rubella IgM (Dieck et al, 1999).

Monitoring of the pregnant patient with a primary parvovirus B19 infection is an important clinical problem. In the context of a human parvovirus B19 infection in a symptomatic, pregnant woman, elevated or rising weekly measurements of maternal alpha-fetoprotein suggest fetal infection, and rising concentrations may be a marker for an increased risk for hydrops fetalis (Carrington et al, 1987). However, some studies have failed to demonstrate any association between the magnitude of the elevation of the α-fetoprotein and the severity of fetal anemia (Simms et al, 2009). Serial fetal ultrasonographic evaluations of infected

pregnant women are recommended to evaluate and follow for fetal hydrops or intrauterine demise. The findings of echogenic bowel, ascites, pleural or pericardial effusion, or scalp edema are considered to be important markers of fetal infection and pathology. Middle cerebral artery Doppler to evaluate for fetal anemia may be another useful prospective surveillance tool, because fetal anemia can be detected using this technique before fetal hydrops is evident (Feldman et al, 2010). Other techniques to diagnose fetal parvovirus B19 infection have been studied and used, but most are not readily available. Virus can be cultured from tissue in suspension cultures of bone marrow cells from persons with hemolytic anemias, but it is difficult to isolate; therefore this method is not feasible for prenatal or postnatal diagnosis. Electron microscopy and histology have permitted visualization of parvovirus in fetal blood, ascitic fluid, tissue, and amniotic fluid, but the utility and sensitivity of these evaluations have not been well studied (Markenson and Yancey, 1998). A number of commercial PCR assays are available, and these can be performed on serum, amniotic fluid, or fetal tissue. Presumptive diagnosis can also be made based on finding IgM antibody in the maternal and fetal blood. PCR for parvovirus B19 DNA or in situ hybridization studies can be performed using maternal blood, amniotic fluid, cord blood, or fetal tissues. The detection of B19 DNA in maternal blood appears to have the best diagnostic sensitivity for identifying maternal B19 infection, and new-generation EIA and IgG avidity assays appear to hold promise for improved serodiagnosis during pregnancy (Enders et al, 2006, 2008).

Treatment

Spontaneous resolution of fetal hydrops with normal neonatal outcome has been reported in approximately one third of cases (Humphrey et al, 1991; Rodis et al, 1998a; Sheikh et al, 1992). Because two thirds of fetuses do not recover without intervention, fetal transfusion is usually recommended (Boley and Popek, 1993; Brown et al, 1994). The earlier fetal transfusion is attempted, the more likely it is to be successful. Cordocentesis allows precise assessment of the magnitude of fetal anemia, which can then be corrected by blood transfusion, typically using packed red blood cells. Using this approach, outcomes have been favorable in most reported series, even among severely anemic fetuses. In one report, packed red cell transfusion was performed in 30 patients with fetal anemia (hemoglobin values ranging from 2.1 to 9.6 g/dL). The overall survival rate was 83.8% (Schild et al, 1999). In a report of 13 cases with severe hydrops fetalis who received intrauterine transfusion, 11 of 13 survived (84.6%), whereas all the nontransfused fetuses with severe hydrops fetalis died (Enders et al, 2004).

Prognosis

Mortality rates for fetal hydrops resulting from all nonimmune causes continue to exceed 50%, even with current aggressive therapies and intensive care (Huang et al, 2007; Wy et al, 1999). Hydrops secondary to parvovirus B19 seems to have a better outcome than that from other causes (Enders et al, 2004; Ismail et al, 2001). Although few long-term prospective studies of infants born to mothers with documented primary parvovirus B19 infection have been conducted, most report normal developmental outcome. One case-control study involving approximately 200 mother–infant pairs found no differences in frequency of developmental delay between infants born to women with confirmed primary parvovirus B19 infection during pregnancy and infants born to mothers with evidence of preconceptional immunity (Rodis et al, 1998b). Other studies have also suggested a favorable long prognosis in children born to women with primary parvovirus B19 infections during pregnancy (Miller et al, 1998).

Prevention

If a pregnant woman has a significant exposure to an infectious case of parvovirus B19, counseling should be provided regarding the potential risk of infection. Anti–parvovirus IgM and IgG serologic analyses and serum PCR should be performed; if they show evidence of primary infection, then serial fetal ultrasonographic evaluations should be performed. Postexposure passive immunization with immunoglobulin is not currently recommended because the period of maternal viremia has passed by the time the diagnosis of acute parvovirus B19 infection is made (Boley and Popek, 1993). Although high-dose IVIG has been used to attempt to prevent hydrops fetalis during pregnancy in the setting of acute infection (Selbing et al, 1995), treatment with this modality in the pregnant woman or the neonate has not been shown to improve fetal outcomes; therefore it is not routinely recommended. Human IgG monoclonal antibodies with potent neutralizing activity have been generated, and these are suggested as candidates for the development of immunotherapeutic approaches for individuals chronically infected with parvovirus B19 virus or for acutely infected pregnant women (Gigler et al, 1999), but these interventions are not commercially available. There has been limited progress in the development of a candidate parvovirus B19 vaccine. Phase 1 studies of a recombinant vaccine based on baculovirus-produced capsids have been conducted, and this vaccine was found to have a favorable safety and immunogenicity profile (Bansal et al, 1993). Efforts are under way to research and develop vaccines to prevent parvovirus B19 infections using other expression systems (Lowin et al, 2005).

Pregnant health care providers should be counseled about the potential risks to their fetus from parvovirus B19 infections and should, at a minimum, wear masks and use standard droplet precautions when caring for immunocompromised patients with chronic parvovirus B19 infection or patients with parvovirus B19–induced aplastic crises. Some hospitals exclude pregnant health care providers from caring for these high-risk patients, but this issue remains controversial.

RUBELLA

Rubella virus is an enveloped, single-stranded, positive sense RNA virus belonging to the family Togaviridae. Although togaviruses are typically vector-borne infections, rubella is the notable exception, being transmitted instead by respiratory droplet. Humans are the only known natural

host for rubella virus. Rubella infection, commonly known as the *German measles*, usually results in a mild illness with an accompanying exanthem in adults and children; however, rubella produces serious consequences in pregnant patients, in whom fetal infection can lead to serious anomalies. An ophthalmologist named Norman Gregg offered the first description of congenital rubella syndrome (CRS) in 1941 while investigating an epidemic of neonatal cataracts (Gregg, 1941). Not until the global pandemic of 1964 to 1965, however, were the multiple teratogenic manifestations of CRS fully appreciated and the permanent neurodevelopmental consequences for newborns fully recognized. The capacity to grow the virus in tissue culture led rapidly to the development of a vaccine and subsequent a reduction in the incidence of CRS in the United States and other developed countries. However, CRS is still encountered in the developing world, and unfounded concerns about the safety of measles-mumps-rubella vaccine have set the stage for potential reemergence of these diseases (Omer et al, 2009). Therefore a working knowledge of CRS remains highly relevant to the care of newborns.

EPIDEMIOLOGY

Since the development of rubella vaccine in 1969, the incidence of rubella in the United States has decreased dramatically. The annual incidence of rubella cases has dropped 99%, from 58 per 100,000 population in 1969 to less than 0.5 per 100,000 population in 1997 to 1999 (Danovaro-Holliday et al, 2001). CRS cases in the United States have demonstrated a similar dramatic decline, and in 2004 the Centers for Disease Control and Prevention (CDC) concluded, against the background of few or no reports of rubella activity from the 50 states and the virtual absence of reported CRS, that endemic rubella had been eliminated from the United States (Centers for Disease Control and Prevention, 2005; Plotkin, 2006; Reef et al, 2006). The persistence of rubella in Latin America serves as the source for a small number of importation cases of rubella that are recognized in the United States annually (Castillo-Solórzano et al, 2003). In parts of the world where routine rubella immunization is unavailable or not used, rubella and CRS continue to be common. Rubella is still an important and potentially preventable cause of birth defects globally, with more than 100,000 cases of CRS occurring annually in developing countries.

Maternal rubella infection that occurs in the period of time from 1 month before conception through the second trimester of pregnancy may be associated with transmission of infection and, depending on the timing of infection, disease in the infant. The frequency of congenital infection after maternal rubella with a rash is 70% to 85% if infection occurs during the first 12 weeks of gestation, 30% to 54% during the first 13 to 16 weeks of gestation, and 10% to 25% at the end of the second trimester (Miller et al, 1982; South and Sever, 1985). The classic findings of congenital rubella are most typically associated with the onset of maternal infection during the first 8 weeks of gestation (Miller et al, 1982). Both the risk of fetal infection and severity of disease decline after the first trimester, and the risk of any teratogenic effect is extremely low after 17 weeks' gestation (Lee and Bowden, 2000).

PATHOGENESIS

Rubella virus is transmitted via respiratory droplets. Once the oral or nasopharyngeal mucosae are infected, viral replication occurs in the upper respiratory tract and nasopharyngeal lymphoid tissue. The virus then spreads contiguously to regional lymph nodes and hematogenously to distant sites. Fetal infection is believed to occur as a consequence of maternal viremia. The mechanism by which rubella infection of the fetus leads to teratogenesis has not been fully determined, but the cytopathology in infected fetal tissues suggests necrosis, apoptosis, or both, as well as inhibition of cell division of precursor cells involved in organogenesis (Atreya et al, 2004; Lee and Bowden, 2000). The rubella replicase protein p90 interacts with a cellular cytokinesis-regulatory component (i.e., the citron-K kinase) in the process leading to tetraploidy and cell cycle arrest. In tissue culture, a number of unusual manifestations of rubella replication have been observed, including mitochondrial abnormalities and disruption of the cytoskeleton. Characteristic markers of apoptosis such as DNA fragmentation, nuclear chromatin condensation, and annexin V staining can be observed following rubella infection in cell culture. Cytoplasmic inclusions have also been reported in some cell lines. Microarray analysis following rubella infection in cell culture demonstrated upregulation of cytokines and interferon, suggesting that the induction of inflammatory responses may serve as another possible mechanism of injury induced by rubella (Adamo et al, 2008). Fetuses infected with rubella demonstrate cellular damage in multiple sites and a noninflammatory necrosis in target organs, including eyes, heart, brain, and ears (Lee and Bowden, 2000).

CLINICAL SPECTRUM

The peak incidence of endemic rubella is in the late winter and early spring months. Up to 50% of primary infections are asymptomatic. The period of maximal communicability extends from a few days before until 7 days after onset of the rash. Often a prodrome of mild systemic symptoms precedes the rash by 1 to 5 days. Viremia can be detected as early as 9 days before the onset of rash. Lymphadenopathy, which can precede a rash, often is present in the posterior auricular or suboccipital region. The rash classically begins on the face and spreads caudally to the trunk and extremities. Symptoms generally last up to 3 days, and the incubation period ranges from 14 to 21 days. Transmission by breastfeeding in a case of postpartum acquisition of infection has been described (Klein et al, 1980). Typical illness in adults and children with acquired rubella infection consists of an acute generalized maculopapular rash, fever, and arthralgias, arthritis, or lymphadenopathy. Conjunctivitis is also common. Encephalitis (1:5000 cases) and thrombocytopenia (1:3000 cases) are complications.

Infants with congenital rubella are usually born at term, but often are small for gestational age. The most common isolated sequela is hearing loss (Miller et al, 1982; Ueda et al, 1979). The next most common findings are heart defects, cataracts, low birthweight, hepatosplenomegaly, and microcephaly. The triad of deafness, cataracts, and congenital heart disease constitutes the classic syndrome.

In addition, systemic illness can occur and be characterized by purpura, hepatosplenomegaly, jaundice, pneumonia, and meningoencephalitis; 45% to 70% of infants have cardiac lesions, including patent ductus arteriosus, peripheral pulmonic stenosis, and valve abnormalities (Reef et al, 2000; Schluter et al, 1998). Recently, an extensive review of published reports of cardiovascular disease in the setting of congenital rubella syndrome demonstrated that branch pulmonary artery stenosis is the most commonly identified isolated lesion (Oster et al, 2010). A variety of other signs may be present. Additional ocular findings are pigmentary retinopathy, microphthalmia, and strabismus. The skin lesions have been described as resembling a blueberry muffin and represent extramedullary dermal hematopoiesis; an identical rash can be observed in congenital CMV infection (Avram et al, 2007; Bowden et al, 1989; Brough et al, 1967; Mehta et al, 2008).

The clinical manifestations of CRS vary to some extent depending on the timing of fetal infection. In a prospective study following pregnant women with confirmed rubella infection by trimester, a full range of rubella-associated defects (including congenital heart disease and deafness) were observed in nine infants infected before the 11th week. Thirty-five percent of infants (9 of 26) infected between 13 and 16 weeks' gestation had deafness alone (Miller et al, 1982). Cataracts typically occur secondary to maternal rubella infection occurring before day 60 of pregnancy; heart disease is found almost exclusively when maternal infection is before the 80th day (i.e., first trimester). Disease manifestations that may have their onset after birth (late-onset disease) include: a generalized rash with seborrheic features that may persist for weeks, acute or chronic interstitial pneumonia, abnormal hearing resulting from presumed labyrinthitis, central auditory imperception, and progressive rubella panencephalitis (Franklin and Kelley, 2001; Phelan and Campbell, 1969; Reef et al, 2000; Sever et al, 1985).

A higher than expected incidence of autoimmune diseases, such as thyroid disorders and diabetes mellitus, have also been reported years after the diagnosis of congenital rubella (Forrest et al, 2002; Gale, 2008; McEvoy et al, 1988; Reef et al, 2000). Infants with late-onset disease have demonstrated immunologic abnormalities, including dysgammaglobulinemia or hypogammaglobulinemia (Hancock et al, 1968; Hayes et al, 1967; Soothill et al, 1966). Hyper-IgM syndrome has also been described in association with autoimmune disease in a child with CRS (Palacin et al, 2007). Other studies have demonstrated dysfunction of cellular immune responses in children with CRS (Fuccillo et al, 1974; South et al, 1975; Verder et al, 1986). The pathogenesis of these rubella-related syndromes is poorly understood. Psychiatric disturbances, including some with features of autism spectrum disorders, have been observed decades after CRS (Hwang and Chen, 2010).

LABORATORY EVALUATION

It is common obstetric practice to screen all pregnant women for rubella antibodies, and because of the devastating consequences of CRS, this is a reasonable policy to continue, even in the setting of eradication of endemic rubella in the United States. Women who are exposed to rubella should be screened for evidence of previous immunity; if none is found, they should be tested for rubella IgG and IgM antibodies. A positive IgM titer or a rise in paired IgG titers is indicative of recent infection. Women with such findings should also be evaluated to try to determine the likely gestational age at time of infection in order to assess the potential risk to the fetus.

The laboratory diagnosis of congenital rubella can be made definitively only during the 1st year of life, unless the virus can be recovered later from an affected site, such as the lens. Diagnosis can be made with any one of the following four criteria:

1. Positive anti-rubella IgM titer, preferably determined with enzyme immunoassays, but indirect assays are acceptable
2. A significant rise in rubella IgG titer between acute and convalescent measurements 2 to 3 weeks apart or the persistence of high titers longer than expected from passive maternal antibody transfer
3. Isolation of rubella virus cultured from nasal, blood, throat, urine, or CSF specimens (throat swabs have the best yield)
4. Detection of virus by reverse transcriptase PCR in specimens from throat swabs, CSF, or cataracts obtained from surgery (Centers for Disease Control and Prevention, 2001)

An infected infant can excrete the virus for many months after birth despite the presence of neutralizing antibody and, thus, may pose a hazard to susceptible individuals. In rare cases the virus can be recovered after 1 year of age. An exception to this rule is the cataract, in which the virus can remain for as long as 3 years. In late-onset disease, the virus can also be found in affected skin and lung.

Other laboratory findings are thrombocytopenia, hyperbilirubinemia, and leukopenia. Radiographic findings include large anterior fontanel, linear areas of radiolucency in the long bones (i.e., celery stalking), increased densities in the metaphyses, and irregular provisional zones of calcification (Chapman, 1991; Reed, 1969). The radiographic changes seen in rubella are not pathognomonic of the disease, but resemble those seen in other congenital viral infections, including congenital cytomegalovirus infection (Alessandri et al, 1995).

TREATMENT AND PROGNOSIS

There is no specific therapy for congenital rubella. Initially the infant may need general supportive care, such as administration of blood transfusion for anemia or active bleeding, seizure control, and phototherapy for hyperbilirubinemia. Long-term care requires a multidisciplinary approach consisting of occupational and physical therapy, close neurologic and audiologic monitoring, and surgical interventions as needed for cardiac malformations and cataracts.

The consequences of fetal rubella infection may not be evident at birth. In one study of 123 infants with documented congenital rubella, 85% of cases were not diagnosed until after discharge from the nursery (Hardy, 1973). Communication disorders, hearing defects, some mental or motor retardation, and microcephaly by 1 to 3 years of age were among the major problems that were discovered

after the newborn period. A predisposition to inguinal hernias was also noted. Longitudinal studies of somatic growth show that most infants with congenital rubella remain smaller than average throughout infancy, but grow at a normal rate. Stunting of growth was more common after rubella infection in the first 8 weeks of pregnancy than after later infection. Even in the absence of mental retardation, neuromuscular development is commonly abnormal. A study of neurodevelopmental outcomes in 29 affected children without mental retardation found that 25 had other abnormalities; hearing loss, difficulties with balance and gait, learning deficits, and behavioral disturbances were found in more than half of the affected children (Desmond et al, 1978).

PREVENTION

There is no effective antiviral therapy against congenital rubella infection, so the most useful practice is to ensure that women who are considering pregnancy are immune. The Advisory Committee on Immunization Practices recommends screening of all pregnant women for rubella immunity and postpartum vaccination of those who are susceptible (Centers for Disease Control and Prevention, 2001). Immunity to rubella appears to confer almost complete protection against CRS. Rare cases of documented subclinical maternal reinfection with rubella have been reported (Morgan-Capner et al, 1991; Saule et al, 1988). In rare cases, maternal reinfection can lead to CRS (Banerji et al, 2005). Approximately 20 cases of CRS after maternal reinfection have been reported in the literature, and none have caused symptomatic CRS when the known reinfection occurred after 12 weeks' gestation (Bullens et al, 2000).

Live attenuated rubella virus vaccine is safe and effective, although the duration of immunity is uncertain. It is typically administered in the United States in a trivalent formulation in combination with measles-mumps-rubella vaccine or in a quadrivalent combination with measles-mumps-rubella-varicella vaccine. The vaccine is recommended for children at 12 to 15 months of age and at 4 to 5 years of age. It is also recommended for women of childbearing age in whom results of both a hemagglutination inhibition antibody test and a pregnancy test are negative. Although no cases of symptomatic congenital rubella infection have been reported as a consequence of vaccination during pregnancy in the more than 500 cases monitored, vaccination is not recommended during pregnancy because of the theoretical hazard to the fetus (Josefson, 2001; Nasiri et al, 2009; Tookey, 2001). A mild rubella-like illness is sometimes seen after immunization, with arthralgia occurring 10 days to 3 weeks after injection. If a woman is found to be susceptible, vaccine should be administered during the immediate postpartum period before discharge. Breastfeeding is not a contraindication to postpartum immunization. Immunization in the postpartum period has rarely produced polyarticular arthritis, neurologic symptoms, and chronic rubella viremia (Tingle et al, 1985).

The problem of management of the pregnant woman who is exposed to rubella or who contracts the disease should be resolved after the known risks are weighed. If serum antibody is detectable at the time of exposure, the fetus is probably protected. If no antibody is detectable, additional serum samples at 2 to 3 weeks after exposure and again at 4 to 6 weeks after exposure should be obtained. These samples can be run concurrently with the first serum to ascertain whether infection has occurred (i.e., seroconversion). There is no evidence that administration of immunoglobulin prevents rubella infection or viremia. Moreover, administering immunoglobulin may provide an unwarranted sense of security, because infants with congenital rubella have been born to women who received immunoglobulin shortly after exposure. Regardless of these limitations, administration of immunoglobulin may be considered if the pregnancy is not terminated. Immunoglobulin can reduce the likelihood of fetal infection, but will not eliminate the risk; therefore the CDC does not routinely recommend the use of immunoglobulin in a pregnant woman for postexposure prophylaxis unless she does not wish to terminate the pregnancy under any circumstances (Centers for Disease Control and Prevention, 2001). Decisions about the termination of pregnancy should be made only after maternal infection has been proved and should also account for the risk of rubella-associated damage to the fetus, which is highest when maternal infection occurs during the first 8 weeks of pregnancy.

LYMPHOCYTIC CHORIOMENINGITIS VIRUS

Lymphocytic choriomeningitis virus (LCMV) is a member of the family Arenaviridae. Rodents are the primary reservoir, particularly mice and hamsters. Like other arenaviruses, LCMV has a bisegmented negative-strand RNA genome. The S segment encodes for the virus nucleoprotein and glycoprotein, whereas the L segment encodes for the virus polymerase (L) and Z protein. Susceptible rodents are infected asymptomatically in utero, can harbor chronic infection, and excrete virus in urine, feces, saliva, nasal secretions, milk, and semen for life. Typically mice remain asymptomatic, although hamsters may demonstrate viremia and viruria with variable symptoms (Jahrling and Peters, 1992). Sequelae of human exposure to LCMV range from asymptomatic infection to nonspecific, flulike symptoms; a proportion of infections have neurologic manifestations. LCMV was first described as a cause of congenital infection in England in 1955 in a 12-day-old infant (Komrower et al, 1955) and later in the United States (Barton and Mets, 2001; Barton et al, 1993, 2001; Larsen et al, 1993). Because LCMV has only recently been recognized as a source of congenital infection, it is likely underdiagnosed (Jamieson et al, 2006).

EPIDEMIOLOGY

Human seroprevalence ranges between less than 1% and 10% worldwide and varies extensively with geographic region (Ambrosio et al, 1994; Childs et al, 1991; Marrie and Saron, 1998; Stephensen et al, 1992). One study noted a higher prevalence in women (Marrie and Saron, 1998). Lower socioeconomic status and older age are associated with higher seroprevalence. Studies conducted in the 1940s through the 1970s found that approximately 8% to 11% of cases of aseptic meningitis and encephalitis were

associated with LCMV infection (Meyer et al, 1960; Park et al, 1997b). In temperate climates, human exposure is more common during the fall and winter, when rodents move indoors. Outbreaks have been reported in laboratory personnel working with hamsters and mice (Dykewicz et al, 1992; Hinman et al, 1975; Vanzee et al, 1975). Multiple outbreaks associated with pet hamsters have also been reported in the United States (Biggar et al, 1975; Maetz et al, 1976) and Europe (Brouqui et al, 1995; Deibel et al, 1975); however, congenital infection is relatively rare. A total of 54 cases have been diagnosed worldwide since the first case in 1955, and 27 of those occurred in the United States (Barton and Mets, 2001; Greenhow and Weintrub, 2003). There has been an increased recognition of congenital LCMV in recent years; 34 of the cases described in a review were reported since 1993 (Jamieson et al, 2006). The true frequency of congenital LCMV infection is unknown, because there is no active surveillance. As with other congenital infections, there may be a wide spectrum of disease, including asymptomatic and subclinical or nonspecific infections.

PATHOGENESIS

Humans acquire LCMV infection from aerosolized particles, bites, or fomite contact with virus excreted from rodents (Jahrling and Peters, 1992). Human-to-human horizontal transmission by organ transplantation has been documented (Fischer et al, 2006). In this report, abdominal pain, altered mental status, thrombocytopenia, elevated aminotransferase levels, coagulopathy, graft dysfunction, renal failure, seizures, and either fever or leukocytosis were variably present within 3 weeks after transplantation. Seven of the eight recipients died, 9 to 76 days after transplantation. The pathogenesis of LCMV infection is poorly understood, although it is likely an immunopathologic process mediated by the host $CD8^+$ T-cell response (Craighead, 2000). It is also postulated that the high rate of spontaneous mutations that arise during LCMV replication allows both variability in pathogenicity and a mechanism of escape from humoral response during the initial phase of infection (Ciurea et al, 2001).

Like other arenaviruses, LCMV replicates either at the site of infection or in corresponding lymph nodes; this localized replication is followed by viremia. It is thought that during the viremic stage, the virus travels to parenchymal organs and the CNS. Pathologic findings include lymphocytic infiltration and extramedullary hematopoiesis. In two congenitally infected infants for whom neuropathology results were available, cerebromalacia, glial proliferation, and perivascular edema were reported (Barton et al, 1993). In adult mice inoculated intracranially with LCMV, subsequent viral proliferation in the ependyma, meninges, or both have been described, with injury mediated by $CD8^+$ T cells (Doherty et al, 1990). This viral infiltration, along with the host inflammatory response, can lead to aqueductal stenosis and subsequent hydrocephalus. Studies in a murine model suggest that cytokine-chemokine cascades mediate much of the neuropathology observed in the setting of CNS infection (Christensen et al, 2009).

CLINICAL SPECTRUM

It is estimated that asymptomatic or mild LCMV infections occur in approximately one third of patients infected; however, the classic presentation of LCMV infection is a nonspecific, flulike, or mononucleosis-like illness that is often biphasic. Symptoms are fever, malaise, nausea, vomiting, myalgias, headache, photophobia, pharyngitis, cough, and adenopathy. After defervescence and resolution of these constitutional symptoms, a second phase of CNS disease may develop. Neurologic manifestations occur in approximately one fourth of infectious episodes and vary from aseptic meningitis to meningoencephalitis. Transverse myelitis, Guillain-Barré syndrome, and deafness have also been reported. Other manifestations are pneumonitis, arthritis, myocarditis, parotitis, and dermatitis. Recovery may take months, but usually occurs without sequelae (Craighead, 2000).

When LCMV infection occurs during pregnancy, maternal symptoms typically appear during the first and second trimesters, but only 50% to 60% of mothers of infants diagnosed with LCMV congenital infection recall having symptoms (Wright et al, 1997). Known maternal exposure to rodents is reported in approximately one fourth to one half of cases (Barton and Mets, 2001). Usually, exposed women are from rural settings, come from lower socioeconomic settings with substandard housing conditions, or have pet rodents in the home (i.e., hamsters).

The complete spectrum of disease secondary to congenital LCMV infection is still uncertain, although chorioretinitis and hydrocephalus are the predominant characteristics reported among children diagnosed with congenital LCMV infection. Chorioretinitis is present in more than 90% of cases. Other ocular findings are chorioretinal scars, optic atrophy (usually bilateral), nystagmus, esotropia, exotropia, leukocoria, cataracts, and microphthalmia (Barton and Mets, 2001; Brezin et al, 2000; Enders et al, 1999). Some ophthalmologic findings resemble those described in the lacunar retinopathy of Aicardi syndrome (Wright et al, 1997), a finding of interest insofar as Aicardi syndrome can, like congenital CMV or LCMV infection, produce intracranial calcifications. A wide range of neurologic defects are described, including microencephaly, encephalomalacia, chorioretinitis, porencephalic cysts, neuronal migration disturbances, periventricular infection, and cerebellar hypoplasia (Bonthius et al, 2007). Congenital LCMV should be considered in the differential diagnosis of neonatal hydrocephalus (Schulte et al, 2006).

Most infants are born at term, and birthweights are generally appropriate or large for gestational age. Thirty-five percent to 40% of infants reported with congenital LCMV have had microcephaly or macrocephaly at birth (Barton and Mets, 2001). Systemic symptoms are rare, although hepatosplenomegaly and jaundice have been noted. Other individual case report findings are pes valgus, dermatologic findings consistent with staphylococcal scalded-skin syndrome (Wright et al, 1997), spontaneous abortion (Biggar et al, 1975), and intrauterine demise secondary to hydrops fetalis (Enders et al, 1999; Meritet et al, 2009). It is important to note that, because systemic symptoms are typically minimal at birth, the diagnosis of congenital LCMV infection often is not considered until an affected infant is a few

months of age, when microcephaly, macrocephaly, visual loss, or developmental delay may be noted.

LABORATORY EVALUATION

Serology is the most reliable and feasible method to diagnose LCMV. In most reports, the diagnosis was established by testing of the infant's serum, CSF, or both; in some, maternal serum testing was the key. Testing all three fluids provides the most information. Because of the low baseline population seroprevalence, positive titers for LCMV are much more useful for diagnosis than detection of antibodies to microbes such as CMV and toxoplasmosis. There is a commercially available immunofluorescent antibody test that detects both IgM and IgG for LCMV. It has better sensitivity than the complement fixation and neutralizing antibody tests that also have been used (Lehmann-Grube et al, 1979; Lewis et al, 1975). Complement fixation titers generally do not rise until more than 10 days after onset of infection, but immunofluorescent antibody results may be positive within the first few days of illness (Deibel et al, 1975). The CDC also has an enzyme-linked immunosorbent assay test for IgM and IgG; it may be more useful for diagnosis in an older child because it can detect increased IgG later than and persistent IgG for longer than the immunofluorescent antibody test. Some studies have found antibody as late as 30 years after suspected exposure. Virus can be cultured in Vero cell lines or inoculated into newborn mice, but use of these methods is uncommon. Reverse transcriptase–PCR has been used in serum and CSF to diagnosis LCMV and as a surveillance tool; it may become more available in the future (Enders et al, 1999; McCausland and Crotty, 2008; Park et al, 1997a).

Information about routine laboratory data in patients with a diagnosis of congenital LCMV infection is minimal, but thrombocytopenia and hyperbilirubinemia have been reported. CSF findings are variable. Up to one half of cases demonstrate a mild increase in white blood cell count (up to 64 cells/μL in one case series of 18 infants), the serum protein concentration may be normal or mildly elevated, and the serum glucose concentration may be normal or mildly decreased (Wright et al, 1997). Among infants reported in whom neuroradiographic imaging was performed, 89% (17 of 19) had hydrocephalus or periventricular calcifications. Flattened gyri, lissencephaly, and schizencephaly have been reported (Barton and Mets, 2001), compatible with a role for LCMV in fetal neuronal migration defects (Bonthius et al, 2007).

TREATMENT

Ribavirin has been used for management of other arenavirus infections and inhibits LCMV growth in vitro (Géssner and Lother, 1989). Although novel approaches are being used to develop antivirals against LCMV and other pathogenic arenaviruses (de la Torre, 2008), there are currently no recommendations for the use of antiviral agents against these viruses. In the outbreak associated with solid organ transplantation, one affected recipient received ribavirin and reduced levels of immunosuppressive therapy and survived (Fischer et al, 2006).

PROGNOSIS

Because congenital LCMV infections have been recognized relatively recently and the existing data come from case reports, there may be a wider spectrum of disease than is currently appreciated. The proportion of asymptomatic infected infants is unknown. For the 25 infant cases reported, estimated mortality rates are 16% to 35% between birth and 21 months of age (Barton and Mets, 2001; Wright et al, 1997). Among infants who survived, 84% (32 of 38) have neurologic sequelae, including spastic quadriparesis, mental retardation, developmental delay, seizures, and visual loss (Barton and Mets, 2001). Sensorineural hearing loss is less common and has been reported in only two infants (Barton and Mets, 2001; Wright et al, 1997). Some ophthalmologists suggest that among patients with developmental delay and visual loss consistent with chorioretinitis, LCMV congenital infection may be underdiagnosed. A study in Chicago of prospectively diagnosed patients with chorioretinitis and patients in a home for severely mentally retarded children with chorioretinal scars found six children with elevated LCMV titers and normal toxoplasmosis, CMV, rubella, and HSV titers (Mets et al, 2000). Two children with chorioretinal scars and elevated LCMV titers have been reported in France (Brezin et al, 2000).

PREVENTION

Public health officials and clinicians should be aware that (1) wild, laboratory, and pet rodent exposure can lead to intrauterine infection with LCMV virus and (2) congenital infection has been associated with potentially devastating ophthalmologic and neurologic sequelae. Pregnant women need to be educated about the potential risks of exposure to infected rodent excreta and instructed to avoid rodents and rodent droppings whenever possible. Obstetricians and neonatologists should seek a history of pet or wild rodent exposure for counseling purposes and to aid in the evaluation of infants with unexplained CNS pathologies. The diagnosis of LCMV should be considered in all unexplained cases of infant hydrocephalus. There are currently no vaccines approved by the U.S. Food and Drug Administration (FDA) for the prevention of arenavirus disease, although candidate multivalent arenavirus vaccines capable of providing T cell–mediated protection against a variety of pathogenic arenaviruses are currently in development (Botten et al, 2010).

ENTEROVIRUSES

Enteroviruses are single-stranded, positive-sense RNA viruses. These viruses belong to the family Picornaviridae (*pico* means very small in Spanish). The enteroviruses of humans include polioviruses 1, 2, and 3, coxsackieviruses A and B (named after Coxsackie, New York the city where these viruses were first identified and characterized), and the echoviruses (*echo* is an acronym for enteric cytopathic human orphan). Of these, poliovirus infection has historically been responsible for the greatest morbidity in infants. Severe, often fatal poliovirus disease used to occur with great frequency in infants infected in the perinatal period,

with a high incidence of residual paralysis in survivors (Bates, 1955; Cherry, 2005). Fortunately, poliovirus infections have become rare in the developed world, because of the widespread implementation of effective immunizations. However, neonatal diseases associated with coxsackieviruses and echoviruses, for which there are no vaccines, remain common and can be associated with serious morbidity and occasional mortality. Typically acquired from a maternal source, these agents are associated with a wide range of clinical syndromes in the neonatal intensive care unit, including CNS infection, myocarditis, and a sepsis-like syndrome. Enteroviruses are also responsible for a large number of hospital readmissions for evaluation of febrile syndromes in infants younger than 2 months.

EPIDEMIOLOGY

Enterovirus infections are seasonal, occurring most commonly during the summer and autumn in temperate climates. The incidence varies from year to year, with outbreaks sometimes caused by a single coxsackievirus or echovirus serotype and sometimes by several (Sawyer et al, 1994). In older children, enteroviruses are transmitted by the fecal-oral route and are typically associated with a variety of febrile syndromes, including febrile exanthematous syndromes, aseptic meningitis, pneumonia with or without pleural effusion, and myocarditis. Disease in newborn infants is relatively uncommon, but reflects the frequency of infection in the general population (Krajden and Middleton, 1983). Enteroviruses may also be associated with nosocomial outbreaks. Nursery and obstetric clinic outbreaks of both coxsackievirus B (Bhambhani et al, 2007; Brightman et al, 1966; Rantakallio et al, 1970) and echovirus infections (Chen et al, 2005; Jankovic et al, 1999; Nagington et al, 1978) have been reported and associated with severe, and sometimes fatal, illnesses.

Enteroviral infections account for at least one third of neonatal febrile admissions for suspected sepsis and for between half and two thirds of all admissions during peak enteroviral season (Byington et al, 1999; Dagan, 1996). Neonatal aseptic meningitis is also frequently caused by enteroviral infections. In a review of neonatal meningitis seen over a 15-year period in Galveston, Texas, enterovirus was the most common cause of meningitis in newborn infants older than 7 days of age (Shattuck and Chonmaitree, 1992). Enteroviruses, along with other viruses, have been implicated as a potential cause of sudden infant death syndrome (SIDS), possibly from myocarditis or pulmonary infection (Grangeot-Keros et al, 1996; Shimizu et al, 1995), but this association has been controversial. In one study of SIDS victims, a comprehensive assessment was undertaken to attempt to identify potential viral infection of the myocardium. Overall, 62 SIDS victims and 11 controls were studied. Enteroviruses were detected in 14 (22.5%), adenoviruses in 2 (3.2%), Epstein–Barr viruses in 3 (4.8%), and parvovirus B19 in 7 (11.2%) cases, whereas control group samples were completely negative for viral nucleic acid (Dettmeyer et al, 2004). However, an evaluation of histopathologic features and PCR analysis from 24 SIDS cases failed to demonstrate any association with viral infection (Krous et al, 2009), leaving this putative association unclear.

ETIOLOGY AND PATHOGENESIS

Neonates can acquire enteroviral infections secondary to in utero transmission, intrapartum transmission during labor and delivery, or postnatally. Intrauterine infections appear to occur via transplacental spread, secondary to maternal viremia, and this mode of transmission appears to be responsible for up to 22% of cases of neonatal enteroviral infection (Kaplan et al, 1983; Modlin, 1986). Enteroviruses have been implicated as a cause of fetal demise (Johansson et al, 1992; Konstantinidou et al, 2007; Nielsen et al, 1988). Intrapartum or postnatal transmission is more common than transplacental transmission. The dominant mode of transmission of serious neonatal infection is through contact with maternal blood, fecal material, or vaginal or cervical secretions, most likely during or shortly after delivery (Hawkes and Vaudry, 2005; Jenista et al, 1984). After acquisition of infection, viremia ensues in the infant, leading to a variety of end-organ diseases. Virus strain or serotype appears to be a factor in predicting the severity of illness, as does the quantity of the inoculum. The presence or absence of transplacental maternally derived antibody also dictates the severity of disease in the infected infant. Severe disease occurs in the absence of type-specific antibody, a scenario that is more likely if the maternal infection is acquired near the time of delivery. Breastfeeding appears to provide a relative degree of protection against acquisition of infection in neonates (Sadeharju et al, 2007).

One of the most comprehensive analyses of the incidence of neonatal enterovirus disease came from a prospective study in Rochester, N.Y. This study demonstrated that approximately 13% of all newborns tested positive for enterovirus from throat or stool cultures during a typical season (June to October; Jenista et al, 1984). Although this result represented a remarkably high incidence, 79% of these infections were asymptomatic. The most common clinical findings in the 21% of symptomatic infections were lethargy and fever. These infants were typically admitted to hospital for an evaluation to rule out sepsis, making enterovirus infection a more common reason for hospitalization owing to an infectious disease than group B streptococcus, herpes simplex virus, and cytomegalovirus infections combined.

It appears that any of the non–polio enteroviruses can cause disease in the newborn infant. A variety of clinical syndromes are associated with certain enteroviruses. A retrospective chart review of 24 neonatal enteroviral infections in Toronto, Canada, found that 10 infants died, 12 had aseptic meningitis, and 5 had myocarditis (Krajden and Middleton, 1983). Of the 24 isolates, 7 were echovirus, 15 were coxsackievirus B, one was coxsackievirus A, and one was nontypable. In infants requiring hospitalization with acute enterovirus disease, coxsackievirus B is associated primarily with myocarditis and aseptic meningitis (Kibrick and Benirschke, 1958). Recent reports have identified coxsackievirus B1 as an emerging cause of life-threatening myocarditis and other severe, fatal syndromes in neonates (Verma et al, 2009; Wikswo et al, 2009). Echoviruses are associated with severe nonspecific febrile illnesses with disseminated intravascular coagulation (Nagington et al, 1978), aseptic meningitis (Cramblett et al, 1973), or

hepatitis (Modlin, 1980). With both coxsackievirus and echovirus, nonspecific febrile illnesses, with or without an exanthem, are commonly observed. Enterovirus 71 is particularly notable for its etiologic role in epidemics of severe neurologic diseases in children (Chen et al, 2010). Nursery-based outbreaks of this neurovirulent enterovirus have also been described (Huang et al, 2010).

Except for transplacental infections, the portal of entry for enterovirus is via the oral or respiratory route. After replication in the pharynx and the gastrointestinal tract, virus seeds the tonsils, cervical and mesenteric nodes, and Peyer's patches. The pathogenesis of enterovirus disease stems from the ensuing viremia, which can lead to infection of the heart, CNS, liver, pancreas, adrenal glands, skin, mucous membranes, and respiratory tract. This feature of enterovirus replication and dissemination helps to explain the diverse disease manifestations that may be observed following infection. The humoral immune response is associated with recovery from systemic and end-organ infection, although virus may continue to be shed in the stool for several weeks. Failure to clear enteroviral infection, particularly from the CNS, should suggest an underlying humoral immunodeficiency, although this would not typically be observed in the neonatal period, when maternally derived Ig is present in the newborn (McKinney et al, 1987; Misbah et al, 1992). Depending on the extent of disease, extensive end-organ pathology may be observed. In coxsackievirus B infections, myocardial necrosis, and inflammation may be seen that are patchy or diffuse, with extensive infiltration by lymphocytes, mononuclear cells, histiocytes, and polymorphonuclear leukocytes. Similar infiltrates are seen in the meninges in both coxsackievirus and echovirus aseptic meningitis. Brainstem encephalitis can be observed with enterovirus 71 infection, often in association with pulmonary edema (Wang and Liu, 2009). When liver or adrenal glands are involved, there is usually extensive hemorrhage as well as inflammation and necrosis; such fatal fulminant infections are often associated with echovirus 11 (Mostoufizadeh et al, 1983).

CLINICAL SPECTRUM

When neonatal disease is acquired vertically from the mother, the infant is typically asymptomatic at birth, although premature delivery is more common. The mother may be febrile at this time or may have a history of recent high fevers and gastrointestinal symptoms. Fever, anorexia, and vomiting develop in the baby after an incubation period of 1 to 5 days. The onset of illness occurs in the first week of life in more than 50% of affected infants (Krajden and Middleton, 1983). At that point, the clinical evolution depends on the infecting virus and the extent of end-organ involvement. In most instances, the disease is mild and self-limited. Symptomatic infections may be characterized by rash, aseptic meningitis, hepatitis, and pneumonia. A review of 29 infants younger than 2 weeks with enteroviral infections reported that 5 of 29 infants had severe multisystem disease, and all survived (Abzug et al, 1993). In another study in Salt Lake City, 1779 febrile infants younger than 90 days and undergoing evaluation for sepsis were enrolled; 1061 had enterovirus testing, and 214 (20%) were enterovirus positive (57% from blood, and 74% from CSF). The mean age of infants with enterovirus infection was 33 days; 91% were admitted, and 2% required intensive care (Rittichier et al, 2005).

These observations underscore the generally benign and self-limited nature of neonatal enterovirus disease; however, morbidity can be substantial in severe disseminated disease. A viral sepsis syndrome—characterized by disseminated intravascular coagulation, refractory hypotension, and death—may occur in the setting of severe disease. Typically these severe infections are acquired in the immediate perinatal period. The mother is commonly symptomatic and may have been empirically treated with broad-spectrum antibiotics for possible chorioamnionitis. A maternal history of suspected chorioamnionitis in the absence of positive bacterial cultures should suggest this association, particularly during the typical "enterovirus season" observed in temperate climates. If myocarditis is present, congestive heart failure is often severe. Some infections, particularly those with echoviruses, are characterized by a rampant and overwhelming hepatitis (Modlin, 1980). Others exhibit primarily pulmonary disease or gastrointestinal involvement including diarrhea and necrotizing enterocolitis (Lake et al, 1976). Intracranial bleeding ranging from small to massive, severe hemorrhage has also been reported as a complication of neonatal enteroviral infection (Abzug, 2001; Abzug and Johnson, 2000; Swiatek, 1997). Other rarely associated findings include disseminated vesicular rash, dermal hematopoiesis, and hemophagocytic syndrome (Barre et al, 1998; Bowden et al, 1989; Sauerbrei et al, 2000). The severity of CNS infection is similarly variable. Enteroviruses, particularly enterovirus 71, can produce overwhelming meningoencephalitis, sometimes with cranial nerve signs. It is more common, however, to see moderate or mild meningitis characterized by temporary irritability, lethargy, fever, and feeding difficulty.

Acquired postnatal enteroviral disease in infants is characterized primarily by high fever, irritability, lethargy, or poor feeding. One fourth of infected infants develop diarrhea or vomiting with or without an erythematous maculopapular rash. Conjunctivitis has also been observed. Respiratory tract symptoms are less common (Dagan, 1996). As noted, there is significant overlap between enteroviral and bacterial neonatal infections, and the two syndromes are difficult to distinguish; therefore many febrile infants will be admitted to the hospital and treated with broad-spectrum antibiotics and, if the CNS is involved, with acyclovir for possible bacterial sepsis and neonatal HSV infection. Such treatment seems unavoidable, except in circumstances in which enterovirus infection can be diagnosed rapidly and definitively. Duration of illness varies from less than 24 hours to longer than 7 days, but generally lasts 3 to 4 days.

LABORATORY EVALUATION

Viral culture from stool or rectal swab, nasopharyngeal swab, blood, buffy coat, urine, or CSF represents the gold standard diagnosis. Stool or rectal swab cultures can remain positive for several weeks following the initial infection, underscoring the importance of fecal-oral transmission in the epidemiology of these infections. Recently,

reverse transcriptase PCR assays have become standardized and are available from many commercial and reference laboratories. Serologic tests for enteroviruses have been reported, but are less useful than culture and PCR (Swanink et al, 1993).

Laboratory evaluation is predicated on the clinical syndrome and the end organs involved. Infants with aseptic meningitis typically have moderate CSF pleocytosis, which can be either lymphocytic or polymorphonuclear, but may lack pleocytosis even in the setting of documented CNS infection (Seiden et al, 2010). Accordingly, during periods of active enterovirus infection in the community, CSF should be sent for PCR even if a pleocytosis is absent. Thrombocytopenia, elevated transaminase levels, hyperbilirubinemia, hyperammonemia, hematologic abnormalities consistent with disseminated intravascular coagulation, anemia, peripheral leukocytosis, and abnormal chest radiographs are among other potential laboratory findings. When myocarditis is a diagnostic possibility, echocardiogram and electrocardiogram are indicated and may reveal diminished LV function, or dysrhythmias. Liver biopsy may be warranted in cases of fulminant hepatic failure (Abzug, 2001).

TREATMENT

The cornerstone of treatment of neonatal enteroviral disease is supportive care. Myocarditis and heart failure can be treated with inotropic support, diuretics, aggressive fluid management, and other supportive measures. Disseminated intravascular coagulation should be treated with blood products and other supportive measures as indicated. There is no evidence that steroids are of benefit. IVIG has been reported anecdotally to treat neonatal enteroviral infections with varying degrees of success (Kimura et al, 1999; Valduss et al, 1993). Only one randomized trial has systematically studied its use in 16 neonates with severe enteroviral infection; nine of these infants were randomized to receive IVIG, at a dose of 750 mg/kg. Decreased viremia and viruria along with faster resolution of irritability, jaundice, and diarrhea was demonstrated in patients administered IVIG with high titers of neutralizing enteroviral-specific antibodies. However, there were no significant differences in other major clinical outcomes, such as duration of hospitalization, fever, and symptoms of acute illness between treatment and control groups (Abzug et al, 1995). To attempt to augment the enterovirus type–specific antibody level in the setting of symptomatic neonatal disease, maternal plasma transfusion has been attempted (Jantausch et al, 1995; Rentz et al, 2006), based on the rationale that neonates typically acquire infection from their mothers in the peripartum period. Although reports of success using IVIG for treatment of neonatal enterovirus infections is largely based on anecdotal reports in limited numbers of patients, its use should be considered for severely symptomatic infections with life-threatening end-organ disease.

The antiviral drug pleconaril has been developed specifically to treat picornavirus infections (enteroviruses and rhinoviruses). A small case series of infants with severe enteroviral hepatitis suggested a beneficial effect (Aradottir et al, 2001). Another small case series indicated that five of six neonates with severe enteroviral infection who were treated with pleconaril survived, with minimal or no sequelae (Rotbart and Webster, 2001). However, a multicenter study of pleconaril treatment for enteroviral meningitis in children younger than 12 months conducted by the CASG and sponsored by the National Institutes of Health demonstrated no significant differences in duration of positivity by culture or PCR, hospitalization, or symptoms comparing the treatment and placebo groups (Abzug et al, 2003). Pleconaril did appear to have an effect on enteroviral meningitis in adults, promoting more rapid resolution of illness (Desmond et al, 2006), but the role of this drug in infants and children remains undefined. The drug continues to be investigational and is only available through the CASG, which is currently comparing pleconaril with placebo in severe symptomatic neonatal enteroviral infections (www.clinicaltrials.gov).

SHORT- AND LONG-TERM PROGNOSIS

Prognostic factors for severe neonatal disease include peripartum maternal illness, earlier age of onset of neonatal disease, absence of serotype-specific antibody, and absence of fever and irritability (Abzug et al, 1993). All these risk factors are most consistent with vertical intrauterine enteroviral infection rather than postnatally acquired infection. The highest mortality rates are associated with the combination of severe hepatitis, coagulopathy, and myocarditis. Severe hepatitis caused by enteroviral infection is associated with mortality rates ranging from 30% to 80% (Abzug, 2001; Modlin, 1986). By the time disseminated intravascular coagulation has developed, the prognosis is grave. Prothrombin time longer than 30 seconds was a risk factor for death in one retrospective case review (Abzug, 2001).

Few long-term follow-up studies have been published, but the available information suggests that infants who survive severe enteroviral neonatal disease have a complete recovery in most instances. Outcomes of 6 of 11 survivors with follow-up ranging from 9 to 48 months reported normal growth and no residual medical problems or liver dysfunction (Abzug, 2001). The long-term prognosis following CNS infection is unclear. A number of early studies of infants younger than 3 months with aseptic meningitis suggested that there may be some impairment of intellectual development in comparison with carefully selected control groups (Farmer et al, 1975; Sells et al, 1975). However, in a series of nine children with enteroviral meningitis and nine matched controls evaluated for sequelae at approximately 4 years of age, no differences in mean intelligence quotient, head circumference, detectable sensorineural hearing loss, or intellectual functioning were detected. Receptive language functioning of the meningitis group was significantly less than that in control subjects (Wilfert et al, 1981). A similar case-control follow-up study of 33 subjects, who were compared with siblings used as controls, reported no neurodevelopmental sequelae (Bergman et al, 1987). Older children with enterovirus 71 infection involving the CNS are at risk for significant neurodevelopmental sequelae (Chang et al, 2007).

PREVENTION

Anecdotal reports of the use of IVIG in nursery outbreaks to prevent further horizontal transmission of enteroviral infection produce conflicting results (Carolane et al, 1985; Kinney et al, 1986; Nagington et al, 1983). Because there are multiple non–polio enteroviral serotypes that cause clinical disease, development of anti-enteroviral immunization is conceptually difficult, although vaccines are in development for enterovirus 71 (Zhang et al, 2010). Standard contact precautions should be used for the treatment of hospitalized infants with known or suspected enteroviral infections.

HUMAN PARECHOVIRUS

Recently two viruses formerly classified with the echoviruses, echovirus 22 and 23, were shown to comprise a separate genus within the Picornaviridae family, the genus *Parechovirus;* these viruses are now referred to as *human parechoviruses types 1* and *2*. A total of 10 distinct parechoviruses have now been recognized (Drexler et al, 2009; Harvala et al, 2010; Pajkrt et al, 2009). These viruses have been recognized recently as significant neonatal pathogens (Harvala et al, 2010). The primary site of parechovirus replication is believed to be the respiratory and gastrointestinal tract. Replication in the gastrointestinal tract is associated with prolonged shedding of infectious virus in the feces. As a result, fecal-oral transmission, as with enteroviruses, appears to be the predominant route of infection. Parechovirus infections may also be acquired via a respiratory route, with subsequent virus shedding detectable in respiratory secretions. Viremia leads to secondary seeding of other organs and systemic symptoms. Neonates with parechovirus infection, particularly parechovirus 3, have a clinical presentation similar to infants with severe enteroviral disease, with a sepsislike illness in severe cases (Verboon-Maciolek et al, 2008a; Wolthers et al, 2008). Hepatitis is also a prominent feature of neonatal infection. The most frequent signs are fever, seizures, irritability, rash, and feeding problems. It has been postulated that parechovirus 3 is a newly emerging infection, and the relative lack of maternal antibody may predispose the neonate to more severe disease (Harvala et al, 2010). Parechovirus can also cause aseptic meningitis and encephalitis in the neonate, with the predominate site of injury being the periventricular white matter (Gupta et al, 2010; Levorson et al, 2009; Verboon-Maciolek et al, 2008b). Parechovirus RNA has also been found at autopsy in children younger than 2 years (Sedmak et al, 2010), including from infants with otherwise unexplained deaths. Management is similar to that for neonatal enterovirus disease—namely, supportive care.

The other virus classified in the *Parechovirus* genus is Ljungan virus (Tolf et al, 2009). This virus was first described in 1998 and was found to cause type 1 diabetes–like symptoms and myocarditis in bank voles; it also appears to be endemic in other wild rodent populations. The virus does not appear to have a role in the development of diabetes in humans (Tapia et al, 2010). This zoonotic virus has recently emerged as a recognized cause of fetal infection (Niklasson et al, 2007, 2009b). Ljungan virus infection appears in particular to be associated with severe CNS abnormalities, including hydrancephaly and hydrocephalus (Niklasson et al, 2009a). A study from Sweden identified a strong epidemiologic association between small rodent abundance and the incidence of intrauterine fetal death in humans. Ljungan virus antigen was detected in this study in half of the intrauterine fetal death cases tested (Niklasson et al, 2009).

HEPATITIS VIRUSES

There are six distinct viruses known to cause viral hepatitis—hepatitis A, B, C, D (delta agent), E, and G. Hepatitis G is of importance for the pregnant patient, although only B and C are of major importance in the newborn. The main features of each virus type are listed in Table 37-3 (Jonas, 2000; Koff, 2007; Krugman, 1992). Hepatitis A virus (HAV) is passed by fecal-oral transmission and is a rare cause of neonatal disease, although it has been nosocomially transmitted in the setting of a neonatal intensive care unit. Hepatitis E virus is similar to hepatitis A in its mode of transmission and clinical manifestations, except for an increased mortality in pregnant women infected with hepatitis E (Aggarwal et al, 2009; Teshale et al, 2010). There are no data regarding perinatal transmission of hepatitis E. Hepatitis D virus may cause only coinfection or super-infection with hepatitis B virus. Its only clinical significance is that hepatitis B infection may become more severe when hepatitis D virus is present. Perinatal transmission has been described (Ramia and Bahakim, 1998), but is uncommon.

Hepatitis G virus (HGV), also known as *GB virus type C*, has been associated with acute and chronic hepatitis and usually is noted as a coinfection with hepatitis B or C. This virus has a tropism for lymphocytes and may influence the course and prognosis in HIV-seropositive patients (Reshetnyak et al, 2008). Perinatal transmission can occur in 60% to 80% of infants born to HGV-viremic mothers, but there has not been any report of clinical hepatitis attributed to the HGV infection in this setting (Ohto et al, 2000; Wejstal et al, 1999; Zanetti et al, 1998; Zuin et al, 1999). The clinical significance and effects of HGV infection are still poorly understood. Hepatitis B and C viruses are both transmitted vertically and among the viral hepatitis are of the greatest important to the care of newborns.

HEPATITIS B

The issues that are most important to neonatologists are the frequency with which hepatitis B virus (HBV) is transmitted to infants at the time of birth, the short-term and long-term consequences of these infections, the importance of greater surveillance for maternal carriage of HBV, the role of antiviral therapy to prevent transmission and disease progression, and the availability of effective HBV immunoprophylaxis (Arfaoui et al, 2010; Krugman, 1988).

Incidence

In certain parts of the world and among certain ethnic groups, as many as 7% to 10% of all infants acquire hepatitis B infections at the time of birth, and almost all of these infections become chronic. In the United States, it has been estimated that approximately 20,000 infants are

TABLE 37-3 Viral Hepatitis Types A, B, C, D, E, and G: Comparison of Clinical, Epidemiologic, Immunologic, and Therapeutic Features

Feature	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D (Delta)	Hepatitis E	Hepatitis G/GBVC
Virus	Hepatitis A virus (HAV)	Hepatitis B virus (HBV)	Hepatitis C virus (HCV)	Hepatitis D virus (HDV)	Hepatitis E virus (HEV)	Hepatitis G virus (HGC), (GB virus type C [GBV-C])
Family	Picornavirus	Hepadnavirus	Flavivirus	Satellite	Calicivirus	Flavivirus
Genome	RNA	DNA	RNA	RNA	RNA	RNA
Incubation period	15-40 days	50-180 days	1-5 months	2-8 weeks	2-9 weeks	Unknown
Mode of transmission						
Oral (fecal)	Usual	No	No	No	Usual	No
Parenteral	Rare	Usual	Usual	Usual	No	Usual
Perinatal	Rare	Yes	Yes	Only with HBV	Unknown	Yes
Other	Food- or water-borne	Sexual contact	Sexual contact less common	Sexual contact less common	Water-borne transmission in developing countries	Sexual contact; probably less common
Sequelae						
Carrier state	No	Yes	Yes	Yes	No	Yes
Chronic disease	No cases reported	Yes	Yes	Yes	No cases reported	Yes; controversial
Interventions						
Immunoglobulin	Yes	Yes	No	No	No	No
Vaccine	Yes	Yes	No	No	No	No
Antiviral therapy	No	Yes	Yes	No	No	No

Modified from Krugman S: Viral hepatitis: A, B, C, D, and E: prevention, *Pediatr Rev* 13:245-247, 1992.

born annually to mothers who are chronic HBV carriers (Mast et al, 1998). Since 1990 the incidence of acute hepatitis B in the United States has declined dramatically, with the largest declines occurring in children younger than 15 years (98%) and in young adults 15 through 24 years of age (90%). The frequency of transmission depends primarily on the prevalence of the hepatitis B carrier state among women of childbearing age. Hepatitis B is a carcinogenic virus; perinatal acquired infection can lead to chronic liver failure and hepatic carcinoma in adult life (Balistreri, 1988; Beasley and Hwang, 1984; Chan and Sung, 2006).

The incidence of neonatal hepatitis B infection depends on the timing of infection and the overall prevalence of the disease in the population under study. Women with acute hepatitis B infection during the first or second trimester rarely transmit the virus to their infants (Krugman, 1988; Stevens, 1994). Transplacental transfer has been described, but appears to be rare. The carriage rate for hepatitis B surface antigen (HBsAg) varies from 0.1% in the United States and Europe to 15% in Taiwan and parts of Africa, with intermediate rates in Japan, South America, and Southeast Asia. Transmission rates among immigrant women in Western countries appear to parallel the rates in their countries of origin (Krugman, 1988).

The most important route of transmission is transmission that occurs during labor and delivery. The likelihood of transmission is great if symptomatic acute disease is present (60% to 70% transmission; Gerety and Schweitzer, 1977). Infants of hepatitis B e antigen (HBeAg)–positive mothers have an 80% to 90% chance of becoming HBsAg carriers (Lee et al, 1978; Okada et al, 1976). The risk of an infant acquiring hepatitis B if born to an HBsAg-positive but HBeAg-negative mother is 5% to 20%. Chronic neonatal infection occurs in less than 10% of infants of HBeAg antigen–negative mothers (Krugman, 1988). Although HBsAg has been found in breast milk, breastfeeding does not appear to have any influence on the rate of transmission (Beasley et al, 1975). The World Health Organization currently recommends that all mothers who are hepatitis B positive breastfeed their infants, and that their infants be immunized at birth.

Etiology and Pathogenesis

HBV is a DNA virus that localizes primarily in hepatic parenchymal cells but circulates in the bloodstream, along with several subviral antigens, for periods ranging from a few days to many years. Several distinct genotypes have been identified, and these subtypes show biologic variability in transmission and disease progression (Magnius and Norder, 1995; Schaefer et al, 2009). Transplacental leakage of HBeAg-positive maternal blood is a potential source of intrauterine infection (Lin et al, 1987). During either acute or persistent viremia in the mother, the virus itself or viral antigens may rarely cross the placenta and cause intrauterine infection, but more commonly infection occurs perinatally during labor or delivery (Chisari and Ferrari, 1995; Xu et al, 2001). The finding of hepatitis antigens in the newborn might not indicate the presence of infection, but rather the passive transfer of antigen only; therefore antigen tests should be interpreted cautiously in this setting. Hepatitis B infection of placental trophoblast has been documented and is compatible with a transplacental route of infection in some circumstances (Bai et al, 2007). Most infants born to mothers infected with HBV have a negative test result for HBsAg at birth, but in the absence of prophylaxis are at risk for becoming

TABLE 37-4 Licensed Monovalent and Combination Hepatitis B Vaccines

Clinical Scenario	Monovalent Vaccines		Combination Vaccines		
	Recombivax Hepatitis B Dose, μg (mL)	Enginerix-B Dose, μg (mL)	Twinrix*	Comvax†	Pediatrix‡
Newborns born to HBsAg-negative mothers	5 (0.5)	10 (0.5)	NA	NA	NA
Newborns born to HBsAg-positive mothers§	5 (0.5)	10 (0.5)	NA	NA	NA
Infants, children, and adolescents <20 yr old	5 (0.5)	10 (0.5)	NA	5 (0.5)	10 (0.5)
Adults >20 yr old	10 (1.0)	20 (1.0)	20 (1.0)	NA	NA

*Twinrix is a combination of Engerix-B (20 mg) and hepatitis A vaccine, licensed for use in people 18 years of age and older in a three-dose series at a 0-, 1-, and 6-month schedule.
†Comvax is a combination of Recombivax HB (5 μg) and *Haemophilus influenzae* type b (PRP-OMP) recommended for use at 2, 4, and 12 to 15 months of age. This vaccine should not be administered at birth.
‡Pediatrix is a combination of diptheria and tetanus toxoids and acellular pertussis (i.e., DTaP), inactivated poliovirus, and hepatitis B (Engerix B, 10 mg). It is recommended for use at 2, 4, and 6 months of age, but should not be administered at birth, before 6 weeks of age, or after 7 years of age.
§Hepatitis B immunoglobulin (0.5 mL) should be adminstered simultaneously with vaccination.

HBsAg-positive during the first 3 months of life, suggesting that transmission is primarily peripartum (Krugman, 1988, 1992; Mulligan and Stiehm, 1994; Shapiro, 1993).

Clinical Spectrum and Laboratory Evaluation

Infants with hepatitis B infection do not show clinical or chemical signs of disease at birth. Without immunoprophylaxis, the usual pattern is the development of chronic antigenemia with mild and often persistent enzyme elevations, beginning at 2 to 6 months of age (Mulligan and Stiehm, 1994). Less commonly the infection becomes clinically manifest, with jaundice, fever, hepatomegaly, and anorexia, followed by either recovery or chronic active hepatitis. Rarely, fulminant hepatitis is seen and can be fatal (Delaplane et al, 1983).

Laboratory tests are essential in the diagnosis of hepatitis B infection. Evaluations of serum enzymes and of bilirubin reflect the extent of liver damage. Several helpful serologic tests identify the virus involved (Krugman, 1988). HBsAg appears early, usually before liver disease is found; it persists in those who become chronic carriers or disappears in the 5% of infants who resolve the infection. HBeAg and anti-HBe testing can be used to assess infectivity; although they are not as frequently used for serodiagnosis, they are useful markers of the likelihood of perinatal transmission. PCR and other nucleic acid detection techniques are important in confirming diagnosis, assessing viral load, and monitoring the response to therapy.

Prevention

The primary goal of prevention strategies for hepatitis B is to prevent chronic infection and chronic liver disease. In the United States over the past two decades, a comprehensive immunization strategy has been implemented consisting of four components:

1. Universal immunization of all infants beginning at birth
2. Prevention of perinatal infection through routine screening of all pregnant women and appropriate immunoprophylaxis of infants born to HBsAg-positive women (or women whose HBsAg status is unknown)
3. Routine immunization of children and adolescents who have not been immunized previously
4. Immunization of nonimmunized adults at increased risk of infection

For infants, the three-dose vaccination schedule should be initiated in the neonatal period or by 2 months of age (Table 37-4). Four doses can be given if a birth dose is given and a combination vaccine is used to complete the series. Vaccination can be delayed until just before hospital discharge in preterm (birthweight less than 2000 g) infants born to HBsAg-negative mothers.

All infants born to HBsAg-positive women should receive both active and passive immunization within 12 hours of birth. The doses and recommended options for administration of the hepatitis B vaccines that are currently licensed in the United States are provided in Table 37-4. If maternal HBsAg status is unknown, it should be checked immediately, and the infant should receive the first dose of HBV vaccine immediately. Infants born to women who test positive, or to women in whom the HBsAg is unknown, should be given hepatitis B immunoglobulin as soon as possible within 1 week after birth. The highest immunization failure rates have been observed in infants of HBeAg-positive women and those infected in utero (Farmer et al, 1987; Tang et al, 1998). It is recommended that infants born to HbsAg-positive mothers undergo postimmunization testing for anti-HBS and HbsAg 3 to 9 months after completion of the series, for identification of breakthrough carriers and of infants who may benefit from revaccination (AAP Committee on Infectious Diseases, 2010a).

Treatment

There is no therapy for acute hepatitis B infection. Interferon (IFN) α and antiretroviral drugs such as lamivudine, an antiretroviral drug that blocks HBV polymerase, and adefovir, a reverse transcriptase inhibitor, have been approved for treatment of chronic hepatitis B in children, but success is widely variable (Giacchino and Cappelli, 2010). Three therapeutic agents for chronic HBV infection in children have been approved in the United States, including standard IFN-α, lamivudine, and adefovir (Kurbegov and Sokol, 2009). These antiviral therapies are summarized in Table 37-2. IFN-α appears to be the

most effective (approximately 30% HBeAg seroconversion; 10% HBsAg seroconversion), although benefits are primarily observed in children with alanine aminotransferase levels more than twofold the upper limit of normal. The virologic response rates for lamivudine mirror those of IFN-α (23% to 31% HBeAg seroconversion) with easier administration and a more favorable safety profile, but lower HBsAg seroconversion (2% to 3%) and high rates of drug resistance. Adefovir demonstrates a favorable safety profile and is less likely to select for resistance than lamivudine, but virologic response was limited to adolescent patients and was lower than that of lamivudine (16% HBeAg seroconversion; <1% HBsAg seroconversion). Entecavir and tenofovir, both approved therapies for adults with chronic HBV infection, are in trials for use in children. Some experts recommend "watchful waiting" of children, because current therapies are only 30% effective at best. Young children are often believed to be immune tolerant of hepatitis B infection (i.e., they have viral DNA present in serum, but normal transaminase levels and no evidence of active hepatitis). These children should have transaminases and viral load monitored, but are not typically considered to be candidates for antiviral therapy.

Prognosis

Most long-term follow-up studies have shown that children vaccinated at birth have high levels of protection until at least 5 years of age. Approximately 5% to 10% of infants born to HbeAg-positive mothers become chronic HBV carriers despite combined active and passive immunoprophylaxis with hepatitis B immunoglobulin and HBV vaccine (Kato et al, 1999). Failure of immunoprophylaxis may be associated with the level of maternal viremia and specific HBV genetic variants (Ngui et al, 1998). Infants who become infected with HBV perinatally have a 90% risk of chronic infection, and 15% to 25% of those with chronic infection die of HBV-related liver disease (primarily hepatocellular carcinoma) as adults. There is some evidence that the risk of carcinoma correlates with specific hepatitis B genotypes (Sherman, 2010).

HEPATITIS C

In 1989, hepatitis C virus (HCV) was found to be the main cause of non-A, non-B, parenterally transmitted hepatitis; subsequently, HCV has been found to account for a significant portion of the cases of sporadic acute and chronic hepatitis (Choo et al, 1989; Reyes et al, 1990; Weiss and Persing, 1995). Hepatitis C virus is a small, single-stranded RNA virus that is a member of the family Flavivirus; this family consists primarily of vector-borne infections, such as St. Louis encephalitis virus and West Nile virus. Hepatitis C virus is an exception in this family because it is not transmitted by insect vectors. Seven genotypes are described, with significant biologic differences in regard to disease progression and responsiveness to therapy (Klenerman et al, 2009). Vertically transmitted hepatitis C infection in infants is associated with a higher rate of chronic hepatitis, but less liver injury compared with adult HCV infections (Tovo et al, 2000).

Incidence

The seroprevalence for anti-HCV antibody in pregnant women ranges from 0.7% to 4.4% worldwide (Conte et al, 2000). In the United States, seroprevalence of hepatitis C decreased during the 1990s and has remained low and stable since then. The overall seroprevalence is estimated to be 1.3%, with a seroprevalence in pregnant women ranging from 1% to 2% (AAP Committee on Infectious Diseases, 2010a). Forty percent to 50% of women with HCV have no identified known risk factors for infection (Bortolotti et al, 1998). Estimates from the 1990s suggested that the vertical transmission rate of HCV is approximately 5% to 11% in HIV-negative mothers, and ranges from 10% to 20% from mothers coinfected with HIV (Hillemanns et al, 2000; Palomba et al, 1996; Polywka et al, 1997; Tajiri et al, 2001). More recent studies, however, suggest a lower rate of vertical transmission, ranging from 2.7% to 3.6% (Ferrero et al, 2003; Syriopoulou et al, 2005). One study has shown, in a multivariate analysis, that higher risk of vertical transmission is related more to maternal use of injection drugs than to HIV infection itself, although the mechanism for this finding is still unclear (Resti et al, 2002). The risk of transmission correlates with maternal viremia, and transmission appears to be rare in the absence of viremia. The risk of HCV infection from transfused blood after the advent of HCV screening is estimated to be less than 1 in 1 million units transfused.

Etiology and Pathogenesis

HCV is transmitted less efficiently than HBV by sexual contact. Risk factors for HCV infection include transfusion, intravenous drug use, frequent occupational exposure to blood products, and household or sexual contact with an infected person (Weiss and Persing, 1995). In children, perinatal transmission is the most common route of infection (Mohan et al, 2010). Preparations of IVIG contaminated with HCV were reported between April 1993 and February 1994, but since that time, routine screening for HCV with PCR and application of a viral inactivation process during manufacturing have been implemented to reduce the risk of transmission (Schiff, 1994).

Perinatal transmission is the leading cause of childhood HCV infection (Mohan et al, 2010). Transmission of HCV from mother to child is thought to occur either in utero or at the time of delivery. Viral genotypes and infection and replication in maternal peripheral blood monocytes can also affect the ability of the virus to infect the fetus or newborn (Azzari et al, 2000; Zuccotti et al, 1995). Perinatal transmission is confined almost always to women with detectable HCV ribonucleic acid (RNA) in the peripheral blood by the PCR, but all children born to women with anti-HCV antibodies should be tested for HCV. Data regarding the correlation of HCV RNA titer in the mother with the risk of vertical transmission are conflicting, although most studies have reported an association (Conte et al, 2000; Lynch-Salamon and Combs, 1992; Ohto et al, 1994; Resti et al, 1998; Tajiri et al, 2001). Maternal peripheral blood mononuclear cell infection by HCV, membrane rupture of longer than 6 hours before delivery, and procedures exposing the infant to maternal

blood infected with HCV during vaginal delivery are associated with an increased risk of transmission. Internal fetal monitoring is also a risk factor for transmission (Mast et al, 2005). Maternal coinfection with HCV and human immunodeficiency virus, maternal history of intravenous drug use and of HCV infection of the sexual partner of the mother are also risk factors for transmission (Fiore and Savasi, 2009; Indolfi and Resti, 2009). Transmission rates as high as 25% have been reported in HCV-infected, HIV-positive women. The effect of vaginal delivery versus cesarean section on transmission rates is unclear (Gibb et al, 2000; Paccagnini et al, 1995); current recommendations do not support the practice of cesarean delivery in women with HCV infection.

Transmission of HCV via breast milk has not been demonstrated conclusively, although HCV can be found in breast milk and colostrum (Gurakan et al, 1994; Zimmermann et al, 1995). Studies comparing breastfed and bottlefed infants born to HCV-infected mothers have not shown a statistically significant difference in vertical transmission (Lin et al, 1995; Resti et al, 1998). Accordingly, maternal HCV infection is not a contraindication to breastfeeding (Mast, 2004); however, it may be prudent for mothers who are HCV-infected and who choose to breastfeed to consider abstaining from breastfeeding if their nipples are cracked and bleeding.

Clinical Spectrum and Laboratory Evaluation

Acquired HCV infection typically causes jaundice in one third of cases and significant increases in alanine aminotransferase (ALT) in almost all persons infected. Most neonates perinatally infected with HCV demonstrate little in the way of clinical symptomatology; they may have elevated liver ALT either transiently or intermittently. The increases in ALT values, when tested, are most commonly noted between 3 and 6 months of age. HCV-RNA PCR results may be negative initially at birth or within the first few days of life, but typically become positive by 1 to 2 weeks of age and remain so until at least 5 years of age. The highest sensitivity of PCR is reported after 1 month of age (Polywka et al, 2006; Thomas et al, 1997). Confirmatory anti-HCV IgG serology should be delayed until exposed infants are at least 15 to 18 months old, when at least 99% will have cleared maternal antibody (Dunn et al, 2001). Before 18 months of age, only a positive HCV PCR result can confirm diagnosis of neonatal infection; positive anti-HCV IgG results simply reflect passively acquired maternal antibody. IgM assays are not available or reliable for perinatal diagnosis of HCV. Liver ultrasonographic findings are usually normal or may consist of a mild diffuse increase in echogenicity. Liver biopsies, when performed, typically demonstrate mild to moderate chronic persistent hepatitis (Palomba et al, 1996; Tovo et al, 2000).

Treatment

Interferon and ribavirin are both approved by the FDA to treat adults and children with chronic hepatitis C. Antiviral agents are summarized in Table 37-2. Only 10% to 25% of adults treated with interferon have a sustained remission of disease (Bonkovsky and Woolley, 1999). Treatment with a combination of interferon and ribavirin achieves remission in closer to half of treated adults (Cornberg et al, 2002). Randomized controlled trials indicate that patients treated with pegylated interferons (so called because they are formulated and stabilized with polyethylene glycol), both as dual therapy with ribavirin and as monotherapy, experience higher sustained viral response rates than do those treated with nonpegylated interferon (Shepherd et al, 2004). Data on the use of these agents in infants and children are limited, although the use of IFN-α2b in combination with ribavirin was recently approved by the FDA (Palumbo, 2009). In a case series of four pediatric patients treated with interferon for 1 year, viremia decreased to undetectable levels during treatment in all four patients, but two patients became viremic again once the treatment was stopped (Tovo et al, 2000). There are significant genotype-dependent differences in responsiveness to antiviral therapy; patients with genotype 1 had the lowest levels of sustained virologic response, and patients with genotype 2 or 3 had the highest (Palumbo, 2009; Shepherd et al, 2004). The use of IFN-α2b in combination with ribavirin provides a much more favorable sustained virologic response in children with HCV genotype 2/3 (84%) than in those with HCV genotype 1 (36%; González-Peralta et al, 2005). For genotype 1 hepatitis C treated with pegylated interferons combined with ribavirin, it has been shown that genetic polymorphisms near the human *IL28B* gene, encoding interferon lambda 3, are associated with significant differences in response to the treatment (Ge et al, 2009; Thomas et al, 2009). Interferon therapies are available only in parenteral formulations and are associated with significant side effects; therefore further research into its utility in pediatric HCV infection is needed.

Infants and children with persistent elevations in liver transaminases should be referred to a pediatric gastroenterologist for evaluation and management. The necessity for, as well as the frequency of, screening tests of liver function has not been established.

Prognosis

In 60% to 80% of HCV-infected adults, chronic hepatitis occurs, and in one third of HCV-infected adults, chronic HCV infection leads to cirrhosis or liver failure within 20 to 30 years after infection (Iwarson et al, 1995; Leone and Rizzetto, 2010). In patients with cirrhosis, the incidence of hepatocellular carcinoma is 2% to 5% per year. There are limited data regarding long-term follow-up in HCV-infected infants, but existing knowledge indicates that most children remain viremic until at least 5 to 6 years of age, and most develop chronic, persistent hepatitis. Studies monitoring infected children beyond 6 years of age have not been completed, but they are at risk for cirrhosis and hepatocellular carcinoma. Transient hepatitis C viremia with subsequent resolution has been reported (Padula et al, 1999; Ruiz-Extremera et al, 2000; Zanetti et al, 1995). All the infants who have been followed for an average of 3 to 4 years have been reported to have normal growth and development (Tovo et al, 2000).

Prevention

Although development of an HCV vaccine is a major public health priority (Houghton and Abrignani, 2005), there is currently no vaccine available. Like all other infants, infants with HCV should receive routine hepatitis B immunization. In addition, they should receive hepatitis A vaccination at 2 years of age. Parents should be advised to avoid unnecessary administration of medicines known to be hepatotoxic. Standard precautions are recommended for the hospitalized infant.

ADENOVIRUS

Adenoviruses are so named because they were originally recovered from human adenoidal tissue; they are medium-sized (90 to 100 nm), nonenveloped icosahedral viruses composed of a nucleocapsid and a double-stranded linear DNA genome. They are the largest of the nonenveloped viruses. There are 53 described adenovirus serotypes in humans.

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

Adenoviruses are responsible for a wide variety of clinical syndromes, including conjunctivitis, respiratory track disease, and gastroenteritis. Adenovirus causes 5% to 10% of upper respiratory infections in children, and many infections in adults as well. No clear seasonality has been described for adenovirus infections.

ADENOVIRUS INFECTIONS IN NEWBORNS

There are a limited number of reports of adenovirus infection in young infants, but published case series indicate that adenovirus can cause serious, life-threatening disease in the neonate. A review of neonatal adenovirus infection (Abzug and Levin, 1991) identified several characteristic historical features, including prolonged rupture of membranes, history of maternal illness, vaginal mode of delivery, and onset of illness within the first 10 days of life. Serotypes 2, 3, 7, 11, 13, 19, 21, 30, and 35 have been implicated (Abzug and Levin, 1991; Andiman et al, 1977; Matsuoka et al, 1990; Osamura et al, 1993; Pinto et al, 1992; Sun and Duara, 1985). Clinical findings in various case reports and case series have included lethargy, fever or hypothermia, anorexia, apnea, hepatomegaly, bleeding, and progressive pneumonia (Figure 37-5). Laboratory abnormalities include thrombocytopenia, coagulopathy, and hepatitis. Acquisition of infection from the mother via vaginal delivery is the presumed mode of transmission in most cases, although transplacental spread has also been implicated.

Although most neonatal adenovirus infection is believe to be acquired in the birth canal, congenital infections have been described, presumably because of transplacental transmission. A wide range of fetal pathologies including pleural effusion, hepatitis, myocarditis, meningitis, and CNS abnormalities have been described (Baschat et al, 2003; Meyer et al, 1985; Rieger-Fackeldey et al, 2000). Adenovirus has been implicated as a potential cause of chorioamnionitis and premature birth (Tsekoura et al, 2010; Van den Veyver et al, 1998).

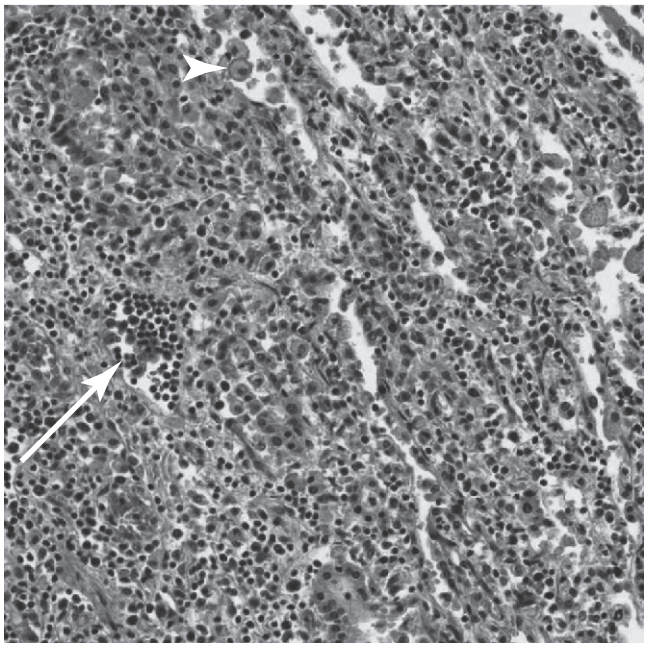

FIGURE 37-5 *(See also Color Plate 19.)* Postmortem histologic analysis from an infant who died from disseminated adenovirus infection at 2 weeks of age. Hematoxylin and eosin stain of lung demonstrating inflammatory infiltrates *(arrow)* and intranuclear inclusions *(arrowhead)*. This infant had a viral sepsis syndrome characterized by hepatic failure, disseminated intravascular coagulation, and pneumonitis from adenovirus infection presumed to have been acquired intrapartum.

PREVENTION AND INTERVENTION

Intravenous ribavirin has been administered to a neonate with disseminated adenovirus infection undergoing extracorporeal membrane oxygenation, with evidence of viral clearance within 48 hours of initiating therapy (Aebi et al, 1997). Adenovirus vaccines were at one time available for use in military personnel (Gaydos and Gaydos, 1995; Tucker et al, 2008), but are not currently in production. Adenoviruses are hardy and resistant to inactivation by physical and chemical methods that kill most viruses, adding to the challenge of hospital infection control during outbreaks of infection.

RESPIRATORY VIRUSES

Although relatively uncommon, any one of the respiratory viruses can cause symptomatic respiratory disease in newborn infants. The association has been described for rhinoviruses, adenoviruses, parainfluenza viruses, influenza virus, and respiratory syncytial virus. Adenovirus, rhinovirus, and parainfluenza virus infections are generally characterized by mild rhinorrhea in neonates. All of these viruses, however, can cause clinical symptoms indistinguishable from those of bacterial infection, leading to increased diagnostic testing and empiric antibiotic treatment. Influenza virus infections are usually mild, but in the absence of maternally transmitted antibody, they can be life threatening, with severe pneumonia, hypoxia, and a

prolonged course. During the H1N1 influenza pandemic of 2009 to 2010, pregnant women were at uniquely high risk for severe influenza (Jamieson et al, 2009), and infections were described in neonates (Sert et al, 2010).

The most extensive nursery outbreaks, however, have been caused by respiratory syncytial virus (RSV; Hall et al, 1979; Wilson et al, 1989). Because of the importance that RSV plays in the newborn nursery, this virus is considered in greater detail in the following section.

RESPIRATORY SYNCYTIAL VIRUS

RSV is the major cause of viral pneumonia and bronchiolitis in infants and children. In temperate climates, it causes large annual epidemics during the winter and early spring months (typically ranging from November through April). During these months, RSV appears to be responsible for up to 20% of all pediatric hospital admissions (Hall et al, 2009). Nosocomial infections are frequent during these times, and illness among hospital staff members is a major factor in its spread from infant to infant. Several nursery outbreaks have been described. In one of these outbreaks, cultures were obtained prospectively so that a full picture of the virus's pathogenicity and epidemiology could be drawn (Hall et al, 1979). Twenty-three of 66 infants hospitalized for 6 days or more were infected. Virtually all infants were symptomatic. Clinical manifestations included pneumonia, upper respiratory infection, apneic spells, and nonspecific signs. Pneumonia and apnea were seen almost exclusively in infants older than 3 weeks, and nonspecific signs were most commonly observed in younger infants. Four (17%) infants died, two unexpectedly, during the course of infection. The spread of infection in the unit was difficult to interrupt; infants in isolettes did not seem to be protected against acquisition of the infection. Eighteen of the 53 nursery personnel were infected during the outbreak; 83% of the infected nursery providers were symptomatic. Of particular importance is the observation that RSV infection, both in term and in preterm infants, is commonly associated with a new onset of apnea (Bruhn et al, 1977). Boys are at greater risk than girls for serious RSV disease. RSV-associated apnea has been the probable explanation for some case reports of deaths attributed to SIDS (Eisenhut, 2006). RSV lower respiratory track disease can be slow to resolve. After discharge from initial hospitalization, risk factors for infant rehospitalization secondary to RSV infection include premature gestational age, chronic lung disease, siblings in daycare or school, chronologic age of less than 3 months, and exposure to tobacco smoke (Carbonell-Estrany and Quero, 2001).

Diagnosis can be confirmed by DFA staining of nasopharyngeal or tracheal aspirate, nasopharyngeal swab, or other respiratory secretions. Culture of RSV can require 3 to 5 days and can be used if DFA staining is not available. PCR is also available for the rapid diagnosis of infection.

Treatment and prevention of RSV infection in infants attracted considerable attention during the 1990s because of the clinical and economic impacts of these infections (Groothuis, 1994; Kinney et al, 1995; Levin, 1994; Meissner, 1994). Considerable debate has ensued concerning the efficacy, safety, and potential effect on health care workers of ribavirin therapy, so its use remains controversial (Meissner, 2001; Ventre and Randolph, 2004; Wald and Dashefsky, 1994). Treatment consists of nebulization of ribavirin by a small-particle aerosol generator supplied by the manufacturer into an oxygen hood, tent, or mask from a solution containing 20 mg of ribavirin per milliliter of water (see Table 37-2). The aerosol has been administered on various schedules for 3 to 5 days (e.g., 12 to 20 h/day). The efficacy of ribavirin in this setting remains unclear. Some long-term benefit on recurrent wheezing may be realized (Ventre and Randolph, 2004). Corticosteroids are not effective in the treatment of RSV.

Prevention efforts have focused on passive and active immunization. Standard immunoglobulin has not been shown to be efficacious for prevention of RSV infection in high-risk infants (Meissner et al, 1993). The efficacy of monthly prophylactic administration of RSV-specific immunoglobulin (750 mg/kg or 150 mg/kg) in 249 infants with cardiac disease or bronchopulmonary dysplasia was examined in a multicenter trial (Groothuis, 1994). In the high-dose (750 mg/kg) group, there were fewer lower respiratory tract infections, hospitalizations, days in hospital, and days in the intensive care unit as well as less use of ribavirin. Subsequently a mouse monoclonal antibody was developed, which provides similar protection against RSV (i.e., palivizumab). Unlike anti-RSV immunoglobulin, which is a pooled human blood product, the monoclonal antibody does not confer the theoretical risk of acquiring bloodborne pathogens. Palivizumab is also substantially easier to administer because it is an intramuscular injection. Recommendations by the AAP for the use of palivizumab are summarized in Box 37-4. Additional preventive measures for high-risk infants include eliminating or minimizing exposure to tobacco smoke, avoiding crowds and situations

BOX 37-4 Guidelines for Prophylaxis in Preterm Infants at Start of RSV Season

PROPHYLAXIS RECOMMENDED

- Infants born at ≤28 weeks, 6 days of gestation during first RSV season*
- Infants born at 29 weeks, 0 days through 31 weeks, 6 days of gestation if less than 6 months of age at beginning of RSV season
- Infants and children less that 24 months of age with chronic lung disease requiring medical therapy (e.g., supplmental oxygen, bronchodilators, diuretics, corticosteroids) within the 6 months before RSV season
- Infants born at 32 weeks, 0 days through 34 weeks, 6 days of gestation if one of the following two risk factors are present:
  - Attending child care
  - Sibling younger than 5 years of age

PROPHYLAXIS CONSIDERED

- Infants with congenital anomalies of the airways
- Infants younger than 24 months of age with hemodynamically significant congenital heart disease, as manifest by congestive heart failure, pulmonary hypertension, and cyanosis
- Infants with severe neuromuscular disease
- Infants with immune deficiencies
- Infants with cystic fibrosis

RSV, Respiratory syncytial virus.
*Earliest date to consider initiation of prophylaxis depends upon geographic location: July 1 for southeast Florida, September 15 for north central and southwest Florida, November 1 for most other areas of the United States.

in which exposure to infected individuals cannot be controlled, careful hand hygiene education of parents, vaccinating against influenza beginning at 6 months of age, and restricting participation in child care during the RSV season whenever feasible. The prospects for infant or maternal immunization with live attenuated and protein subunit vaccines are under active investigation and development (Crowe, 2001; Fretzayas and Moustaki, 2010; Piedra, 2000).

Nosocomial spread of RSV and other respiratory viruses can be minimized by emphasis on hand washing by care providers between contacts with patients. Without additional special precautions, an attack rate of approximately 26% has been observed (Madge et al, 1992). Use of standard contact precautions, such as cohort nursing and the use of gowns and gloves for all contacts with RSV-infected children, can reduce the risk of nosocomial RSV infection to 9.5% (Madge et al, 1992).

GASTROINTESTINAL VIRUSES

The most important of the viruses that cause diarrhea from the perspective of the neonatal nursery are the rotaviruses. This important group of viruses, with at least four serotypes, is responsible for a large proportion of significant and sometimes severe diarrhea in infants 6 to 24 months of age (Cohen, 1991; Greenberg et al, 1994; Haffejee, 1991; Taylor and Echeverria, 1993). Recent evidence suggests that rotavirus extracts an unexpectedly significant burden of disease on infants as young as 2 to 3 months of age (Clark et al, 2010). Nursery-acquired infections are common; surprisingly, such infections appear to be benign in most infants. Two studies performed in nurseries in Sydney, Australia, and in London found that 30% to 50% of 5-day-old babies shed the virus (Chrystie et al, 1978; Murphy et al, 1977). However, more than 90% of the infected infants were asymptomatic. The remaining symptomatic infants had loose stools and vomiting, but this figure was only slightly higher than the proportion of uninfected infants with the same symptoms. The full scope of rotavirus disease in the newborn and in the premature infant remains to be fully defined. The recent advent and licensure of several rotavirus vaccines should have a significant effect on both nosocomial and community-acquired rotavirus disease (Bernstein, 2009).

HUMAN IMMUNODEFICIENCY VIRUS INFECTION DURING PREGNANCY

CHANGING EPIDEMIOLOGY OF THE HIV/AIDS PANDEMIC

From 1980, when previously healthy, young, gay men first began to have complaints of fever, malaise, weight loss, lymphadenopathy, and malaise, to the identification in 1983 of 36 cases in Kinshasa, Zaire (Congo) of acquired immunodeficiency syndrome (AIDS) by a team of representatives from the CDC and National Institutes of Health, the scope of HIV infection has evolved into a global pandemic. The Joint United Nations Program on HIV/AIDS estimated that, as of the end of 2008, up to 35 million individuals were living with HIV/AIDS globally. Relevant to this chapter, women accounted for 60% of all adults living with HIV (Christie et al, 2008).

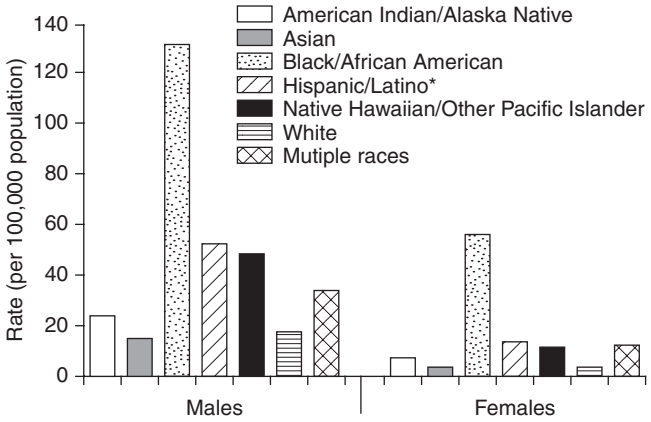

FIGURE 37-6 Estimated rates of diagnoses of HIV infection among adults and adolescents, by sex and race/ethnicity, in 2008 for 37 states with confidential name-based HIV infection reporting. Estimated rates resulted from statistical adjustment that accounted for reporting delays, but not for incomplete reporting. *(From Centers for Disease Control and Prevention:* HIV Surveillance Report 20, 200, *June 2010. Available at www.cdc.gov/hiv/topics/surveillance/resources/reports. Accessed November 24, 2010.)*

Currently, national and international surveillance for HIV infection and the resulting illness of AIDS is routine. In the United States, CDC surveillance data for 2005 to 2008 revealed an 8% increase in the absolute number of newly diagnosed HIV infections, whereas the overall rate of new infections was stable. Women currently account for 25% of the HIV-infected U.S. population, with African American women having the highest rate of diagnosed infection among women (Figure 37-6). In Florida, an HIV prevalence study among pregnant women from 1998 to 2007 found that black women were 11-fold more likely than white women to have HIV infection (Salihu et al, 2010). The incidence of HIV infection is challenging to measure and has not been measured directly. Based on a relatively new antibody test that can distinguish recent (median, 156 days) seroconversion from longstanding infection, it is estimated that there were 13,000 to 15,000 HIV infections among U.S. women in 2006 (Hall et al, 2008).

Estimates of HIV prevalence in pregnant women worldwide are challenging to obtain and may be underestimated, because those who consent to testing and counseling are more likely to be HIV negative. For example, in an urban antenatal clinic in Zambia, 25% of women accepting HIV testing were found to be HIV positive, whereas anonymous sampling of infants' cord blood demonstrated a prevalence of 29% among women who refused testing (p <0.0001 for a difference in HIV prevalence between the two groups; Stringer et al, 2005). In Zimbabwe, HIV prevalence among antenatal clinic attendees has been declining, although rates remain high: 32.1% in 2000 and 23.9% in 2004 (Mahomva et al, 2006). Infection rates in antenatal clinics in KwaZulu-Natal, South Africa, reached 37.5% (Ramogale et al, 2007). In the country of South Africa alone, there are an estimated 220,000 pregnant women living with HIV infection. Most African cities exhibit an HIV prevalence rate in the 20% to 40% range, whereas

estimates in India are markedly lower—closer to 1% to 2% (Dandona et al, 2008; Lionel et al, 2008).

A markedly disproportionate burden of disease is spread among a few countries as evidenced by this summary statement in a 2008 World Health Organization report: "Close to 90% of all pregnant women living with HIV in low and middle-income countries live in 20 countries and 75% are concentrated in 12 countries" (World Health Organization, 2008). The high prevalence of HIV infection among women living in settings where antiretroviral medications are not universally available results in many cases of pediatric HIV infection. Mother-to-child transmission accounts for 90% of HIV infections in children. A recent estimate is that a staggering 2.1 million children younger than 15 years are infected with HIV (World Health Organization, 2008).

In addition to the expansive societal and economic cost directly resulting from maternal HIV infection, there is a ripple effect of HIV infection on prevalence and morbidity of other infections. Tuberculosis and malaria are now common opportunistic infections of HIV in low-income countries. Herpes and HIV are considered "overlapping epidemics" (Corey et al, 2004), and the interplay is complex. Reactivation of HSV increases HIV RNA levels in plasma, and mucocutaneous shedding of HIV-1 is greater during mucocutaneous replication of HSV-2. Less publicized but more morbid effects are seen on the risk for puerperal sepsis, which is increased in HIV-infected women. A study in Zimbabwe demonstrated an 11-fold increase in risk for puerperal sepsis among HIV-infected women compared with HIV-negative women (Zvandasara et al, 2006). The same trend is exhibited in European settings; the European Collaborative Study found a fourfold increased risk for puerperal sepsis among HIV-infected women in 14 HIV reference centers across five countries (Fiore et al, 2004). Clearly the effect of HIV is multidimensional, and interdisciplinary cooperation is essential to effect change.

PATHOGENESIS OF HIV DISEASE

Transmission of the Virus

Transmission of HIV infection requires the exchange of bodily fluids. Numerous studies have demonstrated that casual household or community contacts are not associated with transmission or acquisition of HIV/AIDS. The three general mechanisms by which the virus can be passed from one individual to another are sexual, parenteral, and perinatal.

Different types of exposure to infection are associated with different risks of infection (Royce et al, 1997). One sexual transmission occurs for every 100 to 1000 exposures. Male-to-female transmission risk is about 10-times greater than female-to-male transmission risk. Needlestick injury from an infected source carries a transmission risk of approximately 0.3% (Panlilio et al, 2005), with the risk from needle sharing being significantly greater. The risk of transmission through blood transfusion is greater than 90%, although this rarely occurs in the United States because of current screening methods used by blood banks.

Mother-to-Child Transmission

Transfer of virus from maternal to fetal or neonatal tissues is thought to occur during one of three discrete periods—antepartum (before the onset of labor), peripartum (during labor and delivery), and during breastfeeding. Studies of early viral dynamics in infected neonates suggest that the peripartum period is the time of highest risk (Mofenson, 1997). The risk of vertical transmission is heightened by premature rupture of membranes, high maternal viral load, and low maternal CD4 counts (Ioannidis and Contopoulos-Ioannidis, 1999; Mofenson et al, 1999). Without antiretroviral treatment, the risk of vertical transmission is estimated to be 15% to 20% in Europe, 15% to 30% in the United States, and 25% to 35% in Africa (Volmink et al, 2007). With highly active antiretroviral therapy, the risk of vertical transmission in the United States has been reduced to 1% to 5% (Coovadia, 2009).

Transmission through breast milk carries a 5% to 20% risk of transmission, largely dependent on the viral load and CD4 count of the mother (World Health Organization, 2008). A Kenyan study that randomized infants of HIV-infected mothers to breast versus formula feeding found that breastfeeding increased the risk of HIV transmission by 16% (Nduati et al, 2000b).

Prevention of Mother-to-Child Transmission

The cornerstone of preventing mother-to-child transmission of HIV is knowledge of the mother's HIV status. Updated recommendations from the CDC in 2006 (Branson et al, 2006) reinforced the importance of antenatal testing by stating that:

1. HIV screening should be included in the routine panel of prenatal screening tests for all pregnant women.
2. HIV screening is recommended after the patient is notified that testing will be performed, unless the patient declines (i.e., opt-out screening).
3. Separate written consent for HIV testing should not be required; general consent for medical care should be considered sufficient to encompass consent for HIV testing.
4. Repeated screening in the third trimester is recommended in certain jurisdictions with elevated rates of HIV infection among pregnant women (described as one diagnosed HIV case per 1000 pregnant women per year).

Research has shown that HIV testing rates are highest when included in standard testing for pregnant women both in high-income and low-income countries. A study done in Birmingham, Alabama, found that HIV testing rates increased from 75% to 88% (p <0.001) subsequent to the 1999 Institute of Medicine recommendation to make HIV testing a routine part of antenatal care (Stringer et al, 2001). Similarly, in Zimbabwe, testing rates increased from 65% to 99.9% (p <0.001) after implementation of an opt-out HIV testing approach in antenatal clinics (Chandisarewa et al, 2007).

HIV testing rates in most low-income countries are lower than those seen in Zimbabwe, but modest gains are being made. Globally, HIV testing in low- and middle-income countries rose from 10% of pregnant women attending antenatal clinics in 2004 to 18% in 2007 (World

Health Organization, 2008). As antiretroviral therapy becomes more readily available and the effects of this therapy on vertical transmission become more widely known, the incentive to perform HIV testing among pregnant women should increase.

Maternal Therapy

The introduction of potent antiretroviral therapies in the middle 1990s markedly reduced deaths caused by AIDS in most regions of the developed world. Antiretroviral therapies have not only reversed AIDS mortality trends in the developed world; they have also dramatically altered patterns of HIV transmission from mothers to children. The results of the Pediatric AIDS Clinical Trial Group Study 076 lead to a profound change in the approach to medical care for HIV-positive pregnant women (Connor et al, 1994). This prospective, placebo-controlled, randomized trial demonstrated that zidovudine prophylaxis during pregnancy, delivery, and early infancy reduced the rate of vertical HIV transmission from 25% to 8%. Less than 2 years later, additional antiretroviral agents became available for treatment of HIV infection. It also became possible to monitor viral load via plasma HIV-1 RNA assays. These monitoring and treatment tools created the potential for the well-controlled management of HIV infection in pregnant women seen today, where it is common to see viral loads of less than 1000 copies per milliliter and vertical transmission risk as low as 1%. Numerous studies have been conducted in low- and middle-income countries as well, demonstrating the benefit of antiretroviral therapy during pregnancy for prevention of vertical transmission of HIV (Dorenbaum et al, 2002; Ioannidis et al, 2001; Namukwaya et al, 2010).

Current guidelines exist for antiretroviral therapy in pregnant women (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2010; available at http://aidsinfo.nih.gov/ContentFiles/PerinatalGL.pdf). Antiretroviral therapy is recommended for all HIV positive pregnant women during the latter trimesters of their pregnancy, with reassessment of the need to continue antiretroviral therapy after birth of the infant. If a woman is already receiving antiretroviral therapy that successfully suppresses viremia, it is recommended to continue the same regimen but find substitutes for any teratogenic drug (e.g., efavirenz). If the woman has a new HIV diagnosis, is antiretroviral therapy–naïve, and does not require antiretroviral therapy for her own health, therapy should be initiated for prophylaxis against vertical transmission based on the parameters in Box 37-5. If the mother is symptomatic from her infection or has a history of antiretroviral therapy use, the Perinatal Guidelines should be referenced for additional recommendations (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2010).

Internationally, women in countries with the highest HIV prevalence often have less 25% intrapartum antiretroviral therapy coverage (Figure 37-7). United Nations goals target an 80% coverage rate of antiretroviral therapy in pregnant women, but drug availability still varies widely between countries. Rapid increases in antiretroviral availability in some African countries during 2004 to 2007 prove that such services can be provided quickly and effectively in low-income countries given adequate political and financial support (Figure 37-8) (World Health Organization, 2008).

BOX 37-5 Treatment Recommendations for HIV-Infected, Antiretroviral-Naive Asymptomatic Pregnant Women

- Perform HIV antiretroviral drug resistance testing before initiating combination antiretroviral drug therapy and repeat after initiation of therapy if viral suppression is suboptimal.
- Prescribe a combination antiretroviral drug prophylaxis regimen (i.e., at least three drugs) for prophylaxis of perinatal transmission.
  - Consider delaying initiation of antiretroviral prophylaxis until after first trimester is completed.
  - Avoid use of efavirenz or other potentially teratogenic drugs in the first trimester and drugs with known adverse potential for the mother (e.g., combination stavudine/didanosine).
  - Use zidovudine as a component of the antiretroviral regimen when feasible.
  - If the woman has CD4 count >250 cells/mm^3, use nevirapine as a component of therapy only if the benefit clearly outweighs the risk, because of an increased risk of severe hepatic toxicity.
- Although the use of zidovudine prophylaxis alone is controversial, consider it if the woman has plasma HIV RNA level <1000 copies/mL on no therapy.
- Continue antiretroviral prophylaxis regimen during intrapartum period (zidovudine given as continuous infusion during labor while other antiretroviral agents are continued orally).
- Evaluate the need for continuing the combination regimen postpartum; discontinue the combination regimen unless the woman has indications for continued therapy. If regimen includes a drug with a long half-life, such as NNRTI, consider stopping NRTIs at least 7 days after stopping NNRTI.

Adapted from Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission: [Perinatal Guidelines] *Recommendations for use of antiretroviral drugs in pregnant HIV-1-infected women for maternal health and interventions to reduce perinatal HIV transmission in the United States,* May 24, 2010, pp 1-117. http://aidsinfo.nih.gov/ContentFiles/PerinatalGL.pdf. Accessed November 22, 2010.

Antiretroviral Drug Resistance

Resistance to available antiretroviral drug therapy has become an increasingly important problem requiring continual reevaluation of antiretroviral therapy regimens for women and prophylactic regimens against perinatal transmission in both mother and infant. Drug resistance in the context of longitudinal maternal antiretroviral therapy is beyond the scope of this chapter, but current recommendations for appropriate drug regimens can be accessed in the Perinatal Guidelines (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2010). It is important to conduct resistance testing before antiretroviral therapy initiation in women or infants, with the exception of the recommended 6 weeks of postnatal zidovudine for infants described in the following section). Selection of an appropriate combination drug regimen is best undertaken with the advice of a clinician specializing in the care of HIV-infected pediatric or adult patients.

In low- and middle-income countries, a single dose of nevirapine is often used to prevent vertical transmission of HIV (Guay et al, 1999). Whereas single-dose nevirapine is the most widespread approach to prophylaxis against perinatal transmission of HIV because of cost, limited availability of other drugs, and ease of administration, issues of

nevirapine resistance are paramount. One study published in 2010 was terminated early because of the significant difference in nevirapine resistance and associated treatment failure in infants exposed to single-dose perinatal nevirapine prophylaxis (Palumbo et al, 2010). Another study from Uganda found 100% resistance to nevirapine in 6-month-old HIV-infected infants who had received 6 weeks of daily nevirapine in addition to single-dose nevirapine prophylaxis perinatally. Resistance patterns were less prevalent in infants who had received only the single-dose perinatal prophylaxis (16% at 6 months; p=0.005; Church et al, 2008). Appropriate drug regimens for prophylaxis against perinatal transmission in the face of viral mutation and resistance patterns will likely remain a moving target in high-, middle- and low-income countries.

Delivery Method

In 1999, two studies (one randomized clinical trial and one metaanalysis) showed a decreased risk of vertical transmission of HIV with cesarean section before rupture of membranes or onset of labor (European Mode of Delivery Collaboration, 1999; International Perinatal HIV Group, 1999). This evidence was compelling enough for the ACOG to issue new guidelines in August 1999 recommending that all HIV positive pregnant women be offered elective cesarean at 38 completed weeks of gestation. The current ACOG recommendations, updated in 2000 and again in December 2010, recommend that all HIV-positive pregnant women with plasma viral loads greater than 1000 copies per milliliter be "counseled regarding the benefits of an elective cesarean delivery" in addition to a zidovudine infusion 3 hours before the operation (Jamieson et al, 2007). Currently, no study has answered whether elective cesarean delivery further decreases the risk of transmission in women with undetectable viral loads or in those receiving antiretroviral therapy.

Infant Feeding

In the United States, where replacement feeding (i.e., infant formula) is affordable and safe, it is recommended that HIV-positive mothers avoid breastfeeding entirely to minimize the estimated risk of 9% to 14% of postnatal HIV transmission through breast milk. Cell-associated HIV has been detected in human breast milk even among women receiving highly active antiretroviral therapy.

Globally, there is less clarity on best practices for infant feeding. When formula feeding is not affordable, feasible, acceptable, sustainable, and safe, then breastfeeding appears to be best for all infants of HIV-infected mothers. Current World Health Organization guidelines updated in 2010 recommend that mothers known to be HIV-infected either breastfeed and receive antiretroviral interventions or avoid all breastfeeding. The guidelines further clarify that feeding recommendations should be formulated at a national or subnational level based on local epidemiology and socioeconomic and infrastructure realities rather than trying to modify feeding recommendations for each individual mother (World Health Organization, 2010).

Data from a randomized controlled trial in Zambia showed that abrupt weaning at 4 months after birth versus gradual weaning at the mother's time of choice (median, 16 months) yielded no difference in HIV-free survival at 24 months of age (Kuhn et al, 2008). Among children who became infected, early weaning increased mortality. This finding contrasts with data from Kenya that showed an increased risk of HIV transmission in breastfed infants at 24 months of age (37% risk of HIV infection in breastfed versus 21% risk in formula-fed infants; Nduati et al, 2000a). Most vertical transmission occurred during the first 6 months of breastfeeding, and the overall risk of transmission from breastfeeding was 16%. The 2-year all-cause mortality was similar between the two groups in this study.

Safety of breastfeeding in low-resource settings can be enhanced further by antiretroviral therapy for mothers, breastfeeding infants, or both. A synthesis of related studies was reviewed by Coovadia (2009). The mild-borne transmission of HIV-1C (MASHI) study in Botswana (Thior et al, 2006), the Six Week Extended-Dose Nevirapine study in India, Ethiopia, and Uganda (Six Week Extended-Dose Nevirapine Study Team et al, 2008), the post-exposure prophylaxis of infants (PEPI) study in Malawi (Kumwenda et al, 2008), and the Mitra study in Tanzania (Kilewo et al, 2008) have all assessed the utility of prophylactic antiretroviral agents in breastfeeding infants. There was variation in drug choice and duration, but most of these studies showed decreased vertical transmission in breastfeeding infants on some form of antiretroviral drug. A larger effect on vertical transmission, however, is observed from continuation of maternal antiretroviral therapy throughout the breastfeeding period. Maternal antiretroviral therapy in low-resource settings has decreased the vertical transmission rates during breastfeeding to 1% to 5% (Coovadia, 2009).

Evaluation and Treatment of HIV-Exposed Infants

Infant Testing

Infants born to HIV-infected mothers should have an initial serum evaluation by HIV-DNA or RNA PCR assay. This test is most sensitive if performed initially at 2 weeks of age; however, some physicians also do this testing in the first few days after birth to rule out in utero infection, particularly when the situation is high risk. High-risk situations would include unknown maternal HIV status with concerning history or known maternal HIV infection without prophylactic antiretroviral treatment. A negative test result in the first few days after birth requires confirmatory testing at a later time. Table 37-5 shows the recommended testing and evaluation schedule for an HIV-exposed infant (Havens et al, 2009).

If a mother's HIV status is unknown at the time of delivery, a rapid antibody test should be performed on mother or baby. Test results should be available within a few hours. If this test result is positive, prophylactic antiretroviral therapy should be initiated in the infant within 12 hours of birth, even in the absence of a confirmatory test.

Presumptive HIV-negative status of the infant is achieved with two negative tests results, one at 2 weeks old or later and the other at 4 weeks old or later. These are nucleic acid amplification tests (NAATs) and can be either DNA or RNA PCR. A definitive HIV-negative status is achieved

PCR, polymerase chain reaction; *PCP*, *Pneumocystis jirovechii* pneumonia;

*See text (in Havens et al, 2009) for detailed discussion of each action. If the infant has a diagnosis of HIV-1 infection during this period, laboratory monitoring and immunizations should follow guidelines for treatment of pediatric HIV infection.

†Review maternal health information for possible exposure to coinfections. Frequency of examinations is determined, in part, by frequency of visits for immunizations in infancy.

‡Antiretroviral prophylaxis is initiated as soon as possible after birth, but certainly within 12 hours. Zidovudine prophylaxis is continued for 6 weeks.

§Checked at 4 weeks by some experts and rechecked at 8 weeks if the week 4 hemoglobin level is significantly low.

¶All HIV-1–exposed infants should undergo virologic testing for HIV-1 with HIV-1 DNA PCR or RNA assays at 14 to 21 days of age and, if results are negative, repeated at 1 to 2 and 4 to 6 months of age to identify or exclude HIV-1 infection as early as possible. Any positive test result at any age is promptly repeated to confirm the diagnosis of HIV-1 infection.

‖HIV-1 DNA PCR or RNA assay testing in the first few days of life allows identification of in utero infection and might be considered if maternal antiretroviral agents were not administered during pregnancy or in other high-risk situations. A negative test result at this age requires repeated testing to exclude HIV-1 infection.

**If HIV-1 RNA or DNA testing of the newborn infant was not performed shortly after birth, or if such test results were negative, diagnostic testing with HIV-1 NAAT is delayed until 14 to 21 days of age, because the diagnostic sensitivity of virologic assays increases rapidly by the age of 2 weeks. A negative test result at this age requires repeated testing to exclude HIV-1 infection. *Presumptive uninfected* indicates negative nucleic acid amplification test (NAAT) result at ≥14 days and ≥4 weeks (1 month) of age; *definitive uninfected* indicates negative NAAT result at ≥1 and ≥4 months of age.

††No NAAT is needed at 8 weeks of age if previous test results at 2 and 4 weeks of age were negative. A single negative NAAT result at 8 weeks identifies a presumptively uninfected infant.

‡‡Infants with HIV-1 infection should be given PCP prophylaxis until 1 year of age, at which time infants are reassessed on the basis of age-specific $CD4^+$ T-lymphocyte count and percentage thresholds. Infants with indeterminate HIV-1 infection status should receive prophylaxis starting at 4 to 6 weeks of age until they are deemed to be presumptively or definitively uninfected with HIV-1. Prophylaxis is not recommended for infants who meet criteria for presumptive or definitive lack of HIV-1 infection; therefore an NAAT at 2 and 4 weeks of age allows avoidance of PCP prophylaxis if both results are negative.

§§Many experts confirm the absence of HIV-1 infection with a negative HIV-1 antibody assay result at 12 to 18 months of age.

when a negative NAAT test obtained at 4 weeks old or later is added to a negative NAAT results from 4 months old or later (AAP Committee on Infectious Diseases, 2010b). Many clinicians will also obtain an antibody test at 12 to 18 months after birth. By this time, an HIV-negative infant should have cleared any passively acquired maternal antibodies and have a negative antibody test result, a process referred to as *seroreversion*. If the infant's antibody test is positive at this time, an NAAT test should be repeated in addition to close clinical evaluation for signs of infection.

Infant Treatment

Infants exposed to HIV should receive 6 weeks of prophylactic zidovudine (Table 37-6). It is important that families be given the entire quantity of medication at the time of hospital discharge to avoid challenges for compliance resulting from difficulty in filling a prescription (e.g., limited availability of the proper drug formulation, insurance coverage issues).

If the mother has a positive antibody test and received no intrapartum prophylactic zidovudine, some experts would consider early initiation of additional infant antiretroviral medication. However, a careful analysis of the pros and cons of potential toxicity versus decreased transmission risk is imperative. As stated by the Committee on Pediatric AIDS, "If infant prophylaxis with antiretroviral drugs in addition to ZDV is being considered, decisions and choice of antiretroviral drugs should be determined in consultation with a practitioner who is experienced in care of infants with HIV infection," (American Academy of Pediatrics Committee on Pediatric AIDS, 2008).

If the infant has a positive NAAT test result before 6 weeks of age, antiretroviral treatment should be initiated immediately. As stated in *Red Book Online* (AAP Committee on Infectious Diseases, 2010b), "Initiation of antiretroviral therapy is recommended for all HIV-1-infected infants as soon as infection is confirmed, regardless of clinical, immunologic, or virologic parameters." Before initiation, however, it is recommended that infants have resistance testing, because infants can acquire resistant virus from their mothers. Extensive guidelines exist for selecting an appropriate combination drug regimen (available at: http://aidsinfo.nih.gov/ContentFiles/PediatricGuidelines.pdf). A specialist in the treatment of pediatric HIV infection should also be consulted. Although it was once thought that treatment with antiretroviral therapy should be delayed until an infant had signs of illness, it is now known that infected infants have a decreased mortality when treatment is started early. Several studies in South Africa have found that early antiretroviral therapy slowed disease progression, and one study found a 76% reduction in early infant mortality and a 75% reduction in HIV disease progression when antiretroviral therapy was initiated early (Violari et al, 2008).

TABLE 37-6 Intrapartum Maternal and Neonatal Zidovudine Dosing for Prevention of Mother-to-Child Transmission of HIV

Dosing	Duration
Maternal Intrapartum	
2 mg/kg IV over 1 hour, followed by continuous infusion of 1 mg/kg/h	Onset of labor until delivery
Neonatal	
>35 weeks' gestation: 2 mg/kg by mouth*,† (or 1.5 mg/kg IV) started within 6-12 h of delivery, then every 6 h	Birth to 6 wk
30-35 weeks' gestation: 2 mg/kg by mouth (or 1.5 mg/kg IV) started within 6-12 h of delivery, then every 12 h, advanced to every 8 h at 2 weeks of age	Birth to 6 wk
<30 weeks' gestation: 2 mg/kg by mouth (or 1.5 mg/kg IV) started within 6-12 h of delivery, then every 12 h, advanced to every 8 h at 4 weeks of age	Birth to 6 wk

From Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission: [Perinatal Guidelines] *Recommendations for use of antiretroviral drugs in pregnant HIV-1-infected women for maternal health and interventions to reduce perinatal HIV transmission in the United States,* May 24, 2010; pp 1-117. http://aidsinfo.nih.gov/ContentFiles/PerinatalGL.pdf. Accessed November 22, 2010.

IV, Intravenous.

*Zidovudine dosing of 4 mg/kg given every 12 h has been used for infant prophylaxis in some international perinatal studies. Although there are no definitive data to show equivalent pharmacokinetic parameters or efficacy in preventing transmission, a regimen of zidovudine 4 mg/kg by mouth twice daily instead of 2 mg/kg by mouth four times daily may be considered when there are concerns about adherence to drug administration to the infant.

†A simplified zidovudine dosing regimen has been developed for use in low resource settings. This regimen consists of 10 mg by mouth twice daily for infants weighing less than 2.5 kg at birth and 15 mg twice daily for infants weighing more than 2.5 kg at birth. This regimen could be considered for infants in higher resource settings born after 35 weeks' gestation if simplicity in zidovudine dosing and administration is of prime importance.

Prophylaxis with trimethoprim-sulfamethoxazole against opportunistic infections should also be initiated in any infant with possible HIV infection at 6 weeks of age and continued until at least 1 year of age. With a presumptive HIV-negative diagnosis, prophylaxis can be deferred. Although the occurrence of opportunistic infections has declined with more widespread access to testing and antiretroviral therapy, *Pneumocystis jirovechii* pneumonia remains a common serious opportunistic infection in HIV-1–infected infants, responsible for one third of pediatric AIDS diagnoses (AAP Committee on Infectious Diseases, 2010b). A Cochrane review that evaluated a study in HIV-positive Zambian children found a 33% reduction in mortality among children receiving cotrimoxazole prophylaxis versus placebo (Grimwade and Swingler, 2006).

Side Effects of Antiretroviral Therapy Exposure in Infants

Antiretroviral therapy has been overwhelmingly successful in the prevention of vertical transmission of HIV, but few human studies have assessed drug safety and toxicity in infants (Thorne and Newell, 2007). Most antiretroviral drugs are pregnancy category B or C; however, efavirenz was changed to a D classification in 2005 when an association with infants with neural tube defects was seen (De Santis et al, 2002; Fundarò et al, 2002).

A few case reports of mitochondrial toxicity (hyperlactatemia, some with additional motor or cognitive symptoms) in HIV-uninfected, antiretroviral therapy–exposed infants have come from Europe (Blanche et al, 1999; Noguera et al, 2004; Tovo et al, 2005). Some of the symptoms resolved or improved with time. However, large cohort studies in the United States have not shown excess death owing to mitochondrial dysfunction, although they might be underpowered to detect mild dysfunction.

One study done in Malawi showed a hypersensitivity reaction, primarily consisting of a rash, in 16 of 852 (1.9%) infants treated with nevirapine for 28 weeks. This reaction was not seen in the control group, which received only 1 week of zidovudine and lamivudine (Chasela et al, 2010).

Studies are inconsistent regarding the risk of prematurity in antiretroviral therapy–exposed infants. European studies have shown an increased risk of prematurity in infants born to mothers receiving antiretroviral therapy regimens containing a protease-inhibitor drug (European Collaborative Study and Swiss Mother and Child HIV Cohort Study, 2000; Thorne et al, 2004). Some U.S. studies have not confirmed this association; however, a U.S. study confirmed a significantly increased risk of very low birthweight in infants born to women receiving protease-inhibitor–containing antiretroviral therapy versus other combination antiretroviral therapy (adjusted odds ratio, 3.56) (Tuomala et al, 2002).

Several studies have identified anemia in infants exposed to prophylactic zidovudine; typically it is mild and transient, but occasionally severe anemia develops (Connor et al, 1994; Taha et al, 2002; Wiktor et al, 1999). Slightly longer term effects were seen in a French study in which decreased levels of platelets, lymphocytes, and neutrophils were persistent in the treatment group after adjusting for several factors, including maternal $CD4^+$ count and prematurity (Le Chenadec et al, 2003). Two European studies have found neutropenia in children exposed to antiretroviral therapy up to 8 years of age (Bunders et al, 2005; European Collaborative Study, 2004). These effects are of uncertain clinical significance, but as prenatal and postnatal antiretroviral therapy exposure increases in duration and number of drugs, studies to assess both subtle and significant sequelae in exposed infants will be crucial.

Special Case of HIV-Exposed Uninfected Infants

An increasing area of research is focused on HIV-exposed, uninfected (HIV-EU) infants. HIV-EU infants may be at increased risk of death and morbidity. One study demonstrated a fivefold increased risk of death to the infant

after the death of an HIV-infected mother (Newell et al, 2004). Other studies have found no increase in morbidity among HIV-EU infants when compared with unexposed infants (Taha et al, 2000). Whereas these findings may simply reflect different levels of background disease burden among vulnerable children when their mother is ill or dead, there may be an additional immunologic effect on the infant from the mother's HIV infection. In rural Kenya, a study of tetanus antibody levels found a 22% reduction in cord:maternal ratio of tetanus antibodies after adjusting for maternal vaccination and other factors in infants born to HIV-positive mothers. An even greater reduction in infant antibody titers was seen with maternal HIV and malaria coinfection (Cumberland et al, 2007). A large study in Zambia found that HIV-EU infants had twice the risk of death or severe morbidity when the mother's $CD4^+$ T-cell counts were low even when controlling for maternal mortality, separation due to maternal hospitalization, lower birthweight, and other factors (Kuhn et al, 2005). Another study documented an increase in mortality and morbidity (e.g., respiratory infections) in HIV-EU infants over community baseline in Latin America and the Caribbean (Mussi-Pinhata et al, 2007). All these studies are, however, limited by lack of a control group of unexposed infants in the same study setting. Early evidence supporting the possibility of impaired neonatal immunity in HIV-EU infants needs further investigation.

CONCLUSION

Pediatric HIV infection has become a disease of the developing world, where more than 90% of HIV-exposed and more than 98% of HIV-infected children live. Without therapy, morbidity and mortality are high for all HIV-infected individuals and are worse for children. Exposed, uninfected children face the virtual certainty of becoming orphans by their tenth birthdays and a 50% chance of some day becoming infected.

HIV transmission is preventable, whether sexual, vertical, or parenteral. Progression to AIDS and death is also preventable. Although the arrest of all HIV transmission remains an unfulfilled goal, potent antiretroviral combination therapy has dramatically decreased AIDS deaths and virtually eliminated vertical transmission of the virus in the United States and other high-income countries. Vigilance in researching sustainable prevention measures and continued advocacy at national and international levels can arrest HIV transmission worldwide.

CHAPTER 38

Toxoplasmosis, Syphilis, Malaria, and Tuberculosis

Pablo J. Sánchez, Janna C. Patterson, and Amina Ahmed

TOXOPLASMOSIS

Toxoplasmosis is the disease state that results from infection with the obligate protozoan parasite *Toxoplasma gondii*. *T. gondii* is a coccidian that is ubiquitous in nature, and the cat is the definitive host. The organism exists in the following three forms:

1. An oocyst that is shed in cat feces from sporozoites formed within the cat's intestinal tract
2. A tachyzoite or endozoite that is the proliferative form and was formerly referred to as a *trophozoite*
3. A tissue cyst that has an intracystic form termed *cystozoite* or *bradyzoite*.

Nonfeline mammals or birds ingest infective oocysts from contaminated soil. Tissue cysts then accumulate in the organs and skeletal muscle of these animals. The possible routes of transmission from animal to human are direct contact with cat feces, ingestion of undercooked meat containing infective cysts, and ingestion of fruits or vegetables that have been in contaminated soil. Congenital infection results from placental infection and subsequent hematogenous spread to the fetus.

EPIDEMIOLOGY

Toxoplasmosis is a worldwide medical problem. High prevalence of infection has been documented in Europe, Central and Latin America, and parts of Africa. However, seroprevalence rates differ considerably from one country to another, from one region of a country to another, and even from one ethnic group to another in the same region. These widely disparate seroprevalence rates among different adult populations throughout the world have been explained by differences in eating and sanitation practices that contribute to acquisition of infection. Eating undercooked or raw meat or unwashed raw fruits and vegetables, drinking unpasteurized goat's milk, working with meat, having three or more kittens, and even certain climactic conditions have been associated with higher risks of infection (Jones et al, 2009).

Among women of childbearing age in the United States, the prevalence of antibody to *T. gondii* varies from approximately 3% to 30%, depending on the region of the country (Boyer and McAuley, 1994; Remington et al, 2001). The lowest seroprevalence rates have been found in the Mountain and Pacific states, and the highest rates have been seen in the Northeastern and Southeastern United States. Seroprevalence rates for pregnant women seem to be decreasing, although regional and ethnic differences persist.

The prevalence of congenital infection in Massachusetts and New Hampshire has been documented to be 0.08 per 1000 births through immunoglobulin (Ig) M screening of newborn blood specimens collected on filter paper (Guerina et al, 1994). This finding compares with a rate of 3 to 10 per 1000 live births in Paris and Vienna, where maternal seroprevalence rates of approximately 70% and 40%, respectively, are observed. In Massachusetts, a case-control study involving 14 years of newborn screening for congenital toxoplasmosis found that the mother's birth outside the United States, particularly in Cambodia and Laos, as well as the mother's educational level and higher gravidity were strongly predictive of congenital infection (Jara et al, 2001). With approximately 4 million live births annually in the United States, there are an estimated 400 to 4000 babies born each year with congenital toxoplasmosis (Feldman et al, 2010).

NATURAL HISTORY

Infection of the fetus occurs as a consequence of maternal primary infection during pregnancy or, rarely, just before conception (Villena et al, 1998b). Reactivation of latent *T. gondii* infection during pregnancy does not lead to fetal infection, except among immunocompromised women such as those infected with the human immunodeficiency virus (HIV) or those undergoing chemotherapy (Bachmeyer et al, 2006; Dunn et al, 1997; European Collaborative Study, 1996; Langer, 1983; Mitchell et al, 1990; O'Donohoe et al, 1991; Remington et al, 2001). Under these circumstances, however, the risk is low. In addition, maternal reinfection can result in congenital toxoplasmosis (Gavinet et al, 1997; Hennequin et al, 1997). Acute maternal infection, which is usually acquired early in pregnancy, can lead to fulminant fetal infection resulting in stillbirth, nonimmune fetal hydrops, preterm birth, and perinatal death (Wong and Remington, 1994); however, chronic *T. gondii* infection rarely has been associated with sporadic abortion (Remington et al, 1964).

Infection of the fetus occurs transplacentally during maternal parasitemia. Placental infection is an important intermediary step, and up to 16 weeks may elapse between placental infection and subsequent infection of the fetus. This time delay has been termed the *prenatal incubation period* (Remington et al, 2001). Congenital toxoplasmosis has occurred in twins and triplets (Couvreur et al, 1991; Sibalic et al, 1986; Wiswell et al, 1984). The clinical manifestations are usually similar in monozygotic twins, whereas discrepancies in clinical findings are common in dizygotic twins.

Approximately 40% of infants born to mothers who acquired toxoplasmosis during pregnancy are infected with *T. gondii*. The rate of vertical transmission varies according to the trimester in which the mother became infected, with fetal infection rates increasing as pregnancy advances (Dunn et al, 1999; Remington et al, 2001; Wong and Remington, 1994). Specifically, when maternal infection

occurs in the first trimester, 15% of infants are infected, whereas maternal infection in the second and third trimesters results in transmission rates of 30% and 60%, respectively. The severity of clinical manifestations is greatest, however, when maternal infection is acquired early in pregnancy. Maternal infection in the first trimester results in severe disease in as many as 40% of infected fetuses, and in still birth or perinatal death in an additional 35% of infants. Approximately 15% of newborns have subclinical disease; however, maternal infection in the third trimester is rarely if ever associated with severe fetal disease or still birth, and approximately 90% of infants in such situations have subclinical infection.

Postnatally, transmission of *T. gondii* can occur from transfusion of blood or blood products or from transplantation of organ or bone marrow from a seropositive donor with latent infection. Although the organism has been detected in human milk, transmission by breastfeeding has not been documented.

The majority of newborns with congenital toxoplasmosis lack clinical signs of infection, although thorough evaluation may demonstrate eye or neurologic abnormalities in approximately 20% of cases. Clinically apparent disease is present in approximately 10% to 25% of infected infants (Alford et al, 1969, 1974; Guerina et al, 1994). The clinical manifestations of toxoplasmosis are often indistinguishable from those seen with other congenital infections, such as cytomegalic inclusion disease and congenital syphilis. Approximately one third of infants have a generalized form of the disease that principally involves organs of the reticuloendothelial system. The abnormalities include temperature instability, hepatosplenomegaly, jaundice, pneumonitis, generalized lymphadenopathy, rash, chorioretinitis, anemia, thrombocytopenia, eosinophilia, and abnormal cerebrospinal fluid (CSF) indices (Table 38-1; Boyer and McAuley, 1994; Eichenwald, 1960). The other two thirds of infected infants principally manifest neurologic disease.

Central nervous system involvement is the hallmark of congenital *T. gondii* infection (Diebler et al, 1985; McAuley et al, 1994; Remington et al, 2001). Chorioretinitis, intracranial calcifications, and hydrocephalus are the most characteristic findings, occurring in approximately 86%, 37%, and 20% of symptomatic infants, respectively (see Table 38-1) (Boyer and McAuley, 1994; Eichenwald, 1960; Remington et al, 2001). This constellation of findings has been referred to as the *classic triad of congenital toxoplasmosis;* its presence should alert the clinician to the diagnosis. Intracranial calcifications may be single or multiple, but typically are generalized and located in the caudate nucleus, choroid plexus, meninges, and subependyma (Müssbichler, 1968); they also may occur periventricularly, as in cytomegalovirus infection. They are visualized best by computed tomography (CT), but are often detected on ultrasonography as well. Intracranial calcifications may resolve with appropriate antimicrobial therapy (McAuley et al, 1994). Hydrocephalus may be the only manifestation of disease; it results from the extensive periaqueductal and periventricular vasculitis with necrosis that causes obstruction of the ventricular system. Ventriculoperitoneal shunting is often required (Martinovic et al, 1982; McAuley et al, 1994). Abnormalities of the CSF are common; characteristically, they consist of lymphocytic pleocytosis and a markedly elevated protein content. Microcephaly, when present, indicates severe brain injury. Hypothermia and hyperthermia may occur secondary to hypothalamic involvement. *T. gondii* has been detected in the inner ear and mastoid, with the associated inflammation resulting in deafness. An ascending flaccid paralysis with myelitis has also been reported (Campbell et al, 2001).

TABLE 38-1 Clinical Findings Among Infants With Congenital Toxoplasmosis

	Infants with Findings (%)	
Finding	**Neurologic Disease* (108 Cases)**	**Generalized Disease† (44 Cases)**
Chorioretinitis	94	66
Abnormal cerebrospinal fluid	55	84
Anemia	51	77
Convulsions	50	18
Intracranial calcification	50	4
Jaundice	29	80
Hydrocephalus	28	0
Fever	25	77
Splenomegaly	21	90
Lymphadenopathy	17	68
Hepatomegaly	17	77
Vomiting	16	48
Microcephaly	13	0
Diarrhea	6	25
Cataracts	5	0
Eosinophilia	4	18
Abnormal bleeding	3	18
Hypothermia	2	20
Glaucoma	2	0
Optic atrophy	2	0
Microphthalmia	2	0
Rash	1	25
Pneumonitis	0	41

*Infants with otherwise undiagnosed central nervous system diseases in the first year of life.
†Infants with otherwise undiagnosed non-neurologic diseases during the first 2 months of life.

Chorioretinitis secondary to congenital toxoplasmosis can manifest at any age. It usually manifests as strabismus in infants. Defects in visual acuity are more common in older children. Typically the eye lesion consists of a focal necrotizing retinitis that is often bilateral with involvement of the macula and even the optic nerve. Complications include blindness, iridocyclitis, and cataracts (Arun et al, 2007; Phan et al, 2008).

Other less common manifestations of congenital toxoplasmosis are nonimmune hydrops fetalis, myocarditis, nephrotic syndrome, and immunoglobulin abnormalities with both hypergammaglobulinemia and hypogammaglobulinemia described. Bony abnormalities consisting of metaphyseal lucencies similar to those seen in congenital

syphilis have also been reported (Milgram, 1974). A variety of endocrine abnormalities may occur, including hypothyroidism, diabetes insipidus (Oygur et al, 1998; Yamakawa et al, 1996), precocious puberty, and growth hormone deficiency.

DIAGNOSIS

Isolation of *T. gondii* from body fluids and tissues provides definitive evidence of infection. The organism can be isolated from placenta, amniotic fluid, fetal blood obtained by cordocentesis, umbilical cord blood, infant peripheral blood, and CSF by means of intraperitoneal and subcutaneous inoculation into laboratory mice (Foulon et al, 1999a; Remington et al, 2001; Wong and Remington, 1994). Mouse inoculation may require as long as 4 to 6 weeks for demonstration of the parasite. Although it is not a practical method, isolation of the organism should be attempted whenever possible. It is available at the *Toxoplasma* Serology Laboratory, Palo Alto Medical Foundation (860 Bryant Street, Palo Alto, California 94301; telephone: 415-326-8120). In addition, tissue culture has been used to isolate *T. gondii* from amniotic fluid.

Histopathologic examination of the placenta and tissues obtained at postmortem examination or by biopsy from stillborns or infants should be performed because the specimens may demonstrate the presence of tachyzoites. In addition, tachyzoites have been demonstrated in CSF, ventricular fluid, and aqueous humor by specialized staining techniques.

Polymerase chain reaction (PCR) analysis has been used successfully to detect *T. gondii* DNA in amniotic fluid, placenta, CSF, brain, urine, and fetal and infant blood (Foulon et al, 1999a; Fricker-Hidalgo et al, 1998; Grover et al, 1990; Guy et al, 1996; Hohlfeld et al, 1994; Jenum et al, 1998; Romand et al, 2001). PCR performed on amniotic fluid obtained by amniocentesis has become the preferred method of confirming in utero infection (Kasper et al, 2009). False-negative results have been reported, however, and interlaboratory variability in performance of PCR assays has been documented (Guy et al, 1996; Romand et al, 2001). PCR performed on neonatal CSF is recommended for the evaluation of possible central nervous system involvement.

Serologic assays for measurement of antibodies to *T. gondii* in serum and body fluids are the most widely used methods of diagnosing congenital toxoplasmosis (Boyer, 2001; Boyer and McAuley, 1994; Dannemann et al, 1990; Foudrinier et al, 1995; Guerina et al, 1994; Lappalainen et al, 1993; Madi et al, 2010; Naessens et al, 1999; Naot et al, 1991; Pinon et al, 2001; Rabilloud et al, 2010; Remington et al, 1985; Robert-Gangneux, 2001; Robert-Gangneux et al, 1999a, 1999b; Villena et al, 1999; Wong and Remington, 1994). These tests are commercially available at the *Toxoplasma* Serology Laboratory. The more commonly used tests that detect *T. gondii*-specific IgG antibodies are the Sabin-Feldman dye test, which is considered the gold standard but requires live organisms, indirect immunofluorescent antibody test, IgG enzyme-linked immunosorbent assay (ELISA), direct agglutination, and IgG avidity test.

In addition, a differential agglutination test has been developed as a confirmatory test to differentiate acute from chronic maternal infection. This test compares the IgG serologic titer obtained with the use of formalin-fixed tachyzoites (HS antigen) with those obtained with acetone- or methanol-fixed tachyzoites (AC antigen). The latter preparation contains stage-specific *T. gondii* antigens that are recognized by IgG antibodies only during early infection. An additional assay to assist in ruling out maternal infection acquired in the first 3 months of pregnancy is the IgG avidity test performed by the ELISA technique. This test is based on the principle that, although the antibody-binding avidity or affinity for an antigen is initially low after primary antigenic stimulation, IgG antibodies that are present from previous antigenic stimulation are usually of high avidity. Therefore a high-avidity result in the first trimester would exclude an infection acquired in the previous 12 weeks. Finally, an enzyme-linked immunofiltration assay has been developed that allows discrimination between IgG antibodies of maternal origin and IgG synthesized by the fetus as well as identification of antibody subtypes in infected neonates (Zufferey et al, 1999).

Tests that detect *T. gondii*-specific IgM are (1) the double-sandwich IgM ELISA, which has a sensitivity of 75% to 80% and a specificity of 100% (Guerina et al, 1994); (2) the IgM immunosorbent agglutination assay, which is the most sensitive test but should not be performed on umbilical cord blood, because even small quantities of maternal IgM antibodies contaminating the specimen will yield a false-positive result (Boyer and McAuley, 1994); and (3) the IgM immunofluorescent antibody test. The last test is not recommended because it has a much lower sensitivity than either the IgM ELISA or IgM immunosorbent agglutination assay and it has poor specificity secondary to rheumatoid factors and antinuclear antibodies, contributing to false-positive results. Other tests that are still being investigated include a *T. gondii*-specific IgA ELISA and IgA immunofiltration assay; a *T. gondii*-specific IgE immunofiltration assay; and IgG, IgM, and IgA immunoblotting tests.

Because the majority of adults with acquired *T. gondii* infection are asymptomatic, evaluation of the pregnant woman and fetus is usually prompted by either seroconversion or an elevated maternal *Toxoplasma* spp. IgG titer (Couvreur et al, 1988; Daffos et al, 1988; Montoya et al, 2008). The latter may reflect chronic or past infection; therefore the acuity of the maternal infection is determined serologically with the HS-AC differential agglutination test where agglutination titers to formalin-fixed tachyzoites (HS antigen) are compared with titers against acetone- or methanol-fixed tachyzoites (AC antigen). In general, an acute pattern demonstrates high AC and HS titers, while a nonacute pattern demonstrates high AC titers and low HS titers. This method can differentiate an acute from a remote infection in pregnant women, whereas IgM and IgA antibodies detectable by ELISA or ISAGA are elevated for prolonged periods. If recent maternal infection is documented by an acute pattern on the HS-AC test, seroconversion, or rising IgG antibody titers, the fetus should be evaluated by ultrasonography, and amniotic fluid should be tested for specific *Toxoplasma* spp. DNA with PCR. PCR has supplanted the need for cordocentesis, and a positive result confirms fetal infection (Hohlfeld et al, 1994). Postnatally, serologic testing of paired maternal and infant sera should be performed at a reliable laboratory that will include assays for *Toxoplasma* spp. IgG and IgM antibodies.

Neonatal serum for *Toxoplasma* spp. IgA determination by ELISA also should be considered, because it may yield the only positive result in some infants.

Subinoculation of placental tissue, amniotic fluid, and umbilical cord blood into mice should be considered. If results of these tests suggest possible infection, the newborn should be evaluated fully with complete blood cell count and platelet determination, liver function tests, CSF evaluation (including tests for IgG and IgM antibodies and PCR;) (Wallon et al, 1998), cranial ultrasound or CT imaging of the head, ophthalmologic examination, and hearing evaluation. The presence of neonatal IgM antibody in serum or CSF, or a positive PCR result for blood or CSF, indicates congenital infection. In addition, at-risk infants should undergo serologic follow-up to detect rising serum IgG titers during the 1st year of age or persistence of IgG antibody beyond 12 to 15 months of age, when maternal IgG antibody has disappeared (Robert-Gangneux et al, 1999a, 1999b). Uninfected infants show a continuous decline in *T. gondii* IgG titer with no detectable IgM or IgA antibodies.

Low IgG titers and an HS-AC differential agglutination test that indicate remote maternal infection do not require further evaluation of the mother or infant unless the mother is infected with HIV. Because fetal infection has occurred during chronic *T. gondii* infection in HIV-infected pregnant women, their infants should be evaluated serologically at birth for evidence of congenital infection. It has been suggested that HIV-infected pregnant women who have low $CD4^+$ T lymphocyte counts and who are seropositive for *T. gondii* antibody receive prophylaxis to prevent fetal infection (Beaman et al, 1992; Wong and Remington, 1994). However, insufficient data currently are available to recommend that such therapy be given routinely for this indication. Nevertheless, if such women previously have had toxoplasmic encephalitis, prophylaxis with pyrimethamine, sulfadiazine, and leucovorin (folinic acid) should be considered (Masur et al, 2002).

THERAPY

It is currently recommended that fetuses and infants younger than 1 year who are infected with *T. gondii* receive specific therapy effective against this congenital pathogen, even if they have no clinical signs of disease (Couvreur et al, 1988; Daffos et al, 1988; Foulon et al, 1999b; Friedman et al, 1999; Gilbert et al, 2001; Hohlfeld et al, 1989; Koppe et al, 1986; McAuley et al, 1994; McGee et al, 1992; McLeod et al, 2009; Peyron and Wallon, 2001; Roizen et al, 1995; Vergani et al, 1998; Wallon et al, 1999; Wong and Remington, 1994). On the basis of comparison with untreated historical controls, outcome is improved substantially by neonatal treatment. The effectiveness of maternal and fetal treatment is less clear. Spiramycin has been used in pregnant women with acute toxoplasmosis to reduce transplacental transmission of *T. gondii*. If fetal infection is confirmed after the 17th week of pregnancy, however, treatment with pyrimethamine, sulfadiazine, and folinic acid is recommended. Prenatal treatment of congenital toxoplasmosis is believed to reduce the clinical severity of infection in the newborn while shifting the disease to a more subclinical form. This effect in turn may ameliorate the long-term neurologic complications that are commonly seen among infants who have clinical manifestations in the neonatal period. A recent metaanalysis of the effectiveness of prenatal treatment of toxoplasmosis infection found no evidence that such treatment significantly decreased clinical manifestations of disease in infected infants (Thiebaut et al, 2007).

Neonatal treatment has also resulted in reductions in sensorineural hearing loss and neurodevelopmental and visual handicaps. Table 38-2 shows the recommended guidelines for the treatment of congenital toxoplasmosis. In infants with congenital toxoplasmosis, the treatment consists of pyrimethamine, sulfadiazine, and folinic acids (Boyer and McAuley, 1994; McAuley et al, 1994; McLeod et al, 1992; Remington et al, 2001). The actual duration of therapy is not known, although prolonged courses of at least 1 year are preferred. Currently most experts recommend combined treatment until the patient is 1 year old (Remington et al, 2001; Villena et al, 1998a, 1998b).

Complete blood cell counts and platelet determination must be monitored closely while the patient is receiving therapy, because granulocytopenia, thrombocytopenia, and megaloblastic anemia can occur. These parameters usually improve once a higher dose of folinic acid is administered or pyrimethamine and sulfadiazine are discontinued temporarily. The indications for adjunctive therapy with corticosteroids such as prednisone (0.5 mg/kg twice per day) are CSF protein concentration 1 g/dL or higher and chorioretinitis that threatens vision; corticosteroid treatment is continued until either condition resolves. Current therapies are not effective against encysted bradyzoites and therefore might not prevent reactivation of chorioretinitis and neurologic disease.

PROGNOSIS

Maternal toxoplasmosis acquired during the first and second trimesters has been associated with still birth and perinatal death secondary to severe fetal infection in approximately 35% and 7% of cases, respectively. Among infants born with congenital toxoplasmosis, the mortality rate has been reported to be as high as 12%. In addition, infants with congenital toxoplasmosis are at high risk for ophthalmologic, neurodevelopmental, and audiologic impairments, including mental retardation (87%), seizures (82%), spasticity and palsies (71%), and deafness (15%) (Eichenwald, 1960; Hohlfeld et al, 1989; Koppe et al, 1986; McAuley et al, 1994). Of neonates with subclinical infection, long-term follow-up reveals eye or neurologic disease in as many as 80% to 90% by the time they reach adulthood (Couvreur and Desmonts, 1962; Couvreur et al, 1984; McLeod et al, 2000; Saxon et al, 1973; Wilson et al, 1980). Data from the United States National Collaborative Treatment Trial show that treatment of neonates with congenital toxoplasmosis early and for 1 year resulted in more favorable outcomes than were reported for untreated infants or infants who were treated for only 1 month.

PREVENTION

Pregnant women whose serologic status for *T. gondii* is negative or unknown, as well as women who are attempting to conceive, should be educated on the prevention

TABLE 38-2 Treatment Guidelines for Toxoplasmosis

Condition	Therapy	Dose (Oral Unless Specified)	Duration
Pregnant woman with acute toxoplasmosis	Spiramycin for first 21 wk of gestation or until term if fetus not infected*	1 g every 8 h without food	Until fetal infection documented or excluded at 21 wks; if fetal infection documented, replaced with pyrimethamine, leucovorin, and sulfadiazine (see below)
	Pyrimethamine (if fetal infection confirmed after 18th week of gestation or if infection acquired in last few weeks of gestation) *and*	Loading dose: 100 mg/day in two divided doses for 2 days followed by 50 mg/day	Until delivery
	Sulfadiazine* *and*	Loading dose: 75 mg/kg/day in two divided doses (maximum, 4 g/d) for 2 days; then 100 mg/kg/day in two divided doses (maximum, 4 g/day)	Until delivery
	Leucovorin†	10-20 mg/d	Until delivery
Congenital *Toxoplasma gondii* infection in infant	Pyrimethamine *and*	Loading dose: 2 mg/kg/day for 2 days; then 1 mg/kg/day for 2 or 6 months; then 1 mg/kg/day on Mon, Wed, and Fri each week	≥1 yr
	Sulfadiazine* *and*	100 mg/kg/day in 2 daily divided doses	≥1 yr
	Leucovorin (folinic acid)†	10 mg 3 times weekly	≥1 yr
	Corticosteroids (prednisone)‡	1 mg/kg/daily in 2 daily divided doses	Until resolution of elevated (≥1 g/dL) CSF protein or active chorioretinitis that threatens vision

†Monitor blood and platelet counts weekly; adjust dosage for megaloblastic anemia, granulocytopenia, or thrombocytopenia.
‡When signs of inflammation or active chorioretinitis have subsided, dose can be tapered and eventually discontinued; use only in conjunction with pyrimethamine, sulfadiazine, and leucovorin.

of congenital toxoplasmosis through avoidance of at-risk behaviors that may expose them to cat feces or encysted bradyzoites in raw meat (Centers for Disease Control and Prevention, 2000; Eskild et al, 1996; Foulon et al, 2000; Jones et al, 2001; Wilson and Remington, 1980). Such women should be taught to wear gloves when changing cat litter boxes or gardening and to wash hands after such activities. Daily changing of cat litter will also decrease the chance of infection, because oocysts are not infective during the first 1 to 2 days after passage. In addition, feeding cats commercially prepared foods rather than undercooked meats or wild rodents reduces the likelihood of their becoming infected and capable of transmitting the infection to a pregnant woman. Oral ingestion of *T. gondii* can be prevented by either cooking meat to well done, smoking it, or curing it in brine, and by washing kitchen surfaces that come into contact with raw meat. Vegetables and fruits should be washed, and hands and kitchen surfaces should be cleaned after handling fruits, vegetables, and raw meat. Flies and cockroaches may serve as transport hosts for *T. gondii*, so their access to food must be prevented.

Routine serologic screening of women during pregnancy has been an effective means of prevention in such countries as France and Austria, where the incidence of congenital toxoplasmosis is high. No such screening is currently recommended in the United States. However, high-risk women, including those who are immunocompromised, should be screened early in pregnancy. Neonatal screening for IgM antibody has also been advocated so that asymptomatic infants can be detected and treated before neurologic symptoms develop (Peterson and Eaton, 1999). This strategy, however, has been hampered by the lack of readily available and reliable IgM test kits. Moreover, such screening will not detect the approximately 25% of infected infants who lack anti-*Toxoplasma* spp. IgM antibody. Further study involving cost analyses is needed to define the best preventive strategy for congenital toxoplasmosis in specific populations, regions, and countries.

SYPHILIS

Syphilis is caused by infection with the spirochete *Treponema pallidum*. In adults, this spirochete is transmitted through sexual contact, but infants acquire the infection from their mothers, either in utero or during delivery. The history of syphilis epidemics is one of intermittent peaks. During the 1930s and 1940s in the congenital syphilis clinic of the Harriet Lane Home (Baltimore, Md.), 60 to 80 infants and children attended each week for arsenic therapy. Many more were lost to follow-up before completing their 2- to 3-year course of treatment. It was unusual if fewer than three or four new examples were discovered in the general outpatient department in the course of 1 week. Then, for several decades, the frequency of new cases of congenital syphilis declined.

INCIDENCE AND EPIDEMIOLOGY

After years of declining incidence, congenital syphilis is again on the rise. Recent Centers for Disease Control and Prevention (CDC) surveillance data show a 23% increase in congenital syphilis cases from 2005 to 2008 as shown in Figure 38-1 (Centers for Disease Control and Prevention, 2010a). This increase is directly linked to a rise in primary and secondary syphilis in women from 2004 to 2007. In 2008, there was a total of 431 congenital syphilis cases in the U.S. Half of these cases were in infants born to black mothers, primarily in the South. Approximately 30% of the mothers of these infected infants did not receive prenatal care. When mothers did receive prenatal care and their infants still became infected, 27% were screened <30 days before delivery (likely resulting in a false negative test) and 24% screened positive but were not treated (Centers for Disease Control and Prevention, 2010a). An outbreak was also reported among Pima Indians in Arizona in 2007-2009 in which a total of 106 cases were identified, including six congenital cases, two of which resulted in stillbirth (Centers for Disease Control and Prevention, 2010b). A similar epidemic was seen in Alabama with a peak of 238 cases in 2006 with the largest increase seen in heterosexual women (Centers for Disease Control and Prevention, 2009).

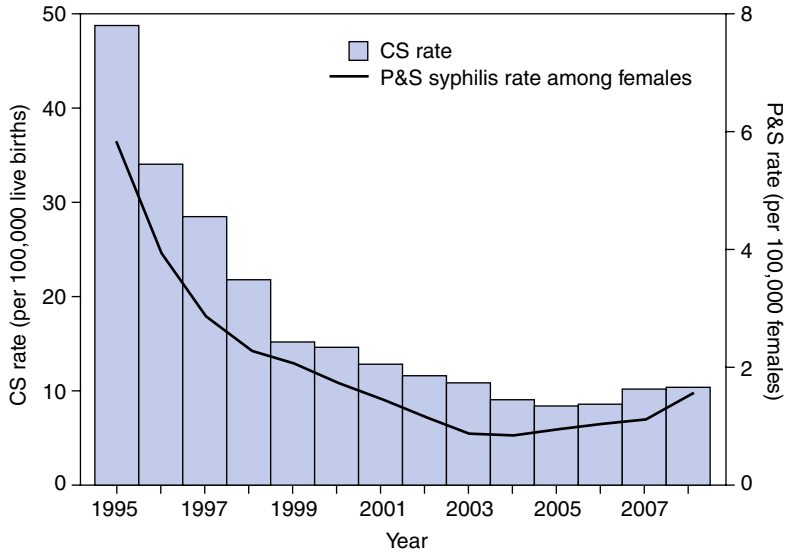
Worldwide more newborns are affected by congenital syphilis than by any other neonatal infection (Schmid, 2004). Countries such as Ethiopia, Swaziland, and Mozambique have prevalence rates of maternal syphilis as high as 12% to 13% (World Health Organization, 2007). There are an estimated 2 million pregnancies affected annually, and most women infected with syphilis within 1 year of their pregnancy will transmit the infection to their infant. Adverse outcomes in these pregnancies are severe: 17% to 40% result in stillbirth, 10% to 23% in neonatal death, and 10% to 30% result in congenital syphilis infection (World Health Organization, 2007).

The global problem of congenital syphilis is further confounded by the high prevalence of HIV, which reaches 25% to 40% in some African cities. Mothers who are coinfected with syphilis and HIV may be less likely to respond to penicillin treatment, which increases the risk of congenital syphilis in the fetus (Lukehart et al, 1988). In addition, HIV-infected mothers with untreated syphilis may be at increased risk of transmitting HIV to their fetus secondary to a placentitis that allows the virus to pass from maternal to fetal circulation (Pollack et al, 1990). In one study of HIV-infected women from Tanzania, coinfection with syphilis doubled the risk of still birth (Kupka et al, 2009). The extent of negative synergy between these two infections will become increasingly clear as research progresses.

PREVENTION

Screening for syphilis in pregnancy is the primary method of preventing congenital syphilis. The American Academy of Pediatrics and the American Congress of Obstetricians and Gynecologists in *Guidelines for Perinatal Care* (2002) recommend screening all pregnant women at the first prenatal visit, after exposure to an infected partner, and at delivery. Reinforcing this recommendation is the Reaffirmation Recommendation Statement by the U.S. Preventive Services Task Force (2009) that "Grade A evidence" is present for screening all pregnant women for syphilis infection.

As summarized by Miller and Karras (2010) in reference to the latest CDC surveillance data, "the increase in the



* CS rates from 1995 to 2006 were calculated using yearly live birth data as denominators. Rates for 2007 and 2008 were calculated using live birth data for 2006. Available at http://www.cdc.gov/nchs/births.htm.

† P&S syphilis rates were calculated using bridged race population estimates for 2000-2007 based on 2000 U.S. Census counts. Available at hhtp://wonder.cdc.gov/wonder/help/bridged-race.html.

FIGURE 38-1 Congenital syphilis (CS) rate among infants less than 1 year old and the rate of primary and secondary syphilis (P&S) among females 10 years or older. National Electronic Telecommunication System for Surveillance, United States, 1995-2008. *(Data from Centers for Disease Control and Prevention: Congenital syphilis: United States, 2003-2008,* MMWR Morb Mortal Wkly Rep *59:413, 2010.)*

congenital syphilis rate, the substantial burden of primary and secondary syphilis among black women in the south, and the high case/fatality ratio associated with congenital syphilis require that congenital syphilis prevention be given high priority in areas with high syphilis morbidity and evidence of heterosexual syphilis transmission."

ETIOLOGY AND PATHOGENESIS

The organism responsible for syphilis is *Treponema pallidum*. This delicate, corkscrew-shaped, flagellated, highly motile spirochete is almost identical in appearance to *Treponema pertenue*, which causes yaws. Because *Treponema* spp. enter the fetal bloodstream directly, the primary stage of infection is completely bypassed. There is no chancre and no local lymphadenopathy. Instead, the liver, the immediate target of the invasion, is flooded with organisms that then penetrate all the other organs and tissues of the body to a lesser degree. Other sites of invasion include skin, mucous membranes of the lips and anus, bones, and the central nervous system. If fetal invasion has taken place early, the lungs may be heavily involved in a characteristic pneumonia alba, but this condition is usually life threatening. *Treponema* spp. may be found in almost any other organ or tissue of the body, but seldom cause inflammatory and destructive changes in loci other than the ones named previously.

Under the microscope, the tissue alterations consist of nonspecific interstitial fibrosis with or without evidence of low-grade inflammatory response in the form of round cell inflammation. Necrosis follows fairly regularly in bone, but only rarely in other tissues. Localization and gumma formation are not common in the neonate; however, extramedullary hematopoiesis in the liver, spleen, kidneys, and other organs can be seen.

Syphilis in infants is acquired primarily by transplacental transmission, which can occur at any time during pregnancy but ordinarily occurs during 16 to 28 weeks' gestation. Fetuses infected early may die in utero or are at high risk for significant neurodevelopmental morbidity. The usual outcome of a third-trimester infection is the birth of an apparently normal infant who becomes ill within the first few weeks of life. Virtually all infants born to women with primary or secondary infection have congenital infection, but approximately half are clinically symptomatic. As hospitals and insurers strive to cut costs, early discharge of new mothers has hindered identification of congenitally infected, asymptomatic infants whose mother's infections occurred late in the third trimester and whose syphilis serologic test results are not yet positive at the time of delivery (Dorfman and Glaser, 1990). It is critical that at-risk infants have a source of primary health care capable of tracking both maternal and infant syphilis status (Chhabra et al, 1993; Zenker and Berman, 1991). Early latent infection results in a 40% infant infection rate, and late latent infection results in a 6% to 14% infant infection rate (Wendel, 1988).

CLINICAL PRESENTATION

Congenital syphilis is challenging to diagnose in neonates because 60% of infected infants are asymptomatic. Early presentation is typically within the first 4 weeks after birth and is characterized by the signs and symptoms summarized in Table 38-3. Persistent rhinitis ("snuffles") was estimated to occur in two thirds of patients in the early literature, but is now less prevalent (Ingall et al, 2006). Prematurity and low birthweight is seen in 10% to 40% of infants (Saloojee et al, 2004). Additional diagnoses associated with congenital syphilis include nonimmune hydrops, nephrotic syndrome, and myocarditis.

Cutaneous lesions can appear at any time from the 2nd week after birth and onward. These copper-colored lesions can be either sparse or numerous; round, oval, or iris-shaped; and circinate or desquamative (Figure 38-2). Even more characteristic than their appearance is their distribution, which most frequently includes the perioral, perinasal, and diaper regions. Palms and soles are also involved, but the rash is soon replaced there by diffuse reddening, thickening, and wrinkling. In heavily infected infants, the rash may become generalized. Mucocutaneous junctions become involved in typical fashion. The lips become thickened and roughened and tend to weep.

TABLE 38-3 Clinical Features of Congenital Syphilis in the Neonatal Period

Feature	Prevalence (%)
Hepatomegaly with or without splenomegaly	33-100
Radiographic bone changes	75-100
Lymphadenopathy	50
Blistering skin rash	40
Respiratory distress	34
Jaundice	33
Pseudoparalysis of Parrot	12
Fever	16

Radial cracks appear that traverse the vermillion zone up to and a bit beyond the mucocutaneous margins of the lips. These cracks are the beginnings of the radiating scars that may persist for many years as rhagades. Similar mucocutaneous lesions involve the anus and vulva, but in these locations, the white, flat, moist, raised plaques known as *condylomata* are also encountered, although less frequently.

Radiographs of the bones show characteristic osteochondritis and periostitis in 80% to 90% of infants with symptomatic congenital syphilis (Figure 38-3). In most cases, the bone lesions are asymptomatic, but in a few they are severe enough to lead to subepiphyseal fracture and epiphyseal dislocation with an extremely painful pseudoparalysis of one or more extremities. Approximately 20% of asymptomatic, congenitally infected infants have metaphyseal changes consistent with congenital syphilis. Radiographic alterations include an unusually dense band at the epiphyseal ends, below which is a band of translucency whose margins are at first sharp but that later become serrated, jagged, and irregular. The shafts become generally more opaque, but spotty areas of translucency throughout may give them a moth-eaten look. The periosteum of the long bones becomes more thickened. Epiphyses separate because the dense end plate breaks away from the shaft by fracture through the subepiphyseal zone of decalcification. Pseudoparalysis of Parrot can occur because of bone pain from these changes.

Signs of visceral involvement include hepatomegaly, splenomegaly, and general glandular enlargement. Palpable epitrochlear nodes are not pathognomonic, but are highly suggestive of congenital syphilis. The liver may be greatly enlarged, firm, and nontender. Associated with this finding may be jaundice, which appears in the 2nd or 3rd weeks of life, is seldom intense, and does not persist for many days. Anemia, probably indicative of bone marrow infection and hematopoietic suppression, may become severe. Lesions in the gastrointestinal tract and pancreas can occur and produce distention and delay in the passage of meconium.

Clinical signs of central nervous system involvement seldom appear in the newborn infant, although one third to half of those infected suffer such involvement. One study by Beeram et al (1996) found no difference in leukocyte values or protein between the CSF of symptom-free infants born to syphilis-seropositive mothers (positive rapid plasmin reagin [RPR] test result confirmed by positive fluorescent treponemal antibody-absorbent [FTA-ABS]) and symptom-free control infants for whom sepsis for associated sepsis risk factors had been ruled out. In addition, only 2 of the 329 infants born to syphilis-infected mothers with no or inadequate treatment had a positive venereal disease research laboratory (VDRL) test result on their CSF specimen. Another study of neonatal CNS invasion by *T. pallidum* found the sensitivity and specificity of CSF VDRL to be 71% and 92%, respectively (Sanchez et al, 1993). Overall, the added value of CSF evaluation in asymptomatic infants appears marginal, because few cases of congenital syphilis are diagnosed based on CSF abnormalities in the absence of other laboratory or clinical findings. However, the CDC and the European International Union against Sexually Transmitted Infections guidelines still recommend that infants with confirmed disease (e.g., those with increasing quantitative titers) or infants who have a normal physical examination result but with an inadequately treated, syphilis-infected mother have a CSF evaluation for VDRL, cell count, and protein (Centers for Disease Control and Prevention, 2006; French et al, 2009). Further research may inform future guideline development.

FIGURE 38-3 The radiograph displays the characteristic "celery stalking" and widening of the metaphases in long bones found in untreated congenital syphilis. *(From American Academy of Pediatrics Committee on Infectious Diseases:* Syphilis: clinical manifestations images. Red Book Online Visual Library, *2009*, *American Academy of Pediatrics. Available at http://aapredbook.aappublications.org/cgi/content/figsonly/2009/1/3.129.)*

DIAGNOSIS

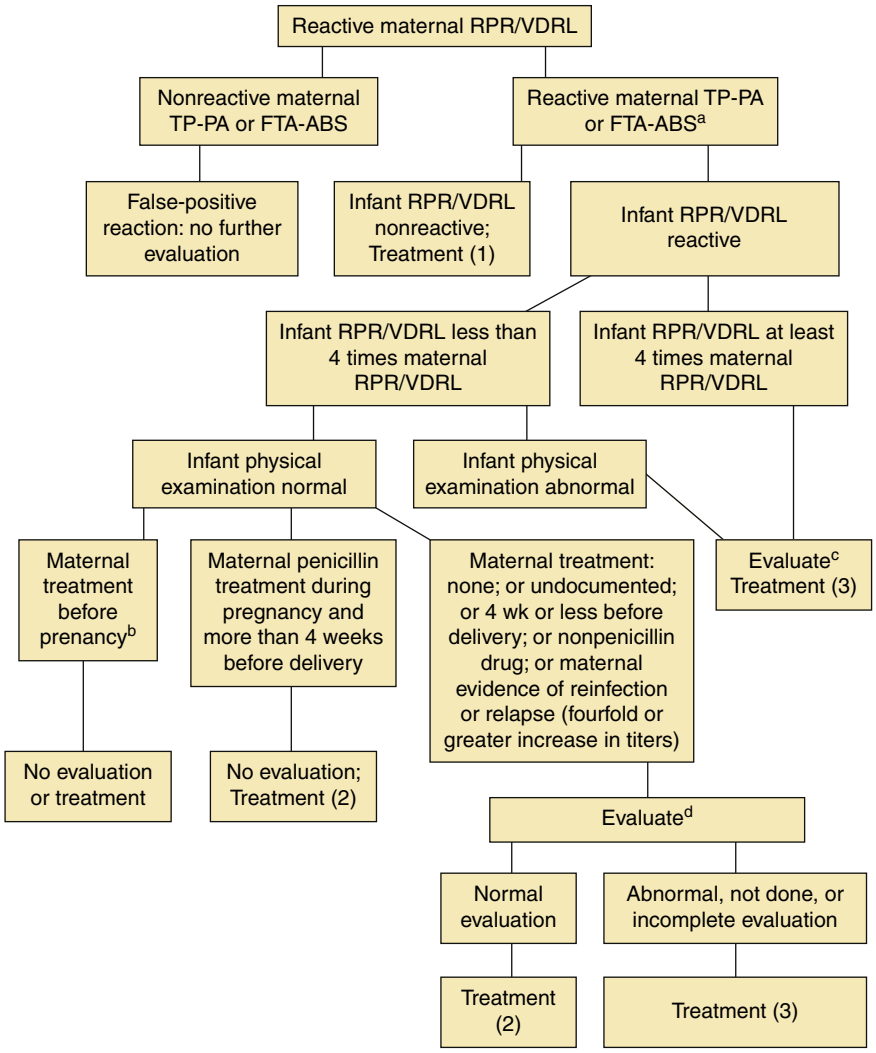
The suggestion of congenital syphilis infection should be spurred by a positive maternal antibody test (RPR or VDRL). If the mother's treponemal test (treponema pallidum particle agglutination assay [TP-PA] or FTA-ABS) is also positive, a RPR or VDRL test should be performed on the infant's serum per current *Red Book* recommendations by the American Academy of Pediatrics (2009). Cord blood is not a reliable testing source for neonatal infection as false-positive RPR rates of 10% and false-negative RPR rates of 5% have been reported (Rawstron and Bromberg, 1991). However, a serum-positive antibody test alone does not confer a diagnosis of congenital syphilis, because of transplacental transfer of maternal nontreponemal and treponemal IgG antibodies. Because IgG is transferred across the placenta, its finding in the baby's serum simply means that the mother either currently has or has had syphilis. She may have been successfully treated during pregnancy and yet still has antibodies in her blood, or she may not have received treatment at all and still has not passed the disease on to her fetus. Conversely, if an antibody test is done on the infant's serum because of clinical suspicion in the absence of a positive maternal antibody test, the infant's antibody test can also be falsely negative if the mother acquired infection late in pregnancy, because she may not have had time to form antibodies herself or has not passed them to her fetus.

IgM does not cross the placenta, so the presence of specific IgM antibodies in the infant is generally diagnostic. Whereas the IgM immunoblot appears to be the best available method to detect *T. pallidum*-specific IgM in neonates, the CDC (2006) does not identify this as a commercially available and recommended test (Herremans

et al, 2010). Treponemal tests on infant serum are not necessary. Comparison of maternal and infant nontreponemal serologic titers at delivery and followed over time are most informative for infant diagnosis. These titers should be accessed via the same test and in the same laboratory to ensure valid comparisons. If the infant titer is fourfold higher than the mother's titer, it is considered highly suggestive of congenital infection. Additional criteria for treatment in the neonate include inadequate maternal treatment in a mother with syphilis and the presence of clinical, laboratory, or radiographic evidence in the infant.

Evaluation of an infant with a concerning physical examination result and maternal profile should include darkfield or fluorescent antibody test of skin lesions or mucous discharge. In addition, a complete blood cell count with differential should be obtained, and CSF studies for cell count, protein and VDRL are recommended. If clinically indicated, long-bone radiographs can be diagnostic.

Clearly the evaluation for congenital syphilis is complex, and serial investigations may be necessary for definitive diagnosis. An algorithm for evaluation is shown in Figure 38-4.



RPR indicates rapid plasma reagin (test); VDRL, Venereal Disease Research Laboratory (test); TP-PA, *Treponema pallidum* particle agglutination (test); FTA-ABS, fluorescent treponema antibody absorption (test).

[a] Test for human immunodeficiency virus (HIV) antibody. Infants of HIV-infected mothers do not require different evaluation or treatment.

[b] Women who maintain a VDRL titer 1:2 or less (RPR 1:4 or less) beyond 1 year after successful treatment are considered serofast.

[c] Evaluation consists of complete blood cell (CBC) and platelet count; cerebrospinal fluid (CSF) examination for cell count, protein, and quantitative VDRL. Other tests as clinically indicated: long-bone and chest radiographs, neuroimaging, auditory brainstem response, eye examination, liver function tests.

[d] CBC, platelet count; CSF examination for cell count, protein, and quantitative VDRL; long-bone radiography.

TREATMENT:

(1) If the mother has had no treatment, undocumented treatment, treatment 4 weeks or less before delivery or evidence of reinfection or relapse (fourfold or greater increase in titers) AND the infant's physical examination is normal, THE treat infant with a single intramuscular (IM) injection of benzathine penicilin (50 000 U/kg). If these criteria are not met, no treatment is required. In both scenarios, no additional evaluation is needed.

(2) Benzathine penicillin G, 50 000 U/kg, IM, × 1 dose.

(3) Aqueous penicillin G, 50 000 U/kg, IV, every 12 hours (1 week of age or younger), every 8 hours (older than 1 week), or procaine penicillin G, 50 000 U/kg, IM, single daily dose, × 10 days.

FIGURE 38-4 Algorithm for evaluation and treatment of infants born to mothers with reactive serologic tests for syphilis. *(From American Academy of Pediatrics Committee on Infectious Diseases:* Syphilis, Red Book Online, *2009, American Academy of Pediatrics. TABLE 38-4 Recommended Treatment of Pregnant Patients With Syphilis

Stages of Syphilis	Drug (Penicillin)	Route	Dose (Units)
Early (<1 yr duration)			
Primary, secondary, or early latent			
HIV antibody-negative	Recommended: benzathine	IM	2.4 million single dose; possibly repeat in 1 wk
HIV antibody-positive*	Recommended: benzathine	IM	2.4 million single dose; possibly repeated weekly for 3 wk
	Alternative: penicillin desensitization		
Latent (>1 yr duration)†	Recommended: benzathine	IM	2.4 million weekly for 3 wk
	Alternative: penicillin desensitization		
Neurosyphilis	Recommended: aqueous	IV	3-4 million every 4 hr for 10-14 days
	Alternative: procaine‡	IM	2.4 million daily for 10-14 days

From Remington JS, Klein JO, Wilson CB, et al, editors: *Infectious diseases of the fetus and newborn infant*, ed 6, Philadelphia, 2006, WB Saunders, p 567.
IM, Intramuscular; *IV*, intravenous.
*With normal cerebrospinal fluid findings, if performed.
†Lumbar puncture to exclude neurosyphilis is recommended for HIV-antibody–positive patients.
‡Probenecid, 500 mg orally, four times per day for 10 to 14 days, should also be prescribed.

TREATMENT AND LONG-TERM OUTCOMES

Treatment of all pregnant women infected with syphilis is recommended. Guidelines for maternal treatment are found in Table 38-4 and are tailored to the stage of disease (e.g., primary, secondary, latent). Treatment of an infected infant requires 10 days of intravenous or intramuscular penicillin. Specific dosing and treatment regimens are outlined in Table 38-5, followed by long-term follow-up recommendations in Table 38-6. Notably, if a single dose is missed during the treatment of an infected infant, restarting the entire series is recommended.

Late manifestations of infection in untreated infants, even if initially asymptomatic, can occur years after birth. Pathognomonic presentations include the Hutchinson triad (interstitial keratitis, eight cranial nerve deafness and Hutchinson's [peg-shaped] teeth), mulberry molars (first lower molar with many small cusps), and Clutton's joints (synovitis with hydrarthrosis, tenderness, and limited range of motion) (Fiumara et al, 1970). Mental retardation can also be a feature of late, untreated congenital syphilis (Brosco et al, 2006).

CONGENITAL MALARIA

Malaria is a parasitic disease of epidemic proportion. An estimated 200 to 500 million cases occur worldwide each year, resulting in 2 to 3 million deaths. The greatest burden of disease occurs in Sub-Saharan Africa, although malaria is increasingly recognized as a significant public health problem in Asia and Oceania. In areas of high transmission, mortality is concentrated largely among young children and pregnant women. Malaria is caused by four *Plasmodium* species: *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*. Of these, *P. falciparum* is the major cause of morbidity and mortality. Humans typically acquire infection through the bite of the *Anopheles* spp. mosquito. Transmission may also occur through blood transfusion or vertically from the mother to fetus, resulting in congenital malaria.

Despite the prevalence of malaria in the developing world, it has historically been believed that congenital malaria occurs infrequently in areas of high transmission (Bruce-Chwatt, 1952; Covell, 1950; McGregor, 1984). As of 1995, only 300 cases of congenital malaria had been reported in the literature (Balatbat et al, 1995), largely from outside of malarious areas. The rarity of vertical transmission has been attributed to the effectiveness of the placenta as a barrier against passage of maternal parasitized red blood cells as well as the protective effect of maternally derived antibodies in the fetus and newborn. Recent reports, however, suggest that congenital malaria is no longer a rare occurrence in endemic areas and has likely been underrecognized and underreported (Akindele et al, 1993; Falade et al, 2007; Fischer, 1997, Ibhanesebhor, 1995; Menendez and Mayor, 2007; Uneke, 2007a, 2007b).

Although endemic malaria has been eliminated from the United States, approximately 1200 cases of malaria are reported to the CDC annually, almost exclusively in travelers and immigrants from endemic countries. From 1966 to 2005, 81 cases of congenital malaria were reported to the National Malaria Surveillance System of the CDC (Lesko et al, 2007). The majority of infants were born to foreign-born women. As an increasing number of people travel to and emigrate from malarious areas, the number of cases of malaria (and consequently congenital malaria) will continue to increase. The lack of familiarity with this disease in the United States renders it a diagnostic and therapeutic challenge for clinicians, with delays in diagnosis potentially leading to significant morbidity and mortality (Griffith et al, 2007). It is therefore critical to maintain a high index of suspicion for congenital malaria in the evaluation of infants born to women from endemic countries.

DEFINITION

Congenital malaria is defined as malaria acquired by the fetus or newborn from the mother, either in utero or at parturition, but there exists no consensus on the application of this definition. Most commonly, *congenital malaria* is defined as the presence of *Plasmodium* spp. parasites

TABLE 38-6 Follow-up after Treatment or Prophylaxis for Congenital Syphilis

Patient Category	Follow-up Procedures
Infants with diagnosis of congenital syphilis	RPR testing every 2-3 mo until negative or decreased fourfold; if RPR titer is stable or increasing after 6-12 mo after treatment, reevaluate and treat again; perform treponemal antibody test after age of 15 mo; if initial CSF analysis is abnormal or infant shows signs of CNS disease, repeat CSF evaluation every 6 mo until normal; with abnormal CSF not due to intercurrent illness on retesting, treat again; careful developmental evaluation, vision testing, and hearing testing are indicated
Infants who received treatment in utero or at birth because of maternal syphilis	RPR testing at birth and then every 3 mo until result is negative; treponemal antibody test after age of 15 mo
Women who received treatment for syphilis during pregnancy	RPR testing as often monthly until delivery, then every 6 mo until negative result obtained or titer decreased fourfold; repeated treatment any time there is a fourfold rise in RPR titer

in the peripheral blood in the first 7 days of life (Covell, 1950; Menendez and Mayor, 2007; Moran and Couper, 1999; Sotimehin et al, 2008; Uneke, 2007a). This definition is applicable in areas of high malaria transmission where, among older infants, it would be difficult to distinguish congenitally acquired from mosquito-acquired disease. Outside endemic areas, where postnatal transmission can be reasonably excluded, clinical onset of disease often does not occur until after the 1st week of life, and age-specific criteria are not useful for the diagnosis of congenital malaria. It is likely that because of the delay in clinical presentation, many cases of congenital malaria in endemic areas are misclassified as being acquired from mosquitoes.

Alternate applications of the definition of congenital malaria include the detection of parasites in peripheral blood or in umbilical cord blood (Fischer, 1997) within the first 24 hours of life (Larkin and Thuma, 1991). It has been argued that congenital malaria should be distinguished from cord blood parasitemia, which is not uncommon in some endemic areas and frequently clears without involving the peripheral circulation. Reinhardt (1978) found parasites in thick smears of umbilical cord blood in 22% of 19 infants born to women in the Ivory Coast, but the peripheral blood smears were negative for all of the infants. Similarly, 4% of 1009 infants born to Tanzanian women had parasites in cord blood, but parasitemia was detected on peripheral smear in only 2 of 11 infants (McGregor, 1984). Parasitemia detected shortly after birth may also resolve without evolving into clinically symptomatic disease. In a recent multicenter study, the correlation between maternal, placental, umbilical cord, and peripheral parasitemia was evaluated in 1875 mother-baby pairs in Nigeria. Thick and thin blood smears were obtained within 4 hours of birth, and smear-positive (cord or peripheral) neonates were retested on days 2, 3, and 7 of life, with treatment for those with symptoms or persistent parasitemia. The overall prevalence of congenital malaria was 5.1%, with parasitemia detected in 19% of infants born to mothers with peripheral parasitemia, 21% of those born to mothers with placental malaria, and 45% of those with positive cord smears. Spontaneous clearance of parasitemia occurred in 62% of infants before day 2, whereas 33% were symptomatic within 3 days of birth (Falade et al, 2007). It has now been well established that (1) maternal and placental parasitemia are important risk factors for congenital malaria, (2) a correlation between umbilical cord parasitemia and neonatal parasitemia exists, and (3) congenital malaria can occur in the absence of symptoms (Mukhtar et al, 2006; Sotimehin et al, 2008; Uneke, 2007a). However, the definition of *congenital malaria* has yet to be standardized to facilitate a better understanding of the epidemiology of this disease and the outcomes of prevention measures.

EPIDEMIOLOGY

Congenital malaria has traditionally been considered a rare consequence of malaria in pregnant women living in endemic areas. Covell (1950) published a review of cases of congenital malaria reported in areas with rates of placental parasitemia ranging from 5% to 74%, and rates of maternal malaria ranging from 1% o 68%. The prevalence of congenital malaria—defined as parasitemia detected in the first 7 days of life—was estimated to be 0.3% (16 of 5324 births) among immune mothers. Subsequent reports supported the observed low frequency of congenital malaria—defined as umbilical cord parasitemia or parasitemia in the first 24 hours of life—among indigenous populations (Bruce-Chwatt, 1952; Cannon, 1958; MacGregor, 1984; Williams and McFarlane, 1970). These observations have been cited repeatedly in the literature to support the notion that congenital malaria is an uncommon occurrence in endemic areas despite the high prevalence of maternal and placental malaria. More recent reports, however, suggest that the prevalence of congenital malaria was underestimated, with rates from endemic and nonendemic areas ranging from 8% to 33% (Desai et al, 2007; Menendez and Mayor, 2007). In Zambia during a season of heavy malaria transmission, incidence rates for congenital malaria ranged from 4% to 15% (Nyirjesy et al, 1993). A survey of seven sites in

Sub-Saharan Africa indicated a prevalence of congenital malaria—defined as umbilical cord blood parasitemia—ranging from 0% to 23% (Fischer, 1995). Congenital malaria, defined as neonatal parasitemia, was detected in 15.3% and 17.4% of neonates born in two sites in Nigeria (Mukhtar et al, 2006; Runsewe-Abiodun et al, 2006). The apparent increase in the frequency of congenital malaria has been attributed to increasing resistance of *P. falciparum* to antimalarial drugs resulting in increased maternal parasitemia, increased virulence of the parasite, and reduced transmission of antibody from mother to newborn because of malaria chemoprophylaxis administered to pregnant women. It is equally likely that congenital malaria was previously underreported because of the difficulty in differentiating congenital malaria from postnatally acquired malaria in neonates, or it was underdetected because of low parasite densities in newborns. It is evident that congenital malaria is not an uncommon occurrence in areas of high transmission. The variability in prevalence of disease may be attributed to differences in the definition of congenital malaria or the methods used for parasite detection. The inconsistency may also represent true environmental differences with differences in levels of maternal immunity.

In contrast to the rarity of congenital malaria in indigenous populations, Covell (1950) found the prevalence of congenital malaria among nonimmune populations (i.e., Europeans residing in or visiting endemic areas) to be approximately 7%. It was postulated that congenital malaria is more common in infants born to these women because of lower levels of malaria-specific maternal antibodies being transmitted to the fetus. Most published reports of congenital malaria describe infants born in nonendemic countries whose mothers emigrated from malarious areas to areas free of malaria. These women presumably developed a recrudescence of disease because of waning immunity from lack of continued exposure

In the United States, the occurrence of congenital malaria is well documented because the country has been free of indigenous disease since the 1950s. From 1950 to 1991, 49 cases of congenital malaria were reported in the literature (Hulbert, 1992), and additional cases were reported during the next 15 years (Balatbat et al, 1995; Baspinar et al, 2006; D'Avanzo et al, 2002; Gereige and Cimino, 1995; Starr and Wheeler, 1998; Viraraghavan and Jantausch, 2000). In an updated review, Lesko et al (2007) tabulated 81 cases reported to the CDC between 1966 and 2005. Almost all the cases were among infants whose mothers were foreign born, suggesting that congenital malaria is primarily a health problem of recent immigrants rather than of U.S.-born travelers to malaria-endemic countries. Forty-four women (54%) had emigrated from Asia, 27 (33%) from South or Central America, and 7 (9%) from Africa. Until 1979, one to two cases were reported annually (Malviya and Shurin, 1984). An abrupt rise to 16 cases around 1981 (Figure 38-5) correlated with an increase in the total number cases of malaria that occurred as a result of a large influx of refugees and immigrants from Southeast Asia, with 15 of the 16 infants being born to mothers from that region (Quinn et al, 1982).

Congenital malaria occurs with all *Plasmodium* species. Among the 107 cases of congenital malaria reported by Covell (1950), mostly from Africa, 64% were infected with *P. falciparum*, 32% by *P. vivax*, and 2% by *P. malariae*. Although *P. falciparum* remains the predominant pathogen in Sub-Saharan Africa, *P. vivax* may account for a larger proportion of cases in Asia. Among 27 cases reported in Thailand between 1981 and 2005, 82% of were cause by *P. vivax* (Wiwanitkit, 2006). *P. malariae* is less frequently a causative agent, with fewer than 10 cases reported worldwide since 1950 (de Pontual et al, 2006). Concurrent infection with *P. malariae* and *P. vivax* has been documented (MacLeod et al, 1982). In the United States, the predominant *Plasmodium* species causing congenital malaria

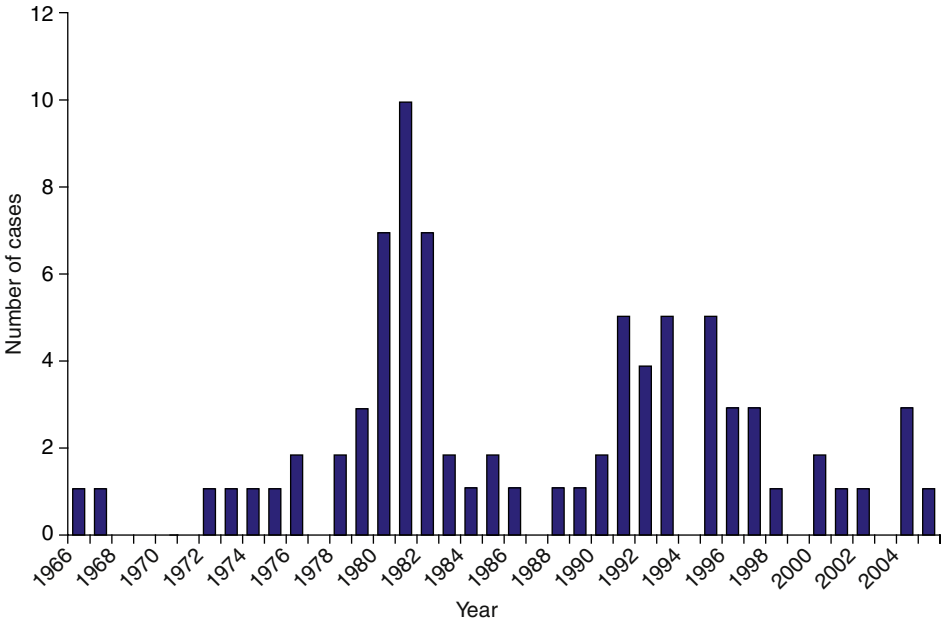

FIGURE 38-5 Number of cases of congenital malaria reported to the National Malaria Surveillance System per year, 1966-2005. *(From Lesko CR, Arguin PM, Newman RD: Congenital malaria in the United States: a review of cases from 1966 to 2005*, Arch Pediatr Adolesc Med *161:1062-1067, 2007.)*

reflects the countries of origin of the mothers, as noted previously. In Hulbert's (1992) review of 49 cases, 82% of infections were caused by *P. vivax*. In the updated review by Lesko et al (2007), the predominant infecting species remained *P. vivax* (81%), although all four species were represented.

PREGNANCY AND MALARIA

Malaria in pregnancy is an immense public health problem in the developing world, with substantial effects on maternal, fetal, and infant health. It is well established that both the frequency of disease and density of parasitemia are higher in pregnant women compared with nonpregnant women (Coll et al, 2008; Desai et al, 2007; Rogerson et al, 2007). In Sub-Saharan Africa, 25 million pregnant women are at risk for *P. falciparum* infection every year (Desai et al, 2007). Among 20 studies conducted between 1985 and 2000, the median prevalence of maternal malaria infection (defined as peripheral or placental infection) in all was 28% (Steketee et al, 2001). Thus, one in four pregnant women in areas of stable transmission in Africa have evidence of malaria infection at the time of delivery. The increased susceptibility likely represents a combination of immunologic and hormonal changes combined with the unique ability of infected erythrocytes to sequester in the placenta (Rogerson et al, 2007). The risk is indisputably greater for primigravidae, with primigravidae having a twofold to fourfold increased risk of placental malaria compared with multigravidae (Desai et al, 2007; McGregor, 1984; Uneke, 2008).

The clinical features of *P. falciparum* malaria in a pregnant woman depend to a large degree on her immune status, which in turn is determined by her prior exposure to malaria. In pregnant women with little or no preexisting immunity, such as women from nonendemic countries or travelers to malarious areas, infection is associated with high risks of severe disease with significant maternal and perinatal mortality. In contrast, women residing in areas of stable malaria transmission usually have a high level of immunity to malaria. Infection may be frequently asymptomatic and therefore unsuspected or undetected, but it is associated with placental parasitization, with consequent effects on maternal and fetal outcomes. The most significant consequence of pregnancy-associated malaria is maternal anemia. It is estimated that in Sub-Saharan Africa between 200,000 and 500,000 pregnant women develop anemia as a result of malaria, and that up to 10,000 maternal anemia-related deaths are a consequence of *P. falciparum* parasitemia (Uneke, 2008). Malaria in pregnancy also has potentially devastating effects on the fetus and newborn, including spontaneous abortion, still birth, premature delivery, congenital infection, and neonatal death (Coll et al, 2008; Fischer, 2003). The most notable consequence is low birthweight (LBW), likely because of fetal growth restriction. In areas of high transmission in Africa, the risk of LBW approximately doubles if women have placental malaria, with the greatest effect in primigravidae (Desai et al, 2007). Pregnancy-associated malaria is believed to be responsible for 30% to 35% of LBW infants and for 75,000 to 200,000 infant deaths each year (Coll et al, 2008).

TRANSMISSION

The timing and mechanism of transmission of *Plasmodium* spp. parasites from the mother to the fetus is not well understood. Postulated mechanisms include maternal transfusion into fetal circulation either during pregnancy or at delivery, or direct penetration of parasitized red blood cells through the chorionic villi or through premature separation of the placenta. In utero transmission is supported by the finding of malarial parasites in fetal tissues at autopsy (Mertz et al, 1981), by umbilical cord blood parasitemia (McGregor, 1984) and the onset of clinical signs of malaria within hours of birth (Brandenburg and Kenny, 1982; Covell, 1950; Gereige and Cimino, 1995). Antenatal transmission is also suggested by findings from Malawi, where approximately 50% of newborns with cord blood parasitemia were infected with parasites of a different genotype than their mothers at the time of delivery (Fischer, 2003). Alternatively, clinical findings in infants with congenital malaria may be delayed for several weeks after birth, suggesting infection at parturition. It is generally understood that the placenta acts as an effective barrier to prevent the transfer of malaria parasites from maternal into fetal circulation, supporting transmission at parturition as the most likely mechanism. Vertical transmission of malaria probably does not occur as a result of transplacental passage of exoerythrocytic parasites. More likely, transmission occurs by transfusion of parasitized maternal erythrocytes through a breach in the placental barrier that may occur either prematurely during pregnancy or during labor. Transmission of malaria by breastfeeding is not known to occur. The fate of the *Plasmodium* spp. parasite is unclear after it is transmitted to the fetus. As discussed previously, parasites detected in umbilical cord blood or shortly after birth may be cleared spontaneously, resulting in no disease manifestation. Alternatively, parasitemia may be maintained and proliferate until multiplication permits the development of clinical disease.

CLINICAL PRESENTATION

The clinical picture of overt congenital malaria is detailed in cases reported outside of endemic areas (Harvey et al, 1969; Hindi and Azimi, 1980; Hulbert, 1992; Lesko et al, 2007). The manifestation of disease, although occasionally noted within hours of birth (Brandenburg and Kenny, 1982; Gereige and Cimino, 1995), is typically delayed until the infant is several weeks old. In the classic review of 49 infants with congenital malaria reported in the United States between 1950 and1992, the mean age at onset of symptoms was 5.5 weeks, with 96% of infants presenting between 2 and 8 weeks of age (Hulbert, 1992). Among cases reported to the CDC from 1966 to 2005 (Lesko et al, 2007), the median age of symptom onset for 81 infants was 21.5 days for all species combined (Figure 38-6). Infants infected with *P. malariae* were significantly older at symptom onset (mean, 53 days) compared with those infected with *P. vivax* or *P. falciparum*.

The prolonged interval between birth and onset of clinical manifestations may be explained by transmission late in pregnancy or at delivery, such that multiple erythrocytic

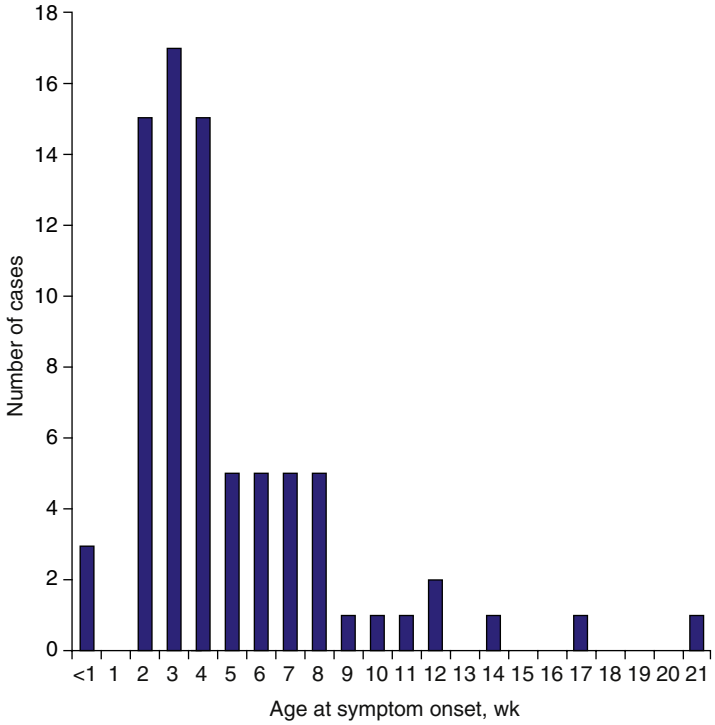

FIGURE 38-6 Age in weeks at symptom onset of infants with reported congenital malaria, United States, 1966-2005. *(From Lesko CR, Arguin PM, Newman RD: Congenital malaria in the United States: a review of cases from 1966 to 2005*, Arch Pediatr Adolesc Med *161:1062-1067, 2007.)*

life cycles are required to produce clinically evident disease. Alternatively, the delay may be attributed to the presence of transplacentally acquired maternal antimalarial antibodies. When such antibodies are present in sufficient concentrations, as in infants born to immune mothers, parasitic replication can be prevented or attenuated, and clinical signs can be mild, delayed, or even absent. The presence of a high concentration of fetal hemoglobin in newborns may also promote resistance to multiplication of parasites. Among infants born to mothers with low or nonexistent immunity, parasitic replication is more likely uninhibited, and clinical signs of malaria may supervene. Preterm infants, who do not benefit from passive immunity, can manifest clinical signs earlier than full-term infants. In a review of premature neonates with congenital malaria, 4 of 5 infants received a diagnosis in the 1st week of life (Ahmed et al, 1998), although the prompt medical evaluation afforded these infants may have facilitated earlier detection.

The clinical features of congenital malaria are nonspecific and often resemble those of bacterial or viral sepsis and other congenital infections. Fever is almost uniformly present, although without the classic paroxysmal pattern described for malaria beyond the neonatal period. Hulbert (1992) noted fever in all 44 infants for whom clinical information was available. In the cases reported from 1966 to 2005, fever was reported in 70 of 81 cases (86%) (Lesko et al, 2007). Hepatomegaly and splenomegaly suggestive of a transplacentally acquired infection are found in a substantial portion of infants (Table 38-7). Anemia (often hemolytic), thrombocytopenia, and hyperbilirubinemia are the most commonly reported laboratory findings. Additional signs, symptoms, and laboratory findings are listed in Table 38-7.

TABLE 38-7 Frequency of Symptoms, Signs, and Laboratory Findings Among 81 Infants With a Diagnosis of Congenital Malaria (United States, 1966-2005)

Symptoms, Signs, and Laboratory Findings	Infants, No. (%)*
Fever	70 (86)
Anemia	28 (36)
Splenomegaly	25 (31)
Hepatomegaly	16 (20)
Thrombocytopenia	12 (15)

Purpura	1 (1)
Tachycardia	1 (1)
Monocytosis	1 (1)

From Lesko CR, Arguin PM, Newman RD: Congenital malaria in the United States: a review of cases from 1966 to 2005, *Arch Pediatr Adolesc Med* 161:1062-1067, 2007.
*Percentages do not total 100% because each case can have more than one symptom, sign, or laboratory finding.

In endemic areas, the traditional belief has been that congenital malaria is rare and that when it occurs the infant is typically asymptomatic and develops no clinical features. The lack of symptoms has been attributed to transplacentally acquired antibodies from the mother as

well as the protective effects of high levels of fetal hemoglobin. Depending on the region, spontaneous clearance of peripheral parasitemia has been documented in 87% to 100% of neonates (Lesko et al, 2007; Mukhtar et al, 2006). Larkin and Thuma (1991) found peripheral parasitemia within 24 hours of age in 19 of 51 newborns (65%), but only 7 had clinical signs of disease. Because all 19 newborns received antimalarial therapy, it is unknown how many would have manifested disease if untreated. More recently, Falade et al (2007) noted spontaneous clearance of parasitemia in 62% of 95 neonates before day 2 of life. Of the remaining infants, 34% were symptomatic within 3 days of birth, with fever and refusal to eat being the most common signs of disease. When active surveillance for malaria was conducted in newborns being evaluated for possible bacterial sepsis in Nigeria, 16 of 203 (8%) neonates had parasitemia, and 10 (5%) met the definition of congenital malaria (Ibhanesebhor, 1995). Predominant features of disease included fever, respiratory distress, anemia, and hepatomegaly. In another area in Nigeria, of 202 neonates less younger than 1 week who were admitted for evaluation of sepsis, 71 (35%) were diagnosed with congenital malaria (Ekanem et al, 2008). Fever was the most common symptom and was present in 93% of infants. Refusal to feed and jaundice were reported in approximately 33%. These observations suggest that, as in infants diagnosed outside endemic areas, the clinical presentation of congenital malaria in endemic areas does not differ significantly from bacterial sepsis. Because the clinical symptoms of congenital malaria may be indistinguishable from that of neonatal sepsis, it is suggested that screening for malaria be included as part of routine investigation of newborns with fever in areas of high malaria transmission (Ekanem et al, 2008; Runsewe-Abiodun et al, 2006).

DIAGNOSIS

Diagnostic tests for malaria include blood smears, rapid antigen detection tests (RDTs) and PCR. Definitive diagnosis of congenital malaria is based on the microscopic demonstration of parasites on stained thick and thin blood films. Thick blood smears test for the presence of parasites by concentration of red blood cells, whereas thin blood smears allow species identification and quantification of parasitemia. In cases of suggested congenital malaria, specimens for smears should be obtained from both the infant and the mother. If test results from the initial set of smears are negative, additional sets should be obtained every 12 to 24 hours; three sets are generally considered sufficient for diagnostic evaluation. Response to therapy may also be measured by clearance of parasitemia on blood films.

RDTs are based on the immunochromatographic detection of parasite-specific antigens circulating in the bloodstream. Many RDTs are commercially available outside the United States, and, depending on the antigens targeted, the tests may detect only *P. falciparum* or all *Plasmodium* species. RDTs are simple to use, do not require specialized training or facilities, and offer a useful alternative to microscopy in situations where reliable microscopic diagnostics are not readily available. However, the tests have demonstrated mixed results in multiple trials, and sensitivity remains a problem, especially at low parasite densities. Information regarding the sensitivity of these tests is limited for neonatal or congenital malaria. In the evaluation of an RDT for the diagnosis of congenital malaria in Nigeria, parasitemia was detected by microscopy in 21 of 192 newborns (10.9%) at 0 to 3 days of age, whereas the RDT result (OptiMAL [Flow Inc, Portland, Oregon]) was negative in all infants, including those diagnosed by microscopy. Whether the poor performance of the test was due to low-level parasitemia or suboptimal state of the parasites, the RDT was determined not to be useful for the diagnosis of congenital malaria (Sotimehin et al, 2007). It is recommended that microscopy be conducted in parallel with RDTs because low level parasitemia may not be detected or, if parasitemia is detected, for species identification and determination of parasite density.

The major advantage of PCR for the diagnosis of malaria is its ability to detect low level parasitemia and identify parasites to a species level. Currently PCR is used mainly to confirm positive blood smears, particularly when the results of the smear are not definitive or there is a mixed species infection. PCR may detect DNA from circulating nonviable parasites after treatment, resulting in difficulty differentiating an active infection from a recently cleared infection. Although PCR is a highly sensitive alternative to microscopy, the infrastructure and expertise required preclude its use in malaria-endemic areas and many health care settings in the United States.

As with malaria in general, the diagnosis of congenital malaria outside of endemic areas is often delayed because of nonspecific features and lack of clinical suspicion. Among the 81 cases reviewed by Lesko et al (2007), a median length of delay of 8.5 days was noted for 15% of the infants. Occasionally the diagnosis is made incidentally. In all four cases of congenital malaria reported by Quinn et al (1982), *Plasmodium* spp. parasites were noted by hematology technicians on routine smears performed for blood cell counts. Maternal history of recent travel to or emigration from an endemic area may suggest the diagnosis, but is often obscured by the lack of clinical or laboratory findings in the mother. Lesko et al (2007) found that, of the mothers for whom a history was available, 67% reported having fever during pregnancy, and 26% reported a diagnosis of malaria during pregnancy. Maternal blood films were performed after either symptomatic illness or malaria diagnosis in the infant. Overall only 42% of women had parasitemia detected, although it is not clear whether an adequate number of smears were conducted for each patient. As a result, lack of peripheral parasitemia in the mother of an infant with suspected congenital malaria does not exclude the diagnosis.

Further confounding the early recognition of disease in the infant is the potentially prolonged lapse between malaria exposure in the mother and transmission of infection to the infant. *P. vivax* and *P. ovale* may remain dormant in the liver, especially if the infected individual did not receive therapy for the exoerythrocytic stage, which can cause a delayed relapse of malaria in travelers or immigrants. *P. malariae* can persist for 20 to 40 years before clinical symptoms or demonstrable parasitemia appear (D'Avanzo et al, 2002). Congenital malaria has been

reported in an infant whose mother lived in the United States for 5 years before delivery and had no signs or symptoms or malaria for more than 20 years (Harvey et al, 1969). In North Carolina, congenital *P. malariae* infection was reported in a 10-week-old infant who was born to a mother who had emigrated from the Democratic Republic of Congo 4 years before delivery (D'Avanzo et al, 2002). In a review by Lesko et al (2007), the median duration from the mother's last exposure to delivery was 9.5 months. The time elapsed since exposure was longest for those with *P. malariae* infection, ranging from 2 to 12 years.

Recognizing that congenital malaria is an exceptional occurrence in the United States, it is still important to include malaria in the differential diagnosis of fever in infants born to mothers who have been exposed to malaria, even if the exposure is remote and even if the woman is asymptomatic. Of 11 infants with congenital malaria in the United States born to women known to have parasitemia at or shortly after delivery, only five underwent testing by blood smears, and all five had negative test results at the time of delivery (Lesko et al, 2007). Data are insufficient to determine the overall risk of an infant developing congenital malaria when born to a woman at risk for parasitemia or identified with parasitemia at birth. Consequently, the evaluation of infants born outside endemic areas to women with epidemiologic risk factors for parasitemia should be individualized. In malaria endemic areas, and as a public health measure, it has been recommended that blood smears should be checked as part of the evaluation of neonates with fever born to mothers who have had fever within a few weeks of delivery (Uneke, 2007a).

TREATMENT

The management of malaria consists of supportive care and antimalarial therapy. Information regarding treatment of congenital malaria is limited, and recommended chemotherapy is similar to that of noncongenital infections. The treatment regimen is based on the infecting species, the possibility of drug resistance, and the severity of disease. For mild infections caused by *P. vivax*, *P. ovale*, and *P. malariae* or chloroquine-sensitive *P. falciparum*, chloroquine orally (10 mg base/kg initially followed by 5 mg base/kg 6, 24, and 48 hours later) is recommended. Treatment with primaquine is not necessary for congenitally acquired *P. vivax* or *P. ovale* infection because, like transfusion-associated malaria, congenital infection does not involve the exoerythrocytic phase.

The treatment of congenital malaria due to chloroquine-resistant *P. falciparum* is poorly defined. In older children, three treatment options currently recommended are: (1) oral quinine plus either tetracycline, doxycycline, or clindamycin; (2) atovaquone-proguanil; or (3) mefloquine. For the treatment of congenital malaria, oral quinine sulfate and trimethoprim-sulfamethoxazole for 5 days was recommended by Quinn et al (1982), who used the regimen to treat a 1-month-old infant. Ahmed et al (1998) used a similar regimen for the treatment of an infant born at 28 weeks' gestation to a mother from Zaire. Other regimens used successfully in neonates include oral quinine sulfate and pyrimethamine-sulfadoxine (Gereige and Cimino, 1995) and intravenous quinine hydrochloride followed by oral quinine (Airede, 1991). Intravenous quinine is no longer available in the United States. Because of the rarity of congenital malaria in the United States, the changing pattern of resistance, and the potential toxicity associated with drugs used for therapy, current treatment recommendations should be sought from the Malaria Branch of the CDC (www.cdc.gov/malaria). For health care professionals, assistance with management of malaria is also available 24 hours a day through the CDC Malaria Hotline (770-448-7788).

Severe malaria occurs most commonly with *P. falciparum* infection and is characterized by one or more of the following: (1) parasitemia greater than 5% of red blood cells, (2) central nervous system or other end-organ involvement, (3) shock, (4) acidosis, (5) severe anemia, or (6) hypoglycemia. Management of severe malaria involves parenteral treatment in an intensive care setting. Until recently, the only parenteral therapy available in the United States was quinidine gluconate. Quinidine is more cardiotoxic than quinine and should be administered with continuous cardiac monitoring. Exchange transfusion may be warranted when parasitemia exceeds 10% or if there are complications at lower parasite densities.

The efficacy of treatment should be monitored by examining blood smears (i.e., malaria smears) every 12 hours until negative for malaria parasites. Response to therapy with chloroquine for non-*P. falciparum* malaria is usually favorable (Brandenburg and Kenny, 1982; Dowell and Musher, 1991; Hindi and Azimi, 1980). It has been suggested that infants born to mothers with parasitemia at delivery should be treated presumptively for congenital malaria (Lesko et al, 2007). Data are insufficient to determine the risk of an infant developing congenital malaria when born to a mother with parasitemia. Although there is evidence from endemic areas that parasitemia detected at or shortly after delivery may clear spontaneously, the clinical relevance of this observation in nonendemic areas is unclear. It is recommended that physicians judge each case individually, considering factors such as access to medical care and reliability of follow up in deciding whether to treat infants presumptively.

PROGNOSIS

Malaria during pregnancy is likely an underappreciated risk factor for increased infant morbidity and mortality in endemic areas. In a review of studies published between 1985 and 2000, Steketee et al (2001) determined population-attributable risks for maternal malaria of 3% to 8% for infant mortality. It was estimated that 75,000 to 200,000 infant deaths annually are associated with malaria during pregnancy, although what proportion of these are related to congenital malaria is unknown. Outside endemic areas, the short-term outcome of congenital malaria has been favorable. Most infants respond rapidly to therapy with clearance of parasitemia. There were no reports of death or adverse outcomes in the 49 cases reported from 1950 to 1992 or in the 81 cases reported to the CDC from 1966 to 2005 (Hulbert, 1992; Lesko et al, 2007). It is unclear, however, whether the outcomes are due to an overall favorable prognosis or reporting bias.

PREVENTION

The prevention of congenital malaria is based on a pregnant woman's avoidance of exposure and use of chemoprophylaxis. Malaria infection in pregnant women is more common and more severe than in nonpregnant women. Malaria also increases the risk for adverse pregnancy outcomes, including prematurity, abortion, and still birth. Nonimmune pregnant women are at the highest risk for these adverse outcomes. Based on these observations, the CDC advises women who are pregnant or likely to become pregnant to avoid travel to areas with malaria transmission. If such travel is unavoidable, consultation with an infectious disease or malaria expert is advised. The use of mosquito netting, mesh screens on windows, insecticides, and mosquito repellents can decrease potential exposure to malaria parasites. For pregnant women traveling to areas where there is no chloroquine-resistant *P. falciparum* malaria, prophylaxis with chloroquine is advised. The safety of chloroquine for the fetus when used at the recommended doses for malaria prophylaxis is well established (MacLeod et al, 1982). For travel to areas where chloroquine resistance has been reported, mefloquine is the only medication that is currently recommended for prophylaxis during pregnancy. Atovaquone-proguanil is not recommended during pregnancy because of insufficient information on potential adverse effects. Doxycycline is contraindicated because of adverse effects on the fetus caused by a related drug, tetracycline, which include dysplasia and discoloration of teeth and inhibition of bone growth. Health care professionals caring for women who cannot take the recommended antimalarial agent should contact the CDC Malaria Hotline (770-488-7788).

Pregnant women originally from areas where malaria is endemic but who are now living in nonendemic areas may be only partially immune. When traveling to their countries of origin, they should be considered nonimmune and thus should receive the same recommendations as nonimmune women.

The burden of malaria among pregnant women in endemic areas is well recognized, and prevention and control strategies for areas of high *P. falciparum* transmission are aimed at reducing maternal and infant mortality. The World Health Organization has proposed a three-pronged approach: (1) intermittent preventative treatment with an effective antimalarial agent at scheduled antenatal visits, (2) insecticide-treated nets, and (3) effective case management of clinical infection. A metaanalysis of more recent intervention trials suggests that successful prevention of these infections reduces the risk of severe maternal anemia by 38%, LBW by 43%, and perinatal mortality by 27% among paucigravidae women (Desai et al, 2007). Unfortunately, the full implementation of antenatal malaria prevention efforts is burdened by the challenges associated with health care delivery in the developing world.

CONGENITAL TUBERCULOSIS

Tuberculosis remains one of the deadliest communicable diseases worldwide. More than 2 billion people, equivalent to one third of the world's population, are infected with *Mycobacterium tuberculosis*. Each year, an estimated 9 million new tuberculosis cases are identified, and 2 million people die from the disease. The greatest burden of disease is in developing countries, where tuberculosis remains a major public health threat. While case rates have declined steadily in the United States and Europe, the corresponding numbers have increased dramatically in the former Soviet Union and Sub-Saharan Africa, in part fueled by the epidemic of human immunodeficiency virus (HIV).

Despite the prevalence of tuberculosis worldwide, congenital tuberculosis occurs rarely, with fewer than 400 cases reported in the English-language literature. The majority of reports describe infants born in low-burden countries to mothers who have emigrated from high-burden countries. Although some reports originate from countries where tuberculosis is endemic, it is likely that congenital tuberculosis is underrecognized and underreported in these areas, largely because of the nonspecific clinical features of disease and the limited diagnostic capability.

In the United States, 10,000 to 15,000 cases of tuberculosis are reported annually. Although the overall rate of tuberculosis infection has been declining steadily since 1992, the proportion of cases in foreign-born populations has increased. More than 50% of cases reported in 2008 occurring among the foreign born. With increased global mobility and the epidemiologic trends of tuberculosis, it is likely that tuberculosis and congenital tuberculosis will continue to be observed in developed countries. The nonspecific features of congenital tuberculosis and the mortality associated with untreated disease underscore the importance of maintaining a high index of suspicion for tuberculosis in pregnant women and young infants.

DEFINITION

Transmission of *M. tuberculosis* from the mother to the neonate can occur in utero, intrapartum, or postpartum. Although congenital infection is classically considered the result of in utero infection of the fetus, the term *congenital tuberculosis* has historically referred to infection acquired either in utero or intrapartum. The infection can be transmitted by direct spread to the fetus from the placenta via the umbilical vein or by aspiration or ingestion of infected amniotic fluid, either in utero or intrapartum.

Beitzke (1935) proposed diagnostic criteria to distinguish congenital tuberculosis from postnatally acquired tuberculosis. The criteria required that the infant have proven tuberculosis lesions and one of the following: (1) a primary hepatic complex as evidence of dissemination of the tubercle bacilli via the umbilical vein or (2) in the absence of a primary complex, the presence of tuberculous lesions in the first few days of life or the exclusion of postnatal infection by separation of the infant at birth from the mother and other potential sources of infection. These criteria were developed before the introduction of chemotherapy, when infant mortality with congenital tuberculosis was high and diagnosis was largely based on autopsy findings. It is difficult and no longer practical to apply Beitzke's criteria. The demonstration of a primary hepatic complex with liver and regional node involvement requires an open surgical procedure; a percutaneous liver biopsy may demonstrate caseating granulomas, but the

primary complex will seldom be identified. Cantwell et al (1994) proposed revised criteria that are more applicable to current practice and improve diagnostic sensitivity. To meet the criteria, the infant must have proven tuberculous lesions and at least one of the following: (1) lesions in the first week of age, (2) a primary hepatic complex or caseating hepatic granulomas, (3) tuberculous infection of the placenta or maternal genital tract, or (4) exclusion or postnatal transmission by thorough investigation of contacts. Whereas the distinction between congenital tuberculosis and postnatally acquired disease may be relevant for academic or epidemiologic purposes, it does not affect the management, treatment, or prognosis of disease.

EPIDEMIOLOGY

From 1953 through 1984, the incidence of tuberculosis in the United States declined steadily, reaching a nadir of 9.4 cases per 100,000 population. From 1985 through 1992, there was a 20% increase in the total number of cases. The resurgence of disease was attributed to multiple factors, including the HIV epidemic, increased immigration, and a decline in public health funding for tuberculosis control. With the availability of antiretroviral therapy for HIV and fortification of public health measures, the epidemiologic trend was reversed. Since 1992, the case rates for tuberculosis have decreased annually to a case rate of 4.2 per 100,000 in 2008. Despite the decrease in the total burden of disease, tuberculosis continues to disproportionately affect the foreign-born and racial and ethnic minorities. In 2008, 59% of all cases of tuberculosis in the United States occurred in foreign-born persons (CDC, 2008).

The current epidemiology of tuberculosis in pregnancy is not well delineated. With the resurgence of tuberculosis in the 1980s, the largest increase in the incidence of disease occurred in the 25- to 44-year age group, and the number of cases among women of childbearing age rose by 40% (Cantwell et al, 1994). In 1991, almost 40% of tuberculosis cases in minority women occurred in those between 15 and 35 years of age (Smith and Teele, 1995). These trends persist through the present time, thus placing women of childbearing age, especially those who are foreign born, and their newborns at continued risk.

The risk of congenital tuberculosis in infants born to women with tuberculosis is unknown. Blackall (1969) reported only three cases among infants born to 100 mothers with tuberculosis. Ratner et al (1951) identified no cases among infants born to 260 mothers with the disease. In a study of 1369 infants separated at birth from their tuberculous mothers and placed in foster care, only 12 became tuberculin-positive during 4 years of observation, and in all 12 cases there was a source of infection in the postnatal environment (Smith and Teele, 1995). The low incidence of congenital tuberculosis is in part attributable to the high likelihood of infertility in women who have endometrial tuberculosis (Balasubramanian et al, 1999). However, in areas with high rates of tuberculosis transmission, neonates may be undiagnosed or underreported, and the incidence of congenital infection or vertical transmission remains unknown.

Fewer than 400 cases of congenital tuberculosis have been reported in the literature, with the majority being in the prechemotherapy era (Laartz et al, 2002). Hageman et al (1980) reported two cases of congenital tuberculosis and reviewed another 24 reported in the English-language literature since the introduction of isoniazid (INH) in 1952. In the subsequent 30 years, more than 30 additional cases of neonates with congenital tuberculosis have been described (Abughali et al, 1994; Cantwell et al, 1994; Chen and Shih, 2004; Doudier et al, 2008; Grover et al, 2003; Hatzistamatiou et al, 2003; Laartz et al, 2002; Manji et al, 2001; Mazade et al, 2001; Nicolaidou et al, 2005; Pejham et al, 2002; Saitoh et al, 2001). The more recent reviews are cited in Table 38-8. Not surprisingly, the majority of infants were born to foreign-born mothers living in nonendemic areas.

PATHOPHYSIOLOGY

In pregnant women, tuberculous bacillemia can result in dissemination of infection to the placenta, the endometrium, or the genital tract. Genital tuberculosis that occurred before pregnancy may be asymptomatic, but often results in sterility, thus likely accounting for the low overall frequency of congenital infection. Vertical transmission may occur in one of three ways: (1) hematogenous spread from the infected placenta via the umbilical vein, (2) in utero aspiration or ingestion of amniotic fluid infected from the placenta or endometrium, or (3) ingestion of infected amniotic fluid or secretions from maternal genital lesions during delivery. The hematogenous route and in

utero aspiration each probably account for approximately half of the cases of congenital tuberculosis.

Tuberculous bacilli have been demonstrated in the decidua, amnion, and chorionic villi of the placenta. It is unlikely that the fetus can be infected directly from the mother without the presence of a caseous lesion in the placenta, although massive involvement of the placenta does not always result in congenital tuberculosis. When a tubercle ruptures into the fetal circulation, bacilli in the umbilical vein can infect the liver, forming a primary focus with involvement of periportal lymph nodes. The bacilli also may pass through the liver and right ventricle and into the lung, or they can enter the left ventricle via the foramen ovale and pass into the systemic circulation. The organisms in the lung remain dormant until after birth, when oxygenation and circulation result in their multiplication and the subsequent development of a primary pulmonary focus. Alternatively, if the caseous lesion in the placenta ruptures directly into the uterine cavity and infects the amniotic fluid, the fetus can inhale or ingest the bacilli, leading to primary foci in the lung, intestine, or middle ear. Pathologic examination of tuberculosis in the fetus and newborn usually demonstrates disseminated disease, with the liver and lungs being principally involved. In Siegel's study (1934) of 38 postmortem cases, the lungs were involved in 97%, the liver in 82%, and the spleen in 76% of the infants. Other sites described are the gastrointestinal tract, kidneys, adrenal glands, and skin (Agrawal and Rehman, 1995; Hageman et al, 1980; Sood et al, 2000). It is not always possible to determine whether sites represent multiple primary foci or are secondary to primary lesions in the lung or liver. The only lesion in the neonate that is unquestionably associated with congenital infection is a primary complex in the liver; all others may be acquired congenitally or postnatally.

M. tuberculosis infection acquired in utero or perinatally may be indistinguishable from postpartum infection. Postnatal acquisition of *M. tuberculosis* acquired by airborne inoculation, either from the mother or another contagious adult in the infant's environment, is the most common route of infection of the neonate. In addition, postnatal infection can occur from ingestion of infected breast milk from a mother with a tuberculous breast abscess. In the absence of a breast abscess, transmission of tuberculosis via breast milk has not been documented. The distinction between congenital tuberculosis and postnatally acquired disease may be important for academic or epidemiologic purposes, but the management, treatment, and prognosis of the disease processes are the same.

CLINICAL PRESENTATION

The clinical presentation of congenital tuberculosis is neither distinctive nor specific. Manifestations of disease resemble those of neonatal sepsis or other congenital infections. The affected infant is commonly born prematurely (Amodio et al, 2005; Davis et al, 1960; Foo et al, 1993; Katumba-Luenya et al, 2005; Premkumar et al, 2008; Wanjari et al, 2008). A retrospective cohort study from Mexico of infants born to 35 mothers with pregnancies complicated by tuberculosis demonstrated an approximately twofold risk of prematurity compared with newborns of mothers without tuberculosis (Figueroa-Damian and Arredondo-Garcia, 2001). Clinical signs may be evident shortly after birth, but typically do not appear until 2 to 4 weeks of age (see Table 38-8). Among the 29 cases reviewed by Cantwell et al (1994), the median age of presentation was 24 days. In an updated review of 16 cases reported since 1994, the mean age at presentation was slightly younger at 17.4 days (Laartz et al, 2002).

Before the availability of INH, congenital tuberculosis was almost uniformly fatal. Notable signs included failure to thrive, jaundice, and central nervous system involvement. In the post-INH era, the most commonly described features of disease are respiratory distress, hepatomegaly with or without splenomegaly, and fever (Abughali et al, 1994; Cantwell et al, 1994; Hageman et al, 1980). Additional findings are listed in Table 38-9. Although it is important to evaluate for meningitis in an infant with suspected congenital tuberculosis, central nervous involvement occurs in fewer than 50% of cases (Hageman et al, 1980; Starke, 1997). Otitis media with aural discharge has been described as the presenting sign of congenital tuberculosis (Ng et al, 1996; Senbil et al, 1997), accompanied by regional lymphadenopathy (Gordon-Nesbitt and Rajan, 1973; Hatzistamatiou et al, 2003; Figure 38-7) or facial palsy (Pejham et al, 2002). It is presumed that the infection is due to the accumulation of infected amniotic fluid in the eustachian tube, either in utero or at birth. Cutaneous manifestations of congenital tuberculosis include papular, pustular, or vesicular lesions often surrounded by erythema (Al-Katawee et al, 2007; Azimi and Grossman, 1996; Hageman et al, 1980; Loeffler et al, 1996; Sood et al, 2000). Biopsy of the lesions is often confirmatory, demonstrating granulomatous inflammation and the presence of acid fast bacilli (AFB) on tissue stain (Hageman et al, 1980; Loeffler et al, 1996). A unique case of congenital tuberculosis involving the spine was recently reported in India (Grover et al, 2003).

DIAGNOSIS

The timely diagnosis of congenital tuberculosis requires a high index of suspicion. Clinical signs of disease in the neonate are nonspecific, and disease in the mother may be unsuspected, contributing to further delay in diagnosis. The diagnosis of congenital tuberculosis should be considered in any neonate with suspected infection who is unresponsive to conventional antimicrobial therapy. Evaluation for suspected disease should include a tuberculin skin test (TST), chest radiography, lumbar puncture, and mycobacterial culture of appropriate specimens. Biopsy specimens of affected tissue, either from the infant or the mother, and the placenta have been confirmatory in several case reports (Abughali et al, 1994; Cantwell et al, 1994; Chou, 2002; Hageman et al, 1980; Laartz et al, 2002; Loeffler et al, 1996).

The TST is the most commonly used diagnostic test for tuberculosis. The test uses 5 tuberculin units of purified protein derivative injected intradermally on the volar surface of the forearm. The reaction is measured 48 to 72 hours later as millimeters of induration. As many as 10% to 40% of immunocompetent children with culture-proven tuberculosis do not initially react to a TST. Host factors such as young age and immunocompromised state can also decrease the sensitivity of the TST. Specificity may be compromised by cross reactivity with bacille-Calmette-Guérin vaccine or with environmental nontuberculous mycobacteria. The TST result is usually negative in neonates with congenital or perinatal tuberculosis, either secondary to immature cell-mediated immunity or because of overwhelming disease (see Table 38-8). Hageman et al (1980) found that only 2 of 14 infants who underwent skin testing had positive test results; on repeated testing, seven infants subsequently demonstrated positive tuberculin skin tests, the earliest being at 6 weeks of age, almost 4 weeks after presentation with clinical signs. Similarly, results of TSTs performed in 9 of 29 patients described by Cantwell et al (1994) were all negative, with results of subsequent testing being positive in 2 of the 9 infants. Among the 16 infants with congenital tuberculosis recently reviewed by Laartz (2002), three of four infants tested had nonreactive TST results.

Recent advances in diagnostic tools for tuberculosis include whole-blood interferon γ release assays (IGRAs), which are immunologically based tests that measure interferon γ production from lymphocytes in response to antigens that are fairly specific to *M. tuberculosis*. The two types of assays currently available include the Quantiferon Gold (Cellestis, Valencia, California) and the enzyme-linked immunosorbent spot assay. Advantages of these tests include lack of cross-reactivity with bacille-Calmette-Guérin vaccine and most nontuberculous mycobacteria. The correlation between IGRAs and TSTs is variable, and negative results do not definitively exclude tuberculosis. Published experience with the use of IGRAs in children is limited, and the negative predictive value of these tests in this population is unclear. Although IGRAs are endorsed by the CDC for use in circumstances in which a TST is indicated (Mazurek et al, 2010), the tests are not recommend for use in children younger than 5 years of age (American Academy of Pediatrics, 2009). Data on the use of IGRAs in newborns is limited to case reports, and these assays should not be substituted for TSTs in the evaluation of congenital tuberculosis.

Given the frequency of respiratory distress in infants with congenital tuberculosis, it is not surprising that chest radiograph findings are frequently abnormal at first examination. Typically, a nonspecific parenchymal infiltrate is noted, although a miliary pattern representative of disseminated disease is occasionally observed (Agrawal and Rehman, 1995; Airede, 1990; Nemir and O'Hare, 1985; Pal and Ghosh, 2008; Polansky et al, 1978; Singh et al, 2006; Figure 38-8). Sixteen of 26 patients (62%) reviewed by Hageman et al (1980) had abnormal radiographic findings on presentation; seven had a miliary pattern and nine had nonspecific changes. Radiographic abnormalities developed subsequently in four additional infants. Among the 29 cases reviewed by Cantwell et al (1994), 23 infants (79%) had chest radiographic abnormalities, the majority being nonspecific infiltrates. Cavitation secondary to progressive pulmonary involvement has been reported (Cunningham et al, 1982). CT imaging of the chest may demonstrate adenopathy suggestive of tuberculosis or confirm miliary disease (Das et al, 2008; Singh et al, 2006). An ultrasound or CT image of the abdomen may reveal enlargement of the liver, spleen, or both, possibly with areas of abscesses (Amodio et al, 2005; Berk and Sylvester, 2004; Grover et al, 2003; Senbil et al, 1997). Congenital tuberculosis involving the spine was identified by radiographs and confirmed by magnetic resonance imaging in India (Grover et al, 2003) (Figure 38-9).

Microbiologic confirmation of disease in the neonate should be sought using specimens from multiple sites. For infants and children unable to expectorate sputum, gastric aspirates are considered the specimens of choice. Additional sources for culture include endotracheal aspirate, bronchial washing, middle-ear discharge, and lymph node tissue. CSF should be analyzed and cultured, although isolation of *M. tuberculosis* from CSF is uncommon (Abughali et al, 1994; Hageman et al, 1980). Traditionally the detection of mycobacterial organisms by smear or culture has been considered difficult, because children have paucibacillary disease relative to adults. With three morning gastric aspirates collected appropriately in hospitalized

FIGURE 38-8 Miliary tuberculosis in a neonate with congenital tuberculosis. *(From Singh M, Kothur K, Dayal D, et al: Perinatal tuberculosis a case series*, J Trop Pediatr *53:135-138, 2006.)*

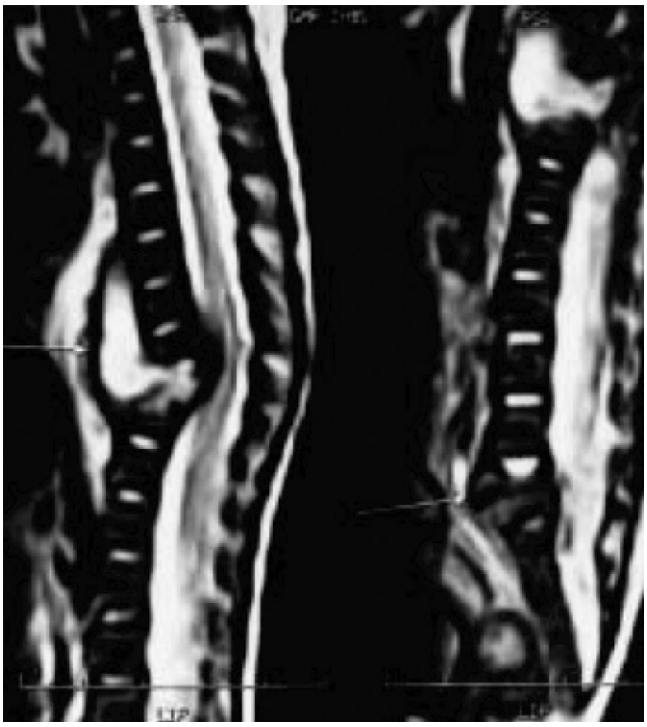

FIGURE 38-9 Saggital magnetic resonance image on the *left* demonstrates destruction of T9 to T11 vertebral bodies with the collapse of T10, leading to a kyphotic deformity causing cord compression. A large prevertebral collection is also seen. The image on the *right* demonstrates destruction with collapse of L5 and S1 vertebral bodies. *(From Grover SB, Pati NK, Mehta R, et al: Congenital spine tuberculosis: early diagnosis by imaging studies*, Am J Perinatol *20:150, 2003.)*

children with a clinical diagnosis of tuberculosis, only 40% of children had positive cultures (Starke and Taylor-Watts, 1989). In comparison, cultures of aspirates from infants evaluated at the same institution had a 75% yield (Starke and Taylor-Watts, 1989; Vallejo et al, 1994).

The improved diagnostic yield in infants likely reflects more widely disseminated and progressive disease, with higher bacillary loads. Hageman et al (1980) found positive cultures of *M. tuberculosis* in 10 of 12 gastric aspirates, 3 of 3 liver biopsy specimens, 3 of 3 lymph node specimens, and 2 of 4 bone marrow biopsy specimens. Among the 31 cases reviewed by Cantwell et al (1994), noninvasive procedures and biopsy were useful for the diagnosis of congenital malaria in the majority infants (Table 38-10). More recent reports confirm the high yield of cultures from a variety of specimens in neonates (Berk and Sylvester, 2004; Chou, 2002; Mazade et al, 2001; Premkumar et al, 2008; Wanjari et al, 2008). Histologic examination of tissue may suggest the diagnosis before culture results are available. Biopsy of skin lesions, lymph nodes, and the liver have suggested the diagnosis in several cases by demonstration of granulomas or acid-fast bacilli on staining before culture results are available (Berk and Sylvester, 2004; Davis et al, 1960; Hageman et al, 1980).

Whereas *M. tuberculosis* can require 7 to 21 days for growth by standard culture technique, results from techniques such as PCR may be available within 48 hours. A comparison of PCR, AFB smear, and culture with clinical diagnosis in children found a sensitivity of 60% and a specificity of 97% (Smith, 2002). Although PCR has been useful for diagnosing congenital tuberculosis in a few case reports, it is not sensitive enough to preclude obtaining specimens for culture. Isolation of *M. tuberculosis* is still important to determine susceptibilities and to optimize treatment.

The mother of a newborn in whom congenital tuberculosis is suspected is often asymptomatic or has subclinical disease. In the series of congenitally infected infants reported by Hageman et al (1980), the majority of mothers did not have a diagnosis until after the disease became apparent in their infants. Cantwell et al (1994) found that 50% of the mothers of infected infants were not ill at the time their newborns exhibited clinical signs of disease. Evaluation of the mother should include a TST, a chest radiograph, and, if the radiograph is consistent with tuberculosis disease, collection of sputum for microbiological confirmation. It is not unusual for the mother to have extrapulmonary disease such as meningitis or peritonitis (Laartz et al, 2002; Naouri, 2005), and evaluation may need to be extended to identify such sites if pulmonary disease is not discovered. In mothers with no clinical evidence of disease, endometritis should be considered. Pathologic examination and culture of the placenta (if available) or endometrial biopsy can confirm the diagnosis of genital transmission (Asensi et al, 1990; Balasubramanian et al, 1999; Cantwell et al, 1994; Cooper et al, 1985; Niles, 1982; Surve et al, 2006). In several case reports, the diagnosis of maternal tuberculosis was solely and ultimately made by endometrial biopsy and culture (Pejham et al, 2002). In addition, culture of amniotic fluid should be performed. All mothers with tuberculosis should be tested for HIV infection and, if the mother is seropositive, the infant should be evaluated for perinatally acquired HIV infection.

TREATMENT AND MANAGEMENT

The successful management of congenital tuberculosis depends on early recognition and treatment of disease. In suspected cases, treatment should not be delayed until results of cultures or other diagnostic tests are available.

TABLE 38-10 Results of Diagnostic Procedures Performed on 29 Infants With Congenital Tuberculosis Reported from 1980 to 1994

Type of Specimen	Acid-Fast Smear*	Mycobacterial Culture	Smear or Culture
Gastric aspirate	8/9	8/9	9/11
Endotracheal aspirate	7/7	7/7	7/7
Ear discharge	2/2	1/1	2/2

*Results expressed as number of positive results per number of patients tested.
†All biopsy specimens of lymph node and liver that tested negative on smear and culture showed histopathologic changes consistent with tuberculosis (i.e., giant cell transformation of granulomas, with or without caseation).

Multiple drug therapy for an extended duration has long been recognized as the standard of care for tuberculosis. Because of the rarity of the condition, clinical trials have not been conducted to establish the optimal treatment regimen for congenital tuberculosis. It is assumed that the regimens used for older infants and children are safe and effective for the treatment of neonates with congenital tuberculosis. Consultation with a pediatric infectious disease specialist or tuberculosis expert is advised.

Until susceptibility results are known, infants with proven or suspected tuberculosis should be treated with a four-drug regimen consisting of INH rifampin (RIF), pyrazinamide (PZA), and ethambutol (Table 38-11). Some experts would recommend administration of three drugs (INH, RIF, PZA) if antimicrobial resistance is not suspected in the mother, because either she or the source case are known to have a susceptible strain or she has no risk factors for resistant *M. tuberculosis*. The adjunctive use of corticosteroids is recommended for the treatment of tuberculosis meningitis based on decreased mortality and morbidity demonstrated in adults and children (Girgis et al, 1991). Supplementation with pyridoxine, although not routinely recommended for otherwise healthy older children, should be provided to breastfeeding infants receiving INH. If the *M. tuberculosis* isolate is determined to be susceptible, the regimen can be narrowed to three drugs (INH, RIF, PZA) for the first 2 months of initial treatment, and subsequently to 2 drugs (INH, RIF) to complete the continuation phase of treatment. Once the infant is discharged to home, directly observed therapy is recommended to ensure adherence and to prevent relapse.

The optimal duration of treatment for infants with congenital tuberculosis is unknown. The typical duration of treatment for susceptible *M. tuberculosis* is 6 months for pulmonary disease, pulmonary disease with hilar adenopathy, or hilar adenopathy alone (American Academy of

TABLE 38-11 Commonly Used Drugs for Treatment of Tuberculosis in Infants, Children, and Adolescents

Drugs	Dose Forms	Daily Dose (mg/kg)	Twice per Week Dose (mg/kg)	Maximum Dose	Adverse Reactions
Ethambutol	Tablets (100,400 mg)	20-25	50	2.5 g	Optic neuritis (usually reversible), decreased red-green color discrimination, gastrointestinal tract disturbances, hypersensitivity

†When isoniazid in a dose exceeding 10 mg/kg/d is used in combination with rifampin, the incidence of hepatotoxic effects may be increased.

Pediatrics, 2009). For extrapulmonary disease, the duration is extended to 9 to 12 months, and for drug-resistant *M. tuberculosis* the duration may be extended even further to prevent failure or relapse. Most experts would treat infants with congenital tuberculosis for 9 to 12 months because of the decreased immunocompetence of neonates (Starke, 1997).

Although there is a fair amount of data to support the safety of INH, data on the safety and pharmacokinetics of other agents are limited. Careful monitoring for signs and symptoms of hepatitis and other adverse effects of drug therapy is recommended. Routine determination of serum transaminases in children is indicated with severe tuberculosis (e.g., military or meningitis), for those with concurrent liver or biliary disease, or for those receiving other potentially hepatotoxic drugs. Routine monitoring of liver function also should be considered for neonates with congenital tuberculosis given the paucity of data on adverse effects of anti-tuberculosis agents in this age group (Patel et al, 2008). The risks of optic neuritis with ethambutol should be considered when this agent is used, and vision should be monitored periodically.

The management of infants born to mothers who have latent tuberculosis infection (LTBI) or tuberculosis disease is outlined in Figure 38-10. Recommendations are based on the categorization of infection in the mother and the potential risk of transmission of tuberculosis to the infant (American Academy of Pediatrics, 2009). Infants born to mothers with potentially contagious tuberculosis should be evaluated for congenital tuberculosis. Separation of the infant and mother is necessary only in cases in which the mother is highly infectious at the time of delivery. The mother with latent tuberculosis infection is not contagious. To prevent reactivation disease in the mother and subsequent exposure of the infant, the mother should receive treatment with INH for LTBI. In addition, latent tuberculosis infection in the mother may be a marker for contagious tuberculosis within the household, and it is recommended that all household members and close contacts of the mother be evaluated for tuberculosis.

Breastfeeding is not contraindicated in women with LTBI. The breast milk of a woman with tuberculosis does not contain tubercle bacilli. For women with tuberculosis who are potentially infectious and separated from the newborn, breast milk may be manually expressed and fed to the infant. Once the mother is noninfectious or the infant is receiving therapy, breastfeeding can be resumed. The exception, however, is the mother with an active tuberculous breast lesion. In this situation the breast milk may be pumped and discarded until resolution of the lesion (Efferen, 2007).

PROGNOSIS

The prognosis for congenital tuberculosis was dismal in the prechemotherapy era, the diagnosis often being only made at autopsy. Although the survival rate subsequently improved, mortality remained approximately 50% secondary to delayed diagnosis. In a review of 26 cases reported between 1952 and 1980, 12 (46%) patients died, 9 of whom were untreated but with a diagnosis made at autopsy. The subsequent reviews demonstrate a decrease in case fatality (see Table 38-8), with earlier diagnosis and treatment. Timely diagnosis and initiation of anti-tuberculosis therapy are critical for a favorable outcome.

PREVENTION

Prevention of congenital tuberculosis requires the treatment and prevention of disease in women of childbearing age. Risk factors for acquiring tuberculosis infection or progressing to disease should be assessed at prenatal visits, and women identified as being high risk for LTBI or progression to disease should undergo tuberculin skin testing as recommended by the CDC (Centers for Disease Control, 2000). Women who are TST positive should undergo evaluation for active disease. The treatment of active tuberculosis during pregnancy is considered standard, and early treatment has been shown to improve maternal and neonatal outcome (Figueroa-Damian and Arredonondo-Garcia, 1998). While not without potential complications, treatment during pregnancy is less of a hazard to a pregnant woman and her fetus than tuberculosis itself. The treatment of LTBI during pregnancy is somewhat more controversial. Some experts advocate treatment during pregnancy, whereas others support a delay in therapy until weeks to months after delivery. Although there is no demonstrated teratogenic potential for the use of INH, there is concern that pregnant and postpartum women are more vulnerable to INH-related hepatotoxicity (Franks et al, 1989).

Most children with pulmonary tuberculosis, especially those younger than 10 years, have paucibacillary disease and often have little to no cough. Isolation of the hospitalized pediatric patient is directed at accompanying adult contacts who may be source cases and potentially contagious. Visitation of the hospitalized pediatric patient should be restricted to adults in whom contagious tuberculosis has been excluded. Hospitalized children with negative sputum AFB smears (if obtained) require standard precautions, assuming that contagious tuberculosis has been excluded in the visitors. Airborne precautions are recommended for the following pediatric patients: (1) children and adolescents with adult-type cavitary disease, (2) extensive pulmonary infection, (3) those with smears positive for AFB, and (4) congenitally infected neonates undergoing endotracheal intubation (American Academy of Pediatrics, 2009).

Compared with older children, neonates likely have a higher concentration of bacilli in their sputum. As noted previously, AFB smears on tracheal aspirates and other specimens are frequently positive in this population compared with older children. Transmission of tuberculosis from congenitally infected neonates to health care workers and other hospitalized infants has been reported and is likely related to aerosolization of bacilli during respiratory manipulation (Crockett et al, 2004; Laartz et al, 2002; Lee et al, 1998; Mouchet et al, 2004). Neonates suspected of having congenital tuberculosis should be placed in respiratory isolation if intubated or if undergoing any procedure with the potential for aerosolization of infected sputum. Exposed infants, visitors, and health care workers should undergo evaluation for tuberculosis infection or disease.

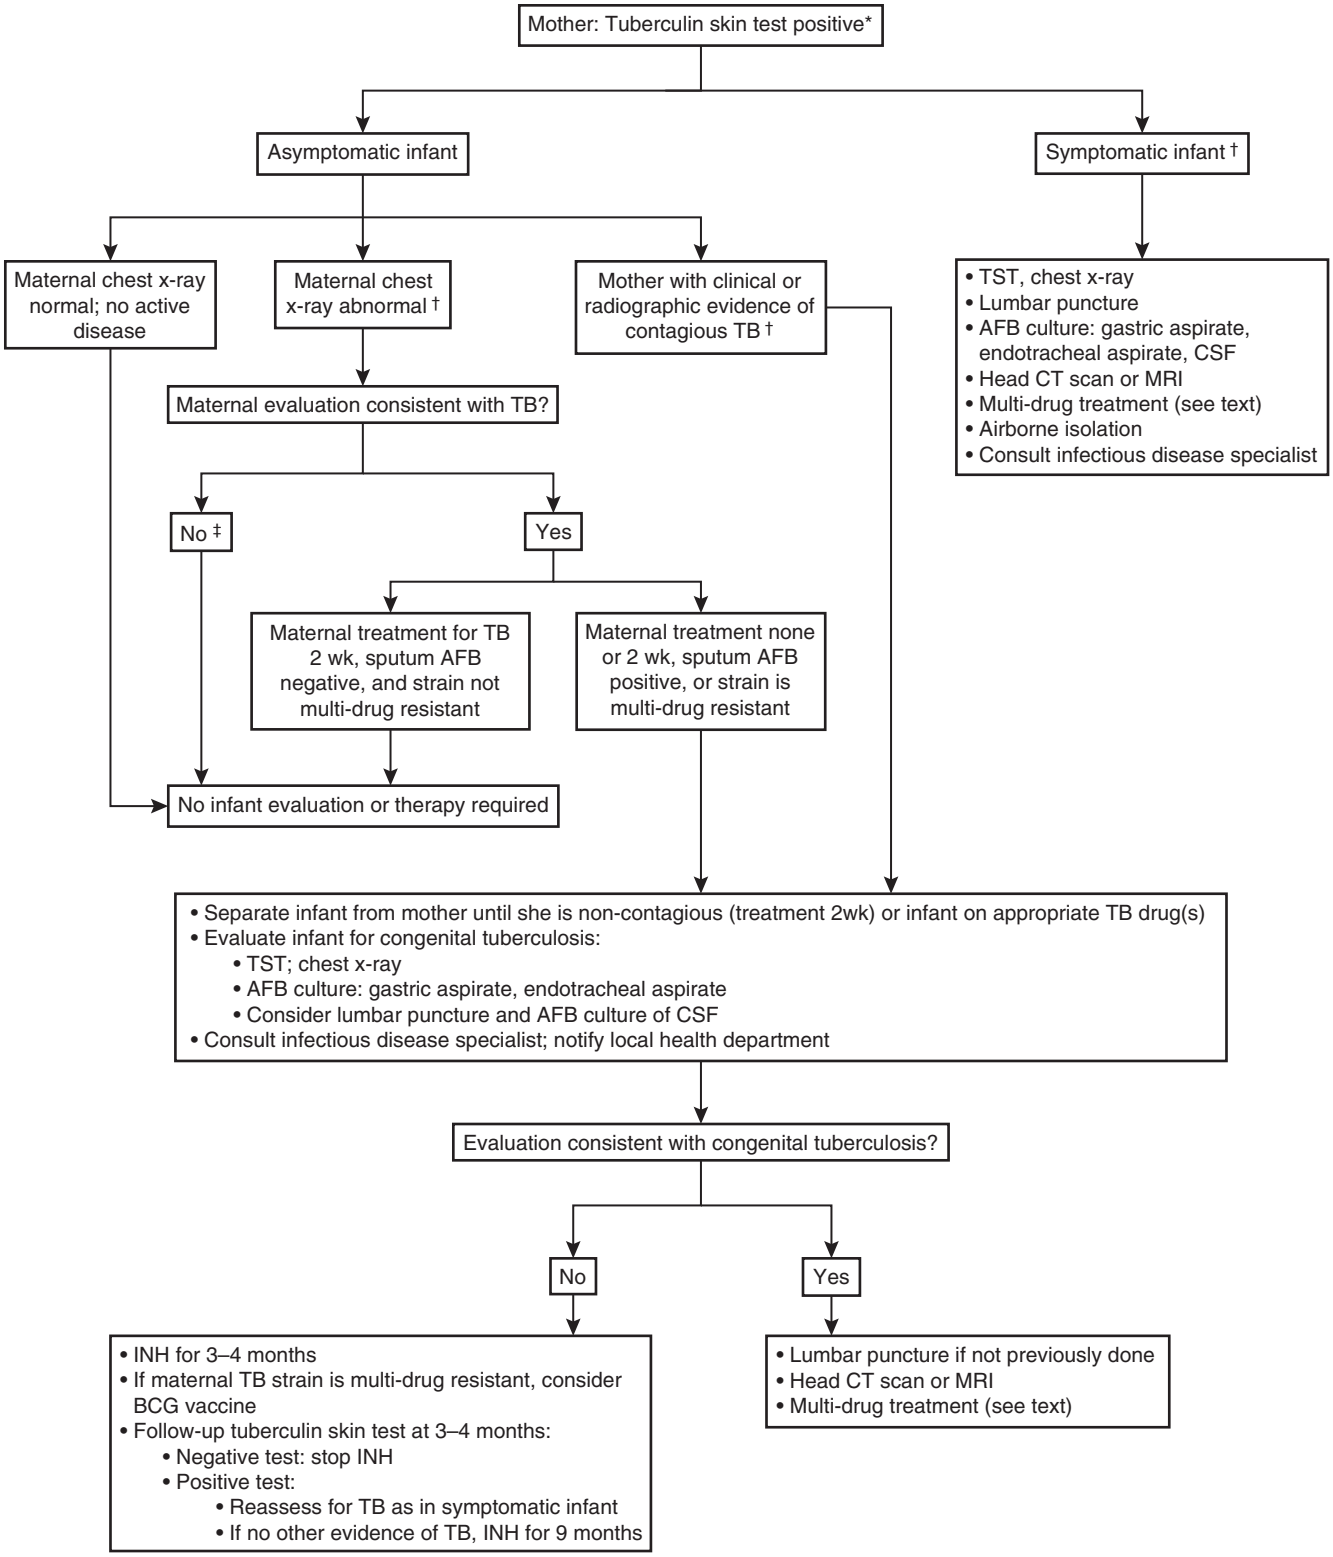

FIGURE 38-10 Management of infants born to mothers with a positive tuberculin skin test (TST) result. *BCG*, Bacille Calmette-Guérin; *CSF*, cerebrospinal fluid; *CT*, computed tomography; *INH*, isoniazid; *MRI*, magnetic resonance imaging. *(Adapted from American Academy of Pediatrics: Tuberculosis. CHAPTER 39

Neonatal Bacterial Sepsis

Patricia Ferrieri and Linda D. Wallen

NEONATAL BACTERIAL SEPSIS

Throughout pregnancy, the fetus is protected from bacterial and viral infections by the chorioamniotic membranes, the placenta, and various antibacterial factors, that are poorly described in amniotic fluid. It is thought that some subclinical infections of the fetus, amniotic fluid, membranes, or placenta may contribute to the onset of preterm labor and the delivery of preterm infants. There are several mechanisms by which bacteria can reach the fetus or newborn and initiate infection. Maternal blood stream infections, caused by bacteria such as *Listeria monocytogenes* and *Mycobacterium tuberculosis*, can reach the fetus and cause infection. Bacteria such as group B streptococcus (GBS) can be acquired from the vagina, cervix, or fecal contamination of the birth canal through either ruptured or intact membranes, leading to amnionitis, intrauterine pneumonitis, and premature delivery (Ancona et al, 1980; Ferrieri, 1990; Larsen and Sever, 2008; Payne et al, 1988). Finally, infection can occur via aspiration of birth canal contents or colonization of mucosal surfaces during passage through the birth canal, leading to pneumonia, followed by bacteremia and sepsis after 1 day or later; this may be the mode by which *Neisseria gonorrhoeae*, *Escherichia coli*, and GBS are acquired.

Early-onset bacterial sepsis remains a major cause of neonatal morbidity and mortality, although the sepsis-associated death rates per 100,000 live births have declined significantly from 2001-2011. Much of this decline in mortality is because of the introduction of intrapartum antibiotic prophylaxis in pregnant women during labor and delivery (Centers for Disease Control and Prevention, 2007, 2009; Schrag et al, 2002; Schrag and Stoll, 2006). Mortality rates in infected premature infants and very immature infants are significantly higher than in term infants. Major improvements in neonatal intensive care and early identification and recognition of infected infants have all contributed to reduced mortality rates in the newborn period.

PATHOGENESIS OF EARLY-ONSET NEONATAL BACTERIAL INFECTIONS

There are multiple portals through which bacteria can enter and infect the newborn. The primary portals of entry appear to be the respiratory tract, as suggested by the high frequency of acute respiratory distress and pneumonia, which occurs in infants with early-onset disease. Acquisition via the placenta is suggested in some instances by the presentation of high-grade bacteremia and severe sepsis clinically apparent at the time of birth in the presence of intact membranes in infants born via cesarean section. The primary maternal event in this sequence, leading to infection of the fetus and newborn infant, is colonization of the maternal genital tract with organisms such as the GBS. Bacteria that reside in the cervix, vagina, or rectum can ascend into the amniotic cavity through intact or ruptured membranes and lead to chorioamnionitis. Bacteria can initially spread into the choriodecidual space and can occasionally cross intact chorioamniotic membranes. Although organisms recovered from the amniotic sac in the mother are usually polymicrobial and include such organisms as the GBS, group D enterococcus, aerobic gram-negative bacteria, and anaerobes such as *Bacteroides* spp. (Gibbs et al, 1980), a single organism causing bacterial sepsis is the rule in de novo sepsis of the newborn infant. Genital microplasmas are at times recovered from women as well as *Chlamydia* spp., but the precise pathogenic role is unclear (Krohn et al, 1995; Pankuch et al, 1984). *Ureaplasma* spp., and *Chlamydia* spp. can be isolated from infants' respiratory tract after birth; these two plus *Mycoplasma hominis* can be recovered from the respiratory tract after birth, but they are not associated with sepsis syndrome.

Although many microorganisms recovered from the amniotic cavity are thought to induce spontaneous preterm labor, and possibly premature rupture of membranes, the exact mechanisms by which this may occur are debatable. Clinical or subclinical chorioamnionitis can incite a marked inflammatory response with the release of cytokines that can contribute to the onset of preterm labor and premature rupture of membranes. Other risk factors for clinical intraamniotic infection include young maternal age, prolonged labor, prolonged rupture of membranes (≥18 hours), internal scalp fetal monitoring, the presence of urinary tract infections, and a history of bacterial vaginosis (Newton et al, 1989; Soper et al, 1989). Despite inherent antibacterial properties in amniotic fluid, these may not be sufficient to overcome a large bacterial inoculum, because of rapid multiplication of bacteria during a prolonged labor or the absence of type-specific maternal antibodies for various pathogens (Ferrieri, 1990).

Infants who immediately display signs of respiratory distress and after birth undoubtedly have onset of infection before or during labor and delivery. Particularly with hypoxia in utero, the infant may gasp and inhale contaminated amniotic fluid, leading to pneumonia, blood stream infection, sepsis, and a severe systemic response syndrome. Infants who display such signs at birth or within a short time after birth have the highest mortality rates. Infants who have an initial asymptomatic period after birth may display symptoms gradually as the organisms multiply in the lung and in the blood. An example of another invasive site of entry is the scalp lesion created by a monitoring device, which becomes contaminated in the setting of amniotic fluid infected with the GBS. An overarching mechanism for continued bacteremia is the absence of sufficient local and systemic host defenses, such as adequate complement levels or type-specific immunity against the invading microorganism (Ferrieri, 1990).

The inflammatory cascade is initiated by activation of macrophages by bacterial cell wall constituents, toxins, or enzymes. A number of proinflammatory cytokines can be released, such as interleukin (IL) 6, IL-8, and tumor necrosis factor-α (TNF-α). These cytokines can alter vascular permeability and vascular tone, decrease myocardial contractility, activate clotting systems, increase pulmonary vascular resistance, and activate other phagocytic cells, such as polymorphonuclear leukocytes (PMNs). Ideally, proinflammatory and antiinflammatory cytokines would be balanced; however, this is usually not the case and the bacteria persist with subsequent consequences. It is common in newborn infants and, particularly in preterm infants, to have dissemination of bacteria to other organs such as the meninges, kidneys, and bone.

EPIDEMIOLOGY OF EARLY-ONSET BACTERIAL INFECTIONS

Before the availability and use of antibiotics in the late 1940s and 1950s, there were few survivors of neonatal bacterial sepsis, contributing to the high perinatal mortality rate of that period. There have been changes in the types of bacteria responsible for neonatal infection over the years. In the 1930s and 1940s, the group A streptococcus was a prominent cause of neonatal sepsis; this organism is now rather rare (Bizzarro et al, 2005). In the 1950s, nursery outbreaks of *Staphylococcus aureus* infections appeared across North America and Europe, prompting changes in techniques of hygiene and encouraging the development and use of penicillinase-resistant antibiotics (Bizzarro et al, 2005). In the 1960s, *Escherichia coli* became the most common cause of bacterial sepsis, followed in the 1970s by the GBS. Even in an era of intrapartum antibiotic prophylaxis of GBS colonized mothers, the GBS remains the most common bacterial pathogen in neonatal centers of North American and Europe, followed by *E. coli* (Schrag et al, 2006). An update on neonatal sepsis at Yale, between 1989 to 2003, revealed an overall decrease in sepsis caused by both GBS and *E. coli* (Bizzarro et al, 2005). Regional differences exist, however, and must be considered before attempting to apply epidemiologic data to individual perinatal units. For example, *Listeria monocytogenes* is a frequent isolate in some western European countries, and *S. aureus* is found commonly in Germany and Scandinavia (Posfay-Barbe and Wald, 2009).

The incidence of early-onset bacterial infection is variable and ranges from one to five per 1,000 live births; however, it is clear that the incidence has declined as a result of intrapartum antibiotic therapy (Centers for Disease Control and Prevention, 2007, 2009). Recent data from the CDC revealed a downward trend from 2000 to 2003 (from 0.52 to 0.31 case per 1000 live births), followed by an increase from 2003 to 2006 (from 0.31 to 0.40 case per 1000 live births) (Centers for Disease Control and Prevention, 2009). Stratified by race, the incidence increased significantly among black infants from 2003 to 2006 (from 0.53 to 0.86 case per 1000 live births), whereas the incidence among white infants did not change significantly (from 0.26 to 0.29 case per 1000 live births). When stratified by gestational age, the average incidence of early-onset GBS disease among preterm infants during 2003 to 2006 was 2.8-fold higher among black infants compared with white infants (1.79 case versus 0.67 case per 1000 live births). It is of interest that both preterm black and white infants had increases in early-onset disease from 2003 to 2006 that were not statistically significant. Early-onset disease among full-term white infants was stable during 2003 to 2006, whereas term black infants had a significant increase of the incidence during this period, from 0.33 to 0.7 case per 1000 live births.

The overall rates of late-onset GBS disease remained stable from 2000 to 2006 (0.36 case versus 0.30 case per 1000 live births) (Centers for Disease Control and Prevention, 2009). No overall incidence trend was observed from 2003 to 2006. When stratified by race, late-onset disease incidence among black infants decreased significantly by 42% from 2005 to 2006 (0.95 case versus 0.55 case per 1000 live births). Between 2003 and 2006 there were no significant trends among black or white infants.

Infants described with early-onset sepsis frequently have one or more identifiable risk factors (Dutta et al, 2010). Prematurity is considered the single greatest risk factor for early-onset bacterial infections. Because it is accepted that ELBW infants have impairment of host defenses, and since preterm birth may be associated with low-grade chorioamnionitis, it is not surprising that the attack rates for infection by pathogens such as GBS are 26- to 30-fold higher in preterm infants, compared to term newborn infants, with an associated high mortality. Other risk factors for early-onset sepsis are maternal age, health and nutrition, colonization with well-known pathogens (e.g., GBS), and rupture of membranes for longer than 18 hours (Schuchat et al, 2000). Neonatal susceptibility to GBS infection is increased with deficiencies in circulating levels of GBS type-specific antibody and complement, which is further heightened by any element of neutrophil dysfunction, as may be seen in the more premature infants (Ferrieri, 1990; Foxman, 2007; Makhoul et al, 2009; Nandyal, 2008).

BACTERIAL PATHOGENS IN EARLY-ONSET INFECTIONS

GROUP B STREPTOCOCCAL INFECTIONS

Since the early 1930s when Rebecca Lancefield reported her grouping system for hemolytic streptococci, group A streptococcus *(Streptococcus pyogenes)* was widely acknowledged as the major pathogen associated with puerperal sepsis. GBS was initially thought to be a commensal until 1938, when Frye reported seven cases of GBS-associated puerperal fever with three deaths (Eickhoff et al, 1964). Before the 1960s, GBS was not recognized frequently as a cause of human disease. However, in the late 1960s GBS emerged as the leading cause of neonatal sepsis in newborn infants (Bizzarro et al, 2005; Zaleznik et al, 2000). Before the era of maternal intrapartum prophylaxis, GBS had a reported national incidence of approximately two per 1000 live births and was associated with approximately 50% mortality in the newborn infant. As mentioned previously, over the past decade with the introduction of antibiotic maternal prophylaxis, there has been a significant decrease in the incidence of GBS to its current rate of approximately 0.32 per 1000 live births for early-onset disease.

Transmission of GBS from Mothers to Infants

In the United States, approximately 20% to 35% of pregnant women are asymptomatic carriers of GBS in the genital and gastrointestinal tract during pregnancy and at the time of delivery (Ferrieri, 1990; Ferrieri et al, 2004b; Zaleznik et al, 2000). The prevalence of GBS colonization during pregnancy varies. Among women who were positive for GBS between 26 and 28 weeks' gestation, only 65% remain colonized at term, whereas 8% of those with negative prenatal cultures were positive for GBS at term (Ancona et al, 1980; Zaleznik et al, 2000). Treatment of GBS-colonized women during pregnancy only temporarily eradicates the organism, and most women are recolonized within several weeks. At birth, 50% to 65% of infants who were born to GBS-colonized mothers have positive GBS cultures from mucous membranes and skin (external ear canal, throat, umbilicus, and anal or rectal sites) (Shet and Ferrieri, 2004). Before the introduction of intrapartum antibiotic prophylaxis, approximately 1% to 2% of colonized infants developed GBS infection, and the overall incidence of neonatal GBS infection was approximately two per 1000 live births in the United States. With intrapartum prophylaxis, approximately 60% to 80% of GBS cases occur in infants born to women with negative antenatal GBS screens (Verani and Schrag, 2010).

A small number of GBS-infected infants acquired their bacteremia because of hematogenous transmission through the placenta. In these situations, the mother commonly displays signs and symptoms of chorioamnionitis, although it may occur in the absence of maternal symptoms (Baker and Edwards, 1995).

Detection of GBS colonization has been emphasized since approximately 1996; studies to determine the optimal sites of sampling have been key to the effectiveness of intrapartum prophylaxis. GBS resides in the genitourinary and gastrointestinal tracts, where large numbers of gram-negative bacteria are also present. The majority of colonization studies have revealed high rates of both rectal and vaginal colonization with GBS (Ancona et al, 1980; Hickman et al, 1999; Zaleznik et al, 2000). The use of the selective broth enrichment medium that inhibits the growth of gram-negative enteric bacilli and other normal flora can increase culture sensitivity for GBS to greater than 90%. The most widely used selective medium is Todd-Hewitt broth with either gentamicin or colistin and nalidixic acid. As recommended in a 2002 publication from the Centers for Disease Control and Prevention, the optimal time for performing antenatal cultures is between 35 and 37 weeks' gestation, and the highest culture yield is obtained when both the lower vaginal area and anal or rectal sites are sampled (Schrag et al, 2002).

Epidemiologic studies of GBS-colonized women have shown that those with heavy colonization (3+ to 4+) are more likely to transmit GBS to their infants (Ancona et al, 1980). The colonization of GBS in pregnant women may be long standing, intermittent, or transient. There is a definite association between GBS colonization and other risk factors for neonatal sepsis; these include preterm labor, preterm delivery, premature rupture of membranes, prolonged rupture of membranes, and maternal fever.

In the past few years, rapid diagnostic tests to detect GBS colonization in pregnant women have included real-time polymerase chain reaction (PCR); compared with broth enrichment cultures, there is an approximately 10% to 15% increased sensitivity (P. Ferrieri, unpublished data). The advantages of PCR detection of maternal vaginal or rectal colonization are the rapid turnaround time, as well as the increased sensitivity. Although more expensive than traditional culture-based detection assays, the results are available 1 to 2 days sooner. The argument that this does not provide semiquantitative data on the degree of GBS colonization in the mother is moot, because even low grade colonization in pregnant women is a risk factor for neonatal GBS sepsis. However, women with heavy (3+ to 4+) colonization, determined by semiquantitative assessment of vaginal or rectal cultures, are more likely to pass the microorganism to their infants (Ancona et al, 1980).

Chemoprophylaxis and Intrapartum Antibiotics

Prevention is of key importance in decreasing invasive GBS disease. The challenge has been to widely promulgate screening cultures in pregnant women. Revised guidelines from the CDC were published in 2002 and presented only the culture screening based approach for prevention and chemoprophylaxis, rather than the two preventive approaches published in 1996: a culture screening-based and a risk-based approach (Schrag et al, 2002). The risk-based approach involved the use of antibiotics based solely on the presence of antenatal or intrapartum risk factors such as maternal fever, preterm labor or premature rupture of membranes (<37 weeks' gestation); prolonged rupture of membranes (≥18 hours); history of a previous newborn infant with GBS disease; and GBS bacteruria during pregnancy. Challenges to the implementation of the CDC guidelines, such as failure to seek prenatal care and the use of suboptimal laboratory culture techniques continue in certain populations. Data for the United States as a whole show a decrease in the incidence of early-onset GBS concurrent with the implementation of maternal GBS screen and intrapartum antibiotic prophylaxis guidelines. The current estimate for the overall United States population for early-onset GBS disease is 0.32 per 1000 live births (Van Dyke et al, 2009).

Intrapartum Antibiotic Prophylaxis

GBS is sensitive to penicillin, which is the drug of choice because of its narrow spectrum; the alternative is ampicillin. If a mother is allergic to penicillin but not at high risk for anaphylaxis, the use of cefazolin has been proposed (Schrag et al, 2002). When patients are at high risk for anaphylaxis in which the GBS is known to be susceptible to clindamycin and erythromycin, they can receive either of these drugs intravenously (IV) until delivery. When GBS is resistant to clindamycin or erythromycin or the antibiotic susceptibility is unknown, vancomycin given every 12 hours IV until delivery is the current recommendation (Schrag et al, 2002). In the United States, GBS exhibits

considerable resistance against erythromycin (5% to 32%) and clindamycin (3% to 21%) (Castor et al, 2008). It is therefore important to have antibiotic testing done on the group B streptococcal isolates from pregnant women. For laboratories performing PCR on maternal vaginal or rectal cultures, it is recommended that the swabs be placed in a selective enrichment broth containing inhibitory antibiotics (either colistin and nalidixic acid or gentamicin and nalidixic acid) against gram-negative bacteria. If the PCR result is positive, the broth culture can be subcultured and antibiotic testing can be pursued. Because of the higher sensitivity of PCR, compared with the selective broth-enrichment culture, the organism will not grow in 10% to 15% of occasions.

Group B Streptococcal Sepsis in Neonates

The majority of infections in newborn infants occur within the first week of life and are designated as early-onset disease (Table 39-1). Late-onset infections occur in infants 7 days or older, with the majority of these infections appearing in the first 3 months of life. Although chemoprophylaxis has led to a significant decrease in the incidence of early-onset GBS disease, there is no evidence that chemoprophylaxis prevents late-onset disease (Cohen-Wolkowiez et al, 2009; Hamada et al, 2008; Jordan et al, 2008). Young infants with early-onset invasive GBS disease usually have pneumonia, sepsis, often; less often they have meningitis, osteomyelitis, or septic arthritis (Koenig and Keenan, 2009). The frequency of meningitis, osteomyelitis, or septic arthritis is higher among infants with late-onset disease.

There are nine antigenically distinct GBS serotypes, based on their capsular polysaccharide analysis (types Ia, Ib, II to VIII) and a proposed new type, IX (Diedrick et al, 2010; Henrichsen et al, 1984; Slotved et al, 2007). In the United States and Western Europe, types Ia, II, and III account for the majority of isolates from infants with early-onset disease (Diedrick et al, 2010; Zaleznik et al, 2000). However, recent studies in the United States have demonstrated that serotypes Ia, III, and V, the latter emerging in recent years (Diedrick et al, 2010; Elliott et al, 1998; Harrison et al, 1998), account for the majority (70-75%) of early-onset invasive disease in newborn infants and parturient women (Diedrick et al, 2010; Zaleznik et al, 2000). Late-onset GBS disease in infants is dominated by serotype III followed by serotypes Ia and V (Shet and Ferrieri, 2004). A polysaccharide capsule is considered the most important virulence factor (Cieslewicz et al, 2005; Kasper et al, 1996; Paoletti et al, 1997, 2001); however, the role of surface localized GBS proteins (Ferrieri et al, 2004a; Johnson and Ferrieri, 1984; Lindahl et al, 2005; Smith et al, 2004) in pathogenesis and immune protection has gained favor (Maione et al, 2005; Tettelin et al, 2005).

The remaining GBS isolates from invasive disease consist primarily of types Ib and II, but types IV, VI, VII, and VIII compose a small fraction. Type IV GBS represented between 0.4% and 0.6% of colonizing GBS isolates (Diedrick et al, 2010), but it was relatively uncommon for type IV isolates to be found in invasive GBS (Ferrieri et al, 2008; Puopolo and Madoff, 2007). Recent studies in the United Arab Emirates, Turkey, and Zimbabwe showed large proportions of type IV GBS among their isolates (Amin et al, 2002; Diedrick et al, 2010; Ekin and Gurturk, 2006; Moyo et al, 2002). In Zimbabwe it was the fourth most common serotype, comprising 4.6% of the colonizing and invasive isolates (Moyo et al, 2002). Serotypes VII and VIII are uncommon in Western countries.

Infected infants have low levels of type-specific antibody to the infecting GBS serotype (Baker and Edwards, 2003). Vaccines against the common GBS serotypes have been shown to elicit a specific antibody response in humans (Baker and Edwards, 2003; Kasper et al, 1996; Paoletti et al, 1997, 2001). Sera from these vaccinated individuals protected against GBS challenge in neonatal mice, thereby showing the potential of vaccines to prevent invasive neonatal GBS disease in infants (Paoletti et al, 1997). The prospect of a multivalent GBS vaccine, with or without conjugated GBS surface localized proteins, makes the study of the common GBS serotypes important because of the possibility of serotype replacement or capsular switch (Cieslewicz et al, 2005; Lipsitch, 1999; Maione et al, 2005; Tettelin et al, 2005).

TABLE 39-1 Manifestations of Early-Onset and Late-Onset Group B Streptococcal Disease

Characteristic	Early-Onset Disease	Late-Onset Disease
Age at onset	Birth through day 6 of life	Day 7 to 3 months
Symptoms	Respiratory distress, apnea	Irritability, fever, poor feeding
Findings	Pneumonia, sepsis	Sepsis, meningitis, osteoarthritis
Maternal obstetrical complications	Frequent	Uncommon
Mode of transmission	Vertical, in utero, or intrapartum	Nosocomial, horizontal
Predominant serotypes	Ia, III, V*	III, Ia, V*
Effect of intrapartum antibiotic prophylaxis recommended by the Centers for Disease Control and Prevention	Reduces incidence by 85%-90%	No effect

*In decreasing order of frequency

ESCHERICHIA COLI INFECTIONS

Historically, *E. coli* has been the second-most common pathogen causing sepsis and meningitis in newborn infants. The antigenic structure of *E. coli* is complex, composed of approximately 150 somatic or cell wall O antigens, 50 flagellar H antigens, and approximately 80 capsular K antigens. However, a limited number of K antigen *E. coli* strains cause meningitis, and approximately 80% of the strains causing meningitis and 40% of the strains causing bacteremia or sepsis express K1 (Mulder et al, 1984). The capsular K1 polysaccharide antigen is highly homologous to the capsular antigen of group B *Neisseria meningitidis*. Because a high percentage of women may have bacteriuria with strains of *E. coli* that express the K1 antigen or are

colonized with it at the time of delivery, it is surprising that *E. coli* sepsis or meningitis is not more common. It has been estimated that disease occurs in 1 in 100 to 200 infants colonized by K1 *E. coli*. Surveillance data from the National Institute of Child Health and Human Development Neonatal Research Network, a consortium of 16 U.S. academic neonatal centers, revealed that in the era of widespread implementation of antibiotic prophylaxis, *E. coli* sepsis increased from 3.2 to 6.8 cases per 1000 live births. This increase was observed in the 1998-2000 era and persisted in 2002 to 2003. Approximately 85% of *E. coli* infections in very low-birthweight (VLBW) infants were ampicillin resistant (Stoll et al, 2002). However, most evidence suggests that intrapartum antibiotic prophylaxis has not been associated with a concomitant adverse impact of increasing *E. coli* or other non-GBS bacterial causes. Among preterm infants, however, the incidence of *E. coli* and ampicillin-resistant *E. coli* infections increased significantly (Bizzarro et al, 2005). A recent retrospective case-control study between 1997 and 2001 concluded that exposure to intrapartum antibiotic prophylaxis therapy in mothers did not increase the odds of invasive, early-onset *E. coli* infection. In fact, among full term infants, exposure to 4 hours or greater of intrapartum antibiotic therapy was associated with decreased odds of early-onset *E. coli* infection (Schrag et al, 2006).

LISTERIA MONOCYTOGENES INFECTIONS

Listeria monocytogenes is a small, facultatively anaerobic, gram-positive motile bacillus that produces a narrow zone of beta hemolysis on blood agar plates, and can be confused with GBS unless a careful Gram stain, a catalase reaction, and other tests are performed. Most disease is due to three primary serotypes: 1a, 1b, and 4b. The last serotype has been described in most outbreaks of listeriosis (Posfay-Barbe and Wald, 2009). Most cases of listeriosis appear to be food borne, including those acquired by pregnant women.

Foods that can be contaminated by *L. monocytogenes* include raw vegetables such as cabbage, raw milk, fish, poultry, processed chicken, beef, and hot dogs (Schlech, 2000). Transmission to the fetus occurs through either a hematogenous (transplacental) route or via an ascending infection through the birth canal. Frequently, infections with *Listeria* spp. early in gestation result in abortion; later in pregnancy, infection with *Listeria* spp. can result in premature delivery of a stillborn or infected newborn. Approximately 70% of *Listeria*-infected women deliver before 35 weeks' gestation. Illness in the mother may be undetected because of vague influenza-like illnesses that may not come to medical attention. In approximately half of perinatal cases, illness in the mother has preceded delivery by 2 days to 2 weeks. At autopsy of stillborn infants or of those who die in the perinatal period, granulomas may be found throughout such organs as the liver and lungs, and infection is widely disseminated, including involvement of the meninges. Treatment of *Listeria* spp. infection or bacteremia during pregnancy can prevent infection in the fetus (Kalstone, 1991). Like GBS infection, *Listeria* spp. infection may have either an early-onset or late-onset presentation. Epidemics of neonatal *Listeria* spp. infection have been described after ingestion of contaminated foods such as cheese or coleslaw. The first clearly documented food borne (coleslaw) outbreak of listeriosis was in 1981 from the Eastern Maritimes in Canada (Schlech, 2000); it was associated with a fatality rate of 27%. There are reports of repeated abortions in women with colonization in the gastrointestinal tract, and cold-enrichment cultures can be performed to try to detect fecal carriage in such women. However, cold enrichment cultures are inferior to selective media for *Listeria* spp. in isolating the organism from various foods or stool specimens. Rapid antigen tests based on nucleic acid amplification are not in common use in clinical diagnostic laboratories. There is no current vaccine for *Listeria* spp. infection, but preventive measures have included the surveillance programs from the U.S. Department of Agriculture, prohibiting the sale of contaminated meats. Between 1996 and 2006, the incidence of *Listeria* spp. infections declined by 36%; however, an outbreak of disease in 2002 related to contaminated turkey meat led to 54 illnesses, eight deaths, and three fetal deaths in nine states (Posfay-Barbe and Wald, 2009).

MISCELLANEOUS BACTERIAL PATHOGENS

Bacteria responsible for early-onset neonatal sepsis have changed dramatically over time. There are regional differences in the organisms commonly responsible for early-onset sepsis. In addition to the organisms mentioned previously, other bacterial pathogens associated with early-onset bacteremia or sepsis in newborn infants are *Enterococcus* spp., viridans group *Streptococcus* spp., *Klebsiella* spp., *Enterobacter* spp., *Haemophilus influenzae* (typeable and nontypeable), *S. aureus*, *Streptococcus pneumoniae*, group A streptococcus and other beta-hemolytic streptococci, and coagulase-negative staphylococci.

CLINICAL SIGNS OF BACTERIAL SEPSIS

There is great variability in the clinical presentations of infants with early-onset bacterial sepsis (Box 39-1). Most infants exhibit respiratory distress in the first 12 hours of life, frequently immediately after birth. In these infants, the progression may be rapid with cardiovascular instability, shock, and death. Presentation within the first 12 hours of life suggests that the infection with pneumonia and bacteremia occurred at or near the time of birth

BOX 39-1 Common Clinical Signs of Neonatal Sepsis

- Abnormal neurologic status: irritability, lethargy, poor feeding
- Abnormal temperature: hyperthermia or hypothermia
- Apnea
- Bleeding problems: petechiae, purpura, oozing
- Cardiovascular compromise: tachycardia, hypotension, poor perfusion
- Cyanosis
- Gastrointestinal symptoms: abdominal distention, emesis, diarrhea
- Jaundice
- Respiratory distress: tachypnea, increased work of breathing, hypoxemia
- Seizures

		Bacterial Infection Present		
		YES	NO	
Laboratory Test Result	POSITIVE	True Positive TP	False Positive FP	Positive Predictive Value = (TP)/(TP+FP)
	NEGATIVE	False Negative FN	True Negative TN	Negative Predictive Value = (TN)/(FN+TN)
		Sensitivity = (TP)/(TP+FN)	Specificity = (TN)/(FP+TN)	

FIGURE 39-1 Diagram of the relationships among sensitivity, specificity, positive predictive value, and negative predictive value. *FN*, Number with infection incorrectly diagnosed as healthy by the test. *FP*, number of healthy infants incorrectly diagnosed as infected by the test; *TN*, number of healthy infants correctly diagnosed as not infected by the test; *TP*, number of infants with infection correctly diagnosed by the test.

or during the immediate postnatal period. Infants with hypoxia in utero may gasp, inhaling contaminated amniotic fluid and setting the stage for early-onset pneumonia, bacteremia, and sepsis.

The signs of early-onset infection may be subtle, with tachypnea suggesting "wet lung disease" or may be more overt with grunting, flaring, and subcostal and intercostal retractions. Because the signs of sepsis can be relatively nonspecific, such as poor feeding and increased sleepiness, they can be overlooked. In newborn or intermediate or intensive care nurseries, one must be attuned to subtle abnormal findings in newborn infants. The clinical signs of neonatal sepsis include hyperthermia or hypothermia, respiratory distress, apnea, cyanosis, jaundice, hepatomegaly, abdominal distention, feeding abnormalities, and neurologic abnormalities. Autopsy findings in preterm infants with fatal early-onset GBS infection suggested that surfactant deficiency respiratory distress syndrome was common (Payne et al, 1988).

LABORATORY TESTING

There are many laboratory tests that have been evaluated for infants with possible sepsis, and the results must be interpreted with caution, assessing the sensitivity and specificity of a particular test as well its positive and negative predictive accuracy (Figure 39-1). The sensitivity of a test is defined as the proportion of individuals with proven or probable sepsis in whom the result is abnormal; the specificity is the proportion of healthy or noninfected infants in whom the result is normal. Ideally, a test would have a high sensitivity and a high specificity, but this is rarely achievable. High sensitivity is the most desirable characteristic when dealing with serious and treatable diseases such as neonatal sepsis. Because sepsis is generally treated with antibiotic agents that have a low toxicity, diagnostic tests do not need to have a high specificity, but should have a high sensitivity, which will allow sepsis to be excluded. A positive predictive accuracy is the probability that an infant with an abnormal laboratory result is infected; a negative predictive value is the probability that infection with a normal or negative result is free of infection. The more sensitive the test, the greater its negative predictive value; the more specific a test, the higher its positive predictive value.

MICROBIOLOGIC CULTURES

Previously, cultures of superficial body sites in newborn infants (external auditory canal, gastric aspirate, umbilicus, and nasopharynx) were used to identify bacterial pathogens when more specific blood culture results were negative. Most centers no longer use surface cultures to make clinical decisions regarding either the institution or the discontinuation of antibiotic therapy, because surface cultures are of limited value in predicting the etiology of bacterial sepsis in newborn infants (Evans et al, 1988; Shenoy et al, 2000). Examination of gastric aspirates by Gram stain as a screening mechanism has also lost favor, as has examination for PMNs. Although the presence of increased numbers of PMNs may represent amnionitis and an inflammatory response, these cells may reflect a maternal origin and have no specificity in predicting bacterial sepsis for the infants (Vasan et al, 1977).

Blood Cultures

The gold standard for detection of bacteremia in newborn infants with suspected sepsis is a positive blood culture. With the introduction of newer blood culture detection instruments that are semiautomated and examined for the presence of growth by CO_2 production by the internal computer of the instrument every minute, the sensitivity of detecting positive blood cultures has increased. Another variable that influences the sensitivity of detection of bacteremia is the volume of blood obtained and placed in the culture bottles. Ideally 1 to 3 mL of blood from infants should be obtained, but this not always possible in very small infants. Most positive blood cultures are detected within 24 to 48 hours using the new technology (Garcia-Prats et al, 2000). However, the use of intrapartum antibiotics for prophylaxis in mothers with either GBS colonization or suspected amnionitis on account of any cause can reduce the ability to detect bacteremia in newborn infants. In a term infant who was asymptomatic at the initiation of antibiotic therapy, it may be reasonable to stop antibiotic administration if the blood cultures remain negative after 48 hours. However, the decision to discontinue treatment with antibiotics should include the assessment of results of other laboratory tests used for sepsis screens, and should not solely rely on a negative blood culture. When

TABLE 39-2 Predictive Values of Components of the White Blood Cell Count and of C-Reactive Protein

Laboratory Result	Sensitivity (%)	Specificity (%)	Predictive Value (%)	
			Positive	Negative
ANC <1750 cells/mm^3	38-96	61-92	20-77	96-99
ANC <10% (≈5580 cells/mm^3 for term)	48	73	4	98
I/T ratio ≥0.2	90-100	30-78	11-51	98
I/T ratio ≥0.3	35	89	7	98
CRP > 1mg/dL	70-93	78-94	27	100

the suspicion of sepsis is high, clinicians should consider continuing antibiotic therapy for a complete course despite negative blood cultures (Ottolini et al, 2003).

Urine Cultures

The frequency of positive urine cultures in infants with early-onset sepsis is relatively low, and it is rare to find bacteriuria in infants with negative blood culture results (DiGeronimo, 1992). Infants with late-onset sepsis tend to have a higher rate of positive urine cultures (Visser and Hall, 1979). In the era of widespread intrapartum antibiotic prophylaxis in the mother, positive urine cultures may be obscured because of excretion of antibiotics in the urine of newborn infants. When pyelonephritis is found in newborn infants, it likely represents metastatic seeding of the kidney during a bout of bacteremia. In the first 72 hours of life, because the yield from urine cultures is low, it is not generally recommended to obtain these specimens. However, in the older newborn infant, a urine sample collected by an aseptic technique (urinary catheter or suprapubic bladder aspiration) is an important part of the sepsis workup.

Cerebrospinal Fluid

Lumbar punctures are deferred in infants with any instability or uncorrected bleeding disorders. The details of examination of cerebrospinal fluid and the diagnostic approach for examining cerebrospinal fluid will be discussed under the section on bacterial meningitis.

WHITE BLOOD CELL COUNT AND NEUTROPHIL INDICES

Normal white blood cell (WBC) counts range from 9000 to 30,000 cells/mm^3 at the time of birth, and differences in the site of sampling can affect these values. The absolute neutrophil count (ANC), the absolute band count of immature neutrophils, and the ratio of immature neutrophils to total neutrophils (I/T) are regarded as more useful than total leukocyte counts in the diagnosis of neonatal sepsis.

The lower limit or total neutrophil count rises to 7200 cells/mm^3 by 12 hours of age, and then declines to approximately 1720 cells/mm^3 by 72 hours of age (Manroe et al, 1979; Schmutz et al, 2008). Postnatally the absolute band count also undergoes similar changes, with peak values of 1400 cells/mm^3 at 12 hours of age, and then declines. In contrast, the I/T ratio is maximum at birth and then declines to a value of 0.12 beyond 72 hours of age (Manroe et al, 1979; Schelonka et al, 1994). However, in VLBW infants there is a greater reference range for the total neutrophil counts (Manroe et al, 1979; Mouzinho et al, 1994). There are no significant differences in I/T ratio or absolute immature neutrophil counts in VLBW infants. There is considerable overlap of the cutoff values of the ANC, absolute band count, and I/T ratio between healthy and infected newborns.

There are a number of clinical conditions that affect the total neutrophil count. Prolonged crying, meconium aspiration syndrome, maternal fever, and asphyxia are all associated with an increase in the total neutrophil count, and there may be an increase in the total immature neutrophil forms, as well as an increased I/T ratio. Maternal hypertension is associated with a decrease in total neutrophils. At high altitudes, a higher upper limit of neutrophil values occurs (Schmutz et al, 2008).

In approximately two thirds of infants with sepsis, the total neutrophil count is abnormal. Neutropenia is the best predictor of sepsis, whereas neutrophilia does not correlate well. The absolute neutrophil band count is not a sensitive marker of sepsis, but has a relatively good predictive value and specificity. The I/T ratio is considered to have the best sensitivity of all of the neutrophil indices (Table 39-2) (Gerdes, 2004).

PLATELET COUNTS

Approximately 25% to 30% of infants exhibit thrombocytopenia at the time of diagnosis of sepsis, and this frequency increases during the course of infection. Accelerated platelet destruction and possibly depressed production caused by bacterial products on the bone marrow are the underlying mechanisms for thrombocytopenia in infected infants. Disseminated intravascular coagulation may be seen in some infants with severe sepsis.

ACUTE PHASE REACTANTS AND ERYTHROCYTE SEDIMENTATION RATE

A number of acute phase reactants have been studied to help identify infants with likely sepsis. Most biochemical markers currently in use are derived from components of

the complex inflammatory response to an invading pathogen. These markers have been studied during the past 20 years and continue to be under investigation. Of issue is the availability of tests for these inflammatory mediators when investigating an infant with possible sepsis, and the value of these tests in assisting with the early diagnosis of sepsis. It is known that some proinflammatory cytokines peak rapidly, within 1 to 4 hours after a sepsis stimulus (Lam and Ng, 2008). C-reactive protein (CRP) rises to a maximum at 12 to 24 hours, and procalcitonin (PCT) rises at 4 hours, peaks at 6 hours, and plateaus 8 to 24 hours after a stimulus. CRP is induced by proinflammatory cytokines. Among the early markers are the proinflammatory mediators, such as IL-1β, IL-6, the chemokine IL-8, TNF-α, and interferon gamma; these activate host defenses against bacterial and other infecting agents, whereas antiinflammatory mediators such as IL-4, IL-10, and transforming growth factor β_1 (TGF-β_1) are important in regulating and limiting the inflammatory response, thus preventing an excessive reaction that could lead to organ damage and tissue cell death (Mehr and Doyle, 2000). Survival should be considered a fine balance between the proinflammatory cytokines and the antiinflammatory mediators. Because of the limitations of other assessment markers of potentially infected neonates, such as WBC counts and band counts, the advantages of having a surrogate marker readily available are apparent.

CRP is probably the most studied acute phase reactant in neonatal sepsis (Benitz et al, 1998; Jaye and Waites, 1997; Lam and Ng, 2008; Weitkamp and Aschner, 2005). Monitoring of CRP levels has been widely promulgated as a way to diagnose neonatal infection and to adjust the duration of antibiotic therapy in infants with suspected versus proven sepsis (Benitz et al, 1998; Ehl et al, 1997; Gerdes, 2004; Philip and Mills, 2000). Depending on the laboratory, a CRP value of 1 to 8 mg/dL is considered the upper limit of normal; it is important to know the different cutoff values in the laboratory supporting one's neonatal units. Theoretically, results can be available within 30 minutes. CRP is produced by the liver in response to stimulation by the proinflammatory cytokine IL-6, which is produced by both T and B cells (Lam and Ng, 2008; Weitkamp and Aschner, 2005). Because exposure of the host to bacterial products results in a substantial and rapid increase in IL-6 concentrations, it appears that IL-6 is potentially a more useful marker than CRP during the early phase of an infection. In one study, the IL-6 concentration had a sensitivity of 89% versus 60% for CRP at the onset of clinical suspicion of a neonatal infection (Lam and Ng, 2008). The negative predictive values of IL-6 are much higher than those for CRP (Lam and Ng, 2008), and this was also found in cord blood IL-6 levels, where the sensitivity of detection was high. This finding can be useful in deciding which infants do not require antibiotic therapy and those in whom antibiotics can be discontinued after a relatively short course.

In a recent study, the high-sensitivity CRP (hsCRP) measurement has been shown to provide increased sensitivity for detecting neonatal infection (Edgar et al, 2010). Not all diagnostic laboratories can provide hsCRP in a timely fashion. In addition, the optimum diagnostic cutoff levels for CRP and hsCRP are debatable.

A recent study examined the combination of hsCRP, serum soluble intercellular adhesion molecule 1 (slSAM-1), soluble E-selectin (sE-selectin), and serum amyloid A, individually and in combination, for the diagnosis of sepsis in a neonatal intensive care unit (Edgar et al, 2010). In this study, all four measurements had some diagnostic value for neonatal infection; however, s1SAM-1, hsCRP, and sE-selectin demonstrated the highest negative predictive value individually (sISAM, 84%; hsCRP, 79%; and sE-selectin, 74%) (Edgar et al, 2010). Use of a combination of these measurements enhanced the diagnostic value, with sensitivities of 90.3% and a negative predictive value of 91.3% (Edgar et al, 2010). However, the application of this set of diagnostic markers is not available for most facilities, and more investigative work is needed to confirm their role in excluding early-onset infection.

In another study, early markers (IL-6, TNF-α, IL-8, interferon gamma, CRP, IL-18, the antiinflammatory cytokine IL-10, the I/T ratio, and PCT, a later marker of infection) were studied for use in detection of early-onset sepsis in 123 newborn infants (Bender et al, 2008). This study concluded that IL-6 combined with PCT was a fair measure of evaluating early-onset infection, and that the traditional I/T ratio was almost as efficient as IL-6. Combining an early marker such as IL-6 and an I/T ratio may reduce the number of diagnostic tests and nonconclusive values. The combined value of IL-6 and PCT at the first blood drawing had a sensitivity of 71% and specificity of 88% (Bender et al, 2008).

There are many studies of procalcitonin in the literature, and most have concluded that procalcitonin is superior to CRP levels in the early diagnosis of neonatal sepsis (Lam and Ng, 2008). PCT is the precursor of calcitonin, normally synthesized in the C-cells of the thyroid gland. PCT is induced by systemic inflammation and bacterial sepsis and is produced by such cells as hepatocytes, nephrons, and monocytes. The physiologic function of PCT is unknown. In bacterial infections, plasma PCT concentrations increase from 0.001 to 0.01 ng/mL (baseline range) to values ranging from 1 to 1000 ng/mL. PCT concentrations rise much faster than CRP (6 to 8 hours versus 48 hours for maximum levels). In healthy newborn infants, plasma PCT concentrations increase gradually after birth, reaching peak levels at approximately 24 hours of age (range, 0.1 to 20 ng/mL) and then decrease to normal values less than 0.5 ng/mL by 48 to 72 hours of age (Stocker et al, 2010). Various studies on the use of PCT as a marker of neonatal sepsis have yielded contradictory results regarding its application to clinical decision making for both diagnosis and adjustment of the length of antibiotic therapy. In a recent study of 121 newborn infants with suspected early-onset sepsis, serial PCT determinations allowed shortening of the duration of antibiotic therapy (Stocker et al, 2010). However, there are currently few institutions or intensive care units that are applying PCT as a regular measurement for diagnosis or for adjustment of length of antibiotic therapy. Larger studies are needed to determine the true value of PCT in diagnosis and therapy.

To date, studies on the role of various cytokine determinations in assisting with diagnosis and treatment of early-onset sepsis are intriguing, but have not translated to widespread use. Other molecular technologies are also

being studied to diagnose neonatal sepsis by the rapid identification and differentiation of gram-negative and gram-positive bacterial bloodstream infections. PCR, using universal bacterial primers, targets conserved regions of the 16SrRNA gene common to all bacteria, but not found in other organisms (Dutta et al, 2009). In one study, universal primer PCR was performed in newborn infants with clinically suspected sepsis. PCR was performed before starting antibiotic therapy, and repeated at 12, 24, and 48 hours after starting drug therapy (Dutta et al, 2009). The sensitivity, specificity, and positive and negative predictive values of universal primer PCR were 96.2%, 96.3%, 87.7%, and 98.8% respectively. Results of testing in two patients were blood culture positive, but 0-hour PCR negative, and results in 7 patients were 0-hour PCR positive, but blood culture result was negative. Of the patients with a result of 0-hour PCR positive, 7 remained positive at 12 hours but none remained positive at 24 and 48 hours after starting antibiotic therapy. Although universal bacterial primer PCR may be a useful test for diagnosing an early episode of culture-proven sepsis, it cannot be used for diagnosis if the patient has been exposed to 12 hours or more of antibiotic therapy (Dutta et al, 2009). Much larger studies are certainly required before this assay can be recommended for routine clinical use in newborn infants suspected of sepsis.

PREVENTION

INTRAPARTUM ANTIBIOTIC PROPHYLAXIS

There were initial concerns about adverse effects of implementing the CDC consensus strategies, but these have proved unwarranted. The primary risks considered were maternal anaphylaxis from administered antibiotics, and these were unfounded. The possibility of the emergence of infections in mothers and infants caused by antibiotic resistant organisms (e.g., *E. coli*) was addressed in part by studies conducted by the Neonatal Network of the National Institute of Child Health and Human Development. In 2002, they reported a change in the pathogens causing early-onset sepsis, with an increase in sepsis caused by *E. coli* from 3.2 to 6.8 per 1000 live births (Stoll et al, 2002). Most of the *E. coli* isolates were resistant to ampicillin. Mothers of infants with ampicillin-resistant *E. coli* infections were more likely to have received intrapartum antibiotic prophylaxis than were those with ampicillin-sensitive strains (Stoll et al, 2002). In another study comparing a period of no prophylaxis to periods of risk-based and universal screening-based prophylaxis, no change in the incidence of infection with ampicillin-resistant organisms was observed overall or among VLBW infants (Puopolo and Eichenwald, 2010). However, an increased proportion of infections was caused by ampicillin-resistant organisms. Mothers of infants with ampicillin-resistant infections were also more likely to have been treated with ampicillin (Chen et al, 2005). A 10-year study of the effect of intrapartum antibiotic prophylaxis on GBS and *E. coli* sepsis in Australasia revealed a steady decline in early-onset GBS infection, but also a trend to decreasing early-onset *E. coli* sepsis in all infants and a stable rate for this infection in VLBW infants (Daley et al, 2004).

INTRAPARTUM MANAGEMENT OF PARTURIENTS

The universal GBS screening strategy recommended by the CDC is done at 35 to 37 weeks' gestation. Antepartum antibiotic therapy is recommended for women with a previous infant with invasive GBS disease, a positive GBS screening culture result during pregnancy, unknown GBS status (culture either not performed or incomplete or results unknown), and any of the following features: delivery before 37 weeks' gestation, rupture of chorioamniotic membranes for greater than 18 hours, intrapartum temperature of 100.4° F (38° C) or higher, and GBS bacteriuria during pregnancy.

Women who are not allergic to penicillin can be given penicillin G (5,000,000 units as a loading IV dose followed by 2.5 million units every 4 hours until delivery) or ampicillin (2g IV as a loading dose followed by 1g every 4 hours until delivery). For women who are allergic to penicillin, the recommendation is to determine, ideally during prenatal care, whether the patient is at high risk for anaphylaxis (i.e., history of immediate hypersensitivity reactions). Women who are not at high risk for anaphylaxis can receive cefazolin (2g IV and 1g IV every 8 hours until delivery). Women who are at high risk for anaphylaxis whose GBS isolate is not resistant to clindamycin or erythromycin can receive clindamycin (900 mg IV every 8 hours until delivery) or erythromycin (500 mg IV every 6 hours until delivery) (Schrag et al, 2002). Women with clindamycin-erythromycin–resistant GBS isolates can receive vancomycin (1g IV every 12 hours until delivery).

INTRAVENOUS IMMUNE GLOBULIN FOR PREVENTION OF EARLY-ONSET SEPSIS

Premature infants are susceptible to early-onset sepsis because of diminished transplacental transfer of immunoglobulins and decreased synthesis of immunoglobulin (Ig) G. An intravenous infusion of immunoglobulin (IVIg) will increase the typically low levels of serum immunoglobulin in preterm infants, and it has been proposed to improve immune function that may lead to improved clinical outcome (Wynn et al, 2009). Clinical trials examining the possible benefit of IV-Ig began over 15 years ago (Chirico et al, 1987; Conway et al, 1990; Haque et al, 1986). The very premature infants are the group most likely to receive and potentially benefit from these adjuvant treatments and preventative interventions. A Cochrane metaanalysis showed a reduction in mortality of newborn infants treated with IV-Ig for what were subsequently proved to be bacterial infections (relative risk, 0.55; 95% confidence interval, 0.31 to 0.98) (Ohlsson and Lacy, 2010). However, a review of the studies included in the metaanalysis revealed the inclusion of few very premature infants. A large international, placebo-controlled, double-blind, randomized clinical trial has recently been undertaken in approximately 5000 newborn infants to examine the benefit of polyclonal IV-Ig treatment for proven or suspected sepsis (Wynn et al, 2010). However, because randomization will allow the inclusion of neonates of all gestational and postnatal ages with suspected or proven infection, the subgroup sample sizes may leave the issue of clinical efficacy for

early- and late-onset sepsis in the different gestational age groups unanswered. A metaanalysis that included almost 4000 preterm (<37 weeks' gestation) or low birthweight (<2500 g) infants showed a modest reduction in the development of sepsis after IV-Ig prophylaxis in preterm neonates (Wynn et al, 2010). Currently available data do not support the suggested immunologic enhancements expected for IV-Ig in very premature neonates. There is continued interest in the potential of IV-Ig as treatment or prophylaxis for infection in very premature infants, but large trials are needed to provide convincing data.

Other immunomodulating factors such as granulocyte colony-stimulating factor (G-CSF) have been studied to both prevent and treat neonatal sepsis. An earlier metaanalysis showed that G-CSF administration improved mortality in all neonates and in the subgroups of neutropenic and preterm infants (Bernstein et al, 2001). A recent Cochrane metaanalysis concluded that prophylaxis with G-CSF does not significantly reduce mortality in all infants, although in premature infants with neutropenia (ANC < 1750) mortality may be improved (Carr et al, 2009). It is possible that combination therapies using IV-Ig and other immunomodulating factors, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), G-CSF, and complement-containing blood products, may lead to improved immune function in these highly susceptible infants; however, these studies are not currently being conducted.

DIAGNOSTIC APPROACH TO NEONATES WITH SUSPECTED SEPSIS

Obviously, all symptomatic newborn infants must be carefully evaluated for the possibility of bacterial sepsis and treated with antibiotics, if necessary. Although the presence of various risk factors should increase the suspicion of sepsis, the absence of risk factors in a symptomatic infant cannot be dismissed. In adjusting to postnatal life, some infants exhibit abnormal signs transiently, such as tachypnea, before becoming asymptomatic. However, any infant who has other findings or is still symptomatic with only one finding by 6 hours of life should have a diagnostic evaluation performed with a complete blood cell count (CBC) and differential, a blood culture, and as appropriate, a lumbar puncture and a chest radiograph. Antibiotic therapy can be stopped when the physical findings are normal, the clinical suspicion of sepsis is low, and the screening results for sepsis, including the blood culture, remain negative. If the blood culture result is positive, the lumbar puncture findings abnormal, or there are clinical signs of sepsis, then the infant should be treated with an appropriate course of antibiotics (Figure 39-2).

Management of the asymptomatic infant with risk factors for sepsis is more controversial. Escobar et al (2000) retrospectively reviewed 2785 newborns with birthweight greater than 2000 g and who were evaluated for sepsis after birth. Asymptomatic status was associated with a significantly decreased odds ratio for infection. Low absolute neutrophil count and meconium-stained amniotic fluid were associated with an increased risk of infection. The highest infection rates occurred in infants whose mother had a clinical diagnosis of "definite" chorioamnionitis, but chorioamnionitis was significantly associated with an increased risk of neonatal infection only in infants whose mothers had not received intrapartum antibiotics (Escobar et al, 2000).

Current practice management for the infant with no signs or symptoms of sepsis, but with risk factors such as maternal chorioamnionitis or incomplete GBS maternal prophylaxis, includes performing a limited sepsis evaluation (CBC with differential and blood culture). If the WBC count, absolute neutrophil count, and the I/T ratio are all normal, then the infant is usually observed in the hospital and discharged at approximately 48 hours. If the screening tests are abnormal, the infant undergoes a complete sepsis evaluation with subsequent antibiotic therapy initiated.

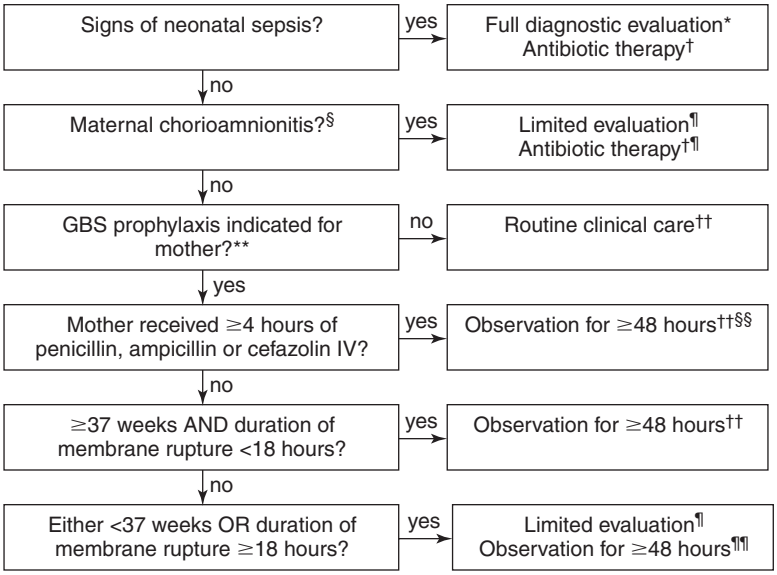
Recent CDC and American Academy of Pediatrics guidelines for the prevention of early-onset neonatal GBS sepsis have a slightly different approach to management of the at-risk asymptomatic infant (see Figure 39-2; Verani and Schrag, 2010). If there are signs of sepsis in the newborn, then a full sepsis workup and antibiotic therapy are recommended. If there is maternal chorioamnionitis, a limited sepsis evaluation and antibiotic are recommended. For infants whose mother received greater than 4 hours of antibiotic therapy, it is recommended that the infant be observed in the hospital for approximately 48 hours. For infants whose mother did not receive more than 4 hours of antibiotic prophylaxis, a 48 hour in-hospital observation is recommended. If the infant is less than 37 weeks' gestation, or the duration of rupture of membranes is greater than or equal to 18 hours, then a limited evaluation and observation in the hospital for approximately 48 hours are recommended.

TREATMENT

ANTIMICROBIAL THERAPY

The choice of antibiotic administration for an infant with suspected early-onset sepsis depends on the predominant bacterial pathogens and the antibiotic susceptibility profiles for the microorganisms causing early-onset disease in a particular geographic region. Any decision to discontinue antimicrobial therapy should be based on the level of suspicion for sepsis at the time treatment was begun, the culture results, laboratory test results, and the clinical behavior and course of the infant. If sepsis is highly suspected in an infant, antibiotics should be considered for a full course even if the culture results are negative.

Empiric therapy for early-onset sepsis generally consists of combinations of antibiotics effective against gram-positive (e.g., GBS, *L. monocytogenes*) and gram-negative pathogens (e.g., *E. coli*). The two most commonly used combinations are (1) ampicillin with an aminoglycoside, usually gentamicin, and (2) ampicillin with a third-generation cephalosporin, usually cefotaxime. Cefotaxime has minimal toxicity and is well tolerated by newborn infants. However, the third-generation cephalosporins, as well as vancomycin, a glycopeptide antibiotic, have been associated with the development of vancomycin-resistant enterococci and, in the case of cephalosporins, with the induction of various β-lactamase producing gram-negative bacteria, including extended-spectrum β-lactamase producing organisms (Bryan et al, 1985). These latter bacteria



* Includes CBC with differential, platelets, blood culture, chest radiograph (if respiratory abnormalities are present), and LP (if patient stable enough to tolerate procedure and sepsis is suspected).

† Antibiotic therapy should be directed towards the most common causes of neonatal sepsis including GBS and other organisms (including gram negative pathgoens), and should take into account local antibiotic resistance patterns.

§ Consultation with obstetric providers is important to determine the level of clinical suspicion for chorloamnionitis. Chorioamnionitis is diagnosed clinically and some of the signs are non-spedific.

¶ Includes blood culture (at birth), and CBC with differential and platelets. Some experts recommend a CBC with differential and platelets at 6-12 hours of age.

** GBS prophylaxis indicated if one or more of the following: (1) mother GBS positive at 35-37 weeks' gestation, (2) GBS status unknown with one or more intrapartum risk factors including <37 weeks' gestation, ROM ≥18 hours or T ≥100.4°F (38.0°C), (3) GBS bacteriuria during current pregnancy, (4) history of a previous infant with GBS disease.

†† If signs of sepsis develop, a full diagnostic evaluation should be done and antibiotic therapy initiated.

§§ If ≥37 weeks' gestation, observation may occur at home after 24 hours if there is a knowledgeable observer and ready access to medical care.

¶¶ Some experts recommend a CBC with differential and platelets at 6-12 hours of age.

FIGURE 39-2 Algorithm for recommended management of newborns at risk for group B streptococcal disease. *(Adapted from Verani JR, Schrag SS: Group B streptococcal disease in infants: progress in prevention and continued challenges,* Clin Perinatol *37:375-392, 2010.)*

are resistant to all β-lactam antibiotics and frequently are resistant to other antibiotics, but not to meropenem. Another disadvantage of the cephalosporin antibiotics is the lack of effectiveness against enterococci or *L. monocytogenes*. *L. monocytogenes* is usually treated with ampicillin and an aminoglycoside until the blood culture result is negative and the infant has shown an improved outcome. In infants with bacteremia and sepsis caused by GBS, gentamicin is frequently combined with ampicillin or penicillin, although there are no data to suggest that the addition of the aminoglycoside improves outcome. However, it is common practice to use the combination of these two drugs during the first few days of therapy and then to continue the full course of therapy with ampicillin or penicillin alone.

When the likelihood of infection is very low, the antibiotic therapy should be stopped. In most hospitals using modern blood culture instrumentation, 48 hours should be considered sufficient to determine whether a blood culture result is negative, assuming that no antibiotics were being given when the culture was obtained (Garcia-Prats et al, 2000). Blood culture bottles with antimicrobial binding resins are in common use in microbiology laboratories, enhancing the ability to demonstrate positive blood cultures. Infants with proven bacteremia, but without meningitis, are commonly treated for 7 to 10 days. The use of antibiotics with nephrotoxicity (i.e., aminoglycosides) should be monitored using appropriate drug levels.

IMMUNOLOGICAL THERAPIES FOR TREATMENT OF EARLY-ONSET SEPSIS

Various adjunctive therapies have been proposed to improve the immune status of the infant in an attempt to mitigate the mortality of neonatal sepsis. These included IV-Ig, granulocyte transfusions and G-CSF or GM-CSF treatment. Overall, there are insufficient data to recommend the routine use of any of these therapies for the treatment of sepsis in newborn infants. However, mortality in cases of subsequently proven infection was reduced in the IV-Ig–treated infants, and a large randomized controlled trial of IV-Ig use was recently completed (Ohlsson and Lacy, 2010). Clinical studies also did not show that granulocyte transfusions provided a significant benefit to neonates with culture-proven early-onset infections (Vamvakas and Pineda, 1996). However, in infants with

overwhelming sepsis, severe neutropenia, and depletion of bone marrow neutrophil stores, treatment with granulocyte transfusions improved survival (Cairo et al, 1992).

Using GM-CSF and G-CSF to enhance the quantity and quality of neutrophils has also been studied in human neonates (Carr et al, 2009). Although these agents have induced circulating numbers of neutrophils and appeared to be relatively safe, they have not significantly reduced neonatal sepsis mortality (Wynn et al, 2009). In two meta-analyses, subgroup analysis showed a significant reduction in mortality in the group of infants with systemic infection and neutropenia (Bernstein et al, 2001; Carr et al, 2009). Future studies may prove that selective use of these therapies is beneficial in specific subgroups of septic infants.

NEONATAL BACTERIAL MENINGITIS

Neonatal bacterial meningitis is ominous because of its mortality and morbidity, and it is associated with the same pathogens that cause bacterial sepsis, with GBS and *E. coli* accounting for approximately 70% of all cases, and *L. monocytogenes* accounting for an additional 5% in the first week of life. On occasion, it is possible to isolate *Streptococcus pneumoniae* and *Haemophilus influenzae*, and in infants who are older than 1 week residing in neonatal intensive care units, coagulase-negative staphylococci are the most common isolates. The underlying pathogenesis of bacterial meningitis is a seeding of the meninges during a bacteremic phase in the infant. Studies in neonatal rats have shown that high-grade bacteremia is more likely to lead to bacterial meningitis than lower grade bacteremia.

GBS meningitis (with a mortality approaching 30% and a morbidity of 50%) usually presents as late-onset disease, and the most common GBS serotype identified is III (Levent et al, 2010). In a recent paper by Ansong et al (2009), GBS meningitis complicated 22 in 145 (15%) episodes of early-onset GBS sepsis and 13 in 23 (57%) of episodes of late-onset GBS sepsis. GBS meningitis can occur in the presence of negative blood cultures, and 20% of infants in this study had negative blood cultures (Ansong et al, 2009).

Approximately 80% of all serotypes of *E. coli* that cause meningitis in newborn infants possess the K1 or capsular antigen. The K1 capsular polysaccharide antigen is considered one of the primary virulence factors of this capsular type of *E. coli*, because antibody against K1 antigen has been shown to be protective in neonatal rat models of infection. Mortality rates for neonatal *E. coli* meningitis vary from 20% to 30% in some centers and 50% to 60% in others (Dodge, 1994).

PATHOLOGY AND CLINICAL MANIFESTATIONS

At autopsy, infants who die of meningitis have purulent exudates of the meninges and the surfaces of the ventricles associated with inflammation. Historically, hydrocephalus and a noninfectious encephalopathy were demonstrated in approximately 50% of infants who died of bacterial meningitis.

The signs and symptoms of neonatal meningitis are not easy to distinguish from those of sepsis. The most common presenting symptoms are lethargy, feeding problems, instability of temperature regulation, vomiting, respiratory distress, and apnea. A bulging fontanel may be seen, but this is usually a late manifestation. Seizures are frequently observed and can be caused by either direct central nervous system inflammation or by metabolic abnormalities such as hypoglycemia or hyponatremia.

DIAGNOSIS

The gold standard for diagnosis of meningitis is the analysis of the cerebrospinal fluid, including the WBC count, glucose and protein levels, Gram stain, and culture. The interpretation of cerebrospinal fluid cell counts in newborn infants may be difficult (Garges et al, 2006; Greenberg et al, 2008; Polk and Steele, 1987; Unhanand et al, 1993). During the first week of life, the cerebrospinal fluid WBC count slowly decreases in full-term infants, but may remain high or even increase in premature infants. There is no change in cerebrospinal fluid WBC counts or protein content with gestational age, but there is a significant decrease with postnatal age (Mhanna et al, 2008). The cerebrospinal fluid cell counts, protein, and glucose concentrations from healthy infants may overlap with those from infants with meningitis, and from 1% to 10% of infants with proven meningitis have normal results on a cerebrospinal fluid analysis (Hristeva et al, 1993; Garges et al, 2006; Greenberg et al, 2008). Finally, approximately 30% of all infants with positive results of cerebrospinal fluid cultures for bacteria have negative blood culture results (Garges et al, 2006; Wiswell et al, 1995).

A Gram stain of cerebrospinal fluid must be examined carefully for every infant with suspected meningitis. The stains for approximately 20% of newborns with proven meningitis are reported as showing "no bacteria seen." Although an increase is expected in neutrophils with bacterial meningitis, one may see a predominance of lymphocytes within a conversion to PMNs. With *L. monocytogenes*, a mononuclear cellular response is found in examination of the cerebrospinal fluid. In clinical care units, it is routine to repeat the cerebrospinal fluid examination and culture 2 to 3 days after the initiation of antibiotic therapy. This examination is especially important if the patient has not responded clinically and is experiencing seizures or continued fever. At times it is difficult to eradicate the organism from the cerebrospinal fluid, and consideration can be given to examining the inhibitory and bactericidal concentrations in cerebrospinal fluid. It is especially important to repeat the cerebrospinal fluid examination before stopping antibiotics in patients with more complicated courses, and for enteric gram-negative bacterial meningitis.

THERAPY

Infants with bacterial meningitis are frequently ill and should be monitored in intensive care units when the critical needs can be met with aggressive management. These patients may require mechanical ventilation, complex fluid management to attenuate the effects of cerebral edema and effects of secretion of inappropriate anti-diuretic hormone (ADH), seizure control, vasopressor support, and cardiopulmonary monitoring. The choice of appropriate antibiotic therapy is based on several factors, including

the achievable cerebrospinal fluid levels of drugs that have in vitro efficacy against the microorganism. In the case of gram-positive bacteria, the use of penicillin and ampicillin will achieve 10- to 100-fold higher concentrations than the minimal inhibitory concentrations needed to inhibit the bacteria, and there is rapid sterilization of the cerebrospinal fluid. In contrast, aminoglycosides, such as gentamicin and tobramycin, achieve only 40% of peak serum levels and may not achieve minimal inhibitory concentrations more than those equal to or slightly greater than found in vitro for gram-negative bacteria.

In many intensive care units, ampicillin and gentamicin are recommended for the initial therapy for neonatal meningitis. An alternative regimen of ampicillin and cefotaxime can also be used, recognizing the potential for the introduction of cephalosporin-resistant gram-negative isolates in the unit. Although used in the past, neither intrathecal nor intraventricular administration of antibiotics has been found to improve the morbidity or mortality of gram-negative meningitis (Shah et al, 2008). Once the microorganism has been identified and the antibiotic susceptibility results are available, either a single drug or a combination of drugs found to be effective in vitro should be used. Usually penicillin or ampicillin is used for GBS meningitis; in the first few days of therapy, dual therapy with an aminoglycoside may be used. For *L. monocytogenes*, it is common to treat with ampicillin with or without gentamicin. Ampicillin or cefotaxime with or without an aminoglycoside can be used for infection with gram-negative enteric bacteria. The precise length of antibiotic therapy depends on the rapidity of response and sterilization of cerebrospinal fluid. In general, continue therapy for approximately 2 weeks after sterilization of the cerebrospinal fluid, or a minimum of 2 weeks for gram-positive meningitis and a minimum of 3 weeks for gram-negative meningitis. In difficult situations, therapy may be required for as long as 4 to 6 weeks.

It may be prudent to repeat a cerebrospinal fluid examination and culture after initiation of therapy, especially if the clinical response is less than satisfactory. If organisms are seen on gram-stained smears of the fluid, modification of the therapeutic regimen should be considered. In general, approximately 3 days or more are required for an antibiotic regimen to sterilize the cerebrospinal fluid in infants with gram-negative meningitis. In infants with gram-positive meningitis, sterilization is usually seen within 36 to 48 hours. Neuroimaging should be considered to exclude parameningeal foci and abscess formation and to assist in assessing the infant's prognosis.

PROGNOSIS

Complications from neonatal meningitis include brain abscess, communicating or noncommunicating hydrocephalus, subdural effusions, ventriculitis, deafness, and blindness. Generally the severity of complications is related to severity of the disease during the early neonatal period. It is imperative to follow hearing competency and to examine these infants for prolonged periods after recovery. The infant who has experienced meningitis may appear relatively healthy at the time of discharge, and only after careful follow-up do perceptual difficulties, reading problems, or signs of brain damage become apparent. Approximately 40% to 50% of survivors have some evidence of neurologic damage, with severe damage being obvious in 11%. Infants who survive neonatal meningitis should have regular audiology, language, and neurologic evaluations until they enter school (Edwards et al, 1985; Stevens et al, 2003).

CHAPTER 40

Health Care–Acquired Infections in the Nursery

David A. Munson and Jacquelyn R. Evans*

For decades, nosocomial or health care–acquired infection (HAI) has been considered by many as an unavoidable problem associated with prolonged stays in an intensive care nursery. Immature skin and immune systems, pathologic skin flora, and necessary invasive interventions all put the premature neonate at high risk for HAI. But some centers have clearly shown that, despite these risk factors, HAIs ranging from catheter-associated infections to acquisition of respiratory viruses can largely be prevented (Andersen, 2005; Bloom et al, 2003; Kilbride et al, 2003). There is a direct financial cost to the health care system associated with infections acquired while in the hospital, but more importantly there is growing evidence that the deleterious effects of the inflammatory response to infection may adversely affect long-term outcomes, including increased rates and severity of bronchopulmonary dysplasia and neurodevelopmental impairment (Adams-Chapman and Stoll, 2001, 2006; Gonzalez et al, 1996; Hintz et al, 2005; Jobe and Ikegami, 1996; Leviton et al, 1999; Rojas et al, 1995; Shah et al, 2008; Stoll et al, 2004).

The growing numbers of surviving very low-birthweight (VLBW) infants magnifies the impact of this problem. Clinicians must make efforts to minimize the exposure of newborns to known risk factors for infection. Continuous surveillance and monitoring of endemic HAI rates and patterns of responsible pathogens are necessary to establish a reference point in each nursery and facilitate early identification of epidemics. Prevention of infections in the neonatal patient requires an expanding skill set in addition to organized hospital-wide initiatives. Familiarity with quality improvement concepts, standardization of practice, and hospital programs such as antimicrobial stewardship are all essential to preventing harm in the smallest patients.

DEFINITIONS

The Centers for Disease Control and Prevention (CDC) provides the following surveillance definition for an HAI: illness associated with a pathogen or its toxins that is not present or incubating at the time of admission to the intensive care unit (Horan et al, 2008). As simple as this definition seems, it does leave some room for confusion for the clinician caring for the neonatal population. Infections that manifest early in the 1st week of life are typically related to perinatal risk factors and vertical transmission from the mother. HAIs are more often related to patient colonization and environmental risk factors. Unfortunately, there is no specific postnatal age that distinguishes maternally transmitted infections from HAIs (Baltimore, 1998), and it may be difficult to differentiate a late-onset, perinatally acquired infection from an HAI. Most sources define HAIs as infections occurring after 3 days of age (Baltimore, 1998; Stoll et al, 2002a). The CDC defines HAI as any infection that occurs after admission to the neonatal intensive care unit (NICU) and that was not transplacentally acquired (Garner et al, 1988). Other authorities suggest that HAI be defined as any infection occurring more than 5 to 7 days after birth (Baltimore, 1998).

The majority of HAIs in the neonatal population are bloodstream infections associated with an intravascular device. Criteria for central line–associated bloodstream infections (CLABSIs), as defined by the CDC, are (1) isolation of a recognized pathogen from one blood culture specimen or of a skin commensal from two blood culture specimens; (2) one or more clinical signs of infection, such as temperature instability, apnea, and bradycardia; and (3) the presence of an intravascular device at the time the culture specimen is collected (Horan and Gaynes, 2004). Ventilator-associated pneumonias are difficult to diagnose in the NICU, but can contribute to morbidity, especially in patients with evolving lung disease. Although the use of Foley catheters is low in the NICU compared with other intensive care units, the acquisition of urinary tract infections while in the NICU is still a problem.

A summary of definitions of important HAIs in infants is provided in Box 40-1. The prevention of the spread of respiratory viruses is another area that demands attention, especially in a unit caring for infants with significant bronchopulmonary dysplasia. The NICU, as with other intensive care units, must remain vigilant in the control of bacteria resistant to antibiotics such as methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococcus (VRE). As community-acquired MRSA is becoming more prevalent, it is becoming more difficult to determine the origin of MRSA in a neonatal patient.

INCIDENCE

WELL BABY (HEALTHY NEWBORN) NURSERY

Accurate rates of HAI in the well baby nursery are difficult to ascertain because there is no systematic reporting or surveillance network for this issue; however, the incidence appears to be low. Some researchers estimate rates of less than 1 per 100 patients discharged (Baltimore, 1998). Typical risk factors for acquiring a HAI, such as invasive procedures and presence of an intravascular device, are uncommon in the healthy newborn population. Discharge

*Acknowledgment: In writing this chapter, the authors excerpted significant portions of the chapter *Nosocomial Infections in the Nursery* by Ira Adams-Chapman and Barbara Stoll from the previous edition of this book.

from the hospital within 48 hours of birth and rooming-in practices have helped further to decrease the risk of exposure in modern mother-baby units. Early discharge may also limit surveillance efforts, because patients may be discharged home before they become symptomatic from HAIs (Goldmann, 1989).

NEONATAL INTENSIVE CARE UNIT

The majority of neonatal HAIs occur in term and preterm infants hospitalized in special care nurseries. It is difficult to determine and compare reports of endemic HAI rates in different NICU populations. Any comparison of surveillance data between institutions is limited by differences in patient demographics (e.g., birthweight, gestational age distribution, underlying severity of disease, birth in the hospital versus elsewhere), back transport policies, and the use of different definitions for HAI.

Among a cohort of 6215 VLBW infants (weight <1500 g) who were monitored by the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network, 21% of those who survived beyond 3 days of age had at least one episode of late-onset sepsis (Stoll et al, 2002b). There was significant variability among the participating centers, with rates ranging from 10.6% to 31.7% at individual sites (Stoll et al, 2002b). Moreover, rates were inversely related to birthweight and gestational age, ranging from 43% for infants weighing 401 to 750 g at birth to 7% for infants weighing 1251 to 1500 g at birth. These data are similar to those reported by Brodie et al (2000). In their study, 19% of 1354 infants weighing less than 1500 g at birth had HAIs, and the rates were highest for infants at the lowest birthweights (39%, <750 g; 27%, 750 to 999 g; 10%, 1000 to 1499 g). A point prevalence survey conducted by the 29 level II to level IV nurseries participating in the Pediatric Prevention Network revealed a prevalence of 11.4% for HAI (Sohn, 2001).

The CDC National Healthcare Safety Network (NHSN) was developed in 2005 and replaced the National Nosocomial Infections Surveillance system that reported national data before that time. Some investigators believe that reporting overall incidence rates may be misleading, because of the wide variations in practice and patient populations in different units; therefore the NHSN system monitors device-associated HAI rates by using an approach that accounts for variability in device use and length of hospital stay (Edwards et al, 2008; Emori et al, 1991; Gaynes et al, 1996). These data are also stratified by birthweight categories and expressed as incidence density per 100 or 1000 patient-days. These two adjustments modify the relative risk on the basis of the severity of the illness and the duration of exposure to the risk factor. A number of states in the United States have mandatory reporting of HAIs through the NHSN, and the number of participating medical centers is growing. The NHSN data are similar to institutional and collaborative epidemiologic data reported elsewhere. Rates of device-associated infections are presented in Table 40-1. These rates remained constant in the 1990s (Gaynes et al, 1996; National Nosocomial Infections Surveillance System Report, 2000), but appear to have dropped considerably in the 2007 report (Edwards et al, 2008), suggesting that preventive strategies for CLABSIs may be having an effect.

BOX 40-1 Definitions of Nosocomial Bacteremia and Pneumonia for Patients Younger than 12 Months, from the Centers for Disease Control and Prevention

NOSOCOMIAL BLOODSTREAM INFECTIONS

- Recognized pathogen isolated from blood culture and pathogen is not related to infection at another site.
- Must have at least one of the following clinical symptoms: fever (body temperature >38°C, rectal), hypothermia (body temperature <37°C, rectal), apnea, bradycardia, and a skin commensal isolated from two blood culture specimens on separate occasions.

PNEUMONIA

- Chest radiograph with new or progressive infiltrate, cavitation, consolidation, or pneumatoceles
- Worsening gas exchange and three of the following:
  - Temperature instability
  - White blood cell count <4000 or >15,000 with ≥10% bands
  - New-onset purulent sputum, change in character of sputum, increased respiratory secretions, or increased suctioning requirements
  - Physical examination findings consistent with increased work of breathing or apnea
  - Wheezing, rales, or rhonchi
  - Cough
  - Bradycardia or tachycardia

URINARY TRACT INFECTION

- Clinical symptoms (fever [body temperature >38°C, rectal], hypothermia [body temperature <37°C, rectal], apnea or bradycardia, dysuria, lethargy or vomiting) and positive urine culture (≥100,000 microorganisms/mL) with no more than two species identified
- May also qualify as a UTI if the above symptoms are present without another cause and has at least one of the following
  - Positive dipstick for leukocyte esterase, nitrate, or both
  - Pyuria
  - Organisms seen on Gram stain of unspun urine
  - At least two urine cultures with the same uropathogen with ≥100 colonies/mL
  - ≤100,000 colonies/mL of a single uropathogen if the patient is receiving an effective antimicrobial agent
  - Physician diagnosis of UTI
  - Physician institutes appropriate therapy for a UTI

UTI, Urinary tract infection.

ANATOMIC SITES OF INFECTION

WELL BABY NURSERY

HAIs in the well baby nursery are most commonly superficial, involving the skin, mouth, or eyes. These infections include omphalitis, pustules, abscesses, and bullous impetigo (Goldmann, 1989). Nursery epidemics of diarrhea caused by bacterial and viral enteropathogens have been reported, but they occur infrequently (Goldmann, 1989).

NEONATAL INTENSIVE CARE UNIT

National and institutional surveillance data demonstrate that bloodstream infections are responsible for the majority of HAIs among NICU patients (Gaynes et al, 1996; National Nosocomial Infections Surveillance System Report, 2000; Sohn et al, 2001). The remaining cases involve the respiratory tract, eye, ear, nose, throat, or gastrointestinal tract (Figure 40-1). Surveillance data for meningitis are limited. Reports suggest that late-onset meningitis may be underdiagnosed in the high-risk population of VLBW infants (Stoll et al, 2002b). There are widespread differences in clinical practice regarding the inclusion of a lumbar puncture with cerebrospinal fluid analysis in the evaluation of a neonate with possible sepsis. This variation in practice has been challenged by recent data suggesting that generally accepted cerebrospinal fluid parameters are not sensitive or specific for meningitis in the neonate (Smith et al, 2008). Although early onset meningitis remains a rare event, clinicians need to consider including a lumbar puncture in the initial evaluation of a neonate with signs and symptoms of infection.

TABLE 40-1 Rate of Device-Associated HAIs

Birthweight (g)	NHSN 2008 CLABSI per 1000 catheter days	NHSN 2008 VAP per 1000 ventilator days
<750	3.7	2.6
751-1000	3.3	2.1
1001-1500	2.6	1.5
1501-2500	2.4	1.0
>2500	2.0	0.9

Modified from Edwards JR, Peterson KD, Andrus ML, et al: National Healthcare Safety Network (NHSN) Report, data summary for 2006 through 2007, issued November 2008. National Healthcare Safety Network Facilities, *Am J Infect Control* 36:609-626, 2008. Level III NICU pooled data.
CLABSI, Central line–associated bloodstream infection; *HAI*, health care–acquired infection *NHSN*, National Healthcare Safety Network; *VAP*, ventilator-associated pneumonia.

RISK FACTORS

Some risk factors for acquiring an HAI are reflections of the patient population and are difficult or impossible to modify. Other risk factors are directly related to the level of supportive care associated with intensive care medicine and may be difficult yet possible to modify. Risk factors for HAI include lower gestational age and low birthweight; invasive procedures; invasive devices, especially intravascular catheters and endotracheal tubes; parenteral nutrition and intravenous lipids; colonization of skin, gastrointestinal tract, and airway with invasive organisms; selected drugs administered to the neonate; and issues surrounding nursery staffing, nursery crowding, and hand washing (Box 40-2) (Gaynes et al, 1996; Kawogoe et al, 2001; Perlman et al, 2007; Stoll et al, 1996, 2002a; Stover et al, 2001; Suara et al, 2000). Minimizing exposure to known risk factors for infection is important to reduce the rate of HAIs in the nursery.

The risk of developing an HAI is inversely related to gestational age and birthweight (Gaynes et al, 1996, Kawogoe et al, 2001; National Nosocomial Infections Surveillance System Report, 2000; Stoll et al, 1996, 2002a; Stover

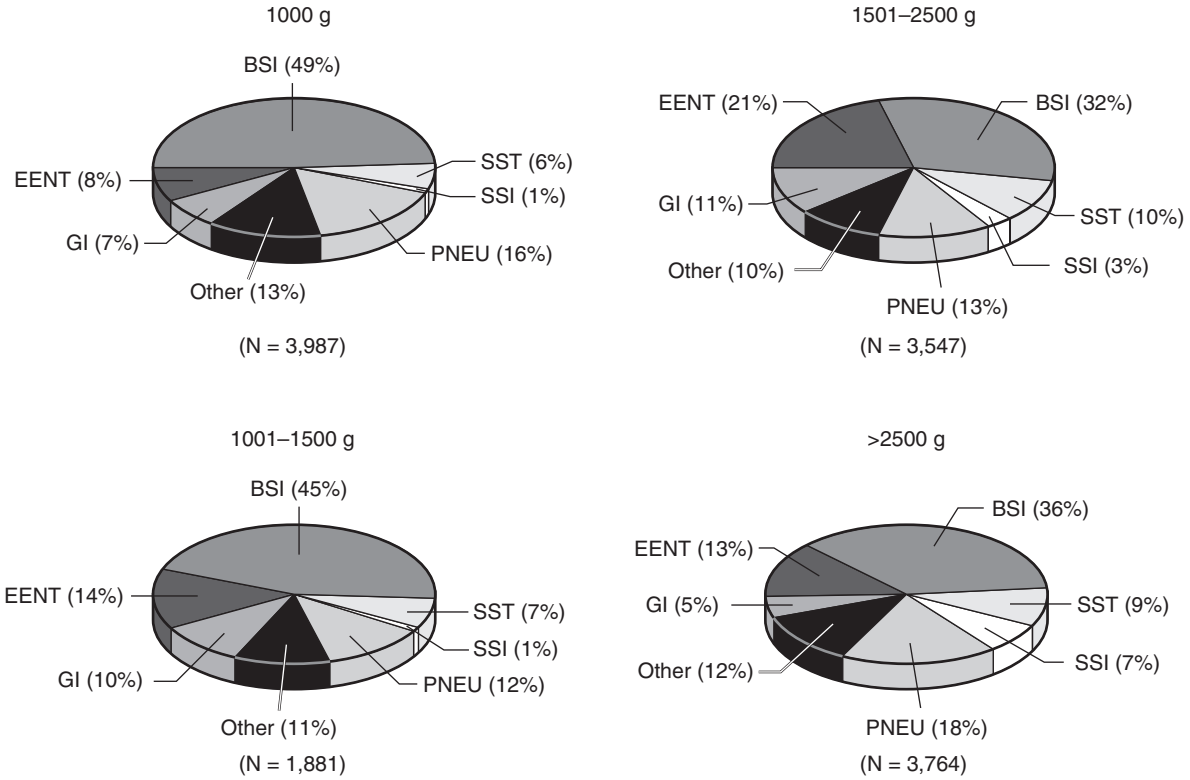

FIGURE 40-1 Distribution of health care–acquired infections by site of infection. *(Data from Gaynes RP, Edwards JR, Jarvis WR, et al: Nosocomial infections among neonates in high-risk nurseries in the United States*, Pediatrics *98:357-361, 1996.)*

BOX 40-2 Risk Factors for Acquiring Health Care–Acquired Infections in the Neonatal Intensive Care Unit

- Prematurity
- Low birthweight
- Invasive device
- Intravascular device (CVC, PAL, PICC, PIVC, umbilical catheter)
- Mechanical ventilator
- Urinary catheter
- Ventriculoperitoneal shunt
- Medications
- Histamine$_2$-blocking agents
- Steroids
- Others
- Prolonged administration of hyperalimentation
- Intralipid administration
- Delayed enteral feedings
- Feeding with formula rather than human milk
- Inadequate nursery staffing and overcrowding
- Poor compliance with handwashing

CVC, Central versus catheter; *PAL,* percutaneous arterial line; *PICC,* peripherally inserted central catheter; *PIVC,* percutaneous intravenous catheter.

et al, 2001; Suara et al, 2000). Previous reports estimate that there is a 3% lower risk of acquiring an HAI with each 500-g increment in birthweight (Goldmann, 1989). Infants with birthweights less than 1000 g have twice the rate of nosocomial bloodstream infections than do infants with birthweights greater than 1000 g (Brodie et al, 2000; Geffers et al, 2008; Gaynes et al, 1996; National Nosocomial Infections Surveillance System Report, 2000; Stoll et al, 2002a; Stover et al, 2001). Severity of illness scores may be more predictive than birthweight alone, because they reflect physiologic stability and the cumulative need for intervention and invasive therapies (Goldmann, 1989; Gray et al, 1995).

The use of any type of invasive device increases the risk for infection. The most common invasive devices used in the nursery are intravascular catheters, mechanical ventilators, ventriculoperitoneal shunts, and urinary catheters. In general, the risk rises as the duration of exposure lengthens. Compared with adult patients, neonates are at higher risk for catheter-related bloodstream infections and at lower risk for ventilator-associated pneumonia and urinary tract infections (Langley et al, 2001; National Nosocomial Infections Surveillance System Report, 2000). These patterns correlate with the frequency with which these invasive devices are used in the neonatal patient population.

Prolonged duration of mechanical ventilation is the primary risk factor for development of hospital-acquired pneumonia. Contamination of respiratory equipment—especially with gram-negative organisms that thrive in moist environments, such as *Acinetobacter*, *Pseudomonas*, and *Flavobacterium* spp.—frequently leads to colonization of the respiratory tract. There is some evidence that aspiration of gastric and oropharyngeal secretions around the uncuffed endotracheal tube may occur, and this could be a mechanism for ventilator-associated pneumonia (Farhath et al, 2008). The various closed-system suctioning devices may decrease the risk of iatrogenic contamination during suctioning. Defining a ventilator-associated pneumonia in the neonatal population remains a challenge. Patients in the NICU do not often meet all of the parameters defined by the CDC (see Box 40-1), but acute worsening of pulmonary function in an infant with a ventilator could represent a new-onset pneumonia. Collaboration among the largest NICUs is needed to better define this entity in the neonatal population.

Intravascular devices commonly used in the neonatal population are peripheral intravenous catheters (PIVs), umbilical catheters, peripherally inserted central catheters (PICCs), surgically placed central venous catheters (CVCs) and percutaneous arterial catheters. Regardless of the type of device used, the rate of catheter-related bloodstream infections is directly related to the number of days the catheters are in place and inversely related to the gestational age and birthweight of the patients (Gaynes et al, 1996; Kawogoe et al, 2001; National Nosocomial Infections Surveillance System Report, 2000; Stoll et al, 2000a; Suara et al, 2000). Coagulase-negative *Staphylococcus* (CONS) remains the primary pathogen associated with catheter-related bloodstream infections (Garland et al, 2001).

PIVs are the most commonly used device for vascular access in neonates. In adults, the removal of such catheters after 72 hours is recommended. Data in neonates are insufficient to recommend elective removal of PIVs after 72 hours, because studies have not shown a clear correlation between the higher colonization rate noted after 72 hours and an increased rate of catheter-related bloodstream infection (Oishi, 2001; Pearson, 1996). Further study is needed to answer this question.

Data comparing the infection rates of the various types of intravascular catheters are limited. Theoretically the risk should be lower for tunneled catheters, because the Dacron cuff proximal to the exit site of a surgically placed catheter can inhibit the migration of organisms into the catheter tract (Mermel et al, 2001). Adult data suggest that tunneled catheters have lower infection rates than nontunneled catheters; however, a report of 79 surgical neonates requiring tunneled lines showed a rate of infection of 9.9 per 1000 catheter days (Klein et al, 2003), comparable to or worse than reported rates of PICC line infections in other NICU populations. This issue needs further study in the neonatal population, especially because PICCs are being used with greater frequency for long-term vascular access in neonates (Stoll et al, 2002a). Some recent trials comparing PIVs to PICC lines for the provision of parenteral nutrition have challenged the notion that the presence of a central line increases the risk of infection above the risk that exists simply with the use of peripheral catheters. It appears that the use of a PICC line decreases the risk of complications associated with PIVs without increasing the rate of infection, at least in the initial weeks of life (Ainsworth et al, 2007). There is certainly much work to be done to determine the ideal access for the different populations cared for in the NICU.

The use of intravenous lipid emulsions increases the risk for infection (Freeman et al, 1990). Lipid emulsions decrease the flow rate through the intravenous catheter and potentiate the growth and proliferation of some microorganisms. Lipid emulsions can interfere with host

defense mechanisms by impairing the function of neutrophils and reticuloendothelial macrophages (Freeman et al, 1990; Langevin et al, 1999; Nugent, 1984). Extrinsic contamination has been reported but rarely occurs in the United States (Hernandez-Ramos et al, 2000). Freeman et al (1990) reported that the use of a lipid emulsion was positively and independently predictive for the development of CONS bacteremia. Infants who demonstrated CONS sepsis were 5.8-fold more likely to have been exposed to lipid emulsions. Administration of such emulsions has also been linked to a higher risk for HAI with *Candida* and *Malassezia* spp. in neonates (Long and Keyserling, 1985; Redline et al, 1985; Saiman et al, 2000).

Histamine-blocking agents and postnatally administered corticosteroids are the medications most commonly associated with an increased risk of HAIs among newborns. It is hypothesized that the reduced gastric pH associated with the use of histamine$_2$-blocking agents promotes bacterial overgrowth and invasion of pathogenic bacteria (Beck-Sague et al, 1994; Stoll et al, 1999). Dexamethasone has been used in ventilator-dependent preterm infants to facilitate weaning from the ventilator and to minimize the risk of chronic lung disease. The use of dexamethasone has decreased in the last decade in VLBW infants secondary to concerns of spontaneous bowel perforation and adverse effects on growth and neurodevelopmental outcome (O'Shea et al, 1999; Stark et al, 2001, Vohr et al, 2000). However, there is renewed interest in a role for steroids after the first week of life, especially in infants who have demonstrated a high risk for developing chronic lung disease (Doyle et al, 2005, 2006, 2007). Because the use of dexamethasone has been associated with an increased risk of infection in VLBW infants (Stoll et al, 1999; Yeh et al, 1997), neonatologists will need to include this concern in any risk-benefit analysis of the use of steroids in their patients.

Nursery design and staffing influence the risk of infection. Overcrowding and larger workloads decrease compliance with hand washing and raise the risk of HAI (Archibald et al, 1997; Fridkin et al, 1996; Harbarth et al, 1999; Robert et al, 2000; Vicca, 1999). Inadequate numbers of staff and the use of temporary or inexperienced staff members both adversely affect the rate of infection. The adverse effects of inadequate staffing and overcrowding were demonstrated by Hayley and Bregman (1982), who showed a relationship between nurse-to-patient ratio and colonization of patients with MRSA. Fridkin et al (1996) found that patient-to-nurse ratio was an independent predictor of development of a catheter-related bloodstream infection. Furthermore, strategic nursery design and improvement in nursing staffing correlate with lower rates of HAIs (Gladstone et al, 1990).

DISTRIBUTION BY PATHOGEN

The predominant pathogens responsible for nosocomial bloodstream infections have changed over time. Goldmann (1989) proposed that these trends are explained by changes in the neonatal intensive care patient population and advancing technology. *S. aureus* was the most common nosocomial pathogen in the 1950s and 1960s. In the 1960s and 1970s, gram-negative organisms emerged as the predominant pathogens; globally, these organisms remain the most important pathogens responsible for HAIs in the nursery (Stoll, 2001). National surveillance data in the United States indicate that CONS is currently the most common nosocomial pathogen (Gaynes et al, 1996; National Nosocomial Infections Surveillance System Report, 2000) (Table 40-2). In the United States, the distribution of pathogens has not changed significantly over the past decade (Gaynes et al, 1996; Stoll et al, 1996, 2002a) (Box 40-3). Among a cohort of infants with birthweights less than 1500 g with late-onset infections, the NICHD Neonatal Research Network reported that gram-positive organisms were responsible for 70% of cases, gram-negative organisms for 18%, and fungi for 12% (Stoll et al, 2002a). These findings are similar to those of a 10-year retrospective analysis of pathogens in a single center, in which gram-positive organisms caused 57% of late-onset infections (Karlowicz et al, 2000). The distribution of infecting pathogens did not differ with birthweight or timing of infection (Stoll et al, 2002a). More recent articles evaluating interventions and mechanisms of infection confirm the continued predominance of CONS in neonatal line infections in the United States (Garland et al, 2008) as do review articles (Curtis and Shetty, 2008).

TABLE 40-2 Distribution of Pathogens Responsible for Bloodstream Infections

Pathogen	No.	%
Coagulase-negative staphylococci	3833	51.0
Staphylococcus aureus	563	7.5
Group B streptococci	597	7.9
Enterococcus spp.	467	6.2
Candida spp.	518	6.9
Escherichia coli	326	4.3
Other *Streptococcus* spp.	205	2.7
Enterobacter spp.	219	2.9
Klebsiella pneumoniae	188	2.5

Data from Gaynes RP, Edwards JR, Jarvis WR, et al: Nosocomial infections among neonates in high-risk nurseries in the United States, *Pediatrics* 98:357-361, 1996.

For the clinician, understanding the specific colonization and resistance patterns in the individual NICU is perhaps more important than being aware of national trends. The emergence of nosocomial pathogens with antimicrobial resistance is a concern. In patients of all ages, reports estimate that 50% to 60% of HAIs are caused by resistant organisms (Jones, 2001; Weinstein, 1998). Organisms showing patterns of increasing antibiotic resistance of importance to NICU patients are VRE, MRSA, and multidrug-resistant gram-negative organisms (Bizzarro and Gallagher, 2007).

GRAM-POSITIVE BACTERIA

CONS is the most common endemic nosocomial pathogen in neonates (Brodie et al, 2000; Garland et al, 1996, 2008; Gray et al, 1995; National Nosocomial Infections Surveillance system report, 2000; Stoll et al, 2002a). The majority of CONS infections are bloodstream infections. Reported

BOX 40-3 Common Pathogens Causing Health Care–Acquired Infections

GRAM-POSITIVE ORGANISMS

- Coagulase-negative staphylococci
- *Staphylococcus aureus*
- *Enterococcus* spp.
- Group B *Streptococcus*

GRAM-NEGATIVE ORGANISMS

- *Escherichia coli*
- *Klebsiella* spp.
- *Pseudomonas* spp.
- *Enterobacter* spp.
- *Serratia* spp.
- *Haemophilus* spp.
- *Acinetobacter* spp.
- *Salmonella* spp.

FUNGAL ORGANISMS

- *Candida albicans*
- *Candida parapsilosis*
- *Malassezia furfur*

VIRAL ORGANISMS

- Respiratory syncytial virus
- Influenza
- Varicella zoster
- Rotavirus
- Enterovirus

Data from Gaynes RP, Edwards JR, Jarvis WR, et al: Nosocomial infections among neonates in high-risk nurseries in the United States, *Pediatrics* 98:357-361, 1996; and Stoll BJ, Hansen N, Fanaroff AA, et al: Late-onset sepsis in very-low-birth-weight neonates: the experience of the NICHD Neonatal Research Network, *Pediatrics* 110:285-291, 2002.

incidence ranges from 51% to 78% among VLBW infants (Gray et al, 1995; Isaacs et al, 1996; Stoll, 1996, 2002a). Gray et al (1995) reported a cumulative incidence of 17.5 episodes of CONS sepsis per 100 patient-days and an incidence density of 6.9 episodes of CONS sepsis per 1000 patient-days.

Known risk factors for CONS infection are low birthweight, lower gestational age, use of central venous catheters, prolonged administration of hyperalimentation, use of intravenous lipid emulsions, postnatal administration of corticosteroids, and prolonged hospital stay (Brodie et al, 2000; Freeman et al, 1990; Goldmann, 1989; Johnson-Robbins et al, 1996). CONS is the pathogen most commonly associated with catheter-related infections, partially because it produces a capsular polysaccharide adhesin (poly-*N*-succinyl glucosamine), which enhances its ability to adhere to intravascular devices. Although some studies suggest that prophylactic use of vancomycin reduces the risk of CONS catheter-related infections, this practice is not recommended because of the serious risk of encouraging antibiotic-resistant organisms, especially VRE and staphylococci. The use of a vancomycin lock, where vancomycin is instilled into the catheter and then removed after a specified dwell time, has more promise in terms of balancing the risk of systemic exposure and prophylaxis against contamination of the catheter lumen. Garland et al (2005) demonstrated a reduction in the rate of CLABSI from 17.8 to 2.4 per 1000 catheter days using this technique. Although promising, several units have achieved comparable reductions without the use of this kind of intervention. Consequently, the role of an antibiotic lock will likely find its place in certain circumstances or in populations that have demonstrated persistently elevated risks for infection.

Enterococci are responsible for both endemic and epidemic HAIs in the NICU. Use of central venous catheters, prolonged hospital stay, and prior antibiotic use are recognized risk factors for colonization with these organisms. The gastrointestinal tract is often the primary source of infection; however, the pathogens are typically spread via the hands of health care workers or through environmental contamination. The widespread use of antibiotics has led to the emergence of VRE. There are published guidelines to prevent the spread of VRE, which include hand washing, isolation, barrier precautions, and cohorting of infected patients (Gross and Pujat, 2001; Hospital Infection Control Practices Advisory Committee, 1995). Educational programs to limit the indiscriminate use of antibiotics have been effective in decreasing the spread of VRE (Goldmann et al, 1996; Isaacs, 2000).

S. aureus has caused epidemics in well baby nurseries and in NICUs. In the nursery, the major reservoirs for staphylococci are colonized or infected infants. These infants transmit the organism to health care workers, who subsequently infect other infants. The skin, nares, and umbilicus are the most common sites of colonization. Unfortunately, routine surveillance cultures are not useful because colonization rates correlate poorly with infection rates. Studies in adult patients have shown that many patients who demonstrate *S. aureus* bacteremia were colonized with the identical strain at the time of admission to the hospital, suggesting that some of the infections with *S. aureus* are community acquired rather than hospital acquired (von Eiff et al, 2001). Similarly, health care workers can be colonized with a community-acquired strain of *S. aureus*, which they then transfer to vulnerable infants. Importantly, there has been a significant increase in methicillin-resistant strains of *S. aureus* causing infections in the NICU. A review of the National Nosocomial Infections Surveillance data from 1995 to 2004 indicated a 308% increase in the incidence of MRSA over that 10-year time frame. As of the 2004, MRSA accounted for 34% of *S. aureus* infections in the reported data (Lessa et al, 2009). Consequently, when covering for a possible *S. aureus* infection, it is critical to select an antibiotic that is effective against methicillin-resistant strains.

Group B *streptococcus* (GBS) remains an important cause of late-onset infection in neonates, but do not have a clear role as an HAI. Intrapartum antibiotic treatment to prevent vertical transmission of GBS from a colonized mother to her infant has led to a decrease in early-onset GBS disease. In contrast, the incidence of late-onset GBS disease has remained unchanged, presumably because prophylaxis does not eradicate colonization of the genital tract or the environment.

GRAM-NEGATIVE ORGANISMS

Gram-negative organisms are a particularly important cause of nosocomial bloodstream infections, pneumonia, and meningitis because they generally cause severe disease.

Escherichia coli is the most common gram-negative pathogen. Other gram-negative organisms responsible for HAI are *Klebsiella*, *Pseudomonas*, *Enterobacter*, *Acinetobacter*, *Serratia*, *Haemophilus*, and *Salmonella* spp. (see Box 40-3).

The attributable mortality is much higher for gram-negative infections than for gram-positive infections. Stoll et al (2002a) reported that infants with gram-negative infections had a 3.5-fold higher risk of death. Karlowicz et al (2000) found that gram-negative infections were associated with fulminant death within 48 hours of a positive blood culture result in 69% of cases. *Pseudomonas* spp. appear to be particularly virulent, causing death in 42% to 75% of infected neonates (Karlowicz et al, 2000; Leigh et al, 1995; Stoll et al, 2002a). A more recent study by Makhoul et al (2005) and colleagues in Israel confirms that gram-negative infections are associated with a substantially higher mortality.

FUNGAL ORGANISMS

Fungal infections are discussed in detail in Chapter 41. Invasive fungal infection is estimated to occur in 1% to 4% of VLBW infants and the incidence in extremely low-birthweight (ELBW) infants has been reported to be significantly higher. The risk may even approach 20% in infants with a birthweight less than 750 g (Bartels et al, 2007; Benjamin et al, 2006; Clerihew et al, 2006; Fridkin et al, 2006; Makhoul et al, 2002, 2007; Rodriguez et al, 2006; Stoll et al, 2002a). Rates and predominant fungal species vary among clinical centers. The smallest and most premature infants appear to be at the highest risk, particularly when they are exposed to broad-spectrum antibiotics or long courses of antibiotics. Other identified risk factors are prolonged mechanical ventilation, prolonged use of central venous catheters, prior use of lipid emulsions, and the use of histamine type 2 antagonists (Benjamin et al, 2001; Long and Keyserling, 1985; Makhoul et al, 2002; Saiman et al, 2000).

Efforts at preventing nosocomial fungal infection have focused on the use of prophylactic fluconazole for VLBW infants. This strategy has been shown to decrease the rate of invasive disease in randomized trials, but the baseline rates in the control arms in some studies have been high (Kaufman et al, 2001). Consequently it has been difficult to determine how generalizable the findings are. Furthermore, metaanalysis has not demonstrated an associated improvement in mortality (Clerihew et al, 2007). A number of retrospective studies describing the implementation of fluconazole prophylaxis in individual units have also suggested a reduction in invasive fungal disease (Aghai et al, 2006; Bertini et al, 2005; Dutta et al, 2005; Healy et al, 2005; Manzoni et al, 2006; Uko et al, 2006). Although no study has found an increase in fluconazole-resistant fungus, resistance remains a concern with any prophylactic strategy. Limiting a prophylactic strategy to units with a high rate of invasive candidal disease and to patients with the highest risk will likely ultimately provide the greatest benefit with the lowest risk.

VIRAL ORGANISMS

Viral organisms that cause HAI in the NICU include respiratory syncytial virus (RSV), rhinovirus, metapneumovirus, influenza, varicella, rotavirus, and enterovirus. Isolated infections generally result from contact with infected caregivers or family members. Nursery epidemics may occur in addition to isolated individual cases.

Respiratory Syncytial Virus

Careful hand washing is the most effective measure to prevent RSV infection. Recommendations for preventing RSV epidemics in the inpatient setting include cohorting of patients, barrier precautions, and careful hand washing (Goldmann, 2001; Hall, 2000; Karanfil et al, 1999; Mlinarić-Galinović and Varda-Brkić, 2000; Snydman et al, 1988). Rapid testing to detect the virus in nasal washings facilitates efforts to cohort infected patients, which has been shown to be an effective control measure (Madge et al, 1992; Snydman et al, 1988). RSV is a fastidious organism capable of surviving on inanimate objects for prolonged periods; therefore some authorities advocate the use of gowns and gloves, because of the increased risk of contamination through casual contact between the patient and the environment (Goldmann, 2001; Hall, 2000; Karanfil et al, 1999; Mlinarić-Galinović and Varda-Brkić, 2000). Several case reports have described the use of palivizumab, an RSV monoclonal antibody, to control nosocomial outbreaks; however, the efficacy of administering monthly injections to hospitalized patients has not been critically or systematically evaluated (Cox et al, 2001; Macartney et al, 2000). Preterm infants born before 32 weeks' gestation and those with chronic lung disease remain at high risk for RSV infection after hospital discharge; therefore the American Academy of Pediatrics (AAP) recommends that all high-risk infants (<32 weeks' gestation, chronic lung disease, or asymptomatic acyanotic congenital heart disease, such as a patent ductus arteriosus or ventricular septal defect) receive up to five doses of palivizumab during the RSV season (American Academy of Pediatrics, 1998, 2009a; Meissner et al, 1999). These guidelines were updated in 2003 to also include patients with cyanotic congenital heart disease. They have been modified again in 2009 to clarify the risk factors for the 32- to 35-week gestational age group (American Academy of Pediatrics, 2009a).

Influenza

Influenza is spread primarily via airborne transmission. Hand washing and immunization of health care workers are the primary tools to prevent nosocomial spread of this virus (Nichol and Hauge, 1997). Most infection control guidelines recommend that every health care worker wear a mask during contact with infected patients. Although several drugs are available for the prophylaxis and treatment of influenza, they have not been studied in newborns and cannot be recommended at this time (Meissner, 2001). At-risk infants should receive the influenza vaccine during the winter months once they reach the age of 6 months.

With the appearance of the novel H1N1 influenza strain, the season for possible flu exposure has increased substantially. In addition, newborns are thought to be in a high-risk population if they are born to mothers who are actively infected. Guidelines for minimizing risk to the infant have been offered by the CDC. Pregnant women

with symptoms that are consistent with H1N1 influenza should receive treatment as soon as possible. If tolerated, the mother should wear a mask during labor and delivery. After the delivery, the infant should be cared for away from the mother until he or she has received 48 hours of treatment and has become afebrile and able to control cough and secretions. The infant should be assisted in lactation if she intends to breastfeed, because the breast milk itself is not thought to be a means of viral transmission (CDC, 2009).

Varicella

Potential exposures and epidemics of nosocomial varicella have been reported, but true nosocomial infection in the NICU is rare. The index case is typically an asymptomatic infected health care worker or family member who has had contact with a susceptible infant before the onset of clinical disease in the health care worker or family member. The incubation period lasts 14 to 16 days, and infected persons are contagious 24 to 48 hours before the appearance of the rash. The relative risk of infection varies according to the intensity of the exposure and the presence of maternal antibody in the infant. The majority of transplacental antibody transfer occurs during the third trimester; therefore most extremely preterm infants are born before this process is complete. ELBW infants may be at risk even if their mothers have a documented titer of varicella antibodies. The AAP recommends administration of varicella zoster immunoglobulin (VZIG) to any newborn whose mother shows signs of varicella infection within 5 days before delivery or within 2 days after delivery. If the exposure is postnatal, whether via a family member or a health care worker, an exposed preterm infant born before 28 weeks' gestation or weighing less than 1000 g birthweight should receive immunoprophylaxis regardless of the mother's varicella history or serologic status. A postnatally exposed preterm infant born after 28 weeks' gestation should receive VZIG only if the mother lacks clinical or serologic evidence of prior disease (American Academy of Pediatrics, 2009b).

Airborne and contact precautions are recommended for all infants with active varicella disease for at least 5 days after vesicles appear and until all lesions have crusted. Airborne and contact precautions should be used for any exposed susceptible patient from 8 to 21 days after the exposure. Administration of VZIG potentially prolongs the incubation period; therefore all exposed infants who receive this product should be isolated for up to 28 days after the exposure. An infant born to a mother with active varicella should be isolated for 21 days, or for 28 days if the infant received VZIG. The infants should also be isolated from the mother until all of her lesions have crusted.

Rotavirus

Although rare, epidemics of rotavirus diarrhea may occur in the nursery (Herruzo et al, 2009; Jain and Glass, 2001; Lee et al, 2001; Widdowson et al, 2000); they are primarily caused by inadequate hand washing and cross-contamination between patients. Standard and contact precautions should be followed throughout the duration of the illness. Some patients have prolonged fecal shedding of low concentrations of the virus; therefore some infection control experts recommend contact precautions for the duration of the hospitalization of such patients. Rotavirus is an important cause of diarrhea in older infants and should be suspected with any apparent epidemic of diarrhea. There are now two live virus vaccines available for the prevention of rotavirus infection, but their use in the NICU remains controversial because of concerns about the possibility of illness occurring in immunocompromised infants via spread of the vaccine related virus. Currently the AAP recommends the administration of rotavirus vaccine at the time of discharge or after discharge (American Academy of Pediatrics, 2009c).

Enterovirus

There are numerous serotypes of enteroviruses, including polioviruses, Coxsackie viruses A and B, echovirus, and nonassigned subtypes (Chambon et al, 1999). Enterovirus infections have been described among neonates in the well baby nursery and the neonatal intensive care setting (Chambon et al, 1999; Isaacs et al, 1989; Sizun et al, 2000; Takami et al, 2000, Wreghitt et al, 1989). Both individual cases and epidemics can occur. The seasonal distribution of enterovirus infections in neonates mirrors what is seen in the community.

The clinical presentation associated with enteroviral infection is variable. Many patients are asymptomatic; however, several case reports describe overwhelming infection with multisystem organ dysfunction and death (Jankovic et al, 1999; Keyserling, 1997). Clinical manifestations of severe disease include meningoencephalitis, hepatic dysfunction, disseminated intravascular coagulation, myocarditis, pneumonitis, gastroenteritis, and muscle weakness (Abzug et al, 1993; Isaacs et al, 1989; Keyserling, 1997; Wreghitt et al, 1989). The severity of disease and the likelihood of death are often more pronounced in perinatally acquired cases than in nosocomially acquired cases, presumably related to the lack of maternal antibody present in the neonate (Isaacs et al, 1989; Modlin et al, 1981).

Infection control measures during an enteroviral epidemic include hand washing with alcohol-based preparations or antimicrobial soaps and cohorting of infected patients. Surveillance cultures of specimens from the throat and rectum may be helpful in identifying asymptomatic colonized infants. Blood and cerebrospinal fluid cultures should be obtained from any patient with clinical symptoms of disease. Polymerase chain reaction analysis is helpful in making a rapid diagnosis (Nigrovic, 2001). No antiviral agents are currently available to treat enteroviral infections in newborns (Nigrovic, 2001). Although commercially available intravenous immunoglobulin preparations have high levels of neutralizing antibodies to common enterovirus serotypes, there is no clear evidence that administration of immunoglobulin alters the process or outcome of enteroviral infection (Abzug et al, 1993; Dagan et al, 1983; Keyserling, 1997); therefore the use of these products remains controversial in patients with enteroviral infection.

EPIDEMICS

Numerous nursery epidemics have been reported. Common sources for infection are contaminated equipment (i.e., breast pump, thermometer, ventilator), environmental

reservoirs, soaps, and lapses in hand hygiene practices (Focca et al, 2000; Hervas et al, 2001; Hoque et al, 2001; Jeong et al, 2001; Jones et al, 2000; McNeil et al, 2001; Reiss et al, 2000; van den Berg et al, 2000; Wisplinghoff et al, 2000; Yu et al, 2000). Clinicians must have a high index of suspicion to detect nursery outbreaks, especially when clusters of infections with unusual pathogens occur in a nursery. Continuous surveillance and monitoring of the endemic infection rates are crucial for determining when there has been a significant change in the baseline pattern of infection for a given nursery. Modern molecular technology facilitates identification and tracking of specific strains of bacteria to help determine the common source of infection (Chambon et al, 1999; Jeong et al, 2001; Jones et al, 2000; Takami et al, 2000).

Epidemics must be identified promptly, and immediate control measures must be instituted. Efforts should be made to identify the causal agent and the mode of transmission. Surveillance of staff members may be necessary, even if they are asymptomatic. Reinforcement of hand-washing policies is of utmost importance. Cohorting infected patients may be helpful in limiting the spread of organisms in the nursery. In an effort to minimize the risk of cross-contamination between patients, staff members caring for colonized or infected infants should not care for infants who are not infected or colonized.

INFECTION CONTROL

The CDC has developed a two-tiered approach to infection control. Standard precautions should be used with all patient contact regardless of the underlying diagnosis or infectious status. These precautions consist of universal precautions (designed to prevent blood and body fluid contamination) and body substance precautions (designed to prevent contamination with moist substances). Transmission-based precautions are necessary when a patient is infected with a known or suspected pathogen that is associated with a high risk of contamination via airborne or droplet transmission or contact with the skin or contaminated surfaces (Garner, 1996).

The routine use of gowns is not an effective measure to decrease the endemic HAI rate in the nursery (Garner, 1996; Goldmann, 1989, 1991). Gowns should be used in specific circumstances in which the risk for contamination is high or the infant is being held. Gowns should be changed after each patient encounter.

Visitation policies are not restrictive in most modern nurseries. Various regulatory agencies have developed guidelines for sibling visitation (Box 40-4) (American Academy of Pediatrics, 1985). Infection and colonization rates have not risen with use of the current standards. Siblings should be screened for infection or recent exposures before visiting.

BOX 40-4 Guidelines for Sibling Visitation in the Nursery

- Siblings should not have been exposed to known communicable diseases (e.g., varicella).
- Siblings should not have fever or symptoms of acute illness (i.e., upper respiratory infection or gastroenteritis).
- Children should be supervised by their parents or a responsible adult during the entire visit.
- Children should be prepared in advance for the visit.

PREVENTION OF HEALTH CARE–ACQUIRED INFECTIONS

Several intensive care nurseries have described their success in decreasing the rate of central line–associated infections (Andersen et al, 2005; Bloom et al, 2003; Kilbride et al, 2003). Until recently it was considered implausible by many that HAIs could be eliminated completely. But the challenge that faces neonatologists, nurses, respiratory therapists, physical therapists, clerks, environmental service staff, and anyone else who affects the care of the neonate now must be framed by the following question: can we get to zero? Much is known about the mechanisms of catheter-related infections and the factors that increase risk. Effective prevention strategies focus on modifying the known risks, such as standardization of procedures that relate to central line care, strategic nursery design, adequate staffing, hand-washing compliance, minimization of catheter days, and promotion of enteral nutrition, especially with human milk (Adams-Chapman and Stoll, 2002; Goldmann, 1989; Horbar et al, 2001). Care "bundles" incorporating a group of interventions aimed at standardizing central line care can be effective if a particular intensive care unit is committed to implementing them. One hundred percent compliance with adequate hand hygiene is required to eliminate the spread of viruses and bacteria, particularly those that are drug resistant. Monitoring, surveillance, and benchmarking of the HAI rates in the nursery are also critical components of any prevention program (Box 40-5). There is power in simply knowing how an individual unit compares to others, and there is empowerment in knowing that preventing HAIs is possible (Schulman et al, 2009).

HAND HYGIENE

Historic Perspective

Hand washing has clearly been shown to be the most effective and least expensive means of preventing the spread of HAI; however, compliance with this simple practice is poor (Jarvis, 1994; Larson, 1999; Pittet, 2000; Pittet et al, 2000). Historically, the benefits of hand washing have been known since the early nineteenth century. Labarraque, a French pharmacist, was one of the first to demonstrate that cleansing the hands with solutions containing lime or soda could be used as disinfectants and antiseptics (Boyce et al, 2002). The issue was further elucidated by Ignaz Semmelweis in the 1850s, who noted that the mortality and puerperal infection rates were higher among women receiving care from physicians than in those receiving care from midwives. He postulated that the puerperal fever in these patients was caused by "cadaverous particles" transmitted from the autopsy suite on the hands of the students and physicians. After

BOX 40-5 Principles for the Prevention of Health Care–Acquired Infections in the NICU

- Observe recommendations for standard precautions with all patient contact.
- Observe recommendations for transmission-based precautions as indicated.
  - Gowns
  - Gloves
  - Masks
  - Isolation
- Use good nursery design and engineering.
  - Appropriate nurse-to-patient ratio
  - Avoidance of overcrowding and excessive workload
  - Readily accessible sinks, antiseptic solutions, soaps, and paper towels
  - Maintain hand-washing practices.
  - Improving hand-washing compliance
  - Washing of hands before and after each patient encounter
  - Appropriate use of soap, alcohol-based preparations, or antiseptic solutions
  - Alcohol-based antiseptic solution at each patient's bedside
  - Emollients provided for nursery staff
  - Education and feedback for nursery staff
- Minimize risk of contamination of CVCs.
  - Maximal sterile barrier precautions during CVC insertion
  - Local antisepsis with chlorhexidine gluconate
  - Minimal entries into the line for laboratory tests
  - Aseptic technique when entering the line
  - Minimal CVC days
  - Sterile preparation of all fluids to be administered via a CVC
- Provide meticulous skin care.
- Encourage early and appropriate advancement of enteral feedings.
- Provide education and feedback for nursery personnel.
- Perform continuous monitoring and surveillance of HAI rates in the NICU.

CVC, Central venous catheter; *HAI,* health care–acquired infection; *NICU,* neonatal intensive care unit.

he instructed physicians to cleanse their hands with a chlorine solution between patients, the maternal infection and mortality rates dropped dramatically (Boyce et al, 2002; Semmelweis, 1983). This intervention represents the first clinical evidence suggesting that cleansing contaminated hands with an antiseptic agent was more effective than washing them with plain soap and water and that hand antisepsis could reduce the spread of contagious disease via the hands of health care workers (Boyce et al, 2002).

Guidelines for Hand Hygiene Practices in the Neonatal Intensive Care Unit

Clinical Indications for Hand Hygiene

Hand hygiene techniques are effective in decreasing the colonization rate of resident and transient flora and have been shown to reduce cross-contamination among patients. Several studies have shown that the hands of health care workers become contaminated during routine patient care activities, including "clean" procedures such as lifting patients and checking vital signs, as well as during contact with intact skin (Casewell and Phillips, 1977; Pittet et al, 1999). Attempts have been made to stratify the type of activity with the likelihood of contamination, but they have not been validated by quantitative bacterial contamination analysis. Direct patient contact and respiratory tract care seem to be particularly associated with contamination (Pittet et al, 1999). Organisms such as RSV, *S. aureus*, and gram-negative bacilli are able to survive on inanimate objects, so changing diapers or holding an infant infected with one of these organisms, and even touching items in the infant's environment, may result in contamination (Boyce et al, 2002; Goldmann, 1989; Hall, 2000).

Recommendations concerning indications and techniques for hand hygiene are summarized in Box 40-6 (Boyce et al, 2002; Garner and Favero, 1986; Larson, 1995). Current recommendations strongly support the use of waterless alcohol-based preparations as the primary agents for hand hygiene, except when the hands are soiled with organic material (Boyce et al, 2002). The bottom line is that hands need to be cleaned before and after every patient contact. Until there is 100% compliance with this simple intervention, HAIs will continue to be a problem.

BOX 40-6 Recommendations for Hand Hygiene Practices in the NICU

INDICATIONS FOR HAND HYGIENE

- Wash hands with a nonantimicrobial soap or an antimicrobial soap and water when hands are visibly soiled or contaminated with proteinaceous material.
- If the hands are not visibly soiled, then alcohol-based, waterless antiseptic agents are strongly preferred for routine decontamination of hands in all other clinical situations.
- Alcohol-based, waterless antiseptic agents should be available at each patient area and other convenient locations, and in individual pocket-sized containers for health care providers.
- Antimicrobial soaps can be considered in settings with few time constraints and easy access to hand hygiene facilities.
- Decontaminate hands after contact with intact patient skin (i.e., checking pulse or lifting).
- Decontaminate hands after contact with body fluids or excretions, mucous membranes, nonintact skin, or wounds.
- Decontaminate hands before applying sterile gloves or inserting a central intravascular catheter.
- Decontaminate hands before inserting indwelling urinary catheters or other invasive devices not requiring surgical procedures.
- Decontaminate hands after removing gloves.
- Decontaminate hands before caring for patients with severe neutropenia or severe immunosuppression.
- Decontaminate hands after contact with inanimate objects in the immediate vicinity of the patient.

RECOMMENDED TECHNIQUES FOR HAND HYGIENE

- When using a waterless antiseptic agent, apply enough of the product to cover all surfaces of the hands and fingers, and rub hands together until they are dry. Each manufacturer has guidelines for the volume to be used; in general, enough should be applied so that it takes 15 to 25 seconds to dry.
- When using a nonantimicrobial or antimicrobial soap, wet hands, apply 3 to 5 mL of solution to the hands, and rub for at least 15 seconds. Be sure to cover all surfaces of the hands and fingers. Rinse hands with warm water, and dry thoroughly. Foot pedals, automatic faucets, or towel barriers should be used to turn off the water.

+++, Excellent; *++*, good, but does not include the entire bacterial spectrum; *+*, fair; –, no activity or not sufficient.
*Hexachlorophene is not included because it is no longer an accepted ingredient of hand disinfection.

Preparations for Hand Hygiene

Washing the hands with soap causes suspension and mechanical removal of microorganisms and dirt from the hands. *Hand disinfection* refers to the same process, but with the use of an antimicrobial product to kill or inhibit microorganisms. Table 40-3 compares properties of the various hand hygiene agents.

The cleansing activity of plain soap results from its detergent properties (Boyce et al, 2002). Hand washing with soap alone reduces bacterial colonization of the hands, but has no significant antimicrobial activity and is ineffective at removing pathogenic flora. Soaps containing antimicrobial agents are typically used in the NICU environment.

The antimicrobial activity of alcohol stems from its ability to denature proteins (Boyce et al, 2002). Because proteins are not readily denatured in the absence of water, solutions containing 50% to 80% alcohol are most effective (Boyce, 2000; Boyce et al, 2002). Alcohol has a rapid onset of action and reduces bacterial colonization, but has no residual activity. The efficacy of alcohol-based products is influenced by the type of alcohol used, concentration, contact time, volume used, and whether the hands are wet when the product is applied (Boyce et al, 2002; Mackintosh and Hoffman, 1984). When used in adequate amounts, alcohol is usually more effective than other hand hygiene products (Boyce, 2000; Boyce et al, 2002).

Chlorhexidine gluconate is a cationic bis-biguanide whose antimicrobial activity is caused by attachment and disruption of cytoplasmic membranes (Boyce et al, 2002). The onset of action is slower than the alcohol-based preparations; however, its major benefit is the persistent antimicrobial activity, which may last up to 6 hours after application (Boyce et al, 2002; Larson, 1995). Varying percentages of this product have been added to other hand hygiene preparations, especially the alcohol-based preparations, to confer greater residual activity.

Hexachlorophene is a bisphenol compound with bacteriostatic properties. Its activity is due to its ability to inactivate essential enzymes systems. It has good activity against *S. aureus*, but weak activity against gram-negative bacteria, fungi, and *Mycobacterium tuberculosis*. Hexachlorophene also has residual activity. Hexachlorophene was used for routine bathing of newborn infants until 1972, when the U.S. Food and Drug Administration (FDA) warned against its use because of an increased occurrence of cystic degeneration of the cerebral white matter in infants who had been bathed in the 3% solution (Shuman et al, 1975). This product should be considered only in term infants during a severe outbreak of *S. aureus*. Most experts recommend diluting the material 1:4 with water to decrease the risk of systemic absorption.

Iodine and iodophors penetrate the cell walls of organisms, impairing protein synthesis and altering the cellular membranes (Boyce et al, 2002). The amount of iodine present determines the level of antimicrobial activity. Combining iodine with polymers (i.e., povidone or poloxamer) increases the solubility, promotes sustained release of iodine, and decreases skin irritation. The activity of this product is affected by pH, exposure time, temperature, the presence of organic (blood or sputum) or inorganic material, and the concentration of iodine.

Compliance

Despite the fact that the benefits of hand washing have been reported since the nineteenth century, compliance with hand-washing protocols remains unacceptably low. The overall compliance rate is approximately 40% (Pittet, 2000). Reported barriers to compliance with hand hygiene recommendations include skin irritation, poor accessibility of sinks or cleansing agents, greater priority for patient needs, insufficient time, heavy workload and understaffing, and lack of information (Box 40-7). A common misconception is that using gloves obviates the need for adequate hand hygiene.

BOX 40-7 Factors Influencing Compliance With Hand Hygiene Practices

OBSERVED RISK FACTORS FOR POOR ADHERENCE TO RECOMMENDED PRACTICES

- Physician status (rather than a nurse)
- Nursing assistant status (rather than a nurse)
- Working in an intensive care unit
- Working during the week compared with the weekend
- Wearing gowns and gloves
- Automated sink faucet
- Activities with high risk of contamination
- High numbers of indications for hand hygiene per hour of patient care

SELF-REPORTED FACTORS FOR POOR ADHERENCE TO RECOMMENDED PRACTICES

- Agents are irritating or drying
- Inconvenient location of sinks and supplies
- Inadequate supplies (e.g., soap, paper)
- Too busy
- Patient needs take priority
- Perceived low risk of acquiring infection
- Gloves obviate the need for hand hygiene
- Lack of knowledge of guidelines and recommendations
- Disagreement with recommendations

Data from Pittet D: Improving compliance with hand hygiene in hospitals, *Infect Control Hosp Epidemiol* 21:381-386, 2000; and Boyce JM: Using alcohol for hand antiseptics: dispelling old myths, *Infect Control Hosp Epidemiol* 21:438-441, 2000.

Leakage and contamination of gloves have been reported (Boyce et al, 2002; Larson, 1995). Disposable single-use gloves should be removed after each patient encounter, and hands should be washed before and after their use.

Hand hygiene is extremely cost effective. The additional hospital charges associated with a single HAI almost equal the yearly hand hygiene budget. Pittet et al (2000) estimated the cost of a hand hygiene intervention program to be less than $57,000 per year. Assuming that only 25% of the observed decrease in infections was attributable to improved hand hygiene practices, they estimated a savings of $2,100 for every infection averted.

PREVENTION OF CENTRAL LINE–ASSOCIATED BLOODSTREAM INFECTIONS

The care and maintenance of central venous catheters may affect the risk of catheter-related bloodstream infection. Before insertion of an intravascular device, attempted sterilization of the skin insertion site is of utmost importance. The recommended technique for skin antisepsis is to use two consecutive 10-second applications or a single 30-second application of the selected antibacterial agent. Sterile water rather than alcohol should be used to remove antiseptics from the skin. Povidone-iodine (10%) solution is commonly used for skin antisepsis; however, data suggest that chlorhexidine gluconate is more effective at decreasing skin colonization and subsequent CLABSIs in adults, as well as colonization of peripheral intravenous catheters in neonates (Darmstadt and Dinulos, 2000; Garland et al, 1995).

Hub colonization and repeated entry into the line for administration of medications or collection of specimens for laboratory studies are both associated with an increased risk for infection. Salzman et al (1993) conducted a prospective study in which surveillance cultures of catheter hubs were performed three times per week, and blood cultures and hub cultures were conducted for any suspected episode of sepsis. These investigators found that 54% of 28 episodes of CLABSI were preceded by or coincided with colonization of the catheter hub with the same pathogen. This mechanism has been confirmed in the neonatal population by Garland et al (2008). Mahieu et al (2001b) reported that catheter manipulation for blood sampling and fluid or tubing changes raised the risk of colonization. Despite the lack of large randomized controlled trials, the available data suggest that the use of heparin in intravenous fluids is associated with a lower risk of bacterial colonization and thrombosis (Appelgren et al, 1996; Mahieu et al, 2001b). It is hypothesized that heparin prevents bacteria from adhering to the catheter and that the preservatives in heparin preparations have some limited antibacterial properties.

Various products have been designed to decrease the risk of catheter-related infection in adult patients. Although data on their use are promising, many of the currently available products are not specifically designed for the neonate, and their safety and efficacy have not been tested in this patient population. Antiseptic- or antibiotic-impregnated catheters have been shown to significantly decrease the risk of CLABSI in adults (Elliott, 2000; Marin et al, 2000; Pai et al, 2000; Tennenberg et al, 1997; Veenstra et al, 1999). Pierce et al (2000) reported that pediatric patients randomly assigned to the use of a heparin-bonded device had a lower incidence of CLABSI than controls (4% versus 33%; $p < 0.005$). Studies are in progress to evaluate the efficacy of antibiotic lock therapy in neonates. Johnson et al (1994) treated a small group of pediatric patients with CLABSIs with antibiotic lock therapy for 10 days. They reported that 10 of 12 catheters were salvaged. There are limited data describing the use of antibiotic lock therapy in neonates. Garland et al (2002) randomly assigned 82 VLBW infants to saline control or vancomycin antibiotic lock therapy of catheters in an effort to prevent CLABSI. These researchers found a significantly lower incidence density of catheter-related infections, no evidence of toxicity, and no cases of VRE in the neonates receiving antibiotic lock therapy.

UMBILICAL CORD CARE

Umbilical cord infections remain a significant cause of neonatal mortality in developing nations, although not in the United States (Zupan and Garner, 2000). In clinical practice, there are numerous approaches to umbilical cord care in the healthy term infant because the available data are insufficient to recommend the use of a specific agent or regimen (Zupan and Garner, 2000). Most authorities agree that the umbilical cord should be separated from the placenta with the use of good aseptic technique. Subsequently, some experts recommend "natural drying," but others support the use of an antiseptic agent such as alcohol, silver sulfadiazine, chlorhexidine, triple dye, or gentian violet (Darmstadt

and Dinulos, 2000; Hsu et al, 1999; Pezzati et al, 2002; Zupan and Garner, 2000). Hexachlorophene and iodine are used sparingly because of concerns about their systemic absorption and toxicity. Studies have shown that antiseptic products decrease umbilical cord colonization. Unfortunately, this decrease has not clearly resulted in a lower incidence of umbilical cord infections. In a meta-analysis that included "no intervention" as an alternative, Zupan and Garner (2000) were unable to determine which regimen was superior. In general, they found that time to cord separation was prolonged when antiseptics were used, but there were no significant differences in the incidence of infection or death with the use of a particular agent for cord care.

SKIN CARE

The skin of VLBW preterm infants is immature and functions as an ineffective barrier to prevent transepidermal loss of water and invasion of bacteria. The stratum corneum (the outermost layer of skin) has both mechanical and chemical properties that decrease the risk of infection (Darmstadt and Dinulos, 2000). This layer of skin matures at approximately 32 weeks' gestation. In a prematurely born neonate, the maturation process is accelerated and is usually complete by 2 to 4 weeks after birth (Darmstadt and Dinulos, 2000).

Unfortunately, there is no consensus on the most effective skin care practices for VLBW infants (Baker et al, 1999; Munson et al, 1999). Neonatologists had hoped that the application of a topical emollient would protect the developing epidermal layer, reduce the risk of infection, and prevent transepidermal water loss. Several studies have documented that such a practice decreases water loss; however, there was no significant reduction in HAI in VLBW infants randomly assigned to receive routine application of one emollient product (Aquaphor) in a study performed by Edwards et al (2001). Infants randomly assigned to emollient therapy had more nosocomial bloodstream infections, particularly with CONS. This difference was most evident in infants with birthweights of 501 to 750 g.

The efficacy of other topical agents warrants further study. Efforts to prevent traumatic injury to the skin of VLBW infants include the use of transparent dressing over bony prominences, semipermeable barriers between the skin and adhesive tape, and water-activated electrodes and the avoidance of agents such as tincture of benzoin, Mastisol, and adhesive removers (Adams-Chapman and Stoll, 2002; Darmstadt and Dinulos, 2000; Hoath and Narendran, 2000).

MANAGEMENT OF HEALTH CARE–ACQUIRED INFECTIONS

CATHETER-RELATED BLOODSTREAM INFECTIONS

Management of neonates with CLABSIs is problematic because of the limited intravenous access in most patients, as well as the lack of consensus among clinicians. Current recommendations for adults regarding catheter removal with associated CLABSI suggest the removal of nontunneled central venous catheters associated with bacteremia or fungemia, unless the pathogen is CONS (Mermel et al, 2001). A patient with a catheter-related infection caused by CONS should undergo catheter removal if culture results are persistently positive or if the patient's condition is unstable (Benjamin et al, 2001; Karlowicz et al, 2000).

Benjamin et al (2001) retrospectively reviewed data on infants with CLABSIs and compared outcomes in patients in whom catheters were removed at the onset of infection with those in whom catheters remained in place. Forty-six percent (59 of 128) of infants in whom catheter sterilization was attempted had complications, compared with 8% (2 of 25) of those in whom catheters were removed. In particular, infants with gram-negative infections were more likely to have complications if their catheters remained in place. A study of infants with CLABSIs caused by CONS found no difference in the complication or mortality rate in patients in whom removal of the catheter was delayed (Karlowicz et al, 2000). However, patients with a CONS infection related to their central line were more likely to have persistently positive culture results when their lines were not removed with the first positive culture (43% versus 13% for immediate catheter removal). The attempt to retain the catheter was never successful if culture results remained positive for more than 4 days. Additional prospective randomized trials are needed to validate these observational data.

ANTIBIOTIC AND ADJUNCTIVE THERAPIES

Antibiotic therapy that is effective against a culture-proven or suspected pathogen is the primary treatment for HAIs. As a general rule, antibiotic choice should initially cover a broad spectrum of pathogens and should then be narrowed as soon as possible to cover the specific bacteria identified once sensitivities are known, or it should be discontinued if infection is not proved and is not likely. One should consider coverage for *Pseudomonas* spp. or other resistant gram-negative organisms in patients with a rapid clinical deterioration (Karlowicz et al, 2000; Stoll et al, 2002a). However, empiric broad-spectrum antibiotic use should be limited as much as possible to avoid complications of resistant bacterial and fungal infections.

A metaanalysis of the prophylactic use of intravenous immunoglobulin (IVIG) in preterm neonates found only a 3% reduction in HAI and no reduction in mortality (Modi and Carr, 2000; Ohlsson and Lacy, 2001a). The benefit in patients with culture-proven sepsis remains unclear, and IVIG is therefore not recommended for routine use in such patients (Modi and Carr, 2000). Some authorities speculate that the benefit of IVIG would be greater if products containing high concentrations of specific antibodies against pathogens frequently responsible for neonatal infections were developed (Hill, 2000; Ohlsson and Lacy, 2001b; Weisman et al, 1994). Hemopoietic colony-stimulating factors (granulocyte and granulocyte-macrophage) are effective in raising the neutrophil count, but have not consistently decreased HAI rates or mortality

(Carr et al, 2003; Modi and Carr, 2000). Studies are being conducted in adults to evaluate the efficacy of administering various cytokine preparations known to modulate the inflammatory response.

CONCLUSION

Interventions to reduce HAI are urgently needed. Infants with HAIs have significantly longer hospital stays (79 versus 60 days; $p < 0.001$) and higher hospital costs (Gray et al, 1995; Mahieu et al, 2001a; Pittet et al, 1994; Stoll et al, 2002a). The higher costs are primarily caused by daily hospital charges and pharmaceutical fees (Mahieu et al, 2001a). The attributable cost of a nosocomial infection has been estimated to be approximately $40,000 per adult case and $1200 per neonatal case (Mahieu et al, 2001a; Pittet et al, 1994). The magnitude of these costs is significant, especially when considering the growing number of surviving VLBW infants, who are at the highest risk for acquiring an HAI. Moreover, infants who experience an HAI are significantly more likely to die than are those who remain uninfected (Stoll et al, 1996, 2002a).

A variety of new therapeutic alternatives is currently being investigated. Clinicians must continue to focus on developing effective prevention strategies, including strict hand-washing policies, minimal use of invasive devices, promotion of enteral nutrition surveillance of infection patterns, and education for the nursery staff members. Quality improvement approaches can be effective in implementing the necessary practices within a given unit.

CHAPTER 41

Fungal Infections in the Neonatal Intensive Care Unit

Margaret K. Hostetter

EPIDEMIOLOGY

Invasive fungal infection occurs in approximately 1% to 2% of all infants admitted to U.S. neonatal intensive care units (NICUs) (Stoll et al, 1996), and the incidence rises dramatically with decreasing gestational age. Among the fungi, *Candida* spp. is the dominant pathogen, with infections evenly distributed among *C. albicans* and non–*C. albicans* species (*C. parapsilosis*, *C. orthopsilosis*, *C. metapsilosis*, *C. glabrata*, *C. guilliermondii*, *C. krusei*, and *C. lusitaniae*). *Candida* spp. are the third most common cause of late-onset sepsis in the NICU, with a fatality rate more than sevenfold greater than that of *Staphylococcus epidermidis*, the most common pathogen (Benjamin et al, 2000; Saiman et al, 2001). Other fungi encountered include *Aspergillus fumigatus*, *A. flavus*, *Malassezia furfur*, *M. pachydermatis*. The yeast *Cryptococcus neoformans* and the fungi *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis* are rarely if ever seen in the NICU.

The most important risk factor for fungal infection is gestational age. In a survey of 2847 infants from six different nurseries, the incidence of candidemia in infants weighing less than 800 g (7.55%) was 25-fold that of the infant weighing more than 1500 g (Figure 41-1) (Saiman et al, 2000). This latter group acquires blood-borne candidal infection in association with congenital anomalies, especially those of the gastrointestinal tract (Rabalais et al, 1996). Candidemia carries a mortality rate exceeding 25% in most studies (Chapman and Faix 2000; Weese-Mayer et al, 1987).

Colonization with ubiquitous fungal species occurs in at least 25% of very low-birthweight infants (Baley et al, 1986), and both the amount of *Candida* spp. in the gastrointestinal tract (Pappu-Katikaneni et al, 1990) and colonization at sites such as endotracheal tubes (Rowen et al, 1994) have been correlated with increased risk of invasive disease caused by *Candida* spp. Prospective studies correlating colonization by other fungal genera (e.g., *Aspergillus*, *Malassezia* spp.) with risk of invasive disease have not been done.

Apart from colonization and gestational age, other host factors that contribute to the susceptibility of the infant in the NICU to fungal infection include 5-minute Apgar scores less than 5, and an age-dependent immunocompromised state ascribable to reduced numbers of T cells, impaired phagocyte number and function, and reduced levels of complement (Marodi et al, 1994; Rebuck et al, 1995; Witek-Janusek et al, 2002; Zach and Hostetter, 1989). Concomitants of nursery care that are thought to increase the risk of fungal infections include length of stay greater than 1 week, indwelling central venous catheters, abdominal surgery, parenteral nutrition, intralipids, H_2 (histamine) receptor antagonists, endotracheal intubation, and prolonged use of broad-spectrum antimicrobials, especially third-generation cephalosporins (Cotten et al, 2006; Saiman et al, 2001; Saiman et al, 2000). Other centers have identified associations with systemic steroids and catecholamine infusions in retrospective studies and with topical petrolatum in a prospective case-control study (Benjamin et al, 2000; Botas et al, 1995; Campbell et al, 2000).

Interestingly, a number of variables appear not to associate with candidal colonization, including the use of antibiotics in the mother, premature rupture of the membranes, the infant's gender, the use of antimicrobial agents other than third-generation cephalosporins in the infant, surgical procedures, or frequency of intubation (Saiman et al, 2001). Although ≈5% of NICU staff members carry *C. albicans* on the hands and 19% carry *C. parapsilosis*, there is no correlation with site-specific rates of infant colonization (Saiman et al, 2001).

This chapter will place major emphasis on infections caused by *Candida* spp. and other fungi, as well as the approach to diagnosis, treatment, and management of infants with fungal infection.

INFECTIONS CAUSED BY *CANDIDA* SPECIES

CONGENITAL CANDIDIASIS

Appearing within the first 24 hours of life in both full-term and premature infants, congenital candidiasis, a very rare entity, manifests as a deeply erythematous skin rash in the setting of pronounced neutrophilia, with white blood cell counts often rising to 50,000 or more, and infrequently *Candida* spp. funisitis (see Local Infections, later). In the full-term infant, there are no invasive consequences, and desquamation typically ensues within 2 to 3 days. In contrast, the condition is life threatening in the premature infant (Dvorak and Gavaller, 1966; Johnson et al, 1981) and is distinguished by a pustular rash, hazy infiltrates reminiscent of respiratory distress syndrome on chest radiograph, and frequently positive blood cultures. The premature infant is thought to acquire the organism from inhaling infected amniotic fluid.

Diagnosis in both premature and full-term infants requires the visualization of the organism on Gram stain from a bullous lesion or an opened pustule. On rare occasions, the placenta has yielded the diagnosis. Treatment for the full-term infant requires only the full-body application of topical antifungal creams containing either nystatin or azoles, such as miconazole or clotrimazole. In the premature infant, initiating parenteral amphotericin B deoxycholate at a dose of 1 to 1.5 mg/kg is mandatory, but respiratory involvement typically heralds death despite anti-fungal therapy.

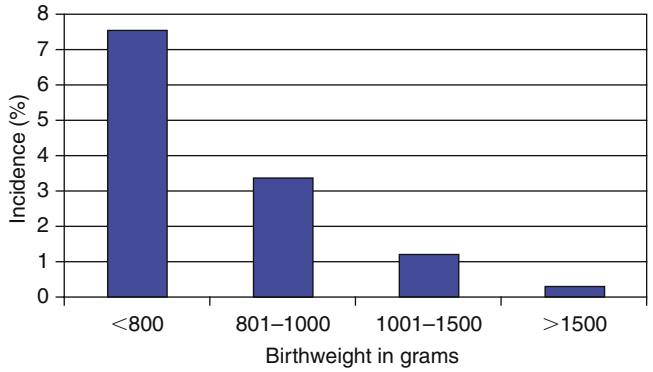

FIGURE 41-1 Incidence of candidemia related to birthweight in grams. *(Data from Saiman L et al: Risk factors for candidemia in Neonatal Intensive Care Unit patients. The National Epidemiology of Mycosis Survey study group*, Pediatr Infect Dis J *19:319-324, 2000.)*

LOCAL INFECTIONS WITH *CANDIDA* SPECIES

Diaper Dermatitis

Diaper dermatitis manifests as an erythematous, erosive dermatitis of the perineal region, typically with pustular satellite lesions beyond the borders of the rash. Predisposing factors include systemic antibiotics, glucosuria, and wet diapers. Care must be taken to differentiate this tractable condition from invasive fungal dermatitis (see Invasive Fungal Dermatitis, later). The infection responds well to topical antifungal ointments.

Funisitis

Infection of the umbilical cord with *Candida* spp., although rare, is an indicator of chorioamniotitis and carries a poor prognosis, especially in the premature infant (Qureshi et al, 1998). A minority (16%) of infants in one study had associated congenital candidiasis. Intrauterine contraceptive devices or cervical cerclage were reported in 16% of the mothers.

Urinary Tract Infection

Isolation of *Candida* spp. from a catheterized specimen or suprapubic aspiration, as opposed to a bagged sample, is a reliable indicator of infection, although asymptomatic colonization of urinary catheters, stents, or nephrostomy tubes can be difficult to distinguish from true infection (Lundstrom and Sobel, 2001).

The presence of candiduria in infants in the NICU is associated with renal candidiasis—the latter manifested by cortical abscesses or fungal mycelia in the collecting system ("fungus balls")—almost half the time and may be a cause of frank obstruction (Bryant et al, 1999). Therefore, in contrast to older children or adults, the finding of candiduria in an infant in the NICU should at least prompt blood cultures and renal imaging. If blood cultures prove to be positive, a full evaluation for disseminated candidiasis should be undertaken (see Systemic Infection, later).

Because of the high prevalence of associated upper tract disease, imaging of the kidneys by ultrasonography should occur after isolation of the organism from a sterile urine specimen. Approximately one half of the patients who eventually develop upper tract manifestations will display them on the first ultrasound (Bryant et al, 1999). Therefore follow-up imaging is recommended both to ensure the clearance of fungal mycelia, if present, and to monitor for later development of this complication. Unfortunately, no standard interval for monitoring has been proposed; however, in the infant with persistent funguria or candiduria, a single negative ultrasound should not be considered definitive.

Removal of a colonized urinary catheter may suffice for treatment in a patient without pyuria or systemic symptoms. Disease confined to the lower tract is best addressed with azoles (e.g., fluconazole, 4 to 6 mg/kg/day). Upper tract disease requires parenteral amphotericin B in systemic doses (1 to 1.5 mg/kg/day). Liposomal amphotericin B may not be an acceptable alternative. The particles in at least one liposomal preparation (Abelcet) appear to be too large to penetrate the adult kidney (Hell et al, 1999), and this author has seen a premature newborn whose persistent candiduria failed to resolve until treatment was changed to amphotericin B deoxycholate.

PERITONITIS

Candida spp. peritonitis typically develops as a consequence of bowel perforation or rarely as a complication of peritoneal dialysis. In the former situation, multiple organisms such as gram-negative rods and enterococci may also be involved, and the neonate is at risk for sepsis with any one of them (Johnson et al, 1980). Peritonitis associated with a peritoneal dialysis catheter usually occurs as an isolated process, and the outcome is much better.

Spontaneous intestinal perforation associated with *Candida* spp. peritonitis with or without sepsis has been described within 7 to 10 days of birth in infants weighing less than 1000 g, typically in the absence of necrotizing enterocolitis (Adderson et al, 1998; Holland et al, 2003; Meyer et al, 1991; Mintz and Applebaum, 1993). Hallmark clinical findings include bluish discoloration of the abdomen and a gasless pattern on abdominal film. A substantial proportion of these infants will have systemic candidiasis, although *Staphylococcus epidermidis* can also be seen. In a small study of seven patients (Holland et al, 2003), deficiency of the muscularis propria was found in six.

Diagnosis requires visualization of the organism on a Gram stain of peritoneal fluid sterilely obtained or culture of the organism from the same source. Isolation of *Candida* spp. from the peritoneal fluid should always prompt a search for bowel perforation, by either radiology or surgical exploration, depending upon the clinical circumstances.

Treatment of *Candida* spp. peritonitis caused by necrotizing enterocolitis or bowel perforation requires surgical evaluation, supportive therapy, and direct address of all contaminating microorganisms in the peritoneal fluid and the bloodstream. The typical regimen may include ampicillin and an aminoglycoside for enterococci and gram-negative rods, clindamycin for anaerobes, and systemic antifungal therapy, most likely with amphotericin B. The isolation of *Candida* spp. from peritoneal dialysate can be treated with removal of the catheter and a short course (7 to 10 days) of amphotericin B therapy in a dose of

0.3 to 0.5 mg/kg/day. The catheter can typically be reinserted within 24 to 48 hours, once the Gram stain is free of yeast cells.

SYSTEMIC INFECTION

CANDIDEMIA ASSOCIATED WITH CENTRAL VENOUS CATHETERS

The association between prematurity and blood-borne candidal infections has been recognized for 25 years (Baley et al, 1984; Johnson et al, 1984). Over this same period of time, the incidence of candidemia has escalated from 25 to 123 cases per 10,000 NICU admissions (Kossoff et al, 1998; Saiman et al, 2000). The median time of onset is approximately 30 days of age (Baley et al, 1984). In a large multicenter study, colonization of the gastrointestinal tract preceded candidemia in 43% of cases (Saiman et al, 2000).

A variety of nonspecific clinical findings may be associated with this presentation of candidal disease, including respiratory decompensation, feeding intolerance, temperature instability, or mild thrombocytopenia. It is unclear whether the latter manifestation relates more to the use of heparin in vascular catheters or to the presence of *Candida* spp. in the blood stream.

Isolation of *Candida* spp. from a blood culture should never be regarded as a contaminant and should prompt an immediate search for evidence of dissemination, which occurs in approximately 10% of premature newborns with candidemia (Noyola et al, 2001; Patriquin et al, 1980). A thorough evaluation includes ophthalmologic examination and ultrasonography of the heart, venous system, and abdomen. When lumbar puncture is performed, 10% to 50% of infants with candidemia may have associated meningitis (Benjamin et al, 2006; Faix, 1984); in one prospective study, almost 50% of extremely low-birthweight (ELBW) infants with *Candida* spp. meningitis (13/27) had negative blood cultures (Benjamin et al, 2006).

Numerous studies have shown that central venous catheters should be removed within 24 hours after identification of yeasts in the blood culture (Karlowicz et al, 2000); in particular, removal of the central venous catheter within 3 days is associated with a significantly shorter median duration of candidemia (3 versus 6 days) and a reduced mortality rate (0% versus 39%). In at least one study of candidemia, delayed removal of central venous catheters was associated with neurodevelopmental impairment at 18 to 22 months (Benjamin et al, 2006). Many experts recommend routine echocardiograms for patients with catheter-associated candidemia to look for thrombi before removal of the catheter. However, even with the prompt removal of the catheter and the institution of appropriate antifungal therapy, a substantial proportion of infants may exhibit prolonged candidemia lasting 1 to 3 weeks (Chapman and Faix, 2000).

DISSEMINATED CANDIDIASIS

Mortality rates approach 30% for this dreaded complication of candidal infection. *C. albicans* is the leading pathogen. Organ involvement is most common in the vascular tree at catheter sites (15.2%), followed by the kidneys (7.7%) (Noyola et al, 2001; Patriquin et al, 1980). Eye involvement occurs in approximately 6% of infants. Thrombi within the vascular bed may be particularly difficult to eradicate with antifungal therapy; infants with right atrial thrombi may benefit from atriotomy (Foker et al, 1984). Other sites less frequently involved include the liver, spleen, and skeletal system. In infection of the bones and joints in premature newborns, *Candida* spp. are typically the second most likely pathogen, preceded by *Staphylococcus aureus* (Ho et al, 1989).

ANTI-FUNGAL THERAPY FOR SYSTEMIC INFECTION

As is true of most medications used in the neonatal ICU, dosing recommendations for antifungal therapies have not undergone rigorous testing in this patient population. With that caveat in mind, it is important to discuss practice guidelines for this difficult clinical problem. Amphotericin B is the standard antifungal therapy for treatment of systemic neonatal fungal infection. The drug binds to ergosterol in the membrane of fungi, facilitating membrane leakage. Rapid institution of parenteral amphotericin B deoxycholate in doses of 1.0 to 1.5 mg/kg/day, given by intravenous infusion over 2 to 6 hours, is the therapy of choice for systemic infection, including catheter-associated candidemia and disseminated candidiasis. No more than 24 hours should elapse before the infant is receiving a dose of 0.7 to 1.0 mg/kg/day. Some experts recommend instituting empiric antifungal therapy in acutely thrombocytopenic ELBW infants (Benjamin et al, 2003). Dose adjustment for renal dysfunction is necessary only if serum creatinine increases significantly during therapy. Amphotericin B has poor cerebrospinal fluid penetration; therefore accompanying meningitis should prompt the addition of 5-flucytosine in doses of approximately 12.5 to 37.5 mg/kg per dose given by mouth every 6 hours (in patients with normal renal function). Peak serum concentrations of this drug should be kept between 40 and 60 μg/mL to avoid bone marrow suppression or hepatotoxicity. Fluconazole may also be added to amphotericin B for meningeal penetration, if 5-flucytosine is unavailable or cannot be used.

Infants being treated with amphotericin B who experience a twofold rise in creatinine, which is evidence of renal tubular compromise or renal tubular acidosis, may benefit from use treatment with one of the liposomal amphotericin preparations. AmBisome has been used in neonates at well-tolerated doses of 5 to 7 mg/kg per dose every 24 hours intravenously, infused over 2 hours (Juster-Reicher et al, 2003; Weitkamp et al, 1998), although the failure of many liposomal preparations to penetrate renal parenchyma can militate against fungal clearance from this organ.

With prompt removal of an offending central venous catheter, and no evidence of dissemination, the duration of therapy for catheter-associated candidemia is typically 10 to 14 days after the blood culture becomes negative (Donowitz and Hendley, 1995). Disseminated candidiasis, including *Candida* spp. meningitis, requires at least 3 weeks or more of parenteral therapy; the course is typically completed when all foci have been eradicated. Most infectious disease experts will use fungicidal doses of parenteral

amphotericin B or a liposomal preparation for the entire course. Azoles (such as fluconazole at 6 mg/kg intravenously at varying dosing intervals) are antifungal agents that interfere with ergosterol synthesis by inhibiting C-14 alpha demethylase, a cytochrome P450 enzyme. Use of an azole to complete the latter part of an antifungal course must account for the inability of the infant's immune system to compensate for the fungistatic activity of the azoles. Azoles such as itraconazole and posaconazole are preferable to fluconazole for aspergillus and zygomycetes, but no studies have been done to recommend neonatal dosing guidelines.

Although not a first-line antifungal medication, echinocandins such as caspofungin, which interrupt biosynthesis of β-(1,3)-D-glucan, an integral part of the fungal cell wall, have also been used in doses of 1 to 2 mg/kg/day to treat invasive candidal disease in the newborn in several case reports; this drug is particularly helpful for species such as *Candida glabrata*, *Candida krusei* or *Candida lusitaniae*, which may have decreased susceptibility or de novo resistance to amphotericin B (Odio et al, 2004; Saez-Llorens et al, 2009).

ANTI-FUNGAL PROPHYLAXIS

Five randomized, controlled trials comparing intravenous fluconazole (3 mg/kg/day) with placebo or no treatment in very low-birthweight (VLBW) or ELBW infants for 4 to 6 weeks (Cabrera et al, 2002; Kaufman et al, 2001; Kicklighter et al, 2001; Manzoni et al, 2007; Parikh et al, 2007) met criteria for analysis in Cochrane reviews (Clerihew et al, 2007). Kaufman and Manzoni reported significantly lower incidence of invasive fungal infection, whereas there was no difference in treated versus untreated infants in other studies (Cabrera et al, 2002; Kicklighter et al, 2001; Parikh et al, 2007). The only study to evaluate neurologic outcomes found no difference in neurologic impairment at 16 months (Kaufman et al, 2001). Fluconazole prophylaxis did not create a significant difference in the risk of death before discharge in any of the five studies or in a metaanalysis (Clerihew et al, 2007). No study documented clinically significant adverse effects of fluconazole or the emergence of fluconazole resistance.

One study from a single center compared nonrandomized fluconazole prophylaxis in 2002 to 2006 with an untreated, retrospective cohort (2000 to 2001) and reported that invasive candidiasis decreased from 0.6% to 0.3%, although the proportion of invasive disease caused by non–*C. albicans* species increased from 26% to 41% after the introduction of fluconazole prophylaxis (Healy et al, 2008). Interestingly, fluconazole prophylaxis in this study was extended to several infants with birthweights greater than 1000 g, if risk factors (e.g., maternal HIV infection, intestinal abnormalities) were present.

The finding that prophylactic fluconazole reduces the incidence of invasive fungal infection must be interpreted with caution (Clerihew et al, 2007, 2008):

1. The incidence of invasive fungal infection in the placebo groups (Kaufman et al, 2001; Manzoni et al, 2007; Parikh et al, 2007) was significantly higher (13% to 16%) than in other large cohort studies of VLBW or ELBW infants in the United States (6% to 7%) or the United Kingdom (1% to 2%).
2. Fluconazole prophylaxis may have impaired the microbiologic isolation of some fungal species and led to underdiagnosis of infection in the treatment group.
3. Six years after the introduction of fluconazole prophylaxis, one study reported that non–*C. albicans* species with relatively reduced susceptibility to the azoles were the most common causes of invasive fungal infection (Parikh et al, 2007). This study did not detect a significant effect of fluconazole prophylaxis in reducing invasive candidal disease.

Based on these results and cautionary notes, infants weighing less than 1000 g who receive third-generation cephalosporins and central venous catheters may be the best group to be evaluated for a statistically significant benefit of fluconazole prophylaxis in preventing invasive fungal infection, neurologic complications, and death before hospital discharge. Study durations less than 6 years may be insufficient to detect the emergence of fluconazole resistance.

INFECTIONS ASCRIBABLE TO OTHER FUNGI

INVASIVE FUNGAL DERMATITIS

Invasive fungal dermatitis typically manifests in the infant weighing less than 1000 g who displays macerated or bruised lesions that are contaminated with fungal species. In the initial report, three of seven confirmed cases had *C. albicans*, *C. parapsilosis*, *C. tropicalis*, *Trichosporon beigelii*, *Curvularia* spp., or *Aspergillus niger* and *A. fumigatus* were cultured from the remainder (Rowen et al, 1995). Among cases considered "probable," seven of eight had *C. albicans*. Systemic complications including fungemia, meningitis, or infection of the urinary tract occurred in four of seven confirmed cases and seven of eight probable cases. More cases than controls had postnatal steroids and prolonged hyperglycemia. Disseminated infection occurred in 69%, all ascribable to *Candida* spp.

Diagnosis requires a skin biopsy specimen demonstrating fungal invasion beyond the stratum corneum or a positive potassium hydroxide preparation of skin scrapings; growth of the identical organism from an otherwise sterile site (blood, cerebrospinal fluid, or urine obtained via supra pubic aspiration) is confirmatory. Treatment requires systemic doses of amphotericin B in the range of 0.7 to 1.0 mg/kg/day; in infants who do not develop systemic infection, oral therapy with fluconazole or topical antifungal creams may suffice. Oral therapy is not advisable for pathogens like *Aspergillus* spp., and repeated skin biopsies may be necessary to define duration of therapy.

LINE INFECTIONS CAUSED BY LIPOPHILIC ORGANISMS

The species *Malassezia furfur* and *Malassezia pachydermatis* are lipophilic organisms commonly carried on the skin, even in patients without tinea versicolor (Marcon and

Powell, 1992). Cutaneous colonization can infect hyperalimentation fluids or parenteral lipid formulations. Infants typically exhibit mild but nonspecific signs: respiratory decompensation, glucose intolerance, or thrombocytopenia (Dankner et al, 1987; Stuart and Lane, 1992). Diagnosis requires isolation of the organism from blood by growth on fungal medium overlaid with olive oil, because *Malassezia* spp. will not grow in the absence of lipids (Marcon et al, 1986). Removal of the intravascular catheter usually suffices for therapy, although some experts recommend the addition of amphotericin B in dosages of 0.5 mg/kg/day for 7 days.

MISCELLANEOUS FUNGAL INFECTIONS

Aspergillus species

Although rarely seen in neonates, systemic infection with *Aspergillus* spp. suggests severe immune system compromise, such as DiGeorge Syndrome or myeloperoxidase deficiency (Chiang et al, 2000; Marcinkowski et al, 2000). Disseminated disease has occurred in premature newborns without additional immunologic abnormalities (Rowen et al, 1992). Diagnosis requires isolation of the fungus from a normally sterile tissue site or visualization by Gomori-methenamine silver stain on a biopsy specimen of infected tissue. Of note, a commercially available enzyme-linked immunosorbent assay for diagnosis of aspergillosis on serum specimens had an 83% rate of false positive results in premature newborns (Siemann et al, 1998). Treatment requires systemic amphotericin B in doses of 1.0 to 1.5 mg/kg/day. Fungistatic therapies such as the triazoles are not recommended for aspergillosis.

Trichosporon beigelii

In a cluster of five neonatal cases of infection caused by *T. beigelii*, a yeast found ubiquitously in soil, no common source was identified (Fisher et al, 1993). Two of three premature infants infected with this organism died. Resistance to achievable concentrations of amphotericin B complicates therapy.

PART X

Respiratory System

CHAPTER 42

Lung Development: Embryology, Growth, Maturation, and Developmental Biology

Maria Victoria Fraga and Susan Guttentag

The primary function of the lung is to accomplish exchange of oxygen and carbon dioxide to accommodate the needs of aerobic cellular respiration. The oxygen consumption of the adult human ranges from 250 mL/min at rest to 5500 mL/min at peak exercise (Warburton et al, 2000). To accommodate these metabolic needs, a large surface area, and a thin alveolar-capillary membrane are required to enable efficient diffusion of oxygen more so than carbon dioxide. Ultimately the zone of gas exchange will attain a surface area of 50 to 100 m^2 and a volume of 2.5 to 3.0 L in the adult human; therefore a primary goal of lung organogenesis is to expand the lung surface area to meet these needs. A second goal of lung organogenesis is to minimize the diffusing distance from alveolus to red blood cell, coordinating the development of an extensive capillary network with a thin, expansive alveolar epithelial surface. A third goal of lung development is production of a protective aqueous barrier overlying the delicate alveolar epithelium while mitigating the effects of the surface tension generated by this barrier, specifically alveolar collapse, through the production of a surface active agent or surfactant.

The trachea, airways, and alveoli are in constant contact with the external environment. Consequently with every inhalation, epithelial surfaces encounter large numbers of microorganisms and potentially toxic particles and gases. Lung organogenesis must also incorporate mechanisms for clearance of microorganisms and allergens that may result in epithelial infection or injury. Similarly the lung must defend against nonparticulate gases that are potentially harmful. Oxygen, although critical to cellular function, can be the source of harmful reactive oxygen species and inhaled pollutants similarly require detoxification. The appropriate development and maintenance of these lung functions are critical to the health and survival of newborn infants. This chapter focuses on developmental aspects of each function that place the premature neonate at increased risk for lung injury and disease.

KEY EVENTS IN LUNG DEVELOPMENT

Lung formation begins early in human gestation (by day 25), and growth extends well into childhood (Burri, 2006; Kumar et al, 2005). Lung development can be organized into stages (embryonic, pseudoglandular, canalicular, saccular, and alveolar), although the timing of these stages is somewhat imprecise and considerable overlap can occur. Figure 42-1 shows a timeline of fetal and postnatal lung development.

DEVELOPMENT OF AIRWAYS AND GAS EXCHANGE SURFACES

The initial phase of lung development, the embryonic phase, is marked by the formation of the lung bud and initial branching of presumptive airways. The lung bud is first recognizable as a laryngotracheal groove of the ventral foregut at 25 days' gestation. Within a few days the groove closes so that the only remaining lumenal attachment to the foregut is in the region of the developing hypopharynx and larynx. The lung bud, consisting of epithelium and surrounding mesenchyme, then begins the first of a series of dichotomous divisions that give rise to the conducting airways and five primordial lung lobes (two left and three right). Tracheoesophageal fistulas, tracheal atresia, and tracheal stenosis result from errors in separation of the laryngotracheal groove, whereas failure of partitioning of the lung bud can result in pulmonary agenesis, most typically of the right lung.

Branching continues into the pseudoglandular stage of lung development. By 7 weeks' gestation, the trachea and the segmental and subsegmental bronchi are evident. By the end of 16 weeks' gestation, all bronchial divisions are completed. It is important to remember that, although the conducting airways will certainly enlarge as the fetus and newborn grow (airway diameter and length increase twofold to threefold between birth and adulthood), large airway branching ceases after 16 weeks' gestation.

Closure of the pleuroperitoneal folds is a critical event of the pseudoglandular phase, reaching completion by 7 weeks' gestation and resulting in separation of the thoracic cavity from the peritoneal cavity. Failure of pleuroperitoneal closure results in a diaphragmatic defect and continuity between these cavities. At 10 weeks' gestation, when the midgut returns to the peritoneal cavity from the umbilical cord, abdominal contents are free to pass into the thoracic cavity and restrict the space into which the lung grows. The resulting congenital diaphragmatic hernia leads to pulmonary hypoplasia of the lung ipsilateral to the diaphragmatic defect as bowel and solid viscera migrate into the thorax. Pulmonary hypoplasia can also extend to the contralateral lung as the mediastinum shifts because of accumulating abdominal viscera in the thorax.

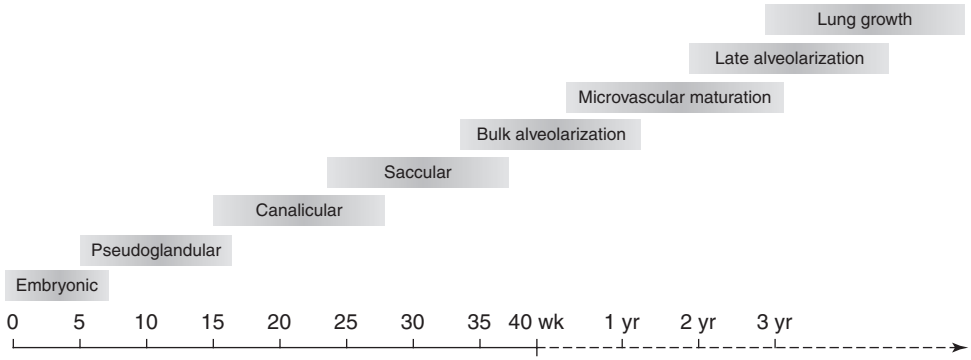

FIGURE 42-1 Human lung development. Timeline of major events in human fetal and postnatal lung development.

The canalicular phase is marked by completion of the conducting airways through the level of the terminal bronchioles, and the development of the rudimentary gas exchange units that are no longer invested with cartilaginous support. The acinus is the gas exchange unit of the lung and encompasses a respiratory bronchiole and all of its associated alveolar ducts and alveoli. A terminal bronchiole with all its associated acinar structures constitutes a lobule. Branching of these distal airspaces continues on a more limited basis during the canalicular phase, finally achieving a total of 23 airway subdivisions.

Evolution of the relationships between the airspaces, capillaries, and mesenchyme acquires greater significance during the saccular phase of lung development (24 to 38 weeks' gestation), enabling an alveolocapillary membrane sufficient to participate in gas exchange (0.6 μm) by approximately 24 weeks. Beyond this point, the efficiency of gas exchange is determined by the available surface area. Lengthening and widening of the terminal sacs expands the gas exchange surface area. Each saccule consists of smooth-walled airspaces with thickened interstitial spaces containing a double capillary network. These will give rise to two to three alveolar ducts, further expanding the available surface area. Expansion of these rudimentary gas exchange units continues well into the 3rd trimester of human gestation; therefore the human lung is not fully mature structurally, even at term delivery.

Postnatal lung development can be subdivided into additional stages (Burri, 2006). True alveoli become evident as early as 36 weeks' gestation, initiating the alveolar phase of lung development. The development of primary alveoli is followed by a further expansion of the gas-exchange surface area through the formation of septae or secondary crests (see Alveolarization, later). Postnatal alveolarization extends from term through 1 to 2 years of age. An initial phase of bulk alveolarization occurs within the first 6 months postnatally, with a more modest addition of secondary alveoli through the remainder of this period. The alveoli of the infant lungs are different from adult alveoli. These immature secondary alveoli contain a double capillary bed, whereas adult alveoli are invested by a single capillary bed. Microvascular maturation, the next phase of postnatal lung development, occurs between the first few postnatal months of life through 3 years of age (see Development of the Pulmonary Vasculature, later).

There is considerable controversy regarding when the lung ceases to add alveoli. Estimates have ranged from as early as 2 years to as late as 20 years old in humans; this is further complicated by the observation that alveolar expansion can occur in response to pneumonectomy in adult animals and humans. The acquisition of alveoli after the maturation of the microvasculature has been termed *late alveolarization*. This activity has been most often demonstrated in subpleural regions of the lung and likely invokes mechanisms similar to secondary crest formation.

The addition of alveoli is not the only means for expanding the surface area of the lung. While alveolarization wanes over the first 3 years of life in the human, growth of the lung continues to expand the gas exchange surface. Between 2 years of age and adulthood, lung tissue expands with lung volume roughly proportionately to the increase in bodyweight of the child. Thus, because of the combined processes of prenatal lung development, postnatal lung development, and lung growth, there is tremendous potential for expansion of the gas exchange surface area that is developmentally programmed into the fetal lung to account for the growing needs of the infant, child, and adult for aerobic cellular respiration. The extent to which these developmental mechanisms can be harnessed after premature birth, with or without superimposed lung injury, is a topic of active investigation.

COMPOSITION OF AIRWAYS AND ALVEOLI

As branching morphogenesis proceeds, the epithelium lining the successive generations of airways and alveoli gives rise to specialized cells that participate in gas exchange, surfactant production, mucociliary clearance, detoxification, and host defense. Differentiation proceeds in a centrifugal fashion from proximal to distal airspaces, lagging behind branching. Temporal and contextual signals foster the regionalization of epithelial cell types.

Proximal Airways

The airway epithelium is tall and columnar, decreasing to a more cuboidal appearance more distally (Jeffrey, 1998; Snyder et al, 2009). The endodermal epithelial lining cells of the trachea and bronchi partition into four cell types: undifferentiated columnar, ciliated, secretory-goblet, and basal cells. Ciliated cells critical to the process of mucus clearance are first apparent between 11 and 16 weeks' gestation and become less prevalent in more distal airways. Three types of secretory cells—those with largely mucous

granules, those with serous granules, and some with both types of granules—can be seen as early as 13 weeks' gestation. The number of mucin-producing goblet cells in airways peaks at mid-gestation in the fetus and declines into adulthood. Finally, immature basal cells expressing epidermal keratin have been noted as early as 12 weeks' gestation. Basal cells have a critical role in regenerating injured large airway epithelium (see Stem and Progenitor Cells in the Lung, later).

Cartilaginous support of the tracheobronchial tree begins and proceeds in a centrifugal fashion beginning in the primitive trachea at 4 weeks, reaching the main bronchi by 10 weeks, and proceeding to the most distal terminal bronchioles by approximately 25 weeks' gestation. Cartilaginous investment of airways is complete by the 2nd month postnatally. Submucosal glands are found in the interstitium between the cartilaginous tissue and surface epithelium, and they have a major role in airway host defense. Submucosal gland development can be characterized by five stages: (1) epithelial budding and invasion of the lamina propria, (2) development of a lumen, (3) initiation of tube branching, (4) dichotomous branching, and (5) repeated dichotomous branching. By comparison, the airways of infants and children contain relatively more submucous glands than do adults. The glands are lined by mucous cells proximally and serous cells more distally, the latter comprising 60% of the total epithelial cell content of the glands. Serous cells secrete water, electrolytes, and proteins with antimicrobial, antiinflammatory, and antioxidant properties, whereas the mucous cells produce primarily mucins. In addition to this host defense role, submucosal glands also contain a population of basal cells that respond to injury of the airway by replenishing the airway epithelium.

Muscular investment of the airways begins as early as 6 to 8 weeks gestation as smooth muscle cells are identifiable around the trachea and large airways. Fetal airway smooth muscle is innervated and able to contract during the first trimester. It is also responsive to methacholine challenge that is reversible with β-adrenergic agonists. Muscularization increases through fetal life and childhood such that there is an increase in the amount of smooth muscle relative to airway size compared with adults. Furthermore, there is a rapid increase in bronchial smooth muscle immediately after birth, whether born at term or prematurely.

An additional airway cell deserves mention because of its role in a wide variety of pediatric diseases. Pulmonary neuroendocrine cells (PNECs) are found throughout the airways, often in innervated clusters known as pulmonary neuroendocrine bodies (NEBs) located at branch points in the bronchial tree (Cutz et al, 2007). Although they arise from foregut endoderm, the cell of origin is distinct from other epithelial components of the lung. Solitary PNECs are sensitive to stretch- and hypoxia-mediated secretion, producing both amines (i.e., serotonin) and peptides (i.e., bombesin) that are important in regulating bronchial tone. Pathologic conditions recently associated with PNECs and NEBs, most often characterized by hyperplasia, include bronchopulmonary dysplasia, disorders of respiratory control (congenital central hypoventilation syndrome and sudden infant death syndrome), cystic fibrosis, and pulmonary hypertension. Neuroendocrine hyperplasia of infancy is a rare form of interstitial lung disease of infancy associated with expansion of the number of PNECs and NEBs, yet little is known about the mechanism of disease.

Distal Airways

The bronchiolar epithelium differs from the more proximal airway epithelium. In addition to being more cuboid in appearance, the epithelium contains progressively fewer ciliated cells and goblet cells, which are ultimately absent from the terminal bronchioles. Instead, the nonciliated, secretory Clara cell is found in increasing numbers and density down the conducting airways, such that the Clara cell is the most abundant cell of the terminal bronchiole (Jeffrey, 1998). Clara cells are first evident by 16 to 17 weeks' gestation, initially exhibiting large glycogen stores that are replaced by secretory granules. Between 23 and 34 weeks' gestation, there is a dramatic increase in Clara cell numbers in distal bronchioles. Clara cells are critical to the host defense and detoxification functions of the lung. This specialized cell produces the highest levels of cytochrome P-450 and flavin monooxygenases in the lung. While critically important in detoxification, these enzymes participate in the bioactivation of procarcinogens as well, placing the Clara cell in a precarious position as a primary target of toxic metabolites. The Clara cell also has an important role in immunoregulation in the distal airways. Important host defense products of the Clara cell include Clara cell secretory protein (CCSP or CC10), surfactant proteins A, and D, leukocyte protease inhibitor, and a trypsinlike protease. The function of Clara cell SP-B in airways is less certain, especially because Clara cells do not produce a mature 8-kDa SP-B protein, but may also contribute to host defense. The secretion of antiproteases from Clara cells suggests that they modulate the protease-antiprotease balance in the distal lung.

Alveolar Epithelium

During the 4th through 6th months of gestation, the epithelial cells lining the acini begin to differentiate further (Mallampalli et al, 1997). The cuboidal epithelial cells accumulate large glycogen stores and develop small vesicles containing loose lamellae. The large glycogen pools provide a ready source of substrate required for the production of increasing amounts of surfactant phospholipids, and they decrease in size as surfactant production advances in the fetal lung. In cells destined to become type 2 cells, lamellar bodies become larger, more numerous, and more densely packed with surfactant phospholipids and proteins, whereas those cells destined to become type 1 cells, upon losing their relationship to mesenchymal fibroblasts, lose the prelamellar vesicles and become progressively thinner, thereby adopting a phenotype more suitable for gas exchange. Alveolar type 1 and 2 cells are readily identified early in the saccular stage of fetal lung development. There remains considerable controversy regarding the origin of type 1 cells. In culture, these cells demonstrate slow turnover, with a doubling time estimated to be between 40 and 120 days, suggesting that they are functionally terminally differentiated in vivo. Furthermore, in response to epithelial denudation occurring with lung injury, type 2 cells proliferate to reestablish epithelial continuity, and then lose

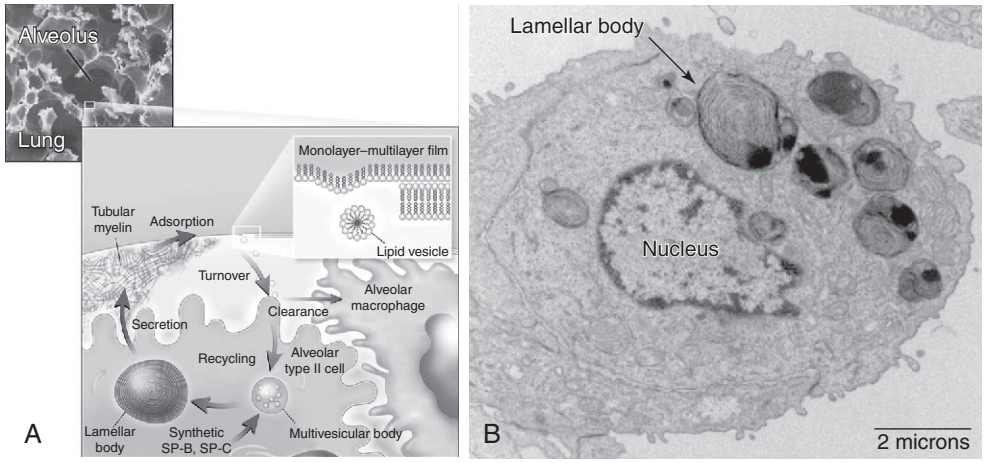

FIGURE 42-2 Surfactant life cycle. A, Schematic diagram depicting the life cycle of surfactant. **B,** Electron micrograph of a type II alveolar epithelial cell showing the prominent lamellar bodies near the apical surface. *(**A,** Reprinted with permission from Whitsett J, Weaver T: Hydrophobic surfactant proteins in lung function and disease*, N Engl J Med *347:2141–2148, 2002. phenotypic features such as lamellar bodies and acquire markers of type 1 cells, suggesting that rapid repopulation of type 1 cells requires a type 2 cell intermediary.

There is increasing appreciation for the alveolar type 1 cell as more than a passive membrane for gas exchange (Williams, 2003). The large surface area and small cytoplasm/nucleus ratio provides for a thin alveolocapillary membrane to facilitate gas exchange. However, this large surface area also provides a large absorptive surface in the lung. The presence of water and ion channels, some distinct from those in type 2 cells, facilitates the maintenance of a relatively dry alveolus. Type 1 cells may also regulate cell proliferation locally, signal macrophage accumulation, and modulate the functions of local peptides, proteases and growth factors.

Although most notable for its role in surfactant production, the alveolar type 2 cell provides additional important functions in the alveolus (Fehrenbach, 2001). Alveolar type 2 cells are local progenitor cells, as mentioned previously. Like type 1 cells, alveolar type 2 cells contain specialized ion and water channels as well as ion pumps in both the apical and basal membranes that contribute to the movement of water and ions across the epithelium (see Static Stretch: Fetal Lung Fluid Protection, later). Type 2 cells contain and secrete important antioxidants (superoxide dismutases 1, 2, and 3, glutathione) and molecules of innate host defense (SP-A, SP-D, lysozyme) to participate in detoxification and sterilization of the alveolar microenvironment.

More recently, it is becoming clear that alveolar type 2 cells may also play a part in exacerbating alveolar pathology. The type 2 cell participates in the coagulation-fibrinolysis cascade through the production of fibrinogen, urokinase-type plasminogen activator, and tissue factor, especially under pathologic circumstances. Type 2 cells are increasingly recognized as a source of cytokine and chemokine production in the lung, as well as growth factors that can promote fibrosis. Finally, cross-talk between epithelial cells, cell matrix, interstitial cells, and local inflammatory cells can foster the resolution of injury and inflammation or prolong lung remodeling after injury with detrimental effects, such as lung destruction and fibrosis. Although previously heralded as the defender of the alveolus, the alveolar type 2 cell have a much more complex role in alveolar health and disease.

SURFACTANT

Pulmonary surfactant is essential to alveolar health. A thin layer of liquid is constantly secreted into the alveolar lumen to protect the delicate alveolar epithelium. The surface tension generated by this aqueous layer opposes alveolar inflation and promotes alveolar collapse at the end of expiration, because of Laplace's law, which states that the collapsing pressure on the alveolus is directly proportional to the surface tension while inversely proportional to the radius of the alveolus. The film of pulmonary surfactant at the air-liquid interface lowers surface tension as alveolar surface area decreases, thereby preventing end-expiratory atelectasis, maintaining functional residual capacity, and lowering the force required for subsequent alveolar inflations.

Pulmonary surfactant is a complex mixture of phospholipids, neutral lipids, and proteins that is synthesized, packaged, and secreted by alveolar type 2 cells (Zuo et al, 2008). The life cycle of surfactant is depicted in Figure 42-2. Storage of surfactant occurs in the lamellar body, a lysosome-derived membrane-bound organelle that undergoes regulated secretion in response to a variety of stimuli, including stretching. In the alveolus, surfactant phospholipids transition through an extracellular storage form—tubular myelin. Phospholipid and protein components are recycled out of the surfactant monolayer at the air-liquid interface and taken back into the alveolar type 2 cell, where they can be repackaged into lamellar bodies. Alternatively, alveolar macrophages are able to engulf and degrade surfactant components.

The predominant surfactant phospholipid is saturated dipalmitoylphosphatidylcholine, with the remaining phospholipids consisting of monounsaturated phosphatidylcholine, phosphatidylglycerol and other phospholipids (Table 42-1). Dipalmitoylphosphatidylcholine is the only surface active component of lung surfactant capable of lowering surface pressure to nearly zero. The presence of unsaturated phospholipids and other lipid components like

TABLE 42-1 Composition of Pulmonary Surfactant

Component	Percentage (by Weight)
Lipid	90
Saturated phosphatidylcholine	45
Unsaturated phosphatidylcholine	25
Phosphatidylglycerol	5
Other phospholipids	5
Neutral lipids	10
Protein	10
Surfactant proteins	5
Serum proteins	5

cholesterol enables the monolayer to remain fluid at body temperature during the respiratory cycle. Phospholipid content in the fetal lung increases with advancing gestation because of increased activity of enzymes responsible for phospholipid synthesis within alveolar type 2 cells. The expression and activity of enzymes of the choline incorporation pathway, the predominant pathway for surfactant phospholipid synthesis, are developmentally regulated and induced by hormones. The inductive hormones that have direct clinical relevance are glucocorticoids and agents that increase intracellular cyclic adenosine monophosphate (cAMP) such as the β-adrenergic agonist (and tocolytic) terbutaline.

Surfactant contains a group of specific proteins with importance to surfactant function and host defense. The four surfactant proteins SP-A, -B, -C, and -D are subdivided based on their physical characteristics into either hydrophobic (SP-B and -C) or hydrophilic (SP-A and -D) proteins. The hydrophobic surfactant proteins play a major role in the surface-active properties of surfactant, whereas the primary roles of the hydrophilic surfactant proteins are in host defense, immunomodulation, and surfactant clearance and metabolism (see Surfactant, earlier).

Together, the hydrophobic proteins facilitate the mobilization of surfactant phospholipid from tubular myelin to the surface monolayer, promote spreading of phospholipids in the surfactant film, and assist in film stability at end-expiration (Zuo, 2008). SP-B plays a central role in alveolar health because of its critical function in surfactant homeostasis. It is a secretory protein that exhibits strong association with membranes, unlike SP-C, which contains a membrane-spanning domain and covalently attached fatty acids (palmitate) that render it integral to phospholipid membranes (Conkright et al, 2001). Both SP-B and SP-C are synthesized as large precursor proproteins that undergo extensive posttranslational processing as they pass through the secretory pathway, ultimately reaching the lamellar body. SP-B is essential for the process of lamellar body formation, and the alveolar type 2 cells of infants with inherited deficiency of SP-B are devoid of lamellar bodies. Because the lamellar body is where SP-C processing is completed, infants with inherited deficiency of SP-B are also deficient in mature SP-C, instead accumulating a larger, nonfunctional precursor of SP-C. Therefore patients with inherited deficiency of SP-B, despite having relatively normal surfactant phospholipid profiles, make a pulmonary surfactant with poor surface tension properties because of the combined defects in SP-B and SP-C. Conversely, because SP-C does not have either a direct nor indirect role in SP-B protein processing, animals with SP-C deficiency have normal SP-B, normal lamellar bodies, and relatively normal surfactant function, and they exhibit no perinatal lethality because of surfactant dysfunction.

Like the enzymes of surfactant phospholipid production, SP-B and SP-C exhibit developmental and hormonal regulation of expression (Mendelson, 2000). In human fetuses, SP-C mRNA is detected as early as 12 weeks' gestation and SP-B mRNA by 14 weeks' gestation, but the mature proteins are not detectable in fetal lung tissue until after 24 weeks' gestation. SP-B protein is not detectable in amniotic fluid until after 30 weeks' gestation, increasing toward term (Pryhuber et al, 1991), because of developmental regulation of posttranslational events in the proteolytic processing of proSP-B and proSP-C (Guttentag, 2008). Consequently, infants delivered prematurely have reduced levels of both surface active components of surfactant, phospholipid, and hydrophobic surfactant proteins, because of the developmental regulation of surfactant proteins and the enzymes of phospholipid production in alveolar type 2 cells. The rate of type 2 cell differentiation, and secondarily surfactant production by the fetal lung, is modulated by levels of endogenous corticosteroids and is accelerated by administering antenatal glucocorticoid to women in preterm labor. The response of the surfactant system to glucocorticoid involves all the lipid and protein components, and it occurs primarily through increased gene expression, thus representing precocious maturation mimicking the normal developmental pattern. Endogenous thyroid hormones, prostaglandins, and catecholamines also have stimulatory effects on type 2 cell maturation and clearance of lung fluid at birth. Certain proinflammatory cytokines (e.g., tumor necrosis factor [TNF]-α and transforming growth factor [TGF-β]) inhibit surfactant production in experimental systems and may downregulate surfactant in conditions such as sepsis and inflammation. A partial list of hormones capable of inducing or inhibiting lung maturation is presented in Table 42-2.

DEVELOPMENT OF THE PULMONARY VASCULATURE

The pulmonary vasculature consists of the vascular supply to the acini and the bronchial circulation (Hislop, 2005). During early fetal life, the airways act as a template for pulmonary blood vessel development. The earliest pulmonary vessels form de novo in the tissue that surrounds the lung bud by differentiation of mesenchymal cells into endothelial cells and then capillaries, a process known as *vasculogenesis.* Mesodermal cells within the mesenchyme investing the developing lung tube differentiate into endothelial cells, proliferate, organize into chords, and develop a central lumen. As each new airway buds into the mesenchyme, a new plexus forms and adds to the pulmonary circulation, thereby extending the arteries and veins. By 5 weeks' gestation, a capillary network surrounds each bronchus and circulation of blood between the right ventricle and the left atrium via this network is evident.

TABLE 42-2 Hormonal Regulators of Lung Maturation

Inducers	Glucocorticoids (cortisol)	Major endogenous modulator of alveolar development and surfactant production
	β-Adrenergic agonists (epinephrine), cAMP	Increase surfactant production and secretion, especially during labor and delivery
	Thyroid hormones (T_3, T_4)	Enhance glucocorticoid effects on lipid synthesis
	Retinoic acid	May interact with glucocorticoids to regulate surfactant phospholipid and protein production
	Bombesin-related peptides, parathyroid hormone–related protein	May contribute to surfactant lipid synthesis
Inhibitors	Protein kinase C activators (proinflammatory cytokines)	Inhibit surfactant protein gene transcription during infection, inflammation
	TGF-β family	Inhibit type 2 cell maturation during early gestation and with inflammation
	TNF-α	Inhibit SP-B and SP-C gene transcription during infection
	Insulin	Inhibit surfactant protein gene transcription in infants of poorly controlled diabetic women
	Dihydrotestosterone	Delayed type 2 cell maturation in males

By the canalicular stage of lung development, continued branching of the airways is accompanied by thinning of the epithelium. At this stage, new blood vessels form from preexisting vessels, a process known as *angiogenesis*. By comparison, angiogenesis is initiated by endothelial cell proliferation and sprouting from established vessels, resulting in the extension of a vascular network into undervascularized regions. Vasculogenesis is the primary mode of pulmonary vascular development until 17 weeks' gestation, when all preacinar airways and their accompanying vessels are present, whereas angiogenesis becomes the predominant mode of vascular development in the later stages of lung development. Although originally thought to be sequential processes, it is generally accepted that vasculogenesis occurring in the periphery and more central angiogenesis occur concurrently during lung development (deMello et al, 1997). Interconnections between vascular networks arising from both angiogenesis and vasculogenesis increase in the saccular phase of lung development.

In the human lung, a second circulatory system, the bronchial circulation, arises from the dorsal aorta supplying systemic blood. The bronchial vasculature develops after the pulmonary circulation, with bronchial vessels first apparent by 8 weeks' gestation. The network of bronchial vessels is extensive, with bronchial arteries demonstrated as distal as the alveolar ducts in the adult respiratory tree. The inappropriate branching of bronchial vessels from the dorsal aorta is implicated in the formation of bronchopulmonary sequestration, a space-occupying lung malformation that can result in hypoplasia of the ipsilateral lung.

Vasculogenesis and angiogenesis are the primary mechanisms of vascular development throughout intrauterine life. The human lung at term contains only a small portion of the adult number of alveoli, and the airspaces walls are represented by a thick primary septum consisting of a central layer of connective tissue surrounded by two capillary beds, each of them facing one alveolar surface (Burri, 2006). As alveolar architecture changes with the appearance of secondary septa, or secondary crests, folding of one of the two capillary layers occurs within the secondary septa. This double capillary network is not present in the adult lung. Microvascular maturation involves fusion of the double capillary network into a single capillary system. The expansion of surface area and lumenal volume compresses the interstitium, bringing the capillary networks in close proximity to potential air spaces and thereby promoting both alveolar surface area expansion and capillary bed fusion. Interestingly, by the third postnatal week during which lung volume increases by 25%, there is a concomitant 27% decrease of the interstitial tissue volume that is believed to promote focal microvascular fusions. Subsequently, there is preferential growth of fused areas that continues until 3 years of age.

Lastly, it is well known that lung volume increases approximately 23-fold between birth and young adulthood, and capillary volume expands 35-fold. It has been recently shown that this increase in capillary volume occurs by insertion of new capillary meshes in the absence of capillary sprouting. This new concept in capillary network growth has been named *intussusceptive microvascular growth*, and involves the formation of transluminal tissue pillars that then expand, resulting in increased capillary surface area (Burri, 2006).

Muscularization can be detected early in development of the pulmonary arteries (Hislop, 2005). Initially the muscular investment of the vasculature is derived from the migration of bronchial smooth muscle cells from adjacent airways. Muscularization of preacinar and resistance arteries of the pulmonary vasculature begins in the canalicular stage and continues through the remainder of gestation. This second phase of smooth muscle cells investing pulmonary vessels develops from the surrounding mesenchyme. Fibroblasts in close proximity to developing arteries alter their cellular shape and begin to express α-smooth muscle actin, a marker of smooth muscle cells. A third phase of vascular muscularization has been described, largely in the distal lung, in which capillary endothelial cells undergo a process of endothelial-mesenchymal transition that encompasses endothelial cell division, separation, and migration from the endothelial layer and expression of smooth muscle cell markers.

Muscularization of pulmonary arteries normally extends to the level of the terminal bronchiole and is minimal to absent in blood vessels surrounding respiratory bronchioles. Abnormal extension of smooth muscle along arterioles supplying acinar structures occurs in infants dying from persistent pulmonary hypertension of the newborn and in severe bronchopulmonary dysplasia.

TABLE 42-3 Composition of Human Fetal Lung Fluid Compared With Other Body Fluids

Component	Lung Fluid	Interstitial Fluid	Plasma	Amniotic Fluid
Sodium (mEq/L)	150	147	150	113
Potassium (mEq/L)	6.3	4.8	4.8	7.6
Chloride (mEq/L)	157	107	107	87
Bicarbonate (mEq/L)	3	25	24	19
pH	6.27	7.31	7.34	7.02
Protein (g/dL)	0.03	3.27	4.09	0.10

MECHANISMS OF LUNG DEVELOPMENT

Fetal and postnatal lung development depend on several key developmental processes: branching morphogenesis to promote branching of the lung bud into the surrounding mesenchyme, static and cyclic stretching of the lung that assist in promoting lung branching, alveolarization to enhance the expansion of the gas exchange surface area, and vasculogenesis and angiogenesis to ensure that the developing epithelial surface area is invested with a similarly extensive vascular supply.

BRANCHING MORPHOGENESIS

Branching morphogenesis is the fundamental mechanism of lung development. Branching is mediated by the accelerated growth of epithelial cells lateral to branch points with concomitant growth arrest at the branch point (Affolter et al, 2009). This process requires extensive communication between the cells lining the tubular lung bud and cells contained within the invested mesenchyme. Classic tissue recombination experiments in which mesenchyme from proximal airways was transplanted to distal airways (and vice versa) indicate that the mesenchyme has an important inductive role in dictating the branching pattern and cell fate of the expanding epithelium. More recently, studies of mouse lung development indicate that three modes of branching—domain branching, planar bifurcation, and orthogonal bifurcation—are the basic mechanisms that characterize the complex three-dimensional development of the respiratory tree through the pseudoglandular phase (Metzger and Krasnow, 1999). These routines occur repetitively during lung development and appear to be set by a genetic clock dictating when side branches form, a bifurcation program determining when a branch bifurcates, and a rotator function controlling the planar orientation of the bifurcation.

STRETCH AND MECHANOTRANSDUCTION

The role of physical factors in modulating lung size is well established; normal lung growth requires adequate space in the chest cavity and appropriate tonic and cyclic distending forces. Genetic defects that compromise the thoracic skeleton and space-occupying lung masses like congenital cystic adenomatoid malformations are associated with pulmonary hypoplasia because of the restriction of intrathoracic space. Denervation of the diaphragm to eliminate fetal breathing movements is also associated with pulmonary hypoplasia, as is the manipulation of fetal lung fluid volume.

Static Stretch: Fetal Lung Fluid Production

Fetal lung fluid is a product of the epithelial lining of the developing lung (Wilson et al, 2007), averaging 4 to 6 mL/kg/h. Because of the resistance imparted by laryngeal abduction, fluid accumulates to a total volume of 20 to 30 mL/kg during gestation, providing end-expiratory pressure of approximately 2.5 cm H_2O pressure (Kitterman, 1996). The composition of fetal lung fluid is distinct from both amniotic fluid and plasma, as shown in Table 42-3. The increased chloride content of fetal lung fluid compared with serum is the result of active chloride secretion by the tracheal and distal pulmonary epithelium, largely because of the chloride channel CLC-2/CLCN2. Fetal lung fluid secretion can be enhanced by prolactin, KGF, PGE2 and PGF2, whereas it is inhibited by a variety of mediators, including β-adrenergic agonists, vasopressin, serotonin, and glucagon.

Fetal lung fluid is an essential component of lung development, but it presents a significant obstacle to the transition to air breathing upon delivery. Three important events must occur to decrease the amount of fetal lung fluid and its potential effect on alveolar surface tension: absorption, bulk removal, and maturation of pulmonary surfactant. The transition to air breathing must be coupled with a conversion from a secretory pulmonary epithelium to one that is absorptive. Enhanced sodium transport across the alveolar epithelium is in part responsible for this change. Much evidence suggests that induction of components of the epithelial sodium channels (ENaC) around the time of birth is a major factor in promoting sodium transport with water passively following the movement of sodium. Absence of the α-subunit of ENaC in transgenic mice is perinatal lethal because of the failure of fetal lung fluid clearance. Induction of ENaC components occurs at a transcriptional level in response to changes in extracellular matrix components, glucocorticoids, aldosterone, and oxygen. By comparison, agents that increase intracellular cAMP levels (i.e., β-agonists, phosphodiesterase inhibitors, and cAMP analogues), while not increasing the number of sodium channels, increase the probability of a channel being open to sodium transport. In addition, glucocorticoid and thyroid hormones have important roles in priming the lung epithelium to be responsive to the actions of β-adrenergic agonists on sodium transport across lung epithelia near term. Water channels consisting of aquaporins

are also induced during the late fetal period to facilitate fluid movement, but their contribution is unclear because of the perinatal survival of mice in which aquaporin 5 or both aquaporins 5 and 1 were absent.

Conversion to an absorptive surface is not sufficient to minimize the fetal lung fluid at the time of term delivery. The absence of uterine contractions is associated with an increased incidence of retained fetal lung fluid in infants delivered by cesarean section without the benefit of labor. On delivery of the head and neck, continued uterine contractions on the fetal thorax promote expulsion of bulk fluid from the fetal lung. However, animal studies have shown that the magnitude of the benefit of thoracic compression during labor is modest (Bland, 2001). The primary mechanism by which labor facilitates clearance of lung fluid is through hormonal effects on fluid clearance, especially through catecholamine-induced changes in the ENaC opening. The onset of air breathing, associated with increased intrathoracic negative pressure, assists in the clearance of residual fetal lung fluid into the loose interstitial tissues surrounding alveoli. Fluid is then reabsorbed via lymphatics and pulmonary blood vessels. It is generally accepted that the amount of residual liquid in the lung after complete transition is approximately 0.37 mL/kg body weight.

Cyclic Stretch: Fetal Breathing Movements

Fetal breathing is an essential stimulus for lung growth (Kitterman, 1996). Fetal breathing is readily detectable as early as 10 weeks' gestation. Fetal breathing occurs for 10% to 20% of the time at 24 to 28 weeks' gestation, increasing to 30% to 40% after 30 weeks' gestation. Originating from the diaphragm, fetal breathing is erratic in frequency and amplitude, and it changes throughout gestation. The volume of fluid moved is small and insufficient to be cleared from the trachea. Respiratory rates range from 30 to 70 breaths/min, and periods of apnea of up to 2 hours have been recorded. Sustained periods of fetal breathing increase in duration with advancing gestation. The frequency of fetal breathing varies with sleep state (inhibited during quiet sleep) and exhibits diurnal variation, with the lowest rates recorded early in the morning. Fetal breathing is hormonally responsive and the inhibition of fetal breathing with the onset of labor is attributed to the action of increased circulating prostaglandins. Maternal medications can influence the frequency of fetal breathing movements. Central nervous system stimulants are associated with increased fetal breathing (i.e., caffeine, amphetamines), whereas depressants are associated with decreased fetal breathing (i.e., anesthetics, narcotics, ethanol). Maternal smoking is associated with reduced fetal breathing, largely because of increased fetal hypoxemia. Animal studies have shown that permanent cessation of fetal breathing, regardless of the insult, is associated with impaired fetal lung growth. However, the effects of short-term alterations in fetal breathing frequency and amplitude on fetal lung development are unknown. Together, constant distention from the production and retention of fetal lung fluid, and episodic cyclic fetal breathing, are important mechanisms for lung growth during fetal life.

ALVEOLARIZATION

Branching morphogenesis is the primary developmental program that establishes the conducting airways of the lung, but it is important to remember that alveolarization is the developmental program that will establish the large surface area involved in gas exchange (Galambos and Demello, 2008). This process will result in a 20-fold increase in surface area between birth (with between 0 and 50 million alveoli) and adulthood (>300 million alveoli). Primitive saccules develop low ridges (primary septa) that subdivide the saccule into an alveolar duct containing primary alveoli and outpouchings between the ridges (secondary septa/crests) that establish secondary alveoli (Figure 42-3). Regions destined for secondary septation exhibit increased elastin deposition (Mariani et al, 1997), and elastin localizes to the tips of the secondary crests as they form. Septae contain a connective tissue core separating two capillary membranes, suggesting that the septum is formed by the folding of a capillary on itself, as mentioned previously. Septation also leads to the development of the pores of Kohn, allowing gaseous continuity between acini. The process of alveolarization is poorly understood, but is receiving much attention because of observations that infants who die after severe bronchopulmonary dysplasia exhibit alveolar simplification with little evidence of secondary septation. It remains unclear to what extent the process of alveolarization is disrupted by preterm birth and whether this developmental program can be resurrected after preterm birth in the absence or presence of lung injury.

INTERDEPENDENCE OF ALVEOLAR AND VASCULAR DEVELOPMENT

Recent evidence suggests that the pulmonary capillary bed actively promotes normal alveolar development and contributes to the maintenance of alveolar structures throughout life (Thebaud and Abman, 2007). The observation that combined abnormalities in the airways and vasculature occur in bronchopulmonary dysplasia supports this hypothesis. Intraacinar arteries and veins continue to develop after birth by angiogenesis as long as alveoli continue to increase in number and size. This process may be reciprocal because vascular growth around the distal airspaces suggests an inductive influence from the alveolar epithelial cells as well.

MOLECULAR BASIS FOR LUNG DEVELOPMENT

The developmental processes that contribute to lung organogenesis are under the regulation of interdependent signaling pathways mediated by secreted growth factors that are themselves under the control of large networks of transcription factors controlling gene expression. Gene regulatory networks common to other organs that depend on branching morphogenesis during development, most notably in the kidney and mammary gland, are also found in the lung. Selected regulatory networks are highlighted in the following sections to illustrate these systems. For more detailed reading, additional references are provided (Kaplan, 2000; Kumar et al, 2005; van Tuyl and Post, 2000; Warburton et al, 2000;).

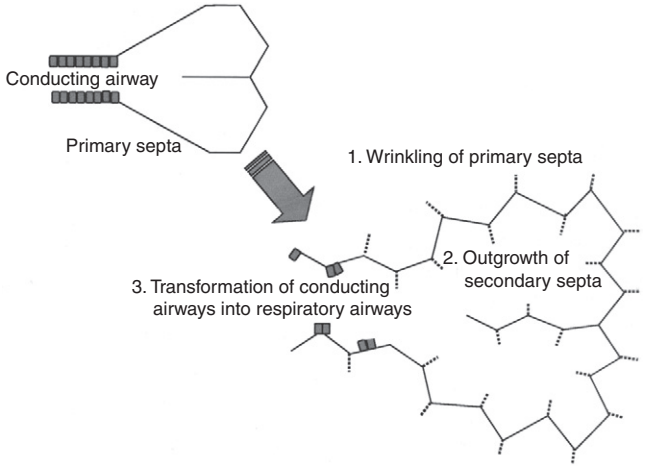

FIGURE 42-3 Development of primary versus secondary alveoli. The development of secondary alveoli from primary alveoli allows for expansion of the total surface area available for gas exchange. Continued growth of primary septa results in a wrinkled appearance that is followed by elastin deposition at points where secondary septae, also known as secondary crests, will form by an in-folding of the epithelium that pulls underlying capillaries into the septum. Finally the more proximal epithelium becomes differentiated into alveolar epithelial cells capable of participating in gas exchange. Shaded cells represent bronchiolar epithelial cells.

GROWTH FACTORS IN LUNG DEVELOPMENT

The initiation of branching morphogenesis is the result of the interplay of signals between the developing lung epithelial tube and its surrounding mesenchyme. Central to this process is the family of fibroblast growth factors (FGFs) that are produced and secreted by mesenchymal cells, and bind to receptors on the plasma membrane of epithelial cells, establishing a system of mesenchymal-epithelial cross talk. In particular, the growth factor FGF10 secreted by mesenchymal cells binds to the receptor FGFR2b on nearby epithelial cells. This signal will be strongest in the closest epithelial cells because of a gradient that develops with diffusion of the secreted FGF10. Binding of ligand to receptor results in signal transduction within the epithelial cell that induces expression of a group of genes via the mitogen-activated protein kinase pathway. One of the genes induced by FGF10/FGFR2b signaling, Sprouty 2 (*Spry2*), inhibits the mitogen-activated protein kinase pathway, resulting in inhibition further FGF10/FGFR2b signaling. Therefore a signal propagated by the mesenchyme has an effect that is subsequently dampened within the epithelial cell. Examination of genes expressed early in the formation of a branch point in response to FGF10 revealed a large number of genes that regulate cell adhesion, cytoskeleton, and cell polarity—all essential elements of cell migration (Lu et al, 2005). Surprisingly, bud initiation was not associated with the expression of genes that promote proliferation, which appears to be more important for branch elongation. Still, animals expressing reduced FGF10 develop pulmonary hypoplasia with reduced numbers of large airways (Abler et al, 2009; Ramasamy et al, 2007). Furthermore, increased FGF10 signaling during fetal lung development in mice by intrapulmonary injections of recombinant FGF10 produced cystic structures with epithelial characteristics dependent on the location of the injection: proximally with Clara cells, distally with alveolar type 2 cells (Gonzaga et al, 2008). These data provide strong evidence that FGF10 signaling has diverse responses—from initiation of branching to differentiation of epithelial cells—depending on the temporal or spatial context of signaling.

Like branching morphogenesis, lung vascular development is a complex and highly organized process that requires multiple vascular signaling molecules to interact in a specific temporospatial sequence. Vascular endothelial growth factor (VEGF) is a critical growth factor in angiogenesis and vasculogenesis. The expression of the VEGF ligand by epithelial cells and VEGF receptors by endothelial cells of the developing human fetal lung reinforces the interdependence of the airspace and vascular development. The expression of VEGF mRNA and protein is localized to the epithelial cells at the distal tips of developing lung branches, and expression levels increase with time (Galambos and Demello, 2007; Hislop, 2005). VEGF gene expression is induced in epithelial cells by the hypoxic environment of the growing fetal lung through the actions of the oxygen-sensing hypoxia-inducible factor (HIF) family of transcription factors. From the single VEGF gene, five different VEGF protein isoforms can be produced, although VEGFA (VEGF165) is the most studied. Each isoform has different affinities for each of the three VEGF receptors (Flt-1/VEGFR1, Flk-1/KDR/VEGFR2, and Flt-4/VEGFR3). Vascular endothelial cells express primarily VEGFR-1 and VEGFR-2, whereas VEGFR-3 is on the plasma membrane of the lymphatic endothelium. VEGF receptors are expressed on the plasma membrane endothelial cells surrounding the developing airways from very early in gestation, and expression of VEGFR2/Flk1 is considered the earliest marker of an endothelial progenitor cell. In vitro and in vivo experiments have shown that VEGFA induces endothelial cell proliferation and migration, both key elements of vascular sprouting, as well as tube formation through interactions with VEGFR2. VEGFR1 appears to have more importance in transforming primitive endothelial tubes into more stable vascular networks, in part by reducing endothelial proliferation through downregulation of VEGF production. The embryonic lethality of animals with reduced VEGF expression attests to the critical importance of VEGF and VEGFR signaling to vascular development in the fetus, though not limited to the developing pulmonary vasculature.

TRANSCRIPTION FACTORS IN LUNG DEVELOPMENT

The ligand-receptor interactions important to branching morphogenesis and pulmonary vascular development are in part determined by the actions of transcription factors on facilitating or reducing gene expression. Transcription factors are also critical in the differentiation of the lung epithelium from the most rudimentary lung bud out to the type 1 and 2 alveolar epithelial cells. The more important transcription factors in epithelial cell determination in the lung include the Gli, hepatocyte nuclear factor (HNF), GATA, and Hox families of transcription factors (Kumar et al, 2005; Warburton et al, 2000).

The most important transcription factor in the lung is thyroid transcription factor-1 (TTF-1), a product of the *Nkx2.1* gene. TTF-1 is considered a master regulator of lung development, as transgenic mice null for *Nkx2.1* exhibit complete absence of lung branching. However, *Nkx2.1* also has a prominent role in establishing cell fate proximally to distally along the branching lung epithelium. TTF-1 expression is detected as early as 11 weeks' gestation in humans, and continues to be expressed by epithelial cells at the distal tips of the branching lung epithelium, ultimately becoming more restricted to Clara cells and alveolar type 2 cells. TTF-1 is critical for the expression of genes that are unique to differentiated epithelium, such as CC10 expression in Clara cells and surfactant proteins in alveolar type 2 cells. DNA binding sites for TTF-1 are found in the promoter regions of all four surfactant proteins, CC10, and *Nkx2.1* itself, creating a positive feedback loop for sustained TTF-1 expression. TTF-1 function is highly dependent on phosphorylation of critical amino acids, although it remains unclear which kinase is involved in this process (DeFelice et al, 2003). Interestingly, VEGFA expression is reduced in animals unable to phosphorylate TTF-1, providing another important link between epithelial and vascular development. TTF-1 is itself regulated by other transcription factors that bind to the promoter region of the *Nkx2.1* gene, specifically HNF-3β and GATA-6. Therefore the ability of networks of transcription factors to bind to gene regulatory elements of DNA in a coordinated fashion during fetal lung development enables the temporospatial expression of growth factor networks that foster branching morphogenesis, the process of differentiation that ultimately gives rise to the approximately 40 cell types that constitute the human lung, as well as critical coordination of both epithelial and vascular development.

OTHER TOPICS IN LUNG DEVELOPMENT

DEVELOPMENT OF PULMONARY HOST DEFENSE

The adult human lung takes in approximately 7 L/min of air contaminated with a variety potential pathogens that can cause epithelial injury. The continuous exposure of the epithelial surface of the conducting airway to inhaled pathogens requires the presence of an efficient innate immune response system to prevent infections. The proximal and distal airway epithelia have a major role in clearing pathogens by secreting antimicrobial as well as antiinflammatory molecules. Components of mucociliary clearance appear as early as 11 weeks' gestation with the differentiation of ciliated epithelial cells and the expression of mucus in mucus-secreting goblet cells within the epithelium and submucosal glands, as discussed previously. The number of goblet cells peaks in mid-gestation (30% to 35% of total airway epithelial cells), decreasing toward term to levels lower than in adults, and then increasing after birth. The postnatal increase in goblet cells occurs after preterm birth as well, giving premature infants a greater number of goblet cells than in term infants. Therefore premature infants are prone to more mucus production in smaller airways than are term infants, and premature infants have relatively fewer ciliated cells to assist in mobilization of secretions.

A number of microbial defense molecules are produced and secreted by epithelial cells into the airways (Bartlett et al, 2008). They include lysozyme, C-reactive protein, lactoferrin, collectins, β-defensins, and the only human member of the cathelicidin family, hCAP-18/LL-37 (Hiemstra, 2007). Two lung collectins were originally identified as surfactant-related proteins—the hydrophilic surfactant proteins SP-A and SP-D. Although originally identified as products secreted by epithelial cells lining airways (Clara cells) and alveoli (type 2 cells), SP-A and SP-D have been found in other sites associated with epithelial surfaces exposed to the external environment (Haagsman et al, 2008). They interact with microorganisms, inflammatory cells, and leukocytes to facilitate clearance of microorganisms from the airspace, and they modulate allergic responses.

The basis for the interactions of the lung collectins with microbes and antigens centers on the binding of sugars by the carbohydrate recognition domains of these proteins (Wright, 2005). Both collectins bind a variety of fungi and *Pneumocystis carinii*, and they have an important role in inhibiting a variety of respiratory viruses, including influenza A and respiratory syncytial virus. Differences in the structure of the carbohydrate recognition domain provide SP-A and SP-D with altered affinities for different sugar molecules, allowing complementary functions and improving the diversity of microbial interactions. Interactions with gram-negative organisms frequently depends on the ability of SP-A and SP-D to bind lipopolysaccharide, whereas the mechanism of SP-A interactions with gram-positive organisms, including group B beta-hemolytic streptococci, are not as clear.

The lung collectins also modulate the functions of a variety of immune cells, including macrophages, neutrophils, eosinophils, and lymphocytes (Wright, 2005). In addition to opsonizing microorganisms, functions of the lung collectins include stimulating chemotaxis of macrophages and neutrophils, enhancing cytokine production by macrophages and eosinophils, attenuating lymphocyte responses by inhibiting T cell proliferation, and modulating the production of reactive oxygen and nitrogen species used in killing microorganisms.

Like the hydrophobic surfactant proteins, SP-A and SP-D exhibit both developmental and hormonal regulation of expression (Mendelson, 2000). In human fetuses, SP-A mRNA is undetectable before 20 weeks' gestation, and SP-A protein is first detectable in amniotic fluid by 30 weeks' gestation, increasing toward term (Pryhuber et al, 1991). In humans, SP-A gene expression is induced by cAMP and glucocorticoids, although the response to glucocorticoids in biphasic, showing attenuation at higher doses. Retinoids, insulin, and growth factors such as TGF-β and TNF-α inhibit SP-A gene expression. Like SP-A, SP-D levels in human lung are low during the second trimester (Dulkerian et al, 1996), are detectable in amniotic fluid, and increase toward term (Whitsett, 2005). Levels of both SP-A and SP-D increase markedly in the first days after preterm birth.

DEVELOPMENT OF DETOXIFICATION SYSTEMS

Although essential to cellular processes, oxygen concentrations beyond the physiologic limits may be hazardous to cells. The lung is particularly susceptible to reactive forms of oxygen and free radicals, because it is the organ with the highest exposure to atmospheric oxygen. The fetal lung is exposed to oxygen tensions of 20 to 25 mm Hg in utero, and the transition to air breathing is associated with a fourfold to sevenfold increase in oxygen tension, presenting a significant oxidant stress. Oxygen free radicals arise from endogenous production through metabolic reactions, or by exogenous exposure, from air pollutants and cigarette smoke, and they can result in lung injury from oxidation of proteins, DNA, and lipids. Therefore it is imperative for the lung to develop an antioxidant detoxification system, and for this system to be functional upon the fetal transition to air-breathing.

Oxygen free radicals are highly toxic substances. Superoxide, produced by the reduction of molecular oxygen by the addition of an electron, is formed by all cells and occurs in particularly high concentrations in phagocytic cells to facilitate the killing of microorganisms. Hydrogen peroxide is generated from the transfer of a single electron to superoxide, and hydroxyl radicals are generated from the interaction of hydrogen peroxide with superoxide. The free electrons of free radicals interact with membrane lipids, resulting in lipid peroxidation, with sulfhydryl and other groups on exposed amino acids in proteins and with DNA causing direct damage. These lipid, protein, and nucleic acid modifications damage airway and alveolar epithelial cells as well as capillary endothelial cells, leading to altered epithelial integrity, interstitial and airspace edema, and infiltration of inflammatory cells. Increased reactive oxygen species levels have also been implicated in initiating inflammatory responses through the activation of transcription factors such as NFκB and AP-1, signal transduction pathways, and chromatin remodeling that foster the expression of proinflammatory mediators (Rahman et al, 2006).

Oxygen can have additional effects beyond the direct toxicity of free radicals. Oxygen levels regulate the activity of plasminogen activator inhibitor-1 and other protease-antiprotease systems within the airspaces, thereby modulating the destructive effects of proteases elaborated from inflammatory cells. Oxygen can also regulate cellular growth responses by altering the secretion of growth factors and DNA synthesis, generally through oxygen-sensing transcription factors, such as the HIF family.

Antioxidants attenuate the effects of oxygen free radicals in the lungs, and in the lung there are both nonenzymatic and enzymatic antioxidants. The major nonenzymatic antioxidants are gluthatione (GSH), vitamins C (ascorbate) and E (primarily α-tocopherol), β-carotene, and uric acid. Enzymatic antioxidants include superoxide dismutases 1, 2, and 3, catalase, and a variety of peroxidases. Animal studies indicate that many of the antioxidant enzymes are induced before term delivery, and limited data suggest that the same is true of human fetuses (Weinberger et al, 2002). Premature animals fail to induce antioxidant enzymes in response to oxidative lung injury (Thibeault, 2000). Therefore preterm infants are significantly more compromised in antioxidant defenses and, because of the need for oxygen in the treatment of respiratory distress syndrome, they are more susceptible to oxygen toxicity.

NOVEL CONCEPTS IN LUNG DEVELOPMENT

STEM AND PROGENITOR CELLS IN THE LUNG

The ability of lung epithelium to replace cells damaged from normal aging or injury has become the focus of recent attention (Rawlins et al, 2008; Warburton et al, 2008). Stem cells are undifferentiated and have an unlimited capacity for self-renewal. Asymmetric divisions allow for self-renewal through one daughter cell while enabling the other daughter cell to become more terminally differentiated. Progenitor cells are more committed, and although capable of self-renewal, they have more restricted cell fates. Thus far, three cell types in the lung have been identified as progenitor cells, having the capacity for self-renewal and for replacement of a variety of specialized lung epithelial cells. Basal cells in large airways and submucosal glands, identified by the expression of Trp63/p63 and cytokeratin 5, are able to self-renew and give rise to ciliated and secretory cells. Clara cells in smaller airways, identified by the expression of CC10/Scgb1a1, seem to be more committed progenitor cells because they are able to self-renew or differentiate into ciliated cells. A subset of Clara cells at the bronchoalveolar duct junction are both CC10/Scgb1a1 and SP-C positive, and thus have the potential to produce either Clara cells or alveolar type 2 cells. The most limited lung epithelial progenitor cell is the alveolar type 2 cell, which divides rapidly to reestablish epithelial continuity in damaged alveoli and then transdifferentiates into alveolar type 1 cells. The mesenchymal progenitor cells that provide for vascular and muscular components of the developing lung have been studied less. Candidate cells have been identified that give rise to endothelial cells in the process of vasculogenesis and airway smooth muscle cells along the branching lung epithelial tubes.

Evidence for the existence of stem-progenitor cells in the lung is strong, but limited largely to mouse models of lung development and lung repair; therefore extrapolation to humans should be done with caution. The capacity for self-renewal is tantalizing, but it means that such cells have a risk for autonomous growth such as cancer. Controversy exists around the potential to harness these populations of cells as a means for correcting errors in lung development (pulmonary hypoplasia), genetic diseases of the lung (cystic fibrosis), and abnormal repair of injured lungs (bronchopulmonary dysplasia).

EPITHELIAL TO MESENCHYMAL TRANSITION

Fibrosis often occurs as the result of severe injury to the lung and has historically been a component of bronchopulmonary dysplasia (BPD). Emerging evidence suggests that expansion of fibroblast populations in fibrotic lesions is not simply the result of increased proliferation of local fibroblast populations, rather the transformation of epithelial cells into mesenchymal components, a process known as *epithelial-mesenchymal transition* (EMT) (Guarino

TABLE 42-4 Potential Effects of Premature Birth on Lung Development and Maturation

Event	Effect of Preterm Birth	Potential Consequences
Development of conducting airways	Branching: no effect; completed to the level of the respiratory bronchi by 24 wk gestation Tone: increased secondary to lung disease in part reflecting developmental deficiency of nitric oxide	None Increased airways resistance
Alveolarization	Variable depending on timing of delivery and severity of lung disease; may also be compromised by excess glucocorticoids	Reduced lung growth and lung surface area with increased alveolar size; impaired pulmonary function
Development of alveolocapillary membrane	Minimal, reaches adult diameter by 24 wk gestation; glucocorticoids induce precocious thinning	Gas exchange largely dependent upon surface area, not alveolocapillary diameter
Type II cell differentiation	Variable immaturity and deficient surfactant production depending on timing of delivery; improved with antenatal glucocorticoids	Developmental deficiency of surfactant content and composition results in RDS
Type I cell differentiation	Variable depending on timing of delivery; cells develop from type II cells	Gas exchange largely dependant upon surface area
Hydrophobic surfactant proteins (SP-B, SP-C)	Variable depending on timing of delivery and other factors, such as infection, that can impair gene transcription	High alveolar surface tension; RDS
Hydrophilic surfactant proteins (SP-A, SP-D)	Variable depending on timing of delivery; both proteins appear relatively late in third trimester	Comprised host defense: ability to clear microorganisms from airways, alveolar space, or both; impaired ability to modulate inflammatory responses
Clara cell differentiation	Variable depending on timing of delivery; these cells appear in middle 2nd trimester, but antioxidant products appear late in 3rd trimester	Impaired antioxidant and antimicrobial defenses; may contribute to chronic lung disease and pneumonia
Induction of antioxidant systems	Variable depending on timing of delivery; expression of antioxidants occurs late in third trimester	Lung injury from oxidant stress exacerbated by need for increased oxygen; may contribute to chronic lung disease
Mucociliary clearance	Variable depending on timing of delivery; goblet cells decrease in number toward term	Increased mucous production may obstruct small airways
Development of the pulmonary capillary bed	Variable depending on timing of delivery in parallel to alveolar development	Variable degrees of impaired gas exchange commensurate with impaired alveologenesis and any superimposed lung injury; pulmonary hypertension
Pulmonary arteries	Variable depending on presence and severity of associated lung disease	Pulmonary hypertension associated with chronic lung disease
Fetal lung liquid	Fluid loss: variable effects depending on magnitude and duration of fluid loss (i.e., prolonged premature rupture of membranes) as well as timing of delivery Fluid retention: variable effects depending on timing of delivery, because hormone surges near term and in labor promote reabsorption before delivery	Pulmonary hypoplasia Transient tachypnea of the newborn
Fetal breathing movements	Variable depending on timing of delivery, but also depending on maternal exposure to substances that reduce fetal breathing movements	Unlikely to have effects in preterm infants unless coexisting conditions severely limit fetal breathing
Respiratory drive	Variable depending on timing of delivery	Apnea of prematurity

RDS, Respiratory distress syndrome.

et al, 2009; Thiery and Sleeman, 2006). EMT is an essential part of gastrulation and the development of cardiac valves. Neural crest cells are the best model system for EMT, because these epithelial cells must lose their local attachments and travel long distances before locating their final niche and differentiating accordingly. The evidence is clear that the changes in cell phenotype characteristic of EMT—from sedentary, interconnected epithelial cell expressing epithelial marker proteins to mobile, proliferative mesenchymal cell expression markers of fibroblasts and secreting collagen and other components of extracellular matrix—are under the control of local growth factors. In the lung, the most prominent growth factor in EMT associated with pulmonary fibrosis is TGF-β, a growth factor essential for normal branching morphogenesis during early lung development.

It remains uncertain whether EMT has a similarly important role in lung development as it does in cardiac development, and whether EMT alone is important to the abnormal repair response to lung injury. EMT has the potential to reduce epithelial populations, resulting in lung destruction, while expanding mesenchymal fibroblast pools and enhancing local matrix deposition that reduces lung elasticity. Many of the models of EMT are derived from lung cancer cell lines or mouse models, limiting their applicability to humans. However, improved understanding of the processes controlling EMT could lead to novel therapies for limiting or reversing pulmonary fibrosis after

lung injury. Furthermore, given the potential for EMT to contribute to lung destruction, a more common feature of the "new BPD," early events in EMT may be particularly important targets of preventive therapy in premature infants.

ROLE OF miRNA IN LUNG DEVELOPMENT AND MATURATION

Regulation of normal development and consequences of abnormal development are at the heart of understanding the implications of preterm birth and developing potential protective lung therapies. The central tenet of DNA to RNA to protein is being challenged by new epigenetic mechanisms—histone modifications, modification of DNA and RNA, silencing RNA, and micro RNA (miRNA)—for regulating gene expression. The evidence that miRNA has an important role in normal fetal development is strong (Nana-Sinkam et al, 2009). miRNAs are small, noncoding RNAs (generally 19 to 25 nucleotides long) found within cells that target genes for RNA degradation or inhibition of protein synthesis. There are more than 500 recognized miRNA, some of which are particularly enriched in lung cell populations. MiRNAs are generated from a process that begins in the nucleus. Long primary miRNA are transcribed, processed, and exported from the nucleus, followed by further cytoplasmic maturation before the final miRNA is able to interact with regions of messenger RNA, usually in the 3' untranslated region of RNA that extends beyond the RNA sequence used for protein translation.

Emerging evidence indicates that miRNA is essential for normal lung development, because targeted deletion of Dicer, a key enzyme in miRNA processing, results in abnormal airway development and excessive apoptosis in the lungs. The miR-17-92 cluster of miRNA is highly expressed in embryonic mouse lung, decreasing into adulthood as lung development progresses. Altered expression of the miRNA cluster miR-17-92 suggests a primary role for these miRNA in maintaining a population of undifferentiated lung epithelium during lung development. Because of their role in regulating developmental and pathologic processes, miRNAs are increasingly seen as targets for therapeutic interventions. Obstacles to miRNAs as therapeutic agents are similar to obstacles encountered in other gene therapies, including mode of delivery, cell and tissue specificity, and the potential for off-target effects.

SUMMARY

Lung branching morphogenesis is coordinated with pulmonary vascular development to provide a large surface area and thin alveolocapillary membrane for adequate gas exchange in the transition to air breathing and to meet the needs of a growing infant and child. Although maturation occurs late in fetal lung development, it is similarly critical in the transition to air breathing. Although the fetal lung developmental program requires an array of transcription factors, hormones, and growth factors promoting branching morphogenesis, lung growth is equally dependent on intact neural input to modulate fetal breathing, stability of an appropriately sized thorax, and the presence of adequate lung and amniotic fluid. Furthermore the maturation of the host defense and detoxification systems minimize the effects of increased oxygen tension and exposure to potential pathogens accompanying the transition to air breathing. Premature birth affects all these functions as illustrated in Table 42-4. Bronchopulmonary dysplasia is the net result of multiple injuries to the underdeveloped lungs of premature newborns that compromise postnatal growth and development, and thus impairing function. Integrated approaches to therapy that reflect the interdependency of these lung functions have the most promise for minimizing the effects of premature birth on childhood and, ultimately, adult lung function.

CHAPTER 43

Control of Breathing

Estelle B. Gauda and Richard J. Martin

The developmental aspects of respiratory control are of considerable interest to physiologists and clinicians for a multitude of reasons. The transition from fetal to neonatal life requires a rapid conversion from intermittent fetal respiratory activity not associated with gas exchange to continuous breathing upon which gas exchange is dependent. In addition, the circuitry that regulates respiratory control serves as a unique link between the maturing lung and brain. The term infant has the repertoire of respiratory and cardiovascular responses that meets his or her metabolic demands during wakefulness, sleeping, crying, and feeding even though the breathing pattern may be punctuated with apneic pauses and sighs (augmented breaths), and the neurocircuitry that controls breathing is not completely developed. In some term infants who appear well, developmental abnormalities in the neurocircuitry and neurochemistry that regulate respiratory rhythmogenesis can lead to profound disorders of breathing, placing them at increased risk for sudden death. Infants who have died of sudden infant death syndrome (SIDS), and those infants with central congenital hypoventilation and Rett syndrome, have provided a window of opportunity for careful epidemiologic, genetic, neurochemical, and anatomic study that has allowed researchers to better understand which genes regulate the development of the respiratory system and how environmental factors in fetal and early neonatal life may adversely affect normal development.

The infant who is born prematurely has also provided a unique opportunity to observe the natural developmental trajectory of respiratory control. Breathing in the most premature infants is akin to fetal breathing, which is episodic, punctuated by periods of disturbingly long apneic pauses interspersed with frequent periods of hyperventilation and sighs (augmented breaths). The purpose of fetal breathing movements is not gas exchange, rather it is lung development by inducing sufficient stretch of the chest wall. For the infant who is born prematurely, the frequent apneic events and hypoventilation associated with oxygen desaturations and bradycardia are of significant concern. The purpose of this chapter is to present what is currently known about the neuroanatomy, neurocircuitry, and neurochemistry that controls breathing during development to better understand how infants breathe, why premature infants have apnea of prematurity, why term infants have apnea of infancy, and how genetic errors and environmental influences modify mechanisms that control breathing during fetal and early neonatal life.

ANIMAL MODELS OF CONTROL OF BREATHING

Much of our understanding of basic mechanisms that lead to a stable respiratory pattern is derived from animal studies, both adult and newborn. Earlier studies used the newborn pig, dog, and cat, as well as fetal and newborn sheep models, to better understand developmental physiology, and much has been gained from these models. However, a more detailed understanding of the neuroanatomy, neurocircuitry, and neurochemistry has been obtained using in vitro models from newborn rats and mice. Of particular relevance, the stage of respiratory development of the rat born at term is similar to that of the human infant born at 25 to 29 weeks' gestation; therefore the newborn rodent model is applicable to breathing in the premature infant. Studies using either of two in vitro models (brainstem slices that include the area that contains the "pacemaker cells mediating rhythmogenesis" and the isolated brainstem spinal cord preparation from fetal and newborn rodents) have led to an explosion of information about all aspects of maturation of respiratory control within the last decade (Richter and Spyer, 2001). Because the stability and viability of the in vitro preparations are best when tissues are used from late embryonic or early postnatal rodents (within first week of postnatal life), data from these in vitro models are relevant to respiratory control during early development.

OVERVIEW OF RESPIRATORY CONTROL

The leading hypothesis regarding autonomic control of breathing is that respiratory rhythm is generated from a core group of synaptically coupled excitatory neurons in the brainstem located in the pre-Bötzinger complex (PBC). These neurons depolarize during the three phases of respiration: inspiration, postinspiration, and expiration. The timing of the respiratory cycle is controlled by inhibitory interneurons that discharge during specific phases of the respiratory cycle. Collectively this complex network of neurons is called the *central pattern generator* (Duffin, 2004; Smith et al, 2009).

Inspiratory, postinspiratory, and expiratory neurons depolarize with each phase of the respiratory cycle coincident with activity motoneurons innervating the muscles of respiration (Figure 43-1). Whereas inspiration is always associated with phrenic nerve activity and contraction of the diaphragm, the first phase of expiration (E1), known as *postinspiratory activity*, can be associated with phrenic nerve activity, and the second phase of expiration (E2) is not (see Figure 43-1).

With development, the intrinsic properties and neurotransmitter profiles of respiratory-related neurons and synaptic inputs from (1) higher brain centers (frontal and insular cortex, hypothalamus, reticular activating system and amygdala, (2) mechanoreceptors in the lungs and upper airways, (3) peripheral chemoreceptors in the carotid body, and (4) central chemoreceptors on the ventral medullary surface modify the excitability of respiratory-related

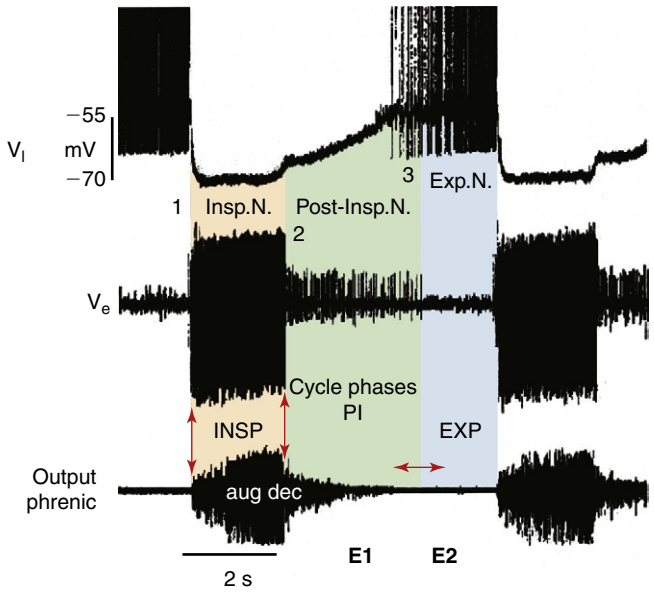

FIGURE 43-1 Simultaneous triple recordings of electrical activities of the main populations of respiratory neurons: *1*, an inspiratory neuron (large spikes, middle tracing); *2*, a postinspiratory neuron (small spikes, middle tracing); *3*, an expiratory neuron (top tracing) and the phrenic nerve (bottom tracing). Note the augmenting (aug) activity of the phrenic nerve during inspiration and the decrementing (dec) activity of the phrenic nerve during the postinspiratory (PI) phase of the respiratory cycle. The postinspiratory phase is the first phase of expiration (E1) and is associated with phrenic nerve activity. In the second phase of expiration (E2), the phrenic nerve is silent. *(Reproduced from Richter DW, Spyer KM: Studying rhythmogenesis of breathing: comparison of in vivo and in vitro models*, Trends Neurosci *24:464-472, 2001.)*

neurons. In addition, the intrinsic "sensing" properties of mechanoreceptors and chemoreceptors are also changing. Last, the integrated respiratory output is also dependent on the strength of the synapse between the premotor respiratory neurons and the respiratory motoneurons innervating the diaphragm, intercostals and muscles of the upper airway, and the corresponding neuromuscular junctions (Figure 43-2). The effect of development on respiratory motoneurons and the neuromuscular junction will not be discussed in depth in this chapter; for further discussion of this topic the reader is referred to two excellent reviews (Greer and Funk, 2005; Mantilla and Sieck, 2008).

MUSCLES OF RESPIRATION

The muscles of respiration include the pump muscles (diaphragm, intercostal muscles, and abdominal muscles) and muscles of the upper airway (alae nares, pharyngeal muscles, and laryngeal muscles). Upper airway muscles modulate the rate of inspiratory and expiratory airflow. During the inspiratory phase of the respiratory cycle the diaphragm, external intercostals (in infants), and posterior cricoarytenoid (laryngeal dilator) contract. During the postinspiratory phase, the diaphragm and the thyroarytenoid (laryngeal constrictor) contract. Diaphragmatic and thyroarytenoid postinspiratory activity is common in newborns, both human (Eichenwald et al, 1993) and animals (England et al, 1985). Because the chest wall of newborn infants, particularly premature infants, is highly compliant, diaphragmatic and laryngeal postinspiratory activity retards expiration to maintain functional residual

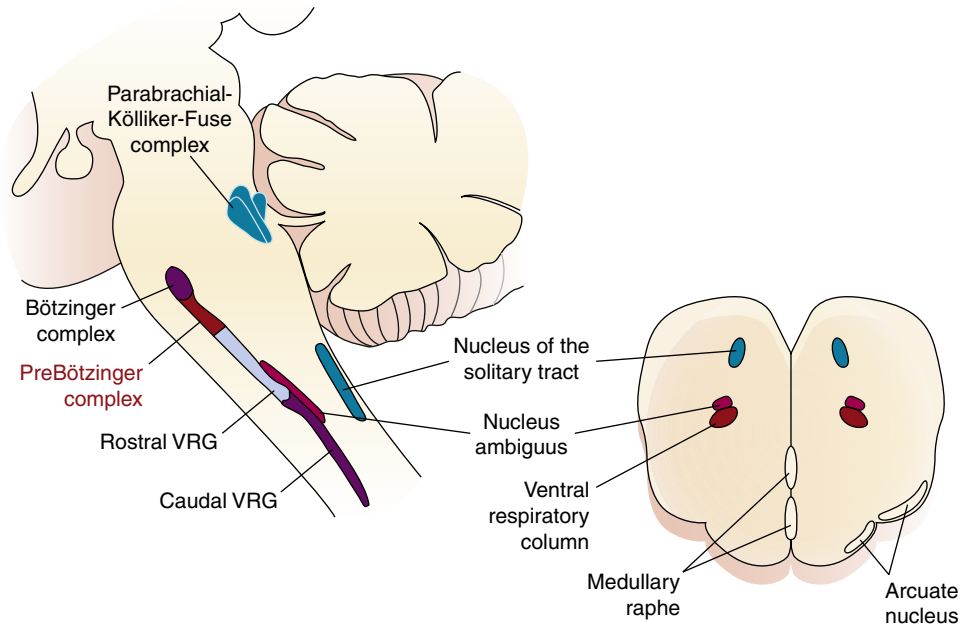

FIGURE 43-2 Schematic illustrating the anatomic relationship between the regions in the human brainstem that compose the respiratory network. These regions include specialized neurons in the dorsolateral pons (parabrachial and Kölliker–Fuse nuclei) nucleus of the solitary tract (nTS), and ventral respiratory column. The ventral respiratory column is organized rostrocaudally extending from the level just below the facial nucleus to the C1 level of cervical cord. The ventral respiratory column consists of the Bötzinger complex, pre-Bötzinger complex, and the rostral and caudal ventral respiratory groups (VRGs). Vagal motor neurons of the nucleus ambiguus innervate the laryngeal muscles. The medullary raphe, arcuate nucleus, located just underneath the ventral medullary surface, contains neurons that depolarize in response to hypercapnia and hypoxia. The retrotrapazoid nucleus (not shown) are CO_2/H^+ chemosensors, and is located rostrally below the facial nucleus on the ventral medullary surface. *(Modified with permission from Benarroch EE: Brainstem respiratory control: substrates of respiratory failure of multiple system atrophy*, Mov Disord *22:155-161, 2007.)*

capacity. This postinspiratory activity is often audible, known as *grunting*, and is heard in infants with low lung-volume disease states, such as surfactant deficiency and atelectasis. As outlined previously, the second phase of expiration (E2) is often quiescent regarding muscle activity; the diaphragm relaxes and the lungs recoil. During forced expiration often seen during exercise and significant hypercapnia, the internal intercostals and abdominal muscles may contract during E2. Brainstem nuclei that are involved in the control of upper airway muscles include the upper airway motoneurons of the nucleus ambiguous, the dorsal motor nucleus of the vagus, and the hypoglossal nucleus (Jordan, 2001; Nunez-Abades et al, 1992). Projections from respiratory-related neurons synapse onto these upper airway motoneurons, thereby regulating the activity of these nerves and muscles during the respiratory cycle.

RESPIRATORY CENTER NEUROANATOMY

As shown in the anatomic illustration (see Figure 43-2) and the schematic (Figure 43-3), the respiratory-related neurons are located in three main areas in the brainstem: (1) the dorsal respiratory group within the nucleus tractus solitarii, (2) the ventral respiratory column (VRC) that extends from the facial nucleus to the ventrolateral medulla at the spinal-medullary junction, and (3) the pontine respiratory group within the dorsolateral pons (Alheid and McCrimmon, 2008). The VRC can be subdivided into a rostral part, involved in rhythmogenesis, and a caudal part involved in pattern formation. The rostral VRC contains both the rostral ventral respiratory group (VRG), which contains a large proportion of bulbospinal inspiratory neurons that project directly to the phrenic and external intercostal motoneurons, and the caudal VRG, which contains bulbospinal expiratory neurons that project to abdominal and internal intercostal motoneurons. Bulbospinal neurons are neurons that originate in the medulla and synapse onto motoneurons in the spinal column. Of importance, within the rostral VRC are two areas that are essential to formation of respiratory rhythm: the Bötzinger complex, and PBC. The Bötzinger complex contains propriobulbar expiratory neurons that provide strong inhibitory inputs onto inspiratory and expiratory bulbospinal neurons in the VRC. Propriobulbar neurons are neurons originating in the brainstem that send projections to other neurons in the brainstem. The PBC contains a core group of synaptically coupled excitatory neurons that have pacemaker properties, similar to the pacemaker cells in the AV node of the heart. These pacemaker cells are rostral to the nucleus

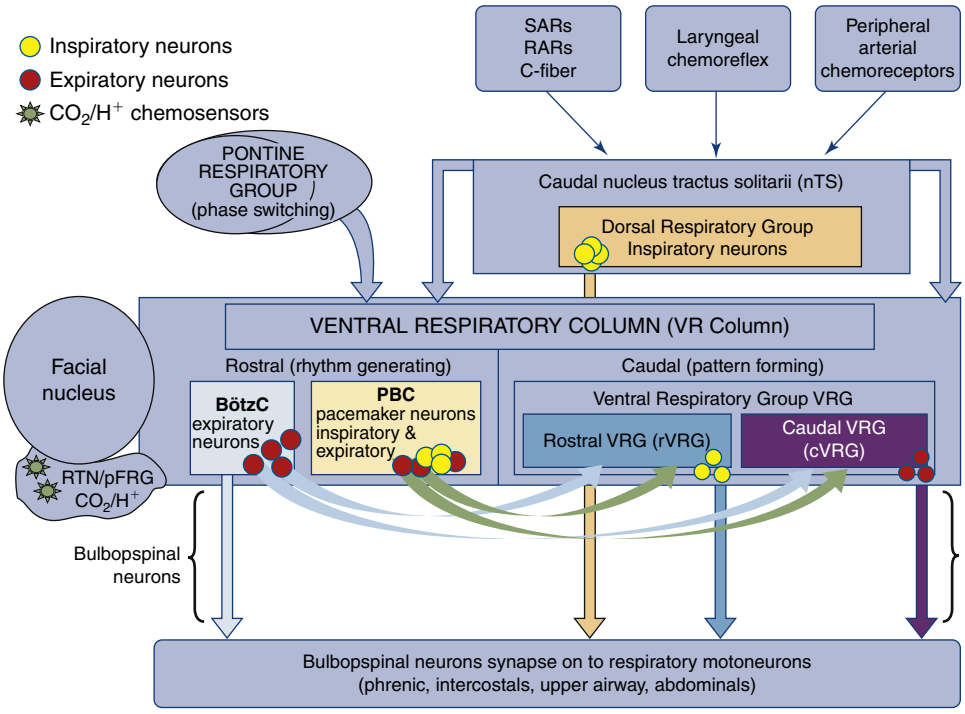

FIGURE 43-3 Simplified schematic illustrating the major pontine-medullary brainstem network controlling respiration and afferent and efferent projections. The pontine respiratory group contains two nuclei that send neuronal connections to respiratory-related neurons in the ventral respiratory column (VRC). The pontine respiratory group mediates phase switching between inspiration and expiration. Within the nucleus tractus solitarii (nTS) are the inspiratory neurons of the dorsal respiratory group with projections to motoneurons in the spinal column. The nTS also receive monosynaptic inputs from vagally mediated reflexes in the lung and upper airways (including slowly adapting receptors [SARs], rapidly adapting receptors [RARs], and C-fibers receptors), laryngeal chemoreceptors, and peripheral arterial chemoreceptors. Projections from second-order neurons in the nTS then synapse on to neurons in the rostral and caudal VRC. The VRC extends from the level of the facial nucleus to C1 in the cervical spinal cord. The rostral VRC is involved in respiratory rhythmogenesis and contains the expiratory neurons of the Bötzinger complex (BötzC) and the pacemakers cells of the pre-Bötzinger complex (PBC). The BötzC and PBC contain propriobulbar neurons that project to inspiratory neurons in the rostral ventral respiratory group (VRG) and expiratory neurons in the caudal VRG. The BötzC also contains bulbospinal neurons that synapse on to phrenic motoneurons in the spinal cord, whereas the PBC only contains propriobulbar neurons. Neurons in the VRG are responsible for shaping the respiratory pattern and receive inputs from second-order neurons in the nTS and from rhythm-generating neurons in the BötzC and PBC. Bulbospinal neurons from the DRG, BötzC, rVRG, and cVRG synapse onto motoneurons that control the activity of the muscles of respiration.

ambiguous, have both intrinsic inspiratory and expiratory bursting properties, and are essential to maintaining respiratory rhythm (Smith et al, 1991). Progressive destruction of the PBC disrupts rhythmogenesis, leading to death in an animal model (Ramirez et al, 1998).

Another important group of neurons are those within the retrotrapezoid nucleus (RTN) located along the ventral medullary surface beneath the facial nucleus (see Figure 43-3). These neurons have chemosensitive properties and depolarize in response to increasing CO_2 and decreasing pH, and they are presumed to synapse on rhythm and pattern generating neurons in the VRC (Guyenet et al, 2008). All these neuronal groups and networks for rhythmogenesis are present in newborn animals born at term (e.g., sheep, cats, pigs) or born prematurely (e.g., rodents) in which rhythmogenesis is well established before birth. Episodic spontaneous fetal breathing movements occur in human fetuses as early as 10 weeks' gestation (de Vries et al, 1985). In rodents, respiratory rhythmogenesis is first detected at embryonic day 15 in rats and day 17 in mice (Thoby-Brisson and Greer, 2008). The emergence of this respiratory related activity in rats is coincident with the characteristic expression of neurokinin 1 receptors of the PBC (Thoby-Brisson and Greer, 2008).

In summary, respiratory rhythm and inspiratory-expiratory patterns emerge from dynamic interactions between: (1) excitatory neuron populations in the PBC and rostral VRG, which are active during inspiration and form the inspiratory motor output; (2) inhibitory neuron populations in the PBC that provide inspiratory inhibition within the network; and (3) inhibitory neuron populations in the Bötzinger complex, which are active during expiration and provide expiratory inhibition within the network and to phrenic motor neurons (see Figure 43-3) (Smith et al, 2009).

NEUROCHEMISTRY MEDIATING RESPIRATORY CONTROL

Glutamate is the major neurotransmitter mediating excitatory synaptic input to brainstem respiratory neurons and respiratory premotor and motor neurons through binding to the α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid kainite (Bonham, 1995) and metabotropic glutamate receptors (Pierrefiche et al, 1994). GABA (gamma-aminobutyric acid) and glycine are the two major inhibitory neurotransmitters mediating inhibitory synaptic input in the respiratory network; they have a key role in pattern generation and termination of inspiratory activity (Haji et al, 2000). GABA (via $GABA_A$ receptors) and glycine (via glycine receptors mediate fast synaptic inhibition via activation of chloride channels (Bianchi et al, 1995). $GABA_B$ receptors, which are metabotropic G-protein coupled receptors, have a greater role in inhibiting respiratory rhythm in adult mammals (Kerr and Ong, 1995). Throughout development, glutamate always functions as an excitatory neurotransmitter; however, it is not the case that GABA and glycine are always inhibitory neurotransmitters. During early development, GABA and glycine mediate excitatory neurotransmission in many neuronal networks, including the respiratory network (Putnam et al, 2005). The expression of $K^{\pm}$ chloride cotransporters (KCC2 and NKCC2) reduces the intracellular chloride concentrations that change the effect of GABA binding to $GABA_A$ receptors from depolarizing during late embryonic and early postnatal to hyperpolarizing with maturation (Rivera et al, 1999).

NEUROMODULATION OF RESPIRATORY PATTERN AND RHYTHM

The baseline excitatory and inhibitory influences mediated by glutamate and GABA–glycine, respectively, on major neuronal networks are further altered by many endogenously released neuromodulators that shape and fine tune respiratory pattern and rhythm throughout development, as outlined in Table 43-1. For example, acetylcholine, substance P, cholecystokinin, cholecystokinin (CCK) and thyrotropin-releasing hormone all exert an excitatory drive, whereas opioids and somatostatin exert an inhibitory drive on respiratory-related neurons. Dopamine, adenosine, serotonin, and norepinephrine can have excitatory and inhibitory influences depending on the specific receptors that the neuromodulator binds. Neurons within the PBC that are the kernel of rhythmogenesis are also distinctly identified by being immunopositive for the glutamate transporter, NK1, μ-opioid, and $GABA_B$-receptors. Although these cells are primarily excitatory and release glutamate, they can be modulated by synaptic inputs that release substance P, opioids, and GABA (Doi and Ramirez, 2008). Recently these rhythmogenic neurons have been found to produce, and be excited by, brain-derived neurotrophic factor (Bouvier et al, 2008).

GENETIC MUTATIONS AFFECTING BIOGENIC AMINES

Some neuromodulators may be more critical for supporting respiratory rhythmogenesis than others. By identifying the genetic mutations that are associated with marked abnormalities in respiratory control, a better understanding of the key role of several neuromodulator systems has been elucidated. For example, serotonergic neurons in the caudal medullary raphe nuclei have extensive projections to phrenic and hypoglossal motoneurons, the nucleus tractus solitarii (nTS), the RTN, and the PBC (Pilowsky et al, 1990; Voss et al, 1990). Thus, as reviewed by Kinney et al (2009), the serotonergic system has a significant influence on the modulation and integration of diverse homeostatic functions. Medullary serotonergic neurons are also CO_2 sensitive (Richerson et al, 2001). In genetically modified mice that do not develop medullary serotonergic neurons, CO_2 sensitivity is reduced by 50% (Hodges et al, 2008). Individuals with Prader–Willi syndrome, who may exhibit breathing abnormalities at birth) have mutations in the *Necdin* gene associated with abnormalities in the brainstem serotonergic system (Zanella et al, 2008a). Mice lacking the *Necdin* gene also have abnormal brainstem serotonergic neurochemistry (Zanella et al, 2008b). In some infants who have died of SIDS, disruptions of the brainstem serotonergic system have been identified (Kinney et al, 2009; Paterson et al, 2006b). Abnormalities in norepinephrine production also disrupt normal breathing. Rett syndrome is an X-linked disorder with mutations in the methyl CpG binding protein 2 (*MECP2*) gene. Affected individuals have severe respiratory disturbances that can be fatal. Genetically

TABLE 43-1 Neurotransmitters and Neuromodulators That Mediate Respiratory Rhythm

Neuromodulator	Receptor Subtype	Source of the Endogenous Ligand	Excitatory or Inhibitory on Respiratory Rhythm	Comment
Glutamate	NMDA, AMPA GluR		Excitatory	Major excitatory neurotransmitter
Ach	M3	PAG, LC, X	Excitatory	
NE	α_1-adrenergic	LC	Excitatory	
Serotonin	5-HT_{2A2B}, 5-HT_3, 5-HT_4	Raphe	Excitatory	
Dopamine	Likely D1	PVN, hypothalamus	Excitatory	
ATP	$P2X_2$	Ventral medulla; CO_2/H^+ cells in the RTN	Excitatory	
Adenosine	$P2Y_1$	Ventral medulla	Excitatory	
Substance P	NK1	nTS, NA	Excitatory	
CCK	CCK_1	nTS, raphe	Excitatory	
TRH	TRH-R, R2	raphe	Excitatory	
GABA	$GABA_A$ $GABA_B$		Inhibitory	Major inhibitory neurotransmitter (can be excitatory during fetal life)
Glycine	GlyR		Inhibitory	Can be excitatory during fetal life
NE	α_2-adrenergic	Pons	Inhibitory	
Dopamine	D_4	PVN, hypothalamus		
Adenosine	A1, A2	Ubiquitous from metabolism of ATP that increases during hypoxia	Inhibitory	Contributes to respiratory depression at baseline (A1), and mediates HVD
Opioid	μ, δ, κ	nTS, PBN, PVN, raphe	Inhibitory	Prominent inhibitory effect during early development
PDGF	PDGF-β	nTS,	Inhibitory	Contributes to HVD

Data combined from Doi A, Ramirez JM: Neuromodulation and the orchestration of the respiratory rhythm, *Respir Physiol Neurobiol* 164:96, 2008; and Simakajornboon N, Kuptanon T: Maturational changes in neuromodulation of central pathways underlying hypoxic ventilatory response, *Respir Physiol Neurobiol* 149:273, 2005.
Ach, Acetylcholine; *ATP*, Adenosine triphosphate; *CCK*, cholecystokinin; *GABA*, gamma-aminobutyric acid; *HVD* , hypoxic ventilatory depression; *LC* locus ceruleus; *NA*, nucleus ambiguous; *NE*, norepinephrine; *nTS*, nucleus tractus solitarii; *PAG*, periaqueductal gray; *PBN*, parabrachial nucleus; *PDGF*, platelet-derived growth factor; *PVN*, paraventricular nucleus; *RTN*, retrotrapezoid nucleus; *TRH*, thyrotropin-releasing hormone; *X*, vagal nucleus.

modified mice that lack the *Mecp2* gene have reduced levels of norepinephrine and serotonin in the medulla and have breathing patterns similar to humans with Rett syndrome (Roux et al, 2008). Pharmacologic treatment to increase brain norepinephrine and serotonin levels stabilizes breathing and prolongs the life of these mice (Roux et al, 2007).

PERIPHERAL MECHANORECEPTOR INPUTS THAT MODULATE RESPIRATORY PATTERN AND RHYTHM

The nTS in the brainstem (see Figure 43-3) is where sensory afferents that are transmitting pressure signals from the upper airway, volume signals from the lung, and chemical signals from the blood and cerebrospinal fluid, synapse onto second-order neurons that send projections either monosynaptically or polysynaptically to phrenic motor neurons via respiratory-related bulbospinal neurons.

VAGALLY MEDIATED REFLEXES

Essentially all bronchopulmonary reflexes that modify depth and duration of inspiration and expiration are mediated through the vagal nerve. The vagal nerve has both myelinated and unmyelinated fibers. Myelinated vagal afferent fibers are activated via (1) slowly adapting stretch receptors (SARs), which are activated by volume and stretch of the lung (mediating the Breuer-Hering Reflex), or (2) rapidly adapting receptors (RARs), which are activated in response to inhaled irritants (e.g., ammonia, cigarette smoke) and large inflations or deflations of the lung (Kubin et al, 2006). Changes in respiratory timing of inspiration and expiration are the respiratory response to activation of SARs, whereas sighing (i.e., augmented breaths) and coughing are the characteristic ventilatory responses to activation of RARs. Unmyelinated vagal afferents, specifically C fibers, are activated by a multitude of chemical stimuli, including CO_2 and capsaicin, in addition to lung edema and elevated temperature. Rapid shallow breathing and apnea are the characteristic ventilatory responses to the activation of C-fibers in the airways.

BREUER–HERING REFLEX DURING DEVELOPMENT

The duration of inspiration and expiration is greatly influenced by lung inflation, and the most well-characterized bronchopulmonary reflex is the pulmonary stretch reflex mediated through SARs, discovered by Josef Breuer in 1868. In adult cats, Breuer showed that expansion of the lungs reflexively inhibits inspiration and promotes

expiration, and that deflation of the lungs promotes inspiration and inhibits expiration (Widdicombe, 2006). In the nTS, these afferents monosynaptically synapse on to second-order neurons called *pump cells* and *inspiratory-β neurons*. These second-order neurons then send projections to respiratory-related bulbospinal neurons in the VRC. Bulbospinal neurons synapse on the phrenic motoneurons in the cervical spinal cord. SARs also influence the activity of a subset of propriobulbar VRC neurons that are involved in rhythmogenesis (for review, see Kubin et al, 2006).

The Breuer–Hering (B-H) reflex does not appear to be important in regulating fetal breathing movements, because vagotomy performed in fetal sheep has little effect on the incidence, frequency, or amplitude of these breathing movements (Hasan and Rigaux, 1992). However, the B-H reflex is important in establishing continuous breathing and adequate gas exchange at birth (Wong et al, 1998). The reflex maintains functional residual capacity in newborns and infants, because vagotomy within 48 hours of birth results in respiratory failure associated with marked atelectasis in newborn sheep (Lalani et al, 2001; Wong et al, 1998). Vagal innervation in utero was initially thought to be necessary for the development of surfactant (Alcorn et al, 1980), but this belief has recently been challenged by new findings from Gahlot et al (2009). These studies showed that vagal denervation performed at 110 to 113 days' gestation (term gestation, 147 days) in fetal sheep had no effect on alveolar architecture, number of type II cells, morphology of lamellar bodies, or the level of surfactant proteins A and B and total phospholipids in lung tissue (Gahlot et al, 2009).

In humans, the contribution of the B-H to tidal breathing is determined by occluding the airway at either end expiration, where the next occluded inspiratory effort is prolonged and expiratory effort is shortened, or end inspiration, where the next occluded expiratory effort is prolonged and inspiratory effort is shortened. The inspiratory and expiratory time of the occluded effort is compared to the inspiratory and expiratory time of the preceding nonoccluded breath to determine the percentage increase or decrease of the inspiratory or expiratory times. With this technique, the B-H reflex has been shown to contribute significantly to tidal breathing in infants, which is strongest at birth and then decreases during the 1st year of life (Rabbette et al, 1994). It is reasoned that the strength of the B-H reflex is inversely related to gestational and postnatal age because of the excessively compliant chest wall in newborns, which collapses at lung volumes less than functional residual capacity. With decreasing lung volumes during expiration, the B-H deflation reflex will become activated and thereby shorten expiratory time and prolong inspiratory time. Several factors increase the strength of the B-H reflex, including premature birth (De Winter et al, 1995; Kirkpatrick et al, 1976), prone sleeping position (Landolfo et al, 2008) and active sleep (Hand et al, 2004) and respiratory distress syndrome (RDS) (Rabbette et al, 1994).

RAPIDLY ADAPTING RECEPTORS DURING DEVELOPMENT

Lung deflation, mechanical stimulation, and chemical irritants also stimulate vagal afferents of RARs causing augmented breaths and increased mucous production (Widdicombe, 2006). RAR afferents synapse on RAR cells and inspiratory Iγ neurons throughout the nTS (Kubin et al, 2006). RAR cells receive monosynaptic excitatory inputs from vagal afferents, which are excited by irritants, particularly ammonia. RAR cells then send projections to the pons respiratory group and bulbospinal inspiratory and expiratory neurons. Stimulation of RARs as a result of lung deflation monosynaptically activates inspiratory Iγ neurons in the nTS, which then send axonal projections to bulbospinal neurons (Kubin et al, 2006).

RARs are particularly important in restoring lung inflation in premature and term infants, because the excessive compliance of the chest wall in newborn infants causes low lung volumes during tidal breathing. RARs become active at low lung volumes, leading to threshold activation of vagal afferents that results in augmented breaths, restoring lung volume. The frequency of augmented breaths is inversely related to gestational age, with premature infants having the greatest number (Alvarez et al, 1993), and the characteristic pattern of the augmented breath differs between newborns and adults. Augmented breaths in infants have a biphasic pattern with two large inspiratory efforts in succession, whereas in adults only one large inspiratory effort is seen. Augmented breaths in preterm and term infants are also relatively larger than those in adults; immediately after the augmented breath, preterm and term infants often hypoventilate or have apnea. In contrast, ventilation often increases after the augmented breath in adults (Qureshi et al, 2009). The increased frequency of augmented breaths and the hypoventilation and apnea after augmented breaths in premature infants suggest that peripheral arterial chemoreceptor inputs may have a greater influence on respiration in infants than in adults. Peripheral arterial chemoreceptors reflexively alter ventilation in response to acute changes in arterial CO_2 and O_2 tensions (discussed later). In response to an augmented breath, Pao_2 rapidly increases and $PaCO_2$ rapidly decreases, which reduces the excitatory input from peripheral arterial chemoreceptors, leading to hypoventilation or apnea. Peripheral arterial chemoreceptors are also key in inducing augmented breaths, because carotid sinus nerve denervation in animals is associated with decreased frequency of augmented breaths (Matsumoto et al, 1997). As a result, increased activity of RARs during lung deflation and increased sensitivity of peripheral arterial chemoreceptors in early development both likely contribute to the increased frequency and ventilatory consequences of augmented breaths in premature infants.

C-FIBER RECEPTORS AND RESPONSES DURING DEVELOPMENT

Pulmonary and bronchial C-fiber receptors are unmyelinated vagal fibers located throughout the respiratory tract, extending from the nose to the lung parenchyma. Pulmonary C-fibers are accessible from the pulmonary circulation, whereas bronchial C-fibers are accessible from the bronchial circulation and have similar sensitivity to various stimuli (Coleridge and Coleridge, 1984). C-fibers are activated by a variety of substances: inflammatory mediators, capsaicin, lobeline, and phenylbiguanidine. Capsaicin and phenylbiguanidine are often used experimentally to

identify vagal afferents as C-fibers and characterize stimulus-response profiles. C-fiber simulation induces central and local effects: cough, apnea, and laryngospasm, followed by rapid shallow breathing, bradycardia, and hypotension mediated by the central reflex pathways. Bronchoconstriction, increased mucous secretion, and bronchial and nasal vasodilation are mediated by local or axon reflexes (Carr and Undem, 2003). The central effects involve transmission of impulses to interneurons in the central nervous system, which influences the activity of autonomic or somatic efferent nerves. The local, direct effects are mediated by the release of neuropeptides, particularly substance P, from C-fiber endings. By far the most common respiratory response from C-fiber stimulation is reflex apnea characterized by prolongation of expiratory time from excitation of postinspiratory neurons and continuous firing of central expiratory neurons (Coleridge and Coleridge, 1984). Central integration of pulmonary C-fiber afferent information also occurs in the subnucleus of the nTS. Unlike the relay pathways that have been carefully delineated for the SARs, and to a lesser extent for the RARs, the specific second-order neurons in the nTS that are activated in response to bronchopulmonary C-fiber stimulation have not been completely identified. It is likely, however, that the central integration of pulmonary C-fiber stimulation occurs within the nTS, because the interruption of synaptic transmission within the subnucleus of the nTS ablates reflex response of pulmonary C-fibers from intraatrial injections of phenylbiguanidine (Bonham and Joad, 1991).

In newborns, the stimulation of pulmonary C-fibers by chemical stimulants causes bronchoconstriction and apnea (Frappell and MacFarlane, 2005). Capsaicin-induced apneic response and the sensitivity of the reflex was greatest in newborn rat pups younger than 10 postnatal days (Wang and Xu, 2006). Bronchopulmonary C-fibers are also stimulated by acidosis, adenosine, reactive oxygen species, hyperosmotic solutions, and lung edema. Furthermore, inflammatory mediators in the local environment sensitize C-fibers to other stimuli (Lee and Pisarri, 2001). Pulmonary C-fiber–mediated respiratory inhibition may be causing persistent apnea beyond term postconceptional age in infants born at the limit of viability who have significant lung disease (Eichenwald et al, 1997). As proposed by Lee and Pisarri (2001), C-fiber activation may also account for the increased frequency of apnea observed in infants with viral infections, especially caused by respiratory syncytial virus (Pickens et al, 1989).

LARYNGEAL REFLEXES

Receptors that respond to changes in upper airway pressure and chemical compounds are abundantly distributed throughout the laryngeal mucosa. These receptors can be slowly adapting, rapidly adapting irritant receptors, or C-fibers. Water receptors that are simulated by hyposmolarity and low chloride content may also be involved. Stimulation of upper airway mechanoreceptors and chemoreceptors modifies activity of upper airway muscles as well as the pattern and timing of diaphragmatic activity. The upper airway reflex that mediates significant cardiorespiratory effects that occur in newborns is the laryngeal chemoreflex (LCR). The LCR is one of the most potent defensive reflexes protecting the respiratory tract from inadvertent aspiration (Harding et al, 1978). These receptors are stimulated by liquid in the airway, which induces coughing, swallowing, and arousal in mature models. However, the response in immature models is apnea followed by hypoventilation, laryngeal constriction, and swallowing. In addition to respiratory inhibition, bradycardia, peripheral vasoconstriction, and redistribution of blood flow also occurs. Of importance, the associated apnea and bradycardia can be life threatening in newborns (Boggs and Bartlett, 1982; Sasaki et al, 1977; Thach, 2001; Wetmore, 1993), and in newborn infants baseline hypoxemia enhances the severity of the apnea and bradycardia induced by the LCR (Wennergren et al, 1989). Afferent fibers for this reflex travel in the superior laryngeal nerve, a branch of the vagus. These afferents synapse onto neurons in the nTS which then send (1) excitatory projections to motoneurons of the recurrent laryngeal nerve in the nucleus ambiguous, causing constriction of the thyroarytenoid muscle (laryngeal constrictor) resulting in laryngospasm; (2) inhibitory projections to phrenic motoneurons in the cervical spinal cord, inhibiting diaphragmatic contraction resulting in apnea; and (3) an excitatory pathway to cardiac vagal neurons in the nucleus ambiguous causing bradycardia. However, the circuitry from second-order neurons in the nTS to cardiac vagal afferent neurons has not been demonstrated clearly. The LCR occurs in the fetus and likely functions to prevent aspiration of amniotic fluid, which contains approximately half the chloride content of pulmonary fluid (Bland, 1990; Reix et al, 2007). With premature birth, the reflex may be involved in the apnea and bradycardic responses associated with feeds and gastroesophageal reflux that reaches the larynx or nasopharynx. Whether the immature response is still present in term infants or how the maturation of the reflex is affected by premature birth has not been determined. Because of its profound inhibitory cardiorespiratory effects, stimulation of the LCR may be an important reflex that is operative in some SIDS cases and infants with acute life-threatening events (Duke et al, 2001; Gauda et al, 2007; Richardson and Adams, 2005; Thach, 2001).

CHEMICAL CONTROL OF BREATHING (CO_2/H^+ AND O_2)

In air-breathing animals, respiratory rhythmogenesis is primarily driven by the level of Pco_2 in the blood and cerebrospinal fluid and, to a lesser extent, by oxygen tension. In fact, for every increase of 1mm Hg in Pco_2, ventilation will increase by 20% to 30%. Specialized chemosensitive cells in the brainstem depolarize in response to changes in CO_2/H^+; they drive breathing through synaptic inputs to respiratory-related neurons (Spyer and Gourine, 2009). Although peripheral arterial chemoreceptors in the carotid body also depolarize in response to increasing CO_2/H^+, these receptors are primarily responsible for modifying breathing in response to changes in oxygen tension (reviewed later). As a result of careful anatomic, physiologic, neurochemical, and genetic studies, the location and the development of central chemoreceptors and some of the genetic factors that drive the development of these receptors in health and disease have been determined. Several groups of neurons in the brainstem, specifically in

the medullary raphe, RTN, nTS, locus ceruleus, and the fastigial nucleus are responsive to CO_2/H^+ in vitro and in vivo; therefore they are characterized as chemosensitive. The demonstration that (1) focal acidification either with acetazolamide (inhibits carbonic anhydrase) or local elevations of CO_2 in these regions in either nonanesthetized or anesthetized adult animals increases ventilation, and (2) focal ablation or disruption of the region inhibits the ventilatory response, is essential for a region to be identified as chemosensitive (Feldman et al, 2003). Although several regions are CO_2/H^+ sensitive, there appears to be some specificity in the contribution of each of the regions in chemical control of breathing wakefulness and sleep (Feldman et al, 2003). The greatest density of CO_2/H^+–sensitive neurons in the brainstem is in serotonergic cells of the raphe of the caudal medulla and glutamatergic neurons of the RTN, located just below the ventral medullary surface. The serotonergic neurons in the caudal raphe project to phrenic motoneurons, where they modulate neuronal plasticity in response to hypoxia (Feldman et al, 2003). The RTN receives afferent polysynaptic excitatory inputs from peripheral arterial chemoreceptors cartoid body (Takakura et al, 2006) and sends projections to neurons in the VRC, including the PBC (Guyenet et al, 2008). In animals older than 7 postnatal days, the activity of the RTN depends on intrinsic pH sensitivity and synaptic drive. The parafacial respiratory group may be the precursor to the RTN, and these neurons have intrinsic bursting properties starting at embryonic day 19 (Guyenet et al, 2008). In humans the arcuate nucleus in the medulla (not to be confused with the arcuate nucleus in the hypothalamus) is believed to be the homologous chemosensitive region, as described in animals based on the following findings: (1) the arcuate nucleus is located along the ventral medullary surface, (2) it contains a large population of glutamatergic neurons and a smaller population of serotonergic neurons (Paterson et al, 2006a), (3) it depolarizes in response to hypercapnia (Gozal et al, 1994), and (4) the absence of the arcuate nucleus in a human infant was associated with lack of CO_2 sensitivity during life (Folgering et al, 1979).

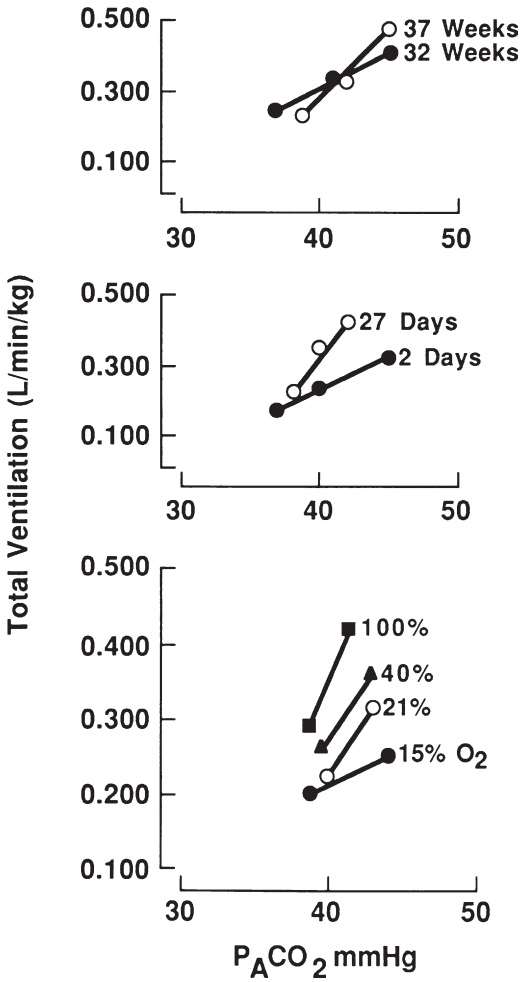

FIGURE 43-4 The relationship between ventilatory sensitivity to carbon dioxide and gestational age *(top panel)*, postnatal age *(middle panel)*, and the concentration of inspired oxygen *(bottom panel)*. *(From Rigatto H, Brady J, Verduzco RT: Chemoreceptor reflexes in preterm infants: the effect of gestational and postnatal age on the ventilatory response to inhaled carbon dioxide*, Pediatrics *55:614-620, 1975; and Rigatto H, Verduzco RT, Cates DB: Effects of O_2 on the ventilatory response to CO_2 in preterm infants*, J Appl Physiol *39:896-899, 1975.)*

DEVELOPMENT OF CENTRAL CO_2/H^+ SENSITIVITY

In fetal sheep, hypercapnia causes an increase in the depth of fetal breathing movements, with no change in inspiratory or expiratory time. In humans, maternal exposure to CO_2 also increases fetal breathing (Ritchie and Lakhani, 1980). Ventilatory responses to CO_2 are present immediately after birth in most mammalian species, and CO_2 sensitivity increases with maturation. However, in the newborn rat, CO_2 sensitivity is robust during the first several days of postnatal life; it declines markedly in the next 2 weeks of life and then gradually increases to reach adult levels by the end of the 3rd week (Stunden et al, 2001). Premature and term infants tested at 2 days of postnatal age have modest ventilatory responses to 2% and 4% CO_2, although the strength of the ventilatory response is less in the more immature infants (Frantz et al, 1976). In premature and late preterm infants, CO_2 sensitivity increases with postnatal age, reaching a mature response within 4 weeks of postnatal development (Figure 43-4) (Frantz et al, 1976; Rigatto et al, 1975a, 1975c). Similar to the response in the fetus, the increase in ventilation is predominately due to an increase in tidal volume and not respiratory rate. Using the increase in inspiratory effort against an occluded airway as an indicator of central respiratory drive, when exposed to 2% and 4% CO_2, the increase in CO_2 sensitivity with postnatal development is due to an increase in central respiratory drive in human infants (Frantz et al, 1976). Premature infants with apnea of prematurity have reduced ventilatory responses to CO_2 compared with control infants at the same postconceptional age (Durand et al, 1985; Gerhardt and Bancalari, 1984). This finding suggests that infants with apnea of prematurity have reduced central respiratory drive to breathe when compared with infants who do not have apnea of prematurity at the same postconceptional age.

It is unknown whether maturation of synaptic inputs from chemosensitive neurons to respiratory related neurons in the brainstem, or maturation of intrinsic properties of chemosensitive neurons, accounts for the increase in CO_2 sensitivity with early postnatal development. Although such

studies of human infants are impossible, data from studies performed in neonatal rats show that intrinsic responses of chemosensitive neurons in the nTS and locus ceruleus are already mature at birth. It is less clear whether there is a developmental increase in the sensitivity of chemosensitive neurons in the medullary raphe, an increase in the number of chemosensitive neurons in the RTN, or both (Putnam et al, 2005). However, within the first several weeks of postnatal development in the rat, the size of brainstem neurons changes, and both dendritic arborization in the nTS and astrocyte proliferation increase. Astrocytes contribute substantially to the pH of the extracellular milieu surrounding chemosensitive neurons (Putnam et al, 2005). It is likely that all these morphologic and neurochemical changes within and between neurons and astrocytes in the brainstem contribute to maturation of CO_2 sensitivity within the early weeks of postnatal development.

MATURATION OF PERIPHERAL CO_2/H^+ CHEMOSENSITIVITY IN THE CAROTID BODY

The arterial chemoreceptors in the carotid body, located at the bifurcation of the carotid artery, are primarily responsible for reflex control of ventilation in response to changes in arterial oxygen tension. Specialized cells within the carotid body also depolarize in response to changes in blood CO_2/H^+, reflexively increasing ventilation in response to acidosis and hypercapnia and reflexively decreasing ventilation in response to hypocapnia. Histologically, the carotid body chemoreceptors consist of (1) type I or glomus cells, similar to presynaptic neurons, that are chemosensitive and contain neurotransmitters and autoreceptors; (2) postsynaptic afferent nerve fibers from the carotid sinus nerve, which oppose glomus cells (Gonzalez et al, 1994), contain neurotransmitters and postsynaptic receptors, and have cell bodies in the petrosal ganglion; (3) type II cells similar to glial cells, which are not chemosensitive; (4) microganglion cells that express cholinergic traits (Gauda et al, 2004); and (5) blood vessels and sympathetic fibers innervating these vessels. The commissural nucleus of the nTS is the primary target for afferents from peripheral arterial chemoreceptors. Although these afferent processes contain glutamate, dopamine, and substance P, it is glutamate, binding to both NMDA and non-NMDA receptors on second-order neurons in the nTS, that is responsible for chemical transmission of excitatory inputs from the peripheral arterial chemoreceptors (Vardhan et al, 1993). These second-order neurons then send tonic excitatory projections to CO_2 sensitivity neurons in the RTN (see Development of Central CO_2/H^+ Sensitivity, earlier), bulbospinal neurons in the dorsal respiratory group, and VRG that synapse onto respiratory motoneurons.

In order to separate the contribution of peripheral arterial chemoreceptors from that of central chemoreceptors on ventilatory control, studies performed in animals have either perfused the carotid body separately from the systemic circulation or directly measured the neuronal output from the carotid body (in vivo or in vitro) in response to changes in arterial gas tension. With these approaches, it has been determined that peripheral chemoreceptors sense changes in arterial CO_2/H^+ more rapidly than do central chemoreceptors (Smith et al, 2006).

Sensitivity of the peripheral arterial chemoreceptors to CO_2 increases with postnatal development in newborn animals (Carroll et al, 1993); however, in human infants, the contribution of peripheral arterial chemoreceptors to ventilatory response to CO_2 is difficult to delineate. Inferences can be made from the ventilatory response that is seen within a few seconds of exposure to a particular concentration of CO_2, O_2, or both, because the response time of the peripheral arterial chemoreceptors is faster than that of the central chemoreceptors. What is inferred is that, after the first 2 days after birth, peripheral arterial chemoreceptors in newborns are highly responsive to changes in Pco_2. Hypoventilation and apnea are frequently seen in newborn infants after a sigh or augmented breath, in which the Pco_2 is rapidly reduced. This response is secondary to a high-gain system that is regulated at the level of the peripheral arterial chemoreceptors. In premature infants, the Pco_2 apneic threshold is close to the Pco_2 that mediates regular breathing (Khan et al, 2005). The level of Pco_2, however, increases the response of the peripheral arterial chemoreceptors to any level of arterial O_2 tension (Pao_2), and this O_2-CO_2 interaction at the carotid body increases with development (Carroll et al, 1993).

MATURATION OF HYPOXIC CHEMOSENSITIVITY

The contribution of afferent inputs from peripheral arterial chemoreceptors during maturation is more easily accessed by determining the acute change in ventilation in response to changes in oxygen tension. This determination is often made according to hypoxic gas exposure in newborn animals; an acute increase in ventilation within 30 seconds of hypoxic exposure is a measure of the strength of the peripheral arterial chemoreceptors. Whereas hypoxic gas exposure is occasionally used in human infants to test peripheral arterial chemoreceptor function, the reduction in ventilation in response to short acute exposure to hyperoxia (Dejours test) is more frequently performed to assess the strength of the reflex during postnatal development. Although the peripheral arterial chemoreceptors can respond to lower than baseline Pao_2 in the fetus, peripheral arterial chemoreceptors do not contribute significantly to fetal breathing, and functioning peripheral arterial chemoreceptors are not necessary for continuous breathing to occur at birth (for a historical overview, see Walker, 1984). However, studies using newborn animals (e.g., cats, dogs, rats, sheep, pigs) show that carotid body denervation shortly after birth destabilizes breathing, often leading to persistent apneic periods and death of the animal within days to weeks (Gauda and Lawson, 2000). Therefore it is believed that trophic factors from peripheral arterial chemoreceptors acting on central mechanisms that control breathing during early postnatal development are the key to stable rhythmogenesis throughout life. The critical period for these trophic influences appears to be within the first 2 weeks of postnatal development (Gauda et al, 2007). Exposures during this critical period of development that can lead to lifelong alterations in chemoreceptor function include environmental exposure to the extremes of oxygen tension (chronic hypoxia and hyperoxia), intermittent hypoxia (associated with apnea of prematurity) (Carroll,

2003; Gauda et al, 2007), nicotine exposure (Gauda et al, 2001; Hafstrom et al, 2005), and maternal separation in male rats (Genest et al, 2004).

Acute insensitivity to changes in oxygen tension associated with birth and then a gradual increase in hypoxic chemosensitivity during the first 2 to 3 weeks of postnatal development are two phases that affect the contribution of peripheral arterial chemoreceptors on breathing. Although oxygen tension less than 25 mm Hg stimulates the carotid body in exteriorized fetal sheep, peripheral arterial chemoreceptors are not functional at any level of hypoxic exposure for the first several days after birth in most mammalian species, including human infants (term and preterm). It is speculated that the resetting of peripheral arterial chemoreceptors occurs at birth because of the increase in arterial oxygen tension during the transition from fetal to neonatal life. After birth, there is a gradual increase in hypoxic chemosensitivity that occurs during the first 2 weeks of postnatal life (Rigatto et al, 1975b). Mechanisms accounting for the increase in hypoxic chemosensitivity of peripheral arterial chemoreceptors with maturation in most mammalian species have been reviewed recently by Gauda et al (2009). Although premature infants may have reduced peripheral chemoreceptor responses soon after birth, by 2 weeks of postnatal age they often have enhanced peripheral arterial chemoreceptor influences on eupneic breathing. Furthermore, premature infants who have a greater frequency of apnea and periodic breathing have a greater reduction in ventilation when exposed to short bouts of hyperoxia (Dejours test) (Rigatto and Brady, 1972), suggesting a greater influence of peripheral arterial chemoreceptors on eupneic breathing in this infant population (Al Matary et al, 2004; Nock et al, 2004).

GENETIC REGULATION OF CENTRAL AND PERIPHERAL CHEMORECEPTOR DEVELOPMENT

Development of central and peripheral chemoreceptors is genetically regulated by the expression of the transcription factor *PHOX2B*. *PHOX2B* is a homeobox gene located on chromosome 4 that is specifically expressed in limited types of neurons involved in autonomic processes (Dauger et al, 2003). Its expression is required for the development of the carotid body, nTS, and catecholaminergic neurons, and it is expressed in chemosensitive glutamatergic neurons in the RTN that receive polysynaptic inputs from peripheral arterial chemoreceptors (Guyenet et al, 2008). Mutations in the *PHOX2B* gene affect the development of key structures that regulate chemical control of breathing. Congenital central hypoventilation syndrome (CCHS) is characterized by impaired ventilatory responses to CO_2 and hypoxia and other abnormalities of autonomic control (Berry-Kravis et al, 2006). More than 90% of individuals with CCHS have mutations in the *PHOX2B* gene (for a review, see Amiel et al, 2009; Dubreuil et al, 2009.

NEONATAL HYPOXIC VENTILATORY DEPRESSION

Although the peripheral arterial chemoreceptors function to increase ventilation in response to hypoxia, minute ventilation significantly declines after 2 to 3minutes of hypoxic exposure. This decline is commonly referred to as *hypoxic roll-off*, *hypoxic ventilatory decline*, or *hypoxic ventilatory depression*. Hypoxic ventilatory depression occurs in individuals at all ages, but it is most pronounced in the fetus and newborn (Bissonnette, 2000). Whereas the hypoxic ventilatory decline is usually still above baseline ventilation in mature models, the hypoventilatory response in newborns is usually below baseline ventilation and is often associated with apnea. Mechanisms accounting for hypoxic respiratory depression are most well characterized in the fetal animals in which the central brainstem nuclei mediating this response are located in the pons. Transverse section of the upper pons results in a sustained hyperventilatory response to hypoxia in fetal and newborn sheep (Gluckman and Johnston, 1987). Hypoxia activates expiratory neurons in the ventrolateral pons, and chemical blockade of this area blocks the hypoxic respiratory depression in newborn rats (Dick and Coles, 2000).

Several neuromodulators have been implicated in mediating hypoxic ventilatory decline, including norepinephrine, adenosine, GABA, serotonin, opioids, and platelet-derived growth factor (see Table 43-1) (Simakajornboon and Kuptanon, 2005). All these neuromodulators have been shown to contribute to the ventilatory depression in newborns, but particular attention has been given to adenosine. Degradation of intracellular and extracellular ATP is the main source of extracellular adenosine, which then mediates its cellular effects by binding to A1, A2a, A2b, and A3 adenosine receptors. In response to hypoxia, brain adenosine levels can increase 2.3-fold in fetal sheep (Koos et al, 1994), and 100-fold in rats in response to ischemia (Winn et al, 1981). Nonspecific adenosine receptor blockers, particularly caffeine and methylxanthine, are commonly administered to premature infants to increase central respiratory drive, and aminophylline inhibits hypoxic ventilatory depression in newborn infants (Darnall, 1985). A_1-adenosine inhibitory receptors are found on respiratory related neurons (Bissonnette and Reddington, 1991). Specific A_1-adenosine receptor agonists depress phrenic output in a reduced brainstem spinal cord preparation, whereas A_1-adenosine receptor blockers reverse this inhibitory effect (Dong and Feldman, 1995). In fetal sheep, the hypoxic respiratory depression appears to be mediated by excitatory A_{2a} receptors, because blockade of A_{2a} receptors eliminates hypoxic ventilatory roll-off in conscious newborn sheep. Xanthine (e.g., caffeine, aminophylline) blocks both A_1 and A_{2a} adenosine receptors; therefore the effectiveness of methylxanthine in stabilizing ventilation and decreasing the frequency of apnea in premature infants may be directly altering the ventilatory response to hypoxia as well as nonspecifically increasing respiratory drive (see Apnea of Prematurity, later).

SLEEP STATE AND BREATHING

Sleep state has a profound influence on breathing in the fetus and newborn, and most disorders of breathing that affect the young and old are worse during sleep. Active sleep (AS) and quiet sleep (QS) in infants is equivalent to rapid eye movement (REM) and non-REM sleep, respectively in older children and adults. Breathing during AS is mostly driven by inputs from the reticular activating

system with less influence from Pco_2, whereas breathing during QS is driven by chemical control. Similar to REM sleep in adults, AS is associated with paralysis of striated muscles. Although this paralysis may be necessary to prevent acting out dreams, paralysis of striated muscles that are involved in breathing can be problematic for the newborn. AS and REM sleep are characterized by rapid eye movements, increase in cerebral blood flow and metabolic rate, and irregular breathing because of inhibition of the intercostals and upper airway dilating muscles. The discoordination between chest wall muscles and the diaphragm during active sleep causes paradoxic breathing: the chest wall moves in during inspiration with the abdomen moving outward. The more compliant the chest wall, the greater propensity for paradoxic breathing, which is common in the most immature infants. In addition, during inspiration, intrathoracic pressure becomes more negative, and this "suction pressure" causes narrowing or collapse of the compliant upper airway, particularly pharyngeal structures, leading to upper airway obstruction. Paradoxic breathing movements seen on physical examination or detected on inductive plethysmography are often interpreted as a sign of upper airway obstruction. During QS, breathing is characterized by smooth, regular breaths of consistent frequency and depth associated with tonic and phasic activity of the muscles of respiration that are in phase with each other. The chest wall and the abdomen move outward during inspiration, whereas they move inward during expiration. AS and QS can be reliably assessed at 30 to 32 weeks' gestation (Curzi-Dascalova et al, 1993). At this gestation, premature infants spend 80% of their sleep time in SA. This time decreases to 50% by term, and in adulthood REM sleep accounts for only 20% of sleep time. Sleep state in normal infants also modifies the time to arousal and the ventilatory responses. The time to arousal upon exposure to a hypoxic, somatosensory or auditory stimuli is greater in AS compared with QS in infants during the first 6 months of life (Horne et al, 2005). Of interest, the arousal latency in response to hypoxic stimulus in AS is longer in preterm infants at 2 to 5 weeks postnatal age than that of term infants at the same postnatal age (Verbeek et al, 2008). The level of oxygen desaturation at the time hypoxic arousal occurs is similar in the two sleep states (Richardson et al, 2007). Respiratory pauses and periodic breathing are more common during AS in both term and premature infants, but the ventilatory response to CO_2 is greater during QS (Cohen et al, 1991). Because of the complexity of the ventilatory response to hypoxia and the frequent occurrence of arousals induced by hypoxic exposure, assessing the affect of sleep state on the ventilatory response to hypoxia in newborns is more difficult. Other than the clear difference in arousal in response to hypoxic stimulus between the two sleep states, differences between sleep states on other respiratory parameters are more variable (Richardson et al, 2007).

Although most disorders of breathing, such as obstructive sleep apnea, become more severe during sleep, the breathing disorder that is most significantly influenced by sleep state in the newborn is CCHS. As noted previously, CCHS is characterized by abnormalities in central chemoreception and chemical control of breathing; therefore, with maturation, as the frequency of QS increases, so does the severity of the disorder. During QS, CO_2 sensitivity is markedly impaired in affected individuals, and exposure to hypercapnia does not significantly increase minute ventilation (Paton et al, 1989). In infants who died of SIDS, their sleep state during their terminal event cannot be known. However, adequate arousal mechanisms are key in preventing respiratory failure and death, and impaired arousal mechanisms are hypothesized to be causative in SIDS. Prone sleeping position increases the percent of QS (Horne et al, 2002), and QS is associated with increased time to hypoxic arousal in human infants (Richardson et al, 2007). A hypoxic microenvironment from rebreathing with defected arousal and autoresuscitative mechanisms is hypothesized to have occurred in infants who have died of SIDS in the face-down (i.e., prone) sleeping position (Patel et al, 2001). Therefore sleep state can have a significant influence on control of breathing during health and disease, especially in the newborn infant.

This chapter has outlined the neurocircuitry and neurochemistry of the respiratory network along with its synaptic inputs that undergo significant maturation during the newborn period. Because these pathways are less developed in premature infants, premature infants have apnea of prematurity, which often requires active therapeutic intervention and can delay hospital discharge. At preterm gestational ages, the components of the respiratory network, similar to other developing organ systems, are plastic and uniquely vulnerable to pathologic processes. Therefore the episodes of intermittent hypoxemia and bradycardia that accompany apnea of prematurity may be a cause of acute and chronic morbidities in this high-risk population. What follows is a discussion of the clinical presentation of physiology and pathophysiology of breathing seen in premature infants and therapeutic interventions.

APNEA OF PREMATURITY

Respiratory pauses are universal features of preterm birth and are most prominent in infants of the lowest gestational age. There is no consensus as to when a respiratory pause can be defined as an apneic episode. It has been proposed that apnea be defined by its duration (e.g., longer than 15 seconds) or accompanying bradycardia and desaturations. However, even the 5- to 10-second pauses that occur in periodic breathing can be associated with bradycardia or desaturation. It should be emphasized that periodic breathing—ventilatory cycles of 10 to 15 seconds with pauses of 5 to 10 second—is a normal breathing pattern that should not require therapeutic intervention. It is thought to be the result of dominant peripheral chemoreceptor activity responding to fluctuations in arterial oxygen tension. Episodic bradycardia and desaturation in preterm infants is almost invariably secondary to apnea or hypoventilation (Figure 43-5) (Martin and Abu-Shaweesh, 2005). The rapidity of the fall in oxygen saturation after a respiratory pause is directly proportional to baseline oxygenation, which is related to lung volume and severity of lung disease.

Apnea is classified traditionally into three categories based on the absence or presence of upper airway obstruction: central, obstructive, and mixed. Central apnea is characterized by total cessation of inspiratory efforts with no

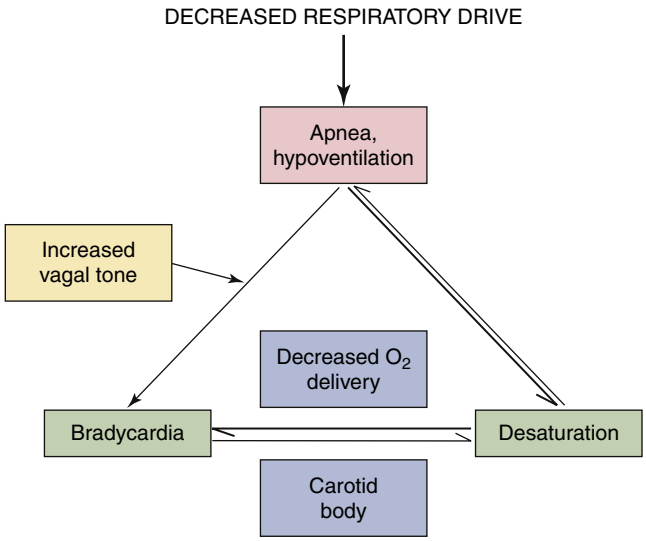

FIGURE 43-5 Schematic representation of the sequence of the events whereby apnea results in various combinations of desaturation and bradycardia. *(From Martin RJ, Abu-Shaweesh JM: Control of breathing and neonatal apnea*, Biol Neonate *87:288-295, 2005.)*

evidence of obstruction. In obstructive apnea, the infant tries to breathe against an obstructed upper airway, resulting in chest wall motion without airflow through the entire apneic episode. Mixed apnea consists of obstructed respiratory efforts, usually following central pauses. The site of obstruction in the upper airways is primarily in the pharynx, although it also may occur at the larynx and possibly at both sites. It is assumed that there is an initial loss of central respiratory drive, and its recovery is accompanied by a delay in activation of upper airway muscles superimposed on a closed upper airway (Gauda et al, 1987). Mixed apnea typically accounts for more than 50% of long apneic episodes, followed in decreasing frequency by central and obstructive apnea. Purely obstructive spontaneous apnea in the absence of a positional problem is probably uncommon. Because standard impedance monitoring of respiratory efforts via chest wall motion cannot recognize obstructed respiratory efforts, mixed versus obstructive apnea is frequently identified by the accompanying bradycardia or denaturation.

THERAPEUTIC APPROACHES FOR APNEA OF PREMATURITY

Presentation of apnea can reflect a nonspecific alteration in either the environment (e.g., thermal) or general well being of preterm infants. For example, neonatal sepsis can manifest as an increase in frequency or severity of apnea, and the underlying cause must be treated. Studies using a rat pup model suggest that the systemically released cytokine interleukin-1β binds to its receptor on vascular endothelial cells at the blood-brain barrier. This binding induces synthesis of prostaglandin E2, which induces respiratory depression in the brainstem (Hofstetter et al, 2007). These studies provide new insight into mechanisms whereby sepsis often manifests as apnea of prematurity. Anemia, presumably via decreased oxygen delivery, is also frequently implicated as a cause of apnea, although transfusion of packed red cells is of variable benefit for apnea of prematurity.

CONTINUOUS POSITIVE AIRWAY PRESSURE

Continuous positive airway pressure (CPAP) at 4 to 6 cm H_2O is a relatively safe and effective therapy. Because longer episodes of apnea frequently involve an obstructive component, CPAP appears to be effective by splinting the upper airway with positive pressure and decreasing the risk of pharyngeal or laryngeal obstruction (Miller et al, 1985). CPAP also benefits apnea by increasing functional residual capacity, thereby improving oxygenation status. At a higher functional residual capacity, time from cessation of breathing to desaturation and resultant bradycardia is prolonged. High-flow nasal cannula therapy has been suggested as an equivalent treatment modality to allow CPAP delivery while enhancing infant mobility. Although this approach is used widely, its efficacy for apnea of prematurity has not been studied in depth. Noninvasive ventilatory strategies, using a nasal mask to deliver intermittent positive pressure, avoid the need for full ventilatory support in some infants. For severe or refractory episodes, endotracheal intubation and mechanical ventilation may be needed. Minimal ventilator settings should be used to allow for spontaneous ventilatory efforts and to minimize the risk of barotrauma.

XANTHINE

Methylxanthine has been the mainstay of pharmacologic treatment of apnea of prematurity for several decades. Both theophylline and caffeine are used and have multiple physiologic and pharmacologic mechanisms of action. Xanthine therapy appears to increase minute ventilation, improve CO_2 sensitivity, decrease hypoxic depression of breathing, enhance diaphragmatic activity, and decrease periodic breathing. The likely major mechanism of action is through competitive antagonism of adenosine receptors. Adenosine acts as an inhibitory neuroregulator in the central nervous system via activation of adenosine A_1 receptors (Herlenius et al, 1997). In addition, activation of adenosine A_{2A} receptors appears to excite GABAergic interneurons, and released GABA may contribute to the respiratory inhibition induced by adenosine (Mayer et al, 2006).

Methylxanthine has some well-documented acute adverse effects. Toxic levels can produce tachycardia, cardiac dysrhythmias, feeding intolerance, and seizures (infrequently), although these effects are seen less commonly with caffeine at the usual therapeutic doses. Mild diuresis is caused by all methylxanthines. The observation that xanthine therapy causes an increase in metabolic rate and oxygen consumption of approximately 20% suggests that caloric demands can be increased with this therapy at a time when nutritional intake already is compromised.

A recent large, international, multicenter clinical trial was designed to test short- and long-term safety of caffeine therapy for apnea of prematurity. In the neonatal period, caffeine treatment was associated with a significant reduction in the postmenstrual ages at which both supplemental oxygen and endotracheal intubation were needed (Schmidt et al, 2007). Of even greater interest was the significant decrease in cerebral palsy and cognitive delay in the caffeine-treated group (Schmidt et al, 2007). This finding raises interesting questions regarding possible mechanisms underlying this beneficial effect of caffeine on

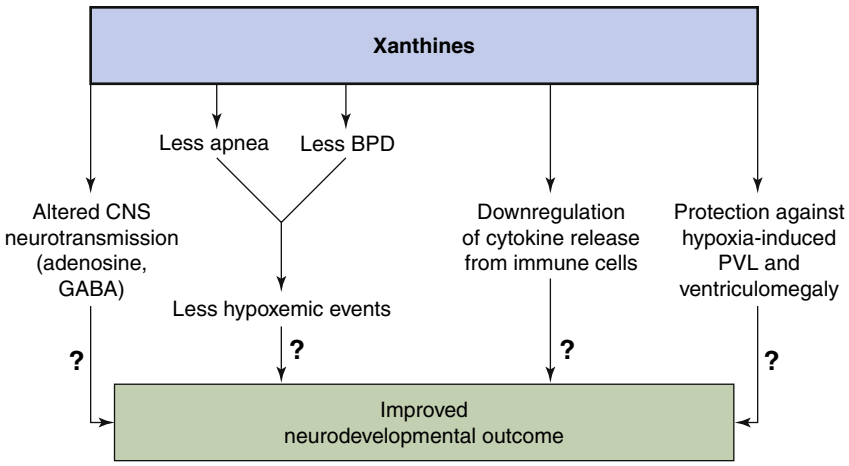

FIGURE 43-6 Multiple proposed mechanisms are demonstrated whereby xanthine therapy for apnea of prematurity improves neurodevelopmental outcome. These outcomes include functional changes in neurotransmitters in the brain, a decrease in hypoxemic episodes that accompany apnea, especially in the presence of BPD, a proposed protective effect of adenosine receptor inhibition on hypoxia induced white matter injury, and the benefit of adenosine receptor blockade on cytokine mediated lung or brain injury. *(Modified from: Abu-Shaweesh JM, Martin RJ: Neonatal apnea: what's new?* Pediatr Pulmonol *43:937-944, 2008.)*

neurodevelopmental outcome (Figure 43-6). These beneficial effects include the observation in animal models that loss of the adenosine A_1 receptor gene is protective against hypoxia-induced loss of brain matter (Back et al, 2006) and a potential benefit of caffeine on immune mechanisms that mediate lung and brain injury (Chavez-Valdez et al, 2009).

RELATIONSHIP TO GASTROESOPHAGEAL REFLUX [GER]

GER is often incriminated as a cause for neonatal apnea. Despite the frequent coexistence of apnea and GER in preterm infants, investigations of the timing of reflux in relation to apneic events indicate that they are rarely related temporally. When these events coincide, there is no evidence that GER prolongs the concurrent apnea (Di Fiore et al, 2005). Although physiologic experiments in animal models reveal that reflux of gastric contents to the larynx induces reflex apnea, there is no clear evidence that treatment of reflux affects the frequency of apnea in most preterm infants. Therefore pharmacologic management of reflux with agents that decrease gastric acidity or enhance gastrointestinal motility generally should be reserved for preterm infants who exhibit signs of emesis or regurgitation of feedings, regardless of whether apnea is present. Therapy for such infants should begin with nonpharmacologic approaches, such as thickened feeds, because acid suppression therapy has been shown to increase the risk of lower respiratory infection in infants (Orenstein et al, 2009). Recent data indicate considerable differences of opinion among neonatologists, pediatric gastroenterologists, and pediatric pulmonologists regarding diagnosis and management of this problem (Golski, 2010).

RESOLUTION AND CONSEQUENCES OF NEONATAL APNEA

Apnea of prematurity generally resolves by 36 to 40 weeks' postconceptional age; however, apnea frequently persists beyond this time in more immature infants. Available data indicate that cardiorespiratory events in such infants return to the baseline normal level at 43 to 44 weeks' postconceptional age (Ramanathan et al, 2001). In other words, beyond 43 to 44 weeks' postconceptional age, the incidence of cardiorespiratory events in preterm infants does not significantly exceed that in term infants. The persistence of cardiorespiratory events may delay hospital discharge for a subset of infants. In these infants, apnea longer than 20 seconds is rare; rather they exhibit frequent bradycardia to less than 70 to 80 beats/min with short respiratory pauses (Di Fiore et al, 2001). The reason that some infants exhibit marked bradycardia with short pauses is unclear, but available data suggest a vagal phenomenon and benign outcome. For a few of these infants home cardiorespiratory monitoring, until 43 to 44 weeks' postconceptional age, is offered in the United States as an alternative to a prolonged hospital stay. The apparent lack of a relationship between persistent apnea of prematurity and SIDS has significantly decreased the practice of home monitoring, with no increase in the SIDS rate. Infants born prematurely experience multiple problems during their time in the neonatal intensive care unit, and many of these conditions can contribute to poor neurodevelopmental outcomes. For example, a history of prior hyperbilirubinemia has been associated with persistent apnea of prematurity in preterm infants and animal models (Amin et al, 2005; Mesner et al, 2008). The problem of correlating apnea with outcome is compounded by the fact that nursing reports of apnea severity may be unreliable, and impedance monitoring techniques will fail to identify mixed and obstructive events. Despite these reservations, available data suggest a link between the number of days that apnea and assisted ventilation were recorded during hospitalization and impaired neurodevelopmental outcome (Janvier et al, 2004). A relationship has also been shown between delay in resolution of apnea and bradycardia beyond 36 weeks' corrected age and a higher incidence of unfavorable neurodevelopmental outcome (Pillekamp et al, 2007). Finally, a high number of cardiorespiratory events recorded after discharge via home cardiorespiratory

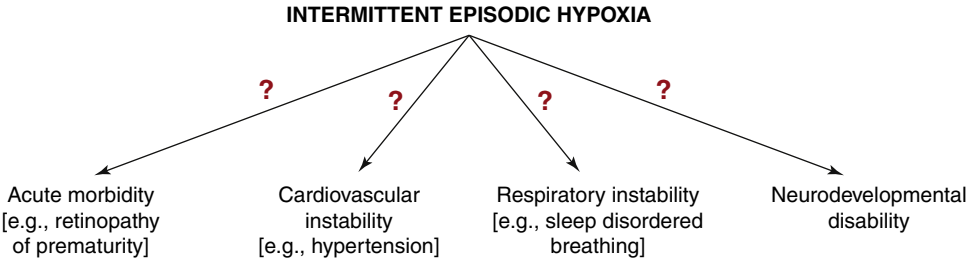

FIGURE 43-7 Proposed acute and longer-term morbidities that might be a consequence of intermittent hypoxic episodes in early postnatal life. *(Modified from Martin RJ, Wilson CG: What to do about apnea of prematurity,* J Appl Physiol *107:1015-1016, 2009.)*

monitoring appear to correlate with less favorable neurodevelopmental outcome (Hunt et al, 2004). Future studies might focus more on the incidence and severity of desaturation events, because techniques for long-term collection of pulse oximeter data are now more advanced. Furthermore, it is likely that recurrent hypoxia is the detrimental feature of the breathing abnormalities exhibited by preterm infants. Figure 43-7 summarizes proposed morbidities that might be attributable to intermittent hypoxic episodes in early life. Recurrent episodes of desaturation during early life and resultant effects on neuronal plasticity related to peripheral and central respiratory control mechanisms may serve as an important future direction for study. Ongoing investigation into the genetic background of infants with CCHS may also serve to enhance our understanding of the problem of apnea in preterm infants (Berry-Kravis et al, 2006).

CHAPTER 44

Pulmonary Physiology of the Newborn

Robert M. DiBlasi, C. Peter Richardson, and Thomas Hansen

LUNG MECHANICS AND LUNG VOLUMES

The lungs possess physical, or mechanical, properties that resist inflation, such as elastic recoil, resistance, and inertance. The dynamic interaction between these properties determines the effort that must be exerted during spontaneous breathing and the resting and extreme values for the volume of gas in the lung.

ELASTIC RECOIL

The lung contains elastic tissues that must be stretched for lung inflation to occur. Hooke's law requires that the pressure needed to inflate the lung must be proportional to the volume of inflation (Figure 44-1). Conventionally, volume of inflation is plotted on the *y*-axis, and the distending pressure is plotted on the *x*-axis. In this way, the constant of proportionality is volume divided by pressure, or lung compliance. Throughout the range of tidal ventilation, the relationship between pressure and volume is linear. At higher lung volumes, as the lung reaches its elastic limit (i.e., total lung capacity), this relationship plateaus, making the pressure-volume relationship nonlinear.

The lungs and the chest wall function as a unit (the respiratory system) coupled by the interface between the parietal and visceral pleura. Therefore, respiratory system compliance (CRS) can be partitioned into lung compliance (CL) and chest wall compliance (CCW), where CRS = 1/CL + 1/CCW. The tendency for the lung to collapse inward at end-exhalation is balanced by the outward recoil of the chest wall resulting in a negative (subatmospheric) intrapleural pressure. The functional residual capacity (FRC) is the volume of gas in the lungs when the elastic forces of these two structures reach equilibrium (Greenspan et al, 2005). Inflation of the respiratory system above FRC requires a positive distending pressure that must overcome the elastic recoil of both the lung (transpulmonary pressure; alveolar-intrapleural pressure) and the chest wall (transthoracic pressure; intrapleural pressure-atmospheric pressure) (Gappa et al, 2006). Deflation below FRC requires an active expiratory maneuver. Residual volume (RV) is defined as the volume of air that cannot be expired with a forced deflation.

As depicted in Figure 44-1, the relative compliance of the lung of the newborn is similar to that of the adult (Krieger, 1963). However, the infant's chest wall is composed primarily of cartilage, whereas in adults the chest wall is completely ossified and therefore, CCW is greater in infants than adult (see Figure 44-1) and pleural pressure is only slightly subatmospheric. Measurements of lung and chest wall compliance suggest that the newborn should have a lower percent RV and a lower percent FRC than the adult. In fact, the percent FRC in the newborn is equal to the adult's, and the infant's percent RV is slightly greater. This seeming paradox exists because FRC and RV are measured while the infant is breathing, and predictions from the pressure volume curves assume that there is no air movement and passive relaxation of all respiratory muscles (Bryan and England, 1984).

Establishment of the FRC is vital to the role of maintaining adequate lung mechanics and gas exchange. The highly compliant newborn chest wall exerts very little outward distending pressure, and thus the lung is more prone to collapse at end-exhalation (Hülskamp et al, 2005. Data suggest three mechanisms by which the newborn can limit expiratory flow and increase the intrapulmonary pressure to maintain a normal FRC during spontaneous breathing: (1) by increasing expiratory resistance through laryngeal adduction (glottic narrowing), (2) by maintaining inspiratory muscle activity throughout expiration, and (3) by initiating high breathing frequencies to limit the expiratory time (Magnenant et al, 2004; te Pas et al, 2008).

RESISTANCE

Resistance to gas flow arises because of friction between gas molecules and the walls of airways (i.e., airway resistance) and because of friction between the tissues of the lung and the chest wall (i.e., viscous tissue resistance). Airway resistance represents approximately 80% of the total resistance of the respiratory system, and tissue resistance and inertial forces account for the remaining 20% (Polgar and String, 1966). In the newborn, nasal resistance represents nearly half the total airway resistance; in the adult, it accounts for about 65% of the airway resistance (Polgar and Kong, 1965).

Gas flows only in response to a pressure gradient (Figure 44-2). During laminar flow, the pressure difference needed to move gas through the airway is directly related to the flow rate times a constant—airway resistance. During turbulent flow, however, this pressure is directly proportional to a constant times the flow rate squared. Gas flow becomes turbulent at branch points in airways, at sites of obstruction, and at high flow rates. Turbulence occurs whenever flow increases to a point that Reynolds' number exceeds 2000. This dimensionless number is directly proportional to the volumetric flow rate and gas density, and it is inversely proportional to the radius of the tube and gas viscosity. Obviously, turbulent flow is most likely to occur in the central airways where volumetric flow is high, rather than in lung periphery where flow is distributed across a large number of airways. Both types of flow exist in the lung, so the net pressure drop is calculated as follows (Pedley et al, 1977):

$$\Delta P = (K_1 \times \dot{V}) + (K_2 \times \dot{V}^2) \quad (1)$$

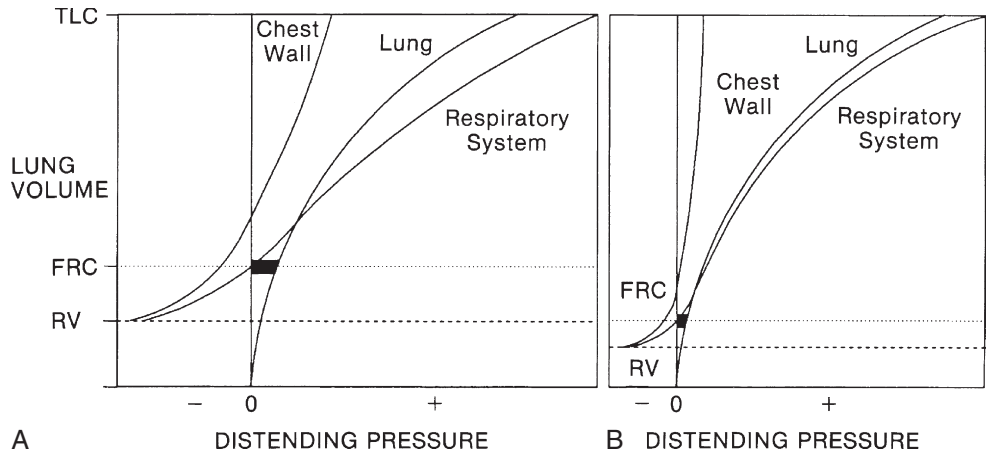

FIGURE 44-1 This is an idealized plot of volume as a function of distending pressure for the lung, chest wall, and respiratory system (lung plus chest wall) of an adult **(A)** and an infant **(B).** These curves are derived by instilling or removing a measured volume of gas from the lung and allowing the respiratory system to come to rest against a shuttered airway. At this point only elastic forces are acting on the respiratory system, and airway pressure is equal to alveolar pressure. Intrapleural pressure can be measured using an esophageal balloon. Because airway pressure is equal to alveolar pressure, the distending pressure for the lung can be measured as *airway pressure – intrapleural pressure*. The distending pressure for the chest wall is *intrapleural pressure – atmospheric pressure*, and the distending pressure for the respiratory system is *airway pressure – atmospheric pressure*. Compliance is the change in volume divided by the change in distending pressure. The shaded area is the resting intrapleural pressure at functional residual capacity. Lung volumes depicted include residual volume *(RV)*, functional residual capacity *(FRC)*, and total lung capacity *(TLC)*.

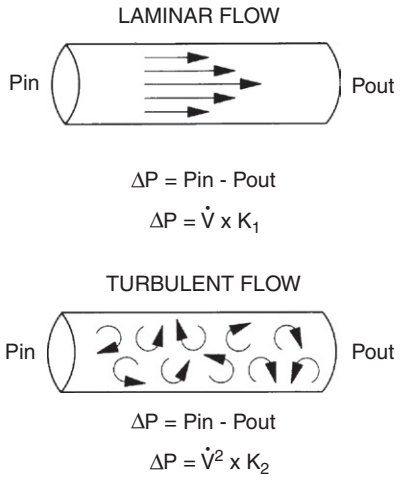

FIGURE 44-2 Gas flow ($\dot{V}$) through tubular structures occurs only in the presence of a pressure gradient (Pin > Pout). For laminar flow, P is directly proportional to $\dot{V}$.

$$\Delta P = \dot{V} \times \frac{8 \times L \times \mu}{\pi \times r^4}$$

In this case, the constant of proportionality (K_1) is directly related to the length of the airway (L) and the viscosity of the gas (μ) and indirectly proportional to the fourth power of the radius of the airway (r). For turbulent flow, ΔP is proportional to $\dot{V}$. The constant of proportionality (K_2) is directly proportional to the length of the airway and the density of the gas and inversely proportional to the fifth power of the radius of the airway.

It is possible to take advantage of the differences between laminar and turbulent flow to determine the site of airway obstruction in the lung. If obstruction to gas flow is in the central airways, turbulent flow is affected the most. Because turbulent gas flow is density dependent, allowing the patient to breathe a less dense gas (such as helium mixed with oxygen) reduces the resistance to gas flow. If the site of obstruction is peripheral, the mixture of helium and oxygen does not appreciably affect resistance.

Inflation of the lung increases the length of airways and might therefore be expected to increase airway resistance; however, lung inflation also increases airway diameter. Because airway resistance varies with the fourth to fifth power of the radius of the airway, the effects of changes in airway diameter dominate, and resistance is inversely proportional to lung volume (Rodarte and Rehder, 1986). Similarly, airway resistance is lower during inspiration than during expiration because of the effects of changes in intrapleural pressure on airway diameter. During inspiration, pleural pressure becomes negative, and a distending pressure is applied across the lung. This distending pressure increases airway diameter as well as alveolar diameter and decreases the resistance to gas flow. During expiration, pleural pressure increases and airways are compressed. Collapse of airways is opposed by their cartilaginous support and by the pressure exerted by gas in their lumina. During passive expiration, these defenses are sufficient to prevent airway closure. When intrapleural pressure is high, during active expiration, airways may collapse, and gas may be trapped in the lung. This problem may be accentuated in the small preterm infant with poorly supported central airways.

INERTANCE

Gas and tissues in the respiratory system also resist accelerations in flow. Inertance is a property that is negligible during quiet breathing and physiologically significant only at rapid respiratory rates.

DYNAMIC INTERACTION

Compliance, resistance, and inertance all interact during spontaneous breathing (Figure 44-3). This interaction is described by the equation of motion for the respiratory system:

$$P(t) = \left(V[t] \times \frac{1}{C}\right) + (\dot{V}[t] \times R) + (\dot{V}[t] \times I) \qquad (2)$$

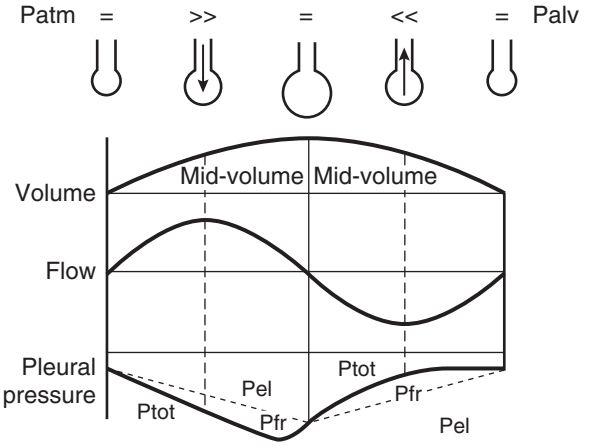

FIGURE 44-3 Gas flows from the atmosphere into the lung only if atmospheric pressure *(Patm)* is greater than alveolar pressure *(Palv)*. At end exhalation, when Patm equals Palv, there is no gas movement in or out of the lung. During a spontaneous inspiration, the diaphragm contracts, the chest wall expands, and the volume in the intrathoracic space increases. As a result, pleural pressure *(Ppl)* decreases relative to Patm, and a gradient is created between Ppl and Palv, distending the lung, increasing alveolar volume, and decreasing Palv. A gradient is also created between Patm and Palv, and gas flows from the atmosphere into the alveolar space. The rate of gas flow increases rapidly, reaches a maximum (peak flow), then decreases as the alveolus fills with gas and Palv approaches Patm. At peak inspiration, Palv equals Patm, and lung volume is at its maximum, as is Ppl. The *curved solid line* connecting end expiration to end inspiration is the total driving pressure for inspiration *(Ptot)*. The *dotted line* represents the pressure needed to overcome elastic forces alone *(Pel)*. The difference between the two lines is the pressure dissipated overcoming flow resistive forces *(Pfr)*. During exhalation, this cycle is reversed.

where P(t) is the driving pressure at time, t, V[t] is the lung volume above FRC, C is the respiratory system compliance, $\dot{V}[t]$ is the rate of gas flow, R is the resistance of the respiratory system, $\ddot{V}[t]$ is the rate of acceleration of gas in the airways, and I is the inertance of the respiratory system. If I is neglected, the equation simplifies to:

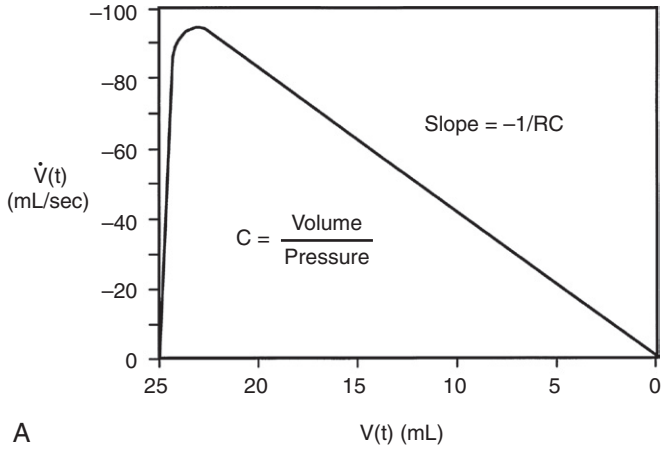
$$P(t) = \left(V[t] \times \frac{1}{C}\right) + (\dot{V}[t] \times R) \qquad (3)$$

At times of zero gas flow (end expiration and end inspiration), the equation further simplifies to:

$$P(t) = (V[t] \times 1/C) \text{ and } C = V(t)/P(t) \qquad (4)$$

This series of equations and Figure 44-3 demonstrate that at points of no gas flow (end expiration and end inspiration), only elastic forces are operating on the lung. During inflation or deflation of the lung, however, both elastic and resistive forces are important.

Although the solution to the equation of motion for the respiratory system is beyond the scope of this discussion, the behavior of the respiratory system during passive exhalation is a special situation for which a solution can be obtained relatively easily using the occlusion technique (Lesouef et al, 1984; McIlroy et al, 1963). Before a passive exhalation maneuver, the infant is given a positive pressure breath, and the airway is occluded—invoking the Hering-Breuer reflex and a brief apnea. Airway pressure is measured, and the occlusion is released. Expired gas flow is measured using a pneumotachometer and integrated to volume; flow is then plotted as a function of volume (Figure 44-4, *A*). During a passive exhalation, there are no external forces acting on



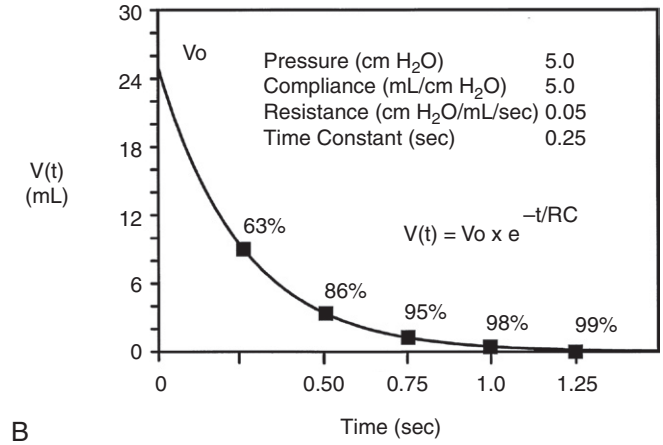


FIGURE 44-4 **A,** Plot of flow of gas out of the lung versus volume of gas remaining in the lung V(t) for a passive exhalation. Flow of gas out of the lung is negative by convention. After an initial sharp increase, flow decreases linearly as the lung empties. Static compliance of the respiratory system is obtained by dividing the exhaled volume by the airway pressure at the beginning of the passive exhalation. Resistance is calculated from the slope of the flow-volume plot –(1/RC) and the compliance. This technique has the advantage of not requiring measurements of pleural pressure and being relatively unaffected by chest wall distortion. **B,** V(t) is plotted as a function of time for a passive exhalation. The graph is an exponential with the equation

$$V(t) = Vo \times e^{-t/RC}$$

V_0 is the starting volume, and *e* is mathematical constant (roughly 2.72). For this example, the time constant of the respiratory system (Trs) is roughly 0.25 second. Calculations show that when exhalation persists for a time equal to one time constant (t = 0.25 sec = 1 × Trs), 63% of the gas in the lung is exhaled. For t = 2 Trs, 86% of the gas is exhaled; for 3 Trs, 95%; for 4 Trs, 98%; and for 5 Trs, 99%. If expiration is interrupted before a time t = 3Trs, gas is trapped in the lung.

the respiratory system (P[t] = 0), so the equation of motion simplifies to a first-order differential equation:

$$\left(V[t] \times \frac{1}{C}\right) + (\dot{V}[t] \times R) = 0$$

Rearranging yields the linear equation

$$\dot{V}(t) = -\left(\frac{1}{[RC]}\right) \times V(t) \qquad (5)$$

where the slope is –1/RC, which can be determined using a linear regression of $\dot{V}(t)$ versus V(t).

This equation states that during passive exhalation, flow plotted against volume is a straight line with slope –1/(RC). The quantity RC has the units of time and is termed the *respiratory system time constant (Trs)*. Trs defines the rate at which the lung deflates during a passive exhalation (see Figure 44-4). Time constants affect the rate of lung inflation in the same manner in which they affect lung deflation (see Chapter 45).

WORK OF BREATHING

The work of breathing is a reflection of the amount of energy required to overcome the elastic and resistive elements of the respiratory system and move gas into and out of the lung during spontaneous breathing. Work of breathing is defined as the cumulative product of distending pressure and the given volume displaced during inhalation or exhalation (Figure 44-5):

$$WOB = \int PdV$$

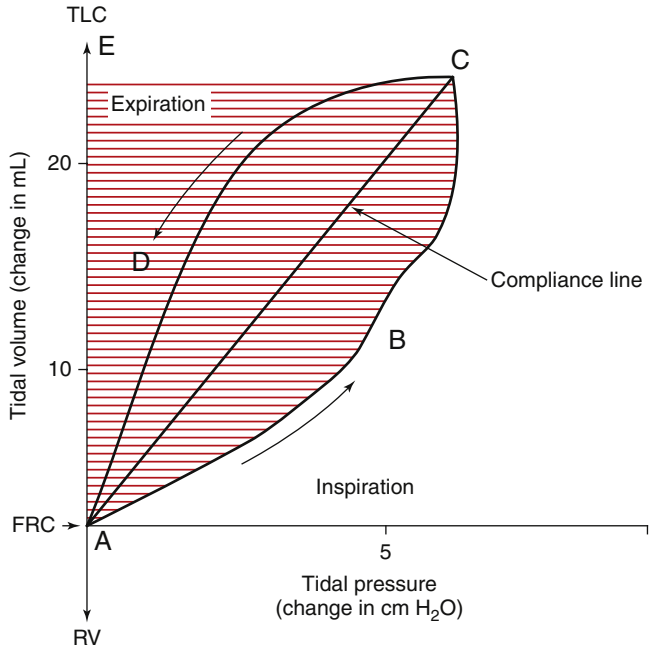

FIGURE 44-5 Pressure-volume loop showing the compliance line (*AC*, joining points of no flow); work done in overcoming elastic resistance (*ACEA*), which incorporates the frictional resistance encountered during expiration (*ACDA*); work done in overcoming frictional resistance during inspiration (*ABCA*); and total work done during the respiratory cycle (*ABCEA*), or the entire shaded area. (*Figure and legend taken from Wood BR: Physiologic principles, In Goldsmith JP, Karotkin EH, editors:* Assisted ventilation of the neonate, *ed 4, Philadelphia, 2003, WB Saunders, pp 15-30.)*

where P is pleural pressure in time relative to pleural pressure at end exhalation and V is the volume in time relative to the volume at end exhalation.

The work of breathing required to ventilate the lungs of normal newborns is approximately 10% of that required in adults (McIlroy and Tomlinson, 1955). However, infants have been shown to have a higher oxygen cost and lower mechanical efficiency associated with the work of breathing than adults (Thibeault et al, 1966). In healthy infants, the majority of the work of breathing is being done by the diaphragm during inhalation. Approximately one third of the total inspiratory work of breathing is related to overcoming the resistance to gas flow in the airways (Mortola et al, 1982). Exhalation is usually passive due to potential energy stored in the lung and the chest wall at end-inhalation but may become active as expiratory resistance increases or lung volumes decrease below FRC.

MEASUREMENTS OF RESPIRATORY SYSTEM MECHANICS

Respiratory system mechanics are objective measurements used to determine the severity of lung disease, changes in pathophysiology, response to therapeutic interventions, and progression of lung growth and development. Table 44-1 shows mechanics values for well and sick newborn infants. Lung mechanics in infants are typically measured during spontaneous breathing (dynamic) and by applying maneuvers during passive breathing conditions (static).

As mentioned previously, the mechanical behavior of the respiratory system (chest wall and lung) can be decoupled effectively by measuring pleural pressure. Because measuring pleural pressure is not feasible, esophageal pressure measured in the distal third of the esophagus, using an air-filled catheter attached to a pressure transducer, can be used to estimate pleural pressure. Thus, transpulmonary pressure is estimated by the difference between airway pressure and esophageal pressure and is useful in measuring lung and chest wall mechanics.

Dynamic compliance takes advantage of gas flow transiently being equal to zero at end inspiration and end expiration (see Figure 44-3). Dynamic compliance is calculated by dividing the change in volume between these two points in time by the concomitant change in distending pressure. Static compliance is the compliance measured when the infant is completely passive and can be estimated using an inspiratory hold at end inhalation during assisted ventilation (McCann et al, 1987).

TABLE 44-1 Lung Volumes and Mechanics of Well and Sick Neonates

Measurements	Units	Normal	RDS	BPD
Tidal volume	mL/kg	5-7	4-6	4-7
FRC	mL/kg	25-30	20-33	20-30
Compliance	mL/cm H_2O	1-2	0.3-0.6	0.2-0.8
Resistance	cm H_2O/L/sec	25-50	60-160	30-170

FRC, Functional residual capacity.
Data from Choukroun et al, 2003; Cook et al, 1957; Gerhardt and Bancalari, 1980; McCann et al, 1987; Polgar and Promadhat, 1971; Polgar and String, 1966; Reynolds and Etsten, 1966.

Another estimate of static respiratory system compliance requires instilling a known volume of gas into the lung, then measuring airway pressure at equilibrium in the absence of airflow and respiratory muscle activity (see Figure 44-1). This single occlusion technique is used to measure compliance during the passive exhalation maneuver described previously (see Figure 44-4). In the normal infant, it is generally assumed that dynamic compliance is equal to static compliance. However, in infants that are tachypneic or who have elevated airway resistance, the dynamic compliance may underestimate the static compliance of the lung (Katier et al, 2006).

As was mentioned earlier, measurements of compliance are affected by lung size. For example, if a 5 cm H_2O distending pressure results in a 25-mL increase in lung volume in a newborn, calculated lung compliance is 5 mL/cm H_2O. In an adult, the same 5 cm H_2O distending pressure increases the lung volume by roughly 500 mL, and calculated compliance is 100 mL/cm H_2O. Although the calculated lung compliances are different, the forces needed to carry out tidal ventilation are similar (i.e., lung function is normal in both circumstances). This example points out that if lung compliances are to be compared, they must be corrected for size. This is usually performed by dividing compliance by resting lung volume to get specific compliance. For the newborn, resting lung volume is roughly 100 mL, so specific compliance is 0.05 mL/cm H_2O/mL lung volume. For the adult, resting lung volume is nearly 2000 mL, so specific compliance is 0.05 mL/cm H_2O/mL lung volume—identical to that of the newborn. Thus, one might expect an infant born small for gestational age to have low lung compliance and normal specific compliance.

Lung compliance changes with volume history, meaning that it decreases with fixed tidal volumes and increases after deep breaths that recruit air spaces that may have been poorly ventilated or collapsed. The periodic sigh in spontaneous breathing is typically associated with an increase in lung compliance and in oxygenation (Frappell and MacFarlane, 2005). However, sighs in premature infants are often followed by apnea and hypoventilation that could lead to destabilization in infants affected with lung disease (Qureshi et al, 2009).

Many respiratory disorders result in nonhomogeneous increases in small airway resistance in the lung (see Table 44-1). Therefore, if lung compliance remains relatively uniform, the product of resistance and compliance (Trs) varies throughout the lung. During lung inflation, units with normal resistance have the lowest Trs and fill rapidly. Units with high resistance have a longer Trs and fill more slowly. At rapid respiratory rates when the duration of inspiration is short, only those lung units with a short Trs are ventilated. In effect, the ventilated lung becomes smaller. As discussed earlier, as the lung becomes smaller, its measured compliance decreases. Therefore, in infants with ventilation inhomogeneities, dynamic lung compliance decreases as respiratory rate increases. This decrease in lung compliance with increasing respiratory rate is termed *frequency dependence of compliance*, and it is suggestive of inhomogeneous small airway obstruction.

Resistance of the total respiratory system can be measured using the passive exhalation technique described previously (see Figure 44-4), or it can be calculated from measurements of distending pressure, volume, and flow (see Figure 44-3). Points of equal volume are chosen during inspiration and expiration. The gas flow and the distending pressure are measured at each point. The pressure needed to overcome elastic forces should be the same for inspiration and expiration and therefore cancel out. Total resistance, consequently, is equal to distending pressure at the inspiratory point minus distending pressure at the expiratory point, divided by the sum of the respective inspiratory and expiratory point gas flows. Investigators have calculated compliance and resistance by measuring distending pressure, gas flow, and volume (see Figure 44-3), then fitting these measurements to the equation of motion (see Equation 3), using multiple linear regression techniques, and solving for the coefficients 1/C and R (Bhutani et al, 1988).

The forced oscillation technique is used to estimate R_{RS} in spontaneously breathing subjects (Goldman et al, 1970). A loudspeaker is used to generate a sinusoidal pressure wave (P_{RS}) to the infant's nose via a face mask, with the mouth occluded, and the resulting gas flow is measured using a pneumotachograph. The $P_{RS}/\dot{V}$ relationship, called impedance (Z), is expressed as an amplitude ratio, called modulus ($|Z|$), and a phase shift (Φ) of both signals (Desager et al, 1996). Applying the simple RLC lung model described earlier in Equation 2 yields:

$$Z_{RS} = R_{RS} + j[\omega I_{RS} - 1/\omega C_{RS}]$$

where $j = \sqrt{-1}$ and $\Phi = 2\pi$ (frequency). The imaginary term on the right in the equation is termed reactance. At low frequencies, $1/\omega C_{RS} >> \omega I_{RS}$, and Φ is negative. At high frequencies, the inertance term predominates, and Φ is positive. At an intermediate frequency, called resonant frequency, the effects of compliance and inertance are equal and cancel each other. The forced oscillations can be superimposed on spontaneous breaths (Jackson et al, 1996), making this technique suitable for infants. Forced oscillations methods can also be used with more complex lung models separating airway impedance from tissue impedance (Peslin et al, 1972).

FRC is measured by inert gas dilution techniques (helium dilution) or inert gas displacement (nitrogen washout) (Figure 44-6). Both of these techniques measure gas that communicates with the airways. The total volume of gas in the thorax at end expiration (thoracic gas volume [TGV]) can be measured using a body plethysmograph and applying Boyle's law. This technique measures all gas in the thorax—even trapped gas that is not in contact with the airways. Obviously, FRC measured by inert gas dilution is less than TGV if significant volumes of trapped gas are present.

ALVEOLAR VENTILATION

The tissues of the body continuously consume O_2 and produce CO_2 (Figure 44-7). The primary function of the circulation is to pick up O_2 from the lungs and deliver it to the tissues, then to pick up CO_2 from the tissues and deliver it to the lungs. The exchange of O_2 and CO_2 with the blood occurs within the alveolar volume of the lungs. The alveolar volume acts as a "large sink" from which O_2 is continuously extracted by the blood and to which CO_2 is continuously added. This mechanism for acquiring O_2 from

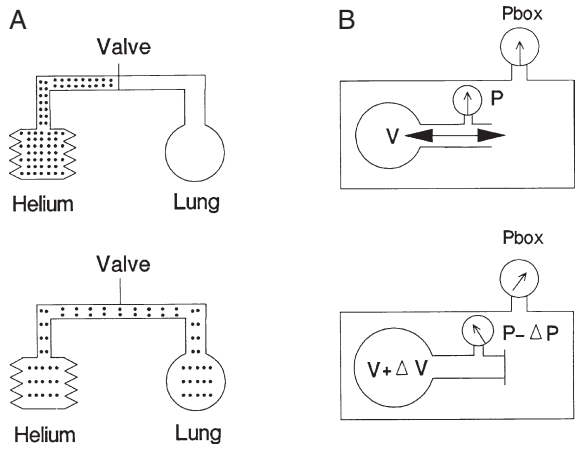

FIGURE 44-6 **A,** Measurement of functional residual capacity (FRC) by helium dilution. At end exhalation, the infant breathes from a bag containing a known volume (V_{bag}) and concentration of helium (He_i) in oxygen. The gas in the infant's lungs dilutes the helium oxygen mixture to a new concentration (He_f): FRC = Bag volume × (He_I – He_f)/He_f. **B,** Measurement of thoracic gas volume (TGV) using a plethysmograph. The infant breathes spontaneously in a sealed body plethysmograph. At end exhalation, the airway is closed with a shutter. As the infant attempts to inspire against the shutter, the volume of the thorax increases and airway pressure decreases. The increase in volume of the thorax can be measured from the change in the pressure inside of the plethysmograph (Pbox). By Boyle's law: P × TGV = (P – ΔP) × (TGV + ΔV), where P is atmospheric pressure, (P – ΔP) is airway pressure during occlusion, and (TGV + ΔV) is thoracic volume during occlusion. Therefore, TGV = (P – ΔP) × ΔV/ΔP. Because ΔP is small compared with P, this can be simplified to TGV = P × ΔV/ΔP.

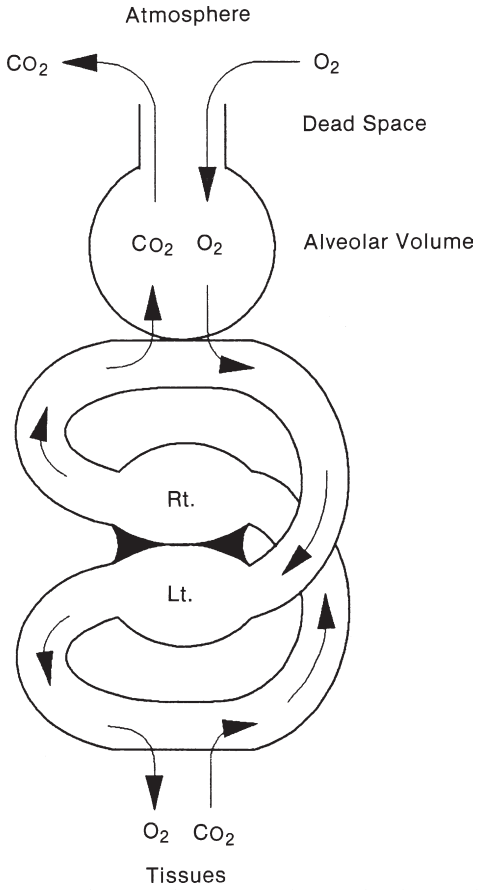

FIGURE 44-7 Schematic showing coupling of alveolar ventilation to tissue oxygen consumption.

the atmosphere and excreting CO_2 into the atmosphere is the alveolar ventilation (Slonim and Hamilton, 1987).

The alveolar volume of the lung includes all lung units capable of exchanging gas with mixed venous blood: respiratory bronchioles, alveolar ducts, and alveoli. Because the conducting airways do not participate in gas exchange, they constitute the anatomic dead space (V_D). At end exhalation, the FRC is the sum of the volume of gas in the alveolar volume and in the anatomic dead space. During normal breathing, the amount of gas entering and leaving the lung with each breath is the tidal volume (V_T):

$$V_T \times \text{respiratory rate (RR)} = \text{minute ventilation } (\dot{V})$$

Part of each V_T is wasted ventilation because it moves gas in and out of the V_D. Therefore, alveolar ventilation ($\dot{V}_A$) can be expressed as:

$$\dot{V}_A = (V_T - V_D) \times RR \quad (6)$$

Alveolar ventilation is an intermittent process, whereas gas exchange between the alveolar space and the blood occurs continuously. Because arterial O_2 and CO_2 tensions (Pao_2 and $Paco_2$) are roughly equal to the O_2 and CO_2 tensions within the alveolar space, these fluctuations in breathing could result in intermittent hypoxemia and hypercarbia. Fortunately the lung has a large buffer—the FRC. The FRC is four to five times as large as the V_T; therefore, only a fraction of the total gas in the lung is exchanged during normal breathing. This large buffer continues to supply O_2 to the blood during expiration and acts as a sump to accept CO_2 from the blood, so alveolar O_2 and CO_2 tensions (P_AO_2 and P_ACO_2) change little throughout the ventilatory cycle.

Alveolar ventilation is linked tightly to metabolism. When alveolar ventilation is uncoupled from the body's metabolic rate, hypoventilation or hyperventilation results. During hypoventilation, less O_2 is added to the alveolar space than is removed by the blood, and less CO_2 is removed from the alveolar space than is added by the blood. As a result, P_AO_2 decreases and P_ACO_2 increases. The net result of hypoventilation is hypoxemia and hypercapnia. Administering supplemental O_2 increases the quantity of O_2 in each breath delivered to the alveolar space, and it may prevent arterial hypoxemia. For example, suppose a 1-kg male infant has a V_T of 6 mL, an anatomic V_D of 2 mL, and a respiratory rate of 40 breaths/min. His alveolar ventilation is 160 mL per minute ([6 mL – 2 mL] × 40/min). If he breathes room air (21% O_2), he delivers 33.6 mL of O_2 to the alveolar space every minute (160 mL/min × 0.21). If he maintains the same V_T but breathes only 20 times per minute, his alveolar ventilation decreases to 80 mL per minute, only 16.8 mL of O_2 (80 mL/min × 0.21) is delivered to the alveolar space each minute, and his P_AO_2 and Pao_2 decrease. If he is allowed to breathe 50% O_2, O_2 delivery to the alveolar space increases to 40 mL per minute (80 mL/min × 0.50), and both his P_AO_2 and Pao_2 increase. Because O_2 administration has no effect on the accumulation of CO_2, it does not prevent hypercapnia.

Hyperventilation delivers more O_2 to the alveolar space than can be removed by the blood and removes more CO_2 than can be added by the blood. As a result, P_AO_2 increases and P_ACO_2 decreases.

Measurements of alveolar ventilation and anatomic V_D in the infant rely on the relationship between CO_2 production (VCO_2), $\dot{V}_A$, and P_ACO_2. The mathematical expression of this relationship states (Cook et al, 1955):

$$F_ACO_2 = \frac{\dot{V}CO_2}{\dot{V}_A} \quad (7)$$

F_ACO_2 is the fraction of CO_2 in total alveolar gas, or

$$F_ACO_2 = P_ACO_2/(P_B - 47) \quad (8)$$

P_B is the barometric pressure, and 47 mm Hg is the vapor pressure of water at body temperature.

Therefore,

$$\dot{V}_A = \frac{[\dot{V}CO_2 \times (P_B - 47)]}{P_ACO_2} \quad (9)$$

If minute ventilation ($\dot{V}$) is measured, dead space ventilation ($\dot{V}_D$) is calculated as:

$$\dot{V}_D = \dot{V} - \dot{V}_A \quad (10)$$

and V_D is calculated by dividing by the respiratory rate.

This method measures the anatomic V_D in the lung. As seen in the next section, portions of some gas exchanging units in the lung can also function as V_D; therefore, the total V_D, or the physiologic V_D, may be greater than the anatomic V_D. Physiologic V_D is calculated by substituting $PaCO_2$ into Equation 9 for P_ACO_2. When $P_ACO_2 = PaCO_2$, all the V_D is anatomic V_D, and the gas-exchanging units are all functioning normally. As physiologic V_D increases, however, $PaCO_2$ increases relative to P_ACO_2. Therefore, the difference between $PaCO_2$ and P_ACO_2 (the $aA.DCO_2$) is a measure of efficiency of gas exchange in the lung.

For clinical purposes, $\dot{V}CO_2$ in Equation 9 is assumed to be a constant so that $\dot{V}_A$ is proportional to $1/PaCO_2$. Thus, increased $PaCO_2$ means that alveolar ventilation has decreased; decreased $PaCO_2$ means that alveolar ventilation has increased.

VENTILATION-PERFUSION RELATIONSHIPS

Under ideal circumstances, ventilation and perfusion of the lung are evenly matched ($\dot{V}/\dot{Q} = 1$), both in the lung as a whole and in each individual air space. The air spaces receive O_2 from the inspired gas and CO_2 from the blood. O_2 is transported into the blood, while CO_2 is transported to the atmosphere. Even though $\dot{V}/\dot{Q}$ is 1, CO_2 and O_2 are exchanged in the lung at the same ratio at which they are exchanged in the tissues: A little less CO_2 is transported out than O_2 is transported in, so the respiratory exchange ratio R equals 0.8. If there is no diffusion defect, the gas composition of the air spaces and the blood comes into equilibrium. N_2 makes up the balance of dry gas. The sum of partial pressures of all gases in the air spaces must equal atmospheric pressure. The ideal alveolar gas composition is PO_2 = 100, PCO_2 = 40, PN_2 = 573, and PH_2O = 47 (all in mm Hg) at an atmospheric pressure of 760 mm Hg. The ideal arterial blood composition is the same. Therefore, differences between alveolar and arterial gas composition under ideal circumstances are all zero. Knowing the values for $PaCO_2$ and inspired gas, ideal alveolar gas composition can be calculated from the alveolar gas equations (Farhi, 1966):

$$P_AO_2 = P_IO_2 - P_ACO_2 \times [F_IO_2 + (1 - F_IO_2)/R] \quad (11)$$

$$\text{where } P_IO_2 = F_IO_2 \times (P_B - PH_2O) \quad (12)$$

$$P_AN_2 = F_IN_2 \times [P_ACO_2 \times (1 - R)/R + (P_B - PH_2O)] \quad (13)$$

Under normal circumstances, and certainly in the presence of lung disease, this ideal situation is not the case; some air spaces receive more ventilation than perfusion, and others receive more perfusion than ventilation. A reduction of ventilation may occur because of atelectasis, alveolar fluid, or airway narrowing. Reduced ventilation in one part of the lung may cause increased ventilation elsewhere. A reduction of perfusion may occur if air spaces are collapsed or overdistended or because of gravitational effects, and increased perfusion may occur in congenital heart disease. As with ventilation, reduced perfusion in one part of the lung may cause increased perfusion in other regions. If an air space is relatively overventilated (high $\dot{V}/\dot{Q}$), its gas composition trends toward that of inspired gas, which in the case of room air is PO_2 = 150 mm Hg and PCO_2 = 0 mm Hg. If an air space is relatively underventilated (low $\dot{V}/\dot{Q}$), its gas composition tends toward that of mixed venous blood, which is PO_2 = 40 mm Hg and PCO_2 = 46 mm Hg. What counts is the $\dot{V}/\dot{Q}$ ratio, not absolute values of $\dot{V}$ or $\dot{Q}$ (West, 1986).

To understand $\dot{V}/\dot{Q}$ imbalance, it is common to view the lung as a three-compartment model (Figure 44-8): $\dot{V}/\dot{Q} = 0$ (Figure 44-8, *A*); $\dot{V}/\dot{Q} = 1$ (Figure 44-8, *B*); and $\dot{V}/\dot{Q} = \text{infinity}$ (Figure 44-8, *C*). The O_2 saturation of blood in each compartment depends on the PO_2 and the O_2 dissociation curve. For illustrative purposes, in a badly diseased lung, 50% of ventilation goes to $\dot{V}/\dot{Q} = 1$ and 50% to $\dot{V}/\dot{Q} = \text{infinity}$, whereas 50% of perfusion goes to $\dot{V}/\dot{Q} = 1$ and 50% to $\dot{V}/\dot{Q} = 0$. Perfusion of $\dot{V}/\dot{Q} = 0$ causes venous admixture, whereas ventilation of $\dot{V}/\dot{Q} = \text{infinity}$ causes alveolar V_D. The mixed alveolar gas composition is easily calculated as the mean. For mixed arterial blood, the PO_2 must be read from the O_2 dissociation curve, but because the CO_2 dissociation curve is fairly linear, the values for CO_2 are easily calculated as the mean. The abnormalities in distribution of $\dot{V}$ and $\dot{Q}$ have created an $Aa.DO_2$ = 70, $aA.DCO_2$ = 23, and $aA.DN_2$ = 32 mm Hg (see Figure 44-8). The $Aa.DO_2$ is greater than the sum of the other two because the O_2 dissociation curve is not linear. Of course, the situation in most lungs is not as extreme as the one illustrated. From this illustration, however, it can be seen that:

1. Open low $\dot{V}/\dot{Q}$ units produce increased $Aa.DO_2$, significant hypoxemia, and increased $aA.DN_2$, but because they are poorly ventilated and have a PCO_2 close to the ideal value, they do not change the $aA.DCO_2$ significantly.
2. High $\dot{V}/\dot{Q}$ units produce increased $Aa.DO_2$ without hypoxemia and increased $aA.DCO_2$, but because they are poorly perfused and have a PN_2 close to the ideal value, they do not change the $aA.DN_2$ significantly.

For the calculation of $Aa.DO_2$ and $aA.DN_2$, it is customary to calculate the ideal alveolar gas composition for O_2 and N_2 from the alveolar gas equations and use these values with those measured for arterial PO_2 and PN_2. This

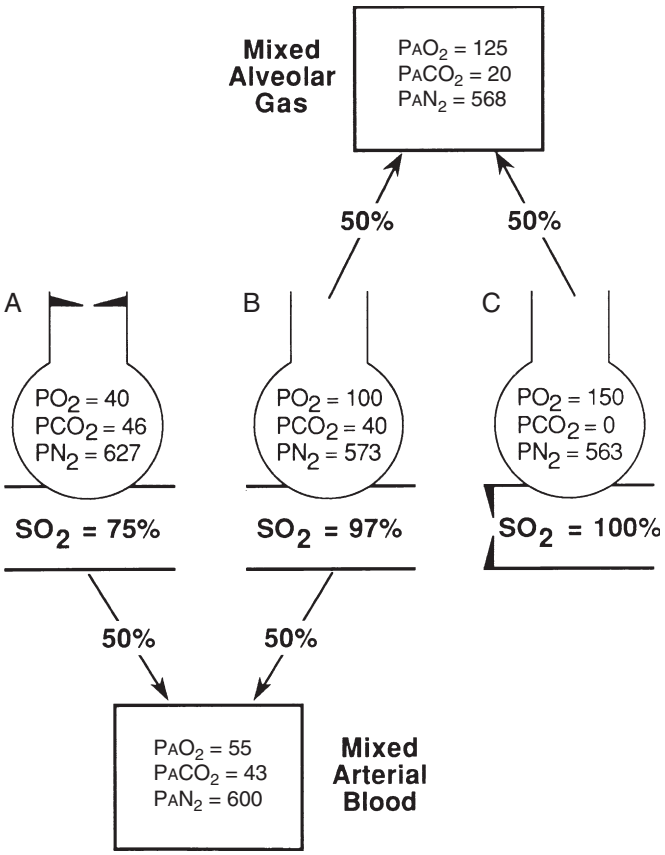

FIGURE 44-8 Three-compartment model of the lung with $\frac{\dot{V}}{\dot{Q}} = O\ (A),\ \frac{\dot{V}}{\dot{Q}} = 1\ (B),\ \frac{\dot{V}}{\dot{Q}} = \text{infinity}\ (C)$

The inspired gas is room air, and *B* is the ideal compartment. The sum of alveolar gas partial pressures is always 713 mm Hg. SO_2 is oxygen saturation in capillary blood. PaO_2 is read from the oxygen dissociation curve for a saturation of 86%. By calculated differences, $Aa.DO_2$ is 70 mm Hg, $aA.DCO_2$ is 23 mm Hg, and $aA.DN_2$ is 32 mm Hg.

emphasizes that part of the $Aa.DO_2$ and $aA.DN_2$ responsible for hypoxemia. For $aA.DCO_2$, both an arterial and mixed alveolar sample are required.

In the newborn, a fourth compartment in the model is important. A significant part of the venous return may be shunted from right to left at the foramen ovale, ductus arteriosus, pulmonary arteriovenous vessels, or lung mesenchyme without airway development, thus adding mixed venous to mixed arterial blood. This substantially increases the $Aa.DO_2$ but has little effect on $aA.DCO_2$ and no effect on $aA.DN_2$. The last mentioned is because there is no significant exchange of N_2 in the body, so venous and arterial PN_2 are the same. The effect on $aA.DCO_2$ is small because venous PCO_2 is only slightly higher than arterial. From this analysis, it can be seen that hypoxemia is produced by a true right-to-left shunt and open low $\dot{V}/\dot{Q}$ units. Diffusional problems are not thought to be important in the newborn. Hypoxemia may be modeled as a venous admixture, the part of mixed venous blood, expressed as a fraction of cardiac output, that when added to blood equilibrated with an ideal lung would produce the measured arterial oxygen saturation. It is calculated as follows:

$$\frac{\dot{Q}va}{\dot{Q}t} = \frac{C_cO_2 - C_aO_2}{C_cO_2 - C_aO_2} \quad (14)$$

where $\dot{Q}va/\dot{Q}t$ = venous admixture, CO_2 = oxygen content, $\dot{c}$ = pulmonary capillary, a = arterial, and $\bar{v}$ = mixed venous blood. For practical application, $C_{\bar{v}}O_2$ is calculated from a constant $a\ \bar{v}.O_2$ difference, which does introduce an error.

If an infant breathes 100% O_2 for 15 minutes, most N_2 is washed out of the lung, and the PO_2 in open low $\dot{V}/\dot{Q}$ units becomes so high that associated blood is 100% saturated with O_2. The remaining venous admixture is attributed to true right-to-left shunt ($\dot{Q}s/\dot{Q}t$). If an infant has the total venous admixture $\dot{Q}va/\dot{Q}t$ measured while breathing room air, then true shunt ($\dot{Q}s/\dot{Q}t$) measured while breathing 100% O_2, the venous admixture caused by open low $\dot{V}/\dot{Q}$ units ($\dot{Q}o/\dot{Q}t$) can be calculated as the difference. The venous admixture caused by open low $\dot{V}/\dot{Q}$ units can also be calculated from the $aA.DN_2$ (Markello et al, 1972):

$$\frac{\dot{Q}o}{\dot{Q}t} = \frac{P_AN_2 - PAN_2}{P_oN_2 - P_AN_2} \quad (15)$$

where P_oN_2 is the P_{N_2} in the units (see Figure 44-8), P_AN_2 is measured, and PAN_2 is the ideal value calculated from the alveolar gas equation. In newborns with a significant value for true shunt, this value really represents venous admixture as a fraction of effective pulmonary blood flow ($\dot{Q}o/\dot{Q}c$.). A better estimate for $\dot{Q}o/\dot{Q}t$ can be obtained from simple arithmetic (Corbet et al, 1974):

$$\frac{\dot{Q}o}{\dot{Q}t} = \left(\frac{\dot{Q}o}{\dot{Q}\dot{c}}\right) \times \frac{\left(1 - \frac{\dot{Q}Va}{\dot{Q}t}\right)}{\left(1 - \frac{\dot{Q}o}{\dot{Q}\dot{c}}\right)} \quad (16)$$

The true right-to-left shunt can then be estimated without 100% O_2 breathing using the equation:

$$\frac{\dot{Q}s}{\dot{Q}t} = \frac{\dot{Q}va}{\dot{Q}t} - \frac{\dot{Q}o}{\dot{Q}t} \quad (17)$$

The normal values for the various indices of ventilation-perfusion imbalance in normal newborn infants are shown in Table 44-2.

HEART-LUNG INTERACTION

EFFECTS OF THE LUNG ON THE HEART

There exists considerable potential for the lung to affect the heart. Because they share the thoracic cavity, changes in intrathoracic pressure accompanying lung inflation are transmitted directly to the heart. In addition, all of the blood leaving the right ventricle must traverse the pulmonary vascular bed, so changes in pulmonary vascular resistance may greatly affect right ventricular function.

EFFECTS OF CHANGES IN INTRATHORACIC PRESSURE ON THE HEART

Negative Intrathoracic Pressure

During spontaneous inspiratory efforts, the chest wall and diaphragm move outward, intrathoracic volume increases, and intrathoracic pressure decreases (Figure 44-9, *A*). The

heart also resides within the thoracic cavity and is subject to the same negative intrathoracic pressure during inspiration. With a decrease in intrathoracic pressure, the heart increases in volume, and the pressure within its chambers decreases relative to atmospheric pressure. Analogous to the lung, when the pressure within the heart decreases, blood is literally sucked back into the heart from systemic veins and arteries. On the right side of the heart, the phenomenon serves to increase the flow of blood from systemic veins into the right atrium, increasing right ventricular preload and ventricular output. On the left side of the heart, ventricular ejection is impaired. During systole, the left ventricle must overcome not only the load imposed by the systemic vascular resistance, but also the additional load imposed by the negative intrathoracic pressure (McGregor, 1979).

In infants with normal lungs, spontaneous respiratory efforts result in relatively small swings in pleural pressure (2 to 3 mm Hg) that have little effect on the pressure within the heart. With airway obstruction or parenchymal lung disease, however, swings in pleural pressure can be much greater (5 to 20 mm Hg), and systemic arterial pressure may fluctuate as much as 5 to 20 mm Hg depending on where in the respiratory cycle ventricular systole occurs. In older children with asthma or some other form of airway obstruction, these fluctuations in blood pressure constitute pulsus paradoxus and are indicative of severe airway obstruction.

Positive Intrathoracic Pressure

During positive-pressure ventilation, the lung inflates and pushes the chest wall and diaphragm outward (Figure 44-9, *B*). This outward push generates a pressure in the thoracic space that is greater than atmospheric pressure. The magnitude of the increase (relative transmission of airway pressure to the pleural space) is determined by the volume of lung inflation (which, in turn, is determined by the airway pressure and lung compliance) and by the compliance of the chest wall and diaphragm. If the lung is compliant and the chest wall rigid, little airway pressure is lost inflating the lung, but considerable pressure is generated in the thoracic cavity as the lung attempts to push the rigid chest wall outward. In this instance, intrathoracic pressure (intrapleural pressure) is much greater than atmospheric and in fact nearly equal to airway pressure. If the lung is poorly compliant and the chest wall highly compliant, most of the airway pressure is dissipated trying to inflate the lungs, and little is transmitted to the thoracic cavity.

The effects of positive intrathoracic pressure on the heart are opposite to those of negative intrathoracic pressure.

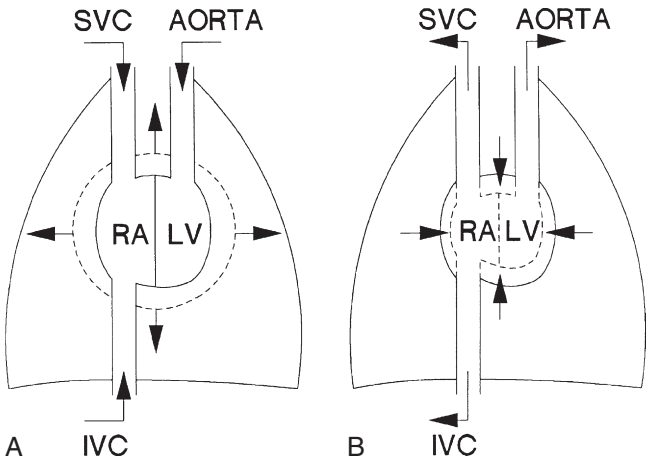

FIGURE 44-9 **A**, Negative intrathoracic pressure increases the volume of the heart and decreases the pressure within the chambers. This facilitates return of blood from the superior vena cava *(SVC)* and inferior vena cava *(IVC)* to the right atrium *(RA)* and impedes ejection of blood from the left ventricle *(LV)* into the extrathoracic aorta. **B**, Positive intrathoracic pressure decreases the volume of the heart and increases pressure within its chambers. This impedes blood return to the right atrium and augments ejection of blood from the left ventricle.

The heart is compressed by the lungs and chest wall, and blood is squeezed out of the heart and the thoracic cavity. Return of blood from systemic veins is impaired, and right ventricular preload and output decrease. If the increase in intrathoracic pressure coincides with ventricular systole, the effect is to augment left ventricular ejection and reduce the load on the left ventricle.

In the infant undergoing positive-pressure ventilation, the degree to which lung inflation compromises venous return is related to the relative compliances of the lung and chest wall. If the infant's lung is poorly compliant and the chest wall is compliant, as in hyaline membrane disease, there is little effect of lung inflation on venous return. If the infant's lung is normally compliant but tight abdominal distention prevents descent of the diaphragm, intrathoracic pressure increases dramatically during positive pressure ventilation, and venous return and cardiac output can be impaired. This mechanism may help explain the circulatory instability of infants after repair of gastroschisis or omphalocele. A similar situation may arise in the preterm infant with pulmonary interstitial emphysema and massive lung overinflation. In these infants, the heart is tightly compressed between the hyperinflated lungs, the other structures of the mediastinum, and the diaphragm. Venous return may be severely limited and venous pressures so increased that massive peripheral edema often accompanies the reduction in cardiac output.

Although the effects of increased pleural pressure on the right atrium are detrimental, the effects on the left ventricle may be extremely beneficial (Niemann et al, 1980). During cardiopulmonary resuscitation, the chest wall is compressed against the lung, and intrathoracic pressure increases. Because the left ventricle is in the thorax, left ventricular pressure increases as well. A gradient is created, favoring flow of blood out of the ventricle and thorax and into the extrathoracic systemic circulation. Between chest compressions, elastic recoil causes the chest wall to pull

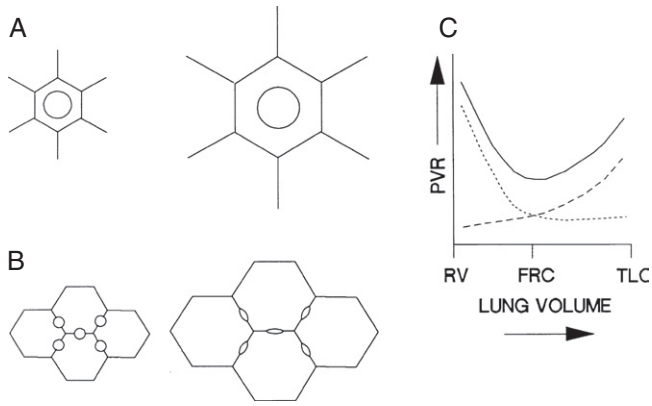

FIGURE 44-10 **A**, Effects of lung inflation on extra-alveolar vessels. **B**, Effects of lung inflation on alveolar vessels. **C**, Effect of lung volume on pulmonary vascular resistance *(PVR; solid line)*. Inflation is from residual volume *(RV)* to functional residual capacity *(FRC)* to total lung capacity *(TLC)*. *Dashed line* represents alveolar vessels; *dotted line* represents extraalveolar vessels.

away from the lung and heart, decreasing pleural pressure, favoring return of venous blood, and priming the heart for the next chest compression. A similar phenomenon may result in augmentation of systemic pressure when ventilator breaths coincide with ventricular systole.

EFFECT OF LUNG INFLATION ON PULMONARY VASCULAR RESISTANCE

The pulmonary interstitium comprises three different interconnected connective tissue compartments, each containing a different element of the pulmonary circulation (Fishman, 1986). The first—the perivascular cuffs—consists of a sheath of fibers that contain the preacinar pulmonary arteries, lymphatics, and bronchi. The second consists of the intersegmental and interlobular septa and contains pulmonary veins and additional lymphatics. The third connects these two within the alveolar septa and contains the majority of the pulmonary capillaries. The first and second compartments represent the extra-alveolar interstitium, whereas the third represents the alveolar interstitium. The perivascular cuffs are surrounded by alveoli and expand during lung inflation (Figure 44-10, *A*). As a result, pressure within each cuff decreases, distending extra-alveolar blood vessels and decreasing their resistance to blood flow. The alveolar interstitium lies between adjacent alveoli and contains the majority of gas-exchanging vessels in the lung. These vessels are exposed to alveolar pressure on both sides and during lung inflation (Figure 44-10, *B*) are compressed so that their resistance to blood flow increases.

Therefore, during lung inflation (Figure 44-10, *C*), the resistance in extra-alveolar vessels decreases, whereas resistance in alveolar vessels increases. As a result, the overall pulmonary vascular resistance decreases initially, with lung inflation reaching its nadir at FRC, and then increases with further inflation.

If transition from intrauterine life to extrauterine life is to be successful, after birth all of the right ventricular output must traverse the pulmonary vascular bed. To some extent, this adaptation is facilitated by a reduction in pulmonary vascular resistance that occurs with inflation of the lungs (see Figure 44-10) to a stable FRC. Inflation of the lung beyond FRC increases pulmonary vascular resistance. If care is not taken during positive pressure ventilation, it is possible to inflate the lung to the point that alveolar vessels close and blood flow through the lung is impaired. When this occurs, either cardiac output decreases or the blood bypasses the lung via the foramen ovale or ductus arteriosus. Clinically, this is manifest as circulatory insufficiency from impaired right ventricular output or hypoxemia from right-to-left shunting of blood, or both.

EFFECTS OF THE HEART ON THE LUNG

Pulmonary Edema

Pulmonary edema is the abnormal accumulation of water and solute in the interstitial and alveolar spaces of the lung (Bland and Hansen, 1985; Staub, 1974). In the lung, fluid is filtered from capillaries in the alveolar septa into the alveolar interstitium (Figure 44-11, *A*) and then siphoned into the lower pressure extra-alveolar interstitium. The extra-alveolar interstitium contains the pulmonary lymphatics, and under normal conditions, they remove fluid from the lung so that there is no net accumulation in the interstitium. Pulmonary edema results only when the rate of fluid filtration exceeds the rate of lymphatic removal. There are only three mechanisms by which this can occur (Figure 44-11, *B*): (1) the driving pressure for fluid filtration (filtration pressure) increases, (2) the permeability of the vascular bed (hence, the filtration coefficient K_f) increases, or (3) lymphatic drainage decreases.

Increased Driving Pressure

Filtration pressure can be increased by increased intravascular hydrostatic pressure, decreased interstitial hydrostatic pressure, decreased intravascular oncotic pressure, or increased interstitial oncotic pressure (Figure 44-11, *C* and *D*). By far the most common cause of increased filtration pressure is increased intravascular hydrostatic pressure (Box 44-1). In the newborn, intravascular hydrostatic pressure increases with increased left atrial pressure from volume overload or a number of congenital and acquired heart defects. In the preterm and term newborn, evidence suggests that alterations in pulmonary blood flow that are independent of any change in left atrial pressure may also influence fluid filtration in the lung. Preterm infants with patent ductus arteriosus and left-to-right shunts exhibit signs of respiratory insufficiency before they develop any evidence of heart failure, and experiments performed in newborn lambs show that fluid filtration in the lung can be increased by increasing pulmonary blood flow without increasing left atrial pressure (Feltes and Hansen, 1986). In the newborn with a reduced pulmonary vascular bed, either from lung injury or from hypoplasia, cardiac output appropriate for body size may represent a relative overperfusion to the lung and can result in increased fluid filtration. This phenomenon has been invoked to explain the lung edema that often complicates the course of the infant with bronchopulmonary dysplasia.

The exact cause of pulmonary edema that accompanies severe hypoxia or asphyxia in the newborn is still a

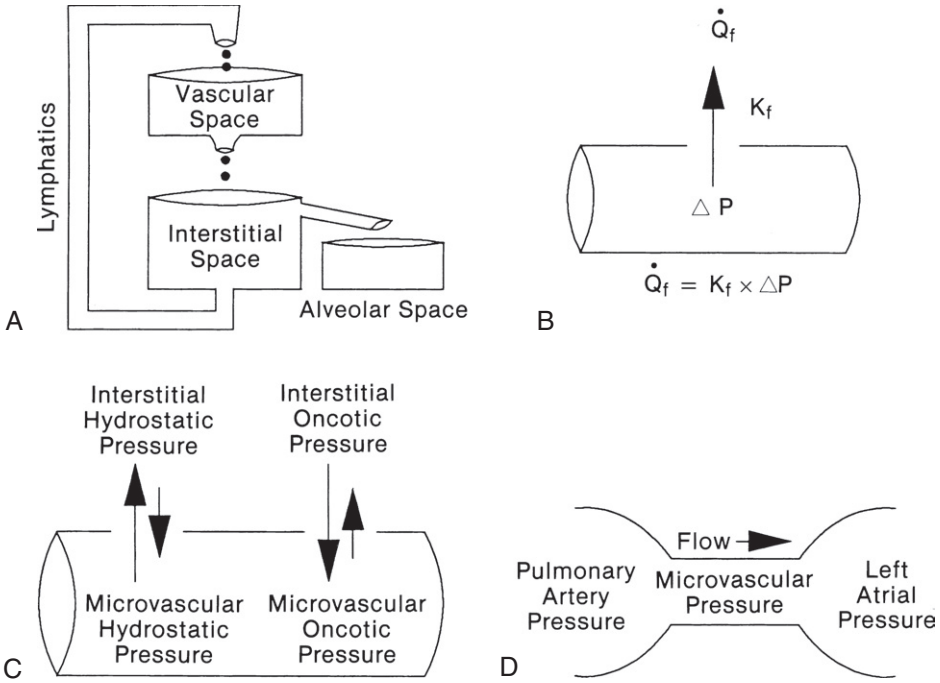

FIGURE 44-11 **A**, In the lung, fluid is continuously filtered out of vessels in the microcirculation into the interstitium and then returned to the intravascular compartment by the lymphatics. Only when the rate of filtration exceeds the rate of lymphatic removal can fluid accumulate in the interstitium. Spillover of fluid into the alveolar space occurs only when the interstitial space fills or when the alveolar membrane is damaged. **B**, Fluid flows out of vessels at a flow rate ($\dot{Q}_f$) that is equal to the driving pressure for fluid flow (ΔP) times the filtration coefficient (K_f): $\dot{Q}_f = K_f \times \Delta P$. K_f can be thought of as the relative permeability of the vascular bed to fluid flux. K_f in the normal lung is a small number so that despite a driving pressure of roughly 5 mm Hg, the net rate of fluid filtration is approximately 1 to 2 mL/kg per hour. **C**, The driving pressure for fluid flow out of the microvascular bed represents a balance of two sets of pressures. Within the blood vessel, hydrostatic pressure tends to push fluid out of the vessel into the interstitium. This pressure is partially opposed by a smaller hydrostatic pressure within the interstitium pushing fluid back into the blood vessel. Within the blood vessel, there also exists a discrete oncotic pressure that results predominantly from intravascular albumin that tends to draw fluid from the interstitium back into the blood vessel. This pressure is partially opposed by an interstitial oncotic pressure tending to draw fluid from the blood vessel into the interstitium. **D**, The intravascular hydrostatic pressure must be less than pulmonary artery pressure (Ppa) for blood to flow into the microvascular bed and greater than left atrial pressure (Pla) for blood to flow out. Intravascular pressure within the microvascular bed is roughly equal to 0.4 (Ppa – Pla) + Pla. The interstitial hydrostatic pressure is roughly equal to alveolar pressure. The intravascular oncotic pressure can be calculated from the plasma albumin concentration. The interstitial oncotic pressure is roughly two thirds of the intravascular oncotic pressure. The balance of these pressures favors filtration out of the vessel (in the normal lamb, this pressure is roughly 5 mm Hg).

BOX 44-1 Increased Intravascular Hydrostatic Pressure

INCREASED LEFT ATRIAL PRESSURE

- Intravascular volume overload
  - Overzealous fluid administration
  - Overtransfusion
  - Renal insufficiency
- Heart failure
  - Left-sided obstructive lesions
  - Left-to-right shunts
  - Myocardiopathies

INCREASED PULMONARY BLOOD FLOW

- Normal pulmonary vascular bed
  - Patent ductus arteriosus
  - Increased cardiac output
- Reduced pulmonary vascular bed
  - Bronchopulmonary dysplasia
  - Pulmonary hypoplasia

controversial issue. Data suggest that it is the result of increased filtration pressure and not the result of any alteration in permeability. Heart failure accounts for some of the increased filtration pressure following severe asphyxia. In addition, there may be some element of pulmonary venous constriction. Finally, there is evidence that hypoxia and acidosis may redistribute pulmonary blood flow to a smaller portion of the lung and result in relative overperfusion and edema, similar to that seen with anatomic loss of vascular bed (Hansen et al, 1984).

Several investigators have suggested that upper airway obstruction may cause pulmonary edema by decreasing interstitial hydrostatic pressure relative to intravascular hydrostatic pressure. Other data suggest, however, that with airway obstruction, vascular pressures decrease with intrapleural pressure in such a way that filtration pressure remains unchanged (Hansen et al, 1985).

Hypoproteinemia in infants results in a decrease in intravascular oncotic pressure. Its effects on filtration pressure, however, are blunted by the simultaneous decrease in protein concentration in the interstitial space of the lung. As a result, edema is unlikely to occur unless hydrostatic pressure also increases (Hazinski et al, 1986).

Increased Permeability

Another possible mechanism for increased fluid filtration in the lung is a change in the permeability of the microvascular membrane to protein—high-permeability

pulmonary edema. In this form of edema, the sieving properties of the microvascular endothelium are altered so that K_f increases and patients may develop pulmonary edema despite relatively normal vascular pressures (Albertine, 1985). Furthermore, even small changes in vascular pressures can result in a dramatic worsening of pulmonary status. High-permeability pulmonary edema usually implies either direct or indirect injury to the capillary endothelium of the lung. Direct injuries result from local effects of an inhaled toxin such as oxygen. Indirect injuries imply that the initial insult occurs elsewhere in the body and that the lung injury occurs secondarily. An example of indirect lung injury is sepsis: Neutrophils activated by bacterial toxins attack endothelial cells in the lung and increase permeability to water and protein (Brigham et al, 1974). Indirect injuries usually involve bloodborne mediators, such as leukocytes, leukotrienes, histamine, or bradykinin. Alveolar overdistention can also cause high-permeability pulmonary edema, presumably by direct injury of the pulmonary vascular bed. This type of vascular injury probably accounts for some of the edema that accompanies diseases such as hyaline membrane disease and bronchopulmonary dysplasia, in which maldistribution of ventilation results in areas of alveolar overdistention (Carlton et al, 1990).

Decreased Lymphatic Drainage

In the normal lung, the rate of lung lymph flow is equal to the net rate of fluid filtration, and as long as lymphatic function can keep up with the rate of fluid filtration, water does not accumulate in the lung. Although lymphatics can actively pump fluid against a pressure gradient, studies show that this ability is limited and that lung lymph flow varies inversely with the outflow pressure (pressure in the superior vena cava). Several groups of investigators have demonstrated that, in the presence of an increased rate of transvascular fluid filtration, the rate of fluid accumulation in the lung is substantially greater if systemic venous pressure is increased (Drake et al, 1985). Recent data suggest that the ability of the lymphatics to pump against an outflow pressure is impaired in the fetus and newborn. In fact, in fetal lambs, lymph flow ceases at an outflow pressure of roughly 15 mm Hg (Johnson et al, 1996). This explains why pulmonary edema often complicates the course of infants with bronchopulmonary dysplasia and cor pulmonale and explains the particular problem of edema with pleural effusions complicating the postoperative course of patients following cavopulmonary shunts.

More recently, investigators have shown that the ability of the lymphatics to pump can be affected by other mediators with pumping increased by α-adrenergics and certain leukotrienes and impaired by nitric oxide, β-adrenergics (Von Der Weid, 2001), and products of hemolysis (Elias et al, 1990).

CONGENITAL PULMONARY LYMPHANGIECTASIS

Congenital pulmonary lymphangiectasis is a rare form of pulmonary lymphatic dysfunction that can be characterized into two groups: (1) cases associated with congenital heart disease and (2) cases not associated with congenital heart disease. The cardiac anomalies may include hypoplastic left heart syndrome, total anomalous pulmonary venous drainage, and pulmonary stenosis, including Noonan syndrome (France and Brown, 1971). The group that does not include associated cardiac anomalies may be of early or late onset and has a wide spectrum of severity. In some individuals, the lesion is asymptomatic, whereas in others it can lead to severe respiratory failure, usually in the first hours after birth but sometimes during the first weeks or months of life. Most infants with this condition die early in the neonatal period. Pulmonary lymphangiectasis has been reported twice as often in males and has been seen in families (Scott Emaukpor et al, 1981).

Usually the radiologist is the first to suggest the diagnosis after observing dilated lymphatic vessels and sometimes small accumulations of pleural fluid on the chest radiograph. The older infant may have no symptoms or mild to moderate tachypnea with various degrees of hypoxemia. If pleural fluid has accumulated, examination of the fluid is important. If the infant has received milk feedings, pleural fluid is chylous, and if not, there is an elevation in mononuclear cells and moderate protein of up to about 4%. These findings in the absence of fever or other signs of systemic illness are diagnostic of impaired lymphatic drainage.

Lung biopsy is probably not indicated and can be hazardous because once the distended lymphatic channels are severed, they can leak fluid for weeks. Only if the diagnosis is in doubt is open lung biopsy appropriate.

In noncardiac associated diffuse lymphangiectasis, only supportive treatment is available. The long-term prognosis depends on the severity of the lesion, but this form of pulmonary lymphangiectasis is compatible with asymptomatic life as an adult (Wohl, 1989).

SYMPTOMS OF PULMONARY EDEMA

As discussed previously, fluid filtered into the alveolar interstitium ordinarily moves rapidly along pressure gradients into the extra-alveolar interstitium where it is removed by the lymphatics. A delay in this process at birth can result in clinical transient respiratory distress (see Chapter 47). The extra-alveolar interstitium has a large storage capacity. Fluid does not begin to spill over into the alveoli and airways until total lung water is increased more than 50%, unless the alveolar membrane is damaged. Therefore, the first signs and symptoms of pulmonary edema are related to the presence of extra fluid in the interstitial cuffs of tissue that surround airways. As fluid builds up in these cuffs, airways are compressed, and the infants develop signs of obstructive lung disease. The chest may appear hyperinflated, and auscultation reveals rales, rhonchi, and a prolonged expiration. Early in the course, chest radiographs reveal lung overinflation and an accumulation of fluid in the extra-alveolar interstitium—linear densities of fluid that extend from the hilum to the periphery of the lung (the so-called sunburst appearance) and fluid in the fissures. With more severe edema, fluffy densities appear throughout the lung as alveoli fill with fluid (Figure 44-12). Heart size may be increased in infants with edema from increased intravascular pressure. Initially, infants present with increased $Paco_2$ secondary to impaired ventilation. Later PaO_2 decreases secondary to ventilation-perfusion

mismatching and alveolar flooding. In adults, a ratio of protein concentration in tracheal aspirate to that in plasma greater than 0.5 may help to differentiate permeability pulmonary edema from high-pressure pulmonary edema (Fein et al, 1979).

TREATMENT OF PULMONARY EDEMA

Treatment of pulmonary edema is directed at relieving hypoxemia and lowering vascular pressures. Hypoxemia should be treated with the administration of oxygen and, if necessary, positive pressure ventilation. Positive end expiratory pressure frequently improves oxygenation in individuals with pulmonary edema by improving ventilation-perfusion matching within the lung. Available evidence suggests that positive pressure ventilation does not reduce the rate of transvascular fluid filtration in the lung (Woolverton et al, 1978). Optimal treatment of pulmonary edema requires correction of the underlying cause. In infants with patent ductus arteriosus (see Figure 44-12) or other heart disease amenable to surgery, this is often easily accomplished. In cases of permeability edema or edema from nonsurgical heart defects, correction of the underlying cause may not be possible. In these instances, the only remaining option is to lower vascular pressures (even in permeability edema, lowering vascular pressures lowers the rate of fluid filtration and may also improve lymphatic function). This can be accomplished by lowering circulating blood volume by use of diuretics and fluid restriction, by improving myocardial function with the use of digitalis or other inotropic agents, or in severe cases by using a systemic vasodilator to reduce afterload and lower vascular pressures directly.

More recent data suggest that clearance of fluid from the alveolar space may be accelerated by β-adrenergic agents (Frank et al, 2000) and by dopamine (Saldias et al, 1999). Whether these agents will have any clinical efficacy remains to be determined.

PULMONARY HEMORRHAGE

Landing (1957) described pulmonary hemorrhage in 68% of lungs of 125 consecutive infants who died in the 1st week of life; massive pulmonary hemorrhage was found in 17.8% of neonatal autopsies at the Johns Hopkins Hospital (Rowe and Avery, 1966). Fedrick and Butler (1971) judged massive pulmonary hemorrhage to be the principal cause of death in about 9% of neonatal autopsies.

Etiology and Pathogenesis

Pulmonary hemorrhage usually occurs between the 2nd and 4th days of life in infants who are being treated with mechanical ventilation. It has been associated with a wide variety of predisposing factors, including prematurity, asphyxia, overwhelming sepsis, intrauterine growth retardation, massive aspiration, severe hypothermia, severe Rh hemolytic disease, congenital heart disease, and coagulopathies. It is often associated with central nervous system injury, such as asphyxia or intracranial hemorrhage. Cole et al (1973) studied a group of infants with pulmonary hemorrhage to determine the clinical circumstances under which the illness occurred as well as the hematocrit and protein composition of fluid obtained from lung effluent and arterial or venous blood. Their results indicated that the lung effluent was, in most cases, hemorrhagic edema fluid and not whole blood (i.e., as indicated by hematocrit values significantly lower than those of whole blood). In addition, they did not find that coagulation disorders initiated the condition but probably served to exacerbate it in some cases. They postulated that the important precipitating factor was acute left ventricular failure caused by asphyxia or other events that might increase the filtration pressure and so injure the capillary endothelium of the lung. Thus, pulmonary hemorrhage may be considered as the extreme form of high-permeability pulmonary edema.

Pulmonary edema following central nervous system injury probably results from increased hydrostatic pressure and some increase in vascular permeability (Malik, 1985). With the massive sympathetic discharge that accompanies central nervous system injury, left atrial pressure increases, and pulmonary arteries and veins constrict. As a result, microvascular pressure increases dramatically and causes dramatic damage to the microvascular endothelium, increasing its permeability to proteins and red blood cells. In infants with overwhelming sepsis and endotoxin production, increased microvascular permeability is apparent in the pulmonary circulation as well, undoubtedly contributing to the massive pulmonary hemorrhage sometimes seen in this group of infants. Pulmonary hemorrhage also has

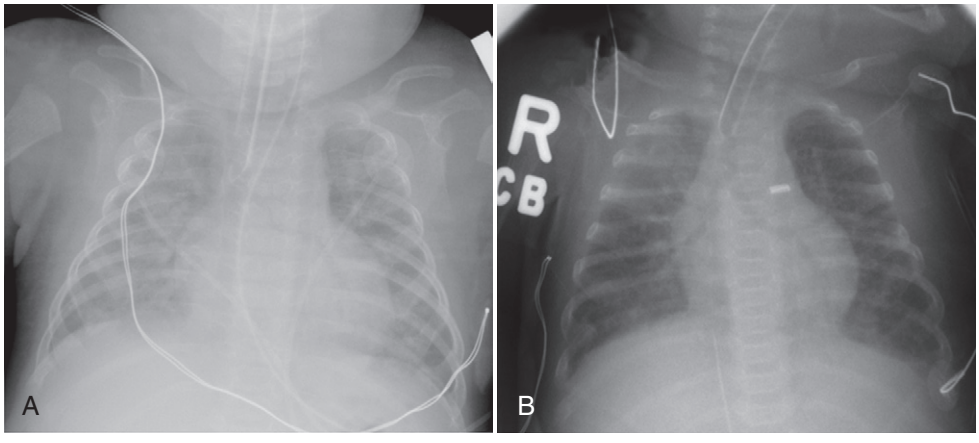

FIGURE 44-12 **A**, Preterm infant with a large patent ductus arteriosus and pulmonary edema. **B**, The same infant 24 hours after the ductus arteriosus was closed by surgical ligation.

been described occasionally in the presence of a large patent ductus arteriosus, with a left-to-right shunt that results in high flow and high pressure injurious to the vascular bed.

Pulmonary hemorrhage is also associated with surfactant replacement therapy. Presumably the hemorrhage results from the rapid increase in pulmonary blood flow that accompanies improved lung function after surfactant therapy. The contribution of the patent ductus arteriosus to this increased blood flow remains to be determined. A meta-analysis suggests that surfactant replacement may be associated with an increased risk of pulmonary hemorrhage. This risk, however, is still extremely small compared to the known benefits of surfactant replacement (Pappin et al, 1994; Raju and Langenberg, 1993).

Diagnosis

Infants with any of the conditions mentioned previously should be observed carefully for possible pulmonary hemorrhage. Particular note should be made of any occurrence of blood-stained fluid from endotracheal tube aspirates, especially if repeated suctioning shows an increase in the amount of hemorrhagic fluid. The infant's chest radiograph may show the fluffy appearance of pulmonary edema in addition to the underlying pathology, and the infant may have increased respiratory distress. Frank pulmonary hemorrhage, when it occurs, is an acute emergency, and the fluid has the appearance of fresh blood being pumped directly from the vascular system, although hematocrit values of the fluid are at least 15 to 20 points lower than the hematocrit of circulating blood, in keeping with hemorrhagic pulmonary edema.

Treatment

Effective treatment of pulmonary hemorrhage requires (1) clearing the airway of blood to allow ventilation; (2) use of adequate mean airway pressure, particularly end expiratory pressure; (3) resisting the temptation to administer large volumes of blood because in most cases the infant has not had a large loss of volume, and thus, administration of excessive volume exacerbates the increase in left atrial pressure and hemorrhagic pulmonary edema; rather, red cell replacement should be done as a slow administration of packed cells after the infant's pulmonary status has been stabilized; and (4) evaluation of the possibility of coagulopathy and administration of vitamin K and platelets, if appropriate.

CHAPTER 45

Principles of Respiratory Monitoring and Therapy

Eduardo Bancalari and Nelson Claure

RESPIRATORY MONITORING

One of the most important aspects of newborn intensive care is monitoring of cardiorespiratory function, ventilation, and oxygenation. This can be accomplished by bedside monitoring devices and laboratory analysis. The information provided by these monitoring techniques is an essential tool in the diagnosis and treatment of respiratory problems in the newborn.

BREATHING FREQUENCY, APNEA, AND HEART RATE MONITORING

Transthoracic impedance is the standard method used to monitor neonatal respiration. This technique is based on changes in the thorax's electrical impedance caused by changes in gas volume during respiration measured by surface electrodes. Transthoracic impedance is mainly used to monitor breathing frequency and to detect apnea (Olsson and Victorin, 1970).

Breathing is detected when the change in impedance exceeds a set threshold. A low threshold decreases sensitivity for apnea, and small disturbances such as cardiogenic oscillations can be falsely considered as breathing. Conversely, a high threshold may lead to false apnea alarms during shallow breathing. Monitors can automatically adjust this threshold or the impedance amplitude, or use sophisticated methods for detecting breathing or apnea. Transthoracic impedance is not reliable in assessing absolute tidal volume, but it can be used to assess relative changes.

This technique is more effective in detecting apneas of central origin than obstructive apnea because the latter can produce internal displacement of gas volumes that still change impedance. More specific techniques are used for diagnosis and classification of apnea, including thermistors and CO_2 monitors to detect gas exhalation and respiratory inductance plethysmography that measures expansion of the chest and abdomen. Transthoracic impedance monitors can also measure heart rate and are used to detect brady- and tachycardia. More sophisticated devices or built-in algorithms are utilized to detect cardiac rhythm anomalies.

VENTILATION MONITORING

The basic clinical determination of the adequacy of ventilation in the mechanically ventilated neonate consists of assessment of chest expansion, breathing frequency and auscultation. This can be complemented by monitoring tidal volume (V_T) and minute ventilation utilizing flow sensors available in most neonatal ventilators. This allows for monitoring of spontaneous breathing, assessment of respiratory system mechanics and detection of excessive or insufficient V_T, hypoventilation, and gas trapping (Becker and Donn, 2007).

These flow sensors are either mainstream (connected between the endotracheal tube and the ventilator circuit) or built into the ventilator. In small infants, mainstream flow sensors have better accuracy than those built into the ventilator because V_T and flow are only a fraction of the gas volumes compressed in the circuit and the circulating bias flow (Cannon et al, 2000; Chow et al, 2002). Although mainstream flow sensors are usually small and typically have a dead space volume <1 mL, they can induce rebreathing of exhaled gases and affect CO_2 elimination in small preterm infants (Claure et al, 2003; Figueras et al, 1997).

BLOOD GAS MONITORING

Determination of arterial blood gas status is key to the management of respiratory failure and lung disease in the neonate. Measurements of oxygen (Pao_2) and carbon dioxide ($Paco_2$) tension in arterial blood are considered the reference standard by which the efficacy and adequacy of ventilation and oxygenation are assessed.

In order to obtain repeated arterial blood samples, placement of invasive catheters is required. In neonates, umbilical artery catheters (UACs) are commonly used during the acute phases of respiratory failure. Samples obtained from a UAC are the most accurate when proper sample handling and laboratory procedures are followed. However, there are important issues that must be considered before their placement and during their use to ensure that the risk-to-benefit ratio remains favorable. UAC have risks during placement and use, including perforation of the vessels, formation of thrombi and emboli, vasospasm and infection. UAC lines with the tip above the celiac plexus are associated with fewer complications than those below the renal or mesenteric artery (Barrington, 2000).

Alternatively, percutaneous lines in the radial, ulnar, or dorsalis pedis artery are used when placement of a UAC is not possible. When an invasive line is not available, arterial punctures to the radial, ulnar, temporal, posterior tibialis, or dorsalis pedis artery are done to obtain blood samples. These latter results should be interpreted carefully because the procedure frequently disturbs the infant and alters blood gases. An alternative is to obtain blood samples from the peripheral capillary bed of the medial or lateral plantar surface. These are obtained after warming of the area, which produces hyperemia or "arterialization." These samples provide a gross estimate of arterial blood gases, and they should also be interpreted cautiously (Courtney et al, 1990). Erroneous estimation usually occurs due to

contamination by venous blood or air. This procedure can also disturb the infant and alter the basal status. Errors in blood gas measurement are often technique related. Contamination by an air bubble can reduce Pco_2 and alter the Po_2 in the direction of the air's oxygen tension. Contamination by fluids can reduce Po_2 and Pco_2 while also affecting pH. Because blood cell metabolism continues, reducing the time from sampling to analysis and cold temperature storage and transport attenuate its effects.

During conditions such as transport or when the turnaround time is important, bedside portable blood analysis devices have proven to be most effective (Murthy et al, 1997). Another alternative measurement method is that of indwelling electrodes inserted through a UAC that provide a continuous stream of blood gas information (Rais-Bahrami et al, 2002).

TRANSCUTANEOUS BLOOD GAS MONITORING

Transcutaneous measurement of O_2 ($TcPo_2$) and CO_2 ($TcPco_2$) tensions provide a noninvasive estimate of Pao_2 and $Paco_2$, respectively. Local hyperperfusion of the skin induced by heating creates a skin-electrode unit under the transcutaneous sensor, and electrochemical measurements in an electrolyte solution within this unit determine the partial pressure of O_2 and CO_2.

During measurement of $TcPo_2$, oxygen diffusing from the capillaries to the skin is reduced by the electrode, and the resulting electrical current is proportional to the Po_2 of the capillary bed. Because skin metabolism continues, local hyperemia is needed to maintain skin perfusion sufficiently high that the measured $TcPo_2$ is not affected by the skin's O_2 consumption. For this reason, accuracy of $TcPo_2$ depends on electrode temperature with improved accuracy at or above 43° C (Huch et al, 1976). Under adequate conditions, $TcPo_2$ correlates with Pao_2 (Peabody et al, 1978). However, conditions such as arterial hypotension and acidosis often result in underestimation due to insufficient skin perfusion (Versmold et al, 1979).

During $TcPco_2$ measurement, CO_2 molecules diffusing from the capillary bed change the pH of the electrolyte solution in the skin-electrode unit. This changes the electric potential between a reference and the electrode that is then translated into $TcPco_2$. Metabolism in the skin produces CO_2, and if the local perfusion is not adequate, the measured values can exceed those of $Paco_2$. $TcPco_2$ measurements can also be affected by conditions affecting peripheral perfusion (Peabody and Emery, 1985) and tend to overestimate $Paco_2$ in hypercapnia as local perfusion decreases (Martin et al, 1988).

Recent reports have demonstrated improved $TcPco_2$ measurement accuracy in preterm infants of <29 weeks' gestation, but inconsistent precision due to large between-patient variability (Aliwalas et al 2005; Bernet-Buettiker et al, 2005; Tingay et al, 2005). $TcPco_2$ measurements have also been shown to be tightly correlated to capillary Pco_2. Although capillary blood gases may not be the optimal reference, these are often the only available method for long-term monitoring because indwelling lines are available only during the acute phase of respiratory failure. In preterm infants, $TcPco_2$ may reduce the need for blood sampling and the number of painful punctures, but the main benefit is the ability to monitor continuously. For this reason, $TcPco_2$ is commonly used as an adjunct to standard blood gas sampling to provide information on trends and respiratory stability. This is particularly useful in the management of invasive ventilatory support where close tracking of the effects of ventilator changes is required.

The thin epidermal skin layer of the neonate has a relatively low metabolism. Nonetheless, some transcutaneous monitors include a metabolic correction factor. Measurements of $TcPo_2$ and $TcPco_2$ require a period of stabilization after sensor application until skin perfusion increases. A tight seal around the skin-electrode unit is required for accuracy. Similar to blood gas sampling, an air bubble transiently lowers $TcPco_2$ and shifts $TcPo_2$ toward the partial pressure of O_2 in room air until the O_2 is reduced.

The transcutaneous electrode is usually applied on the thorax or the thigh. The need for high electrode temperature combined with the premature infant's skin sensitivity requires frequent change of the application site to avoid thermal injury. Transcutaneous measurements have an intrinsic delay with respect to changes occurring in the arterial blood.

END-TIDAL CARBON DIOXIDE MONITORING

Monitoring of the partial pressure of CO_2 in end-tidal gases ($PetCo_2$) is based on the assumption that gases measured at the airway opening at the end of exhalation represent alveolar gases and that these match the arterial levels. $PetCo_2$ is obtained by infrared sensors placed mainstream or by side-stream gas sampling. $PetCo_2$ measurements are dependent on tidal volume size because the exhaled gas has to carry alveolar gas. The accuracy of $PetCo_2$ is affected by lung disease with an increased arterial to alveolar CO_2 gradient that results in underestimation of $Paco_2$ (Sivan et al, 1992). For this reason, $PetCo_2$ is more often used in term or near-term neonates and pediatric patients who require CO_2 monitoring for reasons other than lung disease.

ARTERIAL OXYGEN SATURATION BY PULSE OXIMETRY

Estimation of the oxygen saturation in arterial blood (Sao_2) by pulse oximetry (Spo_2) is based on the differences in the rates of light absorption between oxygenated and deoxygenated or reduced hemoglobin (Hb) in the red and infrared regions of light. Deoxygenated Hb absorbs more red light and less infrared light than oxygenated Hb. As Sao_2 increases, the ratio of the absorption of red light to that of infrared light decreases. It is assumed that in the circulation, changes in this ratio can only be produced by pulsating arterial blood. In neonates, Spo_2 has been shown to correlate well with measured saturation in arterial samples (Hay et al, 1989).

The absorption by pulsatile blood is only a small fraction of the light absorbed by tissue and venous blood. Thus, changes in pulse amplitude or patient movement that disrupt the optical pathway from transmitter to receiver side of the probe, or produce venous blood fluctuations, can affect Spo_2 accuracy, although newer techniques have

reduced the effect of the latter (Hay et al, 2002). The accuracy of Spo_2 is also affected by conditions such as low perfusion or by inappropriate placement such as excessive tightening of the probe (Bucher et al, 1994).

Data indicate reliable detection of hypoxemia spells by pulse oximetry (Bohnhorst et al, 2000; Hay et al, 2002). Nonetheless, some hypoxemia episodes detected by pulse oximetry are considered artifactual because of their temporal association with infant movement. However, increased infant activity leading to heart rate, lung volume, and ventilation changes has been shown to trigger hypoxemia (Bolivar et al, 1995; Dimaguila et al, 1997) with increased frequency during periods when the infants are awake compared to periods of active or quiet sleep (Lehtonen et al, 2002).

OXYGEN THERAPY

PRINCIPLES

Neonates presenting with acute respiratory failure or with some degree of respiratory distress suffer abnormalities of gas exchange that almost invariably result in hypoxemia. Depending on the severity and duration of hypoxemia and the metabolic demands for oxygen, this can lead to reduced O_2 availability and tissue hypoxia. Hypoxemia in the neonate can result from reduced alveolar oxygen content, low ventilation-perfusion ratio, reduced diffusion capacity, and extrapulmonary right-to-left shunts.

The most common form of respiratory therapy for the neonate with hypoxemia consists of oxygen supplementation. The increased fraction of inspired oxygen (Fio_2) increases the alveolar O_2 tension (PAo_2) in both well- and partially ventilated areas of the lung. The resulting increase in the alveolar-arterial O_2 gradient ($A\text{-}aDo_2$) in part compensates for the conditions producing hypoxemia mentioned earlier. The proportion of neonates requiring supplemental O_2 increases with lower gestational ages because premature birth is associated with many of the factors that contribute to hypoxemia.

The primary goal of oxygen therapy is to maintain adequate O_2 availability to the tissues, especially to the central nervous system and the heart, and to improve an incomplete hemodynamic adaptation to extrauterine life evident by persistently elevated pulmonary vascular resistance and patency of the ductus arteriosus. These goals, however, need to be attained without inducing the side effects of O_2 toxicity on the eye, brain, and other organs that are common in the premature infant.

Normal Sao_2 for room-air-breathing term or healthy preterm infants is reportedly greater than 93%, with Pao_2 levels above 70 mm Hg (Fenner et al, 1975; O'Brien et al, 2000; Richard et al, 1993). Maintenance of such oxygenation levels in premature infants with lung disease and immaturity would almost invariably require high inspired O_2 levels. Earlier strategies to "normalize" oxygenation with use of high Fio_2 in this population resulted in high rates of retinopathy of prematurity (ROP) and blindness (Campbell, 1951; Cross, 1973; Crosse and Evans, 1952). Conversely, strict curtailment of supplemental O_2 regardless of the oxygenation level was associated with increased rates of neurologic damage and death (Avery, 1960; Bolton and Cross, 1974; Patz et al, 1952).

The preterm infant is at risk for O_2-induced injury because of an immature antioxidant system that is unable to balance the oxidative effects of O_2 radicals. In the past, severe neonatal lung injury was only partly attributed to exposure to high Fio_2. However, animal experiments have showed that lung damage was caused by high alveolar O_2 independent of Pao_2 (Miller et al, 1970; Northway et al, 1967; Taghizadeh and Reynolds, 1976). In preterm infants, hyperoxia has been linked to neurologic damage and impairment (Ahdab-Barmada et al, 1980; Collins et al, 2001; Haynes et al, 2003). For this reason, when supplemental O_2 is administered to hypoxemic neonates, oxygenation is continuously monitored to avoid hyperoxemia.

METHODS OF ADMINISTRATION

In neonates, supplemental O_2 is usually administered by means of a head box, mask, nasal cannula, nasal continuous positive airway pressure (CPAP), or a mechanical ventilator. In mechanically ventilated infants or in infants receiving nasal CPAP, supplemental O_2 is administered by the mixture of air and O_2 in the ventilator or CPAP device. In all four methods, verifying that correct mixing in the air-O_2 blender produces the desired Fio_2 (by means of an O_2 analyzer) is recommended.

A head box, the least invasive of these methods, is generally used for infants who only need supplemental O_2. Depending on the size of the infant, a minimum flow is required to flush exhaled gases and to minimize entrainment of ambient air. Gas warming and humidification is recommended to avoid drying of the airways and secretions as well as to avoid convective heat losses.

Nasal cannulas deliver a constant flow of the air-O_2 mixture to the nostrils. The actual Fio_2 is determined by the delivered flow and the infant's inspiratory flow. With increasing flows the actual inspired O_2 concentration approaches the mixture delivered by the cannula, whereas higher inspiratory flows, in larger infants or during periods of increased demands, reduce the actual inspired O_2 by entraining more room air (Walsh et al, 2005). The actual Fio_2 during oral breathing has not been determined. Cannula flows >1 lpm can produce positive pressure at the nose at levels similar or above typical CPAP levels (Locke et al, 2003), which can become very high if the prongs fit tightly in the nostrils. Gas conditioning is recommended to avert drying of the nose and the risk of mucosal damage (Kopelman and Holbert, 2003). Nasal cannulas have gained popularity because they are flexible and facilitate access to and mobility of the infant.

TREATMENT STRATEGIES

The effects of the introduction of continuous monitoring of oxygenation in the care of preterm infants in relation to ROP have been inconsistent (Bancalari et al, 1987; Grylack, 1987; Yamanouchi et al, 1987). Data showing that ROP severity was associated with duration of hyperoxemia emphasized the importance of monitoring and curtailing hyperoxemia (Flynn et al, 1987). However, infants with severe ROP were also found to spend considerable periods of time in hypoxemia.

Continuous monitoring of arterial oxygen saturation by pulse oximetry (Spo_2) has become an important and

standard component of neonatal intensive care. The use of Spo_2 has recently been extended to the delivery room for titration of Fio_2 during resuscitation (Dawson et al, 2009; Escrig et al, 2008). Although the optimal range of Spo_2 in premature infants has not been fully defined, existing data suggest deleterious effects of hyperoxemia, with higher rates of ROP and worse respiratory course in neonatal centers that have tolerant policies toward high Spo_2 levels (Anderson et al, 2004; Tin et al, 2001). Observational data indicate that more restrictive policies toward high Spo_2 can reduce rates of ROP (Chow et al, 2003; Wright et al, 2006). Tolerance of high Spo_2 levels in convalescent infants beyond the neonatal period has been proposed to improve growth and neurologic outcome, as well as to stop the progression of threshold ROP. However, clinical trials showed minimal benefits that were outweighed by deterioration in lung function caused by the additional O_2 required to maintain higher Spo_2 (Askie et al, 2003; STOP-ROP Study Group, 2000).

Implementation of policies to curb hyperoxemia should also consider the potential deleterious effects of insufficient oxygenation. Hypoxemia can increase patency of the ductus arteriosus (Noori et al, 2009; Skinner et al, 1999) as well as increase the resistance of the pulmonary vasculature and airways, particularly in infants with established lung disease (Abman et al, 1985; Cassin et al, 1964; Halliday et al, 1980; Tay-Uyboco et al, 1989; Teague et al, 1988).

Observational data showed that policies targeting lower Spo_2 ranges were associated with better outcomes (Chow et al, 2003; Wright et al, 2006). However, it is unknown how closely such ranges were actually maintained and is possible that the side effects of lower Spo_2 levels were not detected because infants were maintained above those ranges most of the time. Those findings should be interpreted with caution in face of recent evidence from a large blinded randomized-controlled trial showing increased mortality when targeting a lower Spo_2 range (Carlo et al, 2010).

The use of pulse oximetry to avoid hyperoxemia and hypoxemia must be done in the context of the sigmoid-shaped oxygen dissociation curve between Pao_2 and Spo_2. Although Spo_2 levels in the upper range can be associated with a wide range of Pao_2 levels (Brockway and Hay, 1998), data indicate that a Spo_2 threshold of 93% or 94% can avoid most Pao_2 values >80 mm Hg (Bohnhorst et al, 2002; Castillo et al, 2008; Hay et al, 1989; Poets et al, 1993). On the other end, most Spo_2 values <80% or 85% are associated with Pao_2 <40 mm Hg. Thus, a moderate and stepwise increase in Fio_2 when Spo_2 decreases below this threshold can adequately correct hypoxemia and is unlikely to produce hyperoxemia unless the additional oxygen is excessive or prolonged unnecessarily. When Fio_2 is increased in response to a hypoxemia spell, Spo_2 should be continuously observed, and Fio_2 should be weaned as the spell ends.

Policies of oxygenation monitoring should clearly identify both intended range and the alarm limits of Spo_2. Although in many centers they coincide, these ranges serve different purposes. The intended range usually defines a prescribed basal level of oxygenation to be maintained by the staff, whereas the alarm limits usually define specific conditions that require immediate intervention.

In practice, the use of the low and high Spo_2 alarms differs. The low Spo_2 alarm, typically set between 85% and 88%, is generally used to detect acute hypoxemia. Setting Spo_2 alarms below these levels is often aimed at ensuring that the caregiver will respond only to the most severe events, thereby indirectly avoiding overuse of supplemental O_2. The high Spo_2 alarm is primarily used to avoid hyperoxemia and is typically set between 93% and 95%. The high Spo_2 alarm level is quite important because it has been shown to be closely linked to the actual mean Spo_2 observed in preterm infants receiving supplemental O_2 (Hagadorn et al, 2006).

Observational data have shown that preterm infants spend only half the time within the intended range of Spo_2, with the remaining 30% of the time above and 20% of the time below this range (Hagadorn et al, 2006; Laptook et al, 2006). Setting Spo_2 alarm limits within 2% of the intended range produces some improvement, but not strikingly so. Staff compliance to Spo_2 alarms plays an important role, with the prescribed high Spo_2 alarm level being frequently altered by the staff (Clucas et al, 2007). Insufficient staff education and communication can also influence the maintenance of Spo_2 within the intended range. However, a recent survey showed that only a third of the caregivers were aware of and could identify their center's oxygenation policies (Nghiem et al, 2008).

Policies for oxygen supplementation for preterm infants who reach term-corrected postmenstrual ages (e.g., 36 weeks) vary significantly between centers (Ellsbury et al, 2002). Centers with policies that target higher Spo_2 have greater proportions of infants on supplemental O_2, and many of those infants could be off O_2 if lower Spo_2 levels are tolerated or if their actual needs are frequently evaluated (Walsh et al, 2004). This is also the case during the discharge period as well as during home oxygen therapy.

Many preterm infants present with hypoxemia spells, and these are more frequent in infants with evolving chronic lung disease (Bolivar et al, 1995; Dimaguila et al, 1997; Garg et al, 1988). These spells often require a transient increase in Fio_2, but a delayed response can prolong the hypoxemia spell, whereas a delayed weaning of Fio_2 after hypoxemia ends can induce hyperoxemia. It is also evident that caregivers often tolerate or maintain high Spo_2 levels with the purpose of reducing the frequency of the spells or attenuating their severity (Claure et al, 2009, 2011). However, this is not truly effective and may actually increase the risk of ROP (McColm et al, 2004). Neonatal center policies should clearly define the response of the caregiver to these events to minimize both excessive and inadequate oxygenation.

Currently, automated systems to adjust the inspired oxygen for maintenance of Spo_2 within a set range are being developed and tested (Claure et al, 2001, 2009, 2011; Urschitz et al, 2004). Reports indicate improvements in terms of maintenance of an oxygenation range as well as reductions in hyperoxemia, exposure to supplemental O_2, and staff workload with these automated systems. Large trials are necessary to determine the effects of this form of Fio_2 control on short- and long-term neonatal outcomes. At the present time, most clinical effort is focused on avoiding the extreme high and low ranges of Spo_2. Forthcoming are the findings of multicenter trials being conducted to compare the effects of maintaining Spo_2 within different ranges in terms of ophthalmic, neurologic, and respiratory outcome. The information obtained from these trials will further refine the oxygen management strategies.

NONINVASIVE RESPIRATORY SUPPORT

Because of the severe complications associated with invasive mechanical ventilation, there has been a persistent search for less invasive alternatives to support infants with respiratory failure. This is especially relevant in the small preterm infant, who is more susceptible to acute complications and chronic pulmonary sequelae. Alternatives have ranged from transdermal oxygenation to lung volume maintenance by sternal traction. The strategies that have shown to be most clinically effective are nasal continuous positive airway pressure and, more recently, nasal intermittent positive pressure ventilation. These strategies can be used to support infants with respiratory failure in lieu of invasive mechanical ventilation.

NASAL CONTINUOUS POSITIVE AIRWAY PRESSURE

CPAP was introduced in 1971 by George Gregory to stabilize lung volume in preterm infants with respiratory distress syndrome (RDS) (Gregory et al, 1971). Initially, the constant pressure was delivered through a mask or head box and later was applied through nasal prongs. With the introduction of surfactant therapy, more infants were intubated and treated with mechanical ventilation, and the use of nasal CPAP declined for a period of several years; in the past decade, however, it has been reintroduced as a safer alternative to mechanical ventilation.

Physiologic Effects

Nasal CPAP (N-CPAP) prevents alveolar collapse and stabilizes functional residual capacity, thereby reducing pulmonary shunts and resulting in improved oxygenation.

N-CPAP also stabilizes large and small airways and can decrease the work of breathing and obstructive apnea episodes. By preventing alveolar closure and reopening with each breath, N-CPAP can also preserve surfactant.

Indications

Nasal CPAP is used primarily in infants with RDS who because of surfactant deficiency have decreased functional residual capacity (FRC). N-CPAP is also effective in the transition period immediately after birth while reabsorption of fetal lung fluid and establishment of FRC is occurring. N-CPAP is also effective in reducing apneic episodes and in stabilizing respiratory function after extubation (Locke et al, 1991; Martin et al, 1977; Miller et al, 1985). Nasal CPAP is also used in infants with increased pulmonary blood flow and pulmonary edema secondary to heart lesions with left-to-right shunting such as patent ductus arteriosus (PDA). Nasal CPAP can also be used effectively in infants with airway obstruction.

Devices for Nasal CPAP

Nasal CPAP has been applied using a variety of systems and devices. Most of the evidence suggests that best results are obtained using double short nasal prongs (De Paoli et al, 2002). The devices used to generate the pressure can be a water column such as the one used for "bubble CPAP" or an adjustable valve at the end of a continuous-flow system or a variable-flow system. Although there are data suggesting that some of these systems are superior to others, in clinical practice the stability and permeability of the nasal interface is probably the most important factor determining the success or failure of this form of respiratory support. Recently, nasal cannulas have been used as a method for generating nasal CPAP. The limitation of this method is that it is difficult to control and measure the actual pressures and inspired oxygen concentrations that are delivered to the infant because both depend on the gas flow and the leaks around the cannulas and through the mouth.

Clinical Application

As mentioned earlier, the major indication for N-CPAP use in preterm infants is RDS. There is considerable debate as to the ideal time to start N-CPAP and about the population of infants in which it should be used. In recent years most centers have used N-CPAP soon after birth in infants who have sufficient respiratory drive. The exceptions are infants who are depressed at birth or those who have severe respiratory failure and are intubated to administer surfactant. The success rate with this strategy depends on the maturity of the infant and the severity of the respiratory failure, but more than 50% of preterm infants who are not depressed at birth can be managed successfully with N-CPAP, avoiding the use of invasive ventilation (Ammari et al, 2005; Dani et al, 2004; Kamper and Ringsted, 1990; Reininger et al, 2005). The sooner N-CPAP is started, the better the results are in infants with RDS (Gittermann et al, 1997; Hegyi and Hiatt, 1981; Jonsson et al, 1997; Verder et al, 1999). It has been suggested that the early use of N-CPAP instead of invasive ventilation could lead to a reduction in the incidence of bronchopulmonary dysplasia (BPD). However, two large prospective randomized trials addressing this question did not show that early use of N-CPAP reduces BPD (Finer et al, 2010; Morley et al, 2008).

The other frequent indication for N-CPAP is to stabilize respiratory functions after weaning from mechanical ventilation and extubation (Andreasson et al, 1988; Engelke et al, 1982; Higgins et al, 1991). Although it is not clear whether the use of N-CPAP in this situation reduces the need for reintubation, it clearly prevents a deterioration of respiratory function (Davis and Henderson-Smart, 1999; Peake et al, 2005).

The other indication for N-CPAP is to reduce the incidence of apneic episodes in preterm infants, in which it has been shown to be very effective (Martin et al, 1977; Miller et al, 1985).

The levels of N-CPAP that are used in clinical practice range from 3 to 8 cm H_2O, but there are few data to justify a specific level. In practice, the level of N-CPAP used is determined by the severity of the lung disease, reflected by the inspired oxygen concentration and the degree of lung expansion in the chest radiograph. The more severe the disease is, the higher the level of N-CPAP that is used. As the respiratory condition improves and the oxygen requirement decreases the level of N-CPAP is reduced to 3 to 4 cm H_2O before removing the prongs.

Complications

The complications of N-CPAP can be related to the pressure that is applied or to the interface with the nose. The application of excessive pressure can cause overdistention and alveolar rupture with pulmonary interstitial emphysema and pneumothorax. It can also reduce venous return, increase pulmonary vascular resistance, and reduce cardiac output. Overdistention of the lung can also reduce compliance and induce hypoventilation.

When the nasal prongs are too large or are applied with too much pressure over the nasal septum, they can produce erosions or pressure necrosis that sometimes makes it impossible to continue the N-CPAP. Avoiding these complications and keeping the nasal prongs in place is a task that requires considerable time and skill. During N-CPAP there is a risk of gas being pushed into the stomach. A nasogastric catheter is often used to avoid accumulation of gas and gastric distention.

NONINVASIVE VENTILATION

Noninvasive forms of respiratory support have been introduced with the aim of avoiding the use of invasive ventilation in infants in respiratory failure. N-CPAP is effective in improving gas exchange by stabilizing lung volume and the airways. However, it is not fully effective in maintaining ventilation in infants with weak inspiratory effort and inconsistent respiratory drive.

Intermittent positive pressure ventilation via nasal devices was among the original forms of support used in preterm infants in respiratory failure (Llewellyn et al, 1970). Recently, it has been reintroduced in neonatal care for indications including respiratory distress and apnea and to facilitate weaning from invasive mechanical ventilation.

Devices for Noninvasive Ventilation

The devices used for neonatal noninvasive positive pressure ventilation consist of conventional time-cycled pressure-limited ventilators that utilize the same circuits and gas conditioning devices used for invasive ventilation, with the main difference being that in lieu of the endotracheal tube, positive pressure is applied through the same interfaces used for N-CPAP.

Noninvasive positive pressure can be delivered in the intermittent mandatory ventilation mode (N-IMV) where the positive pressure cycles are delivered at fixed intervals. In some ventilators, ventilator cycles can be synchronized to the neonate's inspiration to provide nasal synchronized IMV (N-SIMV). Synchronized noninvasive ventilation can also be provided in the assist/control (N-A/C) and pressure support (N-PSV) modes to assist every spontaneous inspiration.

The most commonly reported method for synchronization in noninvasive ventilation is the Graseby pressure capsule placed on the abdomen (Barrington et al, 2001; Bhandari et al, 2007; Friedlich et al, 1999; Khalaf et al, 2001). Mainstream flow sensors have been used for synchronization in noninvasive ventilation, but they are likely to require frequent sensitivity adjustments to avoid autocycling due to variable gas leaks around the interface and the mouth. This is particularly important during noninvasive A/C or PSV. Internal flow sensors are available in many new ventilators. However, data on their use in neonatal noninvasive ventilation are lacking, and it is unlikely that small infants are able to produce flows large enough to be detected by the internal sensors.

Devices that alternate between two levels of positive airway pressure (Bi-PAP) are also available. In these devices the increase in pressure is achieved by an increase in circulating flow instead of a valve. For this reason, in Bi-PAP the increase in pressure is small compared to that in conventional ventilators, and it is achieved over a relatively long time. Synchronization of the increase in airway pressure with the infant's inspiration using the Graseby capsule is available in some countries.

Another approach has been that of applying high-frequency ventilation nasally, but it is unclear what proportion of the oscillating pressure is transmitted to the infant's airways.

Clinical Application

In infants with apnea, the cycling positive pressure at the upper airway may produce an intermittent stimulus that prevents or attenuates the duration of breathing pauses of central origin. In infants with central apnea, resumption of breathing following ventilator cycles has been described, and the reduction of apnea in comparison to N-CPAP is more striking among infants with more frequent apnea spells (Bisceglia et al, 2007; Lin et al, 1998; Ryan et al, 1989).

Noninvasive ventilation can improve gas exchange and ventilation compared to N-CPAP in infants with respiratory insufficiency during the first hours after birth as well as during weaning from mechanical ventilation (Bisceglia et al, 2007; Moretti et al, 1999). In contrast, infants with mild respiratory distress who are stable on N-CPAP and are able to maintain adequate gas exchange only reduced their spontaneous breathing effort when receiving noninvasive ventilation (Aghai et al, 2006; Ali et al, 2007; Chang et al, 2011). In the preterm infant, the chest wall is excessively compliant, and the breathing effort is in part dissipated by an inward motion of the chest. Hence, the reduced breathing effort with noninvasive ventilation can also be explained by a reduction in chest distortion (Ali et al, 2007; Kiciman et al, 1998).

In spite of applying cycles of relatively small positive pressure, Bi-PAP can improve CO_2 elimination and oxygenation (Migliori et al, 2005) compared to N-CPAP. Noninvasive application of high-frequency ventilation was also shown to be useful as a rescue for avoidance of intubation in a group of infants failing N-CPAP (van der Hoeven et al, 1998).

In addition to the effects on apnea, ventilation, and breathing effort, it is possible that the increase in mean airway pressure during noninvasive ventilation can better maintain lung volume than N-CPAP alone. It is also possible that CO_2 removal is improved during noninvasive ventilation by clearance of exhaled gases from the upper airway.

The use of noninvasive ventilation to achieve a reduction in the need for intubation or the duration of invasive mechanical ventilation is aimed at reducing the associated

risks of lung injury. This is obviously more relevant in the smaller and more immature infants in whom N-CPAP more frequently fails. In infants with RDS, nasally delivered IMV has not consistently reduced the rate of intubation compared to N-CPAP (Kugelman et al, 2007; Meneses et al, 2011), but it has been shown to facilitate early extubation after surfactant administration (Bhandari et al, 2007). In some of these trials, noninvasive ventilation reduced BPD appreciably, but this was not a consistent finding. The possible beneficial effects of nasal ventilation during the initial respiratory failure still need to be confirmed.

During weaning from mechanical ventilation, adequate maintenance of lung volume is often achieved by N-CPAP. However, many infants fail because of insufficient ventilation resulting from central apnea, a weak respiratory pump, or poor lung mechanics due to the underlying lung disease. Noninvasive ventilation has consistently been shown to be an effective way to reduce extubation failure (Barrington et al, 2001; Friedlich et al, 1999; Khalaf et al, 2001; Moretti et al, 2008), mainly by reducing apnea and improving gas exchange. Smaller infants and those with poor lung function at extubation were more likely to benefit from nasal ventilation than larger infants or infants with better lung function (Khalaf et al, 2001).

Ventilator cycles delivered at fixed intervals can fall toward the end of spontaneous inspiration or during exhalation and disturb the infant's breathing pattern, whereas delivery of the ventilator cycle when the upper airway is patent may improve transmission of the pressure and reduce the risk of gas being pushed into the esophagus. Both nonsynchronized and synchronized modes of nasal ventilation have been shown to be more effective than N-CPAP, but data are lacking on the superiority of synchronization in terms of efficacy or safety. Data on the most effective mode, frequency, and duration of the cycle and, most importantly, peak pressures during noninvasive ventilation are also lacking. Until more data are available, a conservative approach with relatively low ventilator settings and in ranges near those used for intubated infants recovering from RDS or near extubation is recommended. This is particularly important in setting peak pressures, because V_T monitoring is not available during noninvasive ventilation.

Potential Drawbacks

The risks for gastrointestinal complications observed with N-CPAP may be greater during noninvasive ventilation because of the additional positive pressure. An earlier report indicated an increased rate of gastrointestinal complications (Garland et al, 1985), but more recent clinical trials have not confirmed this.

Because of the additional pressures, the risks for pneumothorax and pulmonary interstitial emphysema may also be increased. Although there are no data on these side effects, caution should be exercised and high peak pressures or ventilator rates should be avoided. The risks for nasal damage and obstruction often observed during N-CPAP are also present in noninvasive ventilation. Proper application and maintenance of the nasal interface and avoidance of excessive force on the nasal septum are important to avoid these complications.

INVASIVE MECHANICAL VENTILATION

Because of the high incidence of respiratory failure in the neonate, mechanical ventilation has been one of the main therapies responsible for the progress in neonatal critical care. This is especially relevant in the small preterm infant who, besides lung immaturity, has a soft chest wall and poor central respiratory drive, making the need for mechanical ventilation very common.

INDICATIONS

The decision to initiate invasive mechanical ventilation in the newborn is very important because of the serious complications associated with this mode of therapy and because in smaller infants, it is often difficult to wean them from respiratory support. There is considerable variation between different centers in the criteria used to initiate mechanical ventilation. Most often, this decision is based on the gestational age of the infant, the severity of the respiratory failure, and the disease process that is underlying the respiratory failure. This is also done considering the alternatives available to support the infant's respiratory function. The experience of the team and the outcomes of infants exposed to mechanical ventilation in each institution should also be an important consideration. In units with vast experience and good outcomes, ventilation may be used more liberally, whereas in units with limited experience and high rates of complications, other alternatives should be considered before embarking on invasive ventilation.

The initiation of mechanical ventilation is usually based on the clinical condition of the infant and the evaluation of arterial blood gases. In the preterm infant, mechanical ventilation is frequently started because of recurrent episodes of apnea and hypoxemia that require some intervention to recover. In more immature infants, ventilation is often begun in the delivery room because of severe respiratory depression and bradycardia not responsive to stimulation. The other common indication for mechanical ventilation is when levels of $Paco_2$ rise rapidly, indicating alveolar hypoventilation. Although there are no specific levels of $Paco_2$, most centers initiate mechanical ventilation when $Paco_2$ rises acutely above 55 to 65 mm Hg and the pH decreases below 7.25 to 7.20.

The introduction of positive pressure ventilation is associated with complications and seldom results in improved lung function. In fact, intermittent positive pressure ventilation (IPPV) frequently results in further deterioration in pulmonary function due to the negative effects of high inspired oxygen concentrations, ventilation-associated infections, and overdistention of the lung. The effectiveness of mechanical ventilation is primarily due to the support of the infant's failing respiratory pump and the reduction in the work of breathing. One exception to this is the infant with RDS in whom the positive airway pressure produces recruitment of distal air spaces with improvement in ventilation-perfusion matching and gas exchange.

In other instances, mechanical ventilation is started because of hypoxemia not responsive to continuous positive airway pressure. Although there are no set levels of Pao_2 or FIo_2 to start ventilation in preterm infants with

RDS, the initiation of mechanical ventilation is frequently associated with the decision to administer exogenous surfactant. The indications for surfactant vary between institutions, but there is good evidence that early administration of surfactant results in better outcomes, and therefore, in an infant with RDS, surfactant is usually given when the inspired oxygen concentration required to maintain acceptable O_2 saturation levels increases above 30% to 40%. If the infant has hypercapnia or clinical signs of significant distress and impending failure, ventilation may be started earlier. In many centers surfactant is given as prophylaxis to all infants below certain gestational age, usually 26 to 28 weeks. After the infant becomes more stable, he or she is extubated to nasal CPAP.

In full-term infants, the indication for mechanical ventilation is usually more conservative because these infants are better able to cope with increased work of breathing. The indication also varies depending on the underlying cause of the respiratory failure. For example, in an infant with respiratory failure due to a congenital diaphragmatic hernia, ventilation is usually started immediately after birth, whereas in an infant with a congenital pneumonia or meconium aspiration, a more conservative approach can be taken, and ventilation may not be started until there is evidence of rising $Paco_2$ and hypoxemia requiring inspired oxygen concentrations up to 40% to 60%. The clinical evaluation of the infant is critical in deciding whether invasive ventilation should be started.

INSPIRED GAS CONDITIONING

During normal breathing, inspired gas is heated and humidified in the nasal passages and airways. By the time it reaches the distal airways, it is fully saturated with water vapor at core body temperature, that is, 100% relative humidity at 37° C for an absolute humidity of 44 mg H_2O per liter of gas. The isothermal saturation point region in the respiratory tract, where inspired gas equilibrates with core body temperature and is fully saturated, is near the main bronchi. As inspiratory flow increases, this point moves distally into the airways.

The nose and airways function as heat and moisture exchangers. There, a portion of heat and water added to the inspired gas is recovered during exhalation, with the net loss depending on the temperature and relative humidity of the gas. This requires continuous replenishment of water to the aqueous mucosal layer by the airway epithelium and loss of heat. In contrast to ambient air at 22° C and 50% saturated (absolute humidity of 9. 7 mg H_2O per liter of gas) medical gases are typically colder (15° C or less) and dry (<2% relative humidity) and therefore require more heat energy and humidity. Hence, all forms of respiratory support where medical gases are used require conditioning of the inspired gas. This is a key component of mechanical ventilation because the endotracheal tube (ETT) bypasses the nose and upper airway.

Inadequate conditioning of the inspired gas can increase water and heat loss (Fonkalsrud et al, 1980). Exposure to dry and cold inspired gas can also produce inflammation of the airway epithelium and increase the risk of airway damage (Marfatia et al, 1975; Todd et al, 1991). Insufficient humidification can also affect the mucociliary transport system, reducing clearance of secretions, pathogens, and foreign particles as well as increase the risk of airway blockage by mucus plugs (Fonkalsrud et al, 1975). These effects are likely to be more striking in small infants, infants with impaired thermoregulation, and those who are fluid and energy limited. In small preterm infants, a few minutes of mechanical ventilation with inadequately conditioned gases can increase airway resistance and reduce lung compliance (Greenspan et al, 1991). Inadequate gas conditioning has also been associated with increased risk for air leaks and augmented need for O_2 (Tarnow-Mordi et al, 1989).

The standard method for conditioning of the inspired gases consists of a heater/humidifier (H/H) device and heated breathing circuits. Dry and cold medical gases are heated in the H/H chamber to 37° C to increase the water carrying capacity to 44 mg per liter of gas at 100% relative humidity. The gas travels through the ventilator circuit, where it is heated to 39° C to prevent condensation. The gas temperature decreases as it travels through the ETT, and gas is delivered at approximately 37° C and near 100% saturated at the distal end.

Many conditions can affect gas conditioning. Air temperature in an incubator or radiant warmer above the 39° C set point can inadvertently reduce heating at the ventilator circuit and result in condensation. To avoid this, the temperature probe can be insulated or place outside the incubator or radiant warmer. If gas heating at the ventilator circuit is not adequate, low ambient temperatures and low circulating gas flows can also produce condensation. In general, presence of water condensate in ventilator circuit and minimal consumption of the humidifier water indicate inadequate conditioning of the gas. Water condensation can occur in the ETT and connector when incubator temperature is low and result in water droplets being pushed into the airway.

Humidity of the inspired gas can also be increased by water nebulization. In contrast to the size of the water vapor molecules (0.0001 μm), the size of aerosolized water particles ranges between 0.5 and 5 μm, which can potentially transport virus or bacteria. Thus, water nebulization is not an efficient or safe method, particularly for prolonged use.

Gas conditioning is also recommended during nasal CPAP or nasal ventilation and oxygen head box or nasal cannula use because the nasal passages and airways may not achieve adequate conditioning of the cold and dry medical gases. These gases are typically heated to 32° C, but heating at or above room temperature may be sufficient. On the other hand, passing the gas through a water bath may not produce a sufficient gain in humidity because of the low water carrying capacity of cold gas. Thick and dry nasal mucus and airway secretions are observed when gas conditioning is insufficient. Lack of conditioning may also affect body temperature and water losses.

CONVENTIONAL POSITIVE PRESSURE VENTILATION

Principles

Neonatal positive pressure ventilation can be described in its basic form as the cycled application of two distinct levels of positive pressure at the infant's airway via an ETT.

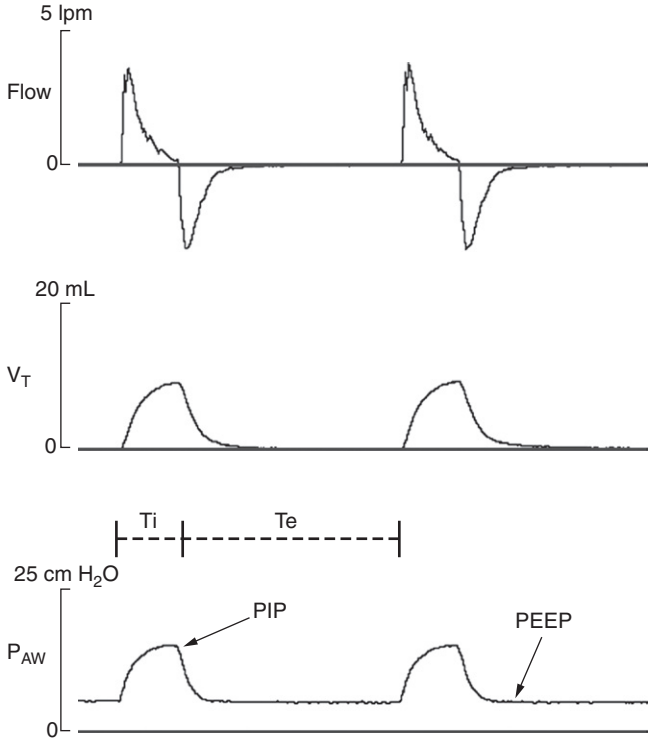

FIGURE 45-1 Time-cycled pressure-limited ventilation. In this example, recordings of flow, tidal volume *(V_T)*, and airway pressure *(P_{AW})* show that ventilator cycles, occurring at intervals determined by Te, increase P_{AW} from the PEEP level to PIP during the set Ti. The increase in pressure with respect to the alveolar pressure drives gas into the lung to achieve V_T. The inspiratory flow, which determines the rate of lung inflation, peaks initially and subsequently declines to zero as the lung is inflated.

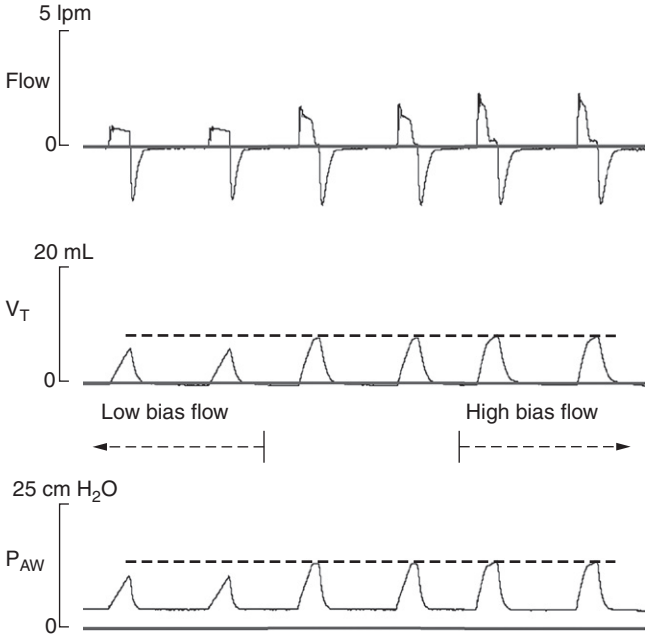

FIGURE 45-2 Effect of circulating bias flow. Recordings of flow, tidal volume *(V_T)* and airway pressure *(P_{AW})* show how increasing bias flow rates in the ventilator circuit change the profile of P_{AW} with a more rapid rise toward the peak pressure. This produces a higher peak flow that indicates faster lung inflation. An insufficient bias flow rate does not permit generating the desired peak pressure with each ventilator cycle and results in a smaller V_T.

The positive end-expiratory pressure (PEEP) provides a continuous distending pressure to the lung and is aimed at maintaining lung volume. This is important because the ETT bypasses the upper airway mechanism that normally prevents lung volume loss by active closure of the glottis. The positive pressure applied at the airway opening is intermittently increased to a predetermined peak inspiratory pressure (PIP) during a set inspiratory time (Ti). The rise in airway pressure produces a gradient with respect to the alveolar pressure that drives a tidal volume (V_T) of gas into the lung. This form of ventilation is known as time-cycled pressure-limited ventilation.

Neonatal ventilators utilize a constant flow of conditioned gas, also known as bias flow, through the breathing circuit to produce positive pressure. A controlled obstruction by a valve at the expiratory port of the ventilator produces PEEP, and the intermittent increase to PIP at intervals determined by the set expiratory time (Te) as shown in Figure 45-1.

The circulating gas flow determines the profile of the airway pressure by modulating the rise to the set PIP. The airway pressure rise is faster and PIP is reached earlier at higher circulating flow rates. A fraction of this bias flow is driven into the infant's airways during tidal inflation. The infant's inspiratory flow, which indicates how fast is the lung being inflated, is in part determined by the profile of the airway pressure. The rapid rise in airway pressure produces a rapid increase in the infant's inspiratory flow to a high peak inspiratory flow that decays as the lung is inflated. In this pattern of rapid lung inflation, most of the V_T is delivered early in the inspiratory phase, as shown in Figure 45-2. In contrast, a slow rising airway pressure produces a slower inflation and a smaller peak inspiratory flow. A low bias flow may not be sufficient to reach the set PIP within a fixed Ti and in consequence produce a smaller V_T, also shown in Figure 45-2. In most neonatal ventilators, the bias flow is constant during both the inspiratory and expiratory phases, whereas other ventilators self-adjust the flow necessary to produce a desired profile. In other ventilators, the caregiver can set a maximal flow to be delivered by the ventilator to the circuit during the cycle, which also modifies the airway pressure profile.

The bias flow should be sufficient to sustain the PEEP level when the infant's spontaneous respiratory flow demands increase. Otherwise, it may create an inspiratory load that the infant has to overcome with each breath. This is noted as a decline in PEEP during spontaneous inspiration toward zero pressure, or it can even become negative. The bias flow is also responsible for removal of exhaled gases, and an insufficient bias flow may cause rebreathing. On the other hand, a very high bias flow produces an almost square inspiratory airway pressure waveform that increases the velocity of lung inflation. This may have undesirable consequences because the lung will be expanded much faster than during a normal physiologic inflation. In general, circulating bias flow rates for ventilated preterm infants are set between 5 and 8 liters per minute, with higher circulating flow rate settings to accommodate gas leaks around the airway or the demands of larger neonates.

Respiratory System Mechanics during Positive Pressure Ventilation

The neonate's respiratory system mechanical properties (i.e., compliance and airway resistance) determine its time constant as their product. The respiratory time constant, which is a measure of the time to achieve equilibrium between the applied pressure and the alveolar pressure, varies with different lung diseases and their severity.

The compliance of the respiratory system (C_{RS}) is a measure of the recoil pressure that opposes expansion volume and is determined by the compliance of lung (C_L) and the chest wall. In the neonate, and most particularly in the preterm infant, C_{RS} is mainly determined by the compliance of lung because the chest wall is highly distensible. Lung diseases characterized by lung restriction, such as respiratory distress syndrome, where the increased lung recoil is indicated by a low C_{RS} and a short time constant, are quite prevalent in preterm infants. In addition, they have a respiratory pump that is often too weak to produce the pressure required to achieve an adequate V_T, and thus they require mechanical ventilation.

During positive pressure ventilation, a decreased C_{RS} is characterized by a smaller V_T for a given peak pressure and a relatively brief duration of inflation. As shown in Figure 45-3, the shorter time constant is illustrated by a shorter duration of inflation with an earlier return of the inspiratory flow to zero. This marks the point when the airway and alveolar pressures are at equilibrium. At this point, the PIP equals the lung's recoil pressure, with C_{RS} as the ratio between V_T and the applied pressure. When C_{RS} decreases, prolonging Ti is ineffective, and a higher PIP is required to maintain V_T constant.

The resistance of the airways opposes the flow of gas, which dissipates part of the driving pressure during lung inflation. In diseases characterized by increased airway resistance, this attenuates the infant's inspiratory flow and results in a slower inflation rate. The longer time constant indicates the increased time required for alveolar pressure to rise and equilibrate with the applied pressure. When airway resistance increases, the set Ti may not be long enough to achieve V_T, as shown in Figure 45-4. Although setting a longer Ti may be reasonable, this should be done cautiously because the increased airway resistance also attenuates the expiratory flow and prolongs the time required to achieve complete exhalation. A long Ti combined with a Te that does not allow complete exhalation will result in gas trapping.

Modes of Conventional Ventilation

Modes of conventional neonatal ventilation are generally classified according to the parameter controlled by the ventilator in each cycle as well as by the timing and duration of the cycle. Ventilator cycles can be pressure or volume controlled depending on whether the ventilator targets a set peak pressure or volume, respectively. Ventilator cycles can be delivered at fixed intervals regardless of the timing with respect to the infant's spontaneous breathing or they can be delivered in synchrony with the spontaneous inspiration. The duration of the inspiratory phase of each ventilator cycle can be constant or it can adapt to the time required to complete lung inflation, deliver the set volume, or to reach the end of spontaneous inspiration.

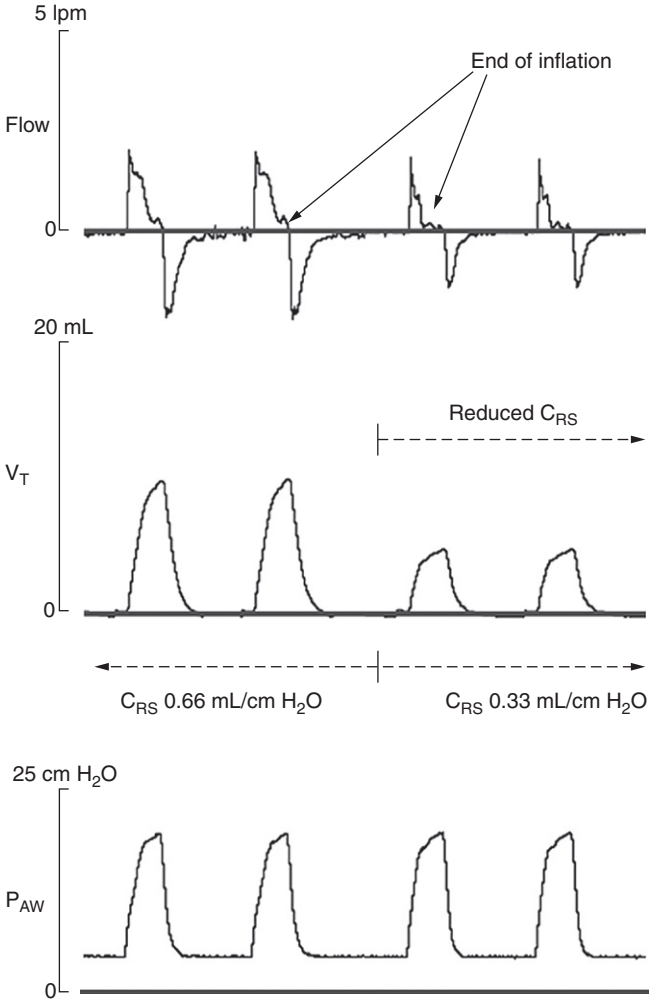

FIGURE 45-3 Effect of lung compliance. In this example, recordings of flow, tidal volume *(V_T)*, and airway pressure *(P_{AW})* show the effects of a decrease in lung compliance *(C_L)*. A reduction in C_L results in a proportional decrease in V_T for the same driving P_{AW}. The effect is also noted by a shorter time constant indicated by an earlier return of the inspiratory flow to zero marking the end of lung inflation.

Intermittent Mandatory Ventilation

The time-cycled pressure-limited (TCPL) ventilation mode described earlier and illustrated in Figure 45-1 has been most commonly known as intermittent mandatory ventilation (IMV). This mode can be classified as pressure controlled because ventilator cycles deliver the PIP set by the caregiver. These cycles are of constant inspiratory duration, that is, Ti, and are delivered at fixed intervals, that is, Te is determined by the set ventilator frequency. For many years IMV has been one of the most commonly used modes of neonatal ventilation during the acute as well as the more chronic phases of neonatal respiratory disease.

In IMV, the increase in airway pressure due to PIP in each ventilator cycle produces a given lung inflation during the set Ti. If Ti is too short, complete lung inflation may not be achieved, whereas a long Ti that maintains a pressure plateau does not achieve a larger V_T and instead

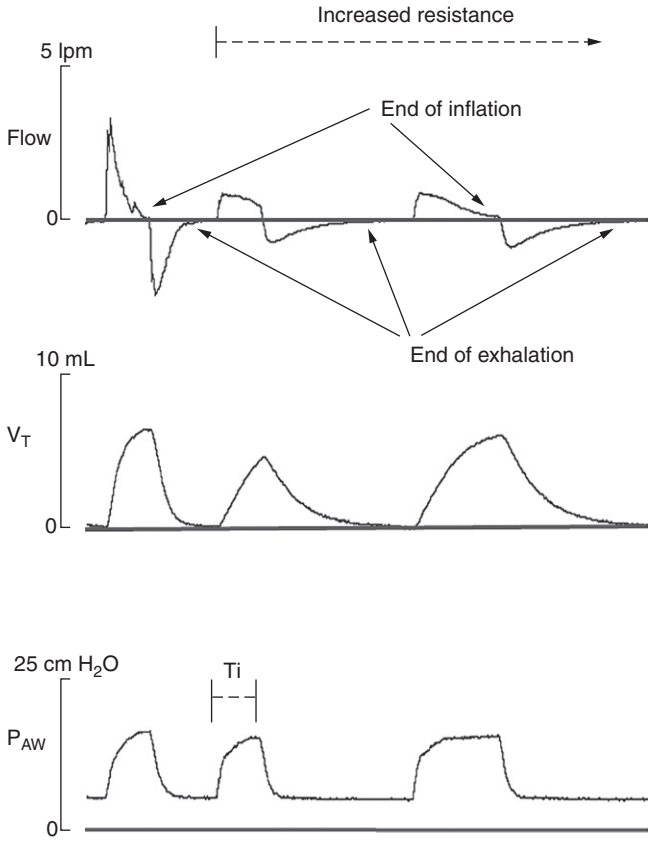

FIGURE 45-4 Effect of airway resistance. In this example, recordings of flow, tidal volume *(V_T)*, and airway pressure *(P_{AW})* show the effects of an increase in airway resistance. The increase in resistance results in a decrease in inspiratory flow that does not permit delivery of V_T in the set Ti. The prolonged time constant is noted by the increased time required to achieve full inflation and to complete exhalation.

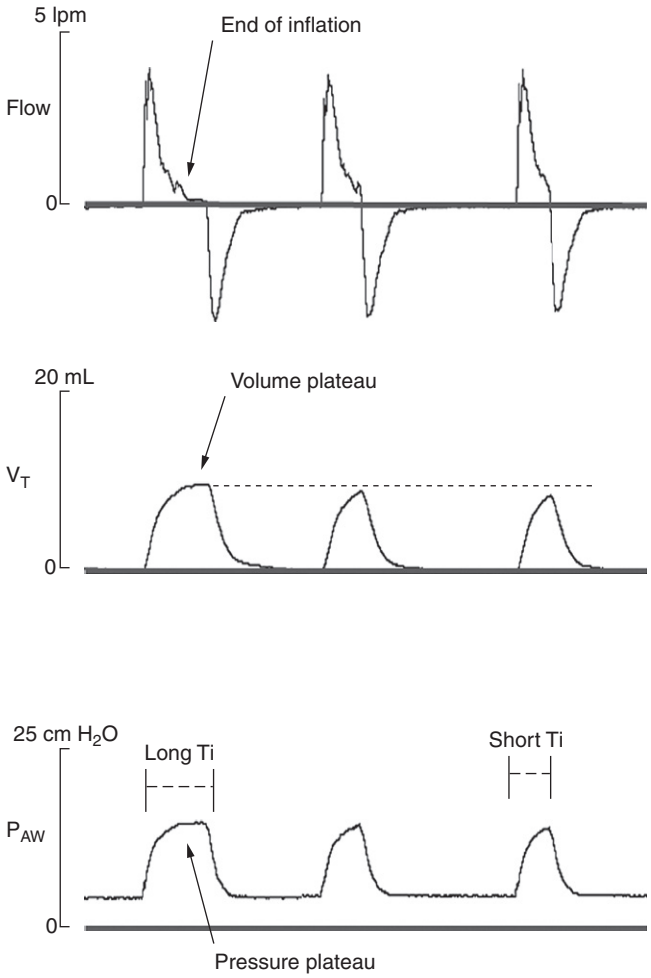

FIGURE 45-5 Inspiratory duration. Recordings of flow, tidal volume *(V_T)*, and airway pressure *(P_{AW})* illustrate the effects of inspiratory time *(Ti)*. A Ti that prolongs the inspiratory phase beyond the time needed to achieve inflation does not increase V_T and only keeps the lung expanded. A Ti of insufficient duration does not permit achieving full inflation, as indicated by an inspiratory flow that does not return to zero and leads to a decrease in V_T.

produces an inspiratory hold while the lung is kept inflated as illustrated in Figure 45-5. In infants with respiratory failure Ti is usually set in the range of 0.25 and 0.4 second. Caution should be exercised when setting ventilator cycles of longer Ti or high ventilator frequencies that could result in gas trapping due to an insufficient Te to allow full exhalation as shown in Figure 45-6. This is particularly important when the infant's time constant is long because of a high airway resistance or when the ventilator frequency results in Te <0. 5 seconds.

During IMV, total minute ventilation results from the ventilation produced by the ventilator and the contribution of the infant's spontaneous breathing effort. During clinical use, PIP is usually adjusted to maintain V_T between 3 and 5 mL/kg of body weight which is considered adequate for infants with lung disease. Ventilator frequency is adjusted depending on the infant's ability to contribute to minute ventilation and maintain sufficient gas exchange. $PaCO_2$ levels between 40 and 50 mm Hg are considered adequate, but higher levels are often accepted in infants with chronic ventilator dependency.

Although the management of IMV is relatively simple, there are some important limitations. With IMV, cycles are often delivered out of synchrony with the infant's inspiration (Greenough et al, 1983a, 1983b). Asynchronous ventilator cycles delivered toward the end of the infant's inspiration can prolong or increase lung inflation. IMV cycles delivered during the infant's exhalation can prolong its duration and in some cases elicit active exhalation against the positive pressure. Reports suggest associations between asynchrony and the occurrence of air leaks and intraventricular bleeding (Greenough and Morley, 1984; Greenough et al, 1984; Perlman et al, 1983, 1985; Stark et al, 1979). In older IMV ventilators, V_T cannot be measured, and PIP is adjusted based on the expansion of the chest, which does not permit determination of hypoventilation and gas trapping and assessment of spontaneous ventilation.

Synchronized Intermittent Mandatory Ventilation

Synchronized intermittent mandatory ventilation (SIMV) is for the most part similar to IMV except that ventilator cycles are delivered in synchrony with the onset of spontaneous inspiration. In SIMV, ventilator management is similar to that of IMV during the different phases of respiratory failure. SIMV was rapidly accepted and has become

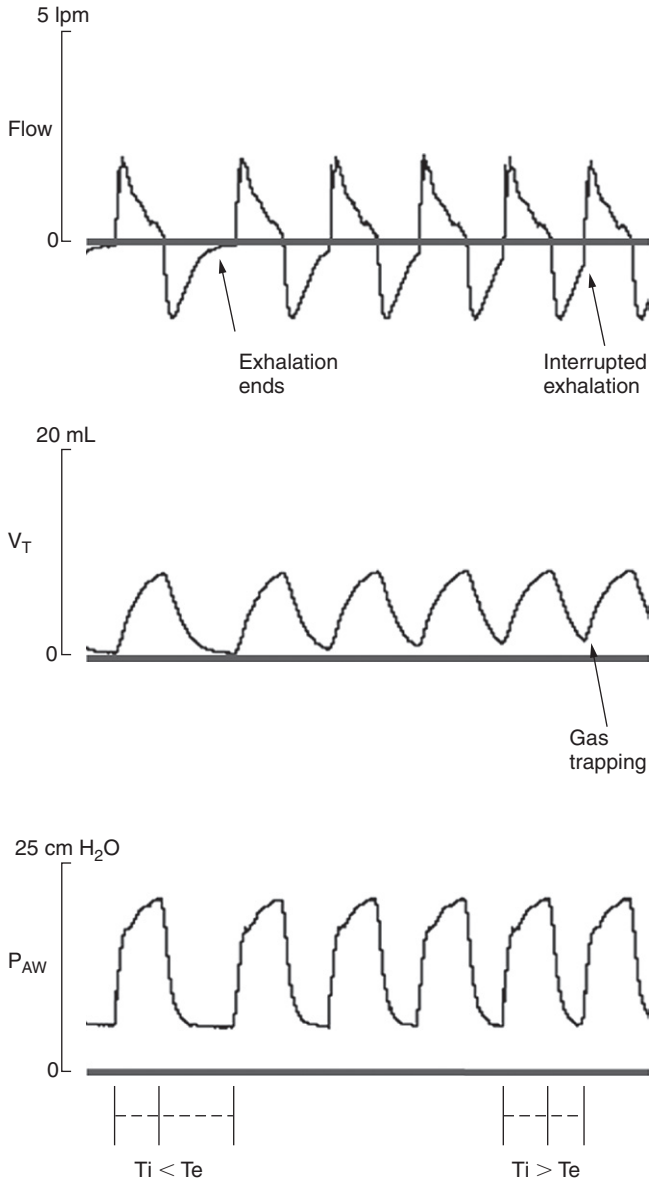

FIGURE 45-6 Gas trapping. Recordings of flow, tidal volume *(V_T)*, and airway pressure *(P_{AW})* illustrate the potential for gas trapping at high ventilator rates. As the ventilator rate increases, Te becomes insufficient to complete exhalation where every exhalation is interrupted by a new ventilator cycle. This produces a volume of gas trapped in the airways and alveoli and a reduction in V_T.

one of the most common modes of neonatal ventilation. During SIMV, spontaneous breathing is continuously monitored by the ventilator, and the first spontaneous inspiration during a time window of constant duration triggers a ventilator cycle. These time windows are opened consecutively, and their duration is similar to the interval between cycles in IMV. If no spontaneous inspiration is detected by the time the window elapses, a backup ventilator cycle is delivered. In this manner the number of ventilator cycles the infant receives every minute is the same as in IMV, but the interval between them is not constant.

Different techniques have been incorporated into neonatal ventilators to achieve synchronization, including the Graseby abdominal pressure capsule, esophageal balloons, transthoracic impedance, airway pressure changes, and flow sensors. The last are used by most neonatal ventilators for synchronization and V_T monitoring.

SIMV produces a greater and more consistent V_T in comparison to IMV because of the increased transpulmonary pressure in ventilator cycles that are in synchrony with spontaneous inspiration (Bernstein et al, 1994; Hummler et al, 1996). Thus, lower PIP and slightly shorter Ti are often sufficient because the infant's inspiratory effort contributes to generating the V_T. As lung disease subsides, the infant's lung mechanics improve, and spontaneous breathing effort becomes more consistent, PIP is gradually adjusted to maintain a V_T between 3 and 5 mL/Kg. During acute respiratory failure, a ventilator SIMV frequency ranging between 40 and 60 b/m is usually required to maintain $Paco_2$ between 40 and 50 mm Hg. At this frequency, SIMV is likely to assist almost all spontaneous breaths. During weaning, SIMV frequency is gradually reduced as spontaneous unassisted breathing can better maintain acceptable $Paco_2$ levels. In infants with chronic lung disease, $Paco_2$ levels between 50 and 65 mm Hg are often tolerated for weaning of the ventilator settings as long as respiratory acidosis is not observed. The relative advantages of SIMV in comparison to IMV include faster weaning and a shorter ventilator dependency with improved respiratory outcome in the smaller infants (Chen et al, 1997; Bernstein et al, 1996).

As the SIMV frequency is weaned, the spontaneous breathing effort must be able to sustain most of the ventilation, thus requiring a greater breathing effort. It has been suggested that the work of breathing in unassisted spontaneous breaths between SIMV cycles is counterproductive and can potentially lead to diaphragmatic fatigue. Conversely, it has also been suggested that exposure to fewer ventilator cycles may reduce the risk of lung injury and improve diaphragmatic fitness toward an eventual extubation. Failure to synchronize leads the ventilator to cycle at the backup IMV rate. Delayed cycling prolongs the duration of inspiration and can disrupt the breathing pattern (Beck et al, 2004), whereas autocycling produce asynchrony between ventilator and infant.

Assist-Control Ventilation

In A/C, every spontaneous inspiration is assisted by a synchronous ventilator cycle. If the ventilator does not detect spontaneous breaths because of either apnea or very shallow breathing, it provides an IMV rate with the same PIP as the assisted breaths. A/C can also be used during the acute and weaning phases of respiratory failure.

A/C is primarily managed by adjustment of PIP to maintain V_T within an adequate range. As the respiratory failure resolves with improving lung mechanics and stronger spontaneous breathing effort, PIP is gradually weaned as V_T remains within an acceptable range. In the more immature infants, the respiratory drive is not consistent, and such infants have frequent apnea. Thus, the "controlled" or backup IMV rate becomes more relevant in the maintenance of ventilation during apnea.

In infants with respiratory failure, the Ti required to achieve lung inflation usually ranges between 0.25 and 0.4 seconds. Longer Ti is not recommended because

of the potential for gas trapping with ventilator cycles delivered at the infant's often high breathing frequency. A long Ti can also disrupt spontaneous breathing (Beck et al, 2004; Dimitriou et al, 1998; Upton et al, 1990). Some ventilators provide flow cycling where Ti terminates at the end of the spontaneous inspiration or at the end of lung inflation. The advantages of A/C include a reduction in spontaneous breathing effort relative to IMV or SIMV because in contrast to these modes, A/C assists every inspiration (Bernstein et al, 1994; Kapasi et al, 2001). It has been suggested that assisting every spontaneous inspiration in A/C prevents diaphragmatic fatigue and can reduce the duration of weaning and ventilator dependency compared to IMV (Baumer, 2000; Beresford et al, 2000; Chan and Greenough, 1993; Donn et al, 1994). However, A/C has not been shown to be more effective than SIMV (Chan and Greenough, 1994; Dimitriou et al, 1995).

In A/C, PIP should be adjusted to avoid a large V_T that can produce hyperventilation, whereas the backup rate should be just sufficient to prevent hypoventilation during apnea. Autocycling is a problem in A/C because neonatal ventilators do not have a limit on cycling frequency and therefore can produce hyperventilation or gas trapping.

Pressure Support Ventilation

In PSV, the ventilator also provides a positive pressure breath with every spontaneous inspiratory effort. The start of the support pressure is in synchrony with the onset of the infant's inspiration and termination of the support pressure occurs toward the end of spontaneous inspiration or when lung inflation is completed, that is, flow cycling. The use of PSV is aimed at unloading the respiratory pump with support pressure that helps overcome the elastic and resistive loads imposed by the preterm infant's underlying lung disease. PSV can be used as a stand-alone mode with an IMV backup rate for apnea or in some ventilators as an adjunct to SIMV to assist the spontaneous breaths, whereas the SIMV cycles with a higher peak pressure are used to maintain lung volume.

Although PSV can be used during both the acute and weaning phases of respiratory failure, it is most commonly used during weaning. A consistent respiratory drive is required for the use of PSV as a stand-alone mode. For this reason, a backup IMV rate is recommended particularly in preterm infants to prevent hypoventilation. During PSV, gas leaks around the ETT can produce autocycling and extend the duration of the cycle. To avoid the risk of hyperventilation or gas trapping, trigger and termination sensitivity levels must be adjusted and limits on cycle duration must be set.

When PSV is used as an adjunct to SIMV, PSV can reduce the spontaneous breathing effort compared to SIMV alone even with support pressures set at a fraction of the peak pressures of the SIMV cycles (Gupta et al, 2009; Osorio et al, 2005; Patel et al, 2009). More importantly, by reducing the need for high SIMV rates, PSV can facilitate weaning in comparison to SIMV alone in preterm infants of birthweight (BW) less than 1000 g (Reyes et al, 2006). In that study PSV set at 30% to 50% of the peak pressure of the SIMV cycles were sufficient to maintain acceptable $Paco_2$ levels with significantly lower SIMV rates.

Volume-Targeted Ventilation

In volume-targeted ventilation, automatic adjustments to the peak positive pressure or the duration of ventilator cycle are done to maintain a target V_T. Volume targeted ventilation modes have been proposed as means to reduce ventilator-associated lung injury caused by ventilation with excessive or insufficient tidal volumes during conventional pressure-controlled ventilation. A number of volume-targeted modes are available in neonatal ventilators. These differ in the timing of the adjustment or in the duration of the mechanical cycle, that is, whether it occurs as the cycle is delivered to the infant or in the subsequent cycle. These modes also differ in the volume parameter that is controlled—whether it is the tidal volume received by the infant or the volume delivered by the ventilator to the circuit, and whether this is measured during the inspiratory phase or during exhalation.

Volume-Controlled Ventilation

In volume-controlled ventilation (VC), the ventilator delivers a set volume of gas into the ventilator circuit in each cycle. VC cycles are delivered in the IMV, SIMV, or A/C modes described earlier. The time required to deliver the set volume depends on the ventilator flow rate, which can be constant during the cycle or variable with an initial peak followed by a gradual decline. The flow continues until the set volume is delivered. The cycle ends before the set volume is delivered if its duration exceeds the set Ti or the airway pressure exceeds the set PIP. In small infants, most of the volume delivered by the ventilator is compressed in the circuit, and the actual V_T delivered to the infant is only a fraction. Some ventilators use algorithms to correct the measured volume by the compressed volume to estimate true V_T.

VC has been proposed as a strategy to facilitate weaning and reduce the complications of positive pressure ventilation. Clinical trials showed that compared to pressure limited ventilation in the A/C mode, VC reduced the weaning time and the duration of mechanical ventilation in infants weighing at least 1200 g at birth (Sinha et al, 1997). Weaning was also faster with VC in infants of birthweight <1000 g, but the total duration of mechanical ventilation did not change and respiratory outcome did not differ significantly (Singh et al, 2006).

Pressure-Regulated Volume-Controlled Ventilation

In pressure-regulated volume-controlled ventilation (PRVC), the peak pressure of pressure-controlled ventilator cycles is adjusted from one cycle to the next to maintain a target volume. The targeted volume can be that delivered by the ventilator or the actual estimated or measured V_T. During PRVC, gas leaks around the ETT can produce overestimation of volume during the inspiratory phase and consequently lead to inappropriate reductions in peak inspiratory pressure.

Compared to conventional IMV, PRVC in A/C mode was effective in reducing the duration of mechanical ventilation

and the incidence of intraventricular hemorrhage (IVH) in infants with RDS of BW <1000 g (Piotrowski et al, 1997). These advantages can be attributed, in addition to volume targeting, to synchronized delivery of PRVC cycles. These advantages were not evident when PRVC was compared to SIMV (D'Angio et al, 2005).

Volume Guarantee Ventilation

In volume guarantee ventilation (VG), the peak pressure of each ventilator cycle is adjusted to maintain a target V_T based on exhaled V_T measured in previous cycles. Measurement of exhaled V_T is aimed at circumventing the effects of gas leaks around the ETT during the inspiratory phase. VG can be used in combination with A/C, PSV, SIMV, or IMV modes.

VG was proposed as a potential alternative to avoid both extremes of V_T and to achieve a consistent weaning of peak pressure. The stability of V_T and gas exchange in infants with RDS can be improved by VG when combined with A/C or PSV as noted by fewer breaths with too small or large V_T and less hypocapnia (Abubakar and Keszler, 2001; Cheema et al, 2007; Herrera et al, 2002; Keszler and Abubakar, 2004). In infants with RDS or who had received surfactant, VG achieved the proper reduction in PIP, but this was dependent on setting a lower target V_T than the V_T attained with the pressure-controlled modes (Abd El-Moneim et al, 2005; Abubakar and Keszler, 2001; Cheema and Ahluwalia, 2001; Herrera et al, 2002; Nafday et al, 2005; Olsen et al, 2002). However, it must be noted that the smaller target V_T was in some cases not sufficient, resulting in increased Pco_2 and spontaneous breathing effort (Herrera et al, 2002).

VG was proposed as a means to attenuate hypoxemia spells triggered by hypoventilation during periods of agitation and decreased compliance in preterm infants. VG reduced the duration of the hypoxemia spells compared to SIMV, but only when the target V_T was increased which resulted in a considerable increase in airway pressure (Polimeni et al, 2006).

New and Experimental Modes

Proportional Assist Ventilation

In proportional assist ventilation (PAV), the ventilator pressure is increased in proportion to the measured volume, flow, or both generated by the infant's inspiratory effort. This achieves a perceived reduction of the elastic and resistive loads imposed by lung disease that commonly prevent the infant from producing an adequate V_T. The proportionality factors by which the positive pressure increases in relation to volume or flow are the elastic (volume proportional) and resistive (flow proportional) gains. The elastic and resistive gain factors must be individualized to each infant's lung compliance and airway resistance. Elastic gain factors that exceed the lung elastance (inverse of compliance) can lead to a runaway increase in pressure, whereas excessive resistive gain factors can produce oscillations in airway pressure. For this reason, PAV devices provide peak pressure and volume limits. Because PAV amplifies only the spontaneous breathing effort, a backup IMV rate is needed to prevent hypoventilation during apnea.

By compensating for the loads induced by lung disease, PAV reduced the breathing effort in infants recovering from RDS (Musante et al, 2001). Compared to conventional modes that deliver a constant pressure during inspiration, PAV produced similar ventilation with lower ventilator and transpulmonary pressures (Schulze et al, 1999, 2007).

Neurally Adjusted Ventilatory Assist

Neurally adjusted ventilatory assist (NAVA) is a mode where the ventilator pressure is adjusted in proportion to the electrical activity of the crural diaphragm measured by esophageal electrodes. NAVA was developed to improve the coupling of the infant's inspiration and the ventilator by overcoming conditions that delay or limit pneumatic triggering of the ventilator cycle. A study in preterm infants approaching extubation showed NAVA can produce comparable gas exchange with lower pressures than PSV, but no physiologic effects of the better synchrony, including breathing effort, were noted. This study showed the feasibility of noninvasive NAVA after extubation (Beck et al, 2009).

Data are lacking on the effects of different NAVA proportionality factors between diaphragmatic electrical activity and ventilator pressure within the same infant or between infants, because electrical activity of the diaphragm cannot be normalized. A backup ventilator rate is needed to prevent hypoventilation during apnea.

Targeted Minute Ventilation

Targeted minute ventilation (TMV) is an experimental mode where the ventilator rate is adjusted to maintain minute ventilation at a target level. If minute ventilation exceeds or decreases below the target level, the ventilator rate is reduced or increased, respectively. If spontaneous breathing can maintain a normal minute ventilation, the ventilator rate is reduced. In preterm infants recovering from RDS, TMV reduced the ventilator rate to half without impairing gas exchange compared to SIMV. Although these infants were able to sustain their ventilation for long periods, at times they required increased ventilator rates (Claure et al, 1997).

Mandatory minute ventilation (MMV) is a form of targeted minute ventilation where the ventilator rate is turned off when spontaneous breathing maintains ventilation. If minute ventilation falls below the target level, a constant ventilator rate of VC cycles is provided. In near-term infants ventilated for reasons other than lung disease, MMV weaned the rate and reduced the mean airway pressure compared to SIMV (Guthrie et al, 2005).

Adaptive backup ventilation is a form of backup support. In this mode, a ventilator rate is provided during apnea as well as during the occurrence of hypoxemia detected by Spo_2. In preterm infants recovering from RDS, this hybrid backup mode reduced the incidence and duration of hypoxemia spells compared to a backup ventilator rate for apnea alone (Herber-Jonat et al, 2006).

HIGH-FREQUENCY VENTILATION

Because of the association between pulmonary overdistention, lung injury, and the development of BPD, the possibility of achieving gas exchange with very small tidal

volumes has been of great interest to neonatologists for many years. This led to the development of instruments that can generate changes in airway pressure at rates in excess of 10 Hertz (600/min) with the aim of producing ventilation with very small tidal volumes, usually much smaller than the dead space.

Gas Transport during High-Frequency Ventilation

During conventional ventilation, gas exchange occurs by introducing of fresh gas into the distal airspaces with each inspiration. In contrast, during high-frequency ventilation (HFV), the volume of fresh gas delivered by each cycle is very small and does not reach the most distal portions of the lung. Therefore, different mechanisms must explain alveolar ventilation and gas exchange. These include bulk flow into the more proximal portions of the lung, enhanced mixing of gas within the conducting airways, and out-of-phase movement between different regions of the lung that have different time constants. There is also enhanced diffusion of gas in large and medium-sized airways due to asymmetrical velocity profiles during inspiration and expiration. Finally, there is molecular diffusion in the more distal air spaces that moves the different gas molecules from areas of higher to lower concentrations. These mechanisms have been mostly explored in adult lung models, and therefore it is not clear how well they apply to the immature or sick neonatal lung.

Devices for HFV

Several types of high-frequency (HF) ventilators have been used in the neonate, including jet ventilators, oscillators, and flow interrupters.

Jet ventilators generate a high-velocity gas flow that is injected through a small-diameter tube that opens into the airway connector. Expiration is passive, and the cycling rate is determined by an electrically operated valve that opens and closes the jet at a predetermined rate and timing. The high velocity of the gas injected into the airway produces a Venturi effect that pulls additional gas from the ventilator circuit. This is known as "gas entrainment." Tidal volume is determined primarily by the driving pressure of the gas, the inspiratory time, and the resistance of the injection port. Because expiration is passive during high-frequency jet ventilation (HFJV), there is a risk of gas trapping and lung overdistention (Bancalari et al, 1987). This risk is higher when the time constant of the respiratory system is increased by airway obstruction and when large tidal volumes are delivered. Because of this, jet ventilators are used at lower rates (4 to 10 Hz). Jet ventilators are used in combination with conventional ventilators that provide PEEP and may also provide conventional positive pressure cycles.

Oscillatory ventilators use a piston or a membrane driven by an electromagnetic force and connected to the ventilator circuit. The mean airway pressure is determined by the gas flow through the circuit and a variable resistance, whereas the tidal volume is generated by the size of the excursion of the piston or membrane. With these devices, the expiratory phase is active because during expiration, airway pressure falls below baseline. This reduces the risk of gas trapping. Flow interrupters are a hybrid between jets and oscillators. They produce airway pressure changes by interrupting the gas source at very high rates using a standard ventilator circuit rather than an injection cannula. They are relatively simple and are usually offered as an additional mode in conventional ventilators. Most do not have enough power to generate sufficient tidal volumes to effectively ventilate large infants or infants with very stiff lungs.

Clinical Experience

The indications for HFV vary widely among different centers. Although some use HFV routinely as a primary mode of support, most centers use HFV as rescue when conventional ventilation has failed. This includes preterm infants who require increasing ventilator settings to maintain Co_2 elimination and oxygenation within acceptable limits and those with evidence of pulmonary interstitial emphysema. In larger infants, HFV is also indicated in situations where conventional ventilation is not sufficient to maintain acceptable Co_2 elimination or oxygenation, and especially in infants with persistent pulmonary hypertension secondary to hypoplastic lungs due to congenital diaphragmatic hernia or oligohydramnios or to severe lung disease due to meconium aspiration or pneumonia.

HFV in RDS

The clinical results with the use of HFV in infants with RDS have been inconsistent. Whereas some studies have shown better outcomes such as increased survival with no BPD (Courtney et al, 2002), others have not shown differences (Johnson et al, 2002). Some studies have suggested a higher risk of air leaks (Thome et al, 1999), and others higher incidence of intracranial hemorrhage with HFV (HIFI Study Group, 1989; Moriette et al, 2001).

Many of the earlier studies were performed before exogenous surfactant was available, and therefore the results are not applicable to the present situation where most preterm infants are exposed to antenatal steroids and, when indicated, receive exogenous surfactant. A meta-analysis of the most recent trials suggests a possible advantage for HFV in the outcomes "BPD at 36 weeks" or "death or BPD" at 36 weeks corrected age. However, when the results were analyzed using adjustments for heterogeneity between trials, the beneficial effect disappeared (Thome et al, 2005). The results of this meta-analysis revealed a significant increase in the risk of air leaks and a trend for higher risk of IVH grades III and IV with HFV. When the results of HFV were compared with conventional ventilation, including only studies where HFV was used with high-volume strategies and conventional ventilation with an optimized low positive pressure and tidal volume strategy, there were no significant differences in any of the outcomes (Bollen et al, 2007; Thome et al, 2005). Because of the inconsistency of the results and the lack of solid evidence of benefits of HFV over conventional ventilation in infants with RDS, the selection of one modality over the other is mostly based on individual preference.

HFV in PPHN

The clinical evidence with the use of HFV in infants with PPHN is not solid and comes from a few, relatively small trials. Some of these studies suggested a decreased need for extracorporeal membrane oxygenation (ECMO) in infants with PPHN treated with HFV compared to those managed with IPPV (Clark et al, 1994). However, other studies have not shown clear advantage of HFV over conventional management (Kinsella et al, 1997; Rojas et al, 2005). HFV may offer some advantage over conventional ventilation in infants with hypoplastic lungs secondary to congenital diaphragmatic hernia (Desfrere et al, 2000).

Other Indications

HFV has also been used in infants with bronchopleural fistulas in an attempt to reduce the amount of gas leak into the pleural space (Gonzalez et al, 1987; Walsh and Carlo, 1989). It can also be used during bronchoscopy or during airway surgery because in contrast to conventional ventilation, it can produce adequate gas exchange with a partially open airway and large gas leaks (Nutman et al, 1989).

Side Effects of HFV

Because during HFV the tidal volumes are extremely small, when HFV is used in unstable lungs there is a possibility of progressive loss of lung volume and atelectasis. For this reason it is necessary to use mean airway pressures that are usually higher than those used during conventional IPPV. In fact there is evidence that during HFV the use of an open lung strategy utilizing recruiting maneuvers and high mean airway pressures produces better outcomes than utilizing lower pressures (Thome et al, 2005). As a result of these higher pressures, it is likely that HFV may negatively influence cardiovascular function (Osborn and Evans, 2003; Trindade et al, 1985; Truog and Standaert, 1985; Weiner et al, 1987) and may also explain the higher incidence of pneumothorax reported in some studies with HFV (Thome et al, 2005).

Because of the effectiveness of HFV in enhancing alveolar ventilation it is easy to drive $Paco_2$ to very low values within a very short period of time. For this reason it is important to monitor $Paco_2$ values closely, especially when HFV is initiated or when settings are changed. Because of the very short inspiratory and expiratory times, it is extremely important to maintain the airway as patent as possible, ensuring a correct position of the endotracheal tube. Any obstruction will produce a decrease in pressure transmission and in tidal volume and can lead to gas trapping. This is even more important with jet ventilation. During jet ventilation, it is also critical to ensure proper humidification of the inspired gas to prevent airway damage that can be produced by the high velocity of gas injected into the airway.

Ventilator Settings during HFV

The ventilator settings during HFV are simpler to adjust than with conventional ventilation. The mean airway pressure determines the lung volume and is adjusted to achieve better ventilation-perfusion ratio and oxygenation. This is done considering the severity and type of lung disease. Most infants with RDS are managed with mean airway pressures between 8 and 15 cm H_2O. Higher levels may be necessary in some cases with severe lung disease and poorly compliant lungs.

The tidal volume is determined by the delta pressure, and this, in combination with the frequency, determines the Co_2 elimination. In contrast to conventional ventilation, during HFV the tidal volume is reduced as the frequency increases because the shorter times for inspiration and expiration prevent the equilibration of pressures between the ventilator circuit and the distal portions of the lung. Therefore, during HFV a reduction in rate may result in larger tidal volumes, more Co_2 elimination, and lower $Paco_2$ levels.

During HF oscillation or with flow interrupters the frequencies used range from 8 to 15 Hz, whereas during jet ventilation lower frequencies between 4 and 10 Hz are used.

The pressure transmission to the distal airways is greatly influenced by the resistance of the tube and the airway, so only a small fraction of the delta pressure generated by the ventilator is transmitted to the terminal airspaces. For this reason, the delta pressure during HFV represents more of a relative value used to adjust the ventilator than the real pressure change in the distal airways.

WEANING FROM MECHANICAL VENTILATION

Weaning from IPPV is extremely difficult in very immature infants who have poor inconsistent respiratory drive, a weak respiratory pump, and immature and many times damaged lungs. This combination of factors explains why they frequently become ventilator dependent for long periods of time.

For many years, infants who were ventilated received most of their minute ventilation from the ventilator and were not allowed to have effective spontaneous ventilation. In recent years this has changed, and ventilators are used as an assist support, preserving the patient's respiratory drive and effort. This has been possible by the introduction of synchronized patient-triggered ventilation (PTV) and has resulted in better outcomes and shorter times on mechanical ventilation.

Because of the high rate of complications associated with prolonged mechanical ventilation, weaning should start as soon as respiratory function is stabilized. The order in which the different ventilator parameters are decreased is determined by the relative risk of complications associated with each of them. With the possibility of measuring V_T, it has become much simpler to define the appropriate PIP that is required to generate an adequate V_T of 3 to 5 mL/kg body weight. As lung compliance improves PIP can be reduced to keep V_T within this range.

The level of PEEP is usually kept between 4 and 8 cm H_2O depending on the type of underlying lung disease and the level of oxygenation and Fio_2 requirement. The PEEP level is decreased gradually as the oxygenation improves until a level of 4 to 5 cm H_2O is reached, and this level is maintained until extubation. The inspired oxygen concentration is adjusted according to the level of arterial oxygen

tension or O_2 saturation measured by pulse oximetry. The ideal ranges of oxygenation have not been defined, but most clinicians accept saturations between 88% and 95% in preterm infants and up to 98% in term infants. In infants with evidence of pulmonary hypertension, higher levels are targeted to prevent pulmonary vasoconstriction.

If V_T measurement is not available, the reduction in PIP is based on the observation of chest movement, the degree of aeration on chest radiograph, and $Paco_2$ levels. The ventilator rate is adjusted depending on the type of ventilation strategy being used. When the infant is ventilated with synchronized modes such as A/C or pressure support (PS), the infant determines the rate of the mechanical breaths so that the set rate is only the backup that the ventilator will provide when the infant's own rate falls below that level. Therefore, this rate is only relevant when the infant becomes apneic or hypoventilates. When the infant is controlled, the rate in the ventilator is not determined by the infant, and the adjustment in mechanical rate is based on the arterial Pco_2 level.

During weaning, it is advisable to do gradual changes and adjust one parameter at a time to evaluate the response of the infant to each change. With the availability of continuous oxygen and Co_2 monitoring, it is not always necessary to wait for results of arterial gas measurement to change ventilator settings, and the weaning can proceed faster.

Synchronized Patient-Triggered Ventilation

The use of patient-triggered synchronized ventilation has become common practice in neonatal units. Most randomized trials comparing PTV with nonsynchronized ventilation have shown reduction in the duration of mechanical ventilation in infants treated with synchronized modes (Greenough, 2001). This may be because, during PTV, the infant retains more control of ventilation, and the effectiveness of the mechanical and spontaneous breaths is enhanced by the summation of the ventilator positive pressure and the negative pressure generated by the respiratory muscles.

A/C and SIMV are the most common modes of synchronized ventilation in the neonate. It has been suggested that assisting each spontaneous inspiration in A/C may avoid respiratory muscle fatigue and facilitate weaning. However, the duration of weaning has not been consistently shorter with A/C than with SIMV (Beresford et al, 2000; Chan and Greenough, 1994). On the other hand, a randomized trial comparing the use of pressure support ventilation as an adjunct to SIMV to assist every spontaneous inspiration revealed a faster weaning and shorter duration of ventilation compared with SIMV alone in preterm infants (Reyes et al, 2006).

Volume Monitoring and Targeting

The continuous monitoring of V_T allows rapid weaning of PIP as the mechanical conditions of the lung improve. This can be achieved by a manual decrease of PIP as V_T increases, or automatically by using volume-targeted ventilation where weaning is achieved automatically independent of the clinician, who only sets the V_T targeted by the ventilator. Evidence from randomized trials using volume-targeting strategies suggest that faster weaning from mechanical ventilation can be achieved, although the results have not been entirely consistent (Singh et al, 2006; Sinha et al, 1997).

Nasal CPAP and Nasal Ventilation

After extubation, the infant is exposed to a number of mechanical impediments that explain the frequent need for reintubation in the smaller preterm infants. These include upper airway damage and retained secretions leading to obstruction and atelectasis, loss in lung volume due to poor respiratory effort, and a highly compliant chest wall. For these reasons, the use of continuous positive airway pressure applied through the nose can significantly reduce the deterioration that occurs frequently after extubation. Surprisingly, despite this improvement in respiratory function, the need for reintubation has not been consistently shown to be reduced by the use of N-CPAP after extubation (Davis and Henderson-Smart, 2003).

In contrast with N-CPAP, the use of nasal ventilation after extubation has been shown to significantly reduce extubation failure (Davis et al, 2001; De Paoli et al, 2003). Although these studies have included small numbers of infants, the effects have been consistent. This is a promising therapeutic alternative that needs further evaluation and the development of suitable equipment to provide synchronized noninvasive support.

Respiratory Stimulants

Respiratory stimulants such as aminophylline and caffeine have been shown to be effective to increase respiratory center activity in preterm infants and to decrease the incidence of severe apneic episodes. These drugs have also been shown to facilitate successful weaning from mechanical ventilation and decrease the need for reintubation. For this reason most preterm infants receive a loading dose of caffeine or aminophylline before extubation, and they are maintained on these stimulants at least during the first days after extubation while they are also maintained on N-CPAP or nasal ventilation (Henderson-Smart and Davis, 2003).

Permissive Hypercapnia

Tolerance of higher carbon dioxide levels may reduce the need for support and reduce the duration of ventilation. However, the results of clinical trials have been inconsistent. Whereas initial trials suggested faster weaning from mechanical ventilation in the group with higher Co_2 levels (Carlo et al, 2002; Mariani et al, 1999), a more recent study showed no benefit in duration of ventilation and a possible increase in mortality and central nervous system (CNS) impairment in infants with higher $Paco_2$ (Thome et al, 2006). Although these results shed doubt on the benefits of high Co_2 levels in premature infants during the acute stages of their clinical course, in infants with chronic lung disease it is necessary to tolerate high Co_2 levels to wean them from mechanical ventilation.

Dead Space Reduction

The large anatomical dead space in preterm infants in addition to the instrumental dead space can also delay weaning from mechanical ventilation (Figueras et al, 1997).

Continuous tracheal gas insufflations (CTGI) pumped through small capillaries to the distal end of the endotracheal tube to produce a continuous washout can reduce arterial CO_2 and shorten the weaning process (Dassieu et al, 2000). This method is limited by the need for special ventilators and endotracheal tube. Continuous washout of the flow sensor by a controlled gas leak can also improve CO_2 elimination and facilitate weaning (Claure et al, 2003; Estay et al, 2010).

Extubation from IMV versus Endotracheal CPAP

For many years infants on mechanical ventilation were extubated only after they had tolerated some time on CPAP via endotracheal tube. This practice was changed after a small, simple trial demonstrated that infants extubated from a low IMV rate had better success rates than those kept on CPAP for 6 hours before extubation (Kim and Boutwell, 1987).

Weaning from High-Frequency Ventilation

Infants ventilated with HFV are frequently switched to conventional ventilation before extubation. However, infants can be extubated directly from HFV following similar steps to those used to wean from conventional ventilation. The reduction in mean airway pressure (MAP) is done after oxygenation and lung expansion is estimated by chest radiographs while the F_{IO_2} is adjusted to maintain the desired oxygenation levels.

The oscillatory amplitude is gradually reduced in response to the levels of P_{aCO_2}. If the MAP is weaned to low levels before the infant has spontaneous respiratory effort, this can lead to hypoventilation, loss in lung volume, and atelectasis. For this reason, it is advisable to lower the delta pressure and allow the CO_2 to rise and stimulate spontaneous respiration before the MAP is lowered below 10 or 8 cm H_2O.

Prediction of Successful Extubation

It is difficult to decide the best time for extubation in ventilated infants. It is obvious that many infants remain intubated for longer than necessary. This is evidenced by the fact that many infants who are accidentally extubated tolerate it well without needing further respiratory support. Various tools have been evaluated to predict successful extubation. These include measurement of lung mechanics, minute ventilation, inspiratory effort strength and ability to cope with mechanical loads, and stability of respiratory pattern during periods when the ventilator cycling is stopped (Kamlin et al, 2006). Some of the tools have been shown to predict with some accuracy successful extubation, but these tests have not been widely accepted in neonatal clinical practice.

The decision to extubate an infant is usually based on the level of inspired oxygen and ventilator support that the infant is requiring to maintain acceptable arterial blood gas levels. In general terms, if an infant needs less than 30% to 40% oxygen, a ventilator rate less than 15 per minute, and peak airway pressures below 15 cm H_2O and keeps acceptable blood gases, most clinicians attempt extubation. The lower the gestational age, the more likely it is that the infant will not tolerate extubation and will require reintubation. In most cases this failure is because of poor respiratory effort or severe apneic episodes.

Automated and Computer-Assisted Weaning

In the targeted minute ventilation mode described earlier, the ventilator rate is automatically reduced during periods of consistent spontaneous breathing where minute ventilation is maintained at or above the target level. In a study of preterm infants recovering from RDS, this experimental mode reduced the ventilator SIMV rate set by the clinical team by half while arterial blood gases remained unchanged (Claure et al, 1997). A similar reduction in rate was observed in near-term infants without lung disease when supported by mandatory minute ventilation, a mode where the ventilator rate is turned off if minute ventilation exceeds a set level or delivers a set rate of volume-controlled breaths when minute ventilation decreases below this level (Guthrie et al, 2005).

Preterm infants often need supplemental O_2, which increases their risk for eye and lung injury, particularly when exposure to oxygen is prolonged. In these infants, hyperoxemia is induced by an excessive F_{IO_2}, and therefore it is modifiable by appropriate weaning. Automated weaning of supplemental oxygen was achieved by systems developed to adjust F_{IO_2} in a continuous manner. Systems of automated F_{IO_2} control have been shown to be as or more effective than routine or dedicated manual control in maintaining oxygenation within a desired range, with most of the improvement due to significant reductions in hyperoxemia (Claure et al, 2009, 2011).

Ventilator management involves adjustments of several parameters that affect the infant's ventilation and gas exchange. Computerized algorithms for ventilator management have been proposed to achieve efficient and consistent weaning. In infants with RDS, ventilator management assisted by one of these algorithms led to improvements in gas exchange and avoided unnecessary increases in ventilator settings (Carlo et al, 1986). Data indicated that during routine care, hypoxemia and hypercapnia were more diligently corrected than hyperoxia and hypocapnia, whereas computer-assisted management was similarly effective in correcting both extremes. The potential benefits of computer-assisted weaning on long-term outcome have not been explored.

ACUTE COMPLICATIONS OF RESPIRATORY SUPPORT

PULMONARY GAS LEAKS

Some of the most serious complications of mechanical ventilation are pulmonary gas leaks. These include pulmonary interstitial emphysema (PIE), pneumothorax, pneumomediastinum, pneumopericardium, pneumoperitoneum, and intravascular gas.

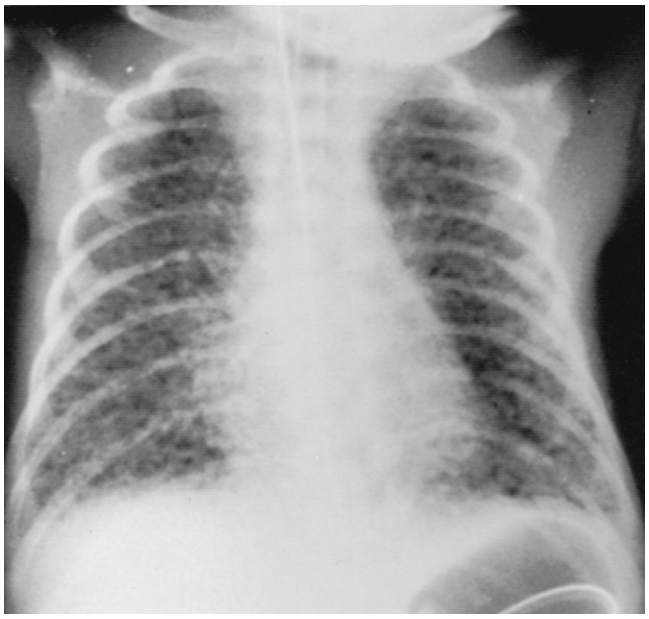

FIGURE 45-7 Pulmonary interstitial emphysema. A grossly hyperinflated lung with coarse radiolucencies extending from the pleura to the hilum. These radiolucencies represent gas bubbles in the perivascular and peribronchial interstitial cuffs.

Pulmonary Interstitial Emphysema

PIE is the result of rupture of air spaces from overdistention. Although it may be seen in infants breathing spontaneously it is much more common in preterm infants undergoing mechanical ventilation and in infants with evidence of pulmonary infection. Once alveolar rupture occurs, gas is forced from the air spaces into the connective tissue sheaths surrounding airways and vessels and into the interlobular septa containing pulmonary veins. The air follows a track along these sheaths to the hilum of the lung, producing the characteristic radiographic appearance of PIE (Figure 45-7). The PIE occupies space within the lung parenchyma, decreasing lung compliance. Gas trapped within the interstitial cuffs compresses airways and increases airway resistance. In addition, gas in the interstitial space impairs lymphatic drainage, increasing interstitial fluid. This leads to significant deterioration in gas exchange with increase in $Paco_2$ and decrease in Pao_2.

The main cause of PIE is airspace overdistention and rupture. Therefore, minimizing pulmonary overdistention should reduce the risk of PIE. Shorter inspiratory times also decrease the incidence of PIE by reducing overdistention and avoiding an inspiratory hold (Heicher et al, 1981; OCTAVE Study Group, 1991).

PIE is a serious complication of mechanical ventilation. Infants with PIE have a significantly increased risk of developing chronic lung disease as well as higher mortality rates (Gaylord et al, 1985; Powers and Clemens, 1993).

Management

Because the gas leak can behave like a check valve, gas trapping occurs, resulting in further alveolar overdistention and rupture. Therefore, the first step in treatment must be to interrupt this cycle by putting to rest the more severely involved areas in the lung. If PIE is unilateral, this can be accomplished by positioning the infant with the involved side down (Swingle et al, 1984). Mechanical ventilation using short inspiratory times (0.1 to 0.2 seconds), low inflation pressures, and small tidal volumes can reduce the gas leak (Meadow and Cheromcha, 1985). Unfortunately, it is difficult to maintain oxygenation and ventilation while using low volumes. A multicenter controlled trial found that HFJV allowed the use of lower peak and mean airway pressures in infants with PIE than did rapid-rate conventional ventilation and led to more rapid improvement in PIE (Keszler et al, 1991).

Pneumothorax

Pneumothorax can occur spontaneously in healthy infants because of the very high transpulmonary pressures produced at birth. However, the incidence is much higher in the presence of underlying lung disease and in infants exposed to mechanical ventilation. Pneumothorax develops in 5% to 10% of spontaneously breathing infants with hyaline membrane disease. Although positive pressure ventilation increases the risk dramatically, treatment with surfactant has markedly lowered this risk.

Pneumomediastinum occurs when gas tracks through the perivascular and peribronchial cuffs to the hilum and then ruptures into the mediastinum. From there, gas can rupture into the pleural space, producing a pneumothorax. If the leak is large, it produces a tension pneumothorax that collapses the lung and results in severe hypoxia and hypercapnia. In addition, by compressing mediastinal structures, venous return to the heart may be impeded, resulting in circulatory collapse.

Diagnosis

Because of the severe consequences of a tension pneumothorax, it is important to diagnose it as early as possible. In the spontaneous breathing infant, pneumothorax usually produces tachypnea, grunting, pallor, and cyanosis. The cardiac sounds may be shifted away from the side of the pneumothorax, and the affected hemithorax and abdomen may appear to be bulging. In the infant on positive pressure ventilation, signs are frequently more dramatic, with sudden onset of hypoxemia and cardiovascular collapse (Ogata et al, 1976). Transillumination of the chest is positive over the affected side, and the pneumothorax is confirmed by chest radiograph that shows gas in the pleural space and partial collapse of the lung with shift of the mediastinum to the opposite side (Figure 45-8).

Management

A small pneumothorax in a spontaneously breathing infant may be observed closely until spontaneous resolution occurs. Infants with larger symptomatic pneumothoraces and all infants receiving positive pressure ventilation require thoracostomy and pleural tube placement. The tube may be inserted at the midaxillary line and directed anteriorly, or placed in the second intercostal space in the midclavicular line and directed toward the diaphragm so that the tip lies between the lung and the anterior chest

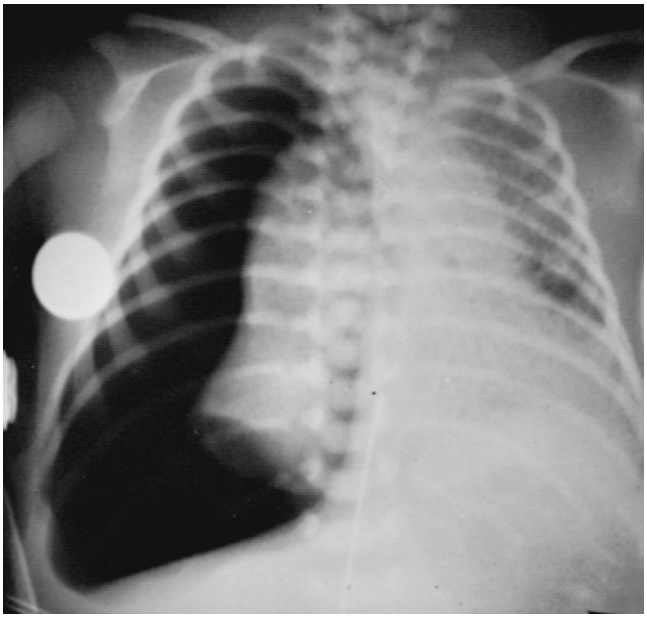

FIGURE 45-8 Tension pneumothorax. The lung on the involved side is collapsed, and the mediastinum is shifted to the opposite side, with bulging of the pleura into the intercostals spaces.

wall. When placing the tube, the operator must avoid puncturing the lung, especially when a trocar, rather than a curved hemostat, is used to direct the tube. It also is possible to drain pneumothoraces using pigtail catheters that are placed percutaneously into the pleural space. This technique produces less trauma but may not be effective when large gas leaks are present. The thoracostomy tube is connected to a water seal with 10 to 20 cm H_2O negative pressure and is left in place until it ceases to drain. The negative pressure should be discontinued, and the tube should be left under the water seal for 12 to 24 hours before removal.

Pneumopericardium

Pneumopericardium results from direct tracking of interstitial gas along the great vessels into the pericardial sac. Gas under tension in the pericardium impairs atrial and ventricular filling, decreases stroke volume, and ultimately decreases cardiac output and systemic blood pressure. Infants present with increasing cyanosis, decreased heart sounds, and decreased systemic blood pressure and pulse pressure. The chest radiograph is diagnostic, showing gas surrounding the cardiac silhouette (Figure 45-9). Needle aspiration alleviates the acute symptoms, but because recurrence rate is high, continuous tube drainage is necessary in most cases.

Pneumoperitoneum

Pneumoperitoneum results from dissection of air from the mediastinum along the sheaths of the aorta and vena cava into the peritoneal cavity. Infants with this condition present sudden abdominal distention and a typical abdominal radiograph. Occasionally, the pneumoperitoneum may be large enough to cause respiratory embarrassment by compromising descent of the diaphragm and may require drainage. This cause of peritoneal free gas must be distinguished from a primary gastrointestinal perforation.

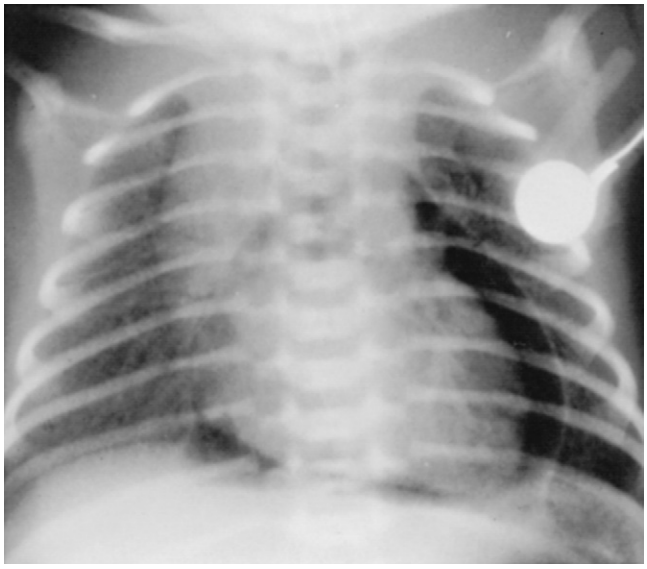

FIGURE 45-9 Pneumopericardium. A thin rim of pericardium is visible and clearly separated from the heart by gas within the pericardial sac.

Intravascular Gas

It has been suggested that the intravascular gas is pumped under high pressure through the pulmonary lymphatics into the systemic venous circulation (Booth et al, 1995). The intravascular gas results in immediate cardiovascular collapse and is often diagnosed when gas is seen in vessels or in the heart chambers when a chest radiograph is taken to determine the cause of cardiovascular collapse. Intravascular gas is usually a fatal complication.

AIRWAY COMPLICATIONS

Prolonged endotracheal intubation can produce airway damage and subglottic stenosis. The risk is increased by a too snugly fitting endotracheal tube, prolonged duration of intubation, and traumatic intubation. Some infants may require tracheostomy and even surgery to repair the stenosis. Inadequate humidification of the inspired gas can produce necrotizing tracheobronchitis, a necrotic inflammatory process involving the trachea and main bronchi. Infants present with acute respiratory deterioration due to airway obstruction, hyperexpansion on chest radiograph, and poor chest movement. Emergency bronchoscopy may be necessary to relieve airway obstruction.

Atelectasis frequently occurs during prolonged ventilation and after extubation from mechanical ventilation. This can also be secondary to airway injury due to trauma produced by suction catheters and by inadequate conditioning of the inspired gas.

VENTILATOR-ASSOCIATED PNEUMONIA

Ventilator-associated pneumonia is a very common complication of mechanical ventilation at any age, and it is likely to occur even more frequently in the

immune-compromised premature infant. Unfortunately, it is not commonly diagnosed in this population because of the lack of specific criteria and the difficulty of differentiating pneumonia from other acute and chronic pulmonary pathologies observed previously in infants requiring prolonged mechanical ventilation. Despite these limitations, it should be suspected any time there is deterioration in lung function with radiographic changes suggestive of pneumonia. Changes in the amount and quality of the secretions obtained from the airway and colonization with pathogens is another indication of possible pulmonary infection that may require antibiotic therapy. Some evidence indicates that a large proportion of ventilated premature infants have aspiration of gastric contents into their airways. This is more common in fed infants and those receiving methylxanthines (Farhath et al, 2006). The consequences of this are not clear, but this could further contribute to the risk of pulmonary infection and chronic lung damage.

CHAPTER 46

Respiratory Distress in the Preterm Infant

J. Craig Jackson

INTRODUCTION

This chapter on the causes of respiratory distress in the preterm infant will focus primarily on respiratory distress syndrome (RDS) also known as hyaline membrane disease and on surfactant replacement therapy. However, the chapter also includes discussion of two less frequent causes - pneumonia/sepsis and pulmonary hypoplasia. Other causes of respiratory distress that are more commonly seen in term infants, such as transient tachypnea of the newborn (TTNB), are discussed in Chapter 47. Table 46-1 lists causes of respiratory distress in newborns of all gestational ages and demonstrates the relative frequency of each diagnosis. This table provides a useful differential diagnosis for respiratory distress in preterm neonates, particularly if polycythemia and hypoglycemia are included. More than half of extremely low birthweight newborns will have some type of respiratory distress (Figure 46-1). In that population respiratory distress syndrome is by far the most common diagnosis (50.8%), followed by transient tachypnea of the newborn (4.3%) and pneumonia/sepsis (1.9%). In higher birthweight preterm newborns, the incidence of any type of respiratory distress is much lower, but in symptomatic babies, the incidence of RDS and pneumonia/sepsis is lower, whereas TTNB is more common. Compared to the three diagnoses featured in Figure 46-1, the incidence of other causes of respiratory distress (see Table 46-1) is very low in preterm infants. However, these less common diagnoses should be considered in preterm infants with respiratory distress who follow an atypical clinical course.

RESPIRATORY DISTRESS SYNDROME

RISK FACTORS

The main risk factor for RDS, by far, is prematurity (see Figure 46-1). Other factors that increase the risk of RDS include perinatal asphyxia, maternal diabetes, lack of labor, absence of antenatal steroid administration to the mother, male gender, and White race. The central feature of RDS is surfactant deficiency due to lung immaturity, commonly a result of premature birth or delayed lung maturation associated with maternal diabetes or male gender. Surfactant dysfunction can also be caused by perinatal asphyxia, pulmonary infection, or excessive fetal lung liquid due to delivery without labor.

PATHOPHYSIOLOGY OF RDS

Because alveoli with insufficient (or dysfunctional) surfactant are unstable and tend to collapse, patients with RDS develop generalized atelectasis, ventilation-perfusion mismatching, and subsequent hypoxemia and respiratory acidosis.

During breathing (either spontaneous or assisted), shear stresses in the alveoli and terminal bronchioles occur due to the repetitive reopening of collapsed alveoli and the overdistention of open alveoli (Nilsson et al, 1978). These forces can quickly damage the fragile lung architecture, leading to leakage of proteinaceous debris into the airways (i.e., hyaline membranes). This debris (Figure 46-2) may impair the function of what little surfactant is present, leading to a downward spiral that may end in respiratory failure and death if not interrupted.

If supportive therapy is successful, the repair phase begins during the 2nd day after birth with the appearance of macrophages and polymorphonuclear cells. Debris is phagocytosed and the damaged epithelium is regenerated. Edema fluid in the interstitium is mobilized into lymphatics, leading to the "diuretic" phase of RDS characterized by high urine output.

With uncomplicated RDS, the patient improves by the end of the first week after birth. However, infants born at <1250 g and larger newborns needing high concentrations of oxygen and positive-pressure ventilation for severe RDS may develop inflammation and inappropriate repair of the growing lung, leading to emphysema and fibrosis (see Chapter 48).

PURPOSE OF SURFACTANT

Surface tension is generated from molecular attractive forces within a liquid that oppose spreading; it is the reason that water 'beads up" on a clean surface. If you try to inflate a bubble under water with a straw (Figure 46-3, *A*), the

TABLE 46-1 Causes of Respiratory Distress

Respiratory distress syndrome	46%
Transient tachypnea of newborn	37%
Pneumonia/sepsis	5%
Meconium aspiration syndrome	2%
Congenital cardiac malformation	2%
Chromosomal disorder/multiple congenital anomalies	1.4%
Spontaneous pneumothorax	1.2%
Perinatal asphyxia	1.1%
Pulmonary hemorrhage	1.0%
Persistent pulmonary hypertension	0.8%
Diaphragmatic hernia	0.8%
Apnea of prematurity	0.6%
Pulmonary hypoplasia	0.3%
Pulmonary dysplasia	0.2%
Hydrothorax	0.2%
Postsurgical diaphragmatic palsy	0.2%
	100%

Data from Rubaltelli FF, Dani C, Reali MF, et al: Acute neonatal respiratory distress in Italy: a one-year prospective study, *Acta Paediatr* 87:1261-1268, 1998.

spreading of the water's surface and enlargement of its surface area will be opposed by its surface tension (T). According to Laplace's law, the pressure (P) required to inflate the bubble is proportional to T divided by the radius of the bubble (r). If you simultaneously try to inflate two interconnected bubbles, the smaller one will deflate into the larger one, because of its smaller radius (Figure 46-3, *B*).

Surfactants are surface active materials that lower surface tension; a detergent is a type of surfactant which causes water to spread out on a surface rather than beading up. The surface tension of clean water resists the creation of bubbles, but the addition of detergent allows bubbles to form. Because the surfactant properties of detergents do not persist, all of the small bubbles eventually collapse into the large ones, and finally even the large ones collapse.

Lung surfactant has the miraculous property of reducing surface tension as the size of the bubble decreases. In clean water with high surface tension, the pressure required to keep open a bubble as the radius decreased would be greater than the pressure keeping open a larger bubble, so the smaller bubbles would eventually collapse into larger ones (or small alveoli would collapse into larger

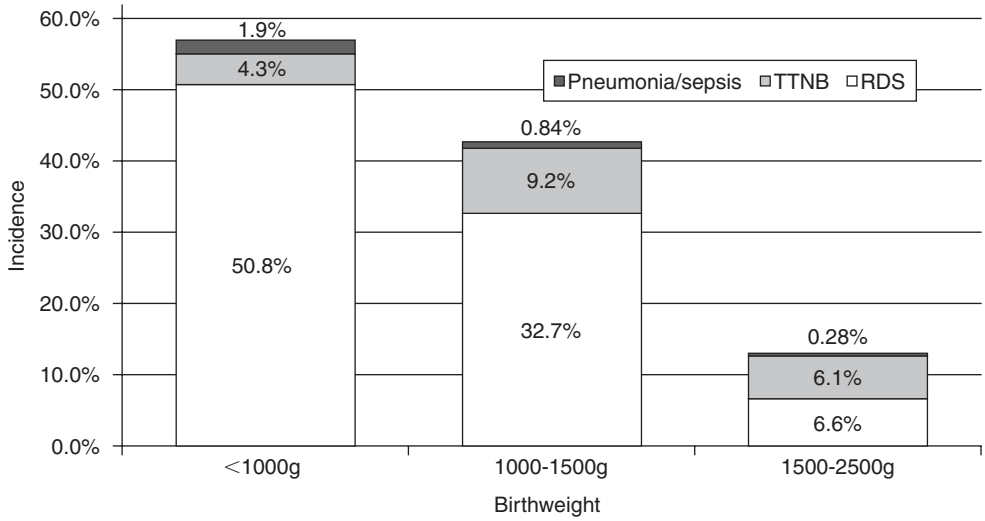

FIGURE 46-1 Incidence of respiratory problems in preterm newborns. (*Data from Rubaltelli FF, Dani C, Reali MF, et al: Acute neonatal respiratory distress in Italy: a one-year prospective study*, Acta Paediatr *87:1261-1268, 1998.*)

The alveolar debris forms hyaline membranes. **A,** Low power. **B,** Higher power. (*From Jackson JC, MacKenzie AP, Chi EY, et al: Mechanisms for reduced total lung capacity at birth during hyaline membrane disease in premature newborn monkeys*, Am Rev Respir Dis *142:413-419, 1990. American Thoracic Society.*)

ones), as shown in Figure 46-3, *B*. However, if the bubbles are lined with good-quality surfactant, the surface tension falls quickly as the radius gets smaller because the surfactant molecules become crowded during deflation (Figure 46-4). When the radius is very small, the surface tension falls almost to zero, and the pressure required to keep the smaller bubble open is negligible. Thus, it does not collapse.

During inflation, as the radius of the bubble increases, surface tension increases even faster. This means that the amount of pressure in the larger bubbles will be higher than in smaller ones; in the lung where bubbles are interconnected, this pressure difference will cause flow *to* the smaller alveoli, thus keeping all the alveoli about the same size.

The cumulative result of the alveoli remaining open during deflation is a nonlinear pressure-volume relationship. The lung with sufficient surfactant retains gas during expiration, compared to rapid and almost complete loss of gas in the surfactant-deficient lung (Figure 46-5, *A*). During inflation, more pressure is required to achieve similar tidal volume (Figure 46-5, *B*), because of poor compliance ($\Delta V/\Delta P$) from having to reopen collapsed alveoli. For instance, to achieve a tidal volume of 5 mL/kg, an infant with RDS may require a pressure increase of 25 cm H_2O; dividing the volume change, ΔV, by pressure change, ΔP, we calculate that the compliance is only 0.25 mL/kg/cm H_2O, which is about one third of normal.

In the absence of adequate amounts of functional surfactant in the newborn lung, there is widespread alveolar collapse with overdistention of open alveoli (Figure 46-6). Because reopening collapsed alveoli requires high pressure, the spontaneously breathing newborn with surfactant deficiency must generate highly negative intrathoracic pressure. Clinically, this is manifested by retractions of the respiratory muscles during inspiration. Newborns may also attempt to prevent alveolar collapse by grunting. This partial closure of the glottis during expiration helps maintain an end-expiratory pressure that may keep unstable alveoli open.

A consequence of widespread alveolar collapse is intrapulmonary shunting of blood past atelectatic lung, without the opportunity for blood in pulmonary capillaries to pick up oxygen from, or deliver carbon dioxide to, the alveoli. In addition, lungs that are poorly inflated have widespread collapse of pulmonary vessels, leading to pulmonary hypertension. The elevated pulmonary artery pressures lead to right-to-left shunting of unoxygenated

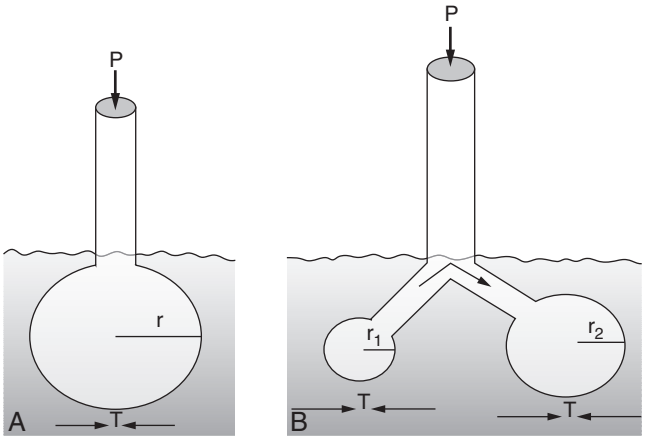

FIGURE 46-3 Effect of surface forces generated by inflating bubbles under water. A, Single bubble of radius *(r)* resists inflation and thus requires pressure *(P)* to overcome the surface tension *(T)*. **B,** If the surface tension is the same in two bubbles of unequal size, the smaller one will collapse into the larger one, because of the Laplace relationship, P = T/r (small r requires larger pressure to stay inflated).

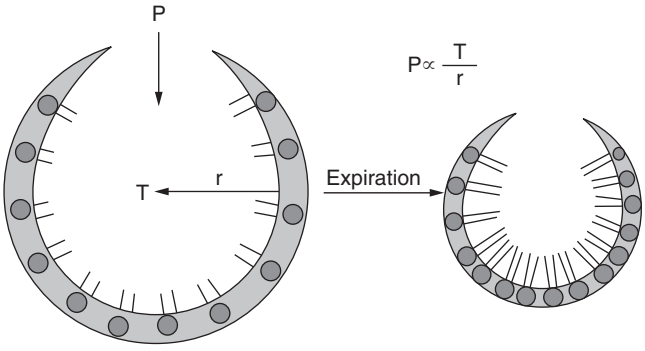

FIGURE 46-4 Surfactant molecules on surface crowding during deflation. (*From Jackson JC: Respiratory distress syndrome (figure 212–1). In: Osborn LM, DeWitt TG, First LR, Zenel JA, editors:* Pediatrics, *Philadelphia, 2005, Elsevier Mosby.*)

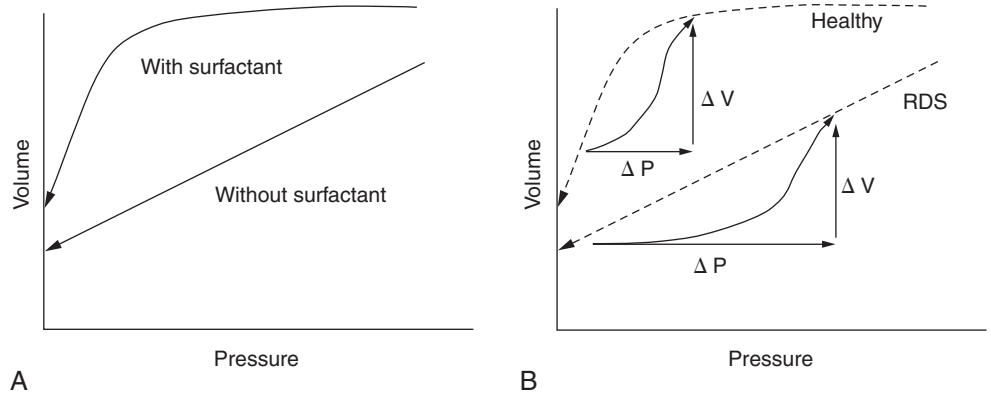

FIGURE 46-5 Effect of surface forces on pressure-volume relationships. During deflation **(A),** the lungs with surfactant retain gas even at very low pressures, because of falling surface tension as the alveoli get smaller. The alveoli without surfactant collapse as the alveoli get smaller. During inflation of RDS lungs **(B),** the starting lung volume (functional residual capacity) is lower, and much more pressure is required during inflation, compared to healthy lungs.

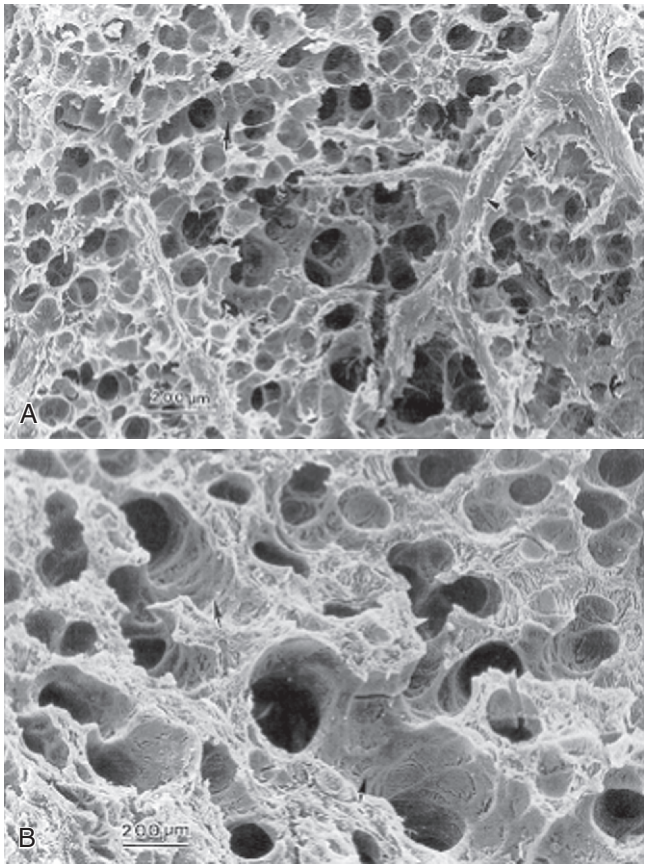

FIGURE 46-6 Histology of RDS. Scanning electron micrograph of lung frozen during inflation with air, in premature monkey healthy premature monkey **(A)** compared to one with RDS **(B).** Lungs affected by RDS have collapsed alveoli full of liquid and proteinaceous debris, with overdistended terminal airways. (*From Jackson JC, Truog WE, Standaert TA, et al: Effect of high-frequency ventilation on the development of alveolar edema in premature monkeys at risk for hyaline membrane disease*, Am Rev Respir Dis *143:865-871, 1991. American Thoracic Society.*)

blood across the patent ductus arteriosus to the descending aorta (see Chapter 52).

ORIGIN AND COMPOSITION OF SURFACTANT

Pulmonary surfactant is composed of approximately 90% lipids and 10% proteins. The main phospholipid in surfactant is dipalmitoylphosphatidylcholine (DPPC), also known as lecithin. It is surface active because of its hydrophilic head and hydrophobic tails (Figure 46-7). However, DPPC by itself does not adsorb efficiently at the air-liquid interface and is in the form of a gel at body temperature. The presence of some unsaturated phospholipids and cholesterol helps to make it more fluid (Mingarro et al, 2008).

The remainder of surfactant's ingredients is shown in Figure 46-8. One of them, phosphatidylglycerol (PG), is sometimes used as a marker of lung maturation; it interacts with the hydrophobic surfactant proteins to improve biophysical activity. Even minor components of pulmonary surfactant play important roles; for instance, free fatty acids improve the stability of the interfacial film, especially after repeated compression. The composition of surfactant is complex because it has evolved to balance the need

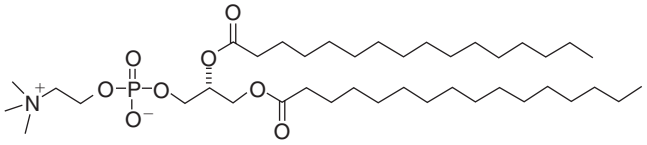

FIGURE 46-7 The main ingredient of lung surfactant, dipalmitoylphosphatidylcholine (DPPC).

for low viscosity for optimal spreading and redistribution along the smallest airways with the need for a stable and low surface tension.

Surfactant phospholipids are assembled in the type II pneumocytes of the lung epithelium into lamellar bodies in the form of bilayered membranes (Figure 46-9). Surfactant-associated proteins SP-B and SP-C are essential for the transition to a monolayer at the air-liquid interface. The molecular structure of the hydrophobic SP-B is complex and it interacts with the phospholipid monolayer as shown in Figure 46-10. Its absence is associated with fatal neonatal respiratory failure. Surfactant-associated proteins SP-A and SP-D are hydrophilic and have roles in immune defense. SP-A is involved in reuptake and reuse of secreted surfactant (see Chapter 42).

CLINICAL SIGNS OF RDS

The cardinal clinical signs of RDS are tachypnea, grunting, and increased work of breathing (Box 46-1). The newborn respiratory rate is elevated in an attempt to increase the exchange of oxygen and carbon dioxide, but with exhaustion, the rate may decline or even stop. Grunting is used to create positive pressure in the lungs to reduce the collapse of air sacs. Signs of increased work of breathing include nasal flaring and retraction of respiratory muscles, especially the intercostal and subcostal muscles. Because the ribcage in premature infants is so flexible, the sternum may deeply retract during inspiration. Cyanosis results from inadequate oxygenation, and pallor from acidosis due to poor elimination of carbon dioxide. The combination of increased work of breathing, cyanosis, and acidosis causes lethargy and disinterest in feeding, and eventually apnea. Rather than progressing through these signs during the first hours of life, newborns with intrapartum asphyxia or extreme prematurity may present with apnea immediately following birth.

On auscultation, breath sounds may be distant or shallow from the fast inspiratory rate and low tidal volume, and fine inspiratory rales may be heard due to reopening of moist, collapsed air sacs. The onset of symptoms is always within hours after birth and, in severe cases, may occur with the first few breaths after delivery. In general, the respiratory distress from RDS tends to get worse over the first 1 to 3 days after birth, and then usually improves gradually over a few days (although the natural course may be interrupted by exogenous surfactant therapy).

Differential Diagnosis

Clinical improvement during first 12 hours after birth suggests TTNB, and onset after the first 24 hours suggests pneumonia and sepsis. Tachypnea without increased work of breathing suggests cyanotic heart disease; the diagnosis of obstructed pulmonary veins from total

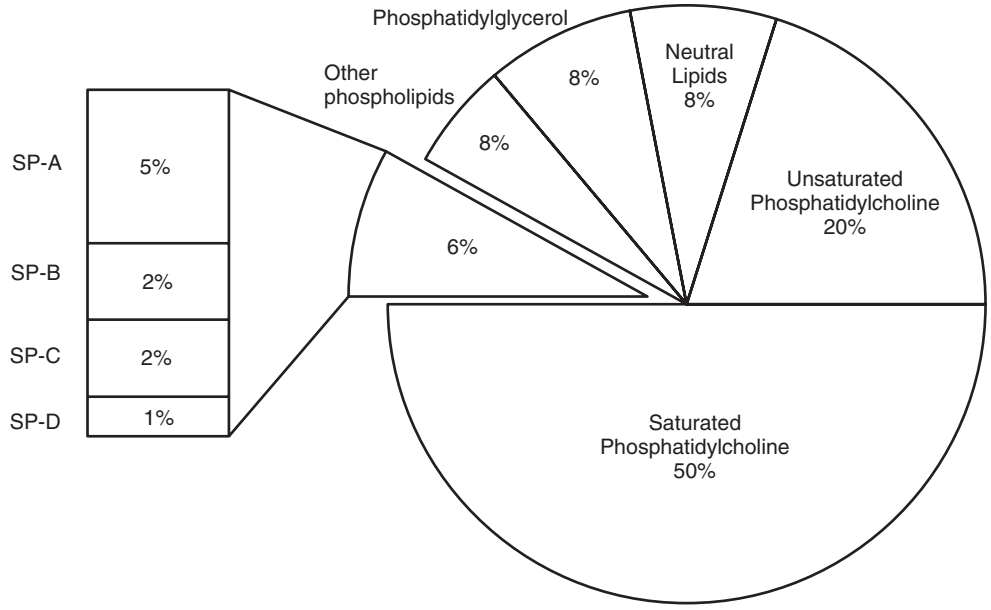

FIGURE 46-8 Composition of surfactant. (*From Jobe AH, Ikegami M: Biology of surfactant*, Clin Perinatol *28:655-669, 2001, WB Saunders.*)

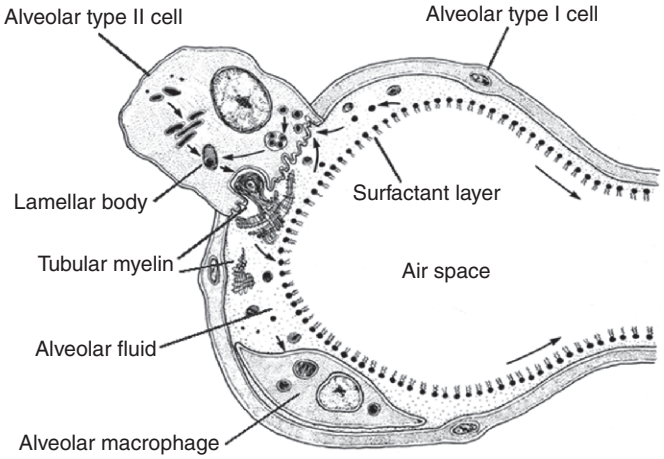

FIGURE 46-9 Assembly of surfactant. (*Republished and adapted from Hawgood S, Clements JA: Pulmonary surfactant and its apoproteins*, J Clin Invest *86:1-6, 1990. The American Society for Clinical Investigation.*)

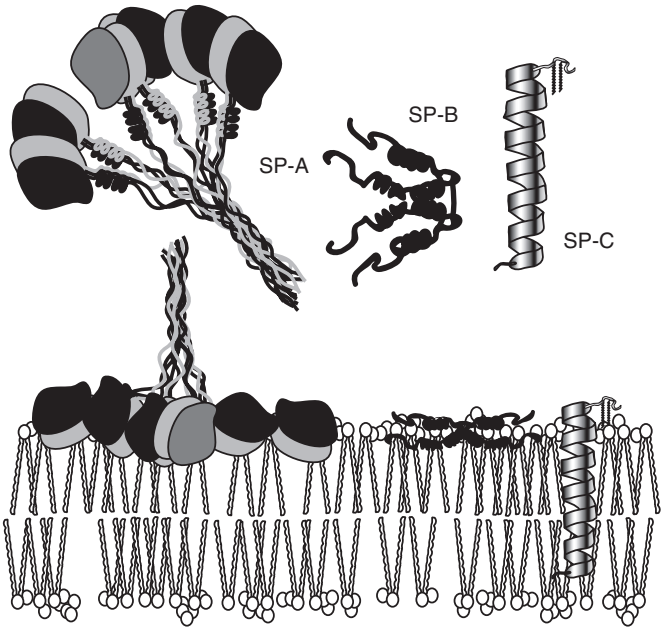

FIGURE 46-10 Structure and interactions of surfactant and proteins. (*From Pérez-Gil J: Molecular interactions in pulmonary surfactant films*, Biol Neonate *81:6-15, 2002. Karger AG Basel.*)

anomalous venous return is occasionally confused with RDS. Hypoventilation without increased work of breathing suggests a central nervous system problem such as intracranial hemorrhage or asphyxia. Asymmetric breath sounds may be due to pneumothorax (which is a complication of RDS), congenital diaphragmatic hernia, or unilateral pleural effusion. Meconium staining of amniotic fluid suggests the possibility of meconium aspiration syndrome, but this is rare in premature infants—green-stained amniotic fluid in this population is more likely to be due to infection or to bile refluxed into the esophagus because of intestinal obstruction, rather than meconium.

LABORATORY FEATURES OF RDS

Initially, the arterial blood gases or oxygen saturation monitor may show only hypoxemia or desaturation. The $Paco_2$ may be normal because of tachypnea, but is almost

BOX 46-1 Clinical Signs of RDS

- Tachypnea
- Grunting
- Increased work of breathing
  - Nasal flaring
  - Retraction of respiratory muscles (intercostal, subcostal, sternal)
- Cyanosis
- Pallor
- Lethargy
- Disinterest in feeding
- Apnea

always elevated. Later, as the infant tires, the $Paco_2$ will rise further and cause respiratory acidosis. With imminent respiratory failure, there may be metabolic acidosis due to inadequate oxygen delivery to tissues, and from poor peripheral perfusion due to respiratory acidosis.

Differential diagnosis: Extremely elevated $Paco_2$ within minutes of birth suggests pulmonary hypoplasia, tension pneumothorax, congenital diaphragmatic hernia, or obstruction of the airways due to debris or an anatomic cause. The tachypneic, cyanotic newborn with low $Paco_2$ may have transient tachypnea of the newborn or cyanotic congenital heart disease. A positive blood culture suggests pneumonia and sepsis. Low blood glucose (<40) suggests symptomatic hypoglycemia, and high hematocrit (>65) suggests symptomatic polycythemia.

RADIOGRAPHIC FEATURES OF RDS

The classic radiographic findings of RDS include a reticulogranular (i.e., ground-glass) pattern and air bronchograms (Figure 46-11). The lungs are diffusely and homogeneously dense because of widespread collapse of alveoli. The appearance is reticular (i.e., netlike) because the small airways are open (black) and surrounded by interstitial and alveolar fluid (white); in severe cases, the lungs may appear complete white on the film. Air bronchograms are commonly seen because the large airways beyond the second or third generation are more visible than usual as a result of radiodensity from engorged peribronchial lymphatics and fluid-filled or collapsed alveoli. Another cardinal feature is low lung volume (e.g., the diaphragms are at the eighth rib level or higher) due to widespread alveolar collapse and low functional residual capacity.

Differential diagnosis: Normal or high lung volumes, especially with prominent interstitial fluid pattern, suggest TTNB. In this case, there are coarse white lines (engorged lymphatics and interstitial water) radiating from the hilum rather than the crisp black lines (air bronchograms) of RDS. Other causes of a coarse (rather than diffuse) fluid pattern include pneumonia with sepsis, and obstructed pulmonary venous drainage due to total anomalous pulmonary venous return. An abnormal cardiac silhouette or size should suggest congenital heart disease, and asymmetry of the lungs suggests pneumothorax, congenital diaphragmatic hernia, or lung anomaly. Very low lung volumes, especially with pneumothorax, may indicate pulmonary hypoplasia.

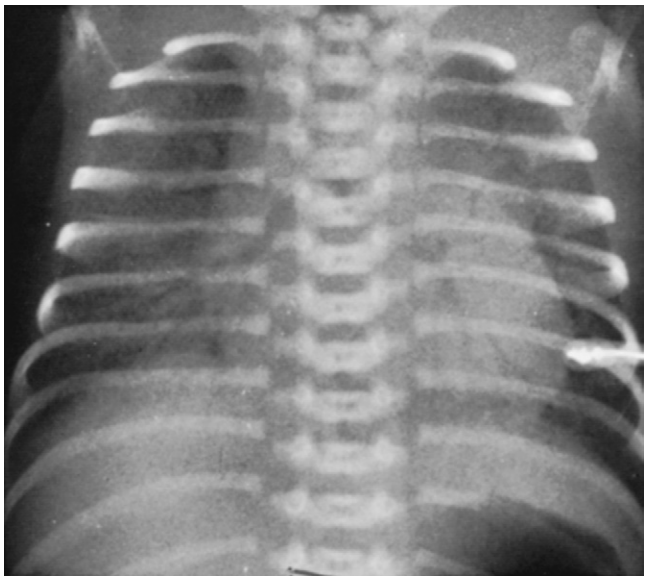

FIGURE 46-11 Radiograph of RDS. Note low lung volumes and reticulogranular pattern. (*From Welty S, Hansen TN, Corbet A: Respiratory distress in the preterm infant. In Taeusch HW, Ballard RA, Gleason CA, editors:* Avery's diseases of the newborn, *ed 8, Philadelphia, 2005, Elsevier.*)

INITIAL DIAGNOSTIC EVALUATION FOR POSSIBLE RDS

The initial diagnostic evaluation (Box 46-2) is shaped by the differential diagnoses listed in Table 46-1, and by the urgency to intervene quickly for serious but infrequent conditions such as bacterial pneumonia and sepsis, hypoglycemia, and polycythemia. It is often helpful to obtain both anteroposterior and lateral radiographs for the initial evaluation. If congenital heart disease is suspected on clinical grounds, an echocardiogram is indicated.

TREATMENT OF PATIENTS WITH RDS

The treatment of patients with RDS is outlined in Box 46-3. All patients with RDS need the basics of warmth, hydration, and nutrition appropriate for the degree of prematurity, as described in other chapters. Because pulmonary edema contributes to surfactant dysfunction in RDS, it is important to avoid excessive intravenous (IV) fluid administration.

Newborns with significant tachypnea (e.g., more than 60 breaths per minute) or increased work of breathing

BOX 46-2 Initial Diagnostic Evaluation for Possible RDS

- Arterial or capillary blood gas
- Blood glucose
- Complete blood count
- Blood culture
- AP and lateral chest radiograph
- Echocardiogram (if clinically indicated)

BOX 46-3 Treatment of Established RDS

- Warmth by radiant warmer or incubator
- Hydration at approximately 60–80 mL/kg/d
- Nutrition
  - Initially D5W or D10W (with protein, if possible)
  - NPO if respiratory rate over 60 or moderate/severe work of breathing
  - Gavage feeds if stable
  - Consider parenteral nutrition if enteral feeds are delayed
- Antibiotics if at risk for pneumonia and sepsis
- Supplemental oxygen
  - Oxygen saturation monitoring, with appropriate target for infants at risk for retinopathy of prematurity
- Exogenous surfactant
- CPAP or mechanical ventilation, as needed

CPAP, Continuous positive airway pressure.

(moderate or severe) often do not have the energy required for oral feeding, and there is some risk of aspiration if nipple feeding is attempted. Initially, IV fluids and nothing by mouth (NPO) status may be appropriate, with consideration of small gavage tube gastric feedings if the baby is otherwise stable. Parenteral nutrition may be indicated because of the increased caloric expenditures associated with work of breathing. Antibiotics should be considered unless the risk of pneumonia and sepsis is negligible.

The techniques of respiratory support are described in other chapters. See Chapter 45 regarding risks and benefits of different modes of respiratory therapy.

RESPIRATORY COMPLICATIONS OF RDS

Air leak complications occur in patients with RDS because of the asymmetry of alveolar inflation and the sheer stresses in terminal bronchioles, leading to dissection of air into the interstitium (causing pulmonary interstitial emphysema) and through the visceral pleura (causing pneumothorax). The former can be seen in up to 50% of patients with RDS, and the latter in 5% to 10%, even in those treated with exogenous surfactant.

Hemorrhagic pulmonary edema (i.e., pulmonary hemorrhage) occurs more frequently in the most premature infants, probably due to left ventricular failure and excessive left-to-right flow through a patent ductus arteriosus, with resultant disruption of the pulmonary capillaries (Cole et al, 1973). It may also be related to insufficient attention to reducing mechanical ventilator settings after lung compliance improves following exogenous surfactant treatment. Onset is typically at 1 to 3 days of age, with sudden respiratory deterioration associated with pink or red frothy fluid in the ET tube, and widespread white-out on chest radiograph. Treatment considerations include increased positive end-expiratory pressure (PEEP); there is also evidence that exogenous surfactant may be beneficial (Pandit et al, 1995).

Bronchopulmonary dysplasia (BPD), also known as chronic lung disease, is probably due to abnormal lung repair following lung injury from RDS (see Chapter 48).

PREVENTION OF RDS

Box 46-4 outlines the key measures for prevention and treatment of RDS.

Antenatal Steroids

Antenatal steroids were shown in 1972 to be effective in reducing the risk of RDS (Liggins and Howie, 1972). A consensus panel convened by the National Institutes of Health concluded that "antenatal corticosteroid therapy is indicated for women at risk of premature delivery with few exceptions and will result in a substantial decrease in neonatal morbidity and mortality, as well as substantial savings in health costs" (NIH Consensus Panel, 1995). They recommended that the treatment be used from 24 to 34 weeks' gestation without limitation by gender or race, and whether or not surfactant therapy was available. Although the beneficial effects were found to be greatest if treatment was begun more than 24 hours before delivery, there was also a benefit when given for less than 24 hours.

A metaanalysis in 2006 (Roberts and Dalziel, 2006) reviewed 21 published trials and concluded that antenatal corticosteroids did not increase a mother's risk of death, chorioamnionitis, or puerperal sepsis. Treatment was associated with a 31% reduction in neonatal death, 34% reduction in RDS, 46% reduction in cerebroventricular hemorrhage, and 54% reduction in necrotizing enterocolitis (all significant at $p < 0.05$ or less).

Although there is now widespread consensus on use of antenatal steroids, many issues remain controversial, including the type of corticosteroid to use; the dose, frequency, and timing of use; and the route of administration. A metaanalysis in 2008 (Brownfoot et al, 2008) reviewed 10 trials and found that antenatal dexamethasone appears to decrease the incidence of intraventricular hemorrhage but possibly increases the rate of NICU admissions, compared with betamethasone. Oral antenatal dexamethasone was found in one study to increase the incidence of neonatal sepsis compared to intramuscular drug (Egerman et al, 1998). More research is needed to optimize antenatal steroid administration.

Because the effectiveness appears to wane if antenatal steroids are given more than 1 week before premature delivery, several trials have been conducted to determine whether one or more repeat doses at weekly intervals was beneficial. Although a metaanalysis (Crowther and Harding, 2007) found modest improvements in occurrence and severity of RDS, there were concerning findings of smaller birthweight and head circumference, indicating that there is insufficient evidence to recommend repeated doses (Bonanno and Wapner, 2009).

Prevention of Asphyxia

Prevention of asphyxia may decrease the incidence and severity of RDS, because asphyxia leads to hypoxemia and acidosis, which reduce surfactant synthesis. Leakage of fluids from capillaries into alveoli may also impair surfactant function. Thus, delivery by cesarean section should be considered for signs of fetal distress if the fetus is deemed to be viable, or if the fetus is in the breech presentation during labor. Compliance with consensus neonatal resuscitation techniques outlined by the American Academy of Pediatrics and American Heart Association (Kattwinkel, 2006) is critical, especially because premature infants are at much higher risk for needing intervention at birth. Maternal transfer to a center experienced in management of premature infants, if it can be accomplished safely, is associated with improved neonatal outcome.

Antenatal steroids
Prevention of asphyxia
Continuous positive airway pressure
Exogenous surfactant
Surfactant, then CPAP

CPAP, Continuous positive airway pressure.

Continuous Positive Airway Pressure

Gregory et al (1971) first introduced continuous positive airway pressure (CPAP) for newborns with RDS, primarily by endotracheal tube. Since then, a variety of devices have been developed, including short nasal prongs that do not add much to the work of breathing (De Paoli et al, 2002). Avery et al (1987) reported that centers that used early nasal CPAP for RDS had a lower incidence of chronic lung disease.

The goals of CPAP are to prevent end-expiratory alveolar collapse, reduce the work of breathing, and better match ventilation to perfusion. If started in the delivery room, it may help the newborn establish functional residual capacity, in addition to stabilizing the chest wall and reducing airway resistance. Furthermore, adequate expansion of the lungs at birth improves pulmonary blood flow. Some have speculated that prophylactic use of CPAP in the delivery room might make intubation for exogenous surfactant unnecessary (De Klerk and De Klerk, 2001), and that avoidance of intubation and mechanical ventilation may lower the risk of BPD (see Chapter 48).

The COIN Trial randomized 25- to 28-weeks' gestation newborns who were breathing spontaneously at 5 minutes of age either to CPAP or to prophylactic intubation with early extubation to CPAP if possible. The investigators found that 46% of the CPAP group eventually required intubation anyway during the first 5 days, and the rate of pneumothorax was 9% compared to only 3% in those intubated routinely ($p < 0.001$) (Morley et al, 2008). This suggests that routine intubation may be safer than immediate CPAP in the extremely premature infant, but it also demonstrated that some patients in this extremely high-risk population do well with early CPAP. Success with CPAP, especially in this population, requires considerable experience and skill (Bohlin et al, 2008).

Recently, some centers have begun using humidified high-flow nasal cannulas in infants with RDS (Lampland, 2009) to achieve the benefits of positive airway pressure with fewer of the perceived disadvantages of CPAP (challenges in keeping the nasal prongs in the nares, easier handling of the patient, and less risk of pressure necrosis of the nasal septum). However, the pressure generated from this therapy, although proven to produce clinical effect, is variable, unpredictable, and unregulated, and the commercially available systems are not approved by the U.S. Food and Drug Administration (FDA) for this indication. It should only be used by practitioners aware of the balance of risks and benefits, and those prepared to recognize and treat pneumothorax and respiratory failure.

The use of CPAP following tracheal administration of exogenous surfactant is discussed later in the section on timing of surfactant administration.

Exogenous Surfactant

Historical Summary

The development of exogenous surfactant for treatment of RDS is one of the most important advances in the history of newborn medicine. This history is well told elsewhere (e.g., Halliday, 2008). The key milestones include von Neergaard's discovery in 1929 that surface tension contributes to lung recoil, Gruenwald's demonstration in 1947 that lungs of stillborn infants have high surface tension, Prattle's speculation in 1955 that absence of surfactant active material contributes to RDS, Clement's description in 1957 of surfactant dysfunction in experimental animals, and Avery and Mead's demonstration in 1959 that RDS in human infants is due to surfactant deficiency. There was an increase in research interest and funding for RDS treatment after U.S. President Kennedy's son, born at 34 weeks' gestation, died of RDS in 1963. In 1972, Enhorning and Robertson used natural surfactant to delay the progression of RDS in preterm rabbits, and in 1980 Fujiwara et al demonstrated the first successful use of exogenous surfactant in human infants. By 1990, exogenous surfactant was widely used throughout the developed world, and many large clinical trials have been conducted since then to refine and improve surfactant treatment and prevention of RDS. Compared to standard therapy without surfactant, a metaanalysis of 13 randomized controlled trials suggests that animal-derived exogenous surfactant reduces the risk of pneumothorax by 58%, pulmonary interstitial emphysema by 55%, mortality by 32%, and the combined outcome of BPD or death by 17% (Seger and Soll, 2009).

Types of Surfactant Available

A list of commonly used surfactant preparations can be found in Table 46-2. The first generation of commercially available artificial surfactants (e.g. Exosurf [colfosceril]) was composed mainly of DPPC and did not have SP-B or SP-C. However, a metaanalysis of 11 randomized controlled trials showed that natural surfactants were faster acting than artificial surfactants with lower incidence of pneumothorax and mortality (Soll and Blanco, 2001).

TABLE 46-2 Surfactant Preparations and Their Sources

Brand Name	Generic Name	Constituents
Nonprotein Synthetic Surfactants		
Adsurf	Pumactant (ALEC)	DPPC, PG
Exosurf	Colfosceril palmitate	DPPC
Protein-Containing Animal Surfactants		
Curosurf	Poractant α	Porcine lung tissue
Alveofact	SF-RI 1	Bovine lung lavage
BLES	Bovine lipid extract surfactant	Bovine lung lavage
Infasurf	Calactant CLSE	Bovine (calf) lung lavage
Surfacten	Surfactant-TA	Bovine lung homogenate
Survanta	Beractant	Bovine lung tissue
Peptide-Containing Synthetic Surfactants		
Venticute	rSP-C surfactant	DPPC, POPG, PA, rSP-C
Surfaxin	Lucinactant	DPPC, POPG, PA, KL4

Adapted from Sinha S, Moya F, Donn SM: Surfactant for respiratory distress syndrome: are there important clinical differences among preparations? *Curr Opin Pediatr* 19:150-154, 2007.
ALEC, Artificial lung-expanding compound; *DPPC*, dipalmitoylphosphatidylcholine; *PG*, phosphatidylglycerol; *rSP-C*, recombinant human SP-C; *POPG*, palmitoyl-oleoyl phosphatidylglycerol; *PA*, palmitic acid.

Clinical trials comparing the available natural surfactants have been inconclusive. Speer et al (1995) showed no differences in a small study, whereas Baroutis et al (2003) showed differences in days of intubation, oxygen use, and duration of hospitalization, but not survival. A comparison of Infasurf and Survanta by Bloom and Clark (2005) was stopped because of lack of statistical significance in the primary outcome variable. Ramanathan et al (2004) compared Curosurf and Survanta, finding that the former was less costly because of fewer doses, but there were no important clinical differences in outcome.

A new generation of synthetic surfactants is under development to lower cost and because of theoretical concerns about immunologic or infectious complications from animal-derived surfactant. These new products have synthetic peptides or proteins, such as KL4 in lucinactant, which mimics the actions of natural surfactant-associated proteins SP-B and SP-C. Lucinactant has been shown to be superior to older synthetic surfactants (Sinha et al, 2005), but its superiority to animal surfactants has not been conclusively proven (Moya et al, 2005). In addition, there are uncertainties regarding the metabolic fate of lucinactant and its component chemicals, and there may be risks from the requirement to convert the lucinactant gel into liquid by using a special warming cradle immediately before instillation (Engle et al, 2008); the authors added that "efforts to develop more effective and safer surfactant formulations continue to be warranted because of concerns with animal-derived surfactants for transmission of microbes, exposure to animal proteins and inflammatory mediators, susceptibility to inactivation, and inconsistent content."

Surfactant Selection

The important issue for clinical providers and managers is which surfactant to stock in their pharmacy, because of the expense of the preparations and the need to standardize dosing guidelines. Compared to first-generation synthetic surfactants, current studies strongly support use of natural surfactants because of reduced risk of air leak and more rapid response to treatment. Among natural surfactants that are commercially available, no differences in long-term outcomes have been conclusively proven. However, poractant alfa (Curosurf) when given as prophylaxis with an initial dose of 200 mg/kg appears to have some advantages when compared to beractant (Survanta) and calfactant (Infasurf), such as fewer repeat doses, quicker oxygen weaning, and potentially less cost. The benefit may be related to the larger amount of phospholipid in each dose. For hospitals currently using beractant and calfactant, the advantages of poractant alfa must be considered in light of the logistical issues and potential drug errors when a hospital changes from one preparation to another, especially when there may be better products on the horizon.

Timing of Surfactant Administration

In theory, surfactant would ideally be given with the first breath. This concept was evaluated by Kattwinkel et al (2004) by delivering the head of the infant, suctioning the nasopharynx, and then instilling calfactant into the airway before delivery of the shoulders. CPAP was initiated immediately after delivery, but the trachea was not routinely intubated. The treatment appeared feasible and safe, but the sample size (23) was too small to prove that the approach was beneficial compared to surfactant instillation via endotracheal tube during the first minutes after delivery.

Prophylactic surfactant generally refers to the administration of doses within the first 15 minutes after birth. To avoid giving an unnecessary, expensive medication and subjecting a newborn to the risks of tracheal intubation, prophylactic endotracheal surfactant should ideally be given only to patients who would have eventually developed RDS and met treatment criteria for surfactant anyway. However, in practice, the clinician can only select those patients at highest risk and for whom clinical trials indicate that the benefits of prophylactic surfactant outweigh the risks. One such population is the baby born at <30 weeks' gestation whose mother was not given antenatal steroids (Table 46-3). In the highest risk populations, a metaanalysis of eight clinical trials suggests that prophylactic surfactant reduces mortality (by 39%), frequency and severity of RDS, pneumothorax (by 38%), and the combined outcome of BPD and death, compared to infants who received placebo or rescue surfactant (Soll and Morley, 2001). However, the criteria for selecting the high risk infants remain controversial. Table 46-3 provides one practical approach for the clinician who must make a decision in the delivery room as to whether to begin surfactant immediately or to wait. However, some centers manage even 25-week gestational newborns with initial CPAP, with only one third eventually needing surfactant (Aly et al, 2004). A randomized study of 27 to 31 weeks' gestation newborns with signs of early RDS demonstrated that infants intubated for surfactant during the first hour of life followed immediately by extubation and CPAP had a lower rate of subsequent ventilation, incidence of pneumothorax, and chronic lung disease compared to newborns treated with early CPAP alone (Rojas, 2009). This observation may be especially important for hospitals not equipped to provide mechanical ventilation for this population.

Early rescue surfactant (usually defined as treatment at 1 to 2 hours after birth) may be indicated for infants of <30 weeks' gestation at the first signs of RDS. The clinical trials showing superiority of prophylactic surfactant over rescue (Soll and Morley, 2001) compared prophylaxis to *late* rescue (needing mechanical ventilation and >40% Fio_2 and typically treated 4 to 6 hours after birth).

TABLE 46-3 Sample Algorithm for When to Begin Exogenous Surfactant

When to Give First Dose of Surfactant	Populations to Consider
Prophylactically, within 15 minutes after birth	<26 weeks' gestation *and* 26 to 30 weeks if (a) no antenatal steroids *or* (b) needs intubation anyway
Early rescue, preferably in first 60 minutes after birth	<30 weeks' gestation at first signs of RDS
Treatment of established RDS, preferably started within 12 hours after birth	All newborns with established RDS, regardless of gestational age, if they need ventilator and at least 30–40% O_2

One clinical trial showed clinical advantages of prophylactic compared to early-rescue surfactant (Kattwinkel et al, 1993) but a historically controlled study showed that aggressive use of CPAP led to a large reduction in the need for any surfactant at all and was associated with lower rates of BPD and other morbidity (De Klerk and De Klerk, 2001). Furthermore, immediate intubation in the delivery room may be associated with significant procedure morbidity, including apnea and bradycardia. Thus, there is no compelling evidence favoring prophylactic over early rescue surfactant for preterm infants at the time of this writing, except in those patients at highest risk (see Table 46-3) such as extremely preterm infants whose mothers did not receive antenatal steroids (Sweet and Halliday, 2009).

Late rescue surfactant: Clinical trials have firmly established the benefits of surfactant compared to no surfactant in preterm infants with established RDS (Engle et al, 2008). However, as noted previously, prophylactic or early rescue surfactant is more beneficial than late rescue in the highest-risk populations. In lower-risk populations (e.g., near-term infants) it is likely that the late rescue approach offers a better balance of benefit, risk of intubation, and cost efficiency than treatment before or at the earliest onset of RDS. Entry criteria in clinical trials of rescue surfactant compared to no surfactant usually required that RDS be severe enough to require mechanical ventilation and at least 30 to 40% supplemental oxygen. Many of the trials were conducted before nasal CPAP was widely used, so the indications for intubating and administering surfactant in infants tolerating CPAP are unknown. However, those with a requirement for very high concentration of supplemental oxygen (e.g., >80%) or with sustained severe hypercarbia (e.g., $Paco_2$ >60 torr) will likely benefit.

Combining surfactant therapy with CPAP: Because of advances in use of CPAP since the first clinical trials of surfactant, some have advocated immediate extubation to CPAP after surfactant dosing (Verder et al, 1999) to avoid complications from the endotracheal tube (including excessive tidal volumes and airway inflammation that may lead to BPD). Stevens et al (2007) reviewed six randomized controlled clinical trials of this treatment approach in infants with clinical signs of RDS. The "early rescue/CPAP" group was intubated for early surfactant therapy followed by immediate extubation to nasal CPAP. In comparison to the late rescue group, early rescue/CPAP was associated with a 33% reduction in need for mechanical ventilation, 48% reduction in air leak syndrome, and 49% reduction in incidence of BPD. They also noted that initiation of surfactant treatment at an Fio_2 of less than 0.45 was associated with lower incidence of air leak, compared to waiting until the Fio_2 was higher.

Methods of Surfactant Dosing

Animal studies suggest that surfactant distribution is better distributed when administered as a bolus rather than by infusing it slowly over several minutes (Fernandez et al, 1998). The package inserts of many surfactant preparations recommend moving the infant into multiple positions for better distribution of surfactant, but there are no clinical trials supporting one particular method. Therefore, surfactant should be given as quickly as tolerated, and with the least disruptive infant positioning.

Exogenous surfactant is generally given via an endotracheal tube. However, tracheal intubation is potentially risky, and sometimes difficult to accomplish, so administration through a laryngeal mask airway (LMA) may be considered. In a pilot study of 8 preterm infants (body weight range 880 to 2520 g) receiving nasal CPAP for RDS, the LMA administration approach appeared to be safe and potentially effective (Trevisanuto et al, 2005).

Number of Surfactant Doses and Dosing Intervals

A metaanalysis of two clinical trials that compared one versus multiple doses of animal-derived surfactant suggests a 49% reduction in incidence of pneumothorax and a trend toward a 37% reduction in mortality when multiple doses are used (Soll and Ozek, 2009). There are no data to suggest that dosing should continue once the patient's ventilator and oxygen requirement are at minimal levels, or beyond four doses. The interval between doses is usually at least 6 hours, and most protocols recommend discontinuation of dosing after 48 hours. In an attempt to reduce the incidence of BPD, clinical trials of surfactant administration at several days of age are underway.

Clinical Care after Dosing

Because natural surfactants may work quickly, the clinician must be prepared after dosing to immediately lower the Fio_2 while carefully monitoring the pulse oximeter. The tidal volume, as measured by the ventilator and/or by careful observation of chest wall movement, may gradually increase, resulting in a need to lower inspiratory pressures to avoid air leak syndrome, lung injury, and possibly pulmonary hemorrhage. Blood gases should be monitored by transcutaneous monitors and/or intermittent sampling. PEEP should be maintained but may be reduced if the starting levels at dosing were high, given that functional residual capacity increases shortly after surfactant administration.

A poor response to exogenous surfactant may occur because the patient does not have surfactant deficiency but rather, lung hypoplasia, pneumonia, or congenital heart disease. Other causes for a lack of response may be poor distribution of the surfactant, such as administration down the right stem bronchus due to malposition of the endotracheal tube, plugging of the tube, or malposition of the tube in the esophagus. A less likely reason is an inadequate dose of surfactant.

The rapid improvement in lung compliance after exogenous surfactant therapy may lead to excessive pulmonary blood flow from left-to-right shunting from a patient ductus arteriosus (Raju and Langerberg, 1993). It is uncertain whether early and aggressive intervention to close the ductus with medication or surgery will reduce the risk of pulmonary hemorrhage.

PULMONARY HYPOPLASIA

DEFINITION AND INCIDENCE

One or both lungs of newborns with pulmonary hypoplasia are smaller than normal, including reduced numbers of lung cells, airways, blood vessels, and alveoli.

Pulmonary hypoplasia is the cause of respiratory distress at birth in only 0.3% of newborns with respiratory symptoms (Rubaltelli et al, 1998), but it is commonly fatal, especially in preterm infants. The incidence is about 1 per 1000 live births, and 90% are associated with congenital anomalies or pregnancy complications (Churg et al, 2005). There is a continuum of severity of pulmonary hypoplasia—from negligible to severe—and therefore all but the most severe cases are difficult to diagnose. This is especially true when attempting to diagnose prenatally by imaging studies, but is also true during clinical assessment of the newborn, and even after postmortem examination of the lungs.

When considering the causes of pulmonary hypoplasia, it is useful to categorize them into associated conditions, each with representative diagnoses, as in Table 46-4. This chapter on respiratory distress in preterm infants focuses on the problem of pulmonary hypoplasia associated with oligohydramnios from preterm premature rupture of membranes (PPROM) because this cause of pulmonary hypoplasia occurs almost exclusively in preterm infants. When PPROM occurs at 15 weeks' gestation, the incidence of pulmonary hypoplasia is 80% and at 19 weeks it is 50%, whereas after 26 weeks it is near zero (Rothschild et al, 1990). Other conditions associated with pulmonary hypoplasia are covered in other chapters.

TABLE 46-4 Categories of Conditions Associated With Pulmonary Hypoplasia

Category	Representative Diagnoses
Restriction of thoracic space	Diaphragmatic hernia or eventration Intrathoracic mass Congenital cystic adenomatoid malformation Bronchogenic cyst Extralobar sequestration Thoracic neuroblastoma Pleural effusions Chylothorax Hydrothorax
Oligohydramnios	Renal Bilateral renal agenesis or dysplasia Bladder outlet obstruction (posterior urethral valves) Nonrenal Prolonged preterm rupture of membranes
Skeletal anomalies	Chondroectodermal dysplasia Osteogenesis imperfecta Thanatophoric dwarfism
Hydrops fetalis	Rh isoimmunization
Neuromuscular and central nervous system anomalies	Fetal akinesia Anencephaly Arnold-Chiari malformation
Cardiac anomalies	Hypoplastic right or left heart Pulmonary stenosis Ebstein's anomaly
Abdominal wall defects	Omphalocele Gastroschisis
Syndromes	Trisomy 13, 18, 21 Larsen's Cerebrocostomandibular Jarcho-Levin Roberts Lethal multiple pterygium

Adapted from Churg AM, Myers JL, Tazelaar H, Wright J, editors: *Thurlbeck's pathology of the lung*, ed 3, New York, 2005, Thieme.

PATHOLOGY

The easiest method of defining pulmonary hypoplasia during postmortem exam is to calculate the ratio of lung weight to body weight. At 28 weeks' gestation, a ratio of 0.015 is at the 5th percentile, whereas at 35 weeks', the 5th percentile is at a ratio of 0.012. The lung-to-body weight ratio may be artificially elevated if the lungs are wetter than usual from edema, hemorrhage, inflammation, or lymphangiectasia—this may lead to the false conclusion that the patient does not have pulmonary hypoplasia. Conversely, the ratio may be artificially low if the body is heavier than usual because of renal cystic disease, hydrops, ascites, tumors, hydrocephaly, and so forth. Therefore, a better method for postmortem diagnosis of pulmonary hypoplasia is to measure the lung volume by inflating the lung with fixative at physiologic pressure and then measuring the displacement of fluid when the lung is immersed. Pulmonary hypoplasia assessed by this method is defined as lung volume less than the 5th percentile of standards for each gestational age (Churg et al, 2005). This method facilitates comparison of postmortem to in utero estimates of lung volume made during antenatal imaging. However, low lung volume does not necessarily correlate with deficiency of lung structure and function. A postmortem technique more physiologically relevant than lung volume is the radial alveolar count, which is proportional to alveolar surface complexity (Churg et al, 2005) and thus gas exchange surface area; however, this procedure is complex and time-consuming.

Impairment of lung development before 16 weeks causes reduced airway branching, reduced cartilage development, reduced acinar complexity and maturation, delayed vascularization, and delayed thinning of the air-blood barrier. Impairment after 16 weeks typically causes reduced acinar complexity and maturation. These outcomes are predictable, given the time in gestation when these structures are developing (Figure 46-12, *A*).

Because the growth of lung blood vessels parallels the development of the airways, pulmonary hypoplasia causes decreased total size of the pulmonary vascular bed, decreased number of vessels per unit of lung tissue, and increased pulmonary arterial smooth muscle. This last phenomenon accounts for persistent pulmonary hypertension after birth.

CLINICAL SIGNS

The preterm newborn with pulmonary hypoplasia often presents with immediate signs of respiratory distress and cyanosis indistinguishable from those in the newborn with severe respiratory distress syndrome (see earlier section on clinical signs of RDS). However, respiratory failure from severe pulmonary hypoplasia often becomes apparent within minutes of birth, whereas respiratory failure from RDS usually progresses over the first few hours after birth. The thorax may appear small or bell-shaped

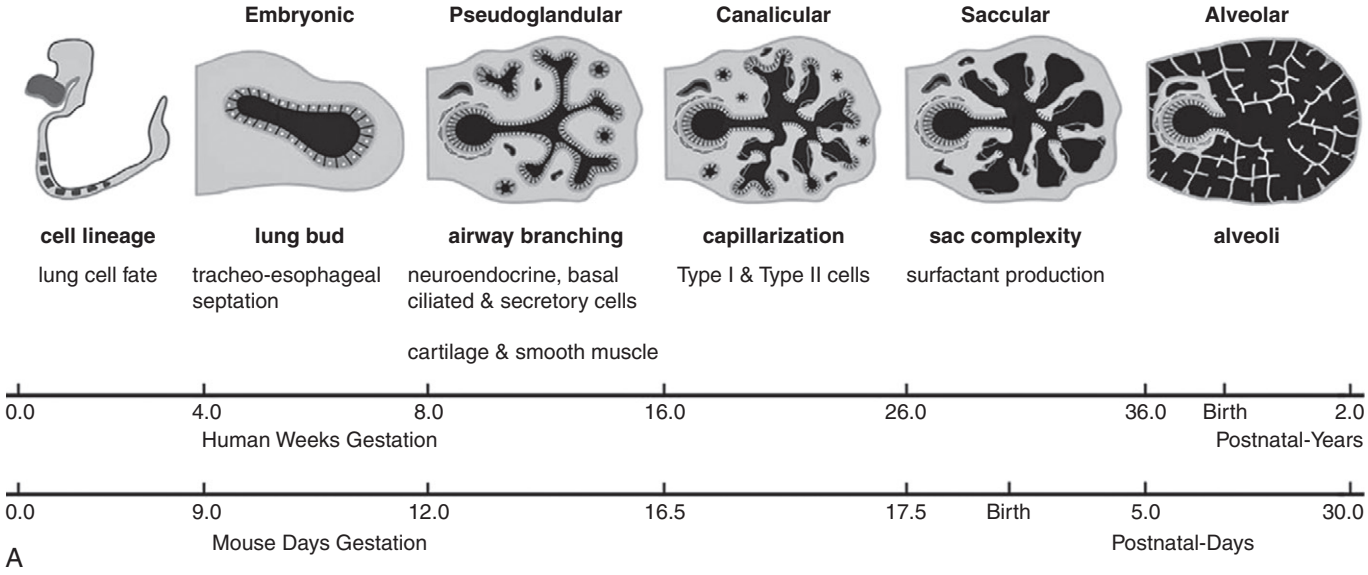
and, if oligohydramnios was severe, there may be flattening of the face and deformation (such as contractures of the extremities). Hypercarbia may be severe on the earliest blood gas measurement, despite aggressive mechanical ventilation. The hypoxemia from surfactant deficiency and lung immaturity may be compounded by right-to-left shunting of deoxygenated blood due to pulmonary hypertension, leading to severe desaturation. If there is also a tension pneumothorax, there may be asymmetry of breath sounds or malposition of heart sounds, as well as impaired cardiac output from impaired venous return to the thorax.

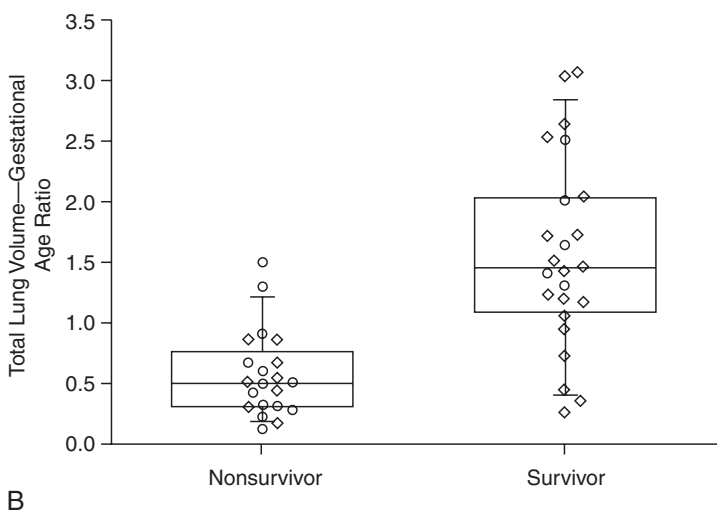
RADIOGRAPHIC SIGNS

Because lung immaturity and surfactant deficiency accompany pulmonary hypoplasia, particularly in preterm infants, the lungs may be radiographically dense with air bronchograms, as with RDS, but the lung volumes may be smaller and the diaphragms higher than in RDS. With severe pulmonary hypoplasia, the thorax may appear bell-shaped, and early pneumothorax is common.

TREATMENT

After birth, treatment for pulmonary hypoplasia is similar to that provided to patients with RDS, including assisted ventilation and exogenous surfactant. Even with cautious ventilation, however, tension pneumothoraces are common and are often the proximate cause of death, so the neonatal team should be prepared for urgent needle decompression of the chest and insertion of a chest tube. Permissive hypercapnia is appropriate, and high-frequency ventilation may be necessary for adequate ventilation and removal of very high arterial Pco_2 levels. If pulmonary





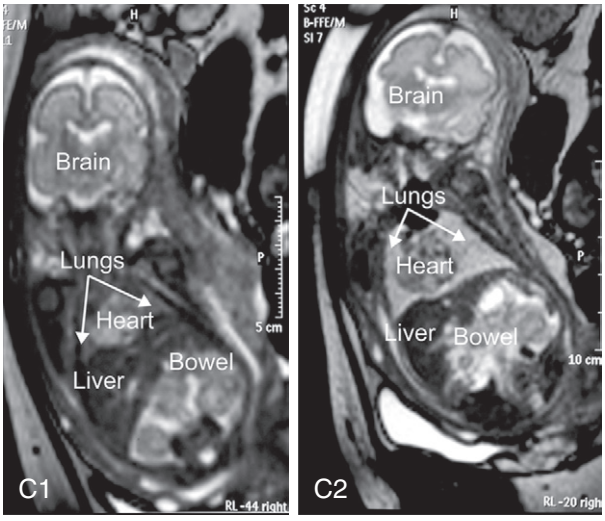


FIGURE 46-12 **A,** Stages of lung development. **B,** Measurement of fetal lung volume by magnetic resonance imaging and outcomes after delivery. **C,** Lung growth after occlusion of the fetal trachea for 6 days: (*C1*) before tracheal occlusion and (*C2*) after tracheal occlusion. hypertension is present, as it commonly is, inhaled nitric oxide for pulmonary vasodilation is logical, but clinical trials with sufficient sample size to prove better survival are lacking (Chock et al, 2009). Extracorporeal membrane oxygenation may be appropriate for larger preterm infants if the pulmonary hypoplasia, surfactant deficiency, and pulmonary hypertension are expected to improve within a few days. However, it is very difficult to select appropriate candidates with pulmonary hypoplasia for extracorporeal membrane oxygenation, and it is often unsuccessful with severe disease or in combination with other major life-threatening malformations.

PRENATAL DIAGNOSIS

An accurate prenatal test for pulmonary hypoplasia is important because it may affect the obstetric management. It would be particularly helpful to be able to discriminate lethal from nonlethal pulmonary hypoplasia, especially before 24 weeks' gestation when termination of the pregnancy may be an option. This is an easier task than quantifying the degree of fetal pulmonary hypoplasia, which—as noted previously—is challenging even for the pathologist.

A metaanalysis of clinical parameters for prediction of fatal pulmonary hypoplasia following prelabor rupture of membranes before 28 weeks' gestation concluded that gestational age at rupture was a better predictor of pulmonary hypoplasia than latency or oligohydramnios (van Teeffelen et al, 2010).

In 1992, ultrasound measurement of the fetal chest circumference was shown to be helpful in predicting fatal pulmonary hypoplasia (Ohlsson et al, 1992), whereas in 2002 the best prediction was achieved by combining clinical, biometric, and Doppler parameters (Laudy et al, 2002). These parameters included thoracic, cardiac, and abdominal circumference, the largest vertical amniotic fluid pocket, and pulsed Doppler measurements of the arterial pulmonary branches. Nonsurvivors with pulmonary hypoplasia due to fetal urinary anomalies were noted to have lower in utero lung volumes as determined by fetal MRI, adjusted for gestational age (Zaretsky et al, 2005), but there was no clear separation between the survivors and nonsurvivors (Figure 46-12, *B*). Furthermore, there was considerable overlap of the confidence intervals before 26 weeks' gestation, which limits the usefulness of MRI assessment of fetal volume for prenatal counseling. Three-dimensional ultrasound measurements of lung volume had better diagnostic accuracy for predicting pulmonary hypoplasia, compared to two-dimensional measurements of thoracic/heart area ratio (Gerards et al, 2008). Although there will continue to be advances in fetal imaging to assess lung volume, it will likely remain difficult to differentiate lethal from nonlethal pulmonary hypoplasia.

The management of the preterm pregnancy with premature rupture of membranes near the limit of fetal viability is beyond the scope of this chapter. However, a recent review article by Waters and Mercer (2009) offers a management algorithm that illustrates the areas of controversy. For the patient who desires conservative management of premature rupture before the limit of viability, the algorithm recommends serial assessments for signs of infection or labor, as well as interval ultrasound examinations to watch for the development of pulmonary hypoplasia. If this occurs, antenatal antibiotics and corticosteroids should be considered if more aggressive management is desired.

PRENATAL TREATMENT

Treatment of oligohydramnios with amnioinfusion with saline has been proposed to improve fetal survival by increasing the latency period (the interval between PROM and delivery) and thus the gestational age at delivery. In a small study, it appeared to reduce the incidence of pulmonary hypertension from about 50% to 10% with PPROM in the 20th week of gestation (De Carolis et al, 2004). However, the procedure restores adequate amniotic fluid volume in only a minority of patients in which it is performed, and there are procedure-related complications such as chorioamnionitis and placental abruption (Tan et al, 2003). When it is successful, the benefit may come from restoration of back-pressure from the amniotic sac fluid to the lungs, stimulating fetal lung growth and development during the critical canalicular stage between 16 and 26 weeks' gestation.

Based on this same logic, there have been efforts to reverse pulmonary hypoplasia in utero by fetal tracheal occlusion. In a case report of PPROM at 16 weeks' gestation, fetoscopic tracheal balloon occlusion was performed at 27 ⅐ weeks (Kohl et al, 2009). Within 6 days, the fetal lung volume as measured by MRI increased from 13 to 70 mL (Figure 46-12, *C*) and the lung blood flow normalized. The fetus was delivered at 28 ⅐ weeks using the EXIT procedure (ex utero–intrapartum treatment), had no signs of pulmonary hypertension, and was discharged home at 8 weeks of age. This approach has been used for fetuses with congenital diaphragmatic hernia (Done et al, 2008), but with mixed results. Whether this technique proves to be valuable for PPROM is uncertain, but the restoration of lung size in only 6 days suggests that pulmonary hypoplasia may be more reversible than previously assumed.

PNEUMONIA

INCIDENCE

The incidence of pneumonia/sepsis in preterm infants with birthweight 1500 to 2500 g is only 0.28%, whereas in patients with birthweight <1000 g the incidence is several-fold higher at 1.9% (see Figure 46-1) (Rubaltelli et al, 1998). If only newborns with respiratory distress are considered, the overall incidence (in mostly term infants) is 5% (see Table 46-1)—the third most likely cause after RDS (46%) and TTNB (37%). The data in Figure 46-1 indicate that the incidence of pneumonia in newborns with respiratory distress who are <1000 g, 1000 to 1500 g, and 1500 to 2500 g is 4%, 2%, and 1%, respectively. The NICHD Neonatal Research Network reported an incidence of blood culture–proven early-onset sepsis (<72 hours after birth) in newborns of birthweight <1500 g of 1.9% during 1991–1993 (Stoll et al, 1996) and 1.5% during 1998–2000 (Stoll et al, 2003). In the earlier period, group B streptococcus was the most frequent pathogen (31%) followed by *Escherichia coli* (16%) and *Haemophilus influenzae* (12%). In the more recent period, the most common pathogens were *E. coli*

(44%), group B streptococcus (11%), coagulase-negative staphylococcus (11%), *viridans* streptococci and other streptococci (8%), *H. influenzae* (8%), *Citrobacter* (2%), *Listeria monocytogenes* (2%), and *Candida albicans* (2%).

CLINICAL SIGNS

The clinical signs of pneumonia after preterm birth are often indistinguishable from the more common problem of RDS. Bacterial pneumonia is usually accompanied by sepsis because newborns are frequently unable to confine bacteria to the lung, and therefore some infants will exhibit clinical signs of sepsis or shock, including poor perfusion and hypotension, in addition to respiratory failure. Many premature infants with pneumonia also have surfactant deficiency from RDS, further obscuring the diagnosis of pneumonia.

LABORATORY AND RADIOGRAPHIC SIGNS

Blood cultures will be positive in some premature newborns with pneumonia, but the presence of maternal antibiotics in the blood of the newborn reduces confidence in a negative result. Leukopenia, increased percentage of immature granulocytes, and elevated inflammatory markers such as C-reactive protein increase the likelihood of sepsis/pneumonia, but with poor positive predictive value. Tracheal aspirate culture (but not Gram stain) obtained immediately after placement of an endotracheal tube may help with diagnosis and guide therapy, especially when the blood culture is negative (Booth et al, 2009).

Premature newborns with pneumonia will have pulmonary infiltrates on chest radiograph, but the radiographic appearance is difficult to distinguish from RDS (although classically in term newborns it has a more coarse and wet appearance). Because newborns are unable to localize pulmonary infection, lobar infiltrates are rarely an indication of pneumonia—plugging of airways with secretions is more likely.

TREATMENT

Antibiotics directed at the most common organisms (see earlier discussion) should be started immediately when pneumonia in the preterm infant is suspected. Ampicillin and gentamicin are reasonable choices, to be administered for 48 hours pending culture results. Empiric vancomycin has the disadvantage of promoting the emergence of vancomycin-resistant organisms, and a delay in treating coagulase-negative staphylococcal bacteremia until cultures are positive is rarely of consequence to the patient. If the blood culture is negative, and the mother has been pretreated with antibiotics, a longer course of antibiotics (e.g., 5 to 7 days) may be prudent, especially if there are laboratory abnormalities such as elevated C-reactive protein and a clinical course suggestive of sepsis or pneumonia.

Because it is so difficult to tell which preterm infants with respiratory distress have pneumonia and which have the more common problems of RDS or TTNB, one approach is to empirically treat with antibiotics all premature newborns with respiratory symptoms. The likelihood of infection in newborns <1000 g with respiratory distress is about 4% (see Incidence, earlier), and so 24 extremely premature newborns will be needlessly treated for every one who will benefit. This number can be reduced by avoiding empiric antibiotics at birth for newborns who are prematurely delivered for maternal indications, such as hypertension. Both PROM and premature labor increase the risk of infection.

Among the possible adverse consequences of unnecessary empiric antibiotics are interference with the colonization of the intestinal tract with nonpathogenic bacteria, selection of antibiotic-resistant bacteria, and fungal infection. On the other hand, the development of bronchopulmonary dysplasia is associated with inflammation from chorioamnionitis (Speer, 2009), and so antibiotics even in the absence of frank pneumonia may be beneficial.

CHAPTER 47

Respiratory Failure in the Term Newborn

Thomas A. Parker and John P. Kinsella

The evaluation and management of respiratory failure in the term newborn poses unique challenges and remains one of the most vexing problems facing clinicians in the newborn intensive care unit. Although some of the pathophysiologic features of respiratory failure in the term infant are similar to the premature newborn condition, several disorders occur more commonly in the term newborn (e.g., meconium aspiration) and are often made more difficult to evaluate and manage because of cardiac and pulmonary vascular abnormalities that complicate the clinical course. Indeed, the traditional perspective of categorizing hypoxemia and respiratory failure in the term newborn as cardiac, pulmonary vascular, or due to air-space (lung) disease is insufficient. For example, the syndrome of persistent pulmonary hypertension of the newborn (PPHN) is defined by severe pulmonary vasoconstriction leading to suprasystemic pulmonary artery pressure with extrapulmonary right-to-left venoarterial admixture across the fetal channels of the oval foramen and the arterial duct. However, PPHN rarely occurs without concomitant parenchymal lung disease and disturbances in cardiac performance.

In this chapter we present an algorithm for evaluation of the term newborn with hypoxemia and respiratory failure, review the syndrome of PPHN, and discuss common causes of respiratory failure in the term newborn.

EVALUATION OF THE TERM NEWBORN WITH HYPOXEMIA/ RESPIRATORY DISTRESS

One of the most anxiety-provoking experiences for many clinicians (particularly those in training) is the initial evaluation and management of a term newborn with hypoxemia/respiratory distress. Traditional textbooks provided a wealth of information about individual conditions once identified. However, there are few sources designed to guide the clinician in an ordered fashion through a comprehensive diagnostic evaluation. In this section, we propose an approach to the evaluation of the hypoxemic newborn that may be useful in clarifying the etiology of hypoxemia/respiratory distress and in determining the proper sequence of diagnostic and therapeutic interventions.

HISTORY

Marked hypoxemia in the newborn can be caused by parenchymal lung disease with V/Q mismatch or intrapulmonary shunting, pulmonary vascular disease causing extrapulmonary right-to-left shunting (PPHN), or anatomic right-to-left shunting associated with congenital heart disease. Evaluation should begin with the history and assessment of risk factors for hypoxemic respiratory failure. Relevant history may include the results of prenatal ultrasound studies. Lesions such as congenital diaphragmatic hernia (CDH) and congenital cystic adenomatoid malformation are diagnosed prenatally with increasing frequency. Although many anatomic congenital heart defects can be diagnosed prenatally, vascular abnormalities (e.g., coarctation of the aorta, total anomalous pulmonary venous return) are more difficult to diagnose with prenatal ultrasound. A history of a structurally normal heart by fetal ultrasonography should be confirmed by echocardiography in the newborn with cyanosis (see later).

Other historical information that may be important in the evaluation of the cyanotic newborn includes a history of severe and prolonged oligohydramnios causing pulmonary hypoplasia. Also important is a history of prolonged fetal bradyarrhythmia and/or tachyarrhythmia and marked anemia (caused by hemolysis, twin-twin transfusion, or chronic hemorrhage) that may cause congestive heart failure, pulmonary edema, and respiratory distress. Maternal illness (e.g., diabetes mellitus), medication use (e.g., aspirin or medications containing nonsteroidal antiinflammatory drugs causing premature constriction of the ductus arteriosus, association of Ebstein's malformation with maternal lithium use), and illicit drug use may contribute to acute cardiopulmonary distress in the newborn. Risk factors for infection that cause sepsis/pneumonia should be considered, including premature or prolonged rupture of membranes, fetal tachycardia, maternal leukocytosis, uterine tenderness, and other signs of intraamniotic infection.

Events at delivery may provide clues to the etiology of hypoxemic respiratory failure in the newborn. For example, if positive-pressure ventilation is required in the delivery room, the risk of pneumothorax increases. A history of meconium-stained amniotic fluid, particularly if meconium is present below the cords, is the sine qua non of meconium aspiration syndrome. Birth trauma (e.g., clavicular fracture, phrenic nerve injury) or acute fetomaternal or fetoplacental hemorrhage may cause respiratory distress in the newborn (Box 47-1).

PHYSICAL EXAMINATION

The initial physical examination provides important clues to the etiology of cyanosis. Marked respiratory distress in the newborn (retractions, grunting, nasal flaring) suggests the presence of pulmonary parenchymal disease with decreased lung compliance. However, it is important to recognize that upper airway obstruction (e.g., Pierre Robin sequence or choanal atresia) and metabolic acidemia also can cause severe respiratory distress. In contrast, the newborn with cyanosis alone or cyanosis plus tachypnea (i.e., nondistressed tachypnea) typically has cyanotic congenital heart disease, most commonly transposition of the great vessels (TGV) or idiopathic PPHN.

BOX 47-1 Neonatal Respiratory Failure: History and Risk Factor Assessment

PRENATAL

Prenatal ultrasound study results
History of oligohydramnios and duration
History of fetal brady/tachyarrhythmia
Maternal illnesses, drugs , medications
History of fetal distress
Risk factors for infection

DELIVERY

History of positive pressure ventilation in DR
Meconium stained amniotic fluid
Hemorrhage
Birth trauma
Low Apgar score

BOX 47-2 Physical Examination

RESPIRATORY DISTRESS (RETRACTIONS, GRUNTING, NASAL FLARING)

Suggests lung parenchymal disease (compliance), upper airway disease or metabolic acidemia

NO SIGNIFICANT RESPIRATORY DISTRESS (TACHYPNEA ALONE)

Suggests hypoxemia caused by cyanotic heart disease without lung disease

BOX 47-3 Acute Response to Supplemental Oxygen (High Fio_2 by Hood, Mask)

MINIMAL OR TRANSIENT CHANGE IN SAo_2

Cyanotic heart disease, PPHN

MARKED IMPROVEMENT IN SAo_2

Parenchymal lung disease, CHD with ductal-dependent systemic blood flow

The presence of a heart murmur in the first hours of life is an important sign in the newborn with cyanosis or respiratory distress. In this setting, it is unusual for the common left-to-right shunt lesions (patent ductus arteriosus, atrial septal defect, ventricular septal defect) to produce an audible murmur because pulmonary vascular resistance (PVR) remains high and little turbulence is created across the defect. A murmur that sounds like a ventricular septal defect in the first hours of life is most commonly caused by tricuspid regurgitation (associated with PPHN or an ischemic myocardium).

The response to supplemental oxygen can also provide important clues to the pathophysiology of hypoxemic respiratory failure in the term newborn (Boxes 47-2 and 47-3).

INTERPRETATION OF PULSE OXIMETRY MEASUREMENTS

The interpretation of preductal (right hand) and postductal (lower extremity) saturation by pulse oximetry provides important clues to the etiology of hypoxemia in the newborn. Right-to-left shunting across the ductus arteriosus (but not the patent foramen ovale) causes postductal desaturation (with a >5% preductal/postductal saturation difference). However, it is important to recognize that variability in oximetry readings may be related to differences in available devices and affected by local perfusion.

If the measurements of preductal and postductal Sao_2 are equivalent, this suggests either that the ductus arteriosus is patent and PVR is subsystemic (i.e., the hypoxemia is caused by parenchymal lung disease with intrapulmonary shunting or cyanotic heart disease with ductal-dependent pulmonary blood flow) or that the ductus arteriosus is closed (precluding any interpretation of pulmonary artery pressure without echocardiography). It is uncommon for the ductus arteriosus to close in the first hours of life in the presence of systemic or suprasystemic pulmonary artery pressures.

The most common cause of preductal-postductal gradients in oxygenation is suprasystemic PVR in PPHN causing right-to-left shunting across the ductus arteriosus (associated with meconium aspiration syndrome, surfactant deficiency/dysfunction, CDH, non-CDH pulmonary hypoplasia, or idiopathic). However, ductal-dependent systemic blood flow lesions (hypoplastic left heart syndrome, critical aortic stenosis, interrupted aortic arch, coarctation) may also present with postductal desaturation. Moreover, anatomic pulmonary vascular disease (alveolar-capillary dysplasia, pulmonary venous stenosis, anomalous venous return with obstruction) can cause suprasystemic PVR with right-to-left shunting across the ductus arteriosus and postductal desaturation.

Finally, the unusual occurrence of markedly lower preductal Sao_2 compared to postductal measurements suggests one of two diagnoses: TGV with pulmonary hypertension or TGV with coarctation of the aorta (Table 47-1).

TABLE 47-1 Role of Pulse Oximetry in Evaluation of Neonatal Hypoxemic Respiratory Failure

Preductal Sao_2 = postductal Sao_2	1. Intrapulmonary shunt: PVR < SVR 2. Cyanotic congenital heart disease with L→R PDA: Ductal-dependent Qp: pulmonary atresia/stenosis, tricuspid atresia, Ebstein's anomaly 3. PPHN:R→L shunt at PFO: PVR > SVR, ductus closed
Preductal Sao_2 > postductal Sao_2	1. PVR > SVR with R→L PDA: PPHN: MAS, RDS, CDH 2. Ductal-dependent Qs: HLHS, IAA, coarctation 3. Anatomic PV disease: alveolar-capillary dysplasia, pulmonary vein stenosis, TAPVR with obstruction
Preductal Sao_2 ≤ postductal Sao_2	1. TGV with pulmonary hypertension 2. TGV with coarctation of aorta

HLHS, Hypoplastic left heart syndrome; *IAA*, interrupted aortic arch; *L→R PDA*, left-to-right shunting across the patent ductus arteriosus; *PV*, pulmonary vein; *PVR*, pulmonary vascular resistance; *Qp*, pulmonary blood flow; *Qs*, systemic blood flow; *SVR*, systemic vascular resistance; *TAPVR*, total anomalous pulmonary venous return; *TGV*, transposition of the great vessels.

BOX 47-4 CXR and Laboratory Evaluation

CHEST RADIOGRAPH

Hypoxemia out of proportion to radiographic changes suggests congenital heart disease with ductal-dependent pulmonary blood flow or extrapulmonary right-to-left shunting with PPHN

ARTERIAL BLOOD GAS, COMPLETE BLOOD COUNT, BLOOD PRESSURE

ABG: Assess respiratory and metabolic acidemia

CBC: For evidence of infection

BP: Ductal-dependent systemic blood flow and closing PDA (e.g., coarctation)

LABORATORY AND RADIOLOGIC EVALUATION

One of the most important tests to perform in the evaluation of the newborn with cyanosis is the chest radiograph (CXR). The CXR can demonstrate the classic findings of respiratory distress syndrome (air bronchograms, diffuse granularity, underinflation), diffuse parenchymal lung disease in pneumonia, meconium aspiration syndrome, and CDH. Perhaps the most important question to ask when viewing the CXR is whether the severity of hypoxemia is out of proportion to the radiographic changes. In other words, marked hypoxemia despite supplemental oxygen in the absence of severe pulmonary parenchymal disease radiographically suggests the presence of an extrapulmonary right-to-left shunt (idiopathic PPHN or cyanotic heart disease; Boxes 47-3 and 47-4).

Other essential measurements include an arterial blood gas to determine the blood gas tensions and pH, a complete blood count to evaluate for signs of infection, and blood pressure measurements in the right arm and a lower extremity to identify aortic obstruction (interrupted aortic arch, coarctation).

RESPONSE TO SUPPLEMENTAL OXYGEN

Marked improvement in SaO_2 (increase to 100%) with supplemental oxygen (by hood, mask, or endotracheal tube) suggests the presence of intrapulmonary shunt or V/Q mismatch due to lung disease or reactive PPHN. The response to mask continuous positive airway pressure is also a useful discriminator between severe lung disease and other causes of hypoxemia. Most patients with PPHN have at least a transient improvement in oxygenation in response to interventions such as high inspired oxygen and/or mechanical ventilation. If the preductal SaO_2 never reaches 100%, the likelihood of cyanotic heart disease is high.

ECHOCARDIOGRAPHY

Echocardiography has become a vital tool in the clinical management of newborns with hypoxemic respiratory failure (Box 47-5). The initial echocardiographic evaluation is important to rule out structural heart disease causing hypoxemia (e.g., coarctation of the aorta, total anomalous pulmonary venous return). Moreover, it is critically important to diagnose congenital heart lesions for which inhaled nitric oxide (iNO) treatment would be contraindicated. In addition to the lesions mentioned earlier, congenital heart diseases that can present with hypoxemia unresponsive to high inspired oxygen concentrations (i.e., dependent on right-to-left shunting across the ductus arteriosus) include critical aortic stenosis, interrupted aortic arch, and hypoplastic left heart syndrome. Decreasing PVR with iNO in these conditions could lead to systemic hypoperfusion, worsening the clinical course and delaying definitive diagnosis.

BOX 47-5 Role of Echocardiography in Evaluation of PPHN and the Use of Inhaled NO

EXTRAPULMONARY SHUNT

Right-to-left shunting at the arterial duct and/or oval foramen is observed in infants with suprasystemic pulmonary hypertension.

If echocardiography demonstrates adequate left ventricular performance, consider iNO use after effective lung recruitment (see functional measurements below)

ANATOMY

Inhaled NO may be contraindicated in the presence of duct-dependent systemic blood flow: e.g., hypoplastic left heart syndrome

LEFT VENTRICULAR PERFORMANCE

Inhaled NO may be contraindicated in the presence of left ventricular systolic/diastolic dysfunction (e.g., mitral insufficiency with L→R atrial shunting with R→L ductal shunting suggesting possible right-ventricle-dependent systemic blood flow

Echocardiographic evaluation is an essential component in the initial evaluation and ongoing management of the hypoxemic newborn. Not all hypoxemic term newborns have echocardiographic signs of PPHN. As noted earlier, hypoxemia can be caused by intrapulmonary right-to-left shunting or V/Q disturbances associated with severe lung disease. In unusual circumstances, right-to-left shunting can occur across pulmonary-to-systemic collaterals. However, extrapulmonary right-to-left shunting at the foramen ovale and/or ductus arteriosus (PPHN) also complicates hypoxemic respiratory failure and must be assessed in order to determine initial treatments and evaluate the response to those therapies.

PPHN is defined by the echocardiographic determination of extrapulmonary venoarterial admixture (right-to-left shunting at the foramen ovale and/or ductus arteriosus), not simply evidence of increased PVR (i.e., elevated PVR without extrapulmonary shunting does not directly cause hypoxemia). Echocardiographic signs suggestive of pulmonary hypertension (e.g., increased right ventricular systolic time intervals, septal flattening) are less helpful.

Doppler measurements of atrial- and ductal-level shunts provide essential information when managing a newborn with hypoxemic respiratory failure. For example, left-to-right shunting at the foramen ovale and ductus arteriosus with marked hypoxemia suggests predominant intrapulmonary shunting, and interventions should be directed at optimizing lung inflation.

Finally, the measurements made with echocardiography can be used to predict or interpret the response or lack of response to various treatments. For example, in the presence of severe left ventricular dysfunction with pulmonary hypertension, pulmonary vasodilation alone may

be ineffective in improving oxygenation. The echocardiographic findings in this setting include right-to-left ductal shunting (caused by suprasystemic PVR) and mitral insufficiency with left-to-right atrial shunting. In this setting, efforts to reduce PVR should be accompanied by targeted therapies to increase cardiac performance and decrease left ventricular afterload.

This constellation of findings suggests that left ventricular dysfunction may contribute to pulmonary venous hypertension, such as occurs in congestive heart failure. In this setting, pulmonary vasodilation alone (without improving cardiac performance) will not cause sustained improvement in oxygenation. Careful echocardiographic assessment will provide invaluable information about the underlying pathophysiology and help guide the course of treatment.

The initial echocardiographic evaluation determines both structural and functional (i.e., extrapulmonary right-to-left shunting in PPHN, left ventricular performance) causes of hypoxemia. Serial echocardiography is important to determine the response to interventions (e.g., pulmonary vasodilators) and to reevaluate cases where specific interventions have not resulted in improvement or with progressive clinical deterioration. For example, in a patient with extrapulmonary right-to-left shunting and severe lung disease, pulmonary vasodilation might reverse the right-to-left venous admixture with little improvement in systemic oxygenation. These observations unmask the critically important contribution of intrapulmonary shunting to hypoxemia.

PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN

As described previously, PPHN is a syndrome associated with diverse neonatal cardiac and pulmonary disorders that are characterized by high PVR causing extrapulmonary right-to-left shunting of blood across the ductus arteriosus and/or foramen ovale. The syndrome of PPHN and the role of iNO are discussed in more detail in other chapters. However, because its relationship to respiratory failure in term newborns is so vital to understanding the clinical pathophysiology and approaches to treatment, we address some historical perspectives in this section. Indeed, in order to understand the acronym PPHN, it is important to consider its historical evolution in term newborns with respiratory failure and critical hypoxemia, and the advances that led to current management strategies.

In the early 1960s, the association of respiratory distress syndrome with pulmonary hypertension and right-to-left ductal shunting was described in the landmark studies of Rudolph et al (1961) and the clinical observations of Stahlman (1964). Although it is now recognized that pulmonary hypertension with right-to-left venoarterial admixture often complicates the course of newborns with diverse diseases, its first recognition in term infants who were hypoxemic (but without significant lung disease) was likely by Roberton et al in 1967. These authors described 13 infants born at or near term who had marked hypoxemia but without other clinical signs of idiopathic respiratory distress syndrome (i.e., decreased lung compliance). They speculated that the cause of hypoxemia was right-to-left shunting, but did not specifically implicate suprasystemic levels of pulmonary vascular resistance as the cause of the hypoxemia. The first clear description of the pathophysiology of PPHN (associated with right-to-left shunting across patent fetal channels) is attributed to Gersony et al, who, in 1969, coined the phrase "persistence of the fetal circulation" (PFC) in describing two newborns with clear lung fields who had critical hypoxemia associated with severe pulmonary hypertension and right-to-left shunting across the foramen ovale and ductus arteriosus. One infant was treated with tolazoline with only transient improvement in oxygenation. In 1970, Lees used the term *primary pulmonary hypertension* to describe this group of newborns. In 1971, Siassi et al described five infants with persistent pulmonary vascular obstruction associated with right-to-left shunting across the ductus arteriosus, and in one case marked medial hypertrophy of the muscular pulmonary arteries demonstrated on autopsy. This observation of a structural abnormality of the pulmonary circulation was further elucidated by Haworth and Reid (1976) in three infants who died with persistent fetal circulation and had extension of smooth muscle into the walls of smaller intra-acinar arteries. The phrase "persistent pulmonary hypertension of the newborn" was first used by Levin et al (1976) to describe a group of newborns with severe pulmonary hypertension, clear chest radiographs, and right-to-left shunting across the ductus arteriosus demonstrated both by simultaneous temporal arterial and umbilical arterial sampling (i.e., postductal desaturation) and by cardiac catheterization.

These initial descriptions of PFC focused on a discreet subset of newborns who had adequate cardiac performance without structural heart disease, absence of significant parenchymal lung disease, and suprasystemic pulmonary vascular resistance causing hypoxemia through right-to-left shunting of blood across the oval foramen and/or the arterial duct. However, it soon became clear that PFC could complicate the course of other diseases of the newborn, including meconium aspiration (initially described by Stahlman in 1964 and later by Fox et al, 1977), and pulmonary hypoplasia/congenital diaphragmatic hernia (Harrison and de Lorimier, 1981).

Nomenclature for this syndrome was clearly quite varied. Although there was initial appeal of the term persistent fetal circulation (PFC) (Behrman, 1976), this description is not quite accurate because of the absence of the placenta and onset of air breathing after delivery. Over time, most authors have embraced PPHN as the proper name for this syndrome, with the classic PFC subtype (idiopathic PPHN) representing a relatively small percentage of the cases now commonly encountered. Pathophysiologic mechanisms and etiologic classifications of PPHN described by Rudolph (1980) and further characterized by Geggel and Reid (1984) and Gersony (1984) provided an important framework for understanding the complex nature of this syndrome as management strategies evolved over the past two decades.

Because of the role of pulmonary hypertension in newborns with hypoxemic respiratory failure (initially severe hyaline membrane disease [HMD] and subsequently PFC, as described earlier), early approaches to management included a focus on pulmonary vasodilation using

one of the few pharmacologic agents available at the time (tolazoline). Its use was first described by Cotton in 1965 in newborns with HMD, and later in infants with PPHN by Gersony et al (1969), Korones and Eyal (1975), and Levin et al (1976). However, its efficacy was limited by variable responsiveness and significant complications including systemic hypotension and gastrointestinal hemorrhage (Goetzman et al, 1976; Stevenson et al, 1979).

Multiple approaches to the treatment of PPHN evolved after its first recognition as a disease marked by severe pulmonary hypertension. However, discovery of the elusive selective pulmonary vasodilator would markedly change our understanding and clinical management of this syndrome. Indeed, the most striking change in the management of PPHN in the past decade has evolved from improved understanding of the role of endogenous NO production and exogenous NO delivery on pulmonary vasoregulation. Because the successful transition from fetal placental dependence to survival at birth requires that PVR rapidly decline and pulmonary blood flow increase, the role of NO in the transitional circulation has been intensively investigated to understand its relationship to the pathophysiology and treatment of PPHN.

NO was recognized as a potent vasodilator by Gruetter et al, as early as 1979, and in 1980, Furchgott and Zawadzki reported that acetylcholine-induced vasorelaxation was dependent on an intact endothelium through the elaboration of an endothelium-derived relaxing factor (EDRF) that diffused to the subjacent vascular smooth muscle. In 1987, investigators from two separate laboratories reported that the biologic activity of EDRF was identical to NO or an NO-containing substance. Palmer et al (1987) induced the release of EDRF from porcine aortic endothelial cells in culture and compared the effects on superfused aortic strips with that of NO in solution. They found that the effects of EDRF were indistinguishable from those of NO. Ignarro et al (1987) used a bioassay cascade superfusion technique with intrapulmonary arteries and veins, identified EDRF pharmacologically and chemically as NO, and found that EDRF and NO produced similar vasorelaxation and were inhibited by common antagonists. Ignarro et al also recognized that NO was inactivated by combining with hemoproteins and speculated that hemoglobin could trap endogenously produced NO that diffused into the vascular lumen, thus preventing any downstream vasorelaxation by this paracrine mediator.

The recognition that the endogenous production of this EDRF/NO mediator could be competitively blocked by modified L-arginine analogues prompted early experiments into the effects of NO in the fetal and transitional pulmonary circulation. Abman et al performed the first experiments on the role of EDRF in the ovine fetal circulation, demonstrating that endogenous EDRF/NO production modulates basal pulmonary vascular tone in the late-gestation fetus, and that pharmacologic NO blockade inhibits endothelium-dependent pulmonary vasodilation (Abman et al, 1990). These investigators also showed that pharmacologic NO blockade attenuates the rise in pulmonary blood flow at delivery, thus implicating endogenous NO formation in postnatal adaptation after birth and linking this laboratory observation to the life-threatening clinical condition of PPHN. In addition, experiments using this ovine model showed that increased fetal oxygen tension augments endogenous NO release (McQueston et al, 1993; Tiktinsky and Morin, 1993), and the increase in pulmonary blood flow in response to rhythmic distention of the lung and high inspired oxygen concentrations are mediated in part by endogenous NO elaboration (Cornfield et al, 1992).

The observation that dilute NO gas could be therapeutically delivered by inhalation was first described by Higgenbottam et al (1988), who reported that brief (10-minute) inhalational NO treatment caused potent and selective pulmonary vasodilation in adults with severe pulmonary hypertension (Pepke-Zaba et al, 1991). Frostell et al (1991) demonstrated the selectivity of iNO in an adult animal model of hypoxic pulmonary vasoconstriction, and the first description of the potent, sustained, and selective vasodilator effect of iNO in newborn lambs was reported by Kinsella et al in 1992.

Clinical approaches to PPHN and the role of iNO are discussed in separate chapters, and in relationship to specific diseases of the term newborn in the following sections.

SPECIFIC PULMONARY CONDITIONS CAUSING RESPIRATORY DISTRESS IN THE TERM NEWBORN

TRANSIENT TACHYPNEA OF THE NEWBORN

Transient tachypnea of the newborn (TTNB) is among the most common causes of respiratory distress in the newborn period, affecting 0.5% to 4% of all late preterm and term neonates. Symptoms of respiratory distress typically start within the first several hours after birth and result from failure of adequate absorption of fetal lung fluid. Studies have consistently shown that risk factors for TTNB include prematurity, delivery by cesarean section (particularly without preceding labor), and male sex (Jain et al, 2009; Riskin et al, 2005).

Early theories of lung fluid clearance focused on the role of thoracic compression during vaginal delivery and were supported by the observation that TTNB is more common among babies born by cesarean section (Milner et al, 1978). However, more recent studies have demonstrated that the complex process of lung liquid clearance likely begins well before term birth (Brown et al, 1983). During fetal life, the lung epithelium is responsible for the production of a substantial volume of alveolar fluid, a process that is essential for normal fetal lung growth (Olver and Strang, 1974). With parturition, increased levels of epinephrine, glucocorticoids, and other hormones effectively cause the lung epithelia to transition from a secretory to a resorptive phenotype (Baines et al, 2000; Barker et al, 1990). Activated endothelial sodium channels (ENaC) at the apical surface of lung type II epithelial cells transport sodium and water from the alveolar space into the type II cells (Olver et al, 1986). Sodium is then actively moved from the type II cell into the interstitium by Na/K ATPase, causing passive movement of water, which is then resorbed into the pulmonary circulation and lymphatics. Supporting a possible role for abnormal activity of ENaC and Na/K ATPase in TTNB, a recent study found that genetic polymorphisms in β-adrenergic receptor encoding genes (which regulate

expression of these channels) are more common in babies with TTNB (Aslan et al, 2008).

The diagnosis of TTNB remains problematic for clinicians. The most typical presenting symptoms, tachypnea/respiratory distress and the need for supplemental oxygen, are common among most neonatal respiratory disorders, and unfortunately, there exist no reliable diagnostic tests for TTNB (Guglani et al, 2008). For those reasons, the diagnosis remains one of exclusion, and vigilance for other, more severe disorders is imperative. Typically, symptoms of TTNB develop within the first several hours after birth. The degree of respiratory impairment, including the respiratory rate, use of accessory respiratory muscles, and impairment in gas exchange, varies widely. Chest radiographs should be considered in any baby presumed to have TTNB. Although radiographs commonly show prominent perihilar markings and fluid in the fissures, clinicians and radiologists often disagree in their interpretation of these findings in TTNB (Kurl et al, 1997).

Once a presumptive diagnosis of TTNB is made, treatment is largely supportive. Oxygen should be provided to maintain normal arterial oxygen saturations. The degree of tachypnea and respiratory distress should determine whether a baby is allowed to feed by mouth. If there is a suspicion of pneumonia or sepsis, empiric antibiotic therapy should be considered. A controlled trial of furosemide administration to accelerate clearance of lung fluid showed no benefit in attenuating the course of TTNB (Wiswell et al, 1985). Alternative or additional diagnoses should be considered in any infant who is deteriorating or requires mechanical ventilation. With supportive care, full recovery is to be expected after TTNB. However, compared with well infants of a similar gestational age, the diagnosis of TTNB is associated with a significantly prolonged hospital course (Riskin et al, 2005). Moreover, recent epidemiologic studies have suggested that newborns with TTNB are at a mildly increased risk for the later development of asthma (Birnkrant et al, 1996; Liem et al, 2007; Schaubel et al, 2006).

MECONIUM ASPIRATION SYNDROME

Meconium aspiration syndrome (MAS) is among the most common causes of hypoxemic respiratory failure in term newborns who require intensive care (Figure 47-1). Recent studies estimate that the incidence of MAS in babies greater than 37 weeks' gestation ranges from 0.4% to 1.8% (Dargaville and Copnell, 2006; Singh et al, 2009). Among babies born after 39 weeks' gestation with lung disease requiring mechanical ventilation, more than half suffer from MAS (Gouyon et al, 2008).

Moreover, MAS is the primary diagnosis for a significant proportion of those newborns who require extracorporeal membrane oxygenation (ECMO) in the United States (26%) and the United Kingdom (51%) (Brown et al, 2010).

Although a significant percentage of term births are complicated by the passage of meconium before or at delivery, fewer than 10% of those exposed to meconium develop MAS. Among those 10%, fetal acidemia is believed to result in increased intestinal peristaltic activity, passage of meconium, and fetal gasping, which draws particulate meconium deep into the lung. Supporting this theory, autopsy studies of babies who died of MAS demonstrate distal muscularization of small pulmonary arterioles, suggesting long-standing hypoxemia (Murphy et al, 1984). Particulate meconium in the distal lung causes check-valve obstruction of air passages and leads to regional hyperinflation and atelectasis. In addition, meconium inactivates surfactant, leading to secondary surfactant deficiency (Moses et al, 1991). Moreover, babies with MAS are at high risk for persistent pulmonary hypertension, which significantly increases their morbidity and complicates their management.

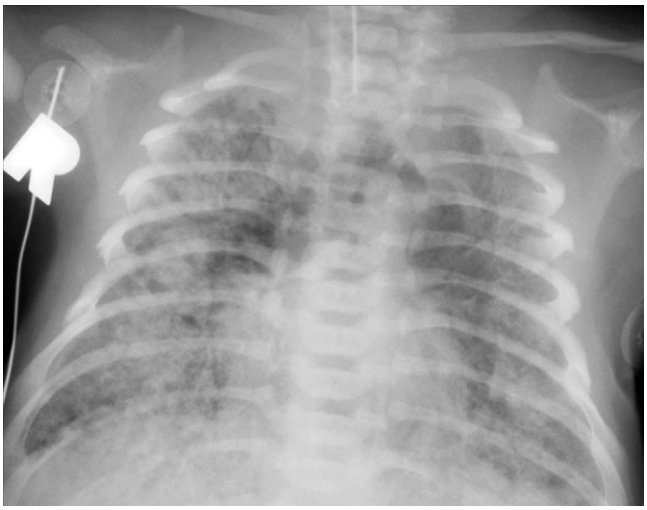

FIGURE 47-1 Chest radiograph of MAS. Term newborn with severe MAS. Note anterior pneumomediastinum and small left anteromedial pneumothorax.

Historically, prevention of MAS has focused on decreasing exposure of the fetal and newborn lung to the noxious effects of intrapulmonary meconium-contaminated amniotic fluid. Infusion of saline into the amniotic cavity (i.e., amnioinfusion) during labor has been studied as a means for diluting meconium and relieving pressure on the umbilical cord, a potential cause for fetal acidemia. In the largest trial investigating this practice, Fraser et al (2005) found no reduction in the risk of MAS. An alternative strategy to decreasing lung exposure to meconium is intrapartum oro- and nasopharyngeal suction of fetuses born through meconium-stained amniotic fluid. Although this practice was widely adopted in the 1970s, more recent studies have failed to demonstrated benefit (Vain et al, 2004), and the practice is no longer endorsed by the American College of Obstetricians and Gynecologists (ACOG) (Committee on Obstetric Practice, 2007). Whether the routine practice of tracheal suction of depressed, meconium-exposed infants immediately after birth is efficacious has not been adequately studied. In recent reports, surfactant lung lavage has demonstrated some promise in improving lung function in animal models of MAS (Dargaville et al, 2003), but a small clinical trial of this practice demonstrated no benefit (Gadzinowski et al, 2008). The lack of clear efficacy among any of these preventative strategies intended to remove meconium likely speaks to the complex and multifactorial nature of the pathophysiology of MAS.

The clinical signs of MAS vary widely among babies and may relate to the degree of antenatal compromise; the timing, volume, and consistency of aspirated meconium; and the presence of associated problems. Clinical signs of MAS

typically present immediately after birth with tachypnea, increased work of breathing, and cyanosis. Other common associated findings are metabolic acidosis, cardiac dysfunction and hypotension, and postductal desaturation indicative of right-to-left shunting of blood at the ductus arteriosus caused by pulmonary hypertension. Because of the potential for ball-valve obstruction of small airways and failure to empty distal lung segments, pneumothorax can complicate the clinical picture. In recent series, the risk of pneumothorax among ventilated babies with MAS ranged between 10% and 24% (Dargaville and Copnell, 2006; Velaphi and Van Kwawegen, 2008). Like the degree of clinical signs, findings on chest radiograph vary widely. The classic chest x-ray shows diffuse, fluffy infiltrates. However, some babies have milder initial radiographic findings, and there is often progression of visible parenchymal disease over time, likely related to secondary surfactant dysfunction.

Approximately half the babies with MAS require mechanical ventilation. Ventilator strategy should be individualized to each baby and to the pathology evident on the chest radiograph. In general, because of the likelihood of increased airway resistance, a conventional strategy utilizing slower rates with long inspiratory and expiratory times allows for better gas dispersion and more adequate emptying during expiration. Gas trapping and regional or generalized hyperinflation can occur, particularly when rapid rates are used with a conventional mode of ventilation. Some babies respond better to ventilation with a high-frequency device, though there is also a high risk of hyperinflation. When severe, hyperinflation causes impaired gas exchange and hypercarbia, limits systemic venous return (adversely affecting cardiac performance), increases the risk of pneumothorax, and may exacerbate pulmonary hypertension.

In addition to management of parenchymal lung disease in MAS, special consideration must be paid to other problems, particularly pulmonary hypertension. The risk for PPHN is quite high, exceeding 50% in some series. Studies demonstrate that iNO improves oxygenation in MAS and is particularly efficacious when combined with a ventilator strategy that focuses on improving lung recruitment such as high-frequency oscillatory ventilation (HFOV) (Kinsella et al, 1997). Treatment with systemic antibiotics should be strongly considered in babies with PPHN for a number of reasons. These include the fact that intrauterine infection might be a precipitating factor in the initial passage of meconium and that in vitro studies suggest that presence of meconium might facilitate the growth of bacteria in the lung.

In spite of the availability of iNO and high-frequency modes of ventilation, some babies do not respond to medical therapy and require treatment with ECMO. Among babies with MAS treated with ECMO, reported survival ranges between 94% and 97%, markedly higher than for newborns treated for other respiratory conditions (Brown et al, 2010; Gill et al, 2002).

SURFACTANT PROTEIN DEFICIENCY

The details of surfactant biology and of respiratory distress syndrome in premature newborns are presented elsewhere in this textbook. However, term newborns may rarely present with a clinical syndrome dominated by respiratory failure that may be indistinguishable from surfactant deficiency in preterm infants. In the setting of unexplained and protracted respiratory failure in term infants, genetic alterations of surfactant-associated proteins, particularly the surfactant proteins B and C (SP-B and SP-C) and the ABC Binding Cassette A3 protein (ABCA3), must be considered and ruled out. As described later, there is considerable overlap in the clinical presentation of babies with mutations of SP-B, SP-C, and ABCA3. Though onset, severity of clinical signs, and a family history of lung disease may offer clues to the underlying disorder, a full histologic and genetic evaluation should be considered. Genetic analysis of blood or buccal swab for mutations of the genes responsible for SP-B, SP-C, and ABCA3 are the definitive tests for each disease, but analysis is both costly and time-consuming. Moreover, analysis is not routinely available, necessitating transport of specimens to a small number of labs specializing in these analyses. In addition, bronchoalveolar lavage (BAL) aspirate should be analyzed by ELISA for the presence of SP-B and pro-SP-C. Lung biopsy, evaluated by both standard and electron microscopy, can also provide important clues to the underlying diagnosis.

Surfactant Protein B (SP-B) Deficiency

Mature SP-B is a small 79-amino-acid hydrophobic protein that plays several key roles in the processing and function of normal pulmonary surfactant (Nogee et al, 2000). Transgenic mouse models suggest that SP-B is critical for phospholipid packaging into lamellar bodies, the formation of tubular myelin, and spreading/function of the surfactant monolayer. In addition, normal SP-B appears to be essential for normal processing of surfactant protein C (Vorbroker et al, 1995). In all babies described to date with SP-B deficiency, the genetic mutation has been inherited from the parents (autosomal recessive) rather than occurring as a spontaneous mutation (Hamvas et al, 1994). Although multiple genetic mutations have been described, approximately 70% of affected babies carry the 121ins2 mutation (Dargaville and Copnell, 2006). In a recent series of term babies referred for genetic evaluation of unexplained respiratory failure, 2 of 17 had detectable mutations of the surfactant protein B sequence (Somaschini et al, 2007).

Almost all babies with recognized deficiency of SP-B develop clinical signs of severe respiratory distress, including tachypnea, grunting, and retractions, within the first several hours of life. Similar to preterm newborns with HMD, chest radiographs classically reveal diffuse, hazy airspace disease with visible air bronchograms. Severe pulmonary hypertension may be a prominent feature of the disease. Treatment with surfactant is either ineffective or unsustained, and progressive respiratory failure is the rule (Hamvas, 2006). Lung transplantation is currently the only effective long-term treatment, with both short- and long-term outcomes similar to those for other infants undergoing lung transplantation (Palomar et al, 2006).

Analysis of fluid obtained by BAL/tracheal aspirate from babies with SP-B deficiency should fail to detect any immunoreactive SP-B. The presence of proSP-C increases suspicion of SP-B deficiency because intact SP-B is necessary

for normal posttranslational processing of the protein to mature SP-C. Histologic findings include alveolar cell hyperplasia, interstitial thickening, and variable degrees of fibrosis and alveolar proteinosis. Staining of lung tissue for pro-SP-B is variable, but staining for mature SP-B should be minimal (because of cross-reactivity with epitopes on pro-SP-B) or absent. Initial DNA analysis focuses on the 121ins2 mutation. More exhaustive testing for other known mutations is warranted if initial testing is negative.

Surfactant Protein C (SP-C) Deficiency

Mature SP-C is a 35-amino-acid hydrophobic protein. SP-C is believed to enhance spreading of surfactant and to participate in normal surfactant catabolism (Whitsett et al, 2005). As with SP-B, multiple mutations of SP-C have been described; however, the majority of these mutations arise spontaneously and result in sporadic disease. Whether the abnormal phenotype associated with SP-C deficiency arises from dysfunction of the alveolar surfactant or from accumulation of abnormal cellular SP-C and consequent type II cell injury is not known.

In contrast to SP-B deficiency, babies with SP-C deficiency have a wide range of clinical presentations. Some may develop symptoms within the first several hours of life, similar to SP-B deficiency, whereas others present later in child- or adulthood with interstitial lung disease. The reasons that underlie the variable onset, presentation, and severity of individuals with SP-C deficiency are not currently understood.

In common with SP-B deficiency, the lung histopathology of patients with SP-C deficiency is nonspecific and widely variable. Common findings include accumulation of alveolar protein and macrophages and epithelial cell hyperplasia. Ultrastructural examination may reveal disorganized lamellar bodies with aggregates of small vesicles with electron-dense cores in the type II cells (Nogee et al, 2001). Allele-specific testing using PCR for the most common 173T mutation provides an initial screen for SP-C deficiency. If negative, direct sequencing of the entire SP-C gene should be undertaken.

ATP-Binding Cassette A3 Gene (ABCA3) Deficiency

The ATP-binding cassette (ABC) transporter proteins are essential for normal transport of compounds in numerous biologic systems (Mulugeta et al, 2002). Deficiencies of individual ATP-binding cassettes have been associated with clinical diseases in a number of different organ systems. The ABCA3 protein is highly expressed in the lung and is involved in the transport of lipids. Individuals lacking the gene for ABCA3 have abnormal accumulation of surfactant-rich lamellar bodies within their type II alveolar cells, with apparent inability to transport surfactant into the alveolar space. A study by Shulenin et al (2004) details a variety of mutations within the ABCA3 gene in a substantial portion of term infants with unexplained respiratory failure and suspected surfactant protein deficiency.

Age at presentation for individuals with ABCA3 deficiency is highly variable, ranging from the immediate newborn period to later in childhood. There may be a family history of consanguinity. Clinical manifestations of disease in the neonate may be indistinguishable from those with SP-B deficiency, with onset of respiratory failure within hours of birth. The disease may be progressive and fatal. In addition, ABCA3 deficiency may also manifest as severe persistent pulmonary hypertension of the newborn (Kunig et al, 2007). A recent report suggests that more mild, transient neonatal symptoms may not prompt a diagnostic evaluation in the newborn period, though recurrent pulmonary symptoms may lead to later investigation (Doan et al, 2007). These reports raise the possibility that deficiency of ABCA3 may be underrecognized in infants or children with a mild or normal phenotype.

The predominant pathologic findings of neonates with ABCA3 deficiency presenting with neonatal respiratory failure include alveolar proteinosis (Bullard et al, 2006), type II cell hyperplasia with dense lamellar bodies, and accumulation of alveolar macrophages in the distal airspace. Inheritance is believed to be autosomal recessive. Unlike SP-B deficiency, a single predominant mutation has not been described; rather, multiple distinct mutations affecting different protein domains have been identified (Brash et al, 2006).

Surfactant Proteins A and D

Although lung structural abnormalities have been described in mice lacking SP-A and SP-D, no phenotype attributable to abnormalities of either of these surfactant-associated proteins has been described in human infants.

CONGENITAL DIAPHRAGMATIC HERNIA

CDH is a complex clinical syndrome caused by a developmental defect in the diaphragm, resulting in a spectrum of potentially severe cardiopulmonary abnormalities (Figure 47-2). The estimated incidence of CDH ranges from approximately 1:2500 to 1:7000 live-born babies

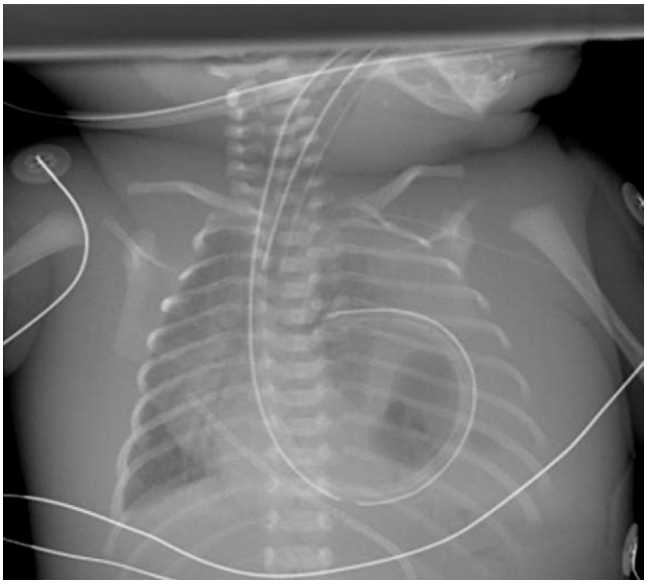

FIGURE 47-2 Chest radiograph of CDH. Note proper position of orogastric tube and UVC (*arrow*) in an infant with left-sided congenital diaphragmatic hernia.

(Prober, 2007). Approximately 80% to 85% of diaphragmatic hernias occur on the left side. In rare circumstances, they may be bilateral. Anatomically, CDH is classically divided by location into posterolateral (Bochdalek) defects, retrosternal anterior (Morgagni) defects, and other anterior or central defects. The vast majority, 90% to 95%, are of the Bochdalek type. However, recent work has suggested that the classical anatomic distinctions cannot always be clearly differentiated (Prober, 2008). Moreover, the implications of hernia location on severity of illness or mortality are not clearly defined.

As many as 30% to 40% of babies with CDH have additional congenital anomalies, most commonly of the heart, central nervous system, and genitourinary system. The remaining 60% to 70% of babies have isolated CDH without other identifiable major anatomic malformations. CDH may occur as an element of several well-recognized syndromes or of a chromosomal abnormality (particularly trisomy 18). A recent study suggests that, in babies with CDH but without a recognized genetic syndrome, 10% to 15% have heart defects, most commonly septal defects, conotruncal malformations, and obstruction of the left ventricular outflow tract (Lin et al, 2007). Coexisting cardiac disease complicates the management of babies with CDH and likely increases mortality.

Medical management of the newborn with a CDH remains one of the most complex and challenging situations for a neonatologist. A host of interrelated issues must be considered, including optimal mechanical ventilation strategies, presence and treatment of pulmonary hypertension, evaluation of cardiac performance, and consideration of support with ECMO. Unfortunately, owing to the relative infrequency of CDH, definitive studies guiding clinical decisions in the management these babies are lacking.

The optimal mode and strategy of mechanical ventilation in CDH has not been definitively established. Previously, aggressive hyperventilation and alkalinization as a means to lower pulmonary vascular resistance was advocated (Bohn et al, 1987). More recently, with the recognition that aggressive mechanical ventilation to the point of hyperventilation may cause significant iatrogenic lung injury and worsen outcome, this approach has generally been abandoned (Sakurai et al, 1999). However, prospective trials to clearly guide ventilator strategy are lacking. Many experts now advocate a gentle ventilation strategy that minimizes peak inspiratory pressure, targets $PaCO_2$ levels between 40 and 60 torr, and tolerates postductal desaturation if preductal saturations are adequate. If a conventional ventilator strategy is used and peak inspiratory pressures needed to achieve these goals are unacceptably high (generally 25 to 30 cm H_2O), transition to HFOV is undertaken (Bohn 2002; Boloker et al, 2002; Finer et al, 1998). As an alternative, some advocate earlier or initial use of HFOV (Bagolan et al, 2004; Frenckner et al, 1997; Reyes et al, 1998). Though definitive evidence in support of this gentle ventilation strategy is lacking owing to the retrospective nature of the cited reports, mortality in several centers has fallen coincident with adoption of this approach.

Pulmonary hypertension (PH) is a well-recognized complication of CDH. Decreased cross-sectional area of the pulmonary circulation, structural remodeling of the pulmonary vessels, and diminished size and function of the left ventricle have all been implicated in the PH associated with CDH. Newborns with CDH should all undergo early echocardiography to ascertain the presence of associated heart defects, to assess the degree of pulmonary hypertension, and to evaluate the function of the left and right ventricles. Treatment of early PH in babies with CDH is controversial. Inhaled nitric oxide did not reduce mortality among a group of infants with CDH failing aggressive medical therapy (Neonatal Inhaled Nitric Oxide Study Group, 1997). Moreover, newborns treated with iNO in that study more frequently required ECMO than the control group, likely related to the adverse effects of pulmonary vasodilation in the presence of severe left ventricular dysfunction, potentially worsening systemic hemodynamics. Current evidence does not support the routine use of iNO in the first 24 hours after birth in infants with CDH. Consideration of its use should be limited to those babies with optimized lung inflation and well-defined PH who do not have evidence of impaired left ventricular performance and right ventricle–dependent systemic blood flow (Kinsella et al, 2005). Other pharmacologic pulmonary vasodilators to treat acute PH in babies with CDH have not been carefully evaluated. In babies with severe PH and a closed ductus arteriosus, consideration should be given to restoration of ductal patency with prostaglandin infusion, to allow the right ventricle to serve as a source of systemic blood flow (Kinsella et al, 2005).

Animal models of CDH demonstrate biochemical and physiologic evidence of surfactant deficiency (Glick et al, 1992). In these models, surfactant replacement lowers PVR and improves gas exchange and lung mechanics (O'Toole et al, 1996; Wilcox et al, 1994). Studies of human babies with CDH also suggest a delay in surfactant maturation, and postmortem studies of babies with CDH commonly demonstrate the presence of hyaline membranes (Hisanaga et al, 1984; Moya et al, 1995). Taken together, these studies raise the possibility that surfactant replacement therapy might have a role in the management of babies with CDH. Although initial anecdotal evidence supported this possibility, a more recent retrospective study of more than 500 term babies with CDH suggested that surfactant treatment was associated with greater ECMO use, increased chronic lung disease, and reduced overall survival (Van Meurs et al, 2004). These findings strongly argue against the routine use of surfactant replacement in babies with CDH.

Owing to the infrequency of CDH and the wide variability in therapeutic approaches (both among centers and over time at individual centers), few studies of long-term outcome have been published. Moreover, almost all represent the experience of single centers. That said, several small recent studies suggest that babies born with CDH are at risk for a number of serious long-term morbidities, including impaired neurodevelopmental outcome, wheezing/asthma, protracted pulmonary hypertension, sensorineural hearing loss, gastroesophageal reflux (GER), scoliosis, and pectus excavatum (Peetsold et al, 2009). One recent study reports lower than anticipated scores on tests of intelligence and adaptive behavior among 11 CDH survivors who were not treated with ECMO (Bouman et al, 2000).

Stolar et al (1995) report that among 51 babies treated with ECMO, the subset of those with CDH had worse cognitive outcome than those with alternative underlying diagnoses. Neurologic (physical) testing was similar between the two groups. Though concerning, these findings must be interpreted with caution, because mean age at evaluation was only 31 months. CDH is also associated with a high rate of sensorineural hearing loss (SNHL), nearly 50% in a recent study (Morini et al, 2008). The causes that underlie the high incidence of SNHL in this population, and whether it represents a genetic/anatomic predisposition or is a result of treatment-related risk factors, have yet to be clarified.

As might be expected, several cardiopulmonary sequelae of CDH have been reported. In a follow-up study of adolescents born with CDH, Trachsel et al (2005) report several abnormalities elicited by pulmonary function testing. Compared with normal controls, CDH survivors demonstrated mild to moderate airway obstruction, and nearly half were responsive to bronchodilators. CDH patients also had decreased inspiratory muscle strength and maximum minute ventilation. In spite of these findings, these adolescents generally had minimal compromise of daily activities. The persistence of pulmonary hypertension in some patients with CDH remains a major concern. After CDH repair and with readiness for extubation from mechanical ventilation, some infants with underlying pulmonary hypertension develop suprasystemic pulmonary artery pressures with discontinuation of iNO. Kinsella et al (2003) has reported successful ongoing treatment of these babies with delivery of noninvasive iNO via nasal cannula. Schwartz et al (1999) report that 38% of their CDH patients who required ECMO had echocardiographic evidence of PH well beyond the newborn period, with a mean follow-up age of over 3 years. Importantly, most of those children had no apparent physical signs or symptoms of PH, supporting the need for proactive, ongoing surveillance. Although recent studies focused on the long-term follow-up of pulmonary vascular disease in these patients are lacking, the American Academy of Pediatrics recommends serial echocardiographic evaluation of children with CDH who have persistent pulmonary hypertension after repair (Lally and Engle, 2008). Newer pharmacologic agents for PH, such as phosphodiesterase inhibitors (sildenafil) or endothelin antagonists such as bosentan may offer effective longer-term therapy for PH, but have not been investigated in this population.

Postnatal nutrition presents a major challenge for many survivors of CDH. Among 121 CDH survivors, Muratore et al (2001) reported that one third had failure to thrive requiring the placement of a gastrotomy tube for the provision of adequate calories, and 25% demonstrated evidence of oral aversion. Many reports have documented the high incidence of GER after repair of CDH, and recent studies report that 12% to 28% require fundoplication for severe GER (Diamond et al, 2007; Fasching et al, 2000; Su et al, 2007).

PULMONARY HYPOPLASIA

In the absence of a diaphragmatic hernia, pulmonary hypoplasia and respiratory failure can develop in association with a number of other conditions. An extensive list of conditions associated with pulmonary hypoplasia has been generated, but most cause either restriction of normal fetal breathing motion or compression of the developing lung. Thus, among the most common causes of pulmonary hypoplasia are low amniotic fluid volumes, neuromuscular disorders, pleural effusions/chylothoraces, and space-occupying lung lesions.

Inadequate amniotic fluid volume to allow for normal fetal breathing can result from a number of circumstances. Because fetal urine is a primary contributor to amniotic fluid volume, any abnormality of renal development that limits fetal urine production or urine flow can result in pulmonary hypoplasia. In addition, preterm premature rupture of membranes (PPROM), particularly with persistent leak of amniotic fluid, can result in pulmonary hypoplasia. Estimates of the risk of pulmonary hypoplasia with PPROM vary widely, and multiple studies have attempted to define the variables related to oligohydramnios sufficient to result in pulmonary hypoplasia (Hadi et al, 1994; Kurkinen-Raty et al, 1998; Vergani et al, 1994). Though absolute criteria are not adequately defined, most authors agree that gestational age at onset of oligohydramnios is a critical determinant of risk (Kurkinen-Raty et al, 1998; Nimrod et al, 1984). In some studies, longer latency from rupture of membranes to delivery (particularly in excess of 4 weeks) and the severity of resulting oligohydramnios (median amniotic fluid pocket ≤2 cm) also increase the risk of pulmonary hypoplasia (Kurkinen-Raty et al, 1998; McIntosh and Harrison, 1994). Vergani et al (2004) found that, among babies born to mothers with prolonged premature rupture of membranes before 28 weeks' gestation, mortality was approximately 50%, and nearly half of those who died had pulmonary hypoplasia. Amnioinfusion to reestablish amniotic fluid volume may decrease the incidence of pulmonary hypoplasia (Vergani et al, 2004).

Definitive diagnosis of pulmonary hypoplasia can only be made at autopsy. Norms have been established for both the gestational age–corrected ratio of lung weight to body weight and for histologic evaluation of radial alveolar counts (Askenazi and Perlman, 1979; Lauria et al, 1995). Clinical criteria for pulmonary hypoplasia are less well defined. Neonates may present with a bell-shaped chest and elevated diaphragms on chest radiograph. Management of pulmonary hypoplasia should focus on maximizing lung inflation while avoiding pneumothorax, the incidence of which ranges widely, depending on the study (Klaassen et al, 2007; Leonidas et al, 1982). Ventilator strategies include permissive hypercapnia to minimize lung injury and use of HFOV. If pulmonary hypertension is defined echocardiographically, use of iNO should be considered. With sustained postnatal ventilatory support, the pulmonary hypertension associated with pulmonary hypoplasia may resolve over time. For additional discussion of pulmonary hypoplasia in preterm infants, see Chapter 46.

SUMMARY

The initial evaluation of respiratory distress/hypoxemia in the term newborn presents one of the most difficult challenges faced by pediatricians and neonatologists. An ordered approach using information derived from the

history, physical examination, pulse oximetry measurements, radiographic and laboratory measurements, and echocardiography can help elucidate the cause of hypoxemia and respiratory failure and direct each step of clinical management. Recognizing the important contributions of parenchymal lung disease, pulmonary vasoconstriction, and cardiac performance is critical to successful clinical management of the term newborn with respiratory failure.

CHAPTER 48

Bronchopulmonary Dysplasia

Roberta L. Keller and Roberta A. Ballard

HISTORICAL OVERVIEW

Bronchopulmonary dysplasia (BPD), also referred to as *chronic lung disease of prematurity*, is the most common chronic lung disease of childhood. BPD was first described by Northway et al in 1967 as a severe chronic lung injury in premature infants who survived hyaline membrane disease after treatment with mechanical ventilation and oxygen. Four distinct clinical stages were described radiographically and pathologically, progressing from typical respiratory distress syndrome (RDS), with alveolar interstitial edema as well as atelectasis, to massive fibrosis and consolidation of the lung with areas of cystic emphysema and overinflation.

BPD as originally described occurred predominantly in larger preterm infants born at 30 to 34 weeks' gestation with a history of severe respiratory distress necessitating high levels of ventilatory support and oxygen exposure for a prolonged period of time. These infants were born before the introduction of antenatal corticosteroids or postnatal surfactant replacement therapy and at a time when ventilators were first being adapted for use in the newborn.

Since that time, much has been learned about BPD, and the disorder as originally described has become rare. The infants who are more commonly affected with BPD today are those of extremely low birthweight and born at less than 26 weeks' gestation. After exposure to antenatal corticosteroids, combined with postnatal exogenous surfactant for treatment of RDS, these infants frequently do remarkably well initially, requiring low levels of supplemental oxygen and ventilatory support. They often have a subsequent period of several days during which there is minimal or no requirement for ventilatory support, before entering into a more chronic phase of variable requirements for assisted ventilation and supplemental oxygen. The form of BPD seen in the contemporary tiny preterm infant who has had minimal initial respiratory distress has been termed the *new* BPD, with arrested lung development affecting both alveologenesis and the pulmonary vascular bed (Abman, 2001, 2008; Bancalari, 2001; Jobe, 1999). Although the initial definition of BPD was a persistent requirement for supplemental oxygen 28 days after birth, in a subsequent attempt to define the functional implications of abnormal postnatal lung development, the need for oxygen at 36 weeks postmenstrual age (PMA) was found to be a better predictor of later pulmonary illness in extremely premature infants (Shennan et al, 1988). The definition of BPD was reviewed most recently at a National Institutes of Health–sponsored workshop (Jobe and Bancalari, 2001). This group specified diagnostic criteria including the need for oxygen, positive pressure ventilation, and/or continuous positive airway pressure (CPAP) at 36 weeks' PMA to better characterize the severity of BPD, with an oxygen reduction challenge test (to room air) performed in infants who are receiving supplemental oxygen only (Table 48-1). Using similar criteria, data from the NICHD Neonatal Network demonstrated increasing frequency of respiratory morbidity and neurodevelopmental impairment at follow-up with increasing severity of BPD (Ehrenkranz et al, 2005). Further, the definition of BPD using the need for supplemental oxygen alone was equally predictive of later pulmonary morbidity as was the need for oxygen plus an abnormal chest radiograph.

In the presurfactant era, there was remarkable consistency in the postmenstrual age at which infants surviving without later pulmonary morbidity were weaned off supplemental oxygen (Shennan et al, 1988). Subsequent studies have shown substantial proportions of infants with no BPD who do have later respiratory morbidity and even higher proportions of infants with BPD who have no respiratory morbidity (Ehrenkranz et al, 2005). Because survival for the most immature newborns has improved since the introduction of surfactant replacement therapy and the broadening use of antenatal corticosteroids, it may be that later assessments of pulmonary status, at 40 weeks PMA, for example, will prove better measures of later lung function and respiratory morbidity (Keller et al, 2009).

BRONCHOPULMONARY DYSPLASIA

EPIDEMIOLOGY

BPD is now relatively rare in infants born beyond 32 to 34 weeks' gestation, but it may be increasing in the smallest, most immature infants born at less than 26 weeks' gestation or less than 1000 g as survival has improved. In the NICHD Neonatal Network, the incidence of BPD at 36 weeks postmenstrual age in all infants weighing 501 to 1500 g at birth increased from 19% in 1990 to 22% in 2000, with another increase to 27% in 2003. Increased survival has been associated with these trends. As a result, survival without morbidity was unchanged from 1990 to 2002, with BPD now a greater chronic health burden in former premature infants than it was previously (Fanaroff et al, 2007). Comparable infants from the larger Vermont Oxford Network had an incidence of BPD of 29% in 2003 and 26% in 2007. The highest rates of BPD are in the smallest infants, 66% for those 501 to 750 g and 40% for those 751 to 1000 g birthweight (from 2007), but both networks report wide variability in the incidence of BPD at different centers. For infants less than or equal to 1000 g at birth, the incidence of BPD was 44% in infants in the NICHD Neonatal Network (from 1995 to 1999) (Ehrenkranz et al, 2005). Increasing severity of BPD was associated with decreasing gestational age, male sex, and race (relatively higher incidence for white infants and lower incidence for black infants).

TABLE 48-1 Diagnostic Criteria for Bronchopulmonary Dysplasia

Treatment with F_{IO_2} greater than 0.21 for at least 28 days	
PLUS	
Failure of room air challenge test at 36 weeks' postmenstrual age	
CLASSIFICATION OF SEVERITY	
Mild	Requires up to 0.30 effective F_{IO_2}*
Moderate	Requires greater than 0.30 effective F_{IO_2}*
Severe	Requires ventilatory support, usually with oxygen

Data from Jobe AH, Bancalari E: Bronchopulmonary dysplasia, *Am J Respir Crit Care Med* 163:1723-1729, 2001.
F_{IO_2}, Fraction of inspired oxygen.
*Effective F_{IO_2} is based on infant's weight and the concentration and flow of oxygen through a nasal cannula or in a hood.

The level of respiratory support after the initial recovery from RDS may be the best indicator of the risk of subsequent BPD in very immature infants. In the Extremely Low Gestational Age Newborn (ELGAN) study, three patterns of respiratory support in infants <28 weeks' gestation 3 to 14 days of age were described (Laughon et al, 2009b). The overall incidence of BPD was 51%. Infants with a persistently low level of oxygen supplementation had the lowest rate of BPD (17%), infants with a deterioration in their pulmonary status (initially low level of oxygen supplementation increasing in the 2nd week) had an intermediate incidence of BPD (51%), and infants with persistently higher oxygen requirements had the highest rate of BPD (67%). Mechanical ventilation was also closely associated with these patterns of oxygen supplementation. At postnatal day 7, fewer than 5% of infants in the low-oxygen group were receiving mechanical ventilation, almost 40% of the pulmonary deterioration group were intubated, and 50% of the higher oxygen group were intubated. Consistent with these data, infants enrolled in the placebo arm of the Nitric Oxide Chronic Lung Disease (NO CLD) Trial had an incidence of BPD or death of 75% if they were requiring mechanical ventilation at 7 days (Ballard, 2007; Ballard et al, 2006).

PATHOBIOLOGY

The etiology of BPD is clearly multifactorial and involves derangements in multiple aspects of lung function (e.g., surfactant production), repair from injury (e.g., elastin deposition) and growth and development (e.g., alveologenesis). Various factors contribute to this process, including a susceptible host with immature lung structure, and developmental deficiencies of factors crucial to lung development and function such as surfactant, nitric oxide, innate immune defense, and antioxidant capability (Figure 48-1). Inadequate nutrition, resulting in postnatal growth failure, may further exacerbate structural lung abnormalities and impair the ability of these infants to recover.

Pathologic Findings in the "New" Form of the Disease

In the chronic stage of BPD as originally described, the lung had extensive alveolar fibrosis, airway abnormalities and pulmonary vascular remodeling (Bonikos et al, 1976, Northway et al, 1967). In contrast in the "new" BPD, the lungs are more uniformly inflated with minimal airway injury and less prominent fibrosis. The major abnormalities are a decrease in alveolar number (referred to as *alveolar hypoplasia*) and dysregulated microvascular growth (Bhatt et al, 2001; Burri, 1997; Coalson et al, 1999; De Paepe et al, 2006, 2008; Husain et al, 1998; Maniscalco et al, 2002). In the very preterm infants in whom this new BPD is seen (Figure 48-2), the lung is completing the canalicular stage of development at the time of birth; some investigators have noted an arrest of the lung at the saccular stage of development (De Paepe et al, 2006). There are a number of factors that interfere with the progress of postnatal alveologenesis which may contribute to the disordered lung development seen in contemporary premature newborns.

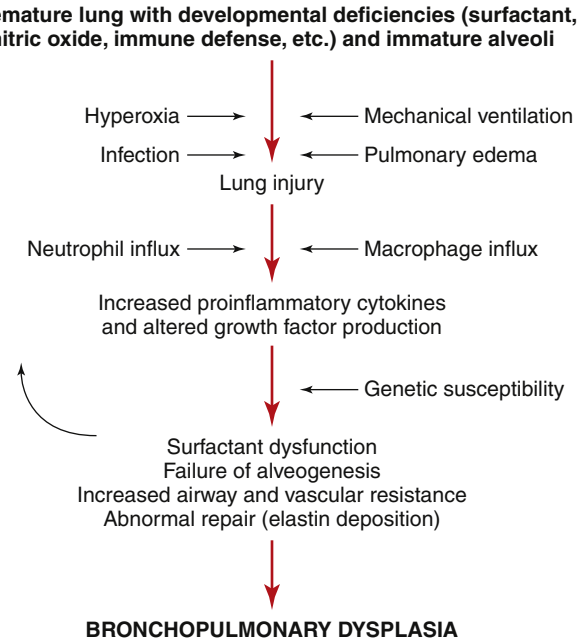

FIGURE 48-1 The pathogenesis of BPD. Lung injury in the immature lung secondary to hyperoxia, mechanical ventilation, and infection initiates an inflammatory response with an altered milieu of growth and inflammatory factors. Continuing insults contribute to the long-term changes in lung structure that characterize BPD. *BPD*, Bronchopulmonary dysplasia.

ETIOLOGIC FACTORS

We currently understand BPD to have a multifactorial etiology with many contributing factors.

Host Susceptibility and Genetic Predisposition

By far the most important factor in the pathogenesis of BPD is prematurity, although infants with intrauterine growth restriction are at increased risk (Bose et al, 2009; Lal et al, 2003). In addition, it has been known for some time that infants born to certain families are more likely to have RDS at any given gestational age than those in other families. Twin studies have supported this clinical impression, revealing that 50% to 80% of the variance in the

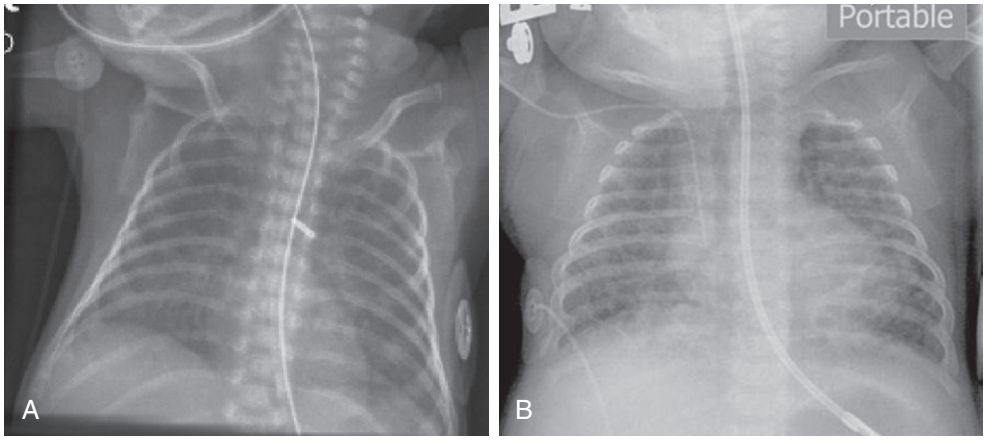

FIGURE 48-2 Radiographs of bronchopulmonary dysplasia characteristic of the new and old forms of the disease. A, Bilateral fine granular opacification consistent with atelectasis or edema in an infant with moderate disease. **B,** Bilateral coarse interstitial opacification consistent with fibrosis or edema and areas of hyperinflation in an infant with severe disease.

occurrence of BPD is due to genetic factors (Bhandari et al, 2006; Lavoie et al, 2008). In addition, a family history of asthma and reactive airway disease may increase the risk of BPD (Hagan et al, 1995; Nickerson and Taussig, 1980). Several studies have described the association of BPD with single nucleotide polymorphisms (SNPs) for genes involved in the inflammatory response, innate immunity, surfactant function and the extracellular matrix such as interleukins, collectins, surfactant-associated proteins, and proteases. Other pathways that are candidates for altering an infant's risk of BPD include (1) factors affecting alveologenesis and vascular growth and remodeling, such as those involved in vascular endothelial growth factor (VEGF), nitric oxide (NO), and transforming growth factor-β_1 (TGF-β_1) production and signal transduction; and (2) factors affecting the response to oxidative stress. In addition to further evaluations of these and other candidate gene relationships in larger and confirmatory patient populations, genome-wide association studies, wherein the entire genome is sequenced, could yield more information about the genes responsible for the familial associations that have been seen. These investigations may ultimately lead to more directed therapies for high-risk, susceptible infants.

Inflammation

A complex inflammatory response clearly plays a major role in the development of BPD (Yoon et al, 1999). This response may be triggered by a number of other factors thought to be a part of the pathobiology of BPD. These triggers include a fetal inflammatory response and increased concentrations of inflammatory cytokines in amniotic fluid, cytokines produced as a result of neonatal infection, and other neonatal inflammatory insults such as oxidant damage due to oxygen toxicity and volutrauma associated with mechanical ventilation.

The inflammatory response is reflected in increased numbers of neutrophils in tracheal aspirate samples as early as the 2nd day of life (Arnon et al, 1993). Although alveolar macrophages are essential for recognition, ingestion, and elimination of lung pathogens, they also produce fibroblast, epithelial, and endothelial cell growth factors, leading to lung tissue repair. In addition, they can have deleterious effects through release of oxygen radicals and can release fibronectin, a large glycoprotein that is a growth factor for fibroblasts, as well as releasing the growth factor TGF-β, which stimulates the growth of mesenchymal cells and inhibits proliferation of epithelial cells. Selected cytokines, chemokines, and other inflammatory factors are found to be elevated in lung lavage fluid of infants in whom BPD develops, while levels of IL-10, CC10, and VEGF are reported to be decreased in infants with BPD (see Box 48-1) (Bose et al, 2008; Ryan et al, 2008). A recent study of blood cytokine levels in preterm infants found that higher concentrations of IL-1β, IL-6, and interferon-γ were associated with BPD or death (Ambalavanan et al, 2009). Studies of mediators in lung fluid, compared to plasma, may have the advantage of reflecting the milieu adjacent to the epithelium and therefore lung inflammation rather than the systemic fetal or neonatal inflammatory response. Box 48-1 lists the factors found in tracheal aspirate or lavage samples that are associated with the development of BPD in the preterm infant.

Neonatal Infection

Airway microbial colonization with a variety of organisms, including *Ureaplasma urealyticum*, is associated with a diagnosis of chorioamnionitis, evidence of lung inflammation and an increased risk of BPD (Bhandari et al, 1998; Cordero et al, 2001; Groneck et al, 1996; Young et al, 2005). Recovery of *Ureaplasma* spp. or *Mycoplasma hominis* from cord blood in preterm infants has also been associated with an increased neonatal inflammatory response (Goldenberg et al, 2008), and postnatal bacterial sepsis with gram-positive, gram-negative, or fungal organisms is associated with an increased risk of BPD (Gagliardi et al, 2007; Stoll et al, 2002). There has been a lot of interest in the relationship of fastidious organisms to preterm lung disease. *Ureaplasma urealyticum* infection has been associated with precocious pulmonary interstitial fibrosis on postmortem evaluation (Viscardi et al, 2002), and a recent systematic review demonstrated a significant association between recovery of *Ureaplasma* from the respiratory tract

and BPD at 36 weeks (OR 1.6; 95% confidence interval [CI] 1.1, 2.3), although studies with smaller sample sizes were more likely to report a significant association than those with larger ones (Schelonka et al, 2005). Despite these data, in small randomized studies, early appropriate antibiotic (macrolide) therapy does not alter recovery of the organism from tracheal aspirate samples or the incidence of BPD, regardless of colonization status (Baier et al, 2003; Ballard et al, 2009a, 2009b). Thus, if the new BPD in the tiny preterm infant is a syndrome of arrested lung development, it may be that even short-term exposure to microbial organisms and the resultant inflammatory response (increasing with prolonged ventilation) contribute to the arrest of normal alveolarization and microvascular growth.

Oxygen Toxicity and Oxidative Stress

In the initial cases of BPD reported by Northway et al (1967), it was clear that exposure to high oxygen concentration was a factor in development of the disease. Subsequent reports have continued to show an association between high levels of supplemental oxygen or prolonged oxygen exposure and lung damage in ventilated preterm infants. More recent evidence (STOP-ROP, 2000) suggests that even a slight increase in inhaled oxygen concentration over a prolonged time increases respiratory morbidity. In experimental animals, prolonged hyperoxic exposure recapitulates the clinical and morphometric findings of the older and newer forms of BPD (Coalson et al, 1995; Warner et al, 1998), and oxidative stress has been implicated in the pathogenesis of the morphometric changes in these models (Chang et al, 2003; Ratner et al, 2009). The damage to the lung caused by oxygen toxicity appears to be mediated by reactive oxygen species that are produced during univalent reduction of molecular oxygen. These species include superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), and hydroxyl radical (OH^-). Evidence suggests the presence of an oxidant-antioxidant imbalance in lungs that are at risk for BPD. Vento et al (2009) found that even short exposure to hyperoxia during resuscitation increased the duration of mechanical ventilation and the incidence of BPD in extremely premature newborns. The infants resuscitated with high oxygen in that study had higher ratios of oxidized-to-reduced glutathione levels in blood as well as increased urine levels of oxidized proteins and DNA in the 1st week of life. Similarly, preterm infants exposed to higher inspired oxygen concentrations during resuscitation in another small randomized study had increased total blood hydroperoxides (Ezaki et al, 2009). Other observational studies have found higher concentrations of lipid peroxidation metabolites, as well as excess carbonylated proteins, in preterm infants later developing BPD, compared to preterm controls without BPD, further supporting the concept of oxidant-antioxidant imbalance (reviewed in Saugstad, 2003). Antioxidant defenses are decreased in preterm infants, and critical nutrients such as retinoic acid (shown to suppress both superoxide and hydrogen peroxide formation in stimulated neutrophils and macrophages) are deficient (reviewed in Shenai, 1999). Nitric oxide, either endogenous or exogenous in origin, may function as either a pro- or antioxidant. However, no significant differences were seen in plasma carbonylated or nitrosylated protein levels in infants treated with inhaled nitric oxide (iNO) versus placebo in the randomized NO CLD Trial over the first 10 days of gas administration, when iNO dose was 10 to 20 ppm (Ballard et al, 2008). An early randomized trial of allopurinol, a xanthine oxidase inhibitor studied for its potential neuroprotective effects, demonstrated no differences in the incidence of BPD at 28 days (Russell et al, 1995). In a more recent trial, intratracheal recombinant human superoxide dismutase did not affect the incidence of BPD at 36 weeks, but treated infants had less pulmonary morbidity than control infants at 1-year follow-up (Davis et al, 2003). The effect of lower target oxygen saturation parameters on the incidence of BPD was studied in the NICHD Neonatal Network Surfactant Positive Airway Pressure and Pulse Oximetry Trial (SUPPORT) Trial (Carlo et al, 2010). Although the incidence of BPD and BPO or death was decreased in infants managed with lower oxygen saturations, these differences were small in magnitude and not statistically significant. In addition, infants tended to be maintained at the higher end of the target range with substantial overlap between the two groups.

Ventilation With Volutrauma

As is the case with exposure to high oxygen, the association between overdistention of the preterm lung and the development of BPD is well established. It is clear that overinflation produces stress fractures of the capillary endothelium, epithelium, and basement membrane. This mechanical injury causes leakage of fluid into the alveolar spaces, with additional inflammatory response and the release of additional proinflammatory cytokines. The relative contribution of high peak inspiratory pressures (*barotrauma*) versus overdistention of the lung (*volutrauma*) to lung injury previously was a source of some controversy. Hernandez et al (1989) compared the respective roles of high tidal volume with high peak inspiratory pressure (PIP) in immature New Zealand White rabbits to look at the effect on microvascular permeability in animals that were treated with chest wall restriction with a full-body plaster cast. Preventing overdistention also prevented any significant increase in microvascular permeability, even with manometer-indicated pressures up to 45 cm H_2O. In contrast, when isolated excised lungs were ventilated with peak inspiratory pressures of only 15 cm H_2O for 1 hour (with overdistention), there was an 850% increase in microvascular permeability. This finding suggests that preterm infants with relatively healthy lungs and highly compliant chest walls may experience significant lung

injury even at apparently low ventilator pressures. In addition, in the preterm lamb model, manual ventilation with as few as six very large breaths at birth may compromise the therapeutic effect of subsequent surfactant administration, leading to significant lung damage (Bjorklund et al, 1997; Dreyfuss et al, 1998). Evidence that exposure to high tidal volumes in preterm human infants contributes to BPD comes from several sources. In particular, there is an association between hypocarbia and an increased incidence of BPD (Garland et al, 1995; Kraybill et al, 1989), as well as a known strong association between the occurrence of pneumothorax and pulmonary interstitial emphysema with lung overdistention.

Multiple attempts have been made to decrease the incidence of BPD through improved ventilatory strategies (see also Chapter 45 on the principles of respiratory care). The use of high-frequency oscillatory ventilation (HFOV) as a primary mode of ventilation is one such strategy (Courtney et al, 2002; Johnson et al, 2002; Moriette et al, 2001). Although a statistically significant decrease in the incidence of BPD has been described in some studies, none of the studies using HFOV achieved large clinically relevant differences in outcome. A recent (2009) Cochrane Collaboration metaanalysis of randomized clinical trials of HFOV (with 10 of 17 trials published since 2000) found that there was not a significant overall effect of ventilation mode on the incidence of BPD (RR 0.90; 95% CI 0.78, 1.03) (Cools et al, 2009). In addition, over time, as lung protection strategies on conventional ventilation have become more standard, any benefit of high frequency ventilation on the incidence of BPD has decreased (Bollen et al, 2003). On the other hand, a randomized trial to evaluate a minimal ventilation strategy (higher $PaCO_2$ and lower pH targets compared to more standard $PaCO_2$ and pH targets) demonstrated no differences in the incidence of BPD or death (63% vs. 68%), other major morbidities, and long-term outcomes (Carlo et al, 2002). However, the need for ventilatory support at 36 weeks PMA was significantly lower in the minimal ventilation group compared to the routine conventional ventilation treatment group (1% vs. 16%). Thus, the more permissive approach to assisted ventilation appears to influence the severity of BPD, although this approach alone may be insufficient to prevent the disorder.

In 1987, Avery and associates published a descriptive review of treatment center differences in the incidence of BPD. At one neonatal center, use of nasal CPAP immediately after delivery was associated with a much lower incidence of BPD than that reported by the other centers. Van Marter et al (2000) compared the practices and outcomes for neonatal units in Boston and at Columbia University and found that the incidence of BPD at Columbia overall was much lower, as was the use of interventions, including mechanical ventilation, surfactant administration, indomethacin treatment, and sedation. The use of nasal CPAP was higher and infants at Columbia were intubated less frequently than at the other centers. These investigators found that the best predictor of subsequent BPD at any time point from day 1 to 7 was the requirement for mechanical ventilation at that time, regardless of which institution the infant was in.

The need for early ventilation identifies the sickest infants who would usually die without intervention. In a report from Columbia University, mortality was 66% among infants ≤1250 g birthweight who received mechanical ventilation (after initial resuscitation) (Ammari et al, 2005). These infants generally were more depressed at delivery, with lower Apgar scores. Among infants who received nasal CPAP after resuscitation, 55% of those <26 weeks were intubated by 72 hours of age. Gestational age <26 weeks, birthweight ≤750 g, severe RDS by radiograph, and poor initial oxygenation had positive predictive values of 50% to 55% for failure of CPAP, and infants who required intubation were more likely to have a diagnosis of pneumothorax, severe intracranial hemorrhage, and BPD. This group of infants was supported with "bubble" CPAP, where the end expiratory pressure is created by an underwater seal. Bubble CPAP has been shown to deliver consistently higher intraprong pressures than ventilator-delivered CPAP set to the same end-expiratory pressure (Kahn et al, 2008). Nasal CPAP, in general, and bubble CPAP, in particular, have been successful in maintaining a greater proportion of premature infants extubated after mechanical ventilation, a strategy that may be particularly indicated in the most premature babies (Gupta et al, 2009; Ho et al, 2002). Other advances in the delivery of nasal CPAP since the initial description of its use in preterm infants include the use of a dedicated variable-flow nasal CPAP system, with nasal prongs or a nasal mask, which appears to significantly decrease the work of breathing in comparison to ventilator-delivered nasal CPAP (DeKlerk and DeKlerk, 2001; Pandit et al, 2001).

The preferential application of nasal CPAP to prevent BPD was studied in the Continuous Positive Airway Pressure or Intubation at Birth (COIN) Trial. Infants from 25 to 28 weeks' gestation needing assisted ventilation at 5 minutes of age were randomized to receive nasal CPAP or mechanical ventilation (Morley et al, 2008). There was a significant decrease in the need for oxygen supplementation at 28 days of age (65% vs. 54%), but no difference at 36 weeks PMA (39% vs. 34%). More infants in the mechanical ventilation group received surfactant, and significantly more infants in the CPAP group had pneumothoraces (9% vs. 3%). In addition, 46% of the infants in the CPAP group still required intubation in the first 5 days of life, with many of these babies in the lowest gestational age group (25 to 26 weeks). The NICHD Neonatal Network SUPPORT Trial also evaluated the strategy of preferential application of nasal CPAP to extremely premature infants (Finer et al, 2010). Of the infants in the CPAP group, 83% were ultimately intubated, and there was no significant difference in the incidence of BPD or BPD or death at 36 weeks' PMA. Thus, it appears that the most premature infants are very likely to be intubated, regardless of the strategy used, even at the most experienced centers.

It is clear that loss of functional residual capacity (FRC) with onset of generalized atelectasis can also be a major contributor to the development of BPD. In infants who are being ventilated below a normal FRC, repetitive opening and closing of lung units occurs in the presence of maldistribution. This then leads to areas of significant overdistention. There is accumulating evidence from both

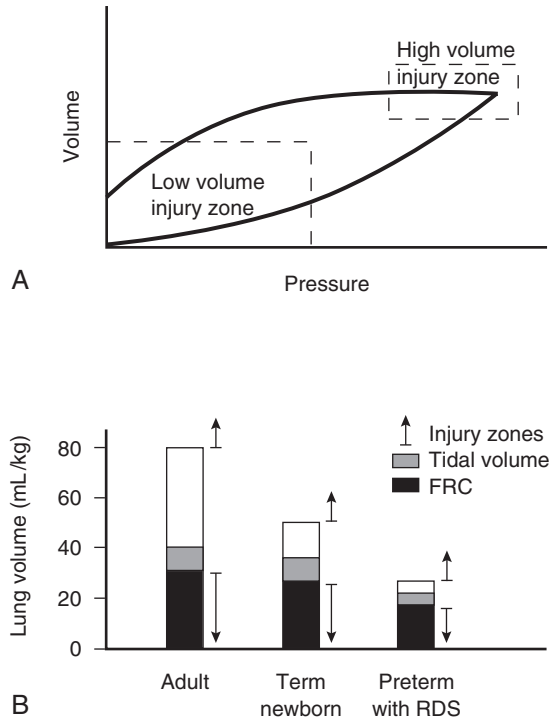

FIGURE 48-3 **A,** Static pressure-volume curve indicating areas of lung injury from either high-volume ventilation or low-volume ventilation with atelectasis. **B,** Lung volumes for a normal adult, a term newborn, and a preterm with RDS. The low- and high-volume injury zones are indicated by *arrows*. The preterm lung is susceptible to injury with ventilation because of the small volume/kg between the two injury zones. *FRC*, Functional residual capacity; *RDS*, respiratory distress syndrome.

animal and human newborn studies that the optimal use of PEEP is associated with a lower risk for BPD. Figure 48-3 demonstrates the appearance of static pressure-volume curves for infants either with normal lungs or with RDS and also depicts the potential areas of lung injury from either high-volume ventilation or low-volume ventilation with atelectasis. There is general agreement that the least injurious approach to supporting ventilation in the preterm infant would be to avoid intubation and stabilize FRC with CPAP. However, many preterm infants are too small or too sick to tolerate the use of nasal CPAP alone and therefore will require intubation and mechanical ventilation. At this time, the approach that would seem most likely to contribute to prevention of BPD is the use of an optimal PEEP to support a normal FRC combined with low-tidal-volume ventilation.

Pulmonary Edema and Patent Ductus Arteriosus

It is clear from animal studies (Bland et al, 2000) that abnormalities of lung fluid balance contribute to BPD. Persistent patency of the ductus arteriosus is thought to contribute to development of BPD through this mechanism. A recent retrospective study from the NICHD Neonatal Network found that a patent ductus arteriosus (PDA) was an independent risk factor associated with the development of BPD, as were higher fluid intake and lesser weight loss in the first 10 days of life (Oh et al, 2005). Post-hoc analyses of infants enrolled in the Trial of Indomethacin Prophylaxis in Preterms (TIPP) suggest that the relationship of the diagnosis of PDA to BPD is complex (Kabra et al, 2007; Schmidt et al, 2006a). Although prophylactic indomethacin decreased the risk of PDA among these preterm infants, it increased the risk of BPD among infants who did not have a PDA, an effect that seemed to be explained by increased oxygen requirements and decreased weight loss in the 1st week in indomethacin-treated infants. Further, there was an independent association between surgical ligation and the development of BPD among infants who subsequently received treatment for PDA. A post-hoc analysis of a small randomized trial of prophylactic surgical PDA ligation conducted when the use of antenatal steroids was limited, demonstrated increased BPD among surviving infants who underwent prophylactic ligation, but no difference in the combined outcome of death or BPD at 36 weeks (70% vs. 66%) (Clyman et al, 2009). Antenatal glucocorticoids remain an important modulating factor in the pathophysiology of both PDA and BPD, and although these diagnoses are strongly associated with each other, there is currently no definitive evidence to determine whether treatment of PDA reduces the incidence of BPD (see Chapter 54 for full discussion of PDA) (Bose and Laughon, 2006).

Poor Nutrition

All of the aforementioned etiologic factors are intensified by the inadequate nutritional status that is virtually always present in sick preterm infants. These infants have delayed feeding, inadequate parenteral nutrition due to restricted fluid intake, and a catabolic state secondary to increased work of breathing. A recent publication described growth failure in 75% of extremely low-gestational–age newborns at 28 days of age (Martin et al, 2009). Inadequate nutrition decreases alveolar number, a state that can be reversed by normalizing nutritional intake (Massaro et al, 2004). In addition, there are vitamin deficiencies, particularly of vitamin A; the latter condition has been associated with disruption of epithelial cell integrity in an animal model. They also have diminished amounts of antioxidant agents including vitamin E, which probably leads to potentiation of oxygen free radical injury. Each of these factors leads to increased susceptibility to infection, which leads in turn to a further cycle of impaired defense against injury.

Surfactant Dysfunction

Surfactant dysfunction is common among extremely low birthweight infants who remain intubated beyond the 1st week of life (Figure 48-4) (Merrill et al, 2004). In addition, episodes of infection or respiratory deterioration (sustained increase in inspired oxygen concentration or mean airway pressure), have been associated with worsening surfactant function. Surfactant content of surfactant proteins (SP) B and C is tightly correlated with surfactant function in preterm infants, with lower SP levels correlated with higher surface tension. This is particularly true of SP-B, which is down-regulated by TGF-β (McDevitt et al, 2007); other studies in animals and humans have demonstrated

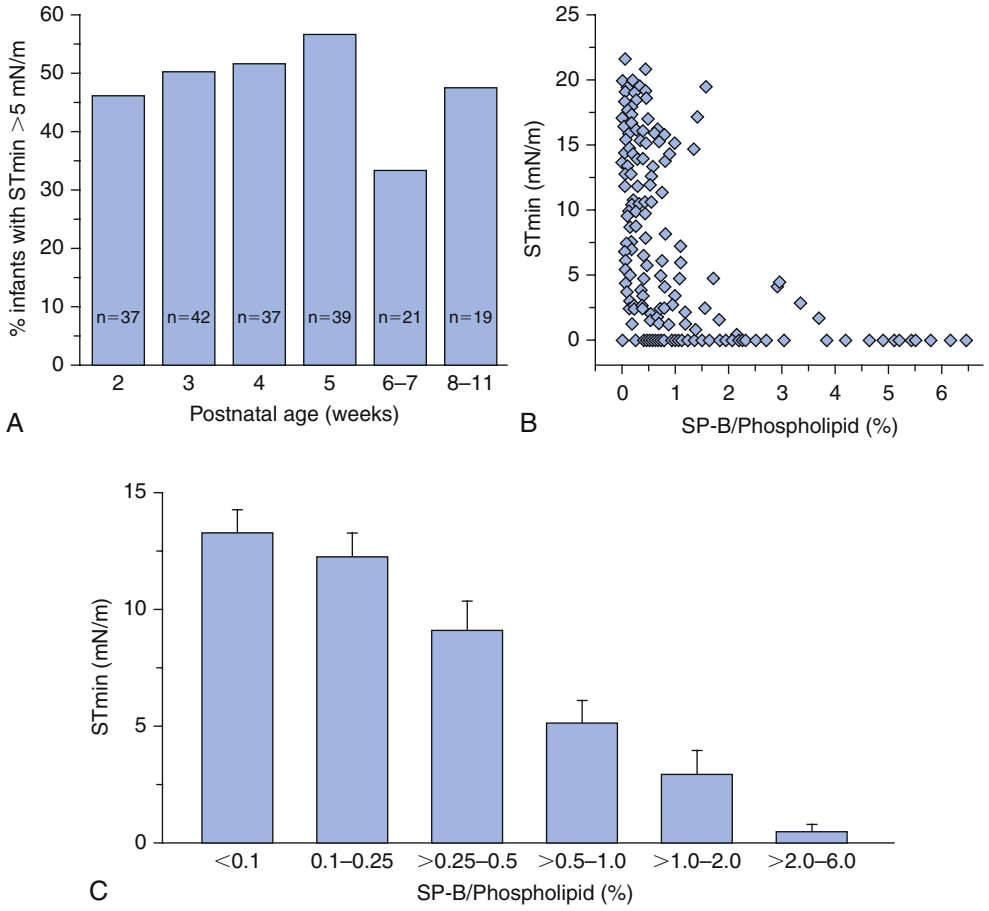

FIGURE 48-4 Surfactant dysfunction in ventilated preterm infants. A, Prevalence of surfactant dysfunction (STmin >5 mN/m) during weeks 2 to 11 of life in ventilated preterm infants. **B** and **C,** Inverse relationship of SP-B content (normalized to phospholipid content) to STmin in ventilated preterm infants; low surface tension is associated with higher SP-B content. *SP-B*, Surfactant protein-B; *STmin*, minimum surface tension. (*Adapted from Merrill JD, Ballard RA, Cnaan A, et al: Dysfunction of pulmonary surfactant in chronically ventilated premature infants*, Pediatr Res *56:918-926, 2004.*)

decreased surfactant protein content or expression after exposure to oxygen and cytokines.

Later administration of animal-based surfactants as rescue for clinical decompensation in preterm newborns has been evaluated, with a short-term decrease in ventilator settings after surfactant administration (Bissinger et al, 2008; Katz and Klein 2006; Pandit et al, 1995). A pilot randomized study of lucinacant (Surfaxin, Discovery Labs, Warrington, PA), a synthetic surfactant containing an SP-B-like polypeptide, from days 3 to 10 at two different doses versus placebo, had no effect on the prevention of BPD or death at 36 weeks (Laughon et al, 2009a). There is a large multicenter trial in progress to study the prevention of BPD or death by an animal-derived SP-B containing a surfactant, calfactant (Infasurf, Ony Inc, Amherst, NY) in combination with inhaled NO, administered to high-risk preterm infants who are requiring mechanical ventilation at 7 to 14 days (Trial of Late Surfactant, TOLSURF).

Adrenal Insufficiency

It has been suggested (Watterberg and Scott, 1995; Watterberg et al, 1996) that preterm infants may have developmental immaturity of the hypothalamic-pituitary-adrenal axis and that the risk of BPD is increased secondary to inadequate response to inflammatory lung injury. Banks et al (2001), reported, however, in a study of cortisol levels in 314 preterm infants, that even the earliest gestation infants (24 to 25 weeks) have an increase in cortisol after delivery and that levels were not associated with gestational age (Figure 48-5). More important, there was only a weak association with severity of illness. Using the CRIB (Clinical Risk Index for Babies) score to adjust for clinical risk factors, low cortisol at 3 to 7 days of life contributed only

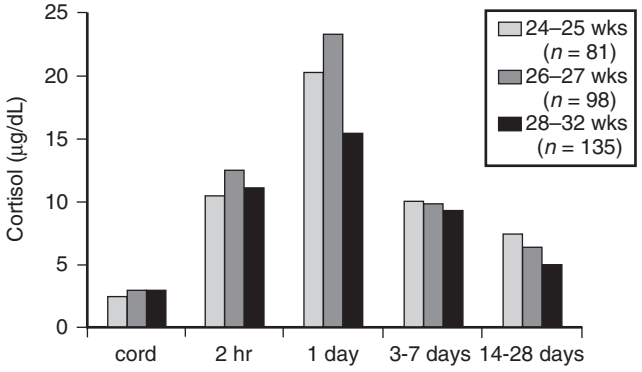

FIGURE 48-5 Plasma cortisol concentrations in premature infants during the first 4 weeks of life. Data are mean levels stratified by gestational age: 24 to 25 weeks (n = 81), 26 to 27 weeks (n = 98), and 28 to 32 weeks (n = 135).

very minimally to increasing the risk for BPD, and there was no correlation at 14 to 28 days. A subsequent cohort of infants from the PROPHET (Prophylaxis of Early Adrenal Insufficiency to Prevent Bronchopulmonary Dysplasia) study demonstrated no relationship between cortisol levels in the 1st week of life and BPD, although increasing cortisol levels were associated with increasing incidence of other acute and chronic morbidities (Aucott et al, 2008). The PROPHET study, and a concurrent study in Finland, were designed to investigate lower dose "replacement" hydrocortisone dosing (0.5 to 2.0 mg/kg/d) for the prevention of BPD (Peltoniemi et al, 2005; Watterberg et al, 2004). Both studies were terminated prematurely, because of concern for increased gastrointestinal perforation in the hydrocortisone-treated group, and no beneficial effect on the primary outcomes of death or BPD was seen. Hydrocortisone was intended as an anti-inflammatory in these trials, and there was a significant interaction between exposure to chorioamnionitis and hydrocortisone treatment in the PROPHET study, with the exposed, treated infants more likely to survive without BPD. There was also a differential beneficial effect of treatment in the subset of infants with chorioamnionitis who also had evidence of fetal inflammation. Infants with lower baseline and ACTH-stimulated cortisol levels were more likely to respond to hydrocortisone in the Finnish study, but not in the larger PROPHET trial. Of interest is the fact that formation of alveolar septae in animals, a critical step in alveologenesis, occurs during a period of low serum glucocorticoid levels. Further, dexamethasone administered to newborn rodents results in persistent impaired septation and alveologenesis (Massaro and Massaro, 2000). Thus, there is not consistent evidence that adrenal insufficiency contributes to BPD in the general population of at-risk premature infants.

Inhibition of Normal Lung Development and Vascular Development

Some of the contributing factors described previously directly impair normal formation of secondary septae and therefore, microvascular development and alveolarization. Others arrest alveolarization by as yet unknown processes that also involve structural differences in the extracellular matrix. These insults, occurring during the saccular stage of lung development, include inflammation and cytokine overexpression, dexamethasone exposure, hyperoxia, hypoxia, and inadequate nutrition (Albertine et al, 1999; Jobe, 1999; Massaro and Massaro, 2000; Massaro et al, 2004).

PREVENTIVE FACTORS

The Bronchopulmonary Dysplasia Group, convened to identify strategies for investigation of therapies to prevent or treat BPD, proposed classes of drugs to prevent or treat evolving BPD (at 7 to 14 days) (Walsh et al, 2006a). These included anti-inflammatory agents such as antenatal and postnatal corticosteroids (PNCS) and other small molecules, antioxidants, inhaled nitric oxide, late surfactant replacement, and improved vitamin A preparations. Additional approaches that have been proposed and evaluated include alternative ventilation strategies and the primary use of nasal CPAP.

Antenatal Steroids

Numerous clinical studies and several large meta-analyses have demonstrated that a single course of antenatal glucocorticoids administered to women at high risk for premature delivery results in a significant decrease in the mortality rate and in the morbidity associated with prematurity, including RDS, intraventricular hemorrhage (IVH), PDA, and necrotizing enterocolitis (NEC). However, the effect of antenatal glucocorticoids on the incidence of BPD among survivors has been inconsistent, although some studies have demonstrated a benefit (Gagliardi et al, 2007; Van Marter et al, 1990). The inconsistent effect of antenatal steroids on BPD may be due to increased survival of higher risk, less mature preterm infants (see also Chapter 46 on RDS).

Surfactant Replacement Therapy

Surfactant replacement therapy is clearly associated with decreased severity of RDS and its associated mortality. Although there is not substantial evidence that survivors have a decreased incidence of BPD, survival without BPD appears to be improved in some of the meta-analyses that have been undertaken (Engle and the Committee on Fetus and Newborn, 2008). In addition, it is possible that later replacement surfactant, during a period of secondary surfactant dysfunction (Merrill et al, 2004), could be an effective way to prevent BPD in those infants who continue to require mechanical ventilation after the 1st week of life.

Gentle Ventilation and Nasal Continuous Positive Airway Pressure

As described previously, there is evidence that volutrauma as well as atelectasis contribute directly to lung damage as well as releasing cytokines, which further the cycle of damage. Numerous trials of ventilatory modes, including patient-triggered ventilation, high-frequency ventilation, and minimal ventilation (with the goal of keeping the $Paco_2$ above 55 mm Hg), have been attempted (see also Chapter 45 on the principles of respiratory care) (Carlo et al, 2002; Stark, 2002). Some of these trials have demonstrated decreased duration of mechanical ventilation; however, none has demonstrated a substantial clinical benefit in prevention of BPD (Greenough et al, 2008).

Although the primary use of nasal CPAP delivered with the bubble CPAP system (as practiced at Columbia University) is associated with lower rates of BPD (Aly et al, 2004; Van Marter et al, 2000), the multicenter COIN Trial did not show a significant benefit on the incidence of BPD at 36 weeks. The failure to show an effect on BPD in the COIN Trial may be related to differences in Pco_2, pH, and Fio_2 limits (65 mm Hg, 7.20, and 0.60, respectively) between the trial centers and Columbia (Ammari et al, 2005), and tolerance for an extended period of transition after delivery of these preterm infants, wherein these

limits may be even more permissive. Additional studies are ongoing; however, given that the pathogenesis of BPD is complex, it may be that other differences in practice, combined with the early initiation of nasal CPAP, preserve lung growth and development and prevent BPD in extremely low gestational age newborns. Regardless, the effects of the more permissive respiratory care limits on neurodevelopmental outcome are still largely unknown. A single study comparing oxygen saturation limits of 91% to 94% versus 95% to 98% from 32 weeks PMA on showed no difference in neurodevelopmental outcomes at 1 year corrected age, although infants in the higher target saturation group had more prolonged oxygen supplementation, a higher incidence of BPD at 36 weeks, and increased need for oxygen supplementation at neonatal discharge (Askie et al, 2003).

Fluid Restriction

Multiple studies suggest that fluid overload contributes to an increased risk of BPD (Oh et al, 2005). In addition, some clinical trial data suggest that excessive fluid administration increases the risk of PDA, NEC, and death (Tammela, 1995). However, extremely restrictive fluid administration contributes to the problem of undernutrition, thereby contributing to failure of alveologenesis.

Vitamin A

Vitamin A is an essential nutrient for maintaining respiratory tract epithelial cells and also is stored in the septal cells of the alveoli involved in alveolar septation. Compelling animal data (Albertine et al, 1999) support the need for vitamin A (Figure 48-6). Because vitamin A is accumulated predominantly in the third trimester, preterm infants have deficient liver stores of this vitamin (Zachman, 1989). These infants, who often are unable to tolerate enteral feedings, are at particular risk for vitamin A deficiency because vitamin A added to parenteral nutrition solutions is degraded by light and can adhere to the intravenous tubing, making it largely inaccessible. A number of clinical trials have investigated whether supplementation with vitamin A, typically by intramuscular injections, would result in a decrease in BPD. The largest study to date, by the NICHD Neonatal Network, also used one of the higher doses that has been studied and demonstrated a significant decrease in BPD or death at 36 weeks following treatment with vitamin A (55% vs. 62%) (Tyson et al, 1999). A recent metaanalysis of all published trials revealed that vitamin A supplementation was associated with a modest reduction in death or BPD at 36 weeks, which was of borderline statistical significance (RR 0.91, 95% confidence interval 0.82, 1.00, NNT 17) (Darlow and Graham, 2007). Vitamin A is well tolerated and relatively inexpensive, although it does involve repeated intramuscular injections. However, a recent survey found that ≤20% of centers routinely administer vitamin A supplementation to at-risk infants, with inadequate evidence or lack of substantial effect cited as the rationale for lack of supplementation at these centers (Ambalavanan et al, 2004). In addition, there was no treatment effect on pulmonary morbidity or neurodevelopmental impairment at 18 to 22 months corrected age in the NICHD trial participants (Ambalavanan et al, 2005).

Postnatal Corticosteroids

Preterm infants who are given PNCS demonstrate some decreased inflammatory markers and suppression of cytokine-mediated inflammatory reactions in their tracheal aspirates (Groneck et al, 1993). Numerous theoretical reasons have been advanced regarding why postnatal administration of steroids might decrease the incidence of BPD, including the potential for increased surfactant synthesis, enhanced β-adrenergic activity, increased antioxidant production, stabilization of cell and lysosomal membranes, and inhibition of prostaglandin and leukotriene synthesis (Watterberg et al, 1999). These potential benefits are balanced against the knowledge that dexamethasone results in persistent decreases in alveolar numbers in animal models (Massaro and Massaro, 2000). Clinical trials have demonstrated acute improvements in dynamic compliance and pulmonary resistance after treatment with PNCS, although small follow-up studies have demonstrated no differences in respiratory morbidity despite fewer children with abnormal pulmonary function at >5 years of age

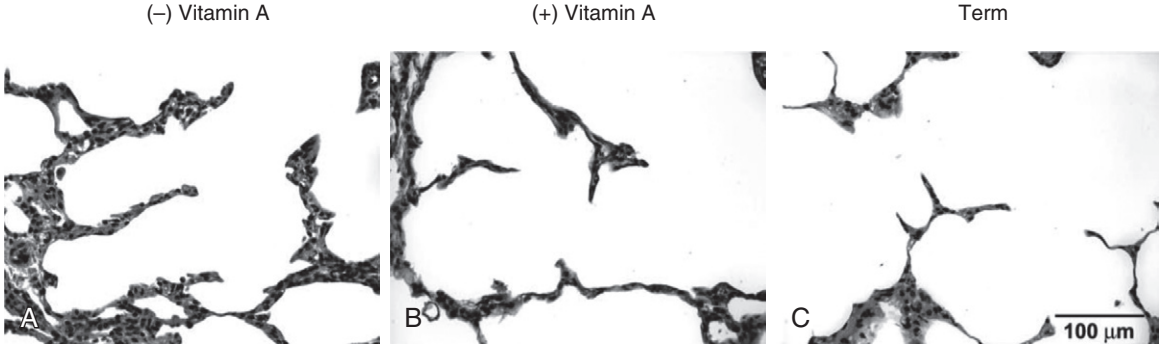

FIGURE 48-6 Histopathology of evolving chronic lung disease (CLD) of prematurity in lambs that were mechanically ventilated for 3 weeks at 20 breaths/minute (approximately 15 mL/kg tidal volume). **A,** Preterm lamb ventilated for 3 weeks, treated daily with saline (the vehicle for vitamin A) given intramuscularly. **B,** Preterm lamb ventilated for 3 weeks, treated daily with vitamin A (5000 U/day) given intramuscularly. **C,** Term lamb ventilated for 3 weeks (control). The most simplified distal air spaces and most thickened alveolar walls are in the lung tissue of the preterm lamb that was not treated with vitamin A (seen in **A**). Secondary septa also are least evident in the preterm lamb that was not treated with vitamin A. All panels are of the same magnification (scale bar = 100 μm).

(Nixon et al, 2007). Based on two recent meta-analyses of treatment before and after 7 days of age (Halliday et al, 2009a, 2009b), postnatal dexamethasone has similar beneficial effects on death or BPD at 36 weeks (RR 0.72 to 0.73; 95% CIs within 0.61, 0.85 for both treatment intervals) and decreased need for mechanical ventilation, with no significant impact on survival to hospital discharge. The aggregation of studies comparing hydrocortisone administered in the 1st week of life to placebo demonstrates no effects on mortality or BPD.

Major concerns exist regarding both short- and long-term side effects of PNCS, including hypertension, hyperglycemia, hypertrophic cardiomyopathy, adrenal suppression, and decreased growth. With administration of PNCS in the 1st week of life, the risk of gastrointestinal perforation is significantly increased, regardless of which steroid is administered (RR 1.81; 95% CI 1.33, 2.48). This effect may be associated with concurrent administration of indomethacin. Individual studies have reported an increased risk of later cerebral palsy (CP) in children treated with dexamethasone in infancy (Shinwell et al, 2000; Yeh et al, 1998). The metaanalyses support this concern with dexamethasone initiated in the 1st week of life (with no effect seen with hydrocortisone), although the relationship was not statistically significant when treatment is initiated after 7 days of age (Halliday et al, 2009a, 2009b). The lack of substantial beneficial effects and the concern regarding adverse effects led the American Academy of Pediatrics and Canadian Pediatric Society to recommend against any routine use of postnatal dexamethasone in 2002 (Committee on the Fetus and Newborn, 2002). A more recent assessment, while acknowledging the uncertainty around specific outcomes, does illustrate the overlap between the number needed to treat (prevent BPD) and the number needed to harm (cause CP) for early dexamethasone treatment (Schmidt et al, 2008). This is further supported by an independent metaanalysis (Shinwell and Eventov-Friedman, 2009), demonstrating significantly increased risk of neurodevelopmental impairment (NDI) and CP with any dexamethasone exposure, and a large cohort study demonstrating a dose-dependent increased risk of death or NDI at 18 to 22 months corrected age, regardless of postmenstrual age at the time of dexamethasone exposure (Wilson-Costello et al, 2009). Thus, the avoidance of postnatal dexamethasone is prudent, given what is known about the risks and benefits, and there are insufficient data to support the use of any other systemic steroid at this point in time. At minimum, infants who might be candidates for dexamethasone therapy would be those with severe, persistent disease, treated under a protocol with a short exposure (3 days), with dosing initiated at <0.25 mg/kg/day, and after informing the family of the short- and long-term effects. Potential criteria for treatment would be Fio_2 >0.60, mean airway pressure >12 to 14 cm H_2O, and age >7 days. Interestingly, Walsh et al (2006b) reported decreasing PNCS rates in three major North American neonatal networks from 2001 to 2003, following the societies' statement, with no concurrent change in the rate of BPD.

Although inhaled steroids initiated in the first 2 weeks of life have been studied for prevention of BPD, there are no data suggesting either immediate or later clinical improvement with this intervention, although there is a trend toward decreased systemic steroid use in these infants (Shah et al, 2007). A pilot study of budesonide with beractant (Survanta, Abbot, Columbus, Ohio) compared to beractant alone for treatment of RDS resulted in a significantly lower rate of death or BPD at 36 weeks (32% vs. 61%), without evidence of substantial adverse effects (Yeh et al, 2008). These findings are somewhat surprising, given that the majority of infants received only a single dose of the study medication. In addition, the incidence of BPD was very high in this study. Thus these findings would need to be confirmed in a larger study to ensure safety and efficacy before adopting this approach.

Antioxidant Therapy

Some evidence in the baboon model of BPD indicates that a catalytic antioxidant metalloporphyrin can protect against hyperoxia-induced lung injury (Chang et al, 2003; Tanswell and Jankov, 2003). Superoxide dismutase is a naturally occurring enzyme that protects against oxygen free radical injury. Human studies have suggested that administration of intratracheal recombinant human superoxide dismutase (rhSOD) is well tolerated and might have beneficial effects on the lung (Davis, 2002; Davis et al, 2003). The large randomized trial of rhSOD, which was stopped prematurely because of lack of efficacy for prevention of BPD, did demonstrate an improvement in respiratory morbidity at 1 year corrected age. Some investigators have raised concern regarding antioxidant therapies in the newborn (Jankov et al, 2001). Further trials of this intervention are needed before it can be recommended as useful in preventing BPD.

Inhaled Nitric Oxide

Prolonged inhaled nitric oxide (iNO) from birth in preterm animal models of BPD improves endogenous surfactant function as well as lung growth, angiogenesis, and alveologenesis (Ballard et al, 2006; Bland et al, 2005; McCurnin et al, 2005). In addition, recovery with iNO attenuates the impaired alveolar and microvascular development associated with prolonged hyperoxia exposure in the rodent (Lin et al, 2005). Prematurity in the baboon, and presumably in the human, is associated with developmentally deficient endogenous NO production (Shaul et al, 2002). Accordingly, iNO in this situation is viewed as replacement therapy. Multiple studies of iNO initiated in the first 72 hours of life for prevention of BPD in ventilated, preterm infants have been conducted, with variable efficacy (Kinsella et al, 1999, 2006; Schreiber et al, 2003; van Meurs et al, 2005). Safety concerns were raised because of increased severe intracranial hemorrhage in a single study that enrolled sicker infants with a higher baseline oxygenation index (van Meurs et al, 2005). However, improved neurologic outcomes have been found in studies that enrolled less ill newborns (Kinsella et al, 2006; Mestan et al, 2005). These studies treated infants for variable duration, up to 21 days, with a dose of 5 to 10 ppm. A large European study enrolled infants at <24 hours of age on CPAP or mechanical ventilation and treated them with 5 ppm for 21 days, but failed to find an effect on BPD (Mercier

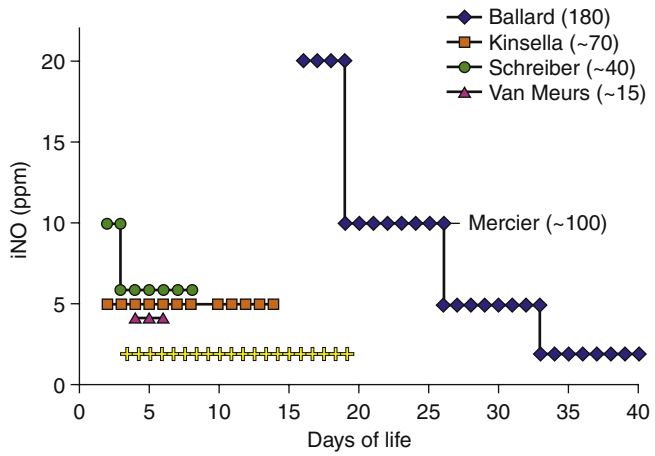

FIGURE 48-7 Summary of large trials of inhaled nitric oxide for prevention of bronchopulmonary dysplasia by day of life versus inhaled nitric oxide dose *(ppm)*. Duration of treatment and total nitric oxide dose is depicted. *INO*, Inhaled nitric oxide. (*Adapted from Truog WE: Inhaled nitric oxide for the prevention of bronchopulmonary dysplasia*, Expert Opin Pharmacother *8:1505-1513, 2007.*)

et al, 2009). In the NO CLD Trial, which enrolled ventilated infants 500 to 1250 g at 7 to 21 days with evolving BPD, infants received at least 24 days of iNO therapy, with a dose of 10 to 20 ppm for at least 10 days (Ballard, 2007; Ballard et al, 2006) (see Figure 48-7 for comparison of dosing and duration of trials). In this study, the rate of survival without BPD at 36 weeks significantly increased from 37% to 44%. Treated infants were also ventilated for fewer days, resulting in a relative cost savings with iNO (Zupancic et al, 2009). There was a significant interaction of treatment with the age at study entry, with infants who entered earlier (at 7 to 14 days), more likely to benefit (increase in survival without BPD from 27% to 49%; NNT = 4). The benefit of treatment persisted at 40 weeks' PMA, with iNO-treated infants more likely to be discharged or hospitalized off all respiratory support, and both the earlier and later (15 to 21 days) treated groups had evidence of benefit at that point in time (Keller et al, 2009). In addition, the smallest infants (500 to 799 g) could be enrolled while receiving nasal CPAP (8.4% of total enrollment), and even with this subset of infants, there was a trend toward a differential benefit of iNO therapy. Pulmonary morbidity at 1 year was decreased in the iNO-treated group (fewer infants requiring supplemental oxygen and decreased use of bronchodilators, diuretics, and inhaled and systemic steroids) (Hibbs et al, 2008). At that point, all subgroups of treated infants appeared to have a benefit from treatment. iNO therapy initiated at 7 to 21 days also was safe; there was no difference in the rate of any comorbidities of prematurity between the treatment and control groups, and at 2 years, there was no difference in the rate of NDI by treatment group (Walsh et al, 2009).

Caffeine

Recently, Schmidt et al (2006b) reported that the administration of caffeine, initiated in the 1st week of life for prevention or treatment of apnea of prematurity, decreased the risk of BPD at 36 weeks from 47% to 36% in infants 500 to 1250 g. The primary intervention for persistent apnea was continuous positive airway pressure, and infants treated with caffeine were permanently weaned off of mechanical ventilation, positive airway pressure, and oxygen earlier (average 0.9 to 1.5 weeks) and had less exposure to PNCS (14% vs. 20%). Caffeine was discontinued at a median of 34 weeks PMA, once apnea episodes had resolved. There was a transient decrease in weight gain in treated infants, but no other substantial adverse effects were seen. In addition, the caffeine-treated group had a significantly lower rate of survival without NDI (40% vs. 46%; OR 0.79; 95% CI 0.65, 0.96) at 18 to 21 months corrected age (Schmidt et al, 2007). For use of caffeine for prevention of BPD, the NNT is 10, and for NDI it is 34 (Schmidt et al, 2008). Although this trial enrolled relatively larger preterm infants who had otherwise met criteria for extubation in the 1st week of life, and the mechanism of the effect of caffeine on BPD is unknown (Bancalari, 2006), caffeine to facilitate extubation or treat apnea of prematurity appears to be a safe and effective therapy for prevention of BPD.

CLINICAL COURSE AND TREATMENT

As mentioned earlier, the classic BPD described by Northway et al is now extremely rare with the advent of antenatal steroids, postnatal surfactant, and ventilators and ventilator strategies better suited for preterm newborn infants. Thus, here we address only the clinical course of the new BPD. As pointed out by Bancalari (2001) and others, a majority of infants who have BPD currently are extremely low-birthweight infants (usually under 1000 g and 28 weeks' gestation) who require prolonged ventilator support, often for management of apnea or poor respiratory effort. Because of exposure to antenatal steroids and treatment with postnatal surfactant, these infants often initially require relatively low concentrations of oxygen and have fairly mild respiratory disease. They are extremely susceptible to infection, however, and in the first weeks of life, they may develop sepsis and/or tracheitis and pneumonia. Infection contributes to the deterioration of respiratory status that occurs during this period in many of these infants; infectious episodes are associated with secondary surfactant dysfunction, as are other episodes of respiratory deterioration (Merrill et al, 2004). A number of other factors are involved in the development of BPD, including high-level oxygen and ventilator support administered during periods of clinical decompensation, which sets up the cycle of ongoing ventilator support and further lung injury.

Management of infants at risk for or with established BPD should be directed at (1) minimizing ventilatory support and overdistention while (2) supporting and maintaining adequate FRC with end-expiratory pressure. These goals can best be achieved with the use of nasal CPAP systems (variable-flow or bubble CPAP delivery) (Courtney et al, 2001; Pandit et al, 2001). Successful use of nasal CPAP requires tolerance of permissive hypercapnia during the transition immediately after birth (the recommendation of the group at Columbia is to tolerate levels as high as 70 mm Hg), as well as subsequent tolerance of $Paco_2$ values in the 60s. This recommendation has led to the need for further investigation of the appropriate level

of Pco_2 in these preterm infants. There has been concern that elevated levels might be associated with IVH or other adverse neurodevelopmental effects. However, recent studies in the human suggest that both *hypo*capnia (not hypercapnia) and hyperoxia place infants at increased risk for disabling cerebral palsy (Collins et al, 2001). In addition, there is some evidence that high $Paco_2$ levels may actually be neuroprotective (Vanucci et al, 1995, 1997). In fact, some data (Laffey et al, 2000) indicate that Pco_2 values up to 100 mm Hg actually protect the lung from reperfusion injury and that buffering the low pH that results from high Pco_2 negates the protective effect of the high Pco_2.

Another management issue that is crucial for maintaining infants on nasal CPAP is the expected level of oxygen saturation to be achieved. Again, there is enormous controversy regarding the appropriate oxygen status of these infants. It should be emphasized that in utero, the fetus is exposed to a Pao_2 of only 25 to 27 mm Hg and arterial oxygen saturations below 80%. Yet, without sufficient data, keeping the preterm infant's oxygen saturation (Sao_2) in a range of 90% to 95% is commonplace. In some institutions, levels have routinely been kept above 95%. The data from the STOP-ROP trial did not demonstrate significant benefit against progression of retinopathy of prematurity with exposure to Sao_2 ranges that were greater than 96%, compared with 89% to 94%, although there was a low likelihood of ophthalmologic harm (STOP-ROP, 2000). Further, Askie et al (2003) reported no effect of lower oxygen saturation targets on subsequent neurodevelopmental outcomes or growth at 1 year corrected age. Finally, both of these trials demonstrated increased adverse pulmonary outcomes in the higher target saturation groups, despite the older gestational age at initiation of additional oxygen supplementation. The SUPPORT Trial and others should report whether keeping oxygen saturation at lower levels (routine Sao_2 in the 80s) might result in improvement in long-term pulmonary and neurodevelopmental outcomes, a strategy that has been advocated by developmental biologists for prevention of later morbidity, in recognition of the normally low oxygen tensions in the intrauterine environment (Maltepe and Saugstad, 2009).

Additional questions that are as yet unresolved relate to specific levels of Fio_2 that are directly toxic to the developing human lung (which affects the threshold at which an infant on NCPAP might be placed on mechanical ventilation) and whether maintenance of chronic oxygen saturations above a certain level might minimize secondary vascular changes associated with pulmonary hypertension in infants with established BPD. However, many practitioners do not feel comfortable discharging infants with BPD without supplemental oxygen unless Sao_2 is consistently ≥92%.

Ventilation

In spite of the development of numerous sophisticated ventilators for the newborn, there is still no clear advantage to any one approach to ventilating the preterm infant (see also Chapter 45). The general approach should be one of preventing atelectasis, sustaining FRC, using a minimal tidal volume (usually 4 to 6 mL/kg), and allowing the infant to trigger his or her own ventilation as much as possible (Carlo et al, 2002). It is also clear that infants can be extubated more successfully if they are extubated directly to nasal CPAP, with either variable-flow or "bubble" CPAP delivery systems (Gupta et al 2009; Ho et al, 2002).

Nutrition

Optimizing both enteral and parenteral nutrition is essential to growth and recovery of preterm infants with BPD. Beginning parenteral nutrition in the first days after birth, as well as the use of aggressive feeding regimens, is crucial to success in these infants. In addition, appropriate vitamin supplementation should be considered, although, as noted previously, vitamin A supplementation is of marginal benefit and is infrequent in North American centers.

Caffeine

Caffeine therapy was initiated in The Caffeine of Prematurity (CAP) Trial in premature infants (500 to 1250 g) for treatment or prevention of apnea. The caffeine was administered as a loading dose of 20 mg/kg followed by a maintenance dose of 5 mg/kg/d, with the dose advanced up to 10 mg/kg/d as needed for ongoing apnea (Schmidt et al, 2006b). Caffeine was demonstrated to be safe and effective for prevention of BPD.

Inhaled Nitric Oxide

Infants treated with inhaled nitric oxide in The NO CLD Trial received a minimum of 24 days of therapy, with iNO continued when infants were extubated, while on nasal CPAP or nasal cannula support (Ballard 2007; Ballard et al, 2006). The dose schedule was 20 ppm × 3 days ± 24 hours (almost all infants received 4 days of therapy) followed by 7 days each of 10 ppm, 5 ppm, and 2 ppm. There was no difficulty in weaning off the gas, and infants did not have acute changes in lung function with iNO initiation (DiFiore et al, 2007). This protocol is becoming accepted practice in a number of institutions, given the favorable risk: benefit profile of the drug, particularly when initiated at 7 to 14 days. Although some have expressed concerns regarding cost of this therapy, it is cost effective and likely to be cost saving, because of the decreased duration of assisted ventilation and neonatal hospitalization, even without considering the longer term effects of preventing BPD (Zupancic et al, 2009).

Diuretics

In infants with well-developed BPD, pulmonary edema is a major component of the illness. Diuretics, therefore, have been used for some time (Hazinski, 2000). There is clear evidence that either daily or alternate-day therapy with furosemide improves lung mechanics and gas exchange in infants with established BPD (Rush et al, 1990). Thiazide-type diuretics alone or in combination with spironolactone also have improved lung function in some studies. There is no evidence for long-term benefits of diuretic therapy; nevertheless, most centers use diuretics at some point in the management of infants with BPD. There are metabolic

effects of diuretic use, some of which are attenuated by every-other-day dosing. If long-term diuretics are administered, it is important that supplemental KCl also be administered to prevent the diuretic-induced metabolic alkalosis associated with hypochloremia as well as hypokalemia. In chronic BPD, an infant who has become hypercarbic will, over time, have a compensatory metabolic alkalosis (pH of 7.30 to 7.35 in the presence of a modestly elevated serum bicarbonate). However, if the infant is receiving diuretics and is not receiving adequate supplements of KCl, the infant's loss of potassium and chloride can lead to a primary metabolic alkalosis. The infant then might hypoventilate to reduce blood pH. Additional potential complications of long-term therapy with loop diuretics include hypercalciuria with nephrocalcinosis and its sequelae, and osteopenia, which can occur in these former premature infants as a result of decreased intrauterine mineral accretion, insufficient postnatal mineral supplementation, and the metabolic effects of the drugs. Ototoxicity is also of concern in this vulnerable population, although it is not known if permanent hearing loss is a direct result of diuretic therapy or an association with more severe neonatal illness.

Bronchodilator Therapy

With established BPD, there is a significant increase in airway resistance, and there may also be persistent or intermittent wheezing. Several studies of short-term, inhaled, or parenteral β_2-adrenergic agonist therapy have demonstrated some improvement in ventilation with such therapy. Inhaled albuterol has been the most widely used agent. Systemic use of bronchodilators has been more restricted because of a high incidence of side effects and a very narrow therapeutic index (DeBoeck et al, 1998). Hazinski (2000) pointed out that there are two pitfalls to the use of β_2 agonist drugs: (1) there can be β agonist–induced vasodilatation, which may lead to hypoxia; and (2) β agonist–induced augmentation of airway instability in an infant with both BPD and tracheomalacia may occur. Both of these pitfalls may lead to complex ventilation-perfusion ($\dot{V}/\dot{Q}$) relations (Hazinski 2000). Baraldi and Fillipone (2007) have reviewed reports of lung function in BPD. In studies of children >6 years of age with the new BPD, obstructive lung disease was present. Subsequently, Hilgendorff et al (2008) evaluated former premature infants at term-corrected age and found bronchodilator-responsive airway disease in 18 of 27 infants despite no clinical evidence of airway obstruction. However, an additional four infants had a paradoxical response to the medication, consistent with airway malacia. Thus, further evaluation of routine bronchodilator therapy in infants with established BPD should be studied, to identify if this use of bronchodilators could, in fact, attenuate later respiratory morbidity (see later discussion).

Postnatal Corticosteroids

As discussed earlier, there has been a widespread effort to prevent chronic lung disease with the use of postnatal dexamethasone. Currently, recommendations of the American Academy of Pediatrics and the Canadian Pediatric Society are that the use of postnatal steroids be restricted to randomized, controlled trials and, when these agents are given outside such trials, they be used only under exceptional circumstances of severity and after fully informing the parents of the potential problems with neurodevelopmental outcome.

Pulmonary Hypertension

Although it is known that infants dying with BPD have dysmorphic pulmonary vascular development (Abman, 2008), the prevalence of pulmonary hypertension in the disease is unknown. The diagnosis is challenging, with some practitioners recommending periodic screening echocardiograms (Bancalari et al, 2005), but the sensitivity and specificity of this technique is not adequate, even in an experienced center (Mourani et al, 2008). Pulmonary hypertension does not universally portend a poor prognosis, with 89% of former premature newborns demonstrating improvement over time (Khemani et al, 2007). Although therapies for chronic treatment of pulmonary hypertension have shown efficacy in older patient populations, the risk-benefit profile for infants and young children is unknown.

Future Directions

Given the pathobiology of BPD, there are multiple potential targets for prevention of the disease. The rationale for late treatment (beginning in the 2nd week of life) with an SP-B containing surfactant is sound, and a Trial of Late Surfactant (TOLSURF) in infants receiving inhaled nitric oxide has been initiated. A recent publication described antioxidant activity in multiple animal-derived surfactant preparations (Dani et al, 2009), and antioxidant supplementation remains promising for the prevention of BPD. Another promising therapy that has not been further pursued is α-1 antitrypsin therapy, to modify the protease-antiprotease imbalance that affects extracellular matrix development (Stiskal et al, 1998), and there is good rationale to target antagonism of TGF-β signaling (Nakanishi et al, 2007). In addition, bone marrow–derived mesenchymal stem cells offer some promise for repair in the rat hyperoxia-injured lung (van Haaften et al, 2009). Budesonide delivered by inhalation with surfactant as an anti-inflammatory agent also deserves further evaluation, possibly given after 7 days of age in combination with iNO.

OUTCOME

The mortality rate among infants with BPD who are discharged on therapy from the hospital is roughly 10%. Mortality was 38% in a recent report of children with BPD and pulmonary hypertension (Khemani et al, 2007). As anticipated, children with severe pulmonary hypertension (systemic-to-suprasystemic) were more likely to die. In long-term follow-up assessments of preterm infants, BPD clearly is one of the major conditions associated with poor neurodevelopmental outcome (along with IVH and periventricular leukomalacia), and exposure to PNCS increases the risk of NDI that is associated with BPD (Wilson-Costello et al, 2009). Poor nutrition, impaired growth, and prolonged and recurrent hospitalization likely

also contribute to these poor outcomes. Children with BPD have increased rates of pulmonary hospitalization and medication use in the first 1 to 2 years of life, and data from the EPICURE study of former preterm infants at ≤25 weeks' gestation show that this pattern persists at 30 months and 6 years of age (Hennessy et al, 2008). Additional long-term morbidity associated with BPD may include upper airway damage secondary to endotracheal intubation (Statement on the care of the child with chronic lung disease, 2003), and systemic hypertension has also been described in severe cases (Alagappan and Malloy, 1998). Given the multiple systems involved, it is likely that these infants would benefit from multidisciplinary follow-up care, including neurodevelopmental screening and intervention, appropriate nutritional and feeding support, and cardiopulmonary care, provided in a coordinated and collaborative environment.

SUMMARY

BPD remains the most common form of chronic lung disease in children. It is estimated that there are between 25,000 and 30,000 infants with BPD at any one time in the United States. The morbidity of the disease is high, with chronic illness and long-term neurodevelopmental impairment, and is accompanied by financial costs to families and society. The American Thoracic Society published a well-referenced position paper on the care of the child with chronic lung disease of infancy and childhood that addresses many of the important ongoing issues in the care of these children (Statement on the care of the child with chronic lung disease, 2003).

It is hoped that combining treatment with caffeine with new approaches to ventilation, including the aggressive early use of nasal CPAP, treatment of high-risk infants with iNO and potentially with late doses of surfactant, further development of anti-inflammatory and antioxidant approaches, and possible stem cell therapy will ameliorate the impact of BPD. Ultimately, therapies tailored to specific biomarkers or genetic susceptibility should be possible.

CHAPTER 49

Surgical Disorders of the Chest and Airways

Roberta L. Keller, Salvador Guevara-Gallardo, and Diana L. Farmer

ANOMALIES OF THE AIRWAYS

NASOPHARYNGEAL OBSTRUCTIVE DISORDERS

Respiratory distress due to nasal obstruction may manifest as a serious, life-threatening event shortly after birth. Because newborns are preferential nasal breathers for the first 2 to 3 weeks of life, nasal obstruction may cause severe cyanosis, particularly during oral feedings, with airway obstruction relieved only when the mouth is open to cry (Ramsden et al, 2009). There are several causes of neonatal nasal obstruction, including congenital choanal atresia, nasal pyriform aperture stenosis, nasolacrimal duct cyst, and nasal hypoplasia. Buckling or, less commonly, dislocation of the nasal septum due to birth trauma can also cause breathing problems; most cases respond to decongestant and steroid nasal drops, but dislocations require surgical manipulation (Prescott, 1995).

Congenital Choanal Atresia

Caused by persistence of the buccopharyngeal membrane, congenital choanal atresia occurs in between 1 per 5000 and 1 per 9000 births and has a significant female preponderance. In the majority of choanal atresia cases, the obstructing membrane is of mixed bony and membranous composition (Brown et al, 1996). Choanal atresia is more frequently unilateral; bilateral malformations are more serious and constitute an emergency at birth (Ramsden et al, 2009). Over half of all cases are associated with other congenital anomalies, bilateral cases more so than unilateral (Burrow et al, 2009; Hall, 1979). The most common collection of anomalies was originally termed the *CHARGE association*, consisting of some combination of *c*olobomas of the eyes, *h*eart defects, *a*tresia of the choanae, *r*etardation of growth or development, *g*enitourinary defects, and *e*ar anomalies associated with deafness (Pagon et al, 1981). The association was officially named *CHARGE syndrome* in 2004, when a common mutation in the *CHD*7 gene on chromosome 8 was identified in 60% of cases (Vissers et al, 2004).

Because the newborn is a preferential nasal breather, there may be serious difficulties soon after birth, especially in cases of bilateral atresia. Unilateral atresia may present simply with unilateral discharge and possibly feeding difficulties, but may not present until later in childhood. The inability to pass a catheter through the nose may suggest the diagnosis. Computed tomographic (CT) scan of the nasopharynx is the method of choice for making a definitive diagnosis and for evaluating the nature and severity of nasal obstruction (Benjamin, 1985; Crockett et al, 1987).

Emergent management of choanal atresia is focused on ensuring the oropharyngeal airway is patent and may necessitate endotracheal intubation. A McGovern nipple, an orogastric tube, or a modified endotracheal tube can be used to overcome the seal between the palate and the tongue (Fulton et al, 2007). Tracheostomy is rarely necessary and typically only required when associated with other anomalies (Asher et al, 1990). Surgical repair is the mainstay of treatment and can be performed within a few days of birth. Patency can be established by various methods according to surgeon preference. Correction can be accomplished using the transnasal approach under endoscopic visualization and relieving the obstruction by using dilators (Stahl and Jurkiewicz, 1985) followed by placement of temporary stents to prevent subsequent closure. The transnasal approach works best with thin buccopharyngeal membranes and tends to have higher recurrence and reoperation rates (Hengerer et al, 2008; Samadi et al, 2003). The transpalatal approach entails surgical correction of the offending defect and is typically performed for thick bony membranes. However, despite the minimal rate of reoperation, this approach is associated with a higher rate of palate growth deformities. In an attempt to avoid altering palate growth, modern endoscopic biting and drilling instruments were introduced to improve the transnasal technique (Josephson et al, 1998; Stankiewicz, 1990), and studies continue to demonstrate increasing support for the endoscopic repair of choanal atresia (Ramsden et al, 2009).

Congenital Nasal Pyriform Aperture Stenosis

Nasal pyriform aperture stenosis is a rare cause of nasal obstruction and should be suspected when encountering difficulty in passing a nasal catheter. Characterized by excessive bone formation in the medial nasal processes of the maxillary bone, the condition may be isolated or associated with other anomalies, such as a solitary maxillary central incisor tooth or, more seriously, midline defects such as pituitary hypoplasia with endocrine insufficiency (Beregszaszi et al, 1996), diabetes insipidus (Godil et al, 2000), other manifestations of holoprosencephaly, and craniosynostosis (Van Den Abbeele et al, 2001). Similar to choanal atresia, an oral airway may be necessary to relieve the breathing difficulty. Although the obstruction can be suitably demonstrated by CT scan of the nasopharynx (Truong and Oudjhane, 1994), because of its high association with holoprosencephaly, a karyotype analysis and brain CT and/or magnetic resonance imaging (MRI) may be required if brain abnormalities are suspected (Devambez et al, 2009). In most cases, nasal obstruction is mild and

may respond to nasal decongestants. In refractory cases of obstruction, sublabial surgery is necessary to remove excessive bone, and nasal stenting is required (Tate and Sykes, 2009).

Pierre Robin Syndrome (Robin Sequence)

Although this suite of upper airway problems was first described by Pierre Robin in 1923, characterization of Pierre Robin syndrome remains difficult and controversial. A constellation of anomalies within the spectrum of cleft palate, micrognathia, and glossoptosis, the Pierre Robin syndrome has recently been linked to mutations in the *SOX9* gene (Benko et al, 2009; Jakobsen et al, 2007). Given the varying definitions published, the incidence of Pierre Robin syndrome is difficult to pinpoint; it has been reported to occur in anywhere from 1 in 8500 to 1 in 20,000 births (Breugem and Mink van der Molen, 2009). It is the abnormal development of the mandible that is of clinical significance, as the micrognathia can lead to airway obstruction and cyanosis (Cozzi and Pierro, 1985). Obstruction is common when the infant is in the supine position, during feeding, and in active sleep, when pharyngeal muscle tone is absent. Excessive air swallowing, followed by gastric distention, vomiting, and tracheal aspiration, are frequent problems. The pharyngeal obstruction is maintained by the generation of large negative pressures in the lower pharynx during inspiration and swallowing (Fletcher et al, 1969). Chronic obstruction leads to carbon dioxide retention, failure to thrive, and development of pulmonary hypertension with right ventricular failure (Johnson and Todd, 1980).

As with the imprecise diagnosis of Pierre Robin syndrome, the severity of respiratory obstruction and the management indicated is varied. Mild cases may present with only mild glossoptosis, and because oral feeds are tolerated without respiratory obstruction, these cases can be managed by side-to-side nursing (Caouette-Laberge et al, 1994; Cole et al, 2008). In the event of respiratory symptoms with feedings or failure to thrive, a nasogastric tube for feedings may be required (Cole et al, 2008). In severe cases of respiratory distress, nasopharyngeal intubation should be performed, typically by passing a 3.5-mm tube through the nose and into the hypopharynx (Heaf et al, 1982; Stern et al, 1972). This prevents the generation of negative pressure and greatly relieves the respiratory difficulty. The nasopharyngeal tube may be left in place for weeks or even months with adequate lavage and suctioning. Other treatments include tongue-lip adhesion surgery to hold the tongue forward and tracheostomy if a nasopharyngeal tube does not adequately relieve the obstruction (Gilhooly et al, 1993). Recent reports of mandibular distraction and velar extension appliances have been introduced in attempts to avoid tracheostomy (Buchenau et al, 2007; Denny and Kalantarian, 2002). Nutrition can be maintained with a hypercaloric formula fed by nasogastric or gastrostomy tube. With adequate airway management and the passage of time, the problem becomes less threatening, especially after a few months, when the infant gains better control of the tongue (Mallory and Paradise, 1979). Oral feedings can then be introduced, usually with a long lamb's nipple to help hold the tongue forward. With adequate nutrition and growth of the mandible, the problem usually resolves by 6 to 12 months of age, when cleft palate repair can safely take place.

Glossoptosis-Apnea Syndrome

Pierre Robin syndrome is not the only condition characterized by mechanical obstruction by the tongue. Infants with Beckwith-Wiedemann syndrome may have considerable breathing difficulties and apnea due to the associated macroglossia. Infants with a normal-sized tongue who also have conditions such as unilateral choanal atresia, choanal stenosis, or swelling of the nasal mucosa may generate considerable negative pressure in the pharynx; this, combined with inadequate muscular control over the tongue, may lead to pharyngeal obstruction with respiratory distress, cyanosis, and severe episodes of apnea (Cozzi and Pierro, 1985).

Pharyngeal Incoordination

Pharyngeal incoordination causes choking and cyanosis with feedings and may be complicated by aspiration pneumonia (Avery and Fletcher, 1974). Affected infants have difficulties in swallowing their own secretions. The condition may be seen in infants with severe hypoxic-ischemic encephalopathy and pseudobulbar palsy, Arnold-Chiari malformation, and Möbius syndrome. Drugs with antimuscarinic effects, such as atropine, can decrease secretions and may produce some relief. Although some infants may gradually improve, long-term management may require initiation of tube feedings or even gastrostomy.

LARYNGEAL DEFORMITIES

Congenital Laryngeal Stridor

A relatively common condition, congenital laryngeal stridor or laryngomalacia is the most frequent cause of stridor in infants (Zoumalan et al, 2007). Laryngomalacia is characterized by the prolapse of poorly supported supraglottic structures—the arytenoids, the aryepiglottic folds, and the epiglottis—into the airway during inspiration, causing respiratory obstruction and difficulty with feeding (Olney et al, 1999). Despite loud, high-pitched inspiratory stridor and significant chest retractions that typically present during the first month of life, the infant seldom has cyanosis, hypercarbia, notable feeding difficulty or growth failure, or an abnormal cry (Richardson and Cotton, 1984). Laryngomalacia is worse in the supine position with the neck flexed and subsides in the prone position with the neck extended (Cotton and Richardson, 1981). Obstruction is worse during episodes of agitation and lessens when the infant is calmed. Severe forms of laryngomalacia may cause apneic events, pulmonary hypertension, or difficulties with feeding and/or weight gain. Although CT scan is effective at demonstrating the abnormal prolapse of the aryepiglottic folds supporting the diagnosis (Galvin et al, 1994), confirmation should be obtained at laryngoscopy (Friedman et al, 1990; Wiatrak, 2000), with specific care

to avoid fixating the supraglottic tissues with the instrument. Some practitioners prefer to pass a flexible fiberoptic bronchoscope through the nose (Berkowitz, 1998), which does not disturb the supraglottic tissues. In some cases, gastroesophageal reflux or episodes of obstructive apnea may be associated with this condition (Belmont and Grundfast, 1984). About 18% of infants with a congenital lesion of the airway have a second lesion of some kind. Thus, the evaluation of stridor must include the examination of the entire upper airway and upper digestive tract (Friedman et al, 1984). Most cases will resolve with conservative management within 12 to 24 months (Thompson, 2007). Conservative therapy entails positioning the infant prone as much as possible, and most demonstrate improvement over roughly 18 months (Smith and Catlin, 1984). However, approximately 20% will require surgical intervention. A very few patients may have severe obstructive apnea, cor pulmonale, and/or failure to thrive. In these cases supraglottoplasty may be indicated. Tracheostomy is reserved for supraglottoplasty failures (Richter and Thompson, 2008).

Vocal Cord Paralysis

Unilateral cord paralysis is usually left-sided and typically presents without marked stridor or retractions manifesting as aspiration. The infant may cough and choke during feedings, as laryngeal closure with swallowing is impaired. The condition is due to a lesion involving the recurrent laryngeal nerve, perhaps caused by excessive stretching of the neck during delivery. Another possible cause is trauma from ligation of a patent ductus arteriosus (Davis et al, 1988). Right-sided vocal cord paralysis has been reported as a complication of extracorporeal membrane oxygenation (ECMO) (Schumacher et al, 1989), presumably as a result of the surgical dissection for insertion of the catheters. Stridor may be less if the infant lies on the paralyzed side, when the affected cord can fall away from the midline (Cotton and Richardson, 1981). The condition tends to improve over a period of several weeks or months. Generally, medialization of the vocal cord is not recommended in neonates under 6 months of age, with tracheostomy preferred in severe cases of respiratory obstruction (Parikh, 2004).

Bilateral cord paralysis is a much more serious condition, accompanied by high-pitched inspiratory stridor; frequently, however, the cry is normal. Usually, severe central nervous system problems are to blame, such as hypoxic-ischemic encephalopathy, cerebral hemorrhage, Arnold-Chiari malformation, hydrocephalus, or brainstem dysgenesis. Associated problems may include pharyngeal incoordination with swallowing difficulty and esophageal dysfunction, recurrent apnea episodes, and tracheal aspiration of mucous secretions and formula. The stridor may resolve slowly if brain swelling subsides after birth, as is the case with ventriculoperitoneal shunt placement. The diagnosis may be suspected at laryngoscopy but should be confirmed by flexible fiberoptic bronchoscopy, rigid bronchoscopy, or ultrafast cine CT scan. Tracheostomy frequently is required (Smith and Catlin, 1984), and the prognosis usually is poor secondary to the underlying problems.

Laryngeal Atresia

Laryngeal atresia is the result of failed recanalization of the larynx during embryologic development, resulting in a newborn with complete laryngeal obstruction presenting with severe respiratory distress. In some cases the larynx may be completely obstructed by a laryngeal web, seen in the delivery room during attempts to intubate the cyanotic infant. An endotracheal tube sometimes can be forced beyond the obstruction into the trachea. Otherwise, a large-bore needle should be inserted percutaneously into the trachea to maintain marginal gas exchange while preparations for emergency tracheostomy are made. Most infants with laryngeal atresia have other lethal malformations (Smith and Catlin, 1984). Most cases are now diagnosed prenatally from ultrasound findings consistent with congenital high airway obstruction syndrome (CHAOS), such as polyhydramnios and enlarged hyperechoic lungs with an associated flattened or inverted diaphragm (Hedrick et al, 1994; Kalache et al, 1997). The mother may be evaluated for ascites or hydrops fetalis due to impaired venous return to the heart; the amniotic fluid lecithin may be very low in such cases. In the absence of other lethal malformations, the characteristic ultrasound diagnosis may permit preparations for emergency tracheostomy after delivery of the infant or an ex-utero intrapartum treatment (EXIT)-to-airway procedure, discussed later. Survivors of fetal intervention for CHAOS have now been seen (Hirose et al, 2004).

CONGENITAL SUBGLOTTIC STENOSIS

Congenital subglottic stenosis, manifesting as inspiratory stridor from birth, is caused by partial obstruction of the cricoid. In a full-term infant the normal subglottic lumen is 4.5 to 5.5 mm in diameter, whereas that of a preterm neonate is 3.5 mm in diameter. A subglottic diameter of 4 mm or less in a full-term infant or 3 mm or less in a premature infant is consistent with a diagnosis of subglottic stenosis. Subglottic stenosis is diagnosed by direct laryngoscopy supplemented with rigid bronchoscopy and chest radiography to evaluate other airway lesions and/or concomitant lung disease, as the latter may be common in the premature infant. Treatment consists of dilation or endoscopic lysis with a carbon dioxide laser in cases of membranous stenosis. However, most cases severe enough to require intervention are cartilaginous and require an anterior cricoid split, obviating the need for and complications of tracheostomy in most cases (Cotton and Seid, 1980; Schroeder and Holinger, 2008; Smith and Catlin, 1984).

Congenital Subglottic Hemangioma

Subglottic hemangioma, often occurring in association with cutaneous hemangioma, may cause inspiratory stridor and expiratory wheezing that progress with enlargement of the tumor (Cotton and Richardson, 1981). The presence of a cutaneous hemangioma in the facial beard distribution is often associated with a subglottic hemangioma (Orlow et al, 1997). This diagnosis is suspected when asymmetric subglottic narrowing is seen on plain radiographs and is confirmed by flexible and rigid endoscopy demonstrating

a sessile vascular lesion, most commonly in the posterolateral subglottis (Ahmad and Soliman, 2007; Rahbar et al, 2004). Although some practitioners have advocated high-dose corticosteroid therapy (Brown et al, 1972) and others have tried intralesional injections of steroids, in many cases intubation or tracheostomy is eventually required. Results of removal by carbon dioxide or potassium-titanyl-phosphate laser have been encouraging, enabling treatment without tracheostomy; however, associated complications such as subglottic stenosis have been reported (Ahmad and Soliman, 2007; Healy et al, 1984; Kacker et al, 2001).

Laryngotracheoesophageal Cleft (Congenital Laryngeal Cleft)

In laryngotracheoesophageal cleft, a longitudinal communication is present between the airway and the esophagus, stretching from the larynx into the upper trachea or sometimes as far as the carina. This rare condition is reported in 1 in 10,000 to 1 in 20,000 births and is caused by an interruption in the cephalic advancement of the tracheoesophageal septum, which prevents the proper fusion of the posterior cricoid lamina (Pezzettigotta et al, 2008). Affected infants have respiratory distress with inspiratory stridor and cyanosis, associated with tracheal aspiration of saliva and feedings. The chest radiograph may show evidence of aspiration pneumonia, and the cine esophagogram shows contrast material spilling into the trachea. The diagnosis can be established with direct laryngoscopy and bronchoscopy. Given the high association with other congenital anomalies and syndromes, such as tracheal atresia, tracheoesophageal fistula, and Opitz-Frias syndrome, a thorough evaluation of all organ systems and genetic karyotype are recommended.

Laryngotracheoesophageal clefts are classified by severity of symptoms into four groups (types I–IV), which are used to determine the management strategy and the need for surgical intervention. For all types, initial management involves adequately securing the airway with an endotracheal tube or tracheostomy (Richardson and Cotton, 1984). Mild cases can sometimes be managed by conservative therapy, including swallow rehabilitation and antireflux medication; otherwise, endoscopic surgery may be necessary for refractory type I and type II clefts (Pezzettigotta et al, 2008). More severe cases requiring extensive reconstruction may require employing an anterior translaryngotracheal approach or even a partial upper sternotomy. Despite these reconstruction attempts, mortality remains high, at nearly 50% among all types of clefts and higher in cases with associated congenital anomalies and type IV clefts (Myer et al, 1990; Roth et al, 1983; Simpson et al, 1996).

TRACHEAL DEFORMITIES AND OTHER TRACHEAL DISORDERS

Tracheal Agenesis

In the rare condition of tracheal agenesis, the trachea is either atretic just below the vocal cords or absent all the way down to the carina (Altman et al, 1972). Clinical manifestations include severe distress, absence of vocal sound, and severe cyanosis. Prenatal presentation may manifest as CHAOS, and EXIT may allow survival in severe cases (Vaikunth et al, 2009). Affected infants usually have a tracheoesophageal fistula as well as severe cardiac malformations, lung lobation defects, and sometimes renal and anal anomalies. Despite the presence of a larynx, intubation cannot be accomplished at delivery; however, if the tracheal tube is positioned in the esophagus and connected to a mechanical ventilator, reasonable gas exchange can be obtained via the tracheoesophageal fistula (Sandu and Monnier, 2007). When the tracheal atresia is high, a tracheostomy can be done. If survival seems possible, gastric division and a gastrostomy for feeding should be performed. Reconstructive surgery is not likely to be successful, however, and the prognosis is extremely poor, if not because of poor ventilation, then because of the underlying malformations.

Congenital Tracheal Stenosis

In congenital tracheal stenosis, a segment of the trachea is narrowed, usually starting in the subglottic region. The affected segment may be short or long; occasionally, the entire trachea is hypoplastic, and the bronchi may be involved. The narrowing is caused by complete or nearly complete tracheal cartilage rings. The patient may have inspiratory stridor, expiratory wheezing, and often cyanotic episodes. Mild inflammation and small mucous plugs may cause life-threatening deterioration. In many cases, other congenital malformations are also present, such as vascular ring anomalies, congenital heart defects, tracheoesophageal fistula (especially the H type), and hemivertebrae (Benjamin et al, 1981); there also is an association with pulmonary agenesis (Voland et al, 1986). A series of cases without accompanying defects has been reported in premature infants who presented with difficulties at tracheal intubation (Hauft et al, 1988).

Patients with this deformity usually can be intubated, but the endotracheal tube cannot be advanced and should not be forced. Mechanical ventilation with generous levels of positive end-expiratory pressure (PEEP) may help stabilize the infant. Tracheostomy is not indicated and interferes with making the diagnosis (Nakayama et al, 1982). Sometimes the diagnosis can be made by chest radiographs, using air as the contrast medium, with inspiration and expiration films. Investigators have described a high-kilovoltage technique, the so-called lateral airways xeroradiogram (Benjamin, 1980). Fluoroscopy often is useful (Lobe et al, 1987). Either flexible fiberoptic bronchoscopy in the NICU or rigid bronchoscopy in the operating room is usually required. Because it is important to examine the lower limits of the stenosis, it may be necessary to proceed with tracheobronchography, but this may sometimes cause acute decompensation (Loeff et al, 1988). Today, ultrafast cine CT scan has become a useful diagnostic technique to define the lower limits of the stenosis (Galvin et al, 1994).

In most cases, the stenosis requires treatment of some kind in the operating room. Balloon dilation alone is not likely to be successful in the case of a complete tracheal cartilage ring, because cartilage cannot be stretched. For short-segment stenosis, balloon dilation with laser may be used: at rigid bronchoscopy, the cartilage ring is split at the midline posterior aspect using the KTP laser, and the bronchoscope is advanced with the aid of serial balloon dilations

(Othersen et al 2000). For longer-segment stenosis, Longaker et al (1990) described segmental resection of the stenosis with end-to-end anastomosis to shorten the trachea, followed by serial balloon dilations through a rigid bronchoscope. Backer et al, described the successful use of free autografts of resected trachea for this type of tracheoplasty. However, for long-segment stenosis, slide tracheoplasty has become the standard treatment (Lipshutz et al, 2000). In this procedure, the stenosis is transected in the middle, the upper segment is incised longitudinally along the anterior aspect, the lower segment is incised longitudinally at the posterior aspect, the incised segments are slid over one another, and the edges are anastomosed, effectively shortening the trachea while widening the narrowed lumen.

The use of cardiopulmonary bypass has improved treatment and is advocated by some as averting the need for complex anesthesiology techniques (Loeff et al, 1988). After midline sternotomy, tracheal resection, and tracheoplasty with shortening of the trachea, the patient may need fixation in a brace for at least 6 weeks to maintain neck flexion and prevent excessive stretching of the anastomosis (Nakayama et al, 1982). Premature infants with congenital tracheal stenosis cannot undergo tracheal resection and tracheoplasty with cardiopulmonary bypass procedures. For these patients, aggressive balloon dilations are recommended, with splitting of the weaker posterior aspect of the tracheal rings (Messineo et al, 1992).

Tracheobronchomalacia (Tracheomalacia)

Tracheobronchomalacia, or the delayed development of tracheal cartilage, is rare and results in an excessively compliant trachea. This condition may be primary or associated with tracheoesophageal fistula, bronchopulmonary dysplasia, extrinsic tracheal compression, or prolonged intubation (Sotomayor et al, 1986). Tracheobronchomalacia should be suspected in infants presenting with respiratory distress, cyanotic spells, or persistent respiratory symptoms including expiratory stridor, persistent or recurrent wet cough, or recurrent respiratory infections (Masters, 2009). Chest radiograph shows diffuse overinflation, and the abnormalities of the trachea can be well demonstrated with ultrafast cine-CT scan (Galvin et al, 1994; Kimura et al, 1990), which provides a particularly good assessment of the peripheral extent of the lesion. At bronchoscopy, the anterior and posterior walls of the trachea are approximated during expiration (Saltzberg, 1983). The bronchoscope may support the walls of the trachea, alleviating the respiratory distress by passage of the bronchoscope to the carina, but potentially disguising the extent of the abnormalities.

Downing and Kilbride (1995) found that the factors associated with the development of tracheomalacia were immaturity, higher mean airway pressure, and prolonged mechanical ventilation. Affected infants may have significant dynamic compression of the trachea. Because the trachea of premature infants is very compliant and may be excessively stretched and injured during mechanical ventilation, very immature infants are particularly prone to tracheomalacia. Some premature infants have greatly enlarged tracheas or tracheomegaly after mechanical ventilation (Bhutani et al, 1986).

Many infants with tracheomalacia spontaneously improve by 1 to 2 years of age, when the cartilage has become strong enough to support tracheal patency (Sandu and Monnier, 2007). Severe cases typically necessitate tracheostomy with an elongated tracheostomy tube. However, current treatments for milder cases include tracheal intubation with continuous positive airway pressure (CPAP) or PEEP, which prevents tracheal collapse, and aortopexy (fixation of the aorta to the sternum), which has the effect of supporting the attached trachea (Bullard et al, 1997; Filler et al, 1992; Jacobs et al, 1994; Wiseman et al, 1985). Many of the most severely affected patients respond well to aortopexy (McCoy et al, 1992).

Tracheal Compression by Vascular Rings

Tracheal compression can be caused by several factors: (1) a double aortic arch, (2) a right aortic arch, (3) a left-sided origin of the (right) innominate artery, (4) a right-sided origin of the left common carotid artery, or (5) an anomalous origin of the left pulmonary artery from the right pulmonary artery (Hendren and Kim, 1978). With a right aortic arch, the trachea is compressed by the main pulmonary trunk, aortic arch, and ligamentum arteriosus. The anomalous innominate or common carotid arteries form a tight crotch, which impinges on the anterior trachea. The anomalous left pulmonary artery returns to the left by passing between the esophagus and the trachea, compressing the trachea between the right and the left pulmonary arteries. Infants with tracheal compression have inspiratory stridor and expiratory wheezing with symptoms usually appearing later in the neonatal period. Affected infants often lie with the head and neck hyperextended to stretch the trachea and make it less compressible. If the esophagus is compressed, feeding is associated with regurgitation.

There are several methods of diagnosis. The chest radiograph may show mild overinflation, a right-sided aorta, and, with appropriate technique, evidence of tracheal narrowing. A barium swallow examination may show indentation of the esophagus. Bronchoscopy should reveal a pulsatile mass at the carina. MRI has proved to be accurate in defining most vascular malformations compressing the airway (Simoneaux et al, 1995), with echocardiography regarded as less reliable in this situation (Rimell, 1997). Recently, it was demonstrated that prenatal diagnosis by ultrasound avoided unnecessary delays in the repair of symptomatic vascular rings and that repair on identification of symptoms prevented the development of secondary tracheobronchomalacia (Tuo et al, 2009). After surgical division of the vascular ring, the respiratory distress may persist for weeks or longer because of localized tracheal deformity (either stenosis or tracheomalacia), emphasizing the need for immediate repair on diagnosis. In cases of isolated vascular rings, repair provides cure with minimal postoperative complications (Ruzmetov et al, 2009).

Tracheal Compression by Extrinsic Masses

The trachea may also be compressed by a bronchogenic cyst, an enteric duplication cyst, a thoracic neurogenic tumor, or a mediastinal teratoma (Benjamin, 1980). These may be demonstrated by anteroposterior and lateral chest

FIGURE 49-1 Direct laryngoscopy, bronchoscopy, and esophagoscopy are performed during an EXIT procedure. Using these methods, airway obstruction can be overcome and endotracheal intubation can be performed. *(From Hirose S, Farmer DL, Lee H, et al: The ex utero intrapartum treatment procedure: looking back at the EXIT*, J Pediatr Surg *39:375-380; discussion 375-380, 2004.)*

films and are especially apparent on CT scan. Such masses may also compress the esophagus and can be demonstrated with a barium swallow.

Congenital High Airway Obstruction Syndrome and the Ex-Utero Intrapartum Treatment Procedure

CHAOS actually describes a spectrum of rare anomalies, including laryngeal web, laryngeal atresia, laryngeal cyst, and tracheal atresia or stenosis. Most cases are sporadic with the true incidence unknown, and thus the natural history of this disease is not well known. CHAOS is characterized by enlarged lungs, dilated distal airway, everted diaphragm, ascites, and, ultimately, nonimmune hydrops fetalis. Prenatal diagnosis is becoming more common with the progress of ultrasound and MRI techniques. The exact nature of the airway obstruction may not be entirely clear, however, and the time required to establish a safe airway soon enough after delivery carries various risks, including anoxic brain injury.

As with any anomaly that causes either direct respiratory airway obstruction or airway compression by means of mass effect, CHAOS poses a difficult problem for the clinical team during delivery. The EXIT procedure was developed as a solution to this problem: By preserving fetoplacental circulation throughout a scheduled cesarean section delivery, a safe fetal airway can be established before umbilical cord ligation (Figure 49-1) (Harrison et al, 1996; Hirose et al, 2004). Infants with CHAOS still require postnatal airway reconstruction after delivery, but once a tracheostomy is in place, laryngeal or tracheal reconstruction is essentially an elective procedure and can be performed once the patient's overall status is optimized (Hirose et al, 2004). The rate of live births seen with the EXIT procedure has been promising, although long-term outcomes have yet to be assessed (Abraham et al, 2010).

DISORDERS OF THE MEDIASTINUM

In the posterior mediastinal space, thoracic neuroblastomas and neurenteric duplication cysts are most commonly encountered in the newborn. Bronchogenic cysts occur in the middle mediastinal space. An enlarged thymus and a mediastinal teratoma are the masses most often seen in the anterior mediastinum.

Thymus

The thymus occupies the upper anterior mediastinum, and it is more prominent in the newborn period than at any other time of life. It may be so large as to reach the diaphragm or obscure both cardiac borders on radiographs. The normal thymus can be distinguished from an abnormal mass by the absence of tracheal deviation or compression. The thymus changes in position with respiration and is less prominent with deep inspiration. It also involutes with stress as well as with corticosteroid therapy. Absence of the thymic shadow in an infant should alert the clinician to the possibility of severe combined immune deficiency syndrome (SCIDS) or DiGeorge syndrome with hypocalcemia and cardiac anomalies.

The cardiothymic-to-thoracic ratio provides an index of thymic size. The shadow of the enlarged thymus is the most common radiopaque mass visualized in the anterior mediastinum of the newborn. The enlarged thymus causes little if any trouble in the neonatal period. Fletcher and associates, as well as Gewolb et al, (1979) noted that a large thymus is present on the first day of life in infants at risk for hyaline membrane disease, presumably because of less-than-normal levels of glucocorticoids before birth (Fletcher et al, 1979).

Congenital Mediastinal Teratoma

Mediastinal teratomas rarely cause symptoms in the newborn infant. However, when an anterior mediastinal mass is associated with respiratory distress in the newborn, the strong likelihood is that the lesion is a mediastinal teratoma. These teratomas are invariably not malignant, and surgical resection is sufficient treatment. Mogilner et al (1992) described a newborn with severe respiratory distress and tracheal compression who underwent emergency thoracotomy and mediastinal teratoma resection. Another infant had emergency resection for respiratory distress but died with poor cardiac function; as in that case, the tumor may be large enough to cause underdevelopment of the heart with severe circulatory insufficiency (Thambi Dorai et al, 1998). In other cases, the tumor may cause mild lung hypoplasia.

Congenital Bronchogenic Cysts

Bronchogenic cysts arise from the foregut and are usually extrapulmonary, located in the mediastinum (just above the tracheal bifurcation), pericardium, abdomen and neck (Langston and Thurlbeck, 1986; Winters and Effmann, 2001; Winters et al, 1997). The minority of bronchogenic cysts are found within the lung, and some pathologists believe that these may not be distinct from

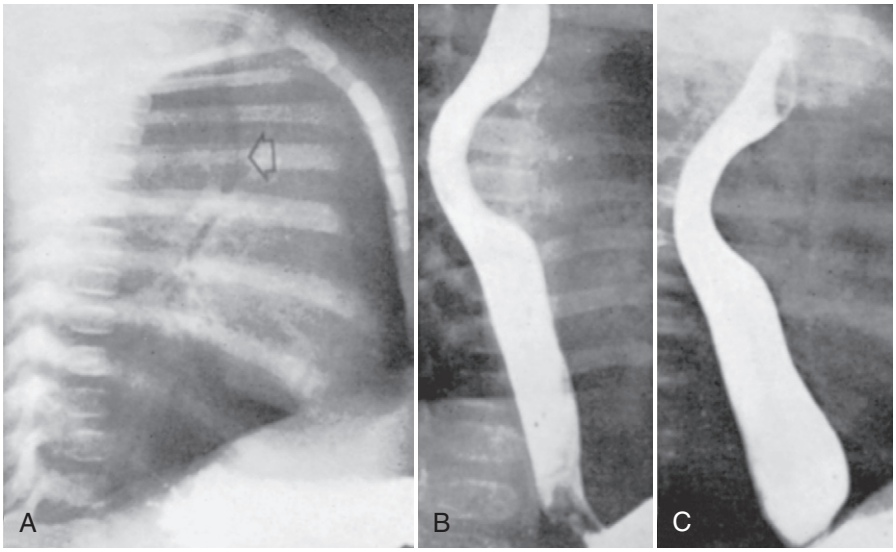

FIGURE 49-2 **A**, The lateral film shows the trachea displaced anteriorly. **B,** The anteroposterior film shows the barium-filled esophagus displaced to the right. **C,** Another lateral film shows the barium-filled esophagus displaced posteriorly. *(From Hope JW, Koop CE: Differential diagnosis of mediastinal masses*, Pediatr Clin North Am *3:379, 1959.)*

intralobar sequestrations or CCAM Type 1 (Stocker, 2009). Bronchogenic cysts can be seen on prenatal ultrasound, although they are more likely to present later as they increase in size over time, with airway compression, recurrent infection, hemoptysis, or pneumothorax (Langston, 2003). Intrauterine airway compression can result in congenital lobar emphysema (CLE; see later discussion). Lesions are filled with fluid and debris, and they can be appreciated by esophagram if external compression is present, or CT scan, with criteria developed to distinguish these cysts from other mediastinal masses (Winters and Effmann, 2001). The diagnosis is made histologically, after resection, with the cyst wall lined by respiratory epithelium and a fibromuscular layer that may contain glands, resembling a bronchus (Stocker, 2009).

In the newborn, bronchogenic cysts are encountered infrequently; most do not come to the attention of the practitioner until later in infancy or childhood. Bronchogenic cysts seldom attain a large size. They contain clear fluid, they are lined with columnar or cuboidal epithelium, and their walls generally contain smooth muscle and cartilage, the latter indicating their bronchial origin. These cysts lie near the carina in the middle mediastinal space. They produce lung overdistention or atelectasis, depending on whether airway obstruction is complete or partial, and this is accompanied by respiratory distress in the newborn infant. Opsahl and Berman reported a case that showed overinflation on the left followed by clearing and then similar overinflation on the right (Opsahl and Berman, 1962). Radiographic examination often shows a mass lesion at or just above the carina, and displacing the lower trachea forward (Figure 49-2, *A*). Ultrasonography may help localize the lesion more accurately. The barium swallow examination may reveal indentation of the esophagus, the cyst pushing it backward at the level of the carina (Figure 49-2, *B* and *C*). Bronchoscopy reveals compression of the trachea and sometimes of one major bronchus, usually from the posterior aspect. Sometimes the bronchogenic cyst may communicate with the airway and contain air. In the immediate newborn period, there may be retention

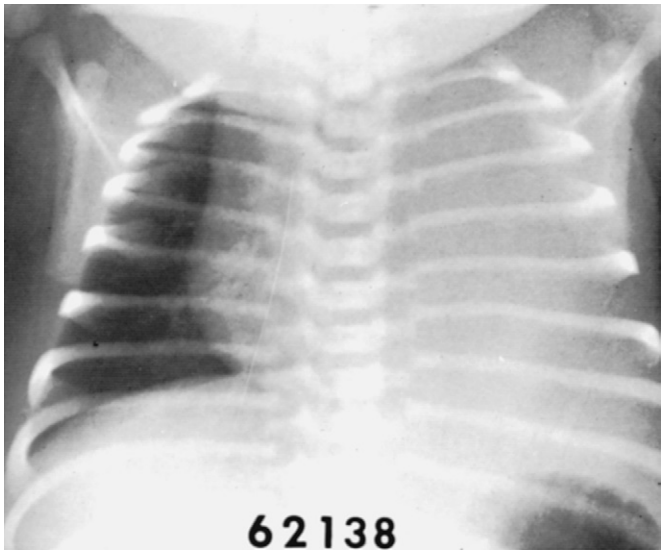

FIGURE 49-3 The left lung shows delayed clearance of lung liquid, associated with bronchial obstruction by a bronchogenic cyst. *(From Griscom NT, Harris GBC, Wohl MEB, et al: Fluid filled lung due to airway obstruction in the newborn*, Pediatrics *43:383, 1969.)*

of fetal lung fluid in the lung compromised by the bronchogenic cyst; the fluid may take days to be cleared. This phenomenon produces a characteristic appearance on the chest radiograph (Figure 49-3). Treatment for bronchogenic cyst consists of early surgical excision, with uniformly good results.

Neurenteric Duplication Cysts

These mediastinal cysts may be derived from the esophagus, stomach, or small bowel, so they may also be called enterogenous cysts. Although they are not encountered frequently, they are far from uncommon in the newborn. They are duplicated segments of the foregut that have become partially or completely detached from the parent viscus. They lie in the posterior mediastinum but with

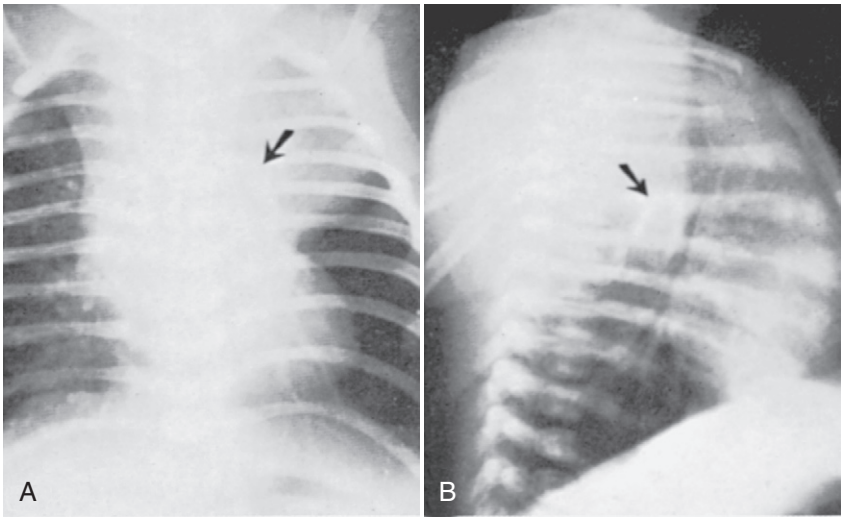

FIGURE 49-4 Congenital thoracic neuroblastoma. The mass is in the left upper hemithorax **(A)** and in the posterior mediastinum **(B)**. *(From Hope JW, Koop CE: Differential diagnosis of mediastinal masses,* Pediatr Clin North Am *6:379, 1959.)*

increasing size may project far into one or the other hemithorax. Their walls are composed of a mucosal layer, characteristic of their site of origin, and one or more muscular layers. They contain secreted fluid that is the same as that of their parent viscus; the fluid in a gastrogenic cyst contains pepsin and hydrochloric acid in the same concentration as in gastric juice.

The foregut becomes duplicated in the course of embryonic development by failure of complete resorption of primitive occluding epithelium, resulting in the formation of a supernumerary wall and eventually a separate lumen and cyst. The high percentage of vertebral anomalies associated with neurenteric duplication cysts led Veeneklaas to suggest that the primary embryonic defect lies in abnormal persistence of the primitive foregut adherence to the notochord (Veeneklaas, 1952). When the foregut descends from its early position in the neck, this adhesion causes anomalies of the vertebral bodies derived from the notochord. This adhesion also breaks off the duplicated portion of the foregut and prevents its complete descent into the thorax and abdomen along with the mature foregut.

Clinical signs depend on the size and location of the duplication cyst. Because all of these cysts are posterior and lie close to the trachea, esophagus, and great vessels, they are seldom present without signs of abnormality. Cyanosis, tachypnea, and dyspnea often are present from birth. Swallowing difficulty and vomiting are less frequent. Recurrent lower respiratory tract infections are findings in a few older infants with such cysts. Frank hemorrhage from the lungs or stomach, or in the form of melena, is not at all uncommon. In most instances, hemorrhage indicates that the cyst is of gastrogenic origin, with peptic acid erosion into the trachea or esophagus. Technetium scans are useful for delineating cysts lined with gastric mucosa. Radiographs of the chest show abnormal densities that are often difficult to distinguish from unusual cardiac contours. The barium swallow examination commonly shows displacement of the esophagus, usually forward because the mass is in the posterior mediastinum. The cyst may partially or totally compress the bronchus, with consequent lung overdistention or atelectasis. Sometimes the symptoms are intermittent as the cyst enlarges or empties. Bronchoscopy may show compression of the trachea or bronchus from without, usually from the posterior aspect. Superina et al (1984) reviewed 25 years of experience with neurenteric duplication cysts; they noted that a spinal component may accompany the mediastinal cyst in as much as 20% of the children. They recommended careful radiographic evaluation of the spinal canal with CT scan and then excision of the intraspinal cyst, if possible, before the onset of neurologic signs in later childhood. The MRI scan may give improved delineation of intraspinal cysts (Azzie and Beasley, 2003). Operative resection is indicated as soon as the diagnosis of mediastinal mass is made. It is neither necessary nor wise to delay exploration, because all intrathoracic masses will eventually become symptomatic.

Congenital Thoracic Neuroblastoma

Neuroblastoma, the most common solid tumor in the mediastinum of infants, arises from sympathetic neural tissue along the vertebral column and is therefore located in the posterior mediastinum. It may extend into both lungs, causing respiratory distress, and it may extend into the spinal canal, later causing neurologic signs. The chest mass may be obvious on routine radiographs obtained for unrelated reasons in the newborn (Figure 49-4), or on chest radiographs taken to evaluate significant respiratory distress (Li et al, 2001). In older infants the diagnosis may follow chest radiography for lower respiratory tract infection, or radiographs may be taken to investigate dyspnea with physical signs of a solid intrathoracic mass. In some cases the tumor mass shows calcification, well visualized with the CT scan. A thoracic neuroblastoma may sometimes be found on fetal ultrasound examination (Moppett et al, 1999).

Differentiation from other posterior mediastinal masses may be impossible before exploration; neuroblastoma is not likely to be so sharply demarcated as a neurenteric duplication cyst. Invasion of neighboring lung parenchyma strongly supports a diagnosis of neuroblastoma. The MRI scan is superior to the CT scan for discerning spread to lymph nodes, spinal canal, and chest wall (Slovis et al, 1997), and also for discerning liver metastases. Elevations

of urinary vanillylmandelic acid and homovanillylic acid may be present, but this finding is less common in the newborn, and its absence does not rule out neuroblastoma. If the patient has systemic hypertension, plasma levels of epinephrine, norepinephrine, and dopamine may be elevated, but this has not been reported in a thoracic neuroblastoma. Also, results of assays for various clinical biologic markers may be positive; for example, serum ferritin and serum lactate dehydrogenase may be elevated, but this is not usual in the newborn. A bone marrow aspirate should be obtained for cytologic evaluation, and a nuclear bone scan should be performed to exclude the possible remote spread of metastases. A number of cytogenetic biologic markers may be detected in the excised tumor tissue (e.g., cellular DNA ditetraploidy, increased N-*myc* oncogene copy number); these usually indicate malignancy in older children (Ladenstein et al, 2001), but again, they are commonly negative in the newborn.

Surgical exploration is indicated for any intrathoracic mass. If the tumor proves to be a neuroblastoma, as much of it should be excised as is feasible. The tumor should be staged by histologic examination according to the system of Evans et al (1971) and subsequent therapy should be dictated by the stage. In general, chemotherapy is not indicated unless distant metastases are present.

The outlook for neuroblastomas in extra-adrenal locations is better than that for their adrenal counterparts (Young et al, 1970). The outlook for neuroblastomas manifesting in the first year of life also is good. Many of these tumors are cystic in nature, and the histologic examination suggests that the neuroblasts are arranged in clumps rather than in sheets; this "neuroblastoma in situ" feature carries a high likelihood of spontaneous regression and therefore a good prognosis. Most neuroblastomas in the newborn are Evans stage A, with a good outlook. So-called stage D (S) also is quite common (Moppett et al, 1999); although there are metastases to the liver, marrow, or skin, the prognosis is still good because metastases to the bone are rare. The clinical markers are seldom elevated, and results of assays for the cytogenetic markers are seldom positive, all of which indicate a reasonable outlook. If the lesion can be completely removed and no bone metastases are found, then most infants survive. Some clinicians suggested that the chance of spontaneous regression is so high in the newborn that even surgery may not be necessary (Li et al, 2001; Morgan, 1995). However, intraspinal spread may occur, in which case the later clinical course is more troublesome, with paraparesis and neurogenic bladder (Moppett et al, 1999); most authors consider surgery to be advisable.

DISORDERS OF THE CHEST WALL

Abnormalities of the bone and muscle of the chest wall may be a mechanical hindrance to ventilation.

SKELETAL DISORDERS

Although abnormalities involving bone are rare, they may be recognized immediately and are sometimes amenable to operative correction.

Defects of Sternal Fusion

Defects in fusion of the sternum are uncommon. Complete separation of the two halves of the sternum allows protrusion of cardiovascular structures, a condition known as *ectopia cordis* (Maier and Bortone, 1949). Lethal malformations of the heart are commonly associated with this condition. Upper sternal clefts are more common. Early operation is advised to shield the underlying structures from injury, and because of the greater ease of approximating the separated parts in the first days of life compared with later (Sabiston, 1958). A lower sternal cleft and ectopia cordis with a congenital heart defect may be associated with congenital apertures in the upper abdominal wall, in the pericardium, and in the anterior diaphragm, with a Morgagni-type diaphragmatic hernia, the so-called pentalogy of Cantrell (Cantrell et al, 1958).

Pectus Excavatum

The most common of the sternal defects is pectus excavatum, sometimes associated with Pierre Robin syndrome or Marfan syndrome. Rarely is it a fixed or severe deformity until several months of postnatal age. A family history of some type of anterior thoracic deformity was found in 37% to 43% of patients (Nuss et al, 1998; Shamberger et al, 1988). The heart may be compressed between the sternum and the vertebral column and displaced to the left, impinging on the space of the left lung. There is usually no respiratory or cardiac distress. Only later in childhood may there be cosmetic and psychological distress sufficient to warrant intervention. Although routine chest radiographs may suffice in evaluating the severity of chest wall deformity, chest CT is typically preferred because this modality provides the bony and cartilaginous anatomic details as well as any information regarding cardiac compression necessary when considering surgical intervention. Using chest CT allows one to calculate the Haller index (HI), or the ratio of the transverse distance to the anteroposterior distance. A normal HI is about 2.5, and most cases of pectus excavatum that qualify for operative correction are greater than 3.25 (Haller et al, 1987). However, the indications for operative correction are debatable. Those with severe cardiac or pulmonary compression, abnormal cardiac or pulmonary function studies, or failed previous repairs are candidates for repair. Periodic evaluation of cardiovascular status with echocardiogram and electrocardiography in addition to assessment of pulmonary function are appropriate in the presence of progressive deformity. In our opinion, correction should not be undertaken until the child is several years of age and then only in those few children in whom the deformity appears to be progressing. Serial photographs are the best way to document changes in pectus excavatum. Results of both minimally invasive and open operative correction are excellent in the majority of patients; surgery is almost always associated with improved self-image and perceived functional activity (Fonkalsrud, 2009; Kelly et al, 2008; Nuss, 2008). Recurrences are possible during later active growth.

Poland Syndrome

Hypoplasia or absence of the pectoral muscles, typically only on one side, is termed Poland syndrome and may be associated with cartilage agenesis of the second through fifth ribs on the ipsilateral side—the ribs of attachment for the pectoralis major muscle. There may be associated syndactyly, hemivertebrae, scoliosis, and hypoplasia of the breast and nipple (Urschel, 2009). Breathing may be paradoxical and the cardiac impulse easily observed through the soft tissues, but there is rarely any severe respiratory distress that would necessitate emergent intervention. Later in childhood, and uncommonly, there may be increasing respiratory symptoms with scoliosis-related lung disease and/or heart failure. No operative intervention is required in infancy, although mammoplasty may be desirable later on in affected girls after puberty.

Thoracic Dystrophies

Asphyxiating Thoracic Dystrophy (Jeune's Syndrome)

A rare deformity of the thoracic cage in approximately 1 in 100,000 to 130,000 live births, asphyxiating thoracic dystrophy is an autosomal recessive chondrodystrophy, associated with short-limbed dwarfism and often polydactyly (Figure 49-5). It was first described by Jeune et al (1955). The ribs are horizontal, hypoplastic, and short, with flared costochondral junctions. The thorax is small, bell-shaped, and rigid; this results in displacement of the liver and spleen well into the abdominal cavity. Some degree of lung hypoplasia may be present, and if present is often severe and lethal (Phillips and van Aalst, 2008). The pelvis shows flaring of the iliac wings and acetabular abnormalities (Kohler and Babbitt, 1970). Prenatal diagnosis with ultrasonography is possible. Renal cystic dysplasia may be present, resulting in hypertension and renal failure. In the past, most patients with this condition did not survive the first month. Oberklaid et al (1977) studied 10 cases and noted that only two patients were alive at the time of the report. One of the two was in excellent health at 15 years of age. The more severely affected infants had respiratory distress from birth. Three patients have been described in one family; because it is an autosomal recessive trait, the expectation would be for an occurrence in one of four siblings, so mutations must be common. No parent-child occurrence has been described. Davis et al (2001) reported an operative technique for lateral thoracic expansion in 10 patients with chest wall deformities limiting thoracic capacity—including 8 patients with classic Jeune syndrome. Three were younger than 1 year of age at the time of surgery, and 6 were ventilator dependent. All of the infants older than 1 year of age at the time of surgery improved, with measured lung volumes increasing in 2 of 3 studied, and thoracic volumes by computed tomography increasing in 4 of 5 studied. The only deaths were in 2 infants younger than 1 year of age at the time of surgery, suggesting that lateral thoracic expansion is a safe and effective procedure for patients beyond the first year of age. A vertical expandable prosthetic titanium rib (VEPTR) procedure has also been introduced for the purpose of progressive expansion of the chest cavity in thoracic insufficiency patients. However, long-term improvements in lung function specifically in patients with Jeune's syndrome have yet to be reported (Phillips and van Aalst, 2008).

Other Thoracic Dystrophies

Severe underdevelopment of the thoracic rib cage, accompanied usually by lethal pulmonary hypoplasia, may be seen in other conditions, such as the thanatophoric dwarfism syndrome, the short rib–polydactyly syndrome, and the camptomelic dwarfism syndrome. Affected infants do not survive for long after birth.

NEUROMUSCULAR DISORDERS

Other causes of thoracic dysfunction are diseases of the nerves and muscles, including congenital myasthenia gravis, congenital spinal muscular atrophy (Werdnig-Hoffmann disease), congenital myotonic dystrophy, glycogen storage disease, and congenital spinal injury. Such conditions are usually recognized in the context of the associated systemic muscular weakness. Newborns with myasthenia gravis have episodes of muscle weakness, poor feeding, weak cry, hypoventilation, and apnea with a positive response to an anticholinesterase medication. In congenital spinal muscular atrophy, there is lung hypoplasia associated with absent fetal breathing, and as a result the thorax is small. Other features include severe hypotonia, muscle fasciculation, respiratory failure, and early death; the inheritance is autosomal recessive. In congenital myotonic dystrophy, there is lung hypoplasia from absent fetal breathing; affected infants have respiratory distress at birth, rapidly need mechanical ventilation, and are soon ventilator dependent. Mothers of these infants have myotonia, difficulty in relaxing muscle contractions; the inheritance is autosomal dominant.

DISORDERS OF THE PLEURAL CAVITY

The pleural cavity lies between the parietal pleura, lining the chest wall, and the visceral pleura, lining the lung and other structures. The blood supply to both pleural surfaces is systemic. Venous drainage of the parietal pleura is to the systemic system and the visceral pleura to the pulmonary system. The pleural surfaces filter fluid into the pleural space and the pleural lymphatics then resorb fluid from the pleural cavity (Wiener-Kronish et al, 1985). This process is hindered in the setting of abnormal lymphatic development or abnormal systemic venous pressures (because the thoracic lymphatic system drains directly to the systemic veins), resulting in chylothorax. Chylothorax can also occur as a result of surgical disruption of the thoracic duct or in the setting of lymphatic malformations. Other causes of hydrothorax in the newborn include hydrops fetalis, transudate associated with congenital lung lesions or group B streptococcal pneumonia, empyema (usually associated with nosocomial pneumonia), or fluid extravasation from a displaced central venous catheter.

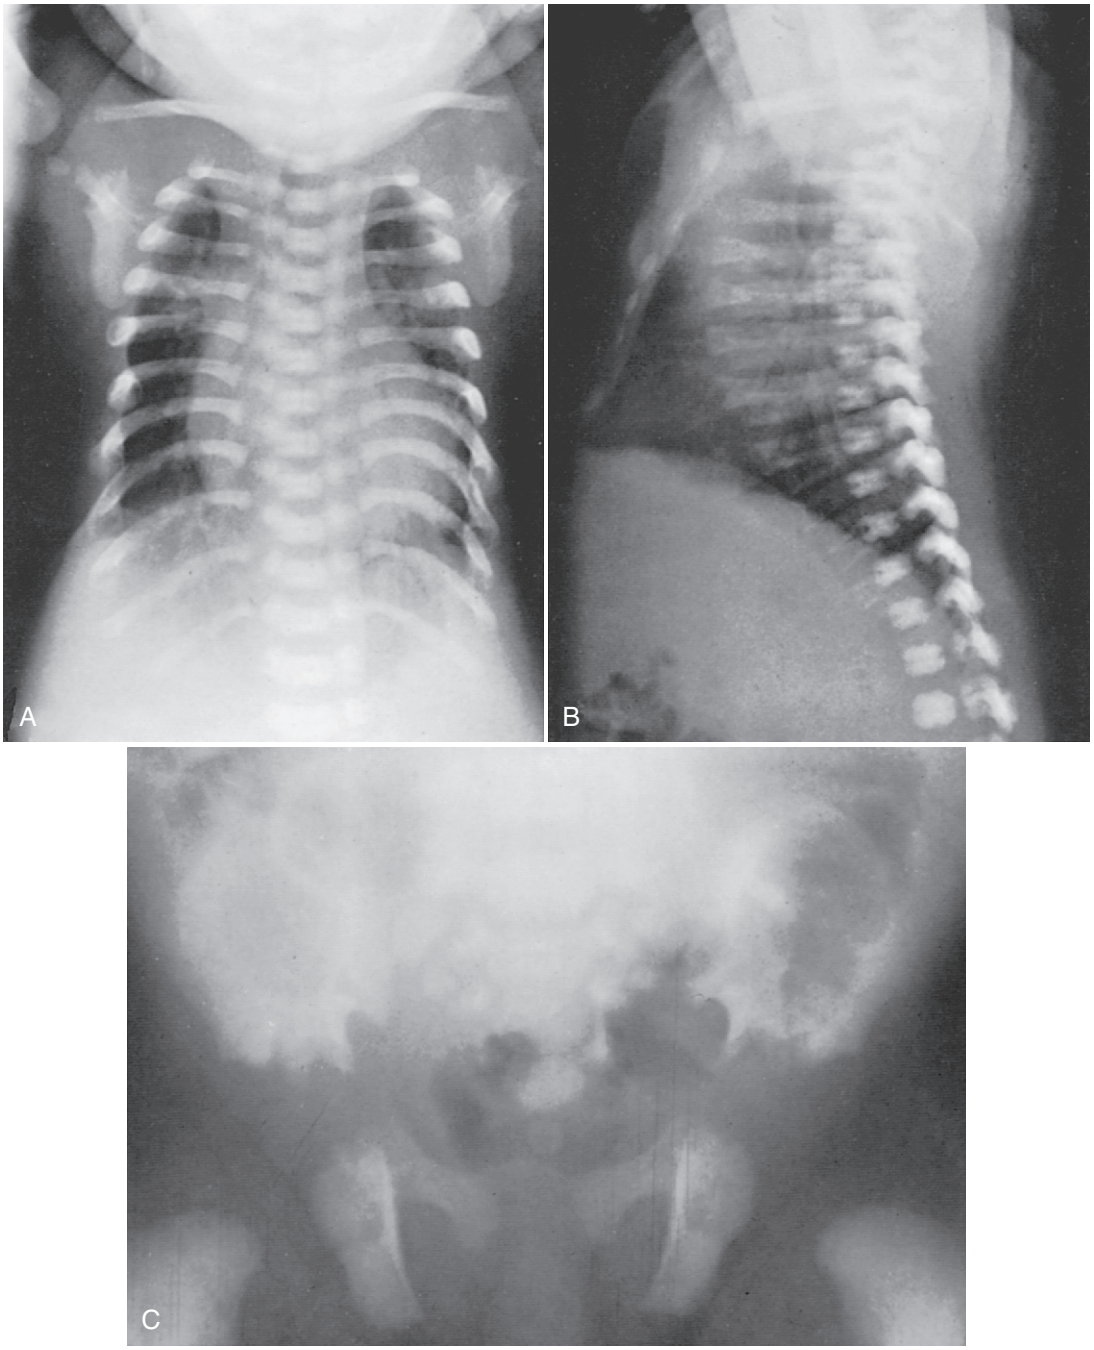

FIGURE 49-5 Radiographs from an infant with asphyxiating thoracic dystrophy. A and **B,** On anteroposterior and lateral views of the chest, the thoracic dimension is seen to be reduced in comparison with the abdominal dimension. **C,** Radiograph of the pelvis shows flaring of the iliac crests and bony protrusions of the acetabulae. *(**A** and **B**, Courtesy of Dr John Kirkpatrick; **C**, from Avery ME, Fletcher BD, Williams RG:* The lung and its disorders in the newborn infant, *ed 4, Philadelphia, 1981, WB Saunders.)*

CONGENITAL CHYLOTHORAX

The prenatal diagnosis of an isolated pleural effusion without an associated thoracic malformation or hydrops fetalis is most likely to be a chylothorax (or lymphatic effusion, because chyle cannot be present in the absence of fat-containing enteral feeds). A large fetal chylothorax may evert the diaphragm and can be the cause of hydrops fetalis, likely due to hypoproteinemia or impaired venous return in the setting of increased intrathoracic pressure. Fetal chylothorax portends a worse prognosis for survival if it is bilateral or associated with hydrops, and prognosis is better if the effusion resolves without reaccumulation (Longaker et al, 1989). Large fetal chylothoraces can result in pulmonary hypoplasia. In utero intervention may be undertaken in cases of large or bilateral effusions, or hydrops, and may improve the chances of survival. These interventions include transabdominal thoracentesis (with ongoing ultrasound monitoring for fluid reaccumulation) and placement of an indwelling thoracoamniotic shunt (if the effusion reaccumulates), to allow continued

drainage of fluid. Fetuses diagnosed with chylothorax should be evaluated for associated conditions that may affect their prognosis, including Down, Noonan, and Turner syndromes.

Newborns with congenital chylothorax often present with severe respiratory distress, requiring immediate respiratory support and urgent drainage of pleural fluid. Characteristics of chylous fluid include a high cell count with a lymphocytic predominance, a high triglyceride level (usually above serum levels, but not present unless enteral feeds initiated), and high protein content (Table 49-1). The introduction of small-volume fat-containing feeds with resultant elevated fluid triglyceride levels can confirm the diagnosis if biochemical indices are otherwise not confirmatory. A review of 39 cases of pediatric chylothorax revealed that the composition was consistent with previously described classic characteristics (Buttiker et al, 1999). Total cell counts were >1000/mm^3 in 92% of cases, and 85% of effusions had >90% lymphocytes (range 57% to 89% in 6 additional children). Fluid triglyceride levels were >1.1 mmol/L (98 mg/dL) in all but one case, with values ranging from 0.56 to 26.6 mmol/L (50 to 2358 mg/dL).

Management of Chylothorax

Neonatal management of chylothorax includes replacement of protein, clotting factors, and immunoglobulins as needed. Ongoing respiratory support may be needed, and often a chronic chest drain is required to decrease respiratory compromise. Feeds are usually restricted, either providing medium-chain triglycerides (MCT) only (because MCT are generally absorbed directly from the intestine without processing to chylomicrons) or a nonfat diet. If these measures fail, a period of total enteric rest is undertaken, with parenteral nutrition administered, until resolution of the chylous effusion. Some practitioners believe that a period of enteric rest is necessary to decrease strain on the lymphatic system, because lymphatic efflux from the intestine is an important component of thoracic lymph fluid. Once chest drainage has resolved, feeds are reintroduced with an MCT-only formula for 3 to 6 weeks before transitioning to a normal diet.

There are no controlled studies demonstrating that one strategy is superior to others to hasten resolution of chylothorax, and in one series, 50% of pediatric chylothoraces resolved with MCT-only diets (Le Coultre et al, 1991). A later series from the same institution had 80% (41 of 51) resolution with conservative, nonoperative management (MCT-only diet or enteric rest) up to 4 weeks' duration (Beghetti et al, 2000). The primary risk of this approach is infection, because these children have prolonged hospitalizations with central venous access, chest drains, no enteral feeds, and protein and immunoglobulin losses. Eight of 51 children had severe infections in this series. Children who were less likely to have spontaneous resolution of chest drainage included patients with elevated central venous pressure who had more prolonged effusions and higher output than those with surgical injury. There were more frequent operative interventions in this group (6 of 14 children), which were undertaken only if 4 weeks of conservative therapy failed to decrease drainage to <10 mL/kg/d (Beghetti et al, 2000). In one series, 4 of 11 children with drainage after 4 weeks resolved their chylothorax by 6 weeks, with 2 of the remaining children too unstable to undergo surgical intervention (Buttiker et al, 1999). Operative interventions include thoracic duct ligation, pleurodesis, and/or placement of a pleuroperitoneal shunt. Most practitioners recommend about 4 weeks of conservative management, awaiting resolution of chylous drainage, because all interventions other than shunt placement require a thoracotomy. Effusions are unlikely to resolve after 6 weeks, and waiting too long for operative intervention may result in significant compromise to the child.

An adjunctive medical approach is the administration of somatostatin or its analogue, octreotide, to decrease pleural drainage. Somatostatin is delivered only via continuous infusion, whereas octreotide can also be given via intermittent subcutaneous injection, because of its longer half-life. The mechanism of effect is thought to be via decreased intestinal secretions and absorption, and therefore intestinal efflux and abdominal lymphatic return (Kalomenidis, 2006). Some practitioners proceed quickly to the use of these medications, believing they decrease the volume and duration of chest drainage compared to conservative management; however, this has not been studied in a controlled setting, so the efficacy and risks of this approach are unknown. Others use these medications once conservative measures have failed. Potential risks of therapy include hormonal effects of glucose instability and hypothyroidism and gastrointestinal effects such as cholelithiasis, hepatocellular injury, nausea, diarrhea, abdominal distention, and decreased intestinal perfusion. In this regard, a case of necrotizing enterocolitis in a newborn post repair of aortic coarctation was reported (Mohseni-Bod et al, 2004), as was a case of strangulation-ileus in an 18-month-old with asplenia syndrome (Matsuo et al, 2003). These serious side effects raise concerns, particularly regarding concomitant feeding during administration of the medications. Octreotide has been reported more commonly in newborns in case reports in the literature, in doses ranging from 7 to 240 μg/kg/d (Helin et al, 2006; Roehr et al, 2006). Dosing is either titrated up until chest drainage is minimal (typically starting at 3.5 μg/kg/h and advancing in several steps to 10 μg/kg/h), or started at the higher dose and titrated down once drainage has abated. The infusion is usually continued for several days after chest drainage is controlled, and then weaned off over several days. There are reports of recurrence after discontinuation of the medication

TABLE 49-1 Characteristics of Chylous Effusions

Characteristic	Description
Appearance	Clear yellow (milky with fat-containing feeds)
Cell count	>1000 cells/mm^3
Lymphocyte proportion	>80%
pH	7.4–7.8
Triglycerides	>110 mg/dL
Cholesterol	65–220 mg/dL
Albumin	1.2–4.1 g/dL
Total protein	2.2–5.9 g/dL

Adapted from Rocha G: Pleural effusions in the neonate, *Curr Opin Pulm Med* 13:305-311, 2007.

(Roehr et al, 2006). Octreotide has also been used in treatment of congenital chylothorax (Bulbul et al, 2009; Paget-Brown et al, 2006; Roehr et al, 2006). Monitoring of serum glucose, thyroid function, liver enzymes and indicators of cholestasis during therapy is recommended.

CONGENITAL THORACIC MASSES AND CYSTS

Fetal lung masses vary in the degree of abnormality of parenchyma and vasculature and likely represent a spectrum of developmental abnormalities, which may be difficult to distinguish antenatally (Ankermann et al, 2004; Langston 2003). In fact, some investigators have suggested classifying these lesions solely on the basis of the vascular supply (systemic vs. pulmonary) and whether or not lung structure is normal (Achiron et al, 2004), because the histology and likely the developmental pathways leading to the individual lesions are overlapping. Some level and degree of fetal airway obstruction has been implicated as the etiology of many of these lesions (Langston, 2003). In antenatal series, congenital cystic adenomatoid malformation of the lung (CCAM) is frequently the most common lesion reported (Achiron et al, 2004). However, in postnatal series, CCAM is often less common (with various imaging modalities and pathology available to clarify the diagnosis after birth), particularly when only cystic lesions are considered (Langston, 2003; Stocker, 2009; Winters and Effmann, 2001). There are multiple reports of "hybrid" lesions, with features of both CCAM and bronchopulmonary sequestration (BPS), emphasizing that these lesions constitute a spectrum of anomalies (Langston, 2003; Winters and Effmann, 2001).

Congenital Cystic Adenomatoid Malformation of the Lung

CCAMs develop from an overgrowth of lung tissue, extending from different levels of the airway. In general, they are unilateral. The lesions may communicate with the airways, allowing them to transition from being fluid-filled in utero to air-filled postnatally, but they do not contain normal alveoli. Stocker et al (1977) originally classified the lesions based on their cystic components, with lesions containing larger cysts demonstrating features consistent with a more proximal airway origin, microcystic lesions demonstrating features consistent with an intraacinar origin, and intermediate cysts demonstrating features consistent with origin from the bronchiole. Subsequent revisions of this classification have included less common proximal and distal lesions and have suggested new nomenclature based on the fact that not all lesions are either adenomatoid or cystic. The term congenital pulmonary airway malformation (CPAM) has been proposed by Stocker (2002), and others have suggested variable, more descriptive terminology which includes both the pulmonary airway malformations and other congenital chest lesions (Achiron et al, 2004; Bush, 2001; Langston, 2003). This chapter uses the terms CCAM and BPS, because much of the literature evaluating surgical approaches, natural history, and follow-up employs these terms. Table 49-2 shows the stages of lung development with the corresponding airway malformation and CCAM/CPAM type. Consistent with this classification, persistent epithelial expression of the nuclear regulatory protein TTF-1 has been found in CCAM types 1 to 3 (see later discussion), indicating developmental arrest in the pseudoglandular stage (Morotti et al, 2000), and targeted fetal airway overexpression of the growth factor FGF-10 in rats produces CCAM-like lesions (Gonzaga et al, 2008).

CCAM Types

Type 0 CCAM originates from the tracheobronchial tree. There is normal lung lobulation, but no formation of alveoli (Stocker, 2002). There are only bronchial-like structures present, indicating an arrest of development in the pseudoglandular stage (Davidson et al, 1998). Lungs may be normal weight or small, but regardless, this lesion is rapidly lethal because of severe, intractable respiratory failure. The lesion has been termed *acinar dysplasia* (Rutledge and Jensen, 1986). It is diffuse and bilateral, recurs in families, and can be associated with other anomalies, suggesting a genetic etiology (Gillespie et al, 2004; Moerman et al, 1998). In a large pathology series, fewer than 2% of the pulmonary airway malformations were characterized as acinar dysplasia (Stocker, 2002).

TABLE 49-2 Stages of Airway Branching and Lung Development With Corresponding Congenital Airway Malformation

Developmental Stage	Developmental Events	CCAM Type	
		Stocker	Adzick
Embryonic 0–7 weeks	Formation of tracheal bud and growth and branching to segmental bronchi	Type 0 Tracheobronchial Type 1 Bronchial/bronchiolar	Macrocystic
Pseudoglandular 7–17 weeks	Completion of airway branching to terminal bronchioles (preacinar); gland formation	Type 2 Bronchiolar	
Canalicular 17–27 weeks	Formation of respiratory bronchioles to prealveolar structures	Type 3 Bronchiolar/alveolar duct	Microcystic
Saccular 28–36 weeks	Formation of secondary septae	Type 4 Distal acinar	
Alveolar 36 weeks–2 years	Formation of alveoli		

From Cha I, Adzick NS, Harrison MR, Finkbeiner WE: Fetal congenital cystic adenomatoid malformations of the lung: a clinicopathologic study of eleven cases, *Am J Surg Pathol* 21:537-544, 1997; Hislop AA: Airway and blood vessel interaction during lung development, *J Anat* 201:325-334, 2002.

In contrast, type 1 CCAM is the most common lesion in postnatal series of airway malformations, identified in 60% to 65% of cases (Stocker, 2002, 2009). Cysts are large, usually greater than 2 cm, and usually limited in number, often with a dominant cyst present. The cysts usually communicate with each other, and they may decrease in size as they drain progressively during advancing gestation. Postnatally, they are aerated, with fluid also present in some lesions. Type 1 CCAMs are restricted to a single lobe in 95% of the cases, with bilateral lesions rare. The lesions are lined by a spectrum of respiratory epithelial cells, ranging from cuboidal to ciliated pseudostratified columnar epithelium, and mucus-producing cells may occur in gland-type tissue. The walls of the lesions may resemble walls of bronchi. Respiratory distress depends on the size of the lesion, with some lesions detected only by incidental imaging, or after infection or malignant transformation. There does appear to be a risk of malignant transformation in nonresected or residual CCAM tissue, which occurs sometimes in patients with evidence of chronic inflammation or a history of recurrent lower respiratory tract infections. The specific link to neoplasm has not been elucidated, though the diagnosis of bronchoalvolar carcinoma (BAC) is made in relatively young patients (10 to 42 years) and a spectrum of malignancy has been described (MacSweeney et al, 2003; Mani et al, 2007). This is the only CCAM type that is associated with malignancy, and the young age of affected patients suggests that the CCAM lesion is the etiology of the malignancy (MacSweeney et al, 2003).

Type 2 CCAMs are characterized by multiple, smaller macroscopic cysts, 0.5 to 2 cm diameter, which may not be evident by chest radiograph. These lesions account for 15% to 20% of congenital pulmonary airway malformations. The lesions are lined by respiratory epithelial cells, ranging from cuboidal to columnar in morphology, and appear as multiple bronchiole-type structures, although intraacinar structures may also be interspersed (Rosado-de-Christenson and Stocker, 1991). These lesions are most commonly associated with other anomalies, in 50% of cases, which include severe bilateral renal dysplasia or agenesis, agenesis of other genitourinary structures, sirenomelia, extrapulmonary sequestration, and diaphragmatic hernia (Stocker, 1977, 2009). Conotruncal cardiac malformations have been described in association with type 1 and type 2 CCAM (Hüsler et al, 2007; Stocker et al, 1977), and ventricular septal defects have been diagnosed in fetuses and infants with all CCAM types.

Type 3 CCAMs are uncommon lesions, occurring in 5% to 10% of CCAM cases (Stocker, 2002). These lesions are generally solid, with microscopic cysts (although single larger cysts can be present), and involve an entire lobe or the entire lung. There is often a mass effect in the thorax, and the lesions can cause lung hypoplasia through compression of adjacent structures. The lesions themselves contain bronchiolar and alveolar duct-type morphology with cuboidal epithelium, and there are alveoli-like structures.

Type 4 lesions have been more recently described, and account for 10% of CCAM (Stocker, 2002). With large cysts present, some of these lesions may be mistaken for type 1 CCAM. They are usually confined to one lobe and tend to be peripheral in location. Infants and children may present with mild respiratory distress, or more severe symptoms if pneumonia occurs, or if the lesion ruptures, causing pneumothorax. CCAM type 4 can also be detected by incidental imaging. The lesions are lined with alveolar type I (flat) and type II (rounded) epithelial cells. The presence of substantial portions of cells representing the more proximal areas of the lung should raise suspicion for pleuropulmonary blastoma (PPB), a distinction that is important (because of malignancy associated with PPB; see later discussion), but one that can be difficult.

Other classification systems for CCAM have included the type 3 CCAM with hyperplastic lung disorders implicating airway obstruction, including polyalveolar lobe and laryngeal atresia, and types 1 and 2 with other bronchopulmonary malformations (Langston, 2003). The approach to CCAM diagnosed in utero has led to a different classification system, based on the natural history of these fetal lesions (see later discussion). Macrocystic CCAM is defined when a lesion contains cysts that are greater than or equal to 5 mm (types 1 and 2 CCAM), and microcystic CCAM is defined as a solid lesion, with cysts less than 5 mm (type 3 CCAM) (Adzick et al, 1985). Some lesions categorized by these criteria on fetal ultrasound have been diagnosed as BPS after postnatal resection (Davenport et al, 2004).

Fetal Diagnosis and Natural History

Fetal diagnosis of CCAM is often made when mediastinal shift due to mass effect from the lesion is identified and a cystic, intermediate, or solid mass is detected. This may occur during routine fetal survey, or when the mother is referred for evaluation of polyhydramnios (thought to occur when the mass compresses the esophagus) (Adzick, 2009). A systemic vascular supply is more consistent with a diagnosis of BPS (Winters and Effmann, 2001). In a recent population-based study from the United Kingdom, confirmed CCAM (postnatal or postmortem) occurred in 9 per 100,000 births, without accounting for lesions that were not further investigated secondary to prenatal resolution (Gornall et al, 2003). In this study, 57% (21 of 37) of fetal CCAMs were confirmed, and 5 cases were missed (prenatal detection rate 21 of 26 [81%]). Generally, growth of CCAM lesions increases until about 28 weeks' gestation, after which time it plateaus and the lesion regresses in size while the fetus continues to grow (Adzick, 2009; Kunisaki et al, 2007). Fetal and neonatal problems that arise as the result of CCAM include the development of nonimmune hydrops, and lung hypoplasia, which may be due to compression of the otherwise normally developing lung. Factors associated with the development of nonimmune hydrops include an everted ipsilateral hemidiaphragm, a predominantly cystic lesion, and a mass-to-thorax ratio (MTR) ≥0.56 (Vu et al, 2007). The MTR is the transverse diameter of the mass divided by the transverse diameter of the thorax in an axial image containing the four-chamber view of the heart. An earlier publication from Crombleholme et al (2002) evaluated factors associated with the development of excessive fluid in a single compartment, which they termed nonimmune hydrops. In this study, the CAM volume ratio (CVR) was evaluated retrospectively and applied prospectively. The CVR calculates the volume of the mass (length × weight × height × 0.52)

divided by the head circumference. With CVR >1.6, 75% (12 of 16) fetuses developed hydrops, and with CVR ≤1.6, only 17% (7 of 42) fetuses developed hydrops. In a series evaluating fetal macrocystic and microcystic lesions, generally the fetuses with microcystic lesions had poorer outcomes, with intrauterine demise or early neonatal death (Adzick et al, 1985). Compared to normal lung, CCAM lesions have unregulated growth, with increased proliferation and decreased apoptosis (Cass et al, 1998), although they are relatively hypovascular (Cangiarella et al, 1995). In fetal CCAM tissue, increased PDGF-B and decreased fatty acid binding protein-7 (FABP-7) expression have been detected (Liechty et al, 1999; Wagner et al, 2008).

Prenatal Management

Initial ultrasound evaluation of the fetus with possible CCAM should include assessment of lesion size with relevant indices, vascular supply, degree of mediastinal shift, ipsilateral diaphragmatic conformation (normal, flat, or everted), polyhydramnios, placentomegaly, and the presence of any other fluid collections (ascites, integumentary edema, pleural or pericardial effusion) indicating the development of hydrops fetalis. Additional prenatal evaluation of the fetus with CCAM should include a full fetal survey to identify other anomalies, a karyotype, and an echocardiogram, to evaluate for congenital heart disease and to assess cardiac inflow patterns and outputs. These cardiac indices may help identify impending hydrops, mandating closer ultrasound follow-up and repeated echocardiographic measurements. Most referral centers recommend at least weekly follow-up ultrasound examinations evaluating lesion size and monitoring for development of hydrops until 28 to 29 weeks' gestation, at which point regression of the lesion should be occurring. Thereafter, ultrasound evaluations can be spread out to every 2 weeks. Some referral centers have advocated twice-weekly surveillance if the CVR is greater than 1.6, until 28 weeks' gestation (Adzick, 2009). In a recent series, 21 of 54 fetal lung masses decreased in size or resolved by delivery (Davenport, 2004; Davenport et al, 2004), and a similar proportion of fetal CCAM cases were not detectable at birth in a population-based study (13 of 37, 35%) (Gornall et al, 2003).

The diagnosis of hydrops in a fetus with CCAM portends a poor prognosis, with either fetal demise or preterm delivery of a compromised infant (Gornall et al, 2003; Grethel et al, 2007; Kunisaki et al, 2007). Thus, impending or definite hydrops is an indication for fetal intervention. The specific intervention depends on the type of lesion. In fetuses with a macrocystic CCAM, a growing, dominant cyst, and impending or definite hydrops, placement of a thoracoamniotic shunt results in a decrease in cyst size and hemodynamic improvement, with relatively good neonatal survival (12 of 16 in two series) (Adzick et al, 1998; Wilson et al, 2004). However, shunt placement at <21 weeks gestation may be associated with chest wall deformity, which can compromise later respiratory function, so other interventions may need to be taken at that early gestation (Merchant et al, 2007). Fetal thoracentesis is rarely effective as definitive treatment, because cyst fluid invariably reaccumulates, but it might serve as a temporizing measure until further treatment can be undertaken. For fetuses with impending hydrops and a microcystic CCAM (or failed decompression of a large cyst), open fetal resection (lobectomy or pneumonectomy) likely improves the chances of survival, although mortality remains high (10 of 23 in one series), and nonsurvivors tended to be more premature (Grethel et al, 2007). This selected approach to fetal resection has resulted in resolution of hydrops and mediastinal shift in survivors (Adzick, 2009). For fetuses at 28 to 30 weeks' gestation, or in the case where fetal surgery is contraindicated because of preterm labor, an EXIT-to-resection procedure may provide a chance for survival (Adzick, 2009; Grethel et al, 2007). EXIT procedures have also been undertaken in later-gestation fetuses with persistent large lesions (mean CVR 2.2) despite other fetal interventions, although the impact of this strategy on survival and other outcomes is unknown (Adzick, 2009; Hedrick et al, 2005). Antenatal glucocorticoid therapy to enhance fetal lung maturation should be administered before undertaking any of these procedures. This practice, utilizing betamethasone (12 mg IM every 24 h × 2 doses), led to the observation that fetuses with microcystic CCAM (type 3) and hydrops resolved their hydrops after betamethasone exposure (Tsao et al, 2003). In this series, three fetuses with mild-to-moderate hydrops treated at 21 to 26 weeks' gestation avoided further fetal interventions, were delivered at term, and survived. Glucocorticoid administration may temporarily arrest cell proliferation and/or push maturation of different cell types in these more distal lung lesions, consistent with known effects of glucocorticoids on the developing lung. However, more severe hydrops, particularly in the case of maternal mirror syndrome, may represent irreversible physiologic changes that compromise the pregnancy regardless of the intervention (Adzick, 2009). There is an ongoing multicenter placebo-controlled trial enrolling mothers carrying nonhydropic fetuses with CVR >1.4 at <26 weeks' gestation, wherein women are randomized to betamethasone versus placebo. The primary outcome is the development of hydrops fetalis, with secondary outcomes of CCAM growth and neonatal survival. This trial should be able to clarify the role of antenatal glucocorticoids in the prenatal management of microcystic/type 3 CCAM.

Postnatal Management

In fetuses that do not develop hydrops fetalis, the prognosis is good and likely depends on the type of lesion and the presence of other anomalies. Generally, the prognosis of type 1 CCAM is good, particularly if fetal intervention is not required. There is resolution of any symptoms after resection, which usually can be accomplished by lobectomy. Type 2 CCAM has a worse prognosis, because of the association with additional serious malformations. Type 3 CCAM was thought to be uniformly lethal from its earliest descriptions (Stocker et al, 1977), and it can be associated with lung hypoplasia. For fetuses with large microcystic CCAM, fetal resection, if indicated, may mitigate hypoplasia. However, more recent series have described substantial spontaneous regression of microcystic CCAM, with an increased rate of in utero resolution compared to macrocystic lesions (Davenport et al, 2004). In a large series from a single referral center, neonatal survival was 98% (118 of 121) (Grethel et al, 2007). Five infants underwent

fetal procedures, with 1 death, and there were 2 neonatal deaths. In a population-based series, there were no postnatal deaths following 20 live births, with a single IUFD and 5 terminations (Gornall et al, 2003). Three fetal interventions (thoracentesis or thoracoamniotic shunt placement) were undertaken in these patients.

Newborns with CCAM may be asymptomatic, or they may present with respiratory distress with or without pulmonary hypertension, which can be severe enough to require ECMO support (Adzick, 2009; Kunisaki et al, 2007). However, even in a series of large fetal CCAM (at least 3 cm x 3 cm), only 4 of 9 infants had respiratory distress requiring resection in the first week of life. For newborns with antenatally diagnosed CCAM, lesions may be detected on chest radiograph, as solid masses, or fluid or air-filled cysts (Figure 49-6). Mediastinal shift, mass effect, or areas of air trapping due to airway obstruction may be appreciated. Some centers use ultrasound as an adjunctive modality in the neonatal period, but many surgeons prefer CT scan as the definitive imaging study, which also can detect lesions that are no longer present on fetal ultrasound (Winters and Effmann, 2001). CT scans can also determine if there are multiple bronchopulmonary malformations, which may also require resection, and the use of intravenous contrast allows for definition of the vascular supply, helping to differentiate CCAM from BPS (Johnson and Hubbard, 2004). For asymptomatic newborns, surgeons will often defer this study until several months of age, because surgical resection is also deferred. The usual surgical approach is lobectomy, for the majority of lesions confined to a single lobe. More diffuse lesions might require bilobectomy or pneumonectomy. These surgical approaches are likely to result in the removal of normal lung, but it also may decrease the risk of air leak and infection after resection (Shanmugam, 2005), and compensatory lung growth does occur after lobectomy (Nakajima et al, 1998). Additional postoperative complications may include prolonged pleural effusion, pneumothorax, pneumonia, and wound infection (Kim et al, 2008; Waszak et al, 1999).

The need for resection in asymptomatic newborns remains controversial, and there is no consensus on this topic. In a national survey of Canadian pediatric surgeons, there was not even consensus between different surgeons within individual centers (Lo and Jones, 2008). The majority of respondents in this survey (67%) endorsed resecting asymptomatic lesions present on CT, with 78% selecting 2 to 12 months as the age for operation. The concerns with not resecting a lesion is that it remains a persistent nidus for lower respiratory tract infection, and there is the potential for malignant transformation. However, the latter concern is confined to type I CCAM. Twenty-nine children with fetal CCAM that were asymptomatic at birth were followed expectantly to >6 months of age (Aziz et al, 2004). Three (10%) developed recurrent pneumonias and underwent surgery at a median of 8 months; 17 children were followed for a median of 3 years without any complications. Although there was no difference in postoperative complications in children undergoing elective resection versus those with recurrent infections, symptomatic children had a significantly longer length of stay.

Generally, children who have undergone resection for CCAM are healthy. Pulmonary function data demonstrate normal vital capacity, residual volume, and expiratory flows between 1 and 2 years postlobectomy (Nakajima et al, 1998). There are some reports of reactive airway disease and lower respiratory tract infection (Kunisaki et al, 2007) and, in more severely affected children, chronic lung disease and pulmonary hypertension (Keller et al, 2006; Kunisaki et al, 2007).

Bronchopulmonary Sequestration

Bronchopulmonary sequestrations do not have a connection to the normal tracheobronchial tree (Rosado-de-Christenson et al, 1993). The lesions have a systemic arterial supply. Sequestrations are categorized into *extralobar* sequestrations, which are lesions that have their own pleural investment and systemic (80% of the time) venous drainage (and are therefore separate from the lung), and *intralobar* sequestrations, which are integral to the lung pleura and drain via the pulmonary venous system. These lesions usually require lobectomy for removal, because they are invested within the lung. The origin of intralobar sequestration is somewhat controversial. Some experts believe it is not a congenital lung lesion, but is rather always acquired after lung infection and injury, because inflammation, fibrosis, and cystic degeneration are its primary pathologic features (Frazie et al, 1997). In this large

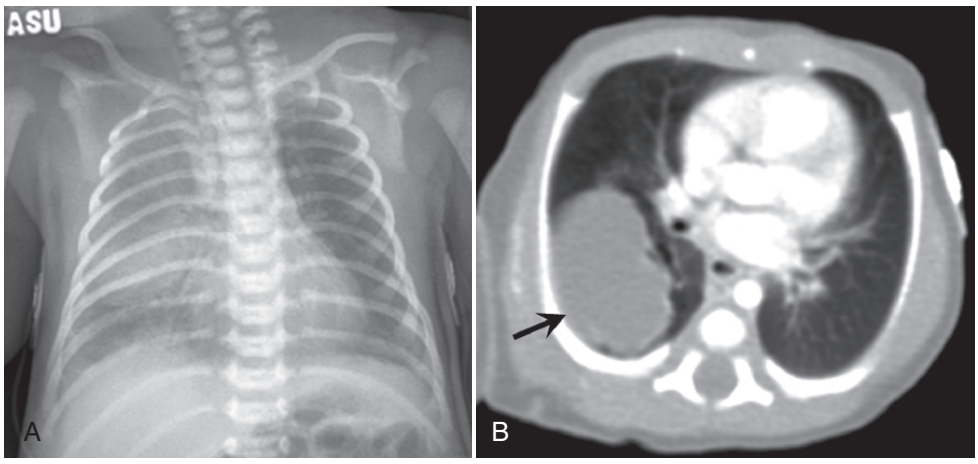

FIGURE 49-6 Chest radiograph **(A)** and thoracic CT with contrast **(B)** from newborn with fetal diagnosis of microcystic CCAM. Right chest mass (*arrow*) measured 2.3 × 3.3 cm at its largest aspect. The infant was asymptomatic.

pathologic series, intralobar lesions, usually diagnosed in adulthood and presenting as lower respiratory tract infection, account for about 75% of BPS. Others believe that intralobar sequestration can be congenital in origin, but is relatively rare in that setting when compared to extrapulmonary sequestration (Winters and Effmann, 2001). Thus, the remainder of this discussion focuses on extralobar sequestration.

Extralobar sequestrations likely originate as an independent bud from the foregut that derives its blood supply from splanchnic vessels (Rosado-de-Christenson et al, 1993). Usually the connection to the foregut is lost during development, although some lesions have persistent connections to the esophagus or the stomach (also referred to as bronchopulmonary foregut malformations). As accessory lobes, they occur within both the thorax and abdomen. As noted, hybrid lesions with features of CCAM and sequestration can occur (Lopoo et al, 1999; Winters and Effmann, 2001). The lesions are usually situated on the left side (65% to 90%), with the most common location between the lower lobe and the hemidiaphragm (approximately 70% of cases). Extrapulmonary BPS can also occur in the abdomen, the mediastinum, the pericardium, and the diaphragm itself. It is more common in males than females (3 to 4:1 ratio), and it also commonly occurs in association with other anomalies, particularly congenital diaphragmatic hernia. Additional associated anomalies include foregut duplication cysts, bronchogenic cysts, CCAM, pericardial defects, and ectopic pancreas. Histologically, these lesions appear as normal lung, except with dilated airway structures and, commonly, lymphangiectasia. A normal-appearing bronchus is present about 50% of the time. Associated pleural effusions are not uncommon (up to 10% of fetal BPS) (Johnson and Hubbard, 2004) and may be secondary to torsion of the vascular pedicle with resultant venous obstruction and elevated pressure or lymphatic abnormalities (Hernanz-Schulman et al, 1991).

Fetal diagnosis of intrathoracic BPS is suspected when there is an echogenic mass, which may also contain cysts. Depending on its size, the mass may be associated with some degree of mediastinal shift (Lopoo et al, 1999). It can be difficult to distinguish BPS from CCAM, but when a systemic arterial supply is identified, the diagnosis of BPS is highly likely. If there is also an associated ipsilateral pleural effusion, the diagnosis is almost certainly BPS (Johnson and Hubbard, 2004). Infradiaphragmatic masses also need to be distinguished from neuroblastoma, other tumors (such as lymphangioma) and adrenal hemorrhage (Curros and Brunelle, 2001; Winters and Effmann, 2001). As with CCAM, BPS often regress spontaneously over time, and if there are no associated anomalies, the outcome of these fetuses is good (Adzick et al, 1998; Lopoo et al, 1999). Close ultrasound follow-up is prudent, however, until regression is documented. When pleural effusion occurs, there is a risk of development of tension hydrothorax. In these cases, repeated fetal thoracentesis or placement of a thoracoamniotic shunt can avert or resolve hydrops fetalis, which may improve the chances for survival (Lopoo et al, 1999).

On postnatal imaging, BPS may be present as a radiographic density on plain film. The presence of linear or cystic lucencies within the radiopaque density suggests a persistent communication between an extralobar sequestration and the gastrointestinal tract (Leithiser et al, 1986; Laberge et al, 2005). An upper gastrointestinal study can demonstrate communication with the GI tract and is indicated for surgical planning if feeding difficulties are present. Ultrasound can also be useful in demonstrating the lesion (most easily seen if it is located at the lung base), and Doppler studies can identify a systemic feeding vessel. The use of contrast-enhanced CT has variable sensitivity for delineation of the vascular supply, although the lesion itself can often be demonstrated even when it has resolved by fetal imaging. MR with angiography can also be useful in demonstrating the lesion and its blood supply. Conventional angiography can also identify the vasculature and may be useful if the child requires cardiac catheterization to delineate additional pathology or physiology (Winters and Effmann, 2001).

Symptomatic BPS is usually identified in the first 6 months of life, with respiratory distress or feeding difficulties. Less commonly, recurrent infection, congestive heart failure (due to a high output state), or pulmonary hemorrhage are present. Distress at birth can be severe, particularly with large lesions complicated by a pleural effusion, or hydrops fetalis. For infants that present with symptoms in the first week of life, early resection is indicated (Azizkhan and Crombleholme, 2008). Because the lesion is delimited, sequestrectomy is not a complex operation. However, the feeding vessels can be very large in more severe cases, mandating a thoracotomy. The primary risk associated with an unresected BPS is recurrent infection, although this risk is not well quantified as there are likely adults with persistent, small, asymptomatic lesions. Thus, as with CCAM, there is controversy as to whether fetal lesions that are not identified on plain film should be further investigated in asymptomatic infants, and in general, whether asymptomatic lesions should be resected. Sequestrectomy can be accomplished thoracoscopically at 3 to 15 months, with rapid recovery and short hospitalization (Albanese et al, 2003). This approach may preserve rib architecture and limit later chest wall deformity (Rothenberg and Pokorny, 1992). Early resection, before infectious complications (the primary risk associated with an unresected lesion) may limit complications, because secondary changes such as emphysema might be averted (Rosado-de-Christenson et al, 1993). Some have attempted coil embolization of the feeding vessel(s), with hope of complete or partial involution of the lesion (Chien et al, 2009; Curros et al, 2000). In some cases, only partial occlusion can be achieved and a second procedure is necessary. Acute complications associated with the procedure include transient lower limb ischemia (due to distal migration of embolic material) and pain, fever, and pleural effusion. These complications are self-limited or treatable. Recanalization can also occur, and children who subsequently develop infection due to a persistent lesion do require surgery.

OTHER CYSTIC LESIONS

Additional cystic lung lesions include congenital lobar emphysema, pleuropulmonary blastoma, and acquired cysts (pneumatoceles or emphysema, in association with infection or bronchopulmonary dysplasia, respectively). Extra pulmonary cystic lesions include foregut cysts

(bronchogenic or enteric duplication cysts) and neuroenteric cysts, which are less common than the other lesions and usually present later in infancy or childhood (Langston, 2003).

Congenital Lobar Emphysema

Because there is no evidence of lung destruction, the common term *congenital lobar emphysema* (CLE) is a misnomer, with this lesion as known as *congenital lobar overinflation* (Langston, 2003). The upper lobes are most commonly affected, with the left upper lobe the single most commonly affected lobe. Lesions occupying multiple lobes are infrequent (Mani et al, 2004). CLE is thought to arise from an obstructed lobar bronchus, which can either be intrinsic (including malacia) or extrinsic in origin. Although the affected lobe is larger than usual, the number of alveoli in the involved area is within normal limits. The exception to this is the subset of these lesions with *polyalveolar lobe*, which was present in 9 of 33 cases of CLE in one series and has an overlapping clinical presentation with CLE (Mani et al, 2004). This form of lung hyperplasia is consistent with pathophysiology associated with fetal airway obstruction (Langston, 2003).

CLE can be detected on fetal ultrasound, although it is difficult to make the correct diagnosis (Babu et al, 2001; Olutoye et al, 2000). Clinical reports have described the appearance of the lesion by ultrasound as cystic and/or echogenic, with mediastinal shift present, and subsequent regression with advancing gestation. As expected, these lesions are suspected to be CCAM or BPS, based on these findings. Fetal MRI can be helpful in characterizing the lesion, although it is not diagnostic (Olutoye et al, 2000). The postnatal clinical presentation and histology (after resection) distinguish CLE from the other lesions. The majority of children with CLE present with respiratory distress, cyanosis or recurrent pulmonary infections in the first 6 months of life, with 13 of 33 (39%) symptomatic on the first day of life in one series (Mani et al, 2004). Chest radiograph demonstrates a hyperinflated lung (transitioning from fluid-filled to air-filled over the initial postnatal days), with compression of other areas of the lung and mediastinal shift. These findings are generally diagnostic. In children with less severe presentation, bronchoscopy or CT scan can be helpful in management decisions, because some surgeons will elect to manage these patients expectantly, with resolution of symptoms in some cases (Stigers et al, 1992). After resection, prognosis is generally good, with compensatory lung growth present on the affected side (McBride et al, 1980). Airway obstruction continues to be a feature of the disease on pulmonary function tests, although these findings could be consistent with either compensatory lung growth exceeding airway growth (dysanapsis) or intrinsic, diffuse airway abnormality.

Pleuropulmonary Blastoma

PPB is a rare but malignant lesion arising from the lung or the pleura. Lesions can be predominantly cystic, predominantly solid, or mixed type and can occur in association with other congenital lung lesions (Priest et al, 1996). The diagnosis and resection of this lesion is important, because of the risk of metastasis, recurrence, and associated malignancies (Priest et al, 1996). Although these lesions tend to present later in childhood than CCAM lesions, there is overlap in the timing of presentation (Stocker, 2002), and PPB can be detected on fetal ultrasound (Miniati et al, 2006); thus, the consideration of this diagnosis in the perinatal period is relevant for counseling and surveillance, even if a newborn is not symptomatic.

Symptomatic infants usually present with respiratory distress. Before resection, most lesions are thought to be CCAM, based on their appearance on fetal ultrasound or postnatal CT scan (Miniati, et al, 2006). Resected lesions contain cuboidal or columnar epithelial cells with underlying rhabdomyosarcoma cells (or other sarcomas). The malignant cells may not be widespread in the lesion, making the diagnosis of PPB challenging even by histology (Hill and Dehner, 2004; Stocker, 2002, 2009). Because of the difficulty in distinguishing CCAM from PPB, careful histologic evaluation of prophylactically resected CCAM is recommended, as those with stellate and spindle cells should be followed closely (Papagiannopoulos et al, 2001). Furthermore, PPB may require a more extensive resection than CCAM, so this distinction is important in determining surgical approach as well (MacSweeney et al, 2003). Tumor cells often have complex chromosomal rearrangements, and affected children can exhibit other neoplastic diseases: medullablastoma, nephroblastoma, thyroid dysplasia and malignancy, and brain sarcoma (Priest et al, 1996; Stocker, 2002). Kindreds also demonstrate multiple malignancies, suggesting that familial surveillance for disease might be indicated (Priest et al, 1996).

Postinfectious Pneumatoceles

A number of infectious agents are more commonly associated with pneumatoceles. In our experience, the most common infection associated with pneumatocele in the newborn (maybe because of its higher frequency of infection) is *Staphylococcus aureus* pneumonia. Other infections seen in the neonatal intensive care unit that are associated with development of pneumatocele include pneumonia due to *Actinomyces* and *Candida* species, *Pseudomonas aeruginosa* and *Klebsiella pneumonia* (Stocker, 2009). Pneumatocele is often present on initial chest radiograph documenting the infiltrate, although they can also occur later in the process. These pneumatoceles can rupture, resulting in pneumothorax, which may be under tension, or they can compress lung tissue through mass effect, resulting in worsening respiratory status. Acutely, urgent interventions may be needed to improve ventilation and oxygenation, and chronically, long-term ventilator support may be necessary, particularly in former premature infants with bronchopulmonary dysplasia (BPD). Both of these scenarios raise the possibility of benefit from surgical intervention to allow functioning lung to expand. Placement of chest drains into the pneumatocele(s), either percutaneously or under direct visualization via video-assisted thoracoscopic surgery (VATS) procedure, can be definitive, because the usual course for these cysts is regression and resolution (Fujii and Moulton, 2008; Kunyoshi et al, 2006) (Figure 49-7). For patients with chronic ventilator dependence, a resection of the affected lobe could be considered, but

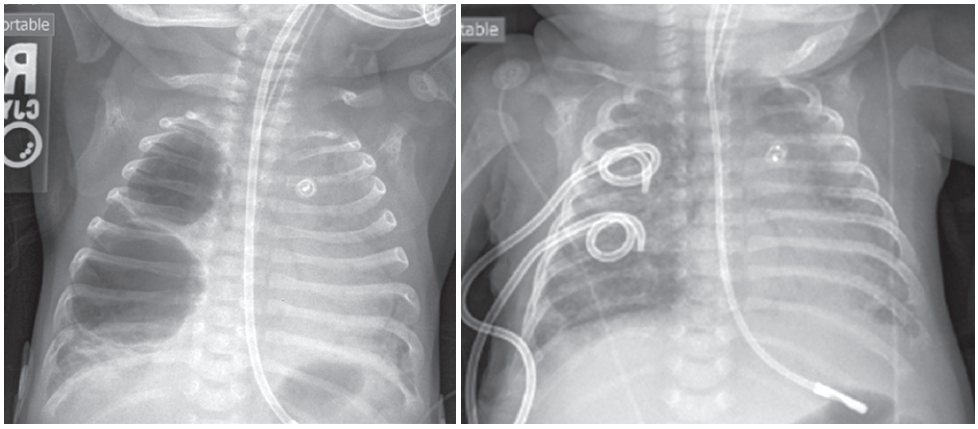

FIGURE 49-7 Chest radiographs from former preterm infant with pneumatoceles secondary to *Staphylococcus aureus* pneumonia. Cysts are compressing lung and causing mediastinal shift (*left*). Placement of draining thoracostomy tubes decompressed the cysts and decreased mediastinal shift, but infant ultimately succumbed to respiratory failure secondary to bronchopulmonary dysplasia.

any potential benefit from the procedure would need to be weighed against the need for thoracotomy (Al-Saleh et al, 2008).

Hyperinflation and Emphysema in Chronic Lung Disease

Similar to postinfectious pneumatoceles, frank cysts or hyperinflated lung in association with chronic lung disease (BPD following prematurity or developmental lung abnormalities) can cause compression on more functional areas of the lung and respiratory compromise (Moylan and Shannon, 1979; Stocker, 2009). In some cases, these infants are acutely decompensated, or they remain ventilator dependent despite maximal medical therapy. Evaluation of six infants with BPD and decompensated lobar hyperinflation in one series revealed extensive lobar bronchomalacia, with almost complete collapse of the affected airway through the expiratory phase or the entire respiratory cycle (Azizkhan et al, 1992). Lobectomy resulted in acute improvement, although ultimately only half of the infants survived.

Miscellaneous Cysts

Lymphatic, lymphangiomatous, mesothelial, and parenchymal cysts can be detected in the thorax, so these lesions may need to be included in the differential diagnosis of cystic lesions (Langston, 2003).

DISORDERS OF THE DIAPHRAGM

CONGENITAL DIAPHRAGMATIC HERNIA

Congenital diaphragmatic hernia (CDH) is a disorder of lung and pulmonary vascular hypoplasia which results from failure of formation of the diaphragm (Areechon and Eid, 1963; Hislop and Reid, 1973; Kitagawa et al, 1971). This may be due to primary deficiency of the embryonic pleuroperitoneal fold, which is one of the critical primordial diaphragmatic structures that must fuse at 6 to 8 weeks' gestation to form an intact diaphragm (Clugston et al, 2006). Failure of this event results in herniation of abdominal contents into the hemithorax, and the subsequent arrest of preacinar airway branching at 10 to 14 weeks' gestation is consistent with this early developmental defect. Hypoplasia is bilateral, although the lung ipsilateral to the hernia is most affected. Airway diameter is substantially decreased, but increase in airway muscle occurs as a later postnatal event (Broughton et al, 1998). Although acinar alveolar counts are normal, overall alveolar hypoplasia is present due to the branching defect ($<10 \times 10^6$ vs. 50×10^6 alveoli at term). Because of the interdependence of lung and vascular growth, both alveolar and capillary surface areas are decreased (Hislop and Reid, 1973; Joshi and Kotecha, 2007; Kitagawa et al, 1971). Vascular branching is impaired, with a decreased diameter of the vessels and increased muscle mass that is inversely related to the degree of lung hypoplasia (Kitagawa et al, 1971; Naeye et al, 1976). Some morphometric reports have demonstrated abnormal distal extension of the muscular media to the intraacinar arteries, whereas others have not demonstrated abnormal distal muscularization (Geggel et al, 1985; Kitagawa et al, 1971). The mechanism of developmental lung and vascular hypoplasia is unknown but may include decreased static transthoracic pressure (secondary to open communication with the peritoneal cavity) and decreased phasic pressure alterations (secondary to impaired fetal breathing movements). Compensatory alveolar growth does occur in survivors, although it is more pronounced in the contralateral lung, and relative perfusion to the ipsilateral lung can be persistently diminished (Okuyama et al, 2006; Thurlbeck et al, 1979; Wohl et al, 1977). These findings are consistent with evidence of greater injury present in the more hypoplastic and vulnerable ipsilateral lung, compared to the contralateral lung in survivors of CDH, with consequent impairment of lung growth (Hislop and Reid, 1973; Thurlbeck et al, 1979; Wohl et al, 1977).

The most common form of CDH is the posterolateral Bochdalek hernia. CDH is more common on the left side (75% to 80% of cases) than the right, likely because of slightly later fusion of the left-sided structures. Bilateral hernias account for 1% to 2% of cases. Morgagni (anterior and medial) hernias are much less frequent in occurrence and usually are not associated with substantial lung hypoplasia, although they may be associated with pericardial, sternal, and abdominal wall defects as part of the pentalogy of Cantrell spectrum. There is a predominance of males to females in CDH (1.4 to 1.6:1 ratio) ,and the occurrence of CDH (including stillbirths) is about 1:4000

births (Gallot et al, 2007; Levison et al, 2006; Yang et al, 2006). Additional anomalies occur in about 40% of affected infants and fetuses (Gallot et al, 2007; Yang et al, 2006). Musculoskeletal (including ribs, vertebrae and digits) and cardiac anomalies are most common, although the patterns of malformation differ in association with right-sided CDH compared to left-sided CDH (Slavotinek et al, 2007). CDH can be associated with aneuploidy (most frequently trisomy 18), and it can present in autosomal recessive (e.g., Fryns syndrome), sex-linked (e.g., Simpson-Golabi-Behmel syndrome) and autosomal dominant (e.g., Cornelia De Lange syndrome) disorders (Slavotinek 2007; Slavotinek, Warmerdam et al, 2007). With the exception of these disorders, recurrence rate is quoted at 1% to 2%, and more recent genetic studies have identified microdeletions in affected infants through use of microarray technology (Kantarci et al, 2006; Slavotinek, 2005). It is unclear whether or not infants with isolated CDH (no other anomalies found by antenatal and postnatal investigation) are at increased risk for these minor chromosomal aberrations, because large-scale investigations have taken place with very limited positive findings. Single gene mutations have been identified in animal models and some humans as causal in CDH, and certain areas of the genome may be critical regions wherein other causal genes might be found (Ackerman and Pober, 2007; Clugston et al, 2006).

In recent population-based studies, overall survival among live-born affected infants ranged from 52% to 61% (Colvin et al, 2005; Gallot et al, 2007; Stege et al, 2003; Yang et al, 2006). Data from the California Birth Defects Monitoring Program (1989–1997) demonstrated improved survival over time (Levison et al, 2006), with overall survival in 1997 up to 72% (Yang et al, 2006). Data from France (1986–2003) also showed modest improvements in survival over time, although other population-based studies have shown no change over a similar era (1991–2001) (Gallot et al, 2007; Stege et al, 2003). Survival of live-born infants with isolated (no additional anomalies) CDH has been higher (63% to 77%) than survival in live-born infants with other anomalies or chromosomal aberrations (19% to 43%) (Gallot et al, 2007; Stege et al, 2003; Yang et al, 2006). Survival is low (<10%) in affected infants with chromosomal abnormalities, and there is a risk of intrauterine fetal demise in both isolated (2%) and non-isolated (11%) CDH. Although individual referral centers have reported survival rates ranging from 75% to 93% (Bohn, 2002; Boloker et al, 2002; Downard and Wilson, 2003), there have been studies documenting a hidden mortality, demonstrating that a proportion of live-born infants die within hours of birth and before arrival at a surgical center (Harrison et al, 1994; Mah et al, 2009). In a recent study from Ontario, Canada, survival decreased from 67% to 58% (133 of 229) for multicenter compared to population-based data, after accounting for infants who never reached a referral center (Mah et al, 2009).

Both population-based and center-based studies have identified some risk factors for mortality for live-born infants undergoing full resuscitative measures and ongoing neonatal care. All of these likely are related to the severity of the CDH, with respect to the degree of lung and vascular hypoplasia. For instance, prenatal diagnosis has been associated with increased mortality and may be due to the identification of more severe CDH (because mediastinal shift will be more pronounced and present earlier in gestation; see later discussion) (Colvin et al, 2005; Gallot et al, 2007; Stege et al, 2003; Stevens et al, 2009). A low 5-minute Apgar score has also been associated with decreased survival in population-based and multicenter studies and may reflect initial cardiorespiratory compromise due to severity of lung hypoplasia (Colvin et al, 2005; Congenital Diaphragmatic Study Group, 2001; Levison et al, 2006; Wilson et al, 1997). Other postnatal factors that are associated with increased mortality include prematurity (<37 weeks) and air leak (Boloker et al, 2002; Colvin et al, 2005; Levison et al, 2006), which are associations with decreased lung development or increased lung injury. Interestingly, two studies have shown somewhat conflicting data around the timing of term delivery and survival. For infants receiving extracorporeal membrane oxygenation (ECMO) support, late term (40 to 41 weeks' gestation) infants had somewhat better survival compared to early term (38 to 39 weeks' gestation) infants, although the relationship was not statistically significant, and fewer ECMO-related complications were seen in the late-term group (Stevens, 2002). However, overall survival was slightly better for early term (37 to 38 weeks' gestation) versus late term (39 to 41 weeks' gestation) in another study that included infants not receiving ECMO support (Stevens et al, 2009). Other data show that infants not born at a tertiary center (outborn), but subsequently transferred to the tertiary center, have higher survival rates than those that are born at a tertiary center (inborn), which may reflect the hidden mortality associated with more severe CDH (Boloker et al, 2002; Levison et al, 2006). For those infants who do undergo surgical repair, the need for a prosthetic patch is associated with subsequent mortality, indicating a larger diaphragmatic defect and likely more severe lung hypoplasia (Bryner et al, 2009; Lally et al, 2006; Wilson et al, 1997).

Prenatal Diagnosis and Management

CDH is usually suspected on prenatal ultrasound when mediastinal shift away from the hernia side is appreciated. Prenatal detection rates are higher with left-sided than right-sided hernias, and bilateral hernias can be difficult to discern because of the distorted anatomy. CDH in fetuses with additional anomalies are also detected at a higher rate than CDH in isolated cases (Gallot et al, 2007). Fetal MRI can be helpful in determining the diagnosis, if the anatomy is difficult to identify. A prenatal diagnosis of CDH mandates careful evaluation for other anomalies, including a fetal echocardiogram, because of the high rate of additional anomalies and the lower survival rates. Some of this evaluation may be limited by the anatomic distortion due to the hernia. A karyotype and other genetic analysis (as indicated) are also recommended. Additional prognostic information regarding the severity of the hernia can be gathered during antenatal evaluation by ultrasound and MRI, although the prognostic ability of these measures is likely center dependent, as survival varies to some extent across centers. The most useful discriminator of CDH severity is herniation of the liver into the hemithorax (Jani et al, 2006; Metkus et al, 1996). Liver herniation can occur with both right-sided and left-sided CDH. In left CDH,

the left lobe of the liver develops in the thorax. Thus, the course of the hepatic vasculature is distorted and indicative of liver herniation. Bowel-only right-sided hernias are very uncommon. Other antenatal discriminators of severity that have been used include stomach herniation and polyhydramnios (a later finding, secondary to GI obstruction or esophageal dysmotility). A number of ultrasound measures have been developed as intrauterine measures of lung size (Keller, 2007). The lung-to-head ratio (LHR) is widely used for this purpose (Metkus et al, 1996). It is the perpendicular area of the lung contralateral to the hernia at the level of the cardiac atria divided by the biparietal diameter. It has been used predominantly in mid-gestation (22 to 27 weeks), with an LHR ≤1.0 combined with liver herniation accepted as the most severe group of CDH. LHR has been studied in left CDH, although it has also been extrapolated to right CDH and likely has prognostic ability, although LHR thresholds for severity could be lower in right CDH since the normal right lung is larger than the left lung (Hedrick et al, 2004; Peralta et al, 2005). Investigators have developed nomograms for normal LHR over 12 to 32 weeks, which has led to an observed-to-expected (O/E) LHR measurement, employing the mean LHR at any gestational age as the "expected LHR," which increases with advancing gestational age because of a more rapid increase in lung area compared to head circumference (Peralta et al, 2005). It follows that the LHR ≤1.0 will represent a higher O/E LHR earlier in gestation than it does later in gestation and the O/E LHR will be higher with right CDH than left CDH for a given LHR and gestational age (Jani et al, 2009). In a large database of 354 fetuses with isolated CDH (including 25 fetuses with right CDH), the O/E LHR was predictive of survival independent of liver herniation (Jani et al, 2007). Subsequent analyses of this data have stratified fetuses with and without liver herniation, because survival does differ between these groups for a given O/E LHR range (Deprest et al, 2009). In these analyses, survival was <20% for fetuses with isolated left CDH and O/E LHR ≤25%. Fetuses with a higher O/E LHR of 26% to 35% survived in greater numbers: 30% if liver was herniated and almost 60% if liver was not herniated. The lower bound of the 95% confidence interval for O/E LHR in unaffected fetuses is 60% (Jani et al, 2007). Decreasing O/E LHR was also related to increasing time on assisted ventilation, prolonged hospitalization and an increased risk for prosthetic patch repair (Jani et al, 2009).

Fetal MRI techniques have also been pursued for prognostic information in CDH. Liver herniation can be determined by fetal MRI, and at some centers it is the preferred technique for this determination. A number of different nomograms to determine lung volume as a percent of normal (based on estimated fetal size or gestational age) have been developed. Recently, Büsing et al (2008) evaluated seven published nomograms for estimation of relative fetal lung volume in 68 fetuses with isolated left CDH evaluated at their center. They generated receiver operating characteristic curves for each of the seven equations and found high (0.800 to 0.900) area under the curve (AUC) for prediction of survival, regardless of technique used. In this dataset, prediction of need for ECMO was not as strong (AUC 0.653 to 0.739), although individual centers have found that relative fetal lung volume is a very useful predictor of the need for subsequent ECMO support (Barnewolt et al, 2007).

Fetal intervention to enhance intrauterine lung growth has evolved to the current technique of endoscopic temporary balloon tracheal occlusion. Only fetuses likely to be the most severely affected newborns are candidates, if additional anomalies are not found after careful investigation. A randomized controlled trial evaluating this technique was terminated prematurely because of unexpectedly high survival in the control group, with no difference in survival between tracheal occlusion and standard care infants (Harrison et al, 2003). The tracheal occlusion procedure was complicated by premature delivery (mean gestational age 30.8 weeks), often stemming from premature rupture of the membranes, and this may have compromised survival in the intervention group. With development of smaller instruments, this technique can now be accomplished as a fully endoscopic procedure (Jani et al, 2009). Incorporation of a second procedure to remove the intratracheal balloon (i.e., plug-unplug) has also decreased the need for delivery by EXIT procedure, allowing for vaginal delivery in the majority of cases, if otherwise indicated. This technique has been accomplished for fetuses with LHR ≤1.0, in an uncontrolled experience in Europe, although the survival rate is promising compared to fetuses that did not undergo intervention with similar prognostic features. At last report, 210 cases were accomplished at 23 to 33 weeks' gestation. Median gestational age at delivery utilizing this technique has increased to 35 weeks, although premature rupture of the membranes occurred in almost half of the affected pregnancies. With operator experience, the procedure has been accomplished more rapidly, and shorter procedures were associated with lower rates of premature membrane rupture. Elective prenatal removal of the intratracheal balloon (i.e., unplug) was accomplished at a median of 34 weeks in 70% of the cases. Survival to neonatal discharge was 47% (98 of 210); 6 deaths were fetal and 10 deaths occurred secondary to difficulty with removal of the intratracheal balloon. From their historical experience, the investigators cite an expected survival of only 24%. In a subset of these fetuses, and some expectantly managed with CDH, Cannie et al (2009) evaluated changes in relative lung volume over gestation by fetal MR. They found that relative lung volume was largely unchanged in fetuses without intervention, and it tended to increase more consistently in fetuses with CDH when tracheal occlusion was undertaken at ≥29 weeks' gestation (n=8). There are several ongoing nonrandomized trials of this minimally invasive technique in the United States. In Europe, investigators are currently undertaking a randomized trial of the technique for fetuses with moderate lung hypoplasia (O/E LHR 25% to 34.9% or 35% to 44.9% with liver herniation) and plan to undertake tracheal occlusion at 30 to 32 weeks' gestation (trial registration number: NCT00763737).

Postnatal Diagnosis and Management

Most newborns with CDH will present immediately or within several hours of birth with respiratory distress, cyanosis, decreased or bronchial breath sounds on the hernia side, and a scaphoid abdomen. An occasional infant will

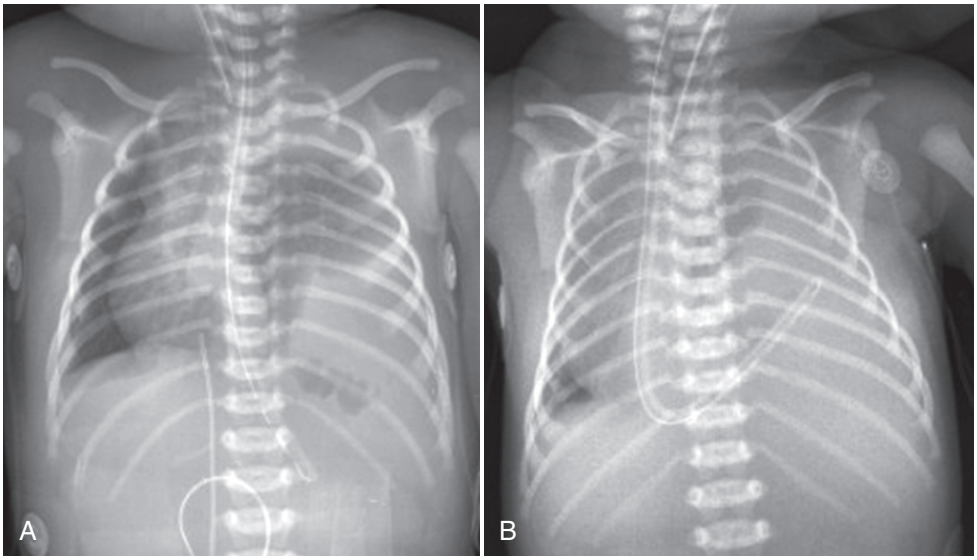

FIGURE 49-8 Chest radiographs in two infants with left congenital diaphragmatic hernia before surgical repair. A, Infant has CDH without liver herniated or stomach herniated into thorax. He subsequently underwent primary repair of the diaphragmatic defect, was extubated within several days of surgery, and was discharged to home without supplemental oxygen. **B,** Infant has severe CDH with liver and stomach herniated into thorax. He subsequently required ECMO support, underwent prosthetic patch repair for diaphragmatic aplasia, and succumbed to respiratory failure and pulmonary hypertension after decannulation from ECMO support.

not have symptoms until several days or months of age and often will have feeding intolerance and mild respiratory distress (Kitano et al, 2005). An initial chest radiograph will show a smaller lung on the hernia side, with bowel gas in the chest and shift of mediastinal structures (Figures 49-8 and 49-9). The findings of a small lung, with no mediastinal shift and usually without concern for herniated bowel, should raise suspicion for other diagnoses, which may require an alternate surgical approach or may not require surgery at all (see later discussion). Newborns with a fetal diagnosis of CDH or those presenting soon after birth are usually endotracheally intubated with a Replogle placed to continuous gastric suction to minimize accumulation of thoracic intraintestinal air. Some centers also routinely use pharmacologic paralysis until surgical repair of the diaphragmatic defect is accomplished and the hernia contents are reduced. Other centers use paralysis only in the most severe cases. Hypoplastic lungs with small alveoli have poor compliance, and thus ventilation is severely reduced (Keller, 2007). Because of the decreased alveolar surface area for gas exchange and the restrictive pulmonary vascular bed, oxygenation is severely impaired. Because these physiologic challenges cannot be overcome without lung growth, most high-volume centers use a gentle ventilation strategy. This strategy attempts to achieve adequate oxygen delivery while minimizing oxygen toxicity and ventilator-induced lung injury and preserving the potential for lung growth. Actual targets for ventilation and oxygenation vary somewhat, but consistency in care within a center is important (Logan et al, 2007). Ventilation target is often Pco_2 45 to 65 mm Hg (permissive hypercapnia). For oxygenation, a more liberal strategy allows for a preductal (right upper extremity) and postductal (descending aorta or lower extremity) arterial saturation (Sao_2) differential, with oxygenation targets based on preductal Sao_2 (permissive oxygenation). Oxygenation targets are generally preductal Sao_2 ≥95% in less severely affected infants and Sao_2 ≥85% in more severely affected infants. Ventilator pressures are limited, with either positive inspiratory pressure (PIP) targeted at ≤25 to 28 cm H_2O or mean airway pressure (Paw) on high-frequency ventilation at ≤15 cm H_2O. Aggressive weaning strategies are used to achieve gentle ventilation goals and to minimize lung injury. Lung recruitment is not an effective strategy to achieve persistent improvements in oxygenation in CDH (Kinsella et al, 1997), and increases in PIP to achieve transient improvements in oxygenation lead to further increases in ventilator support, with worsening compliance due to lung injury and edema (Kays et al, 1999). There are also some centers that advocate low PEEP and high ventilator rates (which are physiologic in lung hypoplasia). With high ventilator rates, gas trapping and auto-PEEP may be an important factor, so limitation of the PEEP set on the ventilator is important (Boloker et al, 2002). In addition, low PEEP (2 to 3 cm H_2O) is associated with higher lung compliance in infants with CDH than PEEP of 4 to 6 cm H_2O (Dinger et al, 2000).

Employment of gentle ventilation strategies has been associated with improved survival at individual centers (Kays et al, 1999; Wilson et al, 1997); however, regardless of actual targets for ventilation and oxygenation and preferential mode of ventilation, it is likely that other aspects of care, such as infant stimulation and positioning and sedation and feeding practices, affect survival and other outcomes. Although there are a number of ancillary treatments employed in infants with CDH (antenatal glucocorticoids, surfactant replacement therapy, inhaled nitric oxide, and other pulmonary vasodilator therapies), there are no studies documenting broad efficacy of these treatments in term infants with CDH. Some have advocated the primary use of high-frequency ventilation in these infants, but there is no evidence of benefit to survival or other

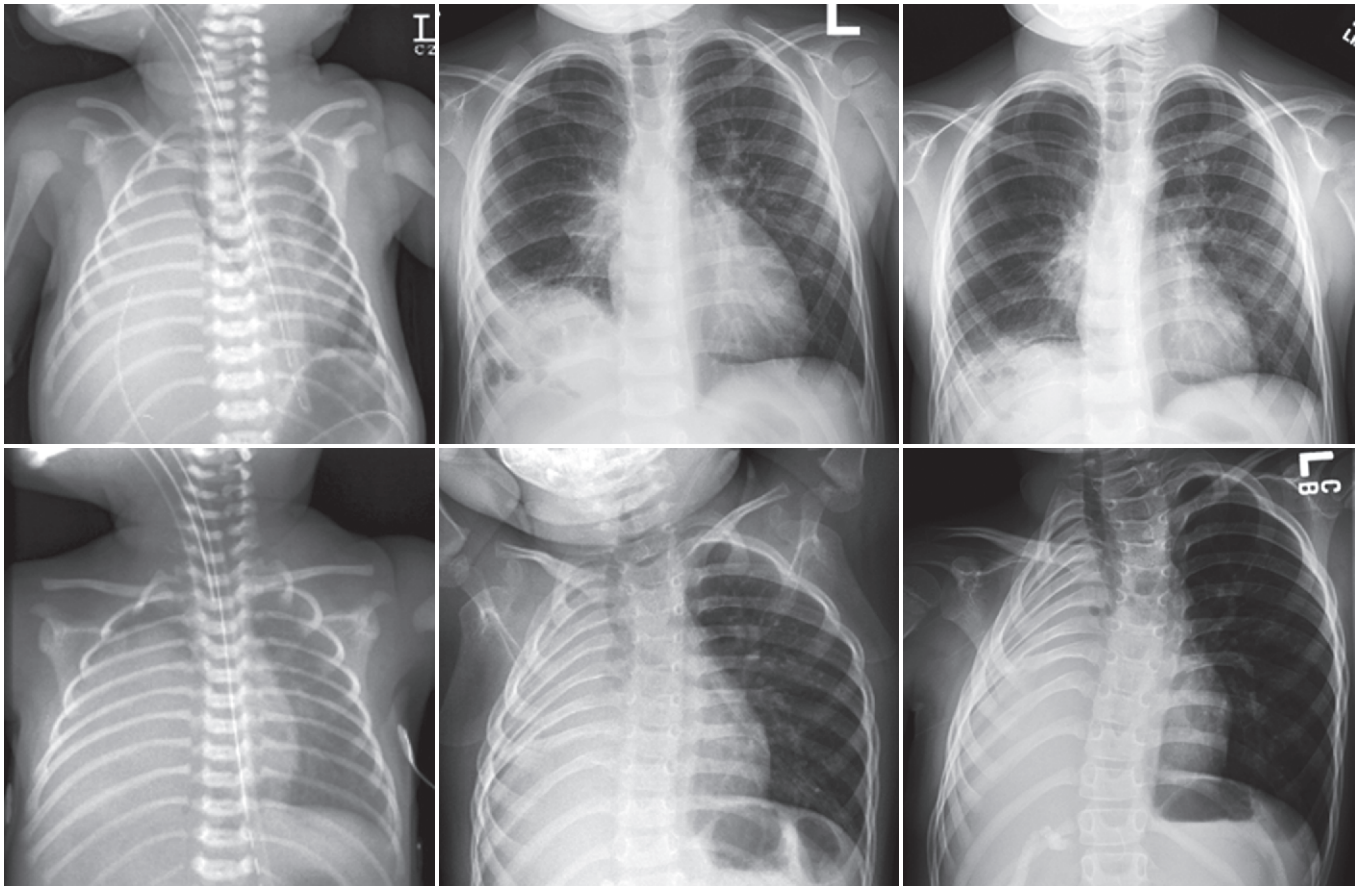

FIGURE 49-9 Chest radiographs in two infants with respiratory distress at admission to the intensive care nursery, and at 3 and 5 years of age (*left to right*). *Upper panel* shows infant with right congenital diaphragmatic hernia with liver herniated into thorax and diaphragmatic aplasia. Note mediastinal shift into left hemithorax, with subsequent improvement in aeration and then normalization of right lung volume. *Lower panel* shows infant with hepatopulmonary fusion. Surgical repair required resection of hypoplastic nubbin of lung. Note lack of mediastinal shift at presentation, compensatory growth of left lung with trachea deviated to the right, and scoliosis.

outcomes based on the mechanical ventilation technique alone (when similar permissive targets are used), although a clinical trial to study this question has been proposed in Europe (trial registration number: NTR1310). In addition, the use of prostaglandin infusion to maintain ductal patency and improve right heart function in cases of prolonged pulmonary hypertension has been advocated (Bohn, 2002). The one ancillary treatment that has shown benefit is the use of extracorporeal membrane oxygenation (ECMO), which improved survival to hospital discharge in the United Kingdom Collaborative study, although the effect dissipated at follow-up with later deaths among initial survivors (Mugford et al, 2008).

ECMO can be used to rescue newborns with CDH, particularly those with lung injury evident by pneumothorax (Sebald et al, 2004), and it may be used in the setting of gentle ventilation (where pneumothorax is a less frequent occurrence), to avoid prolonged high ventilator pressures or Fio_2. Although CDH has become the most common indication for neonatal respiratory ECMO, survival to discharge for these infants in 2003 declined to 40% (Rais-Bahrami, 2005). Because ECMO is a temporary therapy designed to allow for resolution of a reversible process, it is unlikely that all infants with CDH will benefit from ECMO support; some will have lethal pulmonary hypoplasia (Antunes et al, 1995). Thibeault and Haney described persistent pulmonary hypertensive changes in vessels of infants with CDH dying after ECMO support, and others have described recurrent pulmonary hypertension (Payne et al, 1991; Thibeault and Haney, 1998). However, there is a challenge in determining which infants are very unlikely to benefit from ECMO. In our center, the University of California San Francisco (UCSF) Children's Hospital, there is an active inborn service for fetuses with antenatal diagnoses of anomalies such as CDH. Since 1991, no infants with CDH have survived to discharge and remained on ECMO support for >9 days (Table 49-3), despite an overall ECMO survival for infants with CDH that is similar to international data (Rais-Bahrami, 2005). More recently, in infants with CDH, the primary inclusion criterion for ECMO support has been imminent or actual inadequate oxygen delivery (persistent preductal $Sao_2 \leq$ low 80s or worsening metabolic acidosis) within gentle ventilation parameters. Families of infants with severe CDH are given the option to not pursue ECMO support, and ECMO is rarely offered late in the clinical course for infants who have never been weaned from mechanical ventilation. From 2003–2009 (since the full complement of care practices with gentle ventilation and pressure limitation have been formally implemented in our

TABLE 49-3 Infant Survival to Hospital Discharge by Duration of ECMO Support: 1991–2009*

ECMO Duration (days)	2003–2009 (n = 10)	1991–2002 (n = 33)	Survival (%)
1	0	0/2	0/2 (0)
2	0	0/1	0/1 (0)
3	0	2/2	2/2 (100)
4	0/1	1/1	1/2 (50)
5	0/1	5/6	5/7 (71)
6	1/1	5/6	6/7 (86)
7	0	1/1	1/1 (100)
8	1/1	1/2	2/3 (66)
9	0	2/2	2/2 (100)
10–14	0/4	0/8	0/12 (0)
15–23	0/2	0/2	0/4 (0)
Total	2/10 (20)	17/33 (52)	19/43 (44)

*Overall survival from 2003 to 2009 was 78/104 (75%), compared to 2/10 (20%) with ECMO support.

patients), utilization of ECMO support for CDH has been low (10%) in our center, and only 20% (2 of 10) of infants survived with ECMO, all with a duration of ECMO ≤8 days (no infant had pneumothorax). In contrast, survival to discharge during this period for all infants with Bochdalek hernias who had a full attempt of resuscitation and ongoing care (regardless of whether or not there were associated anomalies) was 78 of 104 (75%). Findings from the United Kingdom are consistent with our experience with prolonged ECMO support. The two independent predictors of mortality among infants with CDH were duration of ECMO support >2 weeks and use of renal replacement therapy for renal insufficiency. Survival among both of these groups was approximately 20% (2 of 11 for prolonged ECMO and 4 of 18 for renal insufficiency) (Tiruvoipati et al, 2007). Longer ECMO runs, renal complications, and multiple complications were also independently associated with mortality in infants with CDH in an analysis from the Extracorporeal Life Support Organization (ELSO) database (Stevens et al, 2002). Thus, failure to decannulate an infant at <10 to 14 days of support is likely an indicator of severe lung and vascular hypoplasia. In these severely affected infants, it often takes longer than 4 weeks to resolve pulmonary hypertension (Dillon et al, 2004; Keller et al, 2006), and therefore awaiting resolution of pulmonary hypertension in these cases before decannulation would require prolonged ECMO support. Prolonged ECMO runs are prone to mechanical complications, which may further prolong the ECMO run or be irrecoverable. Thus, it is unclear to what degree prolonging ECMO support could increase survival in CDH, unless there is still evidence of reversibility in the infant's condition. In the case of availability of a specific therapy, such as perfluorocarbon partial liquid ventilation, wherein lung growth might be induced, the benefits of continuing ECMO support might become evident (Hirschl et al, 2003). Although there has been difficulty obtaining this drug in the United States, a larger randomized trial in infants with CDH requiring ECMO support could be indicated. Otherwise, strategies to limit the duration of ECMO support in CDH could be employed, accepting ventilator settings at decannulation that are significantly higher than what might otherwise be acceptable for newborns coming off ECMO support. These strategies could include prevention of complete lung collapse with aggressive pulmonary toilet, because re-recruitment of lung volume can be difficult in these infants (which may be related to small-caliber airways that have been damaged by pre-ECMO support regimens). Also, for infants cannulated prerepair, performance of the CDH repair post-ECMO decannulation could further limit time on ECMO support. Surgical repair of the diaphragmatic defect while on ECMO is associated with higher mortality, even after adjusting for other markers of CDH severity (Bryner et al, 2009). This phenomenon may be related to hematologic complications related to the repair (which are independently associated with decreased survival) (Stevens et al, 2002). However, some centers advocate CDH repair as soon as possible after stabilization on ECMO support (Bryner et al, 2009). In addition, some centers utilize an "EXIT-to-ECMO" approach for fetuses with high risk criteria based on fetal evaluation (low relative lung volume) (Kunisaki et al, 2007). These fetuses are intubated and ventilated during an EXIT procedure. If they meet certain criteria for adequate gas exchange, they are delivered for conventional management. If they do not meet these criteria, they are cannulated and placed on ECMO support. Using this strategy, Kunisaki et al reported a 71% (10 of 14) survival with 11 infants going directly to ECMO support and 7 of 11 surviving. Most infants required prolonged mechanical ventilation and hospitalization.

Repair of the diaphragmatic defect usually occurs after some degree of stabilization of cardiopulmonary status, either with conventional therapy or ECMO support. Two small studies randomizing infants to immediate (<24 hours of age) versus delayed surgery have showed no difference in survival (Moyer et al, 2002). However, Nakayama et al (1991) demonstrated that lung compliance improves before surgery after a short period (several days) of stabilization in infants with CDH, and Sakai et al (1987) demonstrated that compliance worsens with early surgery in almost all infants. We studied infants with severe CDH (liver herniation and LHR <1.4) and found that, although compliance did not improve before surgery after a period of stabilization, compliance did improve within 24 hours after surgery (Keller et al, 2004). Thus, the rationale for delayed surgery is sound with respect to lung function. Some centers advocate very delayed surgery, while awaiting complete resolution of pulmonary hypertension (Wung et al, 1995). However, this approach can be problematic, because pulmonary hypertension may require weeks for resolution (Dillon et al, 2004; Keller et al, 2010). Subsequent failure to reduce the hernia contents is likely to delay establishment of enteral nutrition, with a consequent increased risk of infection and complications from parenteral nutrition. The achievement of even modest reduction in Fio_2 before surgery allows for a transient increase, if needed, after surgery, and even in cases where Fio_2 remains high, the modest improvement in lung function that occurs with surgery may help with

further recovery for the infant in the most severe cases. Another issue with respect to timing of surgery arises when an infant also has congenital heart disease that requires neonatal surgery. Most centers will undertake CDH repair and then proceed to the cardiac surgery once the infant meets reasonable hemodynamic criteria for the surgical intervention (Cohen et al, 2002). In newborns who might require urgent cardiac surgery, survival is unlikely except if the lung hypoplasia is very mild. In a large series of 280 infants with CDH and congenital heart disease, overall survival was 41%, but only 5% for infants with single ventricle physiology and 18% (2 of 11) for infants with TAPVR (Graziano, 2005).

Surgical repair of CDH involves reduction of the hernia contents and closure of the diaphragmatic defect. The surgical approach is usually via laparotomy, to abrogate the detrimental effect of thoracotomy on lung function. Some surgeons will preferentially do a thoracotomy for a right CDH repair. For selected patients, thoracoscopic repair of the diaphragmatic defect is becoming more common (Kim et al, 2009; Yang et al, 2005). Infants who have achieved low ventilator settings and Fio_2 before surgery are likely candidates for this approach, because operative instability or the need for prosthetic patch repair of the diaphragm can result in conversion to an open procedure. A prosthetic patch is placed when a diaphragmatic defect cannot be closed primarily. There is significant variability among surgeons in the need for patch repair, however. Clinical series have demonstrated that it is more common in the case of liver herniation and right CDH (which may also be an association with herniated liver) (Fisher et al, 2008; Kunisaki et al, 2008). Patch repair can be accomplished with use of a polytetrafluoroethylene (PTFE, Gore-Tex) or a bioabsorbable intestinal mucosa (SurgiSIS) material. Polypropylene (Marlex) and other materials have been used sporadically (Riehle et al, 2007). Use of an abdominal silo and/or prosthesis to close the abdominal wall is sometimes necessary and may decrease the need for a prosthetic diaphragm (Bryner et al, 2009; Rana et al, 2008). Some surgeons advocate construction of a latissimus dorsi flap for initial CDH repair when primary closure of the diaphragmatic defect cannot be accomplished (Barbosa et al, 2008). This technique allows for some potential for diaphragmatic function in the innervated flap, which usually remains abnormal at late follow-up even with primary repair (Arena et al, 2005). However, the technique is time-consuming and may not be tolerated in patients during the acute neonatal period, so others have reserved this technique only for hernia recurrence (Sydorak et al, 2003). Generally, use of a prosthetic patch for diaphragmatic closure is associated with increased risk of hernia recurrence, although the actual risk varies widely and may be dependent on multiple factors, including surgical technique (Jancelewicz et al, 2010). Recurrent herniation may be associated with small bowel obstruction. It is also associated with persistent chest wall deformity, which might be due to the severity of the underlying disease or the complication of reherniation (requiring multiple surgical procedures). Some surgeons have moved toward use of composite patches (more than one material), which may decrease the risk of recurrence by allowing for both durability and accommodation of rapid growth in infancy (Jancelewicz et al, 2010; Riehle et al, 2007). Another area of variable practice is related to the intraoperative placement of a thoracostomy tube. Some of this controversy is related to the application of negative pressure, because that creates additional transpulmonary pressure and potential for barotrauma and lowers lung compliance (Dinger et al, 2000). However, negative pressure drainage is not necessary. Because the ipsilateral thorax will fill with fluid after reduction of the hernia contents as a result of the hypoplastic lung, placement of an anterior thoracostomy tube in a supine infant will prevent the accumulation of excess pleural fluid (which can occur with chylothorax). Chylous pleural effusion will cause respiratory compromise. However, it may be difficult to ascertain the cause of this deterioration because mediastinal structures remain shifted for some period of time postoperatively and may be modestly more exaggerated with tension hydrothorax. Chylothorax is not uncommon after CDH repair. In a recent series, it occurred in 7% of infants (10 of 152), and it was more common in infants who required prosthetic patch repair (8 of 10) (Gonzalez et al, 2009). Both surgical trauma and underlying hemodynamics due to right heart failure may contribute to the etiology of this problem in infants with CDH (see Chylothorax earlier, for diagnosis and management).

Long-Term Morbidity

Survivors of CDH have substantial pulmonary and gastrointestinal morbidity at follow-up (Muratore et al, 2001a, 2001b). Gastroesophageal reflux, failure to thrive, and need for tube feedings are common. Although low lung volumes and restrictive lung disease may be seen in the first months of life, obstructive lung disease is the most common finding in early childhood and at later follow-up (Koumbourlis et al, 2006; Vanamo et al, 1996). Children requiring prosthetic patch repair and prolonged mechanical ventilation are most likely to have later morbidity, but the relative contribution of anatomic abnormalities, physiologic derangements, and secondary injury to these outcomes is unknown. Developmental delay and hearing loss also occur and require careful follow-up for early identification and intervention (Cortes et al, 2005; Friedman et al, 2008; Jaillard et al, 2003; Keller et al, 2008).

Hepatopulmonary Fusion

Hepatopulmonary fusion likely represents a severe form of CDH. It has been described variably in the literature as both CDH and severe eventration (Keller et al, 2003; Rais-Bahrami et al, 1996; Robertson et al, 2006). All reported cases have occurred on the right side, although there is a report of a late-presenting left CDH with fusion of liver and lung tissue (Baeza-Herrera et al, 2000). It is not clear if this is the same entity that other authors have described, because these infants usually present in extremis, with respiratory failure and pulmonary hypertension (Keller et al, 2003; Rais-Bahrami et al, 1996; Robertson et al, 2006). The embryology of this defect is speculative, and the distinction between severe CDH versus eventration is probably not critical. However, the diaphragm is not intact, it is usually moderately to severely hypoplastic, and there

is fusion of hepatic and pulmonary tissue without pleura or liver capsule present, no dissectable plane, and a fibrous membrane adherent to the liver and the lung (Slovis et al, 2000). In cases where hepatopulmonary fusion is determined or suspected, there is a lack of mediastinal shift, consistent with severe right lung hypoplasia rather than a mass effect from a large right CDH with herniated liver (Keller et al, 2003; Slovis et al, 2000). The suspicion of this diagnosis is important, because the surgical approach may differ. The need to separate the liver and the lung (usually requiring ligation or resection of part of the hypoplastic lung due to risk of air leak and hemorrhage) will require a thoracotomy. We have utilized contrast MR imaging preoperatively to help make this distinction and found enhanced lung tissue adherent and conforming to the dome of the liver in a case of hepatopulmonary fusion, suggestive of the anatomy subsequently encountered at the time of surgical repair (Keller et al, 2003). The goal of surgery is to separate the thoracic and abdominal cavities, often requiring placement of a prosthetic patch. In our experience, if these children survive, later growth of the right lung is much more restricted than it is in children with severe right CDH (see Figure 49-9). Whether this is due to more pronounced ipsilateral lung hypoplasia, less pronounced contralateral lung hypoplasia, or the need for resection at the time of surgical repair is unclear. However, chest wall deformity and scoliosis are significant problems in these children.

CONGENITAL EVENTRATION OF THE DIAPHRAGM

Congenital eventration of the diaphragm occurs when the hemidiaphragm is partially or completely nonmuscular. The intact diaphragm is elevated with a normal insertion. Thus, intraabdominal organs are present in the thorax, but still confined below the diaphragm. The right and left hemidiaphragms are equally affected, and 13% (6 of 48) of affected infants had bilateral eventration in an early series (Tsugawa et al, 1997; Wayne et al, 1974). With diaphragmatic eventration, movement of the hemidiaphragm is paradoxical, leading to respiratory distress, atelectasis, and recurrent pulmonary infections. Infants presenting later may have gastrointestinal symptoms. Surgical intervention involves plication of the diaphragm to eliminate the paradoxical movement. Results are generally good, with severe lung hypoplasia uncommon and improvement in symptoms without recurrence. However, infants with associated conditions, particularly neuromuscular disorders, may not survive. Some surgeons advocate plication even when symptoms are not present, to preserve potential for lung growth (Tsugawa et al, 1997).

DIAPHRAGMATIC PARESIS

Phrenic nerve injury due to birth trauma or surgical trauma can result in temporary paresis of the diaphragm, with an elevated hemidiaphragm and paradoxical movement evident by ultrasound or fluoroscopy. If infants are persistently symptomatic, diaphragmatic plication may allow for weaning from mechanical ventilation or lesser levels of respiratory support, but these injuries should also recover on their own over time (Tsugawa et al, 1997; Wayne et al, 1974).

NEONATAL SCIMITAR SYNDROME

Scimitar syndrome consists of three findings of right lung hypoplasia, partial anomalous pulmonary venous return, and unilateral pulmonary sequestration. These features may not all be present, and additional cardiac anomalies may also be detected. Scimitar syndrome can be suspected on fetal ultrasound, because of findings of cardiac dextroposition with a small right pulmonary artery (Abdullah et al, 2000). The presentation of scimitar syndrome in the first days of life is usually severe, with tachypnea and pulmonary hypertension (Gao et al, 1993; Huddleston et al, 1999). Some infants will present later with failure to thrive. Chest radiograph reveals an elevated right hemidiaphragm with the mediastinum shifted to the right, consistent with primary lung hypoplasia. The classic finding of the scimitar vein is often not appreciated. The associated cardiac anomalies include left-sided obstructive lesions and atrial and ventricular septal defects. Because these infants have a normally developed diaphragm, the surgical approach will depend on hemodynamic effects of the anomalous venous return and the sequestration (if present). Thus, careful hemodynamic and vascular assessment is critical and may be accomplished through cardiac catheterization and angiography or, in some cases, by MR angiography. Some infants will undergo pneumonectomy, others ligation or coil embolization of systemic feeding vessels, and others no intervention because the hypoplastic lung may have very little blood flow. Pulmonary vein stenosis can also complicate the hemodynamic status, and medical or surgical treatment for additional cardiac lesions may need to be addressed.

PART XI

Cardiovascular System

CHAPTER 50

Embryology and Physiology of the Cardiovascular System

H. Scott Baldwin and Ellen Dees

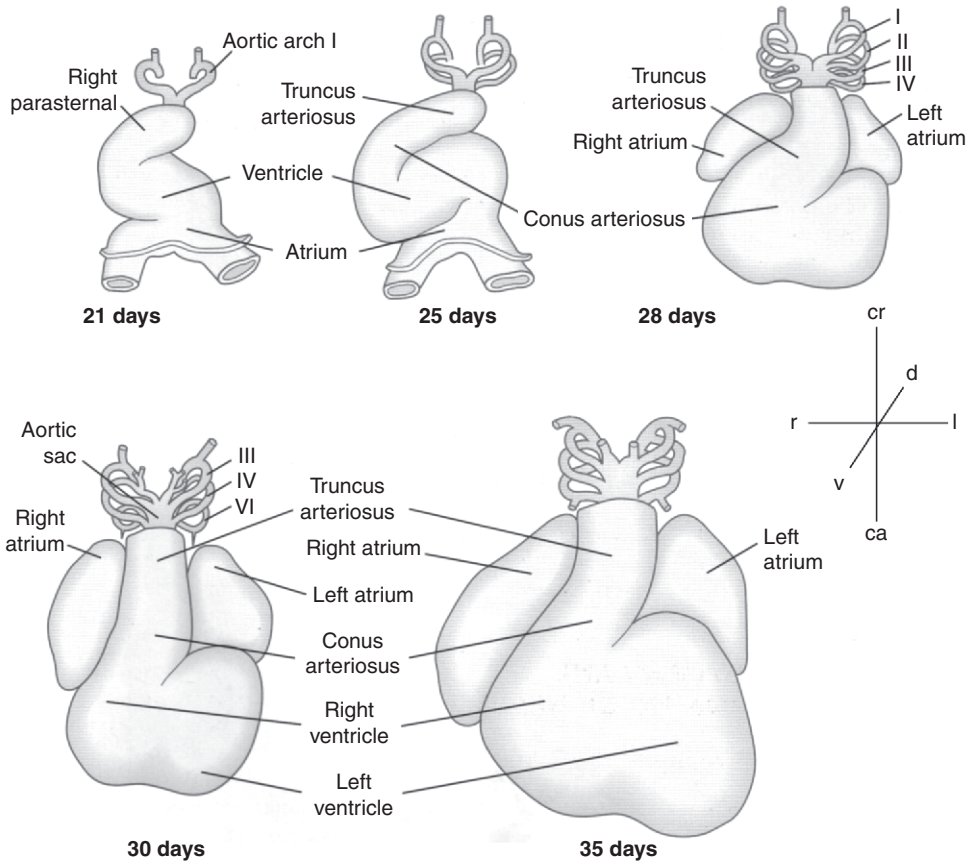
This chapter begins with a review of cardiac anatomy and of the cell types that make up the heart, and then discusses in detail the morphology and physiology of the developing heart. Although we mention certain genes that are important in cardiac development, this is not a comprehensive review of the genetic regulation of heart development, because several reviews have recently become available (Bruneau, 2008; Moon, 2008). Rather, we focus on aspects of heart development of particular interest to clinical neonatologists. These include the creation of inflow and outflow poles of the heart, alignment of these structures with the cardiac chambers, septation of the cardiac chambers, and the physiology of blood flow in the embryo, fetus, and newborn.

The heart begins as a field of cells that move ventrally and midline within the embryo, fusing into a tube. This primitive heart tube is formed in the human embryo by 3 weeks gestation (Figure 50-1, 21 days). At the posterior (dorsal) end of the tube is the venous pole, or sinus venosus. In mammals, this includes connections to the yolk sac (vitelline veins), placenta (umbilical veins), and embryo proper (cardinal veins). At the anterior (ventral) end of the tube is the arterial pole, or bulbus cordis, which will pass flow from the heart tube back into the body. In the primitive heart, this connection is to the aortic sac, which is connected to paired dorsal aortae. The tube itself is divided into an atrial segment, adjacent to the venous pole, an atrioventricular canal, and a ventricular segment adjacent to the arterial pole. Within the primitive heart tube, faint constrictions can be seen between these segments. Each of these segments is histologically and functionally distinct from the beginning—atrial and ventricular myocytes have distinct characteristics even when isolated from the primitive mesoderm. Thus, as the heart tube is being formed it already has primitive compartments. Furthermore, the differentiating cardiomyocytes are forming functional contractile units mature enough to begin spontaneous contractions by the time the heart tube is formed. These are initially peristaltic in nature, moving blood from venous inlet to arterial outlet.

Thus, as soon as the heart forms into an organized tubular structure, its primitive connections to the body are formed and its contractile function is operational, such that it begins to pump fluid to the rapidly growing embryo. Red blood cells begin to enter the circulation from blood islands in the yolk sac by the time the heart starts to beat at 22 days' gestation (Carlson, 2004). For the first 6 weeks, the yolk sac remains the exclusive source of hematopoietic cells, until the liver (and to a lesser extent spleen) take over. The bone marrow gradually becomes populated with hematopoietic cells beginning in the second trimester of pregnancy, and by birth is the major source of blood cells (Carlson, 2004). Development of a circulatory system early is critical to maintaining nutrition and oxygen delivery to developing tissues, which at this point are beyond depending on simple diffusion of nutrients.

From the primitive heart tube state, the heart undergoes significant growth and morphologic alterations. These include establishing laterality, such that the symmetry of the heart tube is lost, and there are well-defined left and right structures within the heart and vessels. As laterality is being established, the heart undergoes a dramatic change in shape, via a process known as cardiac looping. This occurs in the human embryo during week 4 of gestation (see Figure 50-1, 25 to 28 days). From this stage, the heart realigns its inflow and outflow segments, septates, and forms valves in processes that are detailed in this chapter. The final product will be a mature heart (Figure 50-1, bottom panel: human heart at 9 weeks' gestation) with the following structures:

1. A venous pole that is now connected to systemic veins from the upper body (superior vena cava), lower body (inferior vena cava), liver (hepatic veins), and coronary circulation (coronary sinus), all of which pass into the right atrium.
2. A separate left atrium, connected to the venous system separately by ingrowth of pulmonary veins from the lungs.
3. An atrioventricular canal that begins as a single unrestricted opening and septates into two atrioventricular valves. The tricuspid valve opens from right atrium into right ventricle, and the mitral valve opens from left atrium to left ventricle.
4. A primitive ventricular segment that has grown in cell number and by cell hypertrophy into two distinct and separate chambers, a right and left ventricle. By processes known as compaction and trabeculation, the working myocardium of each ventricle has become highly organized and adapted to the unique requirement of a pulmonary (right) or systemic (left) ventricle.
5. An arterial pole that has separated in a spiral fashion to create two separate outflow tracts of the heart. The right ventricle retains the proximal part of the original bulbus cordis connection as the conus; thus its structure differs from that of the left ventricle.



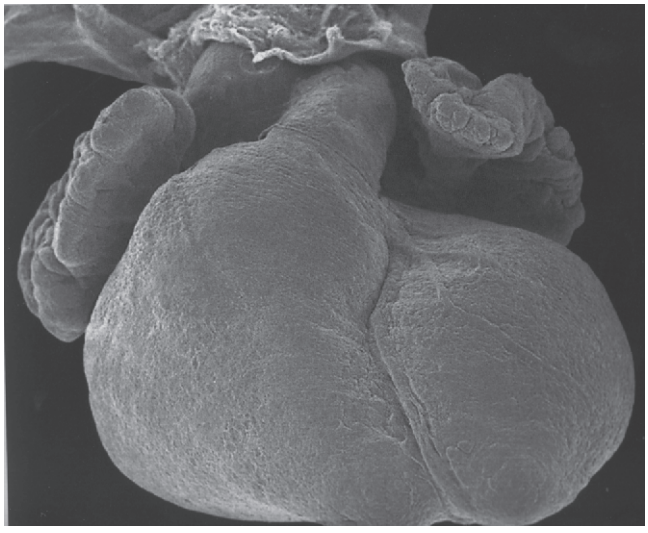


FIGURE 50-1 Morphology of the human heart, 3 to 5 weeks' gestation. Orientation in the body as shown, with cranial-caudal (cr, ca); dorsal-ventral (d, v); and left-right (l, r) planes. The heart tube is initially linear, with the inflow region dorsal/caudal and the outflow ventral/cranial. During week 4, the heart undergoes looping, realigning the segments such that the inflow is shifted dorsal/leftward, and the outflow ventral/rightward. After looping, the atrial and ventricular segments are approximately on the same plane in the cranial/caudal axis. (*Top from Carlson BM:* Human embryology and developmental biology, *ed 4, Philadelphia, 2009, Mosby, p 457.*) Below is a SEM of a human heart at 9 weeks' gestation, after looping, and after septation of the atria, ventricles, and great arteries. (*Bottom from Steding G:* The anatomy of the human embryo, *Basel, 2009, Karger, p 215.*)

The right ventricle is referred to as a tripartite ventricle, with inflow, outflow, and conal segments. The pulmonary valve forms between the conus and the pulmonary artery, and the pulmonary arteries send blood to both lungs. The left ventricle is more conical in shape and is structured as a highly efficient pump. It connects to the aorta, with an aortic valve in between. Because of the spiral septation, the great arteries cross as they arise from the ventricles, with the pulmonary artery coursing anterior to the aorta.

6. Paired dorsal aortae connected to the aortic sac that have extensively remodeled into a single leftward aortic arch and descending aorta. This connects proximally to the coronary arteries, the head and neck arteries, and to a temporary structure important in fetal life, the ductus arteriosus.
7. Networks of coronary arteries have formed within the myocardium of the heart. These grow toward and connect to the aorta as right and left coronary arteries.
8. Networks of myocytes have differentiated into the conduction system of the heart, including the sinoatrial node, the atrioventricular node, and the His-Purkinje system of the ventricles.

CELL TYPES WITHIN THE HEART AND THEIR ORIGINS

The mature heart has three cell layers: the endocardium, an epithelial lining one cell layer thick; the myocardium, a precisely oriented network of myocytes that perform the contractile work of the heart; and the epicardium, an epithelium that covers the external surface of the heart. Beyond this, the heart resides within a pericardial sac, similar in composition and function to the pleura, which covers the lungs.

Much, but not all, of the heart has its embryonic origin from a field of lateral plate mesodermal cells referred to as the cardiogenic mesoderm (Figure 50-2). The primitive heart tube forms as a two-layer structure, with an endocardium and a myocardium, both cell types coming from cardiac mesoderm. The endocardium remains as an epithelium, but a subset of cells delaminate and invade the proteinaceous matrix between the endocardium and myocardium to form the endocardial cushions. These cells will be vital to proper valve development and to complete septation of the atria and ventricles. The myocardium primarily remains muscle, but a subpopulation of these cells also change course and differentiate into Purkinje fibers of the conduction system.

There is a recently appreciated secondary field of cardiac mesoderm that enters the heart after formation of the primitive heart tube and contributes primarily to the ventricles and outflow region of the heart (Kelly and Buckingham, 2002; Mjaatvedt et al, 2001; Waldo et al, 2001). Also termed the anterior heart field, this is a population of cardiac mesoderm anterior and medial to the original heart field, surrounding the aortic sac (Mjaatvedt et al, 2001). Discovery of the anterior heart field was primarily accomplished using cell lineage tracing studies. In chick hearts marked just after fusion of the heart tube, a population of unmarked cells interposed themselves between marked cells of the distal and middle heart tube one day later (Mjaatvedt et al, 2001). Interestingly, if the paired heart fields are completely excised in the chick, a small beating mass of cells resembling an outflow tract still forms, lending further confirmation to the existence of this second population of cardiomyocytes (Mjaatvedt et al, 2001). Studies in mouse compared to chick suggest that the anterior heart field in mouse may extend further into the right ventricle (Kelly and Buckingham, 2002; Zaffran et al, 2004). What differences there are in humans remain unknown. However, the notion that there is a population of cells forming the outflow tract and right ventricle that is distinct from those that form the inflow tract and left ventricle may at least partially explain why heart defects often affect the outflow tract without affecting the inflow tract region of the heart.

Although most of the heart comes from cardiac mesoderm, there are a few critical populations of cells that migrate into the developing heart from outside (see Figure 50-2). One such population is neural crest cells, which migrate in from the developing branchial arches and innervate the heart as well as forming much of the smooth muscle of the proximal aorta. Proper neural crest migration is important to the developing aortic arch system, pulmonary arteries, and ductus arteriosus. Another external population of cell forms that make important contributions to the mature heart is a cluster of cells that forms dorsal and inferior to the heart tube known as the proepicardial organ (Ishii et al, 2007; Nahirney et al, 2003). The origin of these cells is a subject of debate; one leading theory is that they are derived from liver primordium (Ishii et al, 2007). These cells expand

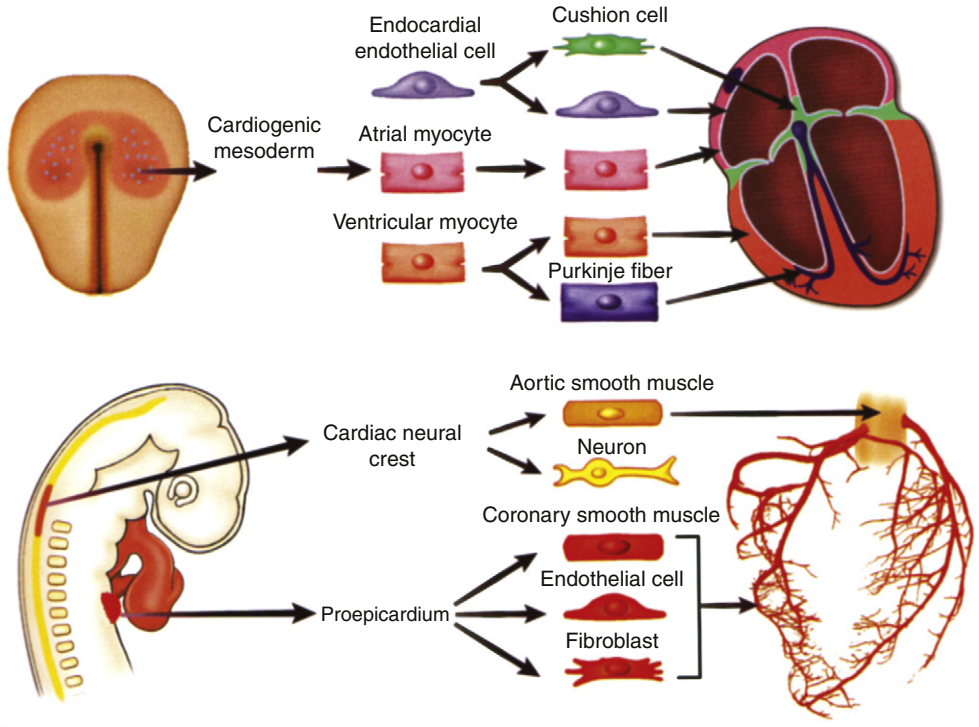

FIGURE 50-2 The cell types of the heart. Most of the heart myocardium and endocardium comes from cardiogenic mesoderm, but there are important cell types that migrate into the developing heart, including cardiac neural crest and proepicardium. (*From Mikawa T: Cardiac lineages. In Harvey RP, Rosenthal N, editors:* Heart development, *San Diego, Calif., 1999, Academic Press, p 31.*)

as an epithelial sheet covering the surface of the heart to form the epicardium. Subgroups of cells delaminate from the sheet and migrate into the myocardium beneath. In the chicken, these cells differentiate into vascular smooth muscle and vascular endothelial cells to form the coronary arteries. They also differentiate into cardiac fibroblasts, which make up a sizable population of cells residing within the myocardium, between myofibers. In the mouse and human, the origin of the coronary endothelial cells is unknown.

Thus, in addition to cardiomyocytes, the heart is composed of cells from epithelial and neural crest origins that migrate in with spatial and temporal precision during cardiac development. The next several sections highlight the steps of this process.

FORMATION OF THE EMBRYONIC CARDIAC CRESCENT AND HEART TUBE

It is important to point out that most of what is known about the early stages of embryonic development come from extensive studies of avian and mouse models (Abu-Issa and Kirby, 2007; Baldwin, 1996, 1999; Combs and Yutzey, 2009; Cui et al, 2009; de Lange et al, 2004; Dyer and Kirby, 2009; Fishman and Chien, 1997; Garcia-Martinez and Schoenwolf, 1992, 1993; Melnik et al, 1995; Redkar et al, 2001; Yutzey and Bader, 1995). This is extended, with some acknowledged gaps, to human development. In its earliest stages, the embryo exists as a bilayer disk of two epithelial sheets of cells suspended between two fluid-filled cavities, the yolk sac and the amniotic cavity. The ventral layer (facing the yolk sac) is the hypoblast, which will eventually be relegated to extraembryonic structures. The dorsal layer (facing the amniotic cavity) is the epiblast, which will actually form all 3 embryonic germ layers: the ectoderm (nervous system and skin), mesoderm (heart, skeleton, muscle and connective tissue), and endoderm (gut). Mesoderm and embryonic endoderm separate from the primitive ectoderm by a process known as gastrulation (Figure 50-3, *A*). Gastrulation begins as a groove form in the epiblast starting at the tail end (caudal) and gradually extending cranially to an endpoint known as the prechordal plate. The groove is known as the primitive streak, and its leading edge the primitive node. Along the primitive streak, epiblast cells delaminate from the epithelial sheet and invade the potential space between the epiblast and hypoblast. The heart forms as a crescent of cells cranial to the prechordal plate and extending along both sides. Fate mapping studies suggest that many cell fate decisions may be set during gastrulation or even before (Fishman and Chien, 1997; Garcia-Martinez and Schoenwolf, 1993). For example, within the cardiac crescent, the apex of the crescent is formed from cells that have migrated through the primitive streak closest to the primitive node and contains precursors of the outflow-tract myocardium. The cells on either side of this region have migrated through the mid-portion of the streak and are ventricular myocyte precursors. Finally, the most lateral and caudal cells are those that have migrated through the most posterior part of the streak and will become atrial myocytes. The exact details of when and how this occurs are still under debate and refinement as better techniques become available (Abu-Issa and Kirby, 2007; Cui et al, 2009; Ehrman and Yutzey, 1999). One concept coming from recent fate-mapping studies using live-cell tracking and time-lapse imaging is that of cells moving as a cohort (tissue motion) rather than individually migrating; this is a way to maintain cells' relative positions within a tissue and, eventually, an organ (Cui et al, 2009).

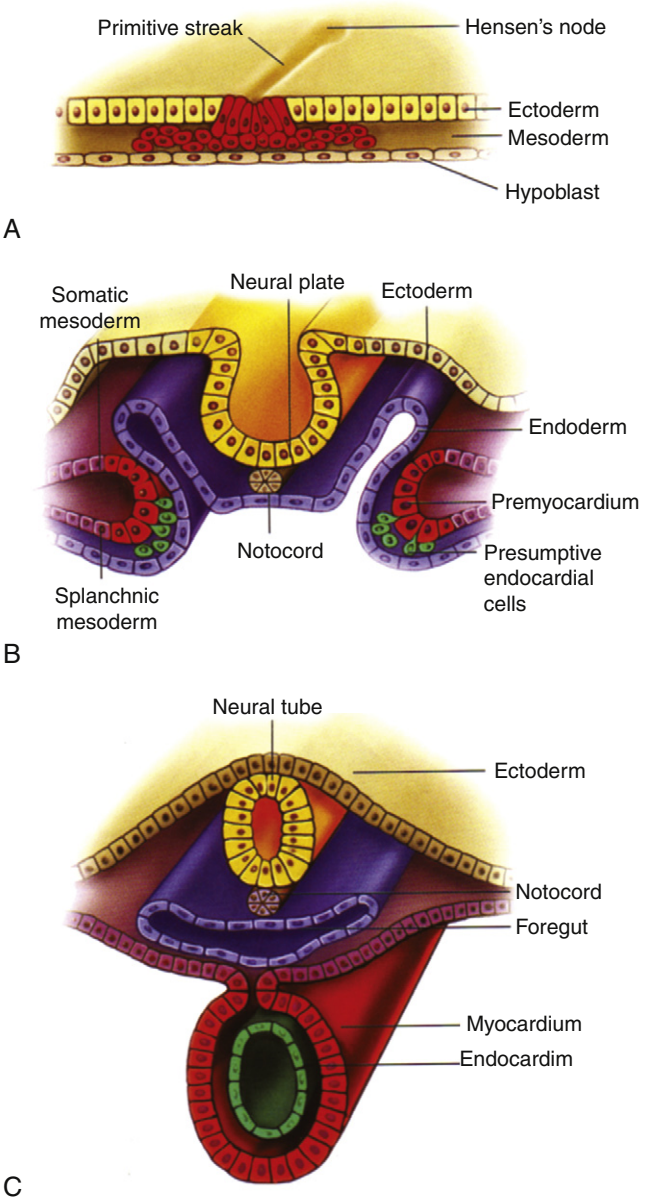

FIGURE 50-3 Gastrulation and the formation of the three germ layers. A, Both mesoderm and endoderm are formed during gastrulation. **B,** As the Mesoderm forms the paired premyocardium, endoderm folds into the gut tube. **C,** The heart tube, now composed of myocardium and endocardium, is pushed ventrally as it forms. (*From Mikawa T: Cardiac lineages. In Harvey RP, Rosenthal N, editors:* Heart development, *San Diego, Calif., 1999, Academic Press, p 20.*)

LOOPING AND LATERALITY OF THE HEART TUBE

The cardiac crescent is a symmetric structure and fuses into an initially symmetric-appearing heart tube. This occurs as the ectoderm dorsal to the crescent is folding to

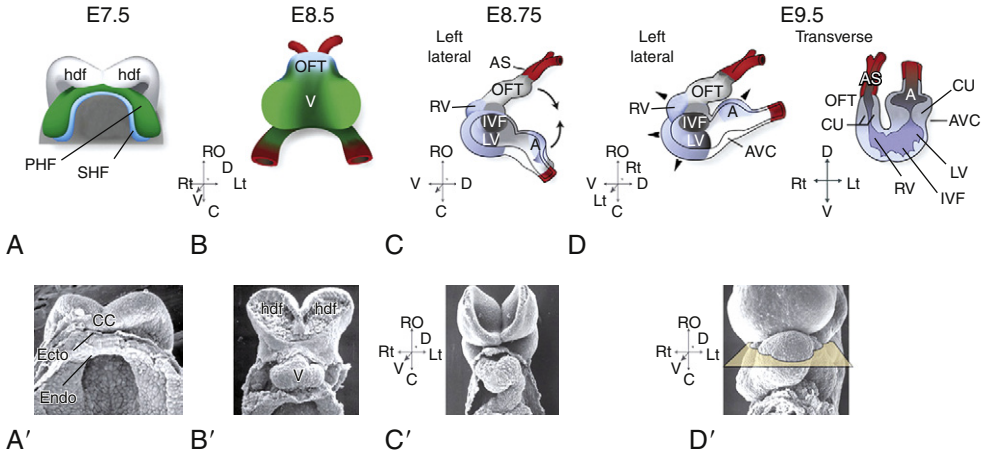

FIGURE 50-4 Diagrams **(A to D)** and corresponding scanning electron micrographs **(A′ to D′)** of embryos during the stages of looping. Shown are mouse embryos, at embryonic days as labeled. Orientation in three dimensions is depicted by the arrows, rostral-caudal *(RO, C)*; dorsal-ventral *(D, V)*; and right-left *(Rt, Lt)*. In **A,** note the primary and secondary heart fields *(PHF* and *SHF)* beneath the headfold *(hdf)*. In **A′,** the cardiac crescent *(cc)* is between the ectodermal *(ecto)* and endodermal *(endo)* germ layers. Labeled in **B** and **B′** are the outflow tract *(OFT)*, primitive ventricle *(V)*, and sinus venosus *(SV)*. The heart begins to loop, as shown by *arrows* in **C;** note the alignment of inflow region *(atrium; A)* and SV with the left ventricle *(LV)*, and of the outflow region (aortic sac *[AS]* and *OFT*) with the right ventricle *(RV)*. The interventricular foramen has begun to septate the ventricles *(IVF)*. By the completion of looping, the ventricular chambers have significantly enlarged, as indicated by the *arrowheads* in **D**. The atria and ventricles are on the same rostral-caudal plane, as shown by the *rectangle* in **D′,** corresponding to the transverse section diagram above. The endocardial cushions *(CU)* begin to form after completion of looping; see next section. (*Adapted from Moon A: Mouse models of congenital cardiovascular disease*, Curr Top Dev Biol *84:174, 176, 2008*.)

create the neural canal, and the endoderm initially ventral to the crescent is folding to create the foregut (Figure 50-3, *B*). As the foregut forms, it moves dorsally, pushing the cardiac crescent ventrally and medially, such that the two arms of the crescent fuse into a tube sitting directly in front of the foregut (Figure 50-3, *C*). As fusion of the heart fields occurs, the heart is already beating. In a human fetus this happens at approximately 22 days' gestation. Over the next week, there is tremendous growth of the head, such that the heart goes from being the most "cranial" structure in the embryo to a position tucked underneath the developing head of the embryo.

As the head grows up and over the heart tube, the heart tube itself begins to undergo a dramatic change in shape known as looping. Here the heart tube loses its symmetry, and distinct left and right morphology can be identified (Steding, 2009). Much is known about the molecular signaling and gene expression patterns involved in looping. The basic left-right asymmetry of the embryo is set during gastrulation by concentration gradients of the factors sonic hedgehog (shh) and fibroblast growth factor 8 (fgf-8). This gradient is created by ciliary motion at the primitive node and causes a cascade of downstream genes to be activated, including nodal, lefty, and pitx-2 (Capdevila et al, 2000; Rodriguez-Esteban et al, 2001; Tsukui et al, 1999). Within the heart tube, several cardiac transcription factors have been shown to be important to looping, including Nkx2-5, MEF2, and Hand2 (Christoffels et al, 2006; Cui et al, 2009; Han and Olson, 2005; Han et al, 2006; Hiroi et al, 2001; Jamali et al, 2001a,b; Karamboulas et al, 2006; McFadden et al, 2005; Srivastava et al, 1997; Tsukui et al, 1999; Yamagishi et al, 2001). Disruption of any of these factors in mice by gene knockout causes embryonic lethality, with a block in heart development at the looping stage. Morphologically, cardiac looping involves differential growth, with higher proliferation of myocytes along the outer curvature than inner (Moorman and Christoffels, 2003), including those being added from the secondary heart field (Kioussi et al, 2002). All of this serves to elongate the outflow tract and enlarge the ventricles relative to the atria (Moorman and Christoffels, 2003). In addition, there are mechanical forces literally pulling, twisting, and realigning structures of the primitive heart tube. This is thought to involve the cytoskeleton, including nonmuscle myosin (Brueckner, 2001; Linask and Vanauker 2008; Supp et al, 1997), microtubules (Icardo and Ojeda, 1984), and nonmuscle actin bundles (Itasaki et al, 1991).

Normal looping occurs to the right (D-looping), that is, the sinus venosus and atria move toward the left and posterior, and the ventricles and bulbus cordis move to the right and anterior. Importantly, the venous pole also moves cranially such that it lines up with the arterial pole along the horizontal body axis. This is seen from several different angles in Figure 50-4. The bulbus cordis remains to the right of the primitive ventricle. This repositioning is critical for proper atrioventricular and ventriculoarterial connections. Also with looping, an outer and an inner curvature of the heart is established. The anterior outer curvature is an area of rapid myocardial growth and expansion to form the ventricular chambers. The posterior inner curvature undergoes slower growth and acts rather like a fulcrum for the looping process. The inner curvature myocardium contributes to the atrioventricular canal and is critical to the formation of the endocardial cushions.

ABNORMALITIES IN CARDIAC LOOPING

Sometimes, looping can occur to the left, with the venous pole and atria moving rightward and the ventricles and arterial pole moving leftward. This is referred to as L-looping and most commonly occurs as an entity termed

congenitally corrected transposition. Here the ventricles loop to the left, and the bulbus cordis ends up to the left of the primitive ventricle. When the great arteries septate, there is L malposition of the great arteries, so the aorta is to the left of the pulmonary artery (parallel, not crossed). The resulting circulation is right atrium to left ventricle to pulmonary artery; left atrium to right ventricle to aorta. In isolation, then, this defect allows for normal circulation—although with the right ventricle, which is structured to pump to the low-pressure pulmonary circulation, as the systemic ventricle. In addition, however, there are often other cardiac defects ranging from a ventricular septal defect with pulmonary valve stenosis to more complex defects involving hypoplasia of one of the ventricles or hypoplasia, aplasia, or malformation of one or more valves.

L-looping may also be associated with more global defects known as heterotaxy syndromes. Heterotaxy syndromes are a heterogeneous group of congenital defects, with the commonality being abnormal left-right asymmetry of the embryo (Ghosh et al, 2009). In heterotaxy, left-right assignments along the body axis are randomized. Thus, it is possible to have mirror-image asymmetry, or bilateral symmetry, with either two right sides or two left sides. This is often termed right or left isomerism. This can affect the abdomen, lungs, and heart. In the abdomen the gut, liver and spleen may be reversed from normal (abdominal situs inversus). There may be malrotation of the bowel and anomalies of the biliary tree. The spleen, being a normally left-sided structure, can be duplicated in left isomerism (polysplenia), and absent in right isomerism (asplenia). Asplenic patients require antibiotic prophylaxis in childhood to protect against bacterial infections. Asplenic patients usually have left-isomerization of the lungs and heart as described later; polysplenic patients have right-isomerization of the lungs and heart as well. Lung abnormalities in heterotaxy manifest in the bronchial and lung anatomy. The normal left lung is bilobed and the left main bronchus travels beneath the left pulmonary artery (hyparterial). The normal right lung is trilobed and the main bronchus travels above the right pulmonary artery (eparterial). Thus, careful examination of a chest x-ray in left isomerism reveals bilateral hyparterial bronchi, and in right isomerism shows bilateral eparterial bronchi.

In the heart, the atrial sidedness is randomized in heterotaxy. Here the atria may be normal (situs solitus), left-right reversed (situs inversus), or unclear (situs ambiguus; including bilateral right or bilateral left atria). The atria are most practically defined by their venous return, systemic to the right atrium and pulmonary to the left. But in heterotaxy this is not always possible, as the pulmonary or systemic veins may return to both atria. The pulmonary veins grow in from the developing lungs normally joining the back wall of the left atrium. When the left-right cues are scrambled, the pulmonary veins often return ipsilaterally: left-sided veins to left-sided atrium and right-sided veins to right-sided atrium. Likewise, the systemic veins may return to either or both atria in heterotaxy—for example, a right superior vena cava to right atrium and left superior vena cava to left atrium. This is because the systemic veins start out as paired symmetric structures (see section on systemic veins), with involution of certain structures occurring as part of the establishment of left-right asymmetry in the embryo. Finally, certain patterns of additional cardiac defects often accompany asplenia/right isomerism. These include failure of septation if the ventricles resulting in a single ventricle, pulmonary underdevelopment (stenosis or atresia of the pulmonary valve), bilateral superior vena cava, and anomalous pulmonary venous return. For polysplenia/left isomerism, commonly associated defects include endocardial cushion defects (see later discussion), left-sided obstructive lesions such as coarctation of the aorta, and interruption of the inferior vena cava (IVC) with azygous continuation to the superior vena cava.

VENTRICULAR INLET SEPTATION: ENDOCARDIAL CUSHIONS

After cardiac looping has occurred, the orientation of the heart tube has changed drastically, but the progression of blood flow through it remains in essentially the same sequence: into the heart from the venous pole, through the common atrium into the common ventricle, and out the conotruncus to the aorta. Inflow and atrial segments are leftward, and the ventricle and outflow are to their right. If the process arrests near this point, a heart may form with its entire inlet portion aligned over the leftward ventricle (a double inlet left ventricle), or its entire outlet portion aligned over the rightward ventricle (a double outlet right ventricle). Both of these entities are seen in humans. What are very rarely seen are a double inlet right ventricle, or a double outlet left ventricle—even if there is L-looping and/or dextrocardia, this basic sequence is maintained.

During the next phase of heart development, the atrioventricular (inlet) and ventriculoarterial (outlet) structures will realign and septate, such that there is a valved inlet and a valved outlet for each ventricle. In human embryos, this occurs during week 7 of gestation (Dhanantwari et al, 2009; Steding, 2009). These valves are formed primarily from the endocardial cushions. The endocardial cushions are also critical to complete ventricular and atrial septation, completing the portions of septum adjacent to the AV valves. This is detailed further in sections on atrial and ventricular septation. Thus, the endocardial cushions form the crux of the heart: a point in the center of the heart at which separate AV canals are to the left and right, and atrial and ventricular septa are aligned above and below.

Within the primitive heart tube, even before looping, there are faint constrictions at the atrioventricular groove and in the forming conotruncus (see Figure 50-4). The endocardial cushions initially appear as swellings in the atrioventricular and conotruncal segments of the primitive heart, by six weeks gestation (Figure 50-5, *A* and *B*). The swellings are caused as cells from the inner lining of the heart (endocardium) delaminate and migrate into the extracellular matrix in between the endocardium and the myocardium. Signaling involving the TGF-β family between the myocardium and endocardium play a crucial role in initiating and maintaining this process (Brown et al, 1996, 1999; Jiao et al, 2006). The delaminating cells change phenotype in a process known as epithelial-to-mesenchymal transformation. The cells lose their epithelial, or sheetlike, characteristics and acquire a mesenchymal

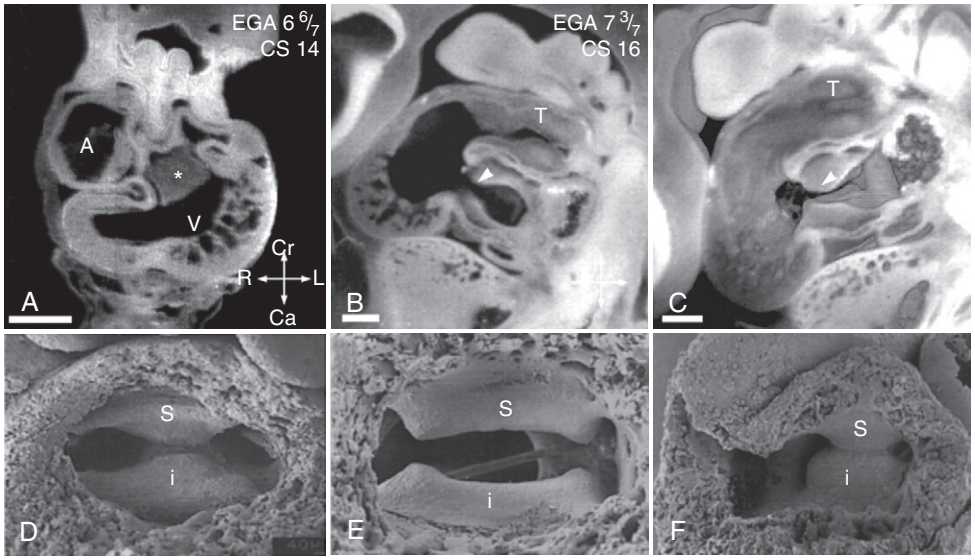

FIGURE 50-5 Formation of the endocardial cushions. A to **C,** Episcopic fluorescence image capture(EFIC) images of sectioned paraffin-embedded human embryos at 6⁶⁄₇ weeks **(A)** and 7³⁄₇ weeks **(B** and **C)** gestation. **C** is a three-dimensional volume reconstruction of the same embryo as **B**. Seen are atria (*A*), ventricles (*V*), AV cushions (* and *arrowhead*) and truncus and semilunar valve cushions (*T*). Scale bar = 0.515 mm in **A** and 0.389 mm in **B** and **C**. (*From Dhanantwari P, Lee E, Krishnan A, et al: Human cardiac development in the first trimester: a high-resolution magnetic resonance imaging and episcopic fluorescence image capture atlas*, Circulation *120:347, 2009*.) **D** to **F** are different views of scanning electron micrographs of human embryos at week 6 gestation, showing the superior (s) and inferior (i) atrioventricular cushions, with the tricuspid (left) and mitral (right) orifices. (*From Steding G:* The anatomy of the human embryo, *Basel, 2009, Karger, p 221*.)

phenotype, losing junctions with neighboring cells, invading the matrix, and proliferating faster (Combs and Yutzey, 2009; Kim et al, 2001; Lincoln et al, 2004; Shelton and Yutzey, 2007). Why some cells respond to such signals and undergo epithelial-to-mesenchymal transformation while neighboring cells remain epithelial is unclear.

In both the AV canal and conotruncus, four distinct cushions form, named by their anatomic locations. For the AV canal these are superior, inferior, left lateral, and right lateral. In the conotruncus they are right superior, right dorsal, left inferior, and left ventral. The AV and conotruncal cushions are separate with one important exception: The left ventral conal cushion and the superior AV cushion are in continuity along the inner curvature of the heart. This proximity will persist in the fully septated heart as aortic-mitral valve continuity. The atrioventricular canal septates as the superior and inferior cushions grow and extend (see Figure 50-5, *D* to *F*), finally fusing in the midline. This results in complete separation of the AV canal into left (mitral) and right (tricuspid) sides. The AV valves form from remnants of the cushions: a leftward mitral valve with two leaflets, and a rightward tricuspid valve with three leaflets.

Failure of complete fusion between the superior and inferior cushions in the midline results in a cleft within the anterior leaflet of the mitral valve. This is a mild form of an endocardial cushion defect, often associated with a primum atrial septal defect (see section on atrial septation) and known as a partial atrioventricular canal. The septal leaflet of the tricuspid valve also forms from this superior and inferior cushions and can be abnormal as well, although this is less often clinically significant. More profound failure of proper AV cushion expansion and fusion results in a complete atrioventricular canal. Here the crux of the heart is unformed. There remains a common orifice overlying both ventricles, with defects in the adjacent atrial and ventricular septa. The common atrioventricular valve has leaflet structure based on the unseptated AV canal, with four or sometimes five separate leaflets corresponding to the two lateral, the superior (referred to as anterior bridging) and inferior leaflets.

The AV canal myocardium, part of the primitive heart tube, does not persist in the adult heart. There is no muscular connection between the mature atrial and ventricles. The process for isolation of the atrial and ventricular muscle appears to occur as the epicardium of the AV sulcus establishes continuity with the developing endocardial cushions beneath; this occurs all along the ventricular margin of the AV canal (Wessels et al, 1996). The only remaining connection between atria and ventricles is within the conduction system, the AV node (Anderson and Ho, 1998, 2003; Anderson et al, 2000). Occasional muscular bridges of tissue remain as accessory muscle connections, which can be clinically important as substrate for arrhythmias (specifically AV reciprocating tachycardias, a common form of supraventricular tachycardia).

VENTRICULAR OUTFLOW TRACT SEPTATION: CONTRIBUTION OF ENDOCARDIAL CUSHIONS

While the AV cushions form a three-dimensional crux of the heart, the conotruncal cushions form a three-dimensional spiral, completing an almost 180-degree rotation (Carlson, 2004; Ya et al, 1998). During septation of the outflow tracts, the primitive bulbus cordis is separable into two segments, the truncus adjacent to the aortic sac, and the conus adjacent to the ventricular myocardium (Figure 50-6, *A*).

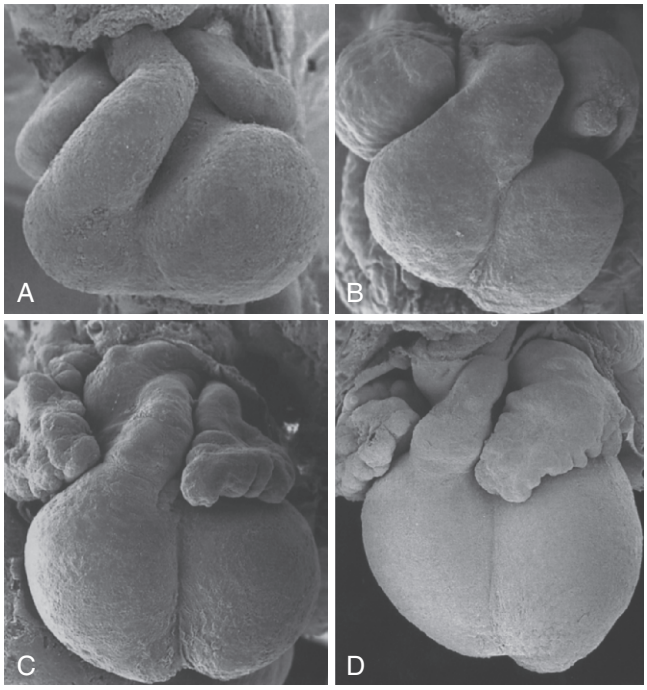

FIGURE 50-6 Septation of the outflow tracts, as viewed externally by scanning electron microscopy. A is a human embryo at 5 weeks' gestation; the conus and truncus of the common outflow tract are labeled. **B** is an embryo at 6 weeks' gestation. **C** and **D** are 7 and 8 weeks' gestation, respectively. Now completely separate pulmonary and aortic outflow tracts are identified. (*Adapted from Steding G:* The anatomy of the human embryo, *Basel, 2009, Karger, pp 211, 213, 214, 215.*)

The right superior and left inferior cushions are within the truncal region and will contribute to the aorticopulmonary septum. The right dorsal and left ventral cushions are within the conus region and are important for pulmonary and aortic valve formation, and for completion of septation between the ventricles at the level of the pulmonary and aortic valves.

Again, for this process to occur correctly, the continuity of the superior AV cushion and left ventral conus cushion is critical. To align the septated great arteries directly over the ventricles, the arterial trunk must shift to the left. There is evidence from mouse models that failure to achieve continuity of the superior AV cushion and left ventral conus cushion results in malalignment of both great arteries over the right ventricle, along with a ventricular septal defect (van den Hoff et al, 1999; Waller et al, 2000). Clinically, this is an entity known as double-outlet right ventricle (DORV). Part of the clinical definition of a DORV is presence of a conus segment of both ventricles (bilateral conus). Anatomically, the normal conus is a muscular "neck" within the right ventricle between the tricuspid and pulmonary valves. Embryologically, this is a remnant of the conus of the primitive heart tube that is retained by the right ventricle. In the left ventricle, the fusion of the superior AV and left ventral conal cushions results in mitral aortic continuity and lack of a conal segment. If this fusion of cushions and leftward shifting of the truncus do not occur, then a conus is retained in the left ventricular outflow tract, which is malpositioned to the right.

VENTRICULAR OUTFLOW TRACT SEPTATION: ROLE OF NEURAL CREST

As discussed in the section on cell types making up the heart, the developing outflow tract has the added complexity of contributions from outside the primitive heart tube. These include two important populations of cells, neural crest and anterior heart field cells. The cell movement of the anterior heart field was discussed in the section on cardiac looping. Recent data regarding gene expression in the secondary heart field have demonstrated newly appreciated roles for several genes already studied in the primary heart field, including *Hand1*, *Nkx2-5*, *Gata4*, and *Mef2* (Dodou et al, 2004; Dyer and Kirby, 2009; Verzi et al, 2005; Ward et al, 2005a, 2005b; Zeisberg et al, 2005). Gene expression defects here can lead to right ventricular hypoplasia and outflow tract abnormalities, including tetralogy of Fallot (Ward et al, 2005; Zeisberg et al, 2005).

The second population of cells that migrate into the developing outflow tracts is the cardiac neural crest. Neural cells originate in the anterior rhombencephalon, and migrate as a sheet through the pharyngeal region and into the aortic arches. The third, fourth, and sixth arches are the primary sites of neural crest migration and activity (see section on arch development and Figure 50-10 for detail). The neural crest cells surround the epithelia of the arch arteries and extend into the truncus and proximal conus. Here they interact with endocardial cushion cells to separate the great arteries and close the conal septum. These neural crest cells are also important for development of the nearby parathyroid, thyroid, and thymus glands. In human DiGeorge syndrome, cardiac conotruncal and arch defects are associated with developmental defects in each of these three glands as well. Extensive work has been done in chick models using neural crest ablation, and these studies show a very high prevalence of persistent truncus arteriosus, interrupted aortic arch, tetralogy of Fallot, DORV, and ventricular septal defects, along with abnormal parathyroid, thyroid, and thymus development (Creazzo et al, 1998; Harvey and Rosenthal, 1999; Kirby and Waldo, 1995; Nishibatake et al, 1987; Waldo and Kirby, 1993; Waldo et al, 1996, 2005).

The genetic defects underlying DiGeorge syndrome have been elusive, but knowledge is advancing. A deletion of up to 3 megabases in chromosome 22 (22q11) has long been known to be associated with DiGeorge, based on kindred studies in families with the syndrome. In humans, the defect is autosomal dominant, with variable penetration, meaning that one copy of the gene deletion is sufficient to cause disease and that the disease severity varied from family member to family member. A similar deletion generated experimentally in mice yielded a model of the cardiovascular features of DiGeorge syndrome (Lindsay et al, 1999). Recently, three independent investigators narrowed in on TBX1 as the responsible gene in these mice (Jerome and Papaioannou, 2001; Lindsay et al, 2001; Merscher et al, 2001). TBX1 is a transcription factor in a family known to be important in embryonic patterning. Homozygous mutations of TBX1 caused obliteration of the third, fourth, and sixth pharyngeal arches with embryonic lethality and caused most of the extracardiac defects as well, along with an abnormal ear, jaw, and pharynx

(Jerome and Papaioannou, 2001). Heterozygous mutants, which are analogous to the human disease state, showed more variable disease. The cardiac defects primarily affected the fourth pharyngeal arch and caused abnormal patterning of the great arteries in 50% of embryos in one study (Lindsay et al, 2001). This group had 1 heterozygous mouse mutant out of 14 that also exhibited parathyroid and thymic insufficiency. Possibly, humans are more sensitive to gene dosage and exhibit the full range of defects in the haploinsufficient state. There may be other modifying genes as well, because there seems to be an important contribution of genetic background to the phenotype in mice, with more severe arch anomalies presenting in more inbred strains (Jerome and Papaioannou, 2001). This is a confounding factor of many gene targeting strategies and perhaps a clue as to why significant phenotypic variation can occur in humans with identical mutations. Interestingly, isolated TBX1 mutations appear to be very rare as causes of clinical DiGeorge syndrome (Beaujard et al, 2009; Portnoi, 2009; Rauch et al, 2010); most patients having a larger megabase deletion.

SEPARATION OF AORTA AND PULMONARY ARTERY: NORMAL DEXTROPOSITION

Within the truncus segment, septation is also occurring during remodeling of the conus. This normally occurs as the truncal cushions fuse in a spiral fashion. Starting at the level of the AV valves, the newly forming pulmonary artery is directly anterior to the aorta. Further along the outflow tract, the pulmonary artery and aorta are more left-right to one another, as the spiral extends. As the aorta arches to the left, the proximal transverse arch passes anterior to the pulmonary artery, completing a 180-degree turn of the spiral (see Figure 50-6). This rotation involves not only the truncal cushions but the rotation of the myocardial tube as well (Bajolle et al, 2006; Lomonico et al, 1986). If this 180-degree twist does not occur or is incomplete, the result is transposed great arteries. This is defined by the aortic valve being anterior to the pulmonary valve. The left-right orientation of the valves is most commonly preserved (aortic rightward), although can vary within a 90-degree range from directly anterior-posterior to directly side by side. L-transposition, aortic leftward, is most often associated with L-looped ventricles or heterotaxy syndromes and is rare in isolated transposition.

CARDIAC VALVE FORMATION

Cardiac valve development begins with the endocardial cushions during week 7 of gestation, but formation of mature atrioventricular (mitral and tricuspid) and semilunar valves (aortic and pulmonic) takes several weeks for completion (Combs and Yutzey, 2009; de Lange et al, 2004; Dhanantwari et al, 2009; Hinton et al, 2006; Kanani et al, 2005; Lincoln et al, 2004; Steding, 2009). As the endocardial cushions enlarge, they protrude into the lumen of the heart. Here, subject to constant flow of blood, the protrusions condense and elongate. Endocardial cells overlying the cushions proliferate slowly, and there is programmed cell death (apoptosis) of mesenchymal cells underneath.

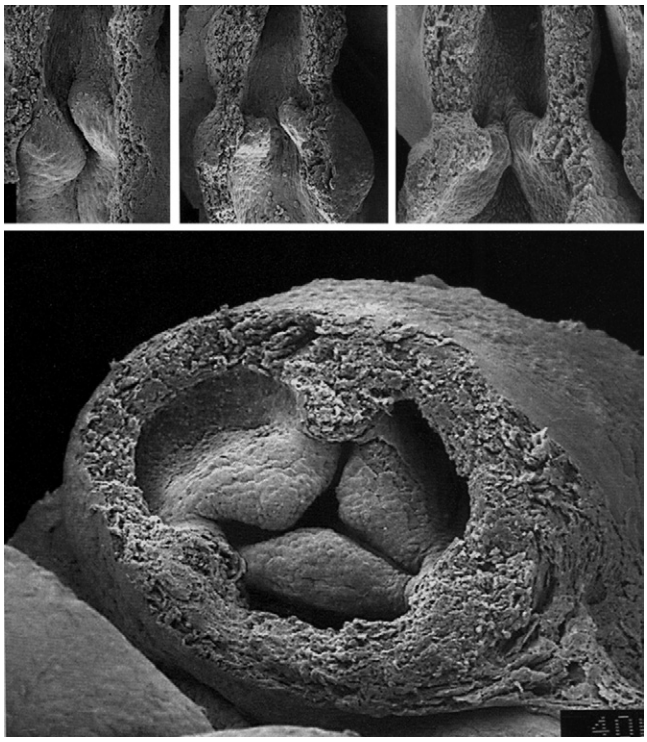

FIGURE 50-7 Semilunar valve formation, as seen by scanning electron microscopy. Human embryos at weeks 7 and 8 above, and week 9 below. The views *above* are coronal sections through the pulmonary trunk, viewed from the ventral side. The embryo *below* is shown from a transverse section through the pulmonary trunk, revealing the pulmonary valve leaflets. (*From Steding G:* The anatomy of the human embryo, *Basel, 2009, Karger, p 239.*)

The valves undergo extensive remodeling of the extracellular matrix; in the case of the semilunar valves, this results in a fibrous layer (primarily collagen) on the arterial side, a spongiosa layer (glycosaminoglycans) in the middle, and an elastic layer (elastin) on the ventricular side (Combs and Yutzey, 2009; Hinton et al, 2006; Shelton and Yutzey, 2007). In the case of the semilunar valves, this remodeling process of the endocardial cushions continues through the last trimester of pregnancy and into the neonatal period (Aikawa et al, 2006; Hinton et al, 2006). The morphology of this process is shown in Figure 50-7.

Recent studies have shed some light on the genetics of cardiac valve disease. For example, Noonan's syndrome is characterized by cardiac malformations including a dysplastic pulmonary valve. Linkage studies of families with Noonan's syndrome uncovered a candidate gene on chromosome 12, the PTPN11 gene (Tartaglia et al, 2001). The PTPN11 encodes for SHP-2, a signaling molecule important for growth factors, cytokines, and hormones (Tartaglia et al, 2001). A specific role in mediating growth factors during semilunar valve formation had been proposed (Chen et al, 2000), and several human mutations in the gene have been shown to cause overactivation of the SHP-2 protein (Tartaglia et al, 2002). This suggests a gain-of-function mechanism for the pathogenesis of Noonan's syndrome, an interesting distinction from the more familiar concept of loss of functioning protein causing disease. Likewise, mutations in the Notch1 receptor and various components of the Notch signaling pathway,

have been associated with the formation of aortic valves and with multiple stages of cardiac development (Garg et al, 2005; High and Epstein, 2008).

DEVELOPMENT OF THE VENTRICLES AND VENTRICULAR SEPTUM

The majority of the ventricular septum is muscular and made up of a protrusion of ventricular myocardium that starts at the apex of the primitive ventricle and extends into the ventricular cavity. The early septating ventricle, then, appears as a bilobed structure (Dhanantwari et al, 2009; Steding, 2009) (Figure 50-8). As the septum extends upward, the separation becomes nearly complete. There is controversy as to how the septum extends so quickly to form a wall between the left and right ventricles. Part of the answer seems to be rapid proliferation of these myocytes, which retain the ability to divide even as a working myocardium. This property is lost soon after birth, as the mature myocardium is for the most part incapable of proliferation. Small muscular ventricular septal defects (VSDs) are very common in newborns. One study screening asymptomatic newborns found an incidence of 53 per 1000 neonates with small muscular VSDs; only one tenth of these infants had physical exam signs of their VSD. Nearly 90% of these small defects were closed by 10 months of age (Roguin et al, 1995). These data and others suggest continued low-level proliferation in human ventricles after birth.

We have said that as the muscular septum grows and extends from the ventricular apex, the separation between the left and right ventricles becomes nearly complete. There are two important regions of the entire ventricular septum that are completed by endocardial cushions, as discussed in the preceding sections. First, the AV endocardial cushions form the posterior septum adjacent to the AV valves. Second, the conal cushions form the conal septum below the great arteries. An important feature of this process not discussed earlier is the fact that these regions of septum contain muscle as well as cushion tissue. The muscle gets there via a process called myocardialization, during which the muscle cells of the inner curvature of the heart invade the conal cushion and superior AV cushions as they form the septum (Harvey and Rosenthal, 1999). These migrating myocytes are nonproliferative, and the entire inner curvature is involved. Thus, the mitral-aortic continuity discussed earlier is completely fibrous and devoid of muscle. Yet the posterior AV septum and the conal septum are muscular structures, because of the process of muscularization. This process is considered by some investigators to complete the looping process; a DORV could then be considered a failure of the final stages of looping.

The left and right ventricles differ not only by their relative positions to one another, but also in their basic muscular structure and in their function. Each ventricle can functionally be subdivided into inflow and outflow regions. The RV, as we have discussed, has a conal segment as well and is therefore referred to as a tripartite ventricle. In the mature heart, the LV is a high-pressure system, connected to systemic pressures, whereas the RV is connected to the lower-pressure pulmonary circulation. The LV form follows its function, with concentric rings of myofibrils that contract with a slight twisting motion, which allows for an efficient ejection of blood. In the embryo, the myocardium thickens and arranges itself in processes known as trabeculation and compaction. Trabeculation refers to projections of muscular tissue into the lumen of the ventricle, such that the inner surface is no longer smooth-walled, but ridged. Compaction refers to the alignment of myocytes from random and loosely packed, as they are in the immature myocardium, into bundles of tightly packed and well-coordinated myocytes working as a unit in the mature myocardium (Harvey and Rosenthal, 1999).

DEVELOPMENT OF THE ATRIA AND ATRIAL SEPTUM

Like the ventricular septum, the atrial septum begins as a ridge of muscular tissue, superior and midline, which expands to divide the right side of the atrium containing the orifice of the sinus venosus from the left side of the atrium containing the orifice of the common pulmonary vein. This structure is known as the septum primum, and it grows inferiorly toward the fusing AV cushions. As discussed previously, the fusing AV cushions will form the

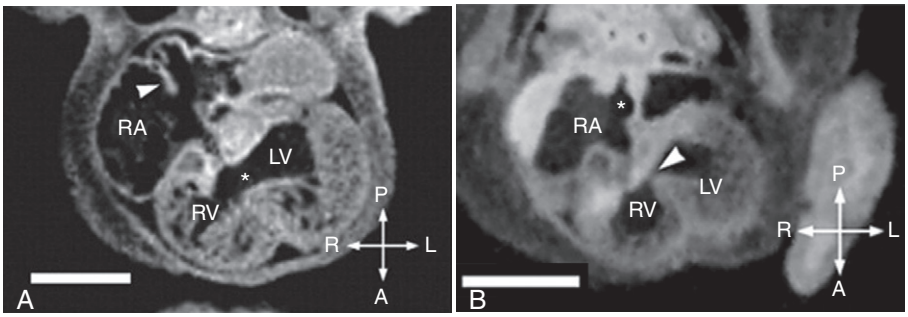

FIGURE 50-8 Atrial and ventricular septation. Human fetal MRI images in transverse plane, showing four chambers of the heart (*LV*, left ventricle; *RA*, Right atrium; *RV*, right ventricle). Orientation as shown by the *arrows: P* (posterior), *A* (anterior), *R* (right), and *L* (left). **A,** Fetus at 7½ weeks' gestation. The atrial septum primum is marked by the *arrowhead*, with the foramen primum below allowing shunting of blood from RA to LA. Between the ventricles, the muscular intraventricular septum is forming but is not yet complete (*). Scale bar is 1.25 mm. **B,** Fetus at 8 weeks' gestation. Here the atrial septum primum (*) is fused with the endocardial cushions inferiorly; not seen is the foramen ovale that allows continuous right-to-left atrial shunting in the fetus. The *arrowhead* shows a small residual ventricular septal defect in the inlet (posterior) septum, not yet closed by endocardial cushion tissue. Scale bar is 1.5 mm. (*Adapted from Dhanantwari P, Lee E, Krishnan A, et al: Human cardiac development in the first trimester: a high-resolution magnetic resonance imaging and episcopic fluorescence image capture atlas*, Circulation *120:345-346, 2009*.)

inferior portion of the atrial septum. Before septum primum and the cushions completing atrial septation, however, small perforations appear, enlarge, and coalesce within the primum septum (see Figure 50-8). The impetus for this is not known. Soon afterward, a new crescent of atrial septum forms on the right atrial side of the septum primum and begins extending alongside the septum primum. During fetal life, blood flow from the right atrium into the left prevents fusion of these two septae. The septum secundum is significantly more rigid than the septum primum, which flaps open to allow continued right-to-left flow (see Figure 50-8). After birth and separation from the low-resistance placenta, the left atrial pressure rises significantly and the atrial shunt reverses. This causes the septum primum to effect a seal against the septum secundum, often leaving a small opening known as the foramen ovale. A patent foramen ovale, generally 3 mm or less with a trivial degree of left-to-right flow, is a normal finding in a newborn and even in many older children and adults. A defect larger than 5 mm may constitute a secundum atrial septal defect (ASD), a true deficiency in atrial septal tissue in the region of the foramen ovale.

Failure of the cushions to form the inferiormost part of the atrial septum results in a primum atrial septal defect. Such defects do not close spontaneously and may be associated with other endocardial cushion defects, most commonly a cleft mitral valve. Finally, there is a small contribution to the atrial septum near the junctions of the superior and inferior vena cavae (see later discussion). Defects in this process result in a sinus venosus ASD, and there are superior or inferior types. Such defects again result from deficiency of atrial septal tissue and do not close spontaneously.

SYSTEMIC AND PULMONARY VEIN DEVELOPMENT

The sinus venosus of the primitive heart tube is a symmetric structure and receives three sets of paired (left and right) systemic veins: the vitelline, umbilical, and common cardinal (Figure 50-9, *A*). This is the situation at 4 to 5 weeks' gestation (Minniti et al, 2002).

The vitelline veins return from the yolk sac, a structure that communicates with the primitive gut via the vitelline duct. The duct normally regresses completely, but an occasional remnant can be seen as a Meckel's diverticulum (Carlson, 2004). Distally, the vitelline veins regress along with the duct and proximally lose their connection to the sinus venosus by 6 weeks. The midportions of these vessels, however, expand within the liver to contribute toward the hepatic and portal veins, and a small segment to the IVC (see Figure 50-9, *A* and later discussion) as well.

The umbilical veins return from the placenta carrying oxygenated blood. These are the first to develop, by 3 weeks' gestation. As the liver develops, the umbilical veins develop connections to the liver venous plexus, and the connection to the sinus venosus involutes. Outside the embryo within the umbilical cord, the left and right umbilical veins fuse into one; thus there is a single umbilical vein in the newborn. Within the embryo, the left and right segments remain separate, and the left umbilical vein becomes connected to the right hepatic veins via a new channel that forms, the ductus venosus (see Figure 50-9, *A*). This circulation is formed by the 7th week of gestation. Again the umbilical veins are carrying oxygenated blood to the right atrium. This flow is primarily directed toward the atrial septum, and therefore primarily through the foramen ovale into the left atrium and systemic circulation.

The cardinal veins carry the venous return from the embryo proper. The left and right common cardinal veins are relatively short segments that connect to the sinus venosus. On each side, anterior and posterior cardinal veins join to form the common cardinal vein, the anterior carrying the venous return from the upper body and the posterior from the lower body. The right anterior and right common cardinal vein will form the superior vena cava in the mature circulation. The left common cardinal vein and left segment of the sinus venosus form the coronary sinus, which receives venous return from the coronary system. These structures are pulled rightward as the IVC forms, such that the opening (os) of the coronary sinus ends up in the right atrium once atrial septation is complete. The IVC is more complex and is made up of five segments, coming from urogenital, mesenteric, and hepatic venous channels fusing together to the right of the spine as their leftward paired counterparts involute. Because numerous vessels go into making the IVC, interruption of the IVC can sometimes occur at various segments. This is most often in the setting of heterotaxy, but can occur in isolation. When the IVC is interrupted, one of two major vessels that connect the lower and upper body venous systems generally enlarges to receive the flow and shunt it into the SVC. These are the rightward azygous vein, which runs from the suprarenal segment of the IVC to the SVC, and the leftward hemiazygous vein, which takes a more tortuous course from the leftward lumbar and renal veins up into the thoracic cavity, where it turns rightward to join the azygous vein. Thus, an interrupted IVC generally has either azygous or hemiazygous continuation to the SVC.

The pulmonary veins grow in progressively from the developing lung vasculature, first as a common pulmonary vein from both lungs. This vein fuses into the back of the left atrium (Wessels et al, 2000). As the atrium expands, the common pulmonary vein becomes increasingly absorbed into the back wall, such that first 2, then 4 of its distal branches eventually enter independently into the left atrium, 2 from the left and 2 from the right lung (see Figure 50-9, *B*). The original atrial segment of the heart tube is not part of the functioning atria in the mature heart, instead relegated to the right and left atrial appendages.

AORTIC ARCH DEVELOPMENT

The primitive heart tube connects to the aortic sac, the precursor to the ascending aorta, and begins pumping to the developing systemic circulation of the embryo as soon as it is formed. The aortic sac connects to paired dorsal aortae posteriorly via an aortic root, which gives rise to a series of arches, the branchial arches (Figure 50-10, *top*). It is along these arches that the neural crest migrates into the conotruncus and supports development of the arch arteries. Again these are paired structures, and there are a total of six pairs, although not all are patent at the same time. Arches 1 to 4 carry the blood flow in the 4-week embryo.

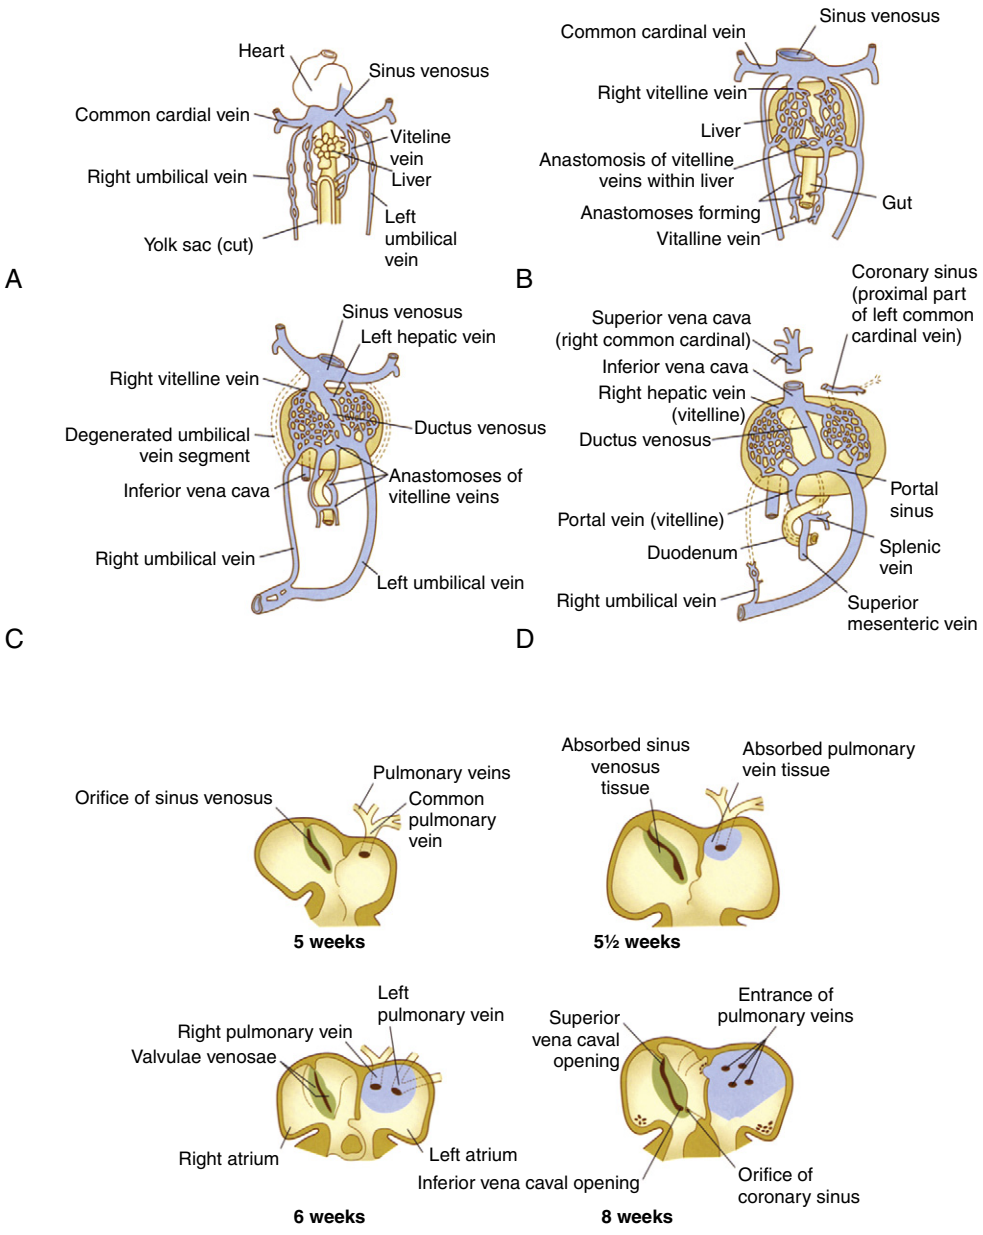

FIGURE 50-9 Stages of development of the systemic veins (*top*) and pulmonary veins (*bottom*). Stages of systemic vein development are shown in **A** to **D**, during which the paired umbilical, vitelline, and cardinal veins give rise to the single umbilical vein, liver vasculature including the portal system, and the inferior and superior vena cavae. Stages of pulmonary vein development are shown by week gestation as labeled; the common pulmonary vein progressively absorbs into the back wall of the left atrium. (*From Carlson BM:* Human embryology and developmental biology, *ed 4, Philadelphia, 2009, Mosby, pp 452-453.*)

Arches 1 and 2 mostly regress completely, although parts contribute to some of the arteries of the face. Arch 3 does not persist as an arch, but contributes to the formation of the carotid arteries, both left and right. The left limb of arch 4 remains in continuity with the aortic root, together making up the true aortic arch and its first branch, the brachiocephalic (innominate) artery. The right limb of arch 4 becomes part of the right subclavian artery, which retains its proximal connection with the brachiocephalic artery (Waldo et al, 1996). This arch remodeling has occurred by 7 weeks' gestation; see Figure 50-10, *bottom*. In some cases, either independently or as part of another developmental cardiac defect, the right limb of arch 4 remains patent and the left forms the left subclavian artery—this forms a right aortic arch with mirror-image branching. Arch 5 is small and never fully develops. Arch 6 forms with the developing pulmonary artery vasculature and makes up the proximal left and right pulmonary arteries and the ductus arteriosus (Waldo and Kirby, 1993). The ductal arch persists throughout fetal life as another means of right-to-left shunt, allowing blood from the right ventricle to bypass the pulmonary circulation and cross over into the descending aorta.

CORONARY ARTERIES

The coronary arteries were for many years assumed to sprout from the ascending aorta and grow over the surface of the heart. This is now known to be incorrect. The coronary arteries derive from the epicardium of the heart. Early in development, bilateral clusters of cells appear near the septum transversum, where the liver bud approaches the heart. These cells spread out over the surface of the heart as an epithelium, forming the epicardium. Some of

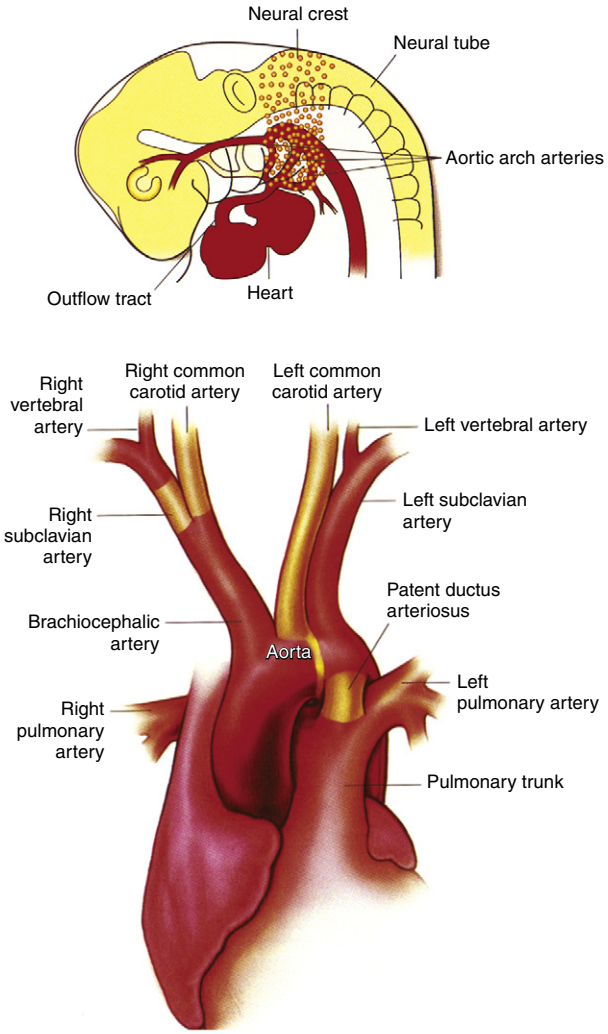

FIGURE 50-10 *Top*, Migration pattern of neural crest cells into pharyngeal arches 3, 4, and 6. *Bottom*, Normal aortic arch at term. Most of the pharyngeal arch segments have regressed. The third arch persists in part as the left and right common carotid arteries. The left fourth arch persists as the true aortic arch, while a portion of the right fourth arch makes up the proximal right subclavian artery. The sixth arch persists as the ductus arteriosus (ductal arch). (*From Kirby ML: Contribution of neural crest to heart and vessel morphology. In Harvey RP, Rosenthal N, editors:* Heart development, *San Diego, Calif., 1999, Academic Press, pp 180-181.*)

the epicardial cells delaminate from the epithelium and migrate into the myocardium below. Lineage tracing studies in the chicken have shown these cells to form the coronary vasculature, both endothelial cells and arterial smooth muscle, and cardiac fibroblasts (Cheng et al, 1999; Mikawa and Fischman, 1992; Mikawa and Gourdie, 1996; Reese et al, 1999). The coronary vessels form, grow, and fuse with one another to form a working vasculature. This corresponds with the process of growth and trabeculation of the ventricles. With increasing complexity and thickness of the myocardium, simple diffusion of nutrients from the blood inside the heart is no longer adequate. The coronary vasculature, then, provides the necessary blood supply to a working myocardium by extending its surface vessels on the right and left to plug into the aorta just above the aortic valve. It is likely that neural crest signaling plays an important guiding role here; this has been suggested in mammals by the presence of neural crest cells in the proximal coronary arteries (Carlson, 2004). Detailed studies in chick have not supported the presence of neural crest in the coronary arteries, however (Waldo et al, 1994). Occasionally this process can go awry, and a coronary artery (usually the left) can join the pulmonary artery instead of the aorta. This does not damage the fetal myocardium given the low oxygen state of the fetus, with little difference in oxygen tension between the aorta and pulmonary artery. After birth, however, ischemia sets in rapidly, often causing a significant myocardial infarction early in life.

CONDUCTION SYSTEM

There has been controversy regarding the origin of the conduction system, and again this controversy was recently resolved. The conduction system was suspected to originate from neural crest by many investigators, thus migrating in from outside the heart. Lineage tracing studies show conclusively that the cells of the conduction system actually differentiate in situ from myocytes (Cheng et al, 1999; Gourdie et al, 1998; Hyer et al, 1999; Moorman et al, 1997; Waldo et al, 1994). There is evidence that the developing coronary vasculature is a source of signaling for this transdifferentiation to occur; the conduction system tends to develop alongside coronary vessels (Hyer et al, 1999). Conduction system myocytes express different markers, junctions, and have different action potential profiles that allow for automaticity (Alyonycheva et al, 1997; Hoogaars et al, 2007; Moorman et al, 1997; Takebayashi-Suzuki et al, 2001; Wessels et al, 1992). Under normal conditions, the automaticity of the remaining conduction system is suppressed as the dominant pacemaker of the heart forms, the sinoatrial (SA) node. The SA node tends to have the fastest depolarization and to set the pace for the heart rate starting at about 1 month's gestation (Phoon, 2001). If the SA node slows down for any reason, other "pacemakers" will substitute. Atrial myocytes tend to have the next most rapid automatic rates, followed by the His bundles, then by ventricular myocytes. The heart rate in a 5-week fetus is 100 beats per minute (Phoon, 2001). This increases gradually to a rate of 160 beats per minute by 8 weeks' gestation, then declines slightly during gestation to the 120s to 130s (Phoon, 2001).

PHYSIOLOGY OF TRANSITION

The fetal heart and circulation at the end of 9 weeks are completely formed (Phoon, 2001). As depicted in Figure 50-11, there are four chambers of the heart, two atria in communication via a patent foramen ovale, and two ventricles with complete septation. The left ventricular myocardium is configured differently from the right such that it is capable of working under higher pressure (afterload). There are fully competent atrioventricular valves (the mitral and tricuspid) and fully competent semilunar valves (the aortic and pulmonary) that ensure one-way flow through the heart. The venous blood from the systemic and pulmonary circulations return fully to the atria. The arterial blood is pumped to the body and to the lungs via the great arteries, with a communication between the two via the patent ductus arteriosus.

Before birth, the placenta is a critical component of the fetal circulation, with a single umbilical vein and two umbilical arteries (see Figure 50-11). A full 50% of the fetal blood volume is in the placenta, and 50% in the body. In the fetus, the systemic cardiac output is combined from left and right ventricles, with the right ventricle actually contributing more than the left to the total (approximately 65% vs. 35%) (Teitel, 1992). This is via the "ductal arch" connecting the main pulmonary artery to the ductus arteriosus and descending aorta. The aortic arch contributes about 60% of its flow to the head and neck vessels, and the rest combines with the ductal flow to reach the lower body and return to the placenta. Blood returning from the placenta (oxygenated) returns via the umbilical veins through the ductus venosus to the IVC and right atrium. This blood is under higher pressure than the systemic return from the fetus and is streamed such that at least 25% is directed across the foramen ovale into the left atrium and systemic circulation. The remainder combines the SVC return to cross the tricuspid valve into the right ventricle. Only about 10% of the right ventricular output actually goes to the lungs; this small amount of blood returns to the heart via the pulmonary veins into the left atrium, mixes with the oxygenated blood that has crossed the foramen ovale from the right atrium, and passes on to the systemic circulation (Teitel, 1992).

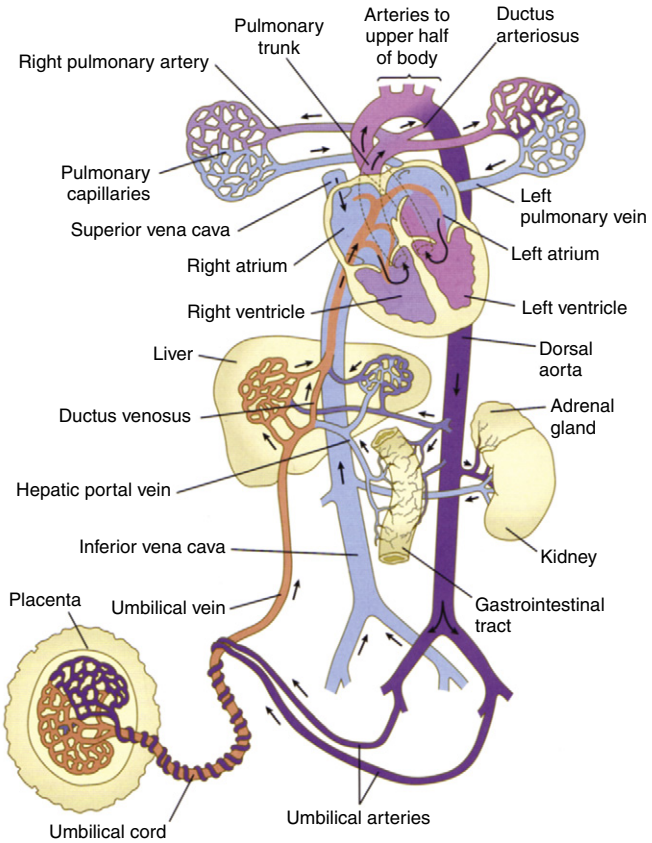

FIGURE 50-11 (*See also Color Plate 20.*) **The fetal circulation at term.** Deoxygenated blood is indicated in *dark gray* and oxygenated in *light gray*, with *shades in between* indicating mixing of blood. Oxygenated blood returns from the placenta to the heart and mixes with deoxygenated blood from the fetal systemic veins. Note that the upper body receives higher oxygen content than the lower body, as deoxygenated blood enters the descending aorta via right to left flow at the ductus arteriosus. (*From Carlson BM:* Human embryology and developmental biology, *ed 4, Philadelphia, 2009, Mosby, p 466.*)

After birth, two major factors trigger changes in circulation. These are the initiation of respirations with lung expansion and alveolar gas exchange, and cutting of the umbilical cord. The result is a drastic reduction in IVC return to the right side of the heart as the placental flow ceases; at the same time there is a drastic increase in capacity of the pulmonary circulation. Thus, return to the right atrium decreases and return to the left atrium increases, as does left atrial pressure. This forces the flap of the foramen ovale up against the atrial wall, reducing the volume and reversing the direction of atrial level shunting. Thus the fetus has a large patent foramen ovale with right-to-left flow, which after birth becomes a smaller orifice with left-to-right flow. Approximately 20% of older children and adults retain a small patent foramen ovale, with a trivial left-to-right shunt. Also immediately after birth, the increased oxygen tension of the blood that occurs with breathing causes the ductus arteriosus to begin constricting (functional closure). This is a function of smooth muscle within the wall of the ductus arteriosus and is prostaglandin sensitive. After functional closure, the permanent process of anatomic closure, involving apoptosis of smooth muscle and proliferation of connective tissue, converts the ductus arteriosus into a fibrous ligament (the ligamentum arteriosus). A similar but slower process occurs in the ductus venosus, also causing it to be closed by fibrosis.

SUMMARY

We have reviewed heart development, with attention to the morphology, cell biology, genetics, and physiology of the heart as it forms and remodels. The field of developmental biology of the heart continues to advance rapidly on all of these fronts. New technologies allow earlier and earlier visualization of the developing human heart, recently as early as week 6 of gestation by cardiac MRI (Dhanantwari et al, 2009), and week 10 to 11 by cardiac ultrasound (Becker and Wegner, 2006; Bennasar et al, 2009; Cook et al, 2004; Gembruch et al, 2000; Marques Carvalho et al, 2008; Neuman and Huhta, 2006; Vimpelli et al, 2006; Weiner et al, 2002). Early ultrasound has the additional benefit of assessment of cardiac physiology in the embryo, using Doppler technology Phoon, 2001. Novel genetic techniques allow us to apply what is learned from animal models to humans, and to recreate human disease in animal models with greater specificity. The common goals to be applied to human disease are early recognition of congenital heart malformations, prevention where feasible, and state-of-the-art intervention to allow an abnormal heart to function as normally as possible. Currently such intervention is surgical and cardiac catheterization–based and continues to evolve. In the future, gene therapy, cardiac stem cell grafting, and in vitro tissue engineering will likely be added to the therapeutic potentials for patients with congenital heart malformations.

CHAPTER 51

Cardiovascular Compromise in the Newborn Infant

Istvan Seri and Barry Markovitz

Although the prevalence of hypotension in the neonates admitted for intensive care is unclear, up to 50% of very low birthweight (VLBW) neonates present with blood pressure values considered to be low in the immediate transitional period (McLean et al, 2008). However, VLBW neonates account for only around 25% of all neonates diagnosed with hypotension in neonatal intensive care units. The lack of clear data on the prevalence of neonatal hypotension is primarily due to the uncertainty about the lower limit of the gestational- and postnatal-age dependent normal blood pressure range in neonates (Engle, 2008). This is illustrated, among others, by the significant differences in the prevalence of the use of vasopressor/inotropes in preterm neonates during the transitional period among different intensive care units across the nation (Al-Aweel et al, 2001).
