Shock is a "state of cellular energy failure resulting from an inability of tissue oxygen delivery to satisfy tissue oxygen demand" (Singer, 2008). As long as pulmonary gas exchange is adequate, shock is caused by hypovolemia, cardiac or vasoregulatory failure, or a combination of these etiologies. According to this definition, when oxygen delivery is inadequate to meet oxygen demand, the organs will fail. This situation, if not corrected, will result in irreversible damage and ultimately death. Oxygen delivery to the organs is dependent on many factors, but fundamentally on the oxygen content of the blood and the volume of blood flowing to those organs. Because oxygen content is primarily determined by the hemoglobin concentration and oxygen saturation, with less contribution from the dissolved oxygen (see later discussion), it is relatively easily evaluated and monitored in the newborn intensive care unit. However, reliably assessing systemic and organ blood flow and tissue oxygen delivery and consumption at the bedside is difficult. These parameters need to be continuously measured in absolute numbers to provide adequate information on the rapidly changing hemodynamic status in sick preterm and term infants. Recent advances in our ability to monitor systemic and organ blood flow and tissue oxygenation as well as vital organ (brain) function at the bedside will likely lead to a better understanding of the complex hemodynamic changes associated with neonatal cardiovascular compromise (Cayabyab et al, 2009). These advances should lead to the development of treatment modalities more appropriately based on the etiology, pathophysiology, and phases of shock, thereby improving clinically relevant outcomes.

At present in clinical practice, tissue perfusion is routinely assessed by monitoring heart rate, blood pressure, capillary refilling time, acid-base status, serum lactate levels, and urine output. However, recent Doppler ultrasound and near infrared spectroscopy (NIRS) data have highlighted that these parameters are relatively poor, although at present are the only routinely available, indicators of acute changes in organ blood flow and tissue oxygen delivery in critically ill neonates (Kluckow and Evans, 1996, 2000; Lopez et al, 1997; Pladys et al, 2001; Tyszczuk et al, 1998). These observations and the lack of evidence that treatment of neonatal cardiovascular compromise improves outcomes (Barrington et al, 2006; Seri and Noori, 2005) call for a paradigm shift in our thinking about pathophysiology, diagnosis, and treatment of neonatal shock. This suggests that the assessment of the hemodynamic status in critically ill neonates should include the complex interactions among blood flow and blood pressure as well as tissue oxygen delivery and consumption (Cayabyab et al, 2009; Noori and Seri, 2008).

PATHOPHYSIOLOGY, PHASES, AND ETIOLOGY OF NEONATAL SHOCK

PRINCIPLES OF OXYGEN DELIVERY

Oxygen is the most vital substrate necessary for mitochondrial respiration and is not stored in the body. As mentioned earlier, interruption of oxygen supply to cells can result in irreversible damage (sometimes within minutes), particularly in vital organs such as the brain and myocardium.

Oxygen delivery ($\dot{D}O_2$) to the tissues is the "raison d'être" of the cardiorespiratory system, and shock is therefore defined as inadequate systemic tissue oxygen delivery (see earlier). Oxygen delivery can be expressed as

$$\dot{D}O_2 = \text{cardiac output (CO)} \times \text{arterial oxygen content } (CaO_2)$$

where

$$CO = \text{heart rate (HR)} \times \text{stroke volume (SV)}$$

and

$$CaO_2 = [1.34 \times \text{hemoglobin concentration [Hb]} \times \text{arterial oxygen saturation } (SaO_2)] + [0.003 \times \text{arterial partial pressure of oxygen } (PaO_2)]$$

Stroke volume is the result of complex interplay among preload, afterload, and contractility (Figure 51-1), all three of which are, at present, impossible to monitor reliably and continuously in real time at the bedside. Preload is the end-diastolic volume of the ventricle (a three dimensional reflection of pre-contractile myocardial cell fiber-length), and, up to a point, the greater the preload, the larger the stroke volume (the Frank-Starling relationship). Afterload is the force the ventricle must generate against the systemic or pulmonary vascular resistance. As long as appropriate perfusion pressure is ensured, the lower the afterload, the better the cardiac output. Contractility (the

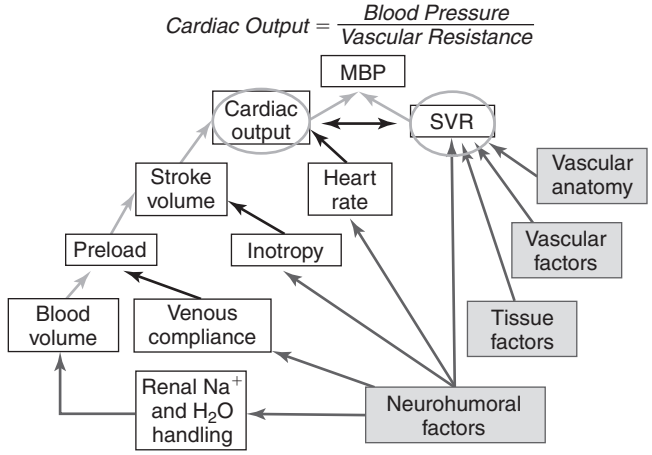

FIGURE 51-1 Factors regulating cardiac output, blood pressure, and systemic vascular resistance. From a physiologic standpoint, SVR and cardiac output are the regulated (independent) variables and MBP is the dependent variable. *MBP*, Mean blood pressure; *Na+*, sodium; *SVR*, systemic vascular resistance. *(Modified from Klabunde RE, www.cvphysiology.com.)*

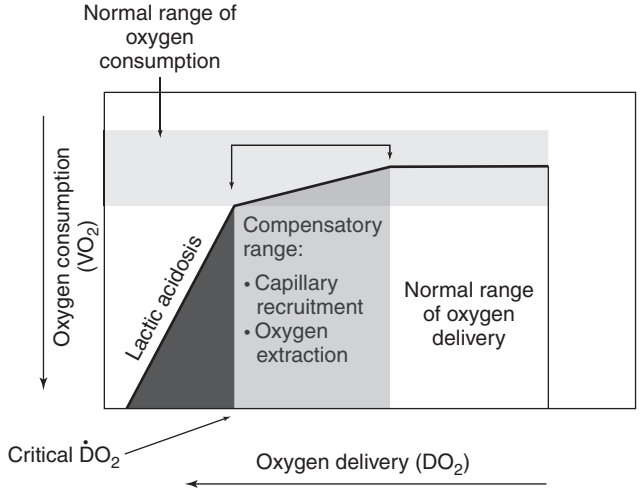

FIGURE 51-2 Relationship between oxygen consumption and delivery. In the normal range of oxygen delivery, oxygen consumption is unaffected by changes in the delivery rate of oxygen to the tissues. As oxygen delivery decreases below the normal range, tissue oxygen consumption remains in the normal range for a while because of activation of local compensatory mechanisms such as capillary recruitment and increased oxygen extraction. However, when oxygen delivery decreases to the "critical" point, compensatory mechanisms can no longer satisfy tissue oxygen demand, and anaerobic metabolism commences, resulting in significantly decreased ATP and increased lactate production.

intrinsic ability to generate force per unit time) may be assessed noninvasively but not continuously by echocardiogram. However, at present most of the measures of cardiac contractility are both preload and afterload dependent. Hence, contractility is not truly an independent variable. Typically, cardiac output in neonates is considered heart rate–dependent, because the neonate's ability to augment stroke volume is somewhat limited compared to children or adults.

From this simple model, it is easily appreciated that if there is an acute decline in CaO_2, by a decrease in either the [Hb] or SaO_2 or both, the cardiac output will increase in response to maintain $\dot{D}O_2$. On the other hand, because neither [Hb] nor SaO_2 can be physiologically increased rapidly, there is no acute compensation for a low cardiac output due to decreases in myocardial contractility and/or preload.

Oxygen consumption can be similarly readily expressed as

$$\dot{V}O_2 = CO \times (CaO_2 - C\bar{v}O_2)$$

where $C\bar{v}O_2$ is the mixed venous oxygen content.

This relationship is based on the Fick principle, from which, knowing flow rate and arterial-venous content difference of a trace element (in this case, oxygen), one can calculate the uptake or removal rate of the tracer.

Normally $\dot{D}O_2$ and $\dot{V}O_2$ are well matched, and O_2 extraction is usually approximately 25%. If the SaO_2 is 100%, SvO_2 would be expected to be 75%. If cardiac output falls, $\dot{V}O_2$ may be maintained constant by capillary bed vasodilation and recruitment and/or by increased O_2 extraction by the tissues. Increased O_2 extraction is manifested as a lower $C\bar{v}O_2$ and therefore greater $CaO_2 - C\bar{v}O_2$ difference. The relationship between $\dot{D}O_2$ and $\dot{V}O_2$ may be graphically displayed as in Figure 51-2. Once oxygen extraction is maximal, at the critical $\dot{D}O_2$ threshold, anaerobic metabolism ensues, resulting in lactic acidosis. If not reversed, the oxygen debt accumulates, and organ failure and death will ensue. In general, during aerobic metabolism 38 mol ATP is produced per 1 mol glucose, whereas during anaerobic metabolic conditions, 2 mol ATP and 2 mol lactate are produced per mol glucose.

Before reaching the stage of delivery-dependent $\dot{V}O_2$, the SvO_2 can be used as a proxy for $\dot{D}O_2$. Assuming $\dot{V}O_2$, [Hb], and SaO_2 are constant over a short period of time, a decline in SvO_2 represents a decreasing cardiac output. SvO_2 may be measured intermittently via a catheter—ideally placed in the pulmonary artery in a patient without intracardiac shunts to obtain a true mixed venous sample. In practice, central venous oxygen saturation is used ($ScvO_2$), measured with a catheter placed at the superior vena cava–right atrial junction. A catheter too low in the right atrium may measure very desaturated blood streaming from the coronary sinus or hepatic veins. Catheters with an oximetric probe at the tip may be used for continuous $ScvO_2$ monitoring in real time. However, for several reasons, measurement of $ScvO_2$ is not done routinely in neonates in neonatal intensive care units except for some neonates with congenital heart disease in the postoperative period following surgical correction of the cardiac condition.

In general, these principles are valuable guides to understanding and managing global $\dot{D}O_2$ and $\dot{V}O_2$, but they do not help us readily when evaluating individual organ $\dot{D}O_2$. Furthermore, the limitations of measuring $\dot{V}O_2$, $\dot{D}O_2$, and even just $ScvO_2$ are often daunting. However, regional tissue oxygen saturation (rSO_2) can be assessed noninvasively with NIRS in different tissues including the brain, kidneys, intestine, and muscle (see later discussion).

Finally, there is a class of neonates where calculations using the Fick principle can be critical in directing therapy. Newborns with congenital heart disease and intracardiac shunts may have perturbations in the usual pulmonary to systemic blood flow ratio (Qp:Qs). Normally, of course, in

patients with parallel circulations and no shunts, Qp:Qs = 1. By comparing the oxygen utilized by the body with that taken up by the lung, Qp:Qs can be estimated.

$$Qs = \dot{V}O_2/(CaO_2 - C\bar{v}O_2)$$

and

$$Qp = O_2 \text{ uptake}/(CpvO_2 - CpaO_2)$$

where pa is pulmonary artery and pv is pulmonary vein.

After substituting and eliminating common terms,

$$Qp{:}Qs = (SaO_2 - SvO_2)/(SpvO_2 - SpaO_2)$$

This formula usually requires two assumptions (unless being measured directly as in the cardiac catheterization laboratory); first, that $SpvO_2$ is 95% to 100%, and second, that SvO_2 measured through a central venous line reflects a mixed venous sample (see also Chapter 55).

The value of this calculation can be easily illustrated with an example. A newborn infant with hypoplastic left heart syndrome is found to have an SaO_2 of 95% and SvO_2 of 80%. Using the formula just given, assuming a $SpvO_2$ of 100% and recognizing that SaO_2 and $SpaO_2$ are the same in this patient, we arrive at a Qp:Qs of 3:1. Such an imbalance may result in congestive heart failure from pulmonary overcirculation (the single right ventricle is now doing 4 cardiac outputs/minute), or there will be inadequate systemic blood flow resulting in shock, or both. This explains why we "aim" for an SaO_2 of 75% in such infants (ideally), because this would represent a Qp:Qs of 1:1.

PHASES OF NEONATAL SHOCK

From a pathophysiologic standpoint, three phases of shock depicting advancing severity have been identified (McLean et al, 2008; Zaritsky and Chernow, 1984).

In the "compensated phase," complex neuroendocrine and autonomic compensatory mechanisms maintain perfusion and oxygen delivery in the normal range to the vital organs (brain, heart, and adrenal glands) at the expense of decreased perfusion to the remaining organs (nonvital organs). This is achieved by vasodilation and vasoconstriction of the vessels to vital and nonvital organs, respectively, in response to a fall in perfusion pressure and/or oxygen delivery (Iwamoto, 1993; Sheldon et al, 1979). Blood pressure is maintained within the normal range, and heart rate increases. As perfusion of nonvital organs is decreased because of the compensatory vasoconstriction of their vascular beds, there often are clinical signs of compromised nonvital organ function such as decreased urine output. In addition, signs of poor peripheral perfusion can often be detected, such as cold extremities and prolonged capillary refill time.

If adequate treatment is not commenced, the infant will most likely develop hypotension due to failure of the neuroendocrine and autonomic mechanisms, and shock enters its "uncompensated phase." Systemic perfusion (cardiac output) will decrease, perfusion of all organs including the vital organs becomes compromised, and lactic acidosis develops (Zaritsky and Chernow, 1984).

If treatment is ineffective in the uncompensated phase of shock, multiorgan failure develops and shock may enter its "irreversible phase," where permanent damage to the various organ systems occurs and further interventions will be ineffective in reversing the patient's condition.

DEVELOPMENTAL REGULATION OF CARDIAC OUTPUT AND ITS DETERMINANTS

Cardiac output is the product of stroke volume and heart rate and is determined by the amount of blood returning to the heart (preload), the strength of myocardial contractility, and the resistance against which the heart must pump (afterload). However, it is important to note that afterload and vascular resistance should not be used interchangeably. Rather, afterload is the load or force the heart faces during contraction and is affected by the impedance of the central vasculature, the resistance of the peripheral vascular beds, the ventricular mass, and the inertia of the blood. If myocardial function is intact, cardiac output depends solely on preload and afterload according to the relationships described by the Starling curve.

Therefore, low cardiac output and thus low systemic blood flow can result from various combinations of the three determinants of cardiac output: low cardiac preload, poor myocardial contractility, or high cardiac afterload. Decreases in preload lead to diminished stroke volume and cardiac output, and it is most often caused by low effective circulating blood volume. This can be due to loss of circulating blood volume following hemorrhage (absolute hypovolemia), or the circulating volume may be inadequate for the vascular space as in vasodilatory shock or as a side effect of administration of lusitropes (relative hypovolemia). Because approximately 75% of the circulating blood volume is on the venous side of the circulation at any given point in time, the increases in venous capacitance caused by venodilation significantly contribute to relative hypovolemia under these circumstances. Because preload is also augmented by the negative intrathoracic pressure generated at each spontaneous inspiration, the positive intrathoracic pressure associated with positive pressure mechanical ventilation reduces venous return and hence preload and cardiac output (Biondi et al, 1988; Henning, 1986).

The strength of myocardial contractility depends on the filling volume and pressure, and the maturity (Friedman, 1972) and integrity of the myocardium. Thus, decreases in preload (hypovolemia, cardiac arrhythmia) as well as prematurity (especially extreme immaturity), hypoxic insults, and infectious (viral or bacterial) agents (Walther et al, 1985) all negatively affect the ability of the myocardium to contract with resultant decreases in cardiac output.

If cardiac afterload is too high, the ability of the myocardium to pump against the increased resistance may become compromised, and cardiac output may fall (Osborn et al, 2002; Roze et al, 1993). Such increases in afterload are associated with enhanced endogenous catecholamine release during the period of immediate postnatal adaptation along with loss of the low-resistance placental circulation. Similar increases in afterload are seen in hypovolemia, hypothermia, or when inappropriately high doses of vasopressor-inotropes are being administered to a patient with intact cardiovascular adrenoreceptor responsiveness (Seri, 2006). High afterload can affect either ventricle, and if the output of one of the ventricles is reduced, this will affect the function of the other ventricle, especially when the

fetal channels are closed. For instance, if the right ventricular output is low because of high pulmonary vascular resistance, the amount of blood traversing the lungs to the left ventricle will be reduced, leading to low systemic blood flow with blood pooling in the systemic venous system.

Hemodynamic changes during transition to extrauterine life have special implications, especially for the preterm neonate. With delivery and the separation of the placenta, the fetal circulation is replaced so that the systemic and pulmonary circuits separate and the cardiovascular system functions as a circulation in series (Kiserud and Acharya, 2004). However, when this process is compromised by ductal patency, the increase in SVR and blood pressure combined with the decrease in pulmonary vascular resistance (PVR) results in left-to-right shunting across the ductus arteriosus (Evans et al, 2004; Noori and Seri, 2008). In the healthy term neonate, the rapidly constricting ductus arteriosus prevents the development of hemodynamically significant left-to-right shunting across the ductus. However, in the preterm neonate, shunts through the persistently patent ductus arteriosus (PDA) and/or foramen ovale may compromise circulation (Kluckow and Evans, 2000a). Indeed, in 50% to 70% of VLBW neonates, the ductus remains open (Noori and Seri, 2008; Reller et al, 1993) and, as the right-sided pressures fall, blood will shunt left to right from the systemic circulation back into the pulmonary circulation. In most VLBW neonates, pulmonary vascular resistance initially decreases relatively rapidly for physiologic and nonphysiologic reasons (Noori and Seri, 2008). Physiologic mechanisms most important in the postnatal decrease of PVR include the mechanical effects of initiation of air breathing on PVR and the increased postnatal oxygenation-associated direct, paracrine, and endocrine vasodilation (Faro et al, 2007). Iatrogenic causes include surfactant administration or the inappropriate targeting of higher arterial oxygen saturations (Kluckow and Evans, 2000a; Noori and Seri, 2008). With the left-to-right ductal shunting, pulmonary overcirculation develops and left ventricular output, the gold standard of bedside assessment of systemic perfusion, cannot be used as a measure of systemic perfusion (Figure 51-3) (Kluckow and Seri, 2008). Indeed, under these circumstances, left ventricular output measures systemic perfusion and ductal blood flow. In earlier studies investigating the posttransitional changes in systemic perfusion and/or the effects of vasoactive agents on cardiovascular function, this fact has often not been acknowledged (Lundstrom et al, 2000; Roze et al, 1993). Therefore, the conclusions drawn from some of these studies (Roze et al, 1993) need to be reevaluated. More recent studies have acknowledged this hemodynamic paradigm and used right ventricular output to assess systemic perfusion in the VLBW neonate during the transitional period (Abdel-Hady et al, 2008; Bouissou et al, 2008; Kluckow and Evans, 2000b; West et al, 2006). However, right ventricular output only represents systemic perfusion as long as left-to-right shunting across the foramen ovale does not become significant. In many preterm neonates, however, as left-to-right shunting across a nonconstricting PDA increases during the first 12 to 36 hours, left atrial volume and pressure increase, often leading to the development of a significant left-to-right shunt across the foramen ovale (Evans and Iyer, 1994b). The left-to-right shunt through the patent foramen ovale (PFO) will then render the use of right ventricular output as a measure of systemic blood flow inaccurate, because right ventricular output now represents systemic inflow and PFO flow (Kluckow and Seri, 2008). This hemodynamic scenario results in the lack of an acceptable conventional measure of systemic blood flow in these neonates. To circumvent this problem, superior vena cava (SVC) flow has been used as a measure of upper body blood flow in preterm neonates with the fetal channels open (Kluckow and Evans, 2000b; Kluckow, 2005). The use of SVC flow has provided novel insights into the mechanisms of transitional hemodynamics, such as the observation that intraventricular hemorrhage (IVH) develops in many VLBW neonates as systemic blood flow improves, resulting in reperfusion of the brain (Kluckow and Evans, 2000c). These observations are supported by the findings of studies using NIRS to assess cerebral oxygen delivery in VLBW neonates during the transitional period (Victor et al, 2006a, 2006b). Although there is an association between low SVC flow during the first postnatal days and poor neurodevelopmental outcome at 3 years of age in VLBW neonates (Hunt et al, 2004), the vulnerability of SVC flow measurements to error and the technical difficulties associated with its use as a surrogate measure of systemic blood flow have forced these measurements to remain a research rather than a clinical tool (Evans, 2008).

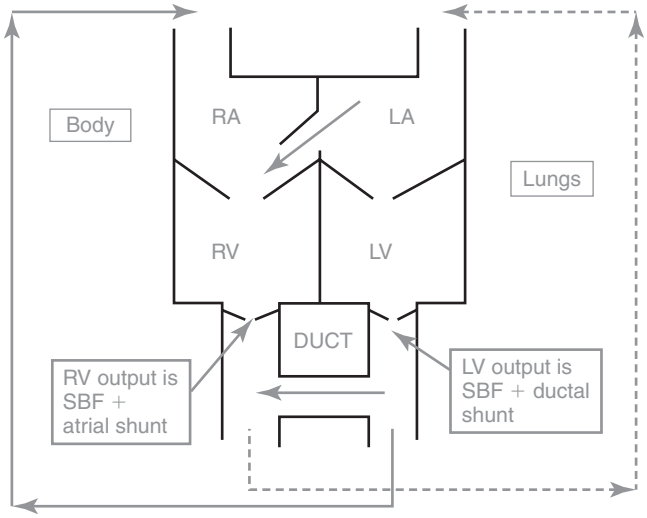

FIGURE 51-3 The impact of left-to-right shunting across the PDA and PFO on LVO and RVO measurements. Effect of left-to-right shunting across the PDA and foramen ovale on LVO and RVO. Under these circumstances, LVO represents the sum of total pulmonary venous return and ductal blood flow, whereas RVO measures the sum of systemic venous return and left-to-right shunting across the PFO. *LVO*, Left ventricular output; *PDA*, patent ductus arteriosus; *PFO*, patent foramen ovale; *RVO*, right ventricular output; *SBF*, systemic blood flow. (*From Kluckow M, Seri I: Clinical presentations of neonatal shock: the VLBW infant during the first postnatal day. In Kleinman CS, Seri I, editors:* Hemodynamics and cardiology. Neonatal questions and controversies, *Philadelphia, 2008, Saunders, pp 147-177.*)

DEVELOPMENTAL REGULATION OF SYSTEMIC BLOOD PRESSURE

Systemic blood pressure is the product of systemic blood flow and systemic vascular resistance. There is an association between low blood pressure and central nervous

system injury in the preterm neonate (Bada et al, 1990; Goldstein et al, 1995; Miall-Allen et al, 1987; Watkins et al, 1999). Yet, blood pressure correlates only weakly with blood flow in this patient population during the period of immediate postnatal adaptation when the fetal channels are open (Kluckow and Evans, 2000b). Thus, in preterm infants during the first postnatal day, blood pressure may be low because resistance is low in the presence of normal or high blood flow. Alternatively, blood pressure may be normal or high because resistance is high in the presence of normal or low blood flow (Evans and Kluckow, 1996, 2000). The uncertainty surrounding the nature of the relationship between blood pressure and systemic blood flow during the transitional period results from our inability to appropriately define the normal blood pressure range (Engle, 2008) and systemic blood flow (see earlier), and to characterize the developmental regulation of organ blood flow and vital organ assignment (see later discussion) in the preterm neonate.

DEVELOPMENTAL REGULATION OF ORGAN BLOOD FLOW AND ITS AUTOREGULATION AND VITAL ORGAN ASSIGNMENT

Even very immature preterm neonates autoregulate their cerebral blood flow (CBF) (Seri et al, 1998; Tsuji et al, 2000; Tyszczuk et al, 1998). However, the autoregulatory blood pressure range in this patient population is believed to be narrow, and the "normal" blood pressure is very close to the lower elbow of the autoregulatory curve (Greisen, 2005, 2008). Organ blood flow autoregulation is impaired in preterm neonates who are more immature and sicker (McLean et al, 2008; Tsuji et al, 2000; Wong et al, 2008). In these patients, changes in blood pressure are mirrored by changes in CBF with a high coherence, and these babies are at higher risk for cerebral injury (O'Leary et al, 2009; Pryds et al, 1989; Tsuji et al, 2000; Wong et al, 2008). Factors that impair cerebral and other organ blood flow autoregulation include birth asphyxia, acidosis, infection, hypoglycemia, tissue hypoxia and ischemia, and sudden alterations in arterial carbon dioxide tension ($PaCO_2$) (Greisen, 2008). It is of clinical importance that the CO_2-CBF reactivity is more robust than the pressure-flow reactivity, as 1 mm Hg change in $PaCO_2$ results in 4% change in CBF, whereas 1 mm Hg change in blood pressure is associated with a 1% change in CBF only (Greisen, 2005; Müller et al, 2002). The impairment of CBF autoregulation in the preterm neonate during the immediate postnatal period has been proposed to contribute to cerebral injury with loss of vascular reactivity to both blood pressure and CO_2 (O'Leary et al, 2009; Pryds et al, 1989). However, the finding that impaired autoregulation may also be a consequence of a preceding ischemic insult (Greisen, 2008) makes clarification of this question particularly difficult.

The vessels of the vital organs respond to decreased perfusion pressure and/or oxygen delivery with vasodilation (i.e., high-priority vascular beds), whereas the vessels of the nonvital organs, with low-priority vascular beds, vasoconstrict. Several lines of evidence in human neonates and developing animals suggest that the assignment of the forebrain circulation to a high-priority vascular bed may not be complete at birth (Ashwal et al, 1984; Hernandez et al, 1982; Victor et al, 2006b). For instance, the vessels of the forebrain of dog pups vasoconstrict like those of a nonvital organ whereas the vessels of the hindbrain vasodilate in response to hypoxic exposure (Hernandez et al, 1982). The finding that CBF autoregulation also appears in the brainstem first and in the forebrain only later in gestation (Ashwal et al, 1984) supports the notion that there are developmentally regulated differences in the timing of the blood flow autoregulatory functions and vital organ assignment characteristics between the forebrain and the hindbrain. The cellular mechanisms responsible for the assignment of vital and nonvital organ status from a blood flow regulatory standpoint are poorly understood. Based on these findings, it is tempting to speculate that the diminished capacity of the forebrain vessels to vasodilate in the very preterm neonate during the complex process of cardiovascular transition after delivery may contribute to hypoperfusion of the forebrain. These neonates may present with blood pressure values in the perceived normal range while being in the compensated phase of shock. Because this early phase of shock is difficult to recognize immediately after delivery, forebrain hypoperfusion and, on adaptation to the extrauterine environment, the ensuing reperfusion can go unnoticed. This proposed vital organ assignment-associated reperfusion cycle might contribute to cerebral injury in the very preterm neonate (Noori et al, 2009).

To summarize the pathogenesis of the abnormal circulatory adaptation in the very preterm neonate, there is indirect evidence that the sudden increase in systemic vascular resistance after separation from the placenta combined with myocardial immaturity plays a role in the development of the low flow state (Kluckow and Evans, 2000b). Because the preterm myocardium is adapted to a low-resistance intrauterine environment, characterized by reduced contractile elements, and has a limited ability to respond to increased afterload (Hawkins et al, 1989; Takahashi et al, 1997), it likely struggles to cope with the sudden increase in vascular resistance immediately after birth. This is compounded by shunts out of the systemic circulation through the fetal channels and the negative circulatory effects of positive pressure ventilation. In addition, the vessels of the forebrain initially vasoconstrict as the compensated phase of shock develops. As the final outcome of these hemodynamic events, critically low systemic and forebrain blood flow develops in many of these patients even with blood pressure values in the suspected normal range. Then, as treatment, endocrine, neuroendocrine and other compensatory responses to stress are initiated, the cardiovascular system adapts, and systemic blood flow improves, with reperfusion of the organs including the forebrain. However, if the low flow state is severe, a reperfusion injury may occur during the period of cardiovascular stabilization, especially in the extremely vulnerable immature central nervous system. Thus, hemodynamic compensation of shock in the very preterm neonate during the immediate postnatal period may not protect against central nervous system injury. Finally, patients in the uncompensated phase of shock with recognized circulatory compromise face the very same hemodynamic scenario, as by definition reperfusion of all organs including the brain will take place.

DEVELOPMENTAL REGULATION OF CEREBRAL OXYGEN DEMAND-DELIVERY COUPLING

Very little is known about the regulation of oxygen demand–oxygen delivery coupling in neonates, especially in the transitional period. Yet, several lines of evidence indicate that the very preterm neonate is unable to couple cerebral oxygen demand with blood flow, and instead increases oxygen extraction when oxygen demand is increased (Victor et al, 2006a, 2006b). This phenomenon may be linked to the developmental delay in the vital organ assignment of the forebrain immediately after delivery (see earlier discussion).

PATHOGENESIS OF NEONATAL SHOCK

Etiologic Factors

The etiologic factors leading to the development of neonatal shock include hypovolemia, myocardial dysfunction, abnormal peripheral vasoregulation, or a combination of two or all three of these factors.

Hypovolemia

Hypovolemia may be absolute (loss of intravascular volume), relative (increased venous capacitance), or combined such as is often seen in septic shock. Hypovolemia results in cardiovascular compromise primarily by the decrease in cardiac output (systemic blood flow) caused by the decrease in preload. In addition, if blood loss is the primary cause of hypovolemia, the associated decrease in oxygen carrying capacity contributes to the development of the circulatory compromise. Hypovolemia is probably overdiagnosed in neonatology, because it is a relatively uncommon primary cause of circulatory compromise, especially during the first postnatal day. In the preterm newborn there is no evidence that hypotensive neonates as a group are hypovolemic (Barr et al, 1977; Wright and Goodhall, 1994). However, when hypovolemia occurs, it can be difficult to detect clinically.

Absolute hypovolemia in the newborn can be due to several conditions. Intrapartum fetal blood loss is usually caused by an open bleed from the fetal side of the placenta, and therefore it is likely to be detected. More difficult to diagnose is the closed bleeding of an acute fetomaternal hemorrhage or an acute fetoplacental hemorrhage. The latter can occur during delivery where the umbilical cord comes under some pressure (breech presentation or nuchal cord). Because the umbilical vein is occluded before the artery, blood continues to be pumped into the placenta, and if the cord is clamped early, this blood remains trapped in the placenta. This probably happens to some degree in all babies with tight nuchal cords who, as a group, have lower hemoglobin levels (Shepherd et al, 1985). However, in some neonates, a tight nuchal cord may also cause severe circulatory compromise (Vanhaesebrouck et al, 1987). Postnatal hemorrhage may occur from any site and is frequently associated with perinatal infections or severe asphyxia-induced endothelial damage and the ensuing disseminated intravascular coagulation. Finally, acute abdominal surgical problems and conditions associated with the nonspecific inflammatory response syndrome and subsequent increased capillary leak with loss of fluid into the interstitium can lead to significant decreases in the circulating blood volume. Iatrogenic causes of absolute hypovolemia include inadequate fluid replacement in conditions of increased insensible losses in the very preterm neonate and gastroschisis before closure of the defect, or the inappropriate use of diuretics.

Relative hypovolemia, that is, a decrease in the effective circulating blood volume, may occur in pathologic conditions leading to vasodilation such as in conditions associated with the nonspecific inflammatory response syndrome (sepsis, necrotizing enterocolitis [NEC], asphyxia, major surgical procedures, use of extracorporeal membrane oxygenation [ECMO]). In addition, the use of afterload-reducing agents (e.g., milrinone, PGE_2) may cause significant vasodilation (especially venodilation), thereby decreasing the effective circulating blood volume.

Finally, absolute and relative hypovolemia most frequently occurs in conditions associated with the nonspecific inflammatory response syndrome such as sepsis, asphyxia, and major surgical procedures.

Myocardial Dysfunction

Decreased myocardial contractility results in decreased cardiac output (primarily in stroke volume) and thus decrease in oxygen delivery to the tissues.

Acquired heart disease presenting as circulatory compromise includes primary cardiomyopathies, postasphyxial myocardial dysfunction due to hypoxic-ischemic injury, viral myocarditis, and myocardial dysfunction in the late stages of septic shock. Studies have shown a high incidence of ischemic electrocardiographic changes, elevated blood cardiac enzyme levels, and low cardiac output in neonates after intrapartum asphyxia (Primhak et al, 1985; Tapia-Rombo et al, 2000). For more detail on structural heart disease and cardiomyopathies, see Chapter 55.

Among the different types of congenital heart disease, structural heart defects that produce a ductus-dependent systemic circulation such as the hypoplastic left heart syndrome, critical coarctation, and critical aortic stenosis, if not diagnosed prenatally or immediately after delivery, classically present as acute circulatory compromise with pallor, tachypnea, impalpable pulses, and hepatomegaly as the duct starts closing. The presentation may be initially misdiagnosed as sepsis.

Abnormal Peripheral Vasoregulation

Peripheral vasodilation causes circulatory compromise by resultant decrease in cardiac output and blood pressure and the associated diminution in preload related to the venous return decrease. If myocardial function is intact, compensatory increase in the heart rate may maintain appropriate levels of tissue oxygen delivery for a period of time. Pathologic peripheral vasodilation in neonates occurs primarily in conditions associated with the nonspecific inflammatory response syndrome such as sepsis, NEC, asphyxia, major surgical procedures, use of ECMO, or respiratory distress syndrome of prematurity. It is of clinical importance that preterm neonates born to mothers with chorioamnionitis, especially if they have evidence of funisitis (fetal vessel inflammation), frequently present with hypotension and hyperdynamic, vasodilatory cardiovascular compromise at birth or shortly after delivery (Yanowitz et al, 2002, 2004, 2006).

Clinical Presentations of Shock in Neonates Associated With Multiple Etiologic Factors

Transitional Circulatory Compromise of the Very Preterm Neonate

The transitional circulatory changes in the first 12 to 24 hours after birth denote a period of unique circulatory vulnerability for the extremely preterm infant. During normal postnatal adaptation, pulmonary vascular resistance falls, systemic vascular resistance rises with removal of the placenta from the circulation, the ductus arteriosus closes, and the foramen ovale is closed by the reversal of the atrial pressure gradient. During this time frame, the left ventricle has to double its output. Given that the very preterm infant's cardiovascular system is adapted to the low-resistance intrauterine environment and its myocardium is immature, it is not surprising that these patients have difficulties during this critical period. In addition, as discussed earlier, developmentally regulated factors such as the state of vital organ assignment of the forebrain and cerebral oxygen demand-flow coupling make cardiovascular adaptation of the very preterm neonate an even more complex process (Ashwal et al, 1984; Hernandez et al, 1982; Noori et al, 2009; Victor et al, 2006b). It is important to note that there is much more to understand about the complex interactions between immediate postnatal cardiovascular adaptation and immaturity, organ development, myocardial and vasoregulatory function, and vital organ assignment.

Various studies have revealed an association between low blood pressure and central nervous system morbidities such as IVH (Bada et al, 1990; Miall-Allen et al, 1987; O'Leary et al, 2009; Watkins et al, 1999), white matter damage (Limperopoulos et al, 2007; Tsuji et al, 2000), and poor long-term neurodevelopmental outcome (Batton et al, 2009; Dempsey et al, 2009; Fanaroff et al, 2006; Goldstein et al, 1995; Martens et al, 2003; Soul et al, 2007). However, because blood pressure alone is not an accurate reflection of systemic and organ blood flow in this patient population during the immediate postnatal period (Kluckow and Evans, 1996, 2000; Lopez et al, 1997; Pladys et al, 2001; Tyszczuk et al, 1998), it is important to recognize that successful treatment of hypotension may not necessarily ensure normalization of organ blood flow. Furthermore, blood pressure in the normal range does not necessarily translate into normal cerebral blood flow and tissue perfusion in these patients, because their forebrain may initially function as a nonvital organ from a blood flow regulatory standpoint. This translates to the clinical situation discussed earlier, especially in very preterm neonates immediately after delivery. These patients are suspected to present with the compensated phase of shock with normal blood pressure and decreased "nonvital" organ blood flow, which in their case includes the forebrain. Because the compensated phase of shock is difficult if not impossible to diagnose in very preterm neonates in the transitional period, the clinician may not be aware of the ongoing hemodynamic compromise. Indeed, if only blood pressure is being followed to diagnose cardiovascular compromise, systemic blood flow can only be assumed normal if mean blood pressure is over 40 mm Hg during the first postnatal day in the preterm neonate born before 30 weeks' gestation (Osborn et al, 2001). However, when blood pressure and capillary refill time (CRT) are considered together, a mean blood pressure of ≥30 mm Hg and a CRT of ≤3 s have an 86% positive predictive value for a normal SVC flow used as a surrogate of systemic blood flow in these patients with the fetal channels open (Osborn et al, 2001).

Another special characteristic of the process of cardiovascular adaptation in this patient population is that early shunts through the preterm ductus arteriosus and foramen are not balanced and thus can produce left-to-right shunts of significant clinical importance (Evans and Kluckow, 1996; Kluckow and Evans, 2000a; Kluckow, 2005). Although the immediate postnatal physical constriction of the ductus is characterized by great variation (Kluckow and Evans, 2000a), in those cases in which constriction fails, very large shunts can occur within a few hours of birth, leading to high and not low pulmonary blood flow as previously thought. These abnormal hemodynamic changes may be further augmented by surfactant administration.

As discussed earlier in detail and depicted in Figure 51-3, in the transitional circulation of the preterm infant, neither ventricular output will consistently reflect systemic blood flow because of the shunts across the ductus arteriosus and foramen ovale (Evans and Iyer, 1994b; Evans and Kluckow, 1996). Consequently, measurement of either ventricular output can overestimate systemic blood flow by more than 100% in some cases (Evans and Kluckow, 1996; Noori et al, 2006). As mentioned earlier, SVC flow can be used as a marker of total systemic blood flow (Kluckow and Evans, 2000b), and serial measurements of SVC flow have been used to describe the natural history of systemic blood flow changes in preterm neonates in the early postnatal period (see Figure 51-1) (Kluckow and Evans, 2000c, 2001). These initial studies have found that around 30% of preterm neonates born before 30 weeks have a period of low systemic blood flow, mostly during the first 12 hours of life (Kluckow and Evans, 2000b). Gestational age was the dominant predictor of the low flow state with 70% of neonates born before 26 weeks' gestation having a period of low systemic flow compared to around 10% at 29 weeks. However, a more recent study (Paradisis et al, 2009) found only a <20% incidence of low systemic blood flow in neonates born before 26 weeks' gestation, suggesting that factors other than gestational age may also be important in the developmental low flow state after delivery. Advances in obstetrical, perinatal, and delivery room care, the mode of ventilatory support, and the diameter of the ductus arteriosus (Evans and Iyer, 1994a) are suspected additional factors associated with the decrease in incidence of low SVC flow of the very preterm neonatal population (Noori et al, 2009; Paradisis et al, 2009). The low-flow state can persist for up to 24 hours but usually improves thereafter. As discussed earlier, there is a strong relationship between recovery from the low-flow state and subsequent IVH (Kluckow and Evans, 2000c). The finding that IVH occurs after systemic blood flow has improved indicates the involvement of a hypoperfusion-reperfusion cycle in the pathogenesis of this injury. Follow-up to 3 years identified the low-flow state as a significant risk factor for poor neurodevelopmental outcome (Hunt et al, 2001). In

addition to low SVC flow, hypotension and pressure-passive CBF have also been implicated in the development of IVH (Limperopoulos et al; 2007; Pryds et al, 1989). As mentioned earlier, $PaCO_2$ is even a more potent regulator of CBF than blood pressure (Greisen, 2005; Müller et al, 2002). Hence, hypocapnia and hypercapnia in very preterm neonates during the immediate postnatal period are associated with periventricular leukomalacia (Khwaya and Volpe, 2008; Wiswell et al, 1996) and IVH (Fabres et al, 2007; Kaiser et al, 2006; McKee et al, 2009), respectively. In summary, abnormal circulatory adaptation during the early postnatal transition is one of the causative factors in adverse outcomes of preterm infants born before 30 weeks' gestation (also see earlier discussion).

Vasopressor-Resistant Hypotension

Although the just-described transitional problems may or may not present with low blood pressure (compensated or uncompensated phase of shock), there is a group of preterm neonates in whom persistent hypotension that is resistant to conventional vasopressor-inotropic support develops (Ng et al, 2001, 2006; Noori et al, 2006b; Seri et al, 2001; Watterberg, 2002). Although a well-recognized entity, the underlying systemic hemodynamic changes in this condition only recently have been characterized (Noori et al, 2006). These babies are more likely to be extremely preterm (<27 weeks) and/or have been critically ill or suffered a degree of perinatal asphyxia. The problem may be apparent on the first postnatal day (Ng et al, 2006) but may persist beyond and represent a state of vasodilatory shock with normal to high systemic blood flow and possibly supranormal cardiac output (Lopez et al, 1997). There are striking analogous features of this presentation in preterm neonates to those of vasodilatory shock described in adults, particularly the lack of responsiveness to vasopressor-inotropes (Landry and Oliver, 2001). Potential mechanisms for the uncontrolled vasodilation include dysregulated cytokine release, excess nitric oxide synthesis, overactivation of the K_{ATP} channels in the vascular smooth muscle cell membrane in response to tissue hypoxia, and downregulation of the cardiovascular adrenergic receptors (Hausdorff et al, 1990; Seri et al, 2001). In the preterm infant, the foregoing mechanisms are exacerbated by the immaturity-associated relative adrenal insufficiency (Cole, 2009; Watterberg et al, 1999; Watterberg, 2002) preceding asphyxia or may be secondary to the transitional circulatory failure as described earlier. In the term neonate, an association between congenital diaphragmatic hernia and relative adrenal insufficiency has also been reported (Pittinger and Sawin, 2000).

Sepsis

Although clinical evidence of circulatory compromise is a leading feature of many infectious processes in the newborn, the hemodynamics in neonatal septic shock have not been systematically studied. In older subjects, two distinct hemodynamic patterns occur: warm shock, characterized by loss of vascular tone, increased systemic blood flow, and low blood pressure, and cold shock, characterized by increased vascular tone, low systemic blood flow, and eventually falling blood pressure. Cold shock has been well described in the newborn (Meadow and Rudinsky, 1995), whereas the warm shock phase is more difficult to recognize clinically unless the blood pressure and the cardiovascular status in general are being closely monitored. The mediators of neonatal warm septic shock remain unclear, but in adult sepsis, dysregulated cytokine release and upregulated nitric oxide production as well as deficiency of vasopressin production play an important role (Landry and Oliver, 2001). The significance of this to newborn sepsis remains unclear, but it may have relevance to the vasopressor-resistant hypotension seen in preterm babies (Ng et al, 2001, 2006; Noori et al, 2006; Noori and Seri, 2008; Seri et al, 2001).

Pulmonary Hypertension With or Without Meconium Aspiration Syndrome

Term neonates with severe respiratory failure and pulmonary hypertension have a high incidence of low ventricular outputs (Evans et al, 1998). The low-output state is commonest in the early course of the disease, resolving spontaneously with time and/or clinical improvement. The causes of such circulatory compromise are probably multifactorial but include abnormal postnatal cardiovascular adaptation secondary to perinatal hypoxic-ischemic insult, the negative effects of positive pressure ventilation, and the systemic effect of raised pulmonary vascular resistance. In one study, low left ventricular output was a significant predictor of the need for ECMO in this patient population (Kinsella et al, 1992).

DIAGNOSIS OF CIRCULATORY COMPROMISE

There is no agreement regarding what constitutes the gold standard in diagnosing circulatory compromise. Conventionally, blood pressure has been and still is used as a gold standard. As mentioned earlier, recent data suggest that sole reliance on blood pressure can lead to inaccurate and sometimes significantly delayed diagnosis of circulatory compromise, especially in the very preterm infant during the immediate postnatal period. On the other hand, it is clear from the observations about vasodilatory shock that continuous blood pressure monitoring is imperative. The other commonly used clinical signs of circulatory compromise, such as increased heart rate, slow skin CRT, increased core-peripheral temperature difference, low urine output, and acidosis due to increased lactate production, aid in establishing the diagnosis of circulatory compromise in the preterm or term infant but have significant limitations.

Heart Rate and Blood Pressure

Heart rate is continuously, accurately, and routinely monitored in neonates requiring admission to neonatal intensive care units (NICUs). Because many factors other than those regulating the cardiovascular system affect heart rate, it has a limited yet widely utilized role in the diagnosis of circulatory compromise. As for the blood pressure, in babies with invasive intraarterial access, continuous and accurate measurement of this parameter is routinely done. The accuracy of the noninvasive oscillometric method is less certain, especially when severe hypotension develops. Normal ranges for blood pressure in babies of different gestations have been defined in the literature (epidemiologic

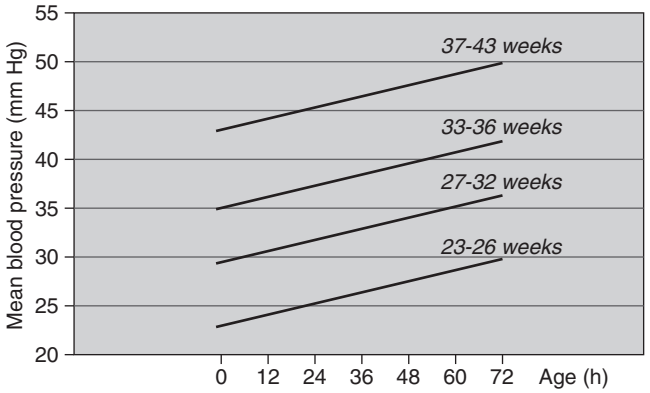

FIGURE 51-4 Gestational and postnatal age-dependent nomogram for mean blood pressure values in neonates during the first 3 days of life. The nomogram is derived from continuous arterial blood pressure measurements obtained from 103 neonates with gestational ages between 23 and 43 weeks. Each line represents the lower limit of 80% confidence interval of mean blood pressure for each gestational age group. Thus, 90% of infants for each gestational age group are expected to have a mean blood pressure equal to or greater than the value indicated by the corresponding line (the lower limit of confidence interval). (*From Nuntnarumit P, Yang W, Bada-Ellzey HS: Blood pressure measurements in the newborn*, Clin Perinatol *26:981-996, 1999.*)

definition of hypotension) and it is clear that gestation and postnatal age are the dominant influences on blood pressure (Lee et al, 1999, Nuntnarumit et al, 1999; for a comprehensive review, see Engle, 2008). The nomogram from the data of Nuntnarumit et al in Figure 51-4 shows the 10th percentile for mean blood pressure of babies from different gestations at different postnatal ages.

The normal gestational- and postnatal-age dependent blood pressure range is not known, primarily because it is affected by additional factors such as disease severity, history of perinatal insult, presence of infection or ductal shunting, and interindividual variations (Engle, 2008; McLean et al, 2008). In addition to the epidemiologic definition of hypotension, increasing severity of hypotension can be defined from a pathophysiologic standpoint as the blood pressure value at which CBF becomes pressure-passive (autoregulatory blood pressure threshold; the definition used for the pediatric and adult patient population), brain function is affected (functional blood pressure threshold), and tissue ischemia develops (ischemic blood pressure threshold) (McLean et al, 2008). Preliminary data are available for the autoregulatory and functional blood pressure threshold in very preterm neonates during the first few postnatal days (Munro et al, 2004; Victor et al, 2006b). However, there is no information on the ischemic threshold in very preterm neonates, and very little is known about these pathophysiologic measures of hypotension in the term neonate or in any neonate beyond the transitional period. Perhaps the best method to define hypotension would be the demonstration of causation between gestational- and postnatal-age dependent blood pressure values and clinically relevant outcome measures such as mortality or long-term neurodevelopmental disability. However, because there are no data available on this interaction, there is uncertainty about the normative values. Besides, treatment may have its own side effects; hence there is controversy about when to intervene in the critically ill neonate with suspected hypotension and circulatory compromise (Barrington and Dempsey, 2006; Noori and Seri, 2008).

In clinical practice, hypotension during the first postnatal day is usually defined in one of three ways: as a mean blood pressure <30 mm Hg, a mean blood pressure below the patient's gestational age in weeks at the time of birth (Lee et al, 1999), or, more recently, a blood pressure value that is accompanied by clinically detectable evidence of circulatory compromise (decreased urine output, poor peripheral perfusion, and/or lactic acidosis) (Dempsey et al, 2009). As mentioned earlier, there is only a weak relationship between mean blood pressure and SVC flow, a surrogate measure of systemic blood flow in preterm neonates with the fetal channels open in the immediate postnatal period (Kluckow and Evans, 1996, 2000; Lopez et al, 1997; Pladys et al, 2001). Thus, if blood pressure alone is used to guide treatment, patients in the unrecognized compensated phase of shock may not be treated appropriately. For instance, in the extremely preterm neonate with mean blood pressure between 20 and 40 mm Hg in the immediate postnatal period, the state of systemic blood flow and CBF is unclear based on the blood pressure values alone. Recent advances in our ability to apply complex, continuous cardiovascular monitoring providing data in absolute numbers using impedance-based electrical cardiometry, NIRS, and amplitude-integrated EEG combined with the intermittent use of Doppler flow measures hold the promise of gaining a better understanding of the hemodynamic changes occurring during transition and beyond in the neonatal patient population (Noori et al, 2009). However, at present only preliminary research data are available with the use of this complex approach.

Capillary Refill

Several recent studies have attempted to validate this widely used clinical tool for accuracy. However, there is no validated standard for assessing decreased peripheral perfusion and its relationship to systemic flow in the newborn. Further, in the different types of shock (warm vs. cold shock) the state of peripheral perfusion is different (vasodilation vs. vasoconstriction). Hence it is impossible to objectively assess the practical utility of this clinical tool in neonates. Accordingly, in VLBW neonates, a poor correlation was recently found between the capillary refill time, assessed on the forehead, sternum, and toe, and mean blood pressure, urine output, and SVC flow (Miletin et al, 2009). An earlier study documented a similar lack of tight relationship in VLBW neonates; only when capillary refill was >5 seconds did CRT have any clinically relevant degree of specificity (Osborn, 2001). Although a CRT of ≤3 seconds is traditionally accepted as normal, a CRT of 4.23 ± 1.47 seconds with a range of 1.63 to 8.78 seconds was reported in a large population of healthy newborns during the first 72 postnatal hours. CRT does not appear to change during the first 72 postnatal hours in healthy term newborns (Raju et al, 1999). Environmental, axillary, hand, and foot temperatures have been reported to indirectly relate to CRT (Raju et al, 1999). Interestingly, the duration of the pressure applied when eliciting CRT affects the measurement in term neonates <4 hours after delivery (LeFlore and Engle, 2005). This study also found

an unanticipated moderate, direct correlation between blood pressure and CRT with a prolongation of CRT at higher blood pressures in this patient population (LeFlore and Engle, 2005). In general, interobserver variability has been reported to be fair, but a variation in the measurement among the different sites (sternum, forehead, hand, and feet) may be significant, although this issue needs to be more systematically studied.

Core-Peripheral Temperature Difference

There are few data to support the accuracy of this test in older infants (Tibby et al, 1999). As for preterm neonates less than 30 weeks' gestational age, there was also no relationship between this measure and SVC flow in the immediate postnatal period (Osborn, 2001). However, because SVC flow measurements have their limitations, these studies need to be repeated when a more accurate and continuous measure of systemic blood flow assessment becomes available for neonates with fetal channels open.

Low Urine Output and Hyperkalemia

Urine output is a frequently utilized clinical measure to assess renal perfusion and function. However, because urine output is low during the first postnatal day as a result of delivery-associated increases in stress hormones (catecholamines, vasopressin, renin-angiotensin) causing renal vasoconstriction and increased tubular reabsorption of sodium and water, its value in assessing compensated shock during the transitional period is limited. After the first 2 to 3 days, however, a decrease in urine output may be the earliest clinical sign of compensated shock in neonates of all gestational ages. In addition, a strong relationship has been documented in very preterm infants between low SVC flow and subsequent low urine output and hyperkalemia (Kluckow and Evans, 2001). However, because hyperkalemia may occur in the very preterm neonate without oliguria (i.e., nonoliguric hyperkalemia of the extremely preterm neonate) (Vemgal and Ohlsson, 2007), and because there could be other causes of hyperkalemia (acidosis), hyperkalemia alone should not be used as a measure of poor systemic perfusion.

Lactic Acid, pH, and Base Excess

In a large series, pH and base excess were found to have little relationship with low SVC flow in preterm babies in the immediate postnatal period (Kluckow and Evans, 1999). This finding is likely explained by lack of a strong relationship between pH, base excess, and lactic acid levels in neonates (Deshpande and Platt, 1997). However, because serum lactate levels can now be sequentially followed routinely on blood gases, and because changes in serum lactate are informative of changes in the cardiovascular status, this indirect measure of cellular oxygen delivery and consumption has been used in clinical practice. Interestingly, combining a CRT of >4 seconds with an elevated serum lactate concentration of >4 mmol/L has a specificity of 97% for detecting a low SVC flow state in VLBW neonates during the first postnatal day (Miletin et al, 2009). One needs to keep in mind, though, that a given serum lactate level primarily represents past hemodynamic events and not necessarily the present state of cardiovascular function. Thus, as with urine output, by the time lactic acidosis develops and is detected, the initiating event may or may not be present anymore. It is not a surprise, therefore, that rising lactate levels are more predictive of adverse outcome than a high value early on followed by a subsequent decline (Deshpande and Platt, 1978).

Organ Blood Flow

With the use of Doppler ultrasonography and, more recently NIRS, blood flow to various organs can be assessed at the bedside. As for CBF, several methodologies have been studied in both preterm and term neonates including Doppler ultrasonography, xenon clearance, and NIRS (Greisen et al, 1984; Lemmers et al, 2006; Seri et al, 1998; Toet et al, 2005, 2006; Tsuji et al, 2000; Tyszczuk et al, 1998). Because peripheral arteries tend to be too small for size measurement, Doppler studies in such vessels are limited to parameters of velocity from which it is not possible to derive blood flow. Consequently, peripheral artery Doppler tends to be more useful for assessing changes over a time frame in which it is unlikely that the vessel size will have changed (Seri et al, 1998). Xenon clearance is not practical outside a research setting. However, recent advances in NIRS technology have introduced the potential of continuous assessment of brain, renal, mesenteric, and muscle oxygenation (i.e., blood flow) at the bedside in the critically ill neonate (Fortune et al, 2001; Lemmers et al, 2008; van Bel et al, 2008) (see next section).

Near-Infrared Spectroscopy

NIRS uses changes in oxygenation over time or the difference between oxygenated and deoxygenated hemoglobin to assess flow. The technology has been very useful as a research tool (Fortune et al, 2001; Lemmers et al, 2008; Meek et al, 1999a; Tsuji et al, 2000; Tyszczuk et al, 1998; van Bel et al, 2008). In addition, with better understanding of biophysical principles that govern light behavior in tissues, and the associated advances in software algorithms and sophisticated NIRS probe development, continuous assessment of regional tissue oxygenation (rSO_2) has become available and gained evidence-based application in neonatal intensive care (Adcock et al, 1999; Andropoulus et al, 2004; Lemmers et al, 2008; Nagdyman et al, 2008; van Bel et al, 2008).

Indeed, commercially available monitors with up to four channels can be now applied to infants, typically on the forehead to gauge cerebral rSO_2 and over the flank, felt to be measuring renal rSO_2. Although more validation is needed with invasive measurements (Nagdyman et al, 2008), it is evident that when cardiac output falls, the renal rSO_2 declines. First, cerebral rSO_2 may be preserved, but any interference with global cerebral blood flow can also be readily detected with this monitor. These monitors are very useful during cardiac surgical procedures on infants (Andropoulus et al, 2004; Azakie et al, 2005; Farouk et al, 2008), where precipitous drops in cerebral rSO_2 may be the only warning of a malpositioned venous or arterial cannula while on cardiopulmonary bypass. In addition, emerging findings suggest that monitoring rSO_2 in critically ill term and preterm neonates without congenital heart disease during transition to extrauterine life (van Bel et al, 2008) and treatment for various conditions such as preterm neonates with a PDA (Cayabyab et al, 2008; Lemmers et al,

2008), asphyxiated infants with or without cooling (Ancora et al, 2009; Meek et al, 1999b; Toet et al, 2006), or term neonates receiving ECMO (Fenik and Rais-Bahrami, 2009; van Heijst et al, 2004) provides clinically useful information (van Bel et al, 2008). Whether titration of therapy based on rSO_2 measurements in neonates with critical conditions other than congenital heart disease requiring surgery (Andropoulus et al, 2004) improves patients' outcomes remains unknown. In our experience, however, renal rSO_2 reliably declines well before signs of uncompensated shock such as hypotension or acidosis develop (see later discussion), enabling earlier intervention.

Echocardiographic Systemic Blood Flow Measures

In the mature circulation, systemic blood flow is the cardiac output. Although the output of both ventricles will be the same, cardiac output is traditionally measured from the left ventricular output. In clinical practice, Doppler ultrasound offers a noninvasive but noncontinuous method to measure cardiac output. Measuring blood flow directly in the pulmonary artery and ascending aorta enables us to evaluate outputs from the right and left ventricles, respectively (Alverson et al, 1982; Evans and Kluckow, 1996; Walther et al, 1985). However, as discussed earlier, in transitional circulation of the newborn infant, neither ventricular output will consistently reflect systemic blood flow because of the shunts across fetal channels (Evans and Iyer, 1994b; Evans and Kluckow, 1996; Kluckow and Seri, 2008). Use of SVC flow as a surrogate for systemic blood flow has been a valuable research tool offering insights into hemodynamic events unfolding during the immediate postnatal period when shunting across fetal channels precludes the use of traditional measures of systemic blood flow assessment (see earlier discussion) (Evans, 2008).

Doppler measures of left ventricular output have been validated against more invasive measures in neonates and older subjects (Mellander et al, 1987). Right ventricular output and SVC flow are less well validated but correlate well with left ventricular output in neonates with no confounding shunts (Evans and Iyer, 1994b; Kluckow and Evans, 2000; Tsai-Goodman et al, 2001). Despite this, the validity of these measures has been questioned based on comparison to cardiac output thermodilution measures in critical care patients (Notterman et al, 1989). However, thermodilution itself has an intrinsic error in that the volume of the required cold saline injection influences cardiac output (Tournadre et al, 1997). Thus, the quest for an ideal gold standard method continues.

There are significant intrinsic errors to Doppler flow measures as well. Intraobserver variability rates of around 10% and interobserver variability rates up to 20% are common (Hudson et al, 1990; Kluckow and Evans, 2000). Most of the error relates to vessel size measurement that is derived from a diameter. Thus, small differences are magnified in the conversion to a cross-sectional area. The other major problem of Doppler flow measurements is that there is reliance on ultrasound technology and echocardiographic skill that may not often be available 24 hours a day in many neonatal intensive care units.

In neonates, most studies quote a normal range for left and right ventricular output between 150 and 300 mL/kg/min (Alverson et al, 1982; Evans and Kluckow, 1996; Walther et al, 1985; West et al, 2006). It is important to note that, in the transitional neonatal circulation, left ventricular output can be affected by ductal shunting to a greater extent than the right ventricular output is affected by atrial shunting. Therefore, right ventricular output is a better measure of low flow than left ventricular output during the first 1 to 2 postnatal days. Accordingly, a relationship has been documented between indirect measurements of systemic (and thus cerebral) perfusion such as right ventricular output and blood pressure (and cerebral function) in preterm infants during the first 2 postnatal days. This is a period when ductal shunting significantly decreases the accuracy of left ventricular output measurements reflecting systemic blood flow (West et al, 2006). SVC flow may also be used to estimate systemic flow in the early postnatal period. The normal range in well preterm babies is between 40 and 120 mL/kg/min, with the median rising from 70 mL/kg/min at 5 hours of age to 90 mL/kg/min at 48 hours (Kluckow and Evans, 2000).

In summary, the mainstay of diagnosing neonatal circulatory compromise has been a combination of blood pressure measurement and evaluation of the previously described clinical parameters. However, none of these parameters has a sufficient degree of accuracy to allow it to be relied on as the sole evaluator of systemic blood flow and tissue perfusion. Therefore, the addition of echocardiographic and NIRS hemodynamic assessment to blood pressure monitoring and thorough continuous clinical evaluation of the patient are necessary to better understand changes in organ blood flow and tissue perfusion, especially in preterm neonates during the vulnerable period of immediate transition to extrauterine life. The goal should be to maintain normal systemic blood flow in the presence of an acceptable blood pressure using the normal range for blood pressure that controls for gestation and postnatal age and following the indirect clinical and laboratory signs of tissue perfusion (urine output, serum lactate levels, CRT). If there is no immediate access to echocardiography or NIRS technology, the clinician will have to rely on blood pressure monitoring while recognizing the limitations of this approach. Over the past few years, training in functional echocardiography for neonatologists has become available in a structured format in several programs in the United States and abroad (Kluckow et al, 2008), although the medicolegal implications of such training remain unknown.

TREATMENT

Selection of the most appropriate treatment strategy requires identification of the pathogenesis for neonatal shock (Kluckow, 2005; Kluckow and Seri, 2008; Seri, 2001; Seri and Noori, 2005). As described earlier, the most frequent etiologic factors responsible for neonatal cardiovascular compromise are inappropriate peripheral vasoregulation, resulting in vasodilation or vasoconstriction, and dysfunction of the immature myocardium (Gill and Weindling, 1993; Kluckow and Seri, 2008; Noori and Seri, 2005; Seri, 1995; Osborn et al, 2002). Absolute hypovolemia is a much less frequent primary cause of neonatal hypotension, especially in preterm infants in the immediate postnatal period (Barr et al, 1977; Wright and Goodhall, 1994).

ASSOCIATION BETWEEN SYSTEMIC HYPOTENSION, HYPOPERFUSION, AND THEIR TREATMENT AND MORTALITY OR NEURODEVELOPMENTAL IMPAIRMENT

The impact of hypotension and/or its treatment on mortality, brain injury, or neurodevelopmental impairment is unclear, primarily because it is assumed that treatment will improve outcomes, and therefore the common practice has been to treat hypotension (Noori et al, 2009). Therefore, there are no prospective studies evaluating the impact of untreated hypotension on clinically relevant short- and long-term outcomes. In addition, the gestational- and postnatal-age dependent definition of hypotension based on physiology, pathophysiology, and clinically relevant outcome measures is lacking (Engle, 2008). Finally, the finding that hypotension as currently defined is unlikely to be predictive of brain injury (McLean et al, 2008; Limperopoulos et al, 2007) is important in examining the association between hypotension and its treatment and neurodevelopmental impairment.

VOLUME ADMINISTRATION

Observations that hypotensive neonates as a group are not hypovolemic (Barr et al, 1977; Wright and Goodhall, 1994), low blood pressure is frequently associated with normal or even high ventricular output and low index of resistance (Pladys et al, 1999) and dopamine is more effective in normalizing blood pressure than volume administration (Lundstrom et al, 2000) support indirectly that absolute hypovolemia is an infrequent primary cause of neonatal hypotension in the transitional period. Therefore, particularly in the preterm infant during the immediate postnatal period, fluid resuscitation is recommended to be minimized. Furthermore, because myocardial dysfunction frequently contributes to the development of neonatal hypotension (Gill and Weindling, 1993) and aggressive volume administration in this patient population increases pulmonary, cardiovascular, gastrointestinal, and central nervous system morbidity and mortality (Kavvadia et al, 2000; Lundstrom et al, 2000; Van Marter et al, 1990), judicious use of fluid administration is highly warranted. However, absolute hypovolemia is a major contributing etiologic factor to neonatal shock in neonates with sepsis and/or in the postoperative period in patients undergoing major surgery. Indeed, early and aggressive resuscitation of children and neonates with sepsis has been documented to decrease mortality (Han et al, 2003) and has been recommended by the American College of Critical Care Medicine (Bierley et al, 2009).

Controversy has recently emerged concerning the type of fluid administration to preterm neonates with cardiovascular compromise. Most studies have shown that isotonic saline is as effective as 5% albumin in increasing the blood pressure (Oca et al, 2003; So et al, 1997). In addition, albumin may impair gas exchange and induce fluid shift from the intracellular compartment (Ernest et al, 1999) and is associated with increased mortality (Nadel et al, 1998). Therefore, given comparable efficacy of isotonic saline and albumin in the face of differences in cost and the suggested increased mortality and morbidity associated with albumin administration (Kavvadia et al, 2000; Lundstrom et al, 2000; Van Marter et al, 1990), isotonic saline has been the initial choice of treatment in the neonatal patient population. However, a recent randomized controlled trial found that in hypotensive, mostly preterm neonates, albumin administration resulted in a greater likelihood of achieving normotension and decreased the subsequent use of vasopressors when compared to isotonic saline (Lynch et al, 2008). The findings of this study need to be replicated before the routine use of albumin can be recommended as the initial treatment for neonatal cardiovascular compromise. Therefore, unless evidence of serum or blood loss or hypoalbuminemia is present, volume support in hypotensive preterm and term infants is provided in the form of 10 to 20 mL/kg of isotonic saline (Noori and Seri, 2008b; Seri, 2001). It is also important to note that, because of the unbalanced nature of normal saline, caution should be exercised with administration in large amounts over a short period of time, as this may worsen the metabolic acidosis (Mirza et al, 1999; Prough and Bidani, 1999). Should the limited-volume administration be ineffective, pharmacologic cardiovascular support with a vasopressor-inotrope or an inotrope is recommended (Kluckow, 2005; Noori and Seri, 2008; Osborn et al, 2002; Seri and Noori, 2005; Seri, 1995, 2001) and should be initiated.

If there is an identifiable volume loss, the type of fluid lost should be replaced. In cases of blood loss, transfusion with packed red blood cells after the initial crystalloid or colloid bolus or packed red blood cells suspended in fresh frozen plasma with a hematocrit around 55% may be used. In cases of increased transepidermal water losses, higher free water administration without an increase in sodium supplementation is indicated. When polyuria is present, the composition and volume of the replacement fluid may be adjusted to the urinary sodium and free water losses. However, replacement of half of the excessive urinary losses with 0.45% saline will usually suffice.

DOPAMINE AND DOBUTAMINE

Dopamine and dobutamine treatment was introduced in the management of neonatal hypotension in the early and mid-1980s, respectively, without appropriately designed randomized and blinded clinical trials. Thus, as mentioned earlier, we have no clear evidence that the use of these sympathomimetic amines (or any other sympathomimetic amine) improves neonatal mortality or morbidity. A number of studies have recently extended their focus beyond the dopamine- and dobutamine-induced heart rate and blood pressure changes by examining the drugs' effect on neonatal myocardial contractility, systemic and organ blood flow (Bouissou et al, 2008; Lundstrom et al, 2000; Noori et al, 2006; Osborn et al, 2002; Pellicer et al, 2005; Roze et al, 1993; Seri et al, 1998, 2002; Zhang et al, 1999; 2009). Some of the earlier studies, however, used left ventricular output to assess the impact of these medications on systemic blood flow even when shunting across fetal channels occurred (Lundstrom et al, 2000; Roze et al, 1993; Zhang et al, 1999). Therefore, the conclusions drawn in these studies need to be carefully reevaluated (Kluckow and Seri, 2008).

Hemodynamic Effects

Dopamine, an endogenous catecholamine, is the sympathomimetic amine most frequently used in the treatment of hypotension in preterm infants (Seri, 1995). It exerts its cardiovascular actions via the dose-dependent stimulation of the cardiovascular dopaminergic, α- and β-adrenergic, and serotoninergic receptors. In addition, by stimulating epithelial and peripheral neuronal dopaminergic and adrenergic receptors, the drug exerts significant renal and endocrine effects independent of its cardiovascular actions (Seri, 1995). Although dopamine affects all three major determinants of cardiovascular function (preload, myocardial contractility, and afterload), the drug-induced increases in myocardial contractility (Lundstrom et al, 2000; Zhang et al, 1999) and peripheral vascular resistance (afterload) (Lundstrom et al, 2000; Roze et al, 1993; Zhang et al, 1999) are the most important factors in increasing systemic blood pressure and improving the cardiovascular status.

The original dose-range recommendation of 2 to 20 μg/kg/min of dopamine was based on pharmacodynamic data obtained in adults without cardiovascular compromise. However, changes in cardiovascular adrenergic receptor expression caused by critical illness (Hausdorff et al, 1990) and relative or absolute adrenal insufficiency and immaturity (Watterberg and Scott, 1995; Watterberg 2002), as well as the dysregulated production of local vasodilators during severe illness, decrease the sensitivity of the cardiovascular system to dopamine, resulting in the emergence of hypotension resistant to conventional doses of the drug (Ng et al, 2001, 2006; Noori et al, 2006; Seri et al, 2001). Thus, with the advancement of the disease process, increased doses of dopamine and other sympathomimetic amines may be needed to exert the same magnitude of cardiovascular response. Therefore, dopamine administration should be tailored to the drug's pharmacodynamic effects in a given patient at the bedside rather than driven by the conventional dose recommendations based on data obtained in healthy adults. Indeed, although many neonatologists do not advance the dose of dopamine beyond 20 μg/kg/min, there is no evidence that, when required to normalize blood pressure, high-dose dopamine treatment with or without additional epinephrine administration has detrimental vasoconstrictive effects (Perez et al, 1986; Seri et al, 2001). However, there are no data available on changes in cardiac output and organ blood flow in response to high-dose catecholamine treatment in vasopressor-resistant neonatal shock, and close attention should be paid to signs of inappropriate vasoconstriction when this therapy is applied. More recently, administration of low-dose hydrocortisone has been shown to ameliorate the need for high-dose vasopressor administration in most patients (Cole, 2008; Ng et al, 2001; Noori et al, 2006; Seri et al, 2001; 2006).

Unlike dopamine, dobutamine is a relatively cardioselective sympathomimetic amine with significant α- and β-adrenoreceptor–mediated direct inotropic effects and limited chronotropic actions (Ruffolo, 1987). Dobutamine administration is usually also associated with a variable decrease in total peripheral vascular resistance and, at least in adults, with improved coronary blood flow and myocardial oxygen delivery (Ruffolo, 1987). Furthermore, unlike dopamine, dobutamine increases myocardial contractility exclusively through the direct stimulation of myocardial adrenergic receptors. Because myocardial norepinephrine stores are immature and rapidly depleted in the newborn, and because dobutamine may decrease afterload, newborns with primary myocardial dysfunction and elevated peripheral vascular resistance are most likely to benefit from dobutamine treatment (Martinez et al, 1992; Osborn et al, 2002). Interestingly, though addition of dobutamine to dopamine in preterm infants with RDS was effective in increasing blood pressure, it was associated with supranormal cardiac output states and low systemic vascular resistance (Lopez et al, 1997). Whether the benefits of supranormal cardiac output by providing adequate tissue oxygen delivery throughout the body outweigh the risks of sustained hypercontractility, potentially resulting in myocardial injury, remains to be investigated.

Randomized studies have uniformly demonstrated that dopamine is more effective than dobutamine in increasing blood pressure in the preterm infant, and a recent metaanalysis of the findings confirmed that dopamine was more successful than dobutamine in treating hypotension, with fewer infants in the dopamine group facing treatment failure (Subdehar and Shaw, 2000). However, there was no difference in short-term adverse neurologic outcome between the two groups. In the absence of long-term outcome data, no firm recommendations can be made regarding the choice of drug in treating hypotension of preterm infants in the immediate postnatal period. In addition, no information was forthcoming on changes in systemic blood flow. However, when carefully titrated to the optimum hemodynamic effect, dopamine (and epinephrine) increased blood pressure and CBF in hypotensive VLBW neonates during the first postnatal day (Pellicer et al, 2004). Neurodevelopmental follow-up of patients enrolled in this study at 2 to 3 years of age did not reveal evidence of an independent vasopressor-inotrope–associated increase in morbidity (Pellicer et al, 2009). Although the findings of this study provide some reassurance concerning the possibility of a dopamine (or epinephrine) associated increase in neurodevelopmental morbidity in VLBW neonates during the first postnatal day, the original study (Pellicer et al, 2005) was not sufficiently powered to put these concerns to rest.

As discussed earlier, because of the weak relationship between blood pressure and systemic blood flow in very preterm neonates during the immediate postnatal period, an increase in blood pressure does not necessarily guarantee that tissue perfusion has improved along with the blood pressure (Kluckow and Evans, 1996, 2000; Kluckow and Seri, 2008; Lopez et al, 1997; Pladys et al, 2001). Therefore, if there is evidence of peripheral vasoconstriction, especially in VLBW neonates during the first postnatal day, high-dose dopamine treatment should only be attempted if systemic blood flow can be monitored by functional echocardiography and/or NIRS. This treatment approach may result in further impairment in systemic blood flow despite improvements in blood pressure (Osborn et al, 2002). However, in present clinical practice these measures of blood flow monitoring are not routinely available, and the neonatologist has to rely on monitoring

blood pressure and the indirect measures of cardiovascular function. If evidence of vasoconstriction is present with higher doses of dopamine (or epinephrine), the neonatologist should consider accepting lower-end blood pressure values for gestational and postnatal age and decrease the dose of vasopressor-inotrope to levels where significant α-adrenoreceptor stimulation is less likely (Kluckow and Seri, 2008; Seri, 1995). In these cases, addition of dobutamine should be considered and the blood pressure maintained at least in the low-normal range because systemic hypotension has been linked to poor long-term neurodevelopmental outcome in the VLBW neonatal patient population (Bada et al, 1990; Miall-Allen et al, 1987). A combination of dobutamine and low-dose dopamine may achieve the most important goals of treatment by maintaining blood pressure and systemic blood flow in acceptable ranges if monitoring of both cardiovascular parameters is possible. In most of these patients, physiologic glucocorticoid and mineralocorticoid replacement with hydrocortisone is likely to be effective, although the potential side effects of early hydrocortisone exposure in preterm neonates should be kept in mind (see later discussion) (Cole, 2008; Kluckow and Seri, 2008; Seri et al, 2001; Seri and Noori, 2005). In summary, because both hypotension and low systemic blood flow have been associated with impaired neurodevelopmental outcome, the primary goal of management of the hypotensive very preterm neonate should be the correction of both measures of cardiovascular function.

A recent study demonstrated that in hypotensive preterm neonates with a significant left-to-right shunting across the PDA, dopamine administration increases systemic blood pressure, pulmonary pressure, and SVC flow, used as a surrogate of systemic blood flow in these patients (Bouissou et al, 2008). Dopamine administration has not been associated with evidence of increased pulmonary vascular resistance and decreased right ventricular output in neonates without a significant left-to-right shunting across the PDA (Clark et al, 2002; Wardle et al, 1999). This finding suggests that when pulmonary blood flow is increased, vasoconstrictive mechanisms may be upregulated in the pulmonary circulation, resulting in more pronounced α-receptor–mediated dopamine-induced pulmonary vasoconstriction. The findings of an earlier study demonstrating a variable pulmonary resistance response to dopamine in preterm neonates with a hemodynamically significant PDA support this notion (Liet et al, 2002).

In hypotensive term and preterm neonates beyond the immediate postnatal period, where vasodilatory shock is the more likely presentation, dopamine administration in doses tailored to the cardiovascular response is warranted and appears to be beneficial (DiSessa et al, 1981; Martinez et al, 1992; Seri and Noori, 2005) unless evidence of primary myocardial dysfunction is present (Seri, 1995, 2001).

The vasodilatory dopamine receptors are primarily expressed in renal, mesenteric, and coronary circulations (Seri, 1995). Dopamine has been shown to selectively decrease renal vascular resistance (Seri et al, 1998, 2002) and increase glomerular filtration rate (Seri et al, 1993) in preterm infants as early as the 23rd week of gestation. However, dopamine appears to decrease mesenteric vascular resistance in preterm infants only beyond the first postnatal day (Hentschel et al, 1995; Robel-Tillig et al, 2007; Seri et al, 1998, 2000), and the effect may be variable (Zhang et al, 1999). Similarly, there are some differences in the reported magnitude of drug-induced increases in ventricular function, cardiac output, and systemic vascular resistance (Clark et al, 2002; Lundstrom et al, 2000; Roze et al, 1993; Zhang et al, 1999). These findings may be best explained by differences in intravascular volume status, postnatal age, developmentally regulated expression of cardiovascular adrenergic and dopaminergic receptors, and severity of adrenergic receptor downregulation among different populations of critically ill infants studied. It is important to note that none of the studies found evidence for a direct effect of dopamine on cerebral blood flow as long as blood pressure was in the autoregulatory range (Lundstrom et al, 2000; Seri et al, 1998, 2000; Zhang et al, 1999). Thus, dopamine administration appears to be devoid of potentially harmful selective hemodynamic effects in the brain. As expected, in hypotensive neonates dopamine (and epinephrine) increase both blood pressure and CBF (Pellicer et al, 2004).

There are very few data available on direct renal, cerebral, or pulmonary hemodynamic effects of dobutamine in the newborn. A nonrandomized study comparing the effects of dopamine and dobutamine on blood pressure and mesenteric blood flow in preterm infants found that both drugs increased blood pressure and were equally effective in decreasing mesenteric vascular resistance (Hentschel et al, 1995). Because dobutamine does not stimulate the dopaminergic receptors, β-adrenoreceptor–induced selective vasodilation may be responsible for the observed mesenteric vasodilation in dobutamine-treated patients.

Epithelial and Neuroendocrine Effects

Independent of the just-described cardiovascular effects, dopamine exerts direct renal (Seri, 1995) and endocrine (Seri, 1995) actions in the newborn. Via its direct effects on sodium, phosphorous and water transport processes and Na/K ATPase activity in renal tubules, dopamine increases sodium, phosphrus, and free water excretion and may increase the hypoxic threshold of renal tubular cells during episodes of hypoperfusion and hypoxemia (Seri, 1995). Via its renal vascular and epithelial actions, dopamine also potentiates the diuretic effects of furosemide (Tulassay and Seri, 1986) and theophylline (Bell et al, 1998). Although dopamine has the theoretical potential to attenuate renal side effects of indomethacin, the data in the literature are contradictory (Seri, 1995). Differences in the level of maturity, disease severity, ductal shunting, intravascular volume status, and indomethacin dose may be responsible for such conflicting results. Among its endocrine actions, the dopamine-induced decreases in plasma prolactin, thyrotropin, and growth hormone levels (Seri, 1995) may be of clinical importance. The decrease in plasma prolactin may attenuate the preterm infant's propensity to edema formation but may also have an immune function (Seri, 1995). The inhibition of thyrotropin release necessitates the postponement of routine neonatal thyroid screening until after dopamine administration has been discontinued (Seri, 1995). The potential impact on long-term neurodevelopmental outcome and immunologic

function of drug-induced alterations in neuroendocrine function has not been investigated in the preterm or term neonate. Because dobutamine does not directly stimulate dopaminergic receptors, its administration is thought to be devoid of neuroendocrine effects.

EPINEPHRINE, NOREPINEPHRINE, AND OTHER CARDIOVASCULAR AGENTS AND HORMONES

In a randomized controlled trial, low to medium doses of epinephrine, when titrated to optimal hemodynamic response, have been shown to increase blood pressure and CBF in hypotensive VLBW neonates (see earlier discussion) (Pellicer et al, 2004). Because of epinephrine's significant effect on glycogenolysis, its administration is associated with an increase in serum lactate levels independent of the drug's cardiovascular actions (Valverde et al, 2005). This effect should be kept in mind when following serum lactate levels to assess the changes in cardiovascular status due to epinephrine administration. Therefore, the epinephrine-induced improvement in perfusion cannot be ascertained by following serum lactate levels alone, because these levels will likely increase independent of drug-induced improvement in the cardiovascular status.

Until very recently, findings on the cardiovascular effects of norepinephrine in neonates were only published in abstract form (Derleth, 1997). However, a recent observational study in late preterm and term neonates with persistent pulmonary hypertension of the newborn (PPHN) treated with inhaled nitric oxide (iNO) and signs of circulatory failure found that medium doses of norepinephrine improve systemic and pulmonary cardiovascular function in these neonates by decreasing the pulmonary artery–to–aortic pressure gradient and improving cardiac performance (Tourneux et al, 2008). Although these findings are encouraging, the routine use of norepinephrine in the treatment of neonates with PPHN and cardiovascular compromise requires further confirmation.

It is not known whether there is a difference in the cardiovascular response and/or side effects of sympathomimetic amines with the combined use of epinephrine and dopamine compared to the use of increasing doses of dopamine beyond 20 μg/kg/min with or without dobutamine. There have been no detrimental vasoconstrictive effects reported using either high doses of epinephrine with or without dopamine, or norepinephrine in preliminary publications (Campbell and Byrne, 1998; Derleth, 1997; Seri and Evans, 1998). These findings are best explained by the decreased cardiovascular sensitivity of these critically ill preterm infants to catecholamines, necessitating the high sympathomimetic support in the first place. However, one must be extremely careful when escalating treatment with these potent vasopressor-inotropes to avoid causing significant vasoconstriction and decreased tissue perfusion. In addition to sympathomimetic amines, arginine-vasopressin has been reported to improve cardiovascular function in a small number of newborns with vasodilatory shock after cardiac surgery (Rosenzweig et al, 1999).

There are very few data available on the cardiovascular effects of milrinone, a phosphodiesterase-III (PDE-III) inhibitor in the neonatal patient population. It has been more widely used to reduce afterload in neonates with congenital heart disease with low cardiac output syndrome after surgery (Hoffman et al, 2003). As for its use in term infants without congenital heart disease, milrinone administration has been shown in a small case series to improve the oxygenation index without compromising systemic blood pressure when given to term neonates with PPHN treated with iNO during the first 2 postnatal days (McNamara et al, 2006). The preferential effect of milrinone on the pulmonary circulation in neonates with PPHN treated with iNO may be due to the upregulation of PDE-III in pulmonary vessels in response to iNO administration. It is unclear if milrinone has a positive inotropic effect in neonates (Barrington and Dempsey, 2006).

Recently, a randomized placebo-controlled blinded clinical trial investigated whether the use of milrinone would minimize or prevent the suspected increase in systemic vascular resistance and the associated systemic hypoperfusion in VLBW infants during the first postnatal day (Paradisis et al, 2009). However, there was no improvement in the incidence of low SVC flow used as a surrogate of systemic blood flow in patients treated with milrinone compared to the placebo group. These findings may be explained, at least in part, by the little-appreciated complexity of the pathophysiology of cardiovascular compromise in the very preterm neonate after delivery. They further suggest that systemic and cerebral hypoperfusion and reperfusion in this patient population may not solely occur because of the inability of the immature myocardium to pump against the sudden postnatal increase in systemic vascular resistance (Noori et al, 2009).

STEROID ADMINISTRATION

There is now overwhelming evidence provided by descriptive studies (Heckmann and Pohlandt, 2002; Helbock et al, 1993; Ng et al, 2001; Noori et al, 2006a; Seri et al, 2001) and confirmed by randomized blinded prospective trials (Bouchier and Weston, 1997; Effird et al, 2005; Gaissmaier and Pohlandt, 1999; Ng et al, 2006; Watterberg et al, 1999) that brief steroid treatment stabilizes the cardiovascular status and decreases the need for vasopressor-inotropic support in the critically ill preterm and term newborn with vasopressor-resistant hypotension. Because there is overwhelming evidence that early and/or medium-to-high cumulative doses of dexamethasone have detrimental effects on the developing brain (Baud et al, 2004; Halliday et al, 2003; O'Shea et al, 1999; Shinwell et al, 2000; Yeh et al, 2004), and because in addition to glucocorticoids, mineralocorticoids also have significant effects on the cardiovascular system (Wehling, 1997; Wehling et al, 1995), even low-dose dexamethasone administration to treat vasopressor-resistant hypotension has fallen by the wayside in recent years. This section therefore addresses only the actions, side effects, recommended doses, and remaining clinically relevant concerns of hydrocortisone administration to treat vasopressor-resistant hypotension in the critically ill neonate. It is of note that the available evidence for the effectiveness of low-dose hydrocortisone to increase blood pressure and decrease vasopressor-inotrope requirement in the preterm neonate is so strong that it would take 74 and 188 future studies demonstrating no

effect of hydrocortisone on blood pressure increase and the decrease in vasopressor requirement, respectively, to eliminate the statistical power of the present findings (Higgins et al, 2010).

Because in most patients and after some time, cardiovascular stability will be achieved by the use of vasopressors-inotropes and/or inotropes alone, it is important to understand the rationale of hydrocortisone administration, especially because the drug has its own side effects (see later discussion). First, it is widely accepted that the sooner one normalizes blood pressure, especially in the VLBW neonate during the immediate postnatal period, the better the outcome. However, because normal blood pressure in the first 24 hours may not guarantee normal cerebral perfusion (see earlier discussion) and because an association but not causation has been documented between hypotension and adverse outcomes, stabilization of the cardiovascular status with little blood pressure fluctuation remains an intuitively desirable goal but one without much direct evidence to support it. More importantly, hydrocortisone specifically addresses the underlying etiology of the cardiovascular instability in most critically ill neonates and thus is the logical choice of treatment. Indeed, findings of developmental endocrinology and cardiovascular physiology as well as recent clinical data support a role for hydrocortisone use in critically ill hypotensive neonates, especially in VLBW neonates. In critical illness, desensitization of the cardiovascular system to catecholamines takes place through the downregulation of cardiovascular adrenergic receptors and second messenger systems (Hausdorff et al, 1990). This process is attenuated or prevented by the regulatory actions of glucocorticoids on the expression of cardiovascular adrenergic receptors and second messenger systems (Hausdorff et al, 1990). In addition, the direct increase in myocardial and vascular smooth muscle cell contractility induced by mineralocorticoids plays an effective role (Wehling, 1997; Wehling et al, 1995). In addition, corticosteroids contribute to the maintenance of capillary integrity, inhibit catecholamine metabolism and reuptake of norepinephrine into sympathetic nerve endings, increase the expression of angiotensin type 2 receptors in the myocardium, and inhibit prostacyclin production and the induction of inducible nitric oxide synthase. Each of these actions of corticosteroids aids in maintaining the sensitivity of the cardiovascular system to catecholamines in response to acute stress or critical illness. In addition, because of the role of glucocorticoids in the physiologic regulation of adrenergic receptor expression (Hausdorff et al, 1990), the emergence of vasopressor resistance in itself may indicate a state of relative adrenal insufficiency. Indeed, the findings of several recent studies indicate that critically ill preterm and term infants are likely to develop relative adrenal insufficiency because of their immature adrenal function (Ng et al, 2004; Watterberg, 2002; Watterberg and Scott, 1995) and hypothalamopituitary axis (Fernandez et al, 2008; Fernandez and Watterberg, 2009), respectively. It is important to emphasize that, based on these findings, it appears that in the VLBW neonate, adrenal unresponsiveness to endogenous or exogenous ACTH (Ng et al, 2004; Watterberg, 2002) and in the late preterm and term neonate, unresponsiveness of the hypothalamopituitary axis to stress (Fernandez and Watterberg, 2009; Fernandez et al, 2008) are the primary causes for the development of relative adrenal insufficiency. Thus, these patients have limited capacity to produce sufficient adaptive increases in endogenous steroid production to prevent the development of cardiovascular adrenergic receptor downregulation and desensitization of the cardiovascular system to catecholamines during their illness. Therefore, in critically ill preterm and term infants with vasopressor-resistant hypotension, steroid administration also serves as hormone substitution therapy.

As for the clinical application and effects of hydrocortisone, available evidence indicates that hydrocortisone in preterm and term infants with vasopressor-resistant hypotension increases blood pressure within 2 hours of the initiation of treatment (nongenomic effects) and decreases vasopressor requirement within 8 to 12 hours of the first dose of the drug (genomic effects) (Figure 51-5) (Ng et al, 2006; Noori et al, 2006; Seri et al, 2001). A recent study in preterm infants without a PDA also documented that the hydrocortisone-induced improvement in blood pressure is associated with improvements in all aspects of cardiovascular function including stroke volume and tissue perfusion (Figure 51-6) (Noori et al, 2006b).

As for the side effects of early or late low-dose hydrocortisone administration, the potential occurrence of short- and long-term sequelae is of great interest. As for the short-term side effects, it has been repeatedly documented that coexposure of preterm neonates to indomethacin and hydrocortisone during the first postnatal week significantly increases the risk of spontaneous gastrointestinal (mostly ileal) perforations (Peltoniemi et al, 2005; Watterberg et al, 2004). This serious untoward effect significantly curtails the use of hydrocortisone in the VLBW neonate during the first postnatal week; the very patient population in whom vasopressor-resistant hypotension and relative adrenal insufficiency are most prevalent during the immediate postnatal period. It is interesting to note that findings of one of these studies suggest that VLBW neonates with low baseline serum cortisol levels may be at less risk for developing ileal perforations when treated with low-dose hydrocortisone and a cyclooxygenase inhibitor during the first postnatal days (Peltoniemi et al, 2005). However, this observation needs to be confirmed before it can be used to predict the likelihood of spontaneous intestinal perforation based on the basal serum cortisol level alone. As for the other short-term side effects of hydrocortisone, one earlier study found an increase in the incidence of systemic fungal infections (Botas et al, 1995). However, none of the other studies have documented a significant increase in bacterial or fungal infections in neonates. Finally, hydrocortisone administration–associated transient hyperglycemia and hypertension have been reported in a few cases in the literature.

As for the potential long-term side effects, the most pressing question is whether low to moderate doses of hydrocortisone interfere with neurodevelopment, especially in preterm neonates. The findings of a recent study indicate that early, low-dose hydrocortisone treatment is not associated with an increased incidence of cerebral palsy and that infants exposed to hydrocortisone in the original placebo-controlled blinded clinical trial during the first 10 postnatal days to prevent the development

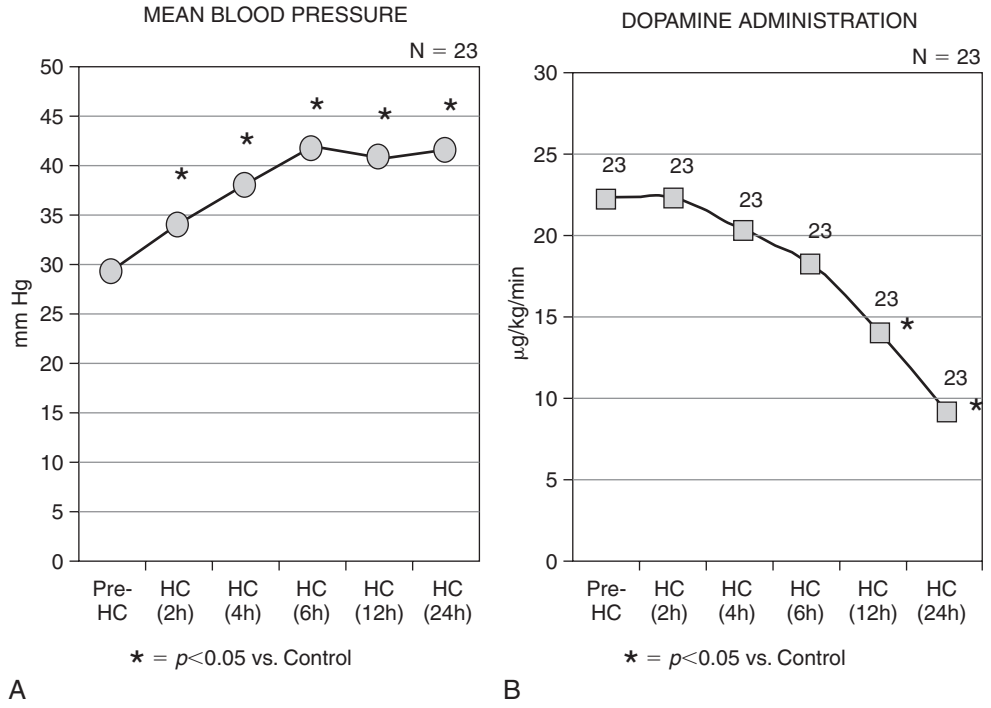

FIGURE 51-5 **Effect of hydrocortisone on mean blood pressure and the dose of dopamine during the first 24 hours of hydrocortisone treatment in 23 preterm neonates with vasopressor-resistant shock. A,** Mean blood pressure (mean ± SD) and **(B)** dopamine requirement (mean ± SD) during the 12 hours before and the first 24 hours after the first dose of hydrocortisone. Before hydrocortisone administration, blood pressure remained low **(A)**, despite significantly increased dopamine doses (**B,** * = $p < 0.05$ vs. baseline [0 h]). However, mean blood pressure increased significantly by 2 hours after the first dose of hydrocortisone (**A,** * = P < 0.05 vs. baseline [0 h]) and continued to rise until 6 hours of hydrocortisone therapy, remaining stable thereafter (**A,** * = $p < 0.05$ vs. baseline [0 h]; * = $p < 0.05$ vs. HC [2 h]). In addition, the dose of dopamine significantly decreased by 12 and 24 hours of hydrocortisone therapy (**B,** * = $p < 0.05$ vs. baseline [0 h]). (*From Seri I, Tan R, Evans J: Cardiovascular effects of hydrocortisone in preterm neonates with pressor resistant hypotension*, Pediatrics *107:1070-1074, 2001.*)

of bronchopulmonary dysplasia (Watterberg et al, 2004) actually showed some evidence of improved developmental outcome at 18 to 22 months corrected age compared to controls (Watterberg et al, 2007). As for the use of higher cumulative doses of hydrocortisone outside the immediate transitional period, the results of a study examining structural and functional brain development at an age of 8 years suggest that hydrocortisone, used for the treatment of bronchopulmonary dysplasia in ventilator-dependent preterm neonates at a median age of 18 days and at cumulative doses over 50 mg, does not interfere with brain development (Lodygensky et al, 2005). Although these findings are reassuring, lack of power (Watterberg et al, 2007) and the retrospective nature of the study design (Lodygensky et al, 2005) warrant caution before the use of early or late and low- to medium-dose hydrocortisone could be declared safe in preterm neonates, at least from a neurodevelopmental standpoint.

SUPPORTIVE MEASURES

Maintenance of a normal intravascular volume, arterial pH, and serum ionized calcium concentrations is necessary for the optimum cardiovascular response to catecholamines. Because a metabolic acidosis of <7.25 may compromise myocardial function in the preterm infant (Fanconi et al, 1993), it is recommended that the arterial pH be maintained above this range in cases of acidosis with a significant metabolic component. However, more data are needed in support of this recommendation in the neonatal patient population. Administration of sodium bicarbonate (Fanconi et al, 1993) or, in cases with severe combined respiratory and metabolic acidosis, the administration of tromethamine rapidly improves arterial pH. However, the efficacy and potential short- and long-term adverse effects of such supportive treatment measures have not been studied in the neonatal patient population, and there is indeed very little evidence that bicarbonate administration in metabolic acidosis caused by tissue hypoperfusion is beneficial (Aschner and Poland, 2008). Finally, although positive pressure ventilation may raise pleural pressure and has the potential to reduce venous return, it may also reduce left ventricular afterload by reducing transmural pressure and decreasing or eliminating the work of breathing. Decreasing or eliminating the work of breathing will also decrease or eliminate the concomitant cardiac output diverted to respiratory muscles. Therefore, the net hemodynamic effect of positive pressure ventilation is improved systemic oxygen delivery independent of any potential improvement in pulmonary gas exchange.

In summary, sustained stabilization of the cardiovascular status with provision of appropriate blood pressure, cardiac output, and tissue perfusion and oxygenation remains a difficult task in most of the critically ill hypotensive newborns. Treatment of these patients requires the ability to preferably continuously monitor the most important measures of cardiovascular function (blood pressure, systemic blood flow, and tissue oxygenation); a thorough

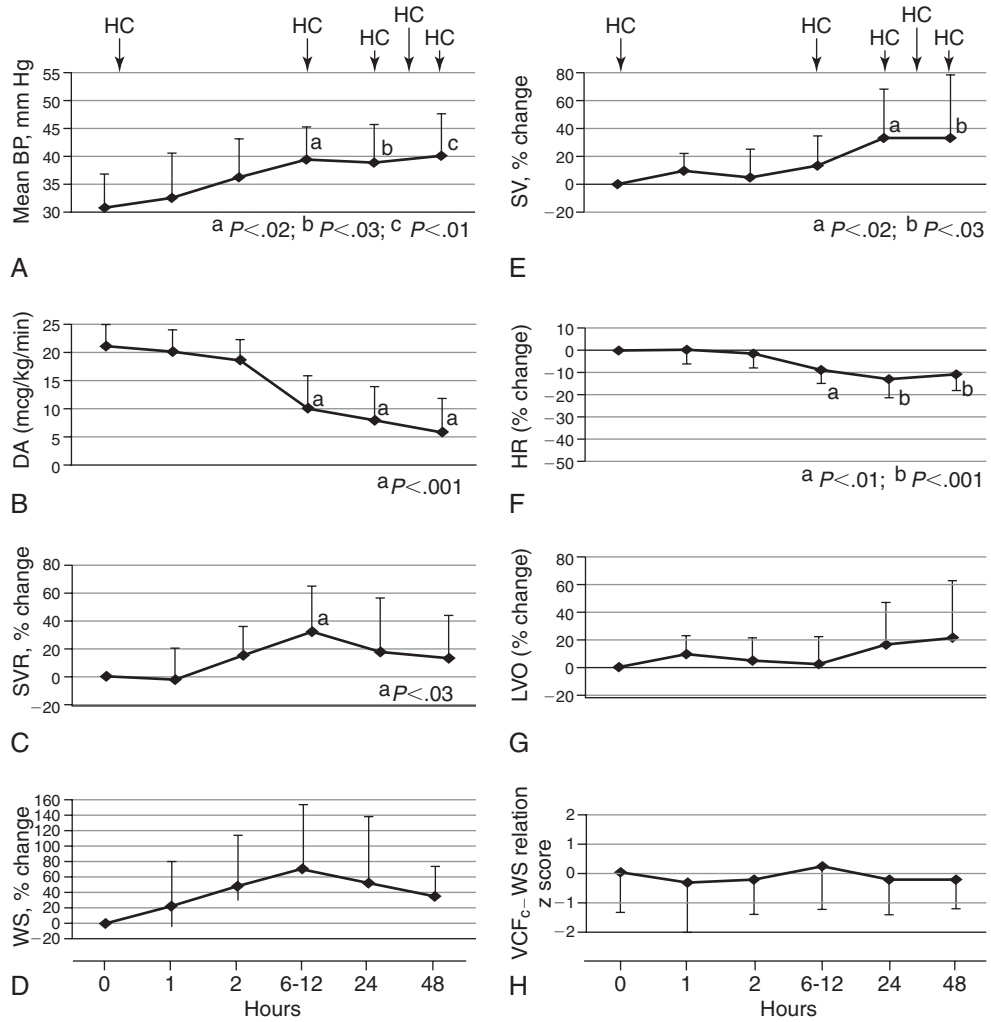

FIGURE 51-6 Effect of hydrocortisone on mean blood pressure and the dose of dopamine during the first 24 hours of hydrocortisone treatment in 23 preterm neonates with vasopressor-resistant shock. Changes in preterm neonates (n=15) in mean BP (**A,** $^{a}P < .02$, $^{b}P < .03$, $^{c}P < .01$) and dopamine dosage (DA) (**B,** $^{a}P < .001$) and percentage changes relative to baseline (0 hour) in SVR (**C,** $^{a}P < .03$), WS **(D),** stroke volume (SV) (**E,** $^{a}P < .02$, $^{b}P < .03$), heart rate (HR) (**F,** $^{a}P < .01$, $^{b}P < .001$), and left ventricular output (LVO) **(G)** are shown at 1, 2, 6 to 12, 24, and 48 hours after the first dose of hydrocortisone. In addition, **H** depicts the changes in load-independent contractility as assessed by the VCFc-WS relation. *HC* with arrows indicate approximate timing of hydrocortisone doses. Significant P values for pairwise comparisons versus the baseline (0 hour) with adjustment for multiple comparisons (Bonferroni) are shown. See text for details. CHAPTER 52

Persistent Pulmonary Hypertension

Robin H. Steinhorn and Steven H. Abman

Neonatal respiratory failure affects 2% of all live births and is responsible for more than one third of all neonatal deaths (Angus et al, 2001). Persistent pulmonary hypertension of the newborn (PPHN) is a frequent complication of respiratory disease in neonates and is defined as the failure to achieve or sustain the normal decrease in pulmonary vascular resistance at birth. PPHN complicates the course of approximately 10% of infants with respiratory failure and can lead to severe respiratory distress and hypoxemia associated with considerable mortality and morbidity (Kinsella and Abman, 1995; Walsh-Sukys et al, 2000). Newborns with PPHN are at risk for severe asphyxia and its complications, including death, chronic lung disease, neurodevelopmental sequelae, and other problems. This chapter reviews the pathophysiology of PPHN and clinical strategies that utilize a physiologic approach to the treatment of newborns with severe PPHN.

NORMAL FETAL PULMONARY VASCULAR DEVELOPMENT AND TRANSITION

Pulmonary hypertension is necessary to support gas exchange during fetal life. Because the placenta, not the lung, serves as the organ of gas exchange, most of the right ventricular output must cross the ductus arteriosus to the aorta, and only 5% to 10% of the combined ventricular output is directed to the pulmonary vascular bed. Even though the surface area of the pulmonary vasculature increases as the fetal lung grows, pulmonary vascular resistance increases with gestational age when corrected for lung or body weight, suggesting that active pulmonary vascular constriction is prominent during late gestation. Multiple pathways appear to be involved in maintaining high pulmonary vascular tone before birth. Pulmonary vasoconstrictors in the normal fetus include low oxygen tension, endothelin-1, leukotrienes, and Rho kinase. Vasoconstriction is also promoted by low basal production of vasodilators such as prostacyclin and nitric oxide (NO).

At birth, a rapid and dramatic decrease in pulmonary vascular resistance redirects half of the combined ventricular output to the lung, leading to an 8- to 10-fold increase in pulmonary blood flow. Increased pulmonary blood flow increases pulmonary venous return and left atrial pressure, promoting functional closure of the one-way valve of the foramen ovale. Systemic vascular resistance increases at birth, at least in part because of removal of the low-resistance vascular bed of the placenta. The largest drop in pulmonary vascular resistance occurs shortly after birth, although resistance continues to drop over the first several months of life until it reaches the low levels normally found in the adult circulation. As pulmonary vascular resistance falls below systemic levels, blood flow through the patent ductus arteriosus (PDA) reverses. In the first several hours of life, the ductus arteriosus functionally closes, largely in response to the increased oxygen tension of the newborn. This effectively separates the pulmonary and systemic circulations and establishes the normal postnatal circulatory pattern.

The most critical signals for these transitional changes in the pulmonary vasculature are mechanical distention of the lung, a decrease in carbon dioxide tension, and an increase in oxygen tension in the lungs. The fetus prepares for this transition late in gestation by increasing pulmonary vascular expression of nitric oxide synthases and soluble guanylate cyclase (Figure 52-1). The importance of the NO–cyclic guanosine monophosphate (cGMP) pathway in facilitating normal transition has been demonstrated by acute or chronic inhibition of nitric oxide synthase (NOS) in fetal lambs, which produces pulmonary hypertension after delivery (Abman et al, 1990; Fineman et al, 1994). The prostacyclin pathway is another important vasodilatory pathway (see Figure 52-1). Cyclooxygenase is the rate-limiting enzyme that generates prostacyclin from arachidonic acid. Although both cyclooxygenase-1 and cyclooxygenase-2 are found in the lung, cyclooxygenase-1 in particular is upregulated during late gestation (Brannon et al, 1998). This upregulation leads to increased prostacyclin production in late gestation and early postnatal life (Brannon et al, 1994; Leffler et al, 1984). In turn, prostacyclin stimulates adenylate cyclase to increase intracellular cyclic adenosine monophosphate (cAMP) levels, which, as with cGMP, lead to vasorelaxation through a decrease in intracellular calcium concentrations.

PATHOPHYSIOLOGY OF PPHN

When the normal cardiopulmonary transition fails to occur, the result is PPHN. The first reports of PPHN described term newborns with profound hypoxemia who lacked radiographic evidence of parenchymal lung disease and echocardiographic evidence of structural cardiac disease (Gersony et al, 1969; Levin et al, 1976). In these patients, hypoxemia was caused by marked elevations of pulmonary vascular resistance leading to right-to-left extrapulmonary shunting of blood across the PDA or patent foramen ovale (PFO) during the early postnatal period. Because of the persistence of high PVR and blood flow through these "fetal shunts," the term *persistent fetal circulation* was originally used to describe these findings.

Subsequently, it was recognized that these physiologic patterns may complicate the clinical course of neonates with diverse causes of hypoxemic respiratory failure. As a result, the term *PPHN* is now commonly used to describe a syndrome characterized by common pathophysiologic features including sustained elevation of pulmonary vascular

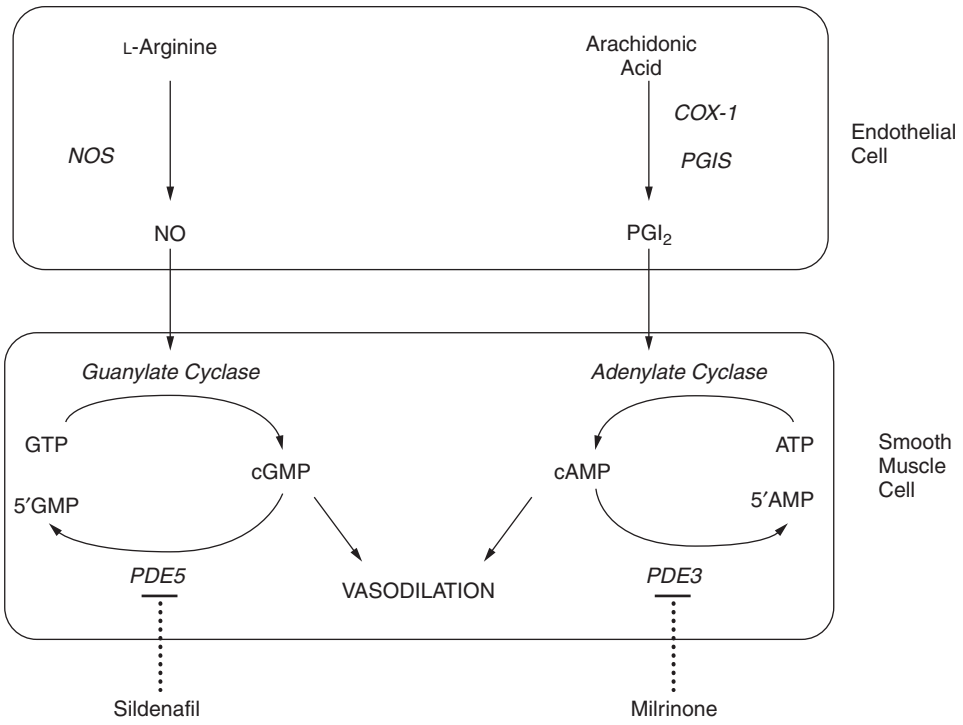

FIGURE 52-1 Nitric oxide *(NO)* and prostacyclin (i.e., prostaglandin I_2 *[PGI_2]*) signaling pathways that regulate pulmonary vascular tone in the developing lung.

resistance and hypoxemia due to right-to-left extrapulmonary shunting of blood flow across the ductus arteriosus or foramen ovale. These physiologic findings may be associated with a wide range of cardiopulmonary disorders such as meconium aspiration, sepsis, pneumonia, asphyxia, congenital diaphragmatic hernia, respiratory distress syndrome (RDS), and others. However, although hypoxemic respiratory failure in term newborns is often presumed to be associated with PPHN-type physiology, many hypoxemic term newborns will lack evidence for extrapulmonary shunting across the PDA or PFO. Thus, the term *PPHN* should generally be reserved to describe neonates in whom extrapulmonary shunting contributes to hypoxemia and impaired cardiopulmonary function. Recent estimates suggest an incidence for PPHN of 1.9/1000 live births, or an estimated 7400 cases/year in the United States (Walsh-Sukys et al, 2000).

PPHN is often characterized as one of three types: (1) maladaptation: the structurally normal but abnormally constricted pulmonary vasculature due to lung parenchymal diseases such as meconium aspiration syndrome, respiratory distress syndrome, or pneumonia; (2) excessive muscularization: the lung with normal parenchyma but remodeled pulmonary vasculature characterized by increased smooth muscle cell thickness and distal extension of muscle to vessels that are usually nonmuscular (Figure 52-2); or (3) the hypoplastic vasculature, associated with underdevelopment of the pulmonary vasculature, as seen in congenital diaphragmatic hernia. This designation is imprecise, however, and high PVR in most patients likely involves overlapping changes among these categories. For example, neonates with meconium aspiration often have clinical evidence of altered vasoreactivity, but excessive muscularization is often found at autopsy. Neonates with congenital diaphragmatic hernia are primarily classified as having vascular hypoplasia, yet lung histology of fatal cases typically shows marked muscularization of pulmonary arteries, and clinically, these patients can respond to vasodilator therapy.

Autopsy studies of fatal PPHN demonstrate severe hypertensive structural remodeling even in newborns who die shortly after birth (Figure 52-3), suggesting that many cases of severe disease are associated with chronic intrauterine stress (Geggel and Reid, 1984). However, the exact intrauterine events that alter pulmonary vascular reactivity and structure remain poorly understood. Epidemiologic studies have demonstrated strong associations between PPHN and maternal smoking and ingestion of cold remedies that include aspirin or other nonsteroidal antiinflammatory products (Alano et al, 2001; Van Marter et al, 1996). Exposure to nonsteroidal antiinflammatory drugs (NSAIDs) during the third trimester can cause constriction of the fetal ductus arteriosus in utero, a finding that has been associated with idiopathic PPHN (Alano et al, 2001; Levin et al, 1979). In experimental models, surgical ductal constriction or ligation performed in fetal lambs produces very rapid antenatal remodeling of the pulmonary vasculature. The physiologic and anatomic findings in these lambs after birth are similar to those observed in human infants, including increased fetal pulmonary artery pressure, pulmonary vascular remodeling, and profound hypoxemia after birth (Wild et al, 1989).

New data suggest that exposure to selective serotonin reuptake inhibitors (SSRIs) during late gestation may increase the likelihood of PPHN (Chambers et al, 2006), although it is not clear how many infants will develop severe disease. In support of this association, newborn rats exposed in utero to fluoxetine develop pulmonary

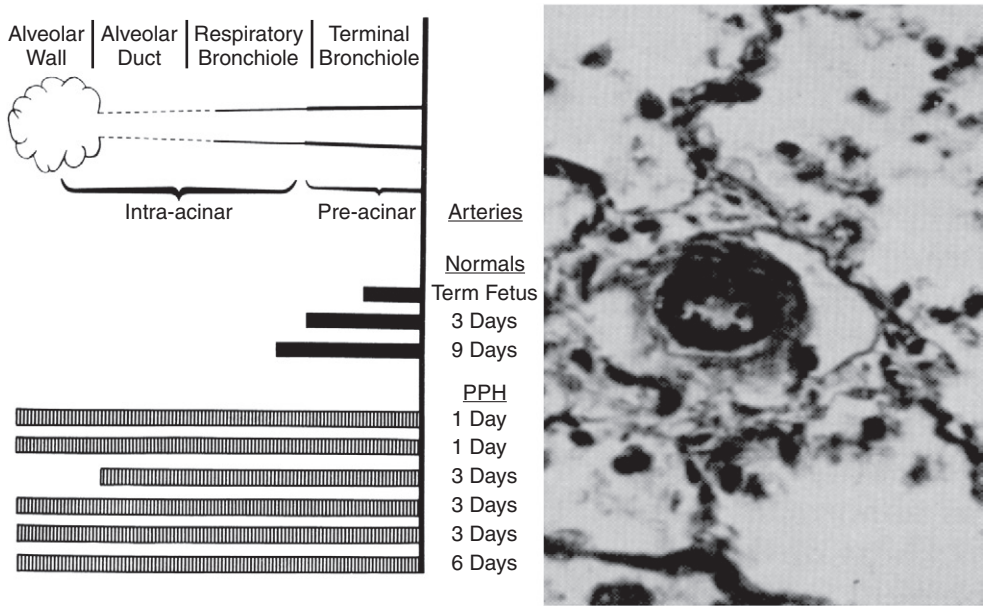

FIGURE 52-2 Vascular maldevelopment of PPHN, showing smooth muscle hyperplasia and extension of smooth muscle to the level of the intraacinar arteries, which does not normally occur until much later in the postnatal period. (*From Murphy JD, Rabinovitch M, Goldstein JD, et al: The structural basis of persistent pulmonary hypertension of the newborn infant*, J Pediatr *98:962-967, 1981.*)

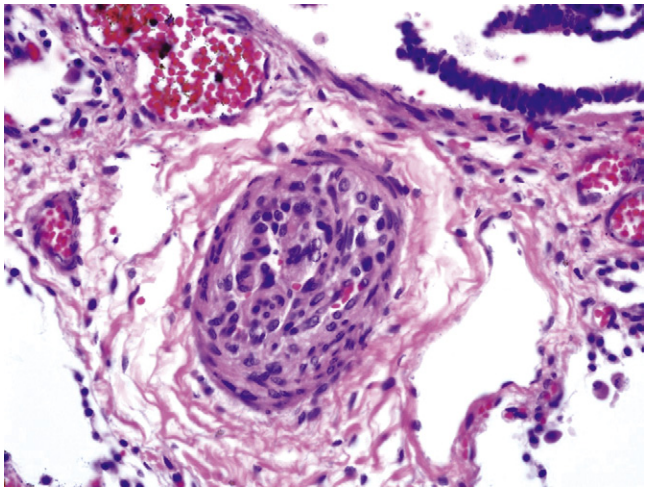

FIGURE 52-3 *(See also Color Plate 21.)* Histology of a pulmonary vessel from an infant with fatal PPHN illustrating the dramatic remodeling that can be associated with severe PPHN.

vascular remodeling, abnormal oxygenation, and higher mortality when compared with vehicle-treated controls (Fornaro et al, 2007). Because SSRIs have been reported to reduce pulmonary vascular remodeling in adult models of pulmonary hypertension, these findings may also serve to highlight the unique nature of fetal pulmonary vascular development.

It is not yet clear whether genetic factors increase susceptibility for neonatal pulmonary hypertension. Studies of adults with idiopathic and familial primary pulmonary hypertension have identified germline mutations in the bone morphogenetic protein receptor type 2 gene (BMPR2), a member of the transforming growth factor-β signaling family. However, whether polymorphisms of genes for the BMP or other transforming growth factor-β receptors, other critical growth factors, vasoactive substances, or other products increase the risk for the neonatal PPHN syndrome is unknown.

Based on work from animal models, there is strong evidence that disruptions of the NO-cGMP, prostacyclin-cAMP, and endothelin signaling pathways play an important role in the vascular abnormalities associated with PPHN. The NO-cGMP pathway has been a topic of particularly intense investigation in the past two decades. Decreased expression and activity of endothelial nitric oxide synthase (eNOS) have been documented in the PPHN lamb model (Shaul et al, 1997; Villamor et al, 1997), and decreased eNOS expression has also been reported in umbilical venous endothelial cell cultures from human infants with meconium staining who develop PPHN (Villaneuva et al, 1998). These important findings were rapidly followed by clinical testing of inhaled nitric oxide (iNO) as a therapy for hypoxemic respiratory failure and PPHN, as described later.

Although prostacyclin appears to be important in the normal pulmonary vascular transition, less is known of the role of abnormal prostacyclin-cAMP signaling in PPHN. Some data suggest that abnormalities in prostacyclin synthesis and downstream adenylate cyclase responses exist, analogous to the abnormalities reported for NO-cGMP signaling (Lakshminrusimha et al, 2009a; Shaul et al, 1991). In addition, production of the vasoconstrictor arachidonic acid metabolite, thromboxane, plays a role in pulmonary hypertension produced by chronic hypoxia (Fike et al, 2005). Circulating levels of the potent vasoconstrictor endothelin (ET-1) are elevated in lambs and newborn infants with PPHN (Kumar et al, 1996; Rosenberg et al, 1993). Endothelin effects are mediated through two receptors: ET-A receptors on smooth muscle cells that mediate vasoconstriction, and ET-B receptors on endothelial cells that mediate vasodilation. There is evidence that in pulmonary hypertension, the balance of ET receptors is shifted to the vasoconstrictor (ET-A) pathways (Ivy et al,

1998). In addition, endothelin may affect vascular tone by increasing production of reactive oxygen species such as superoxide and hydrogen peroxide, which also act as vasoconstrictors (Wedgwood et al, 2001).

OTHER CAUSES OF NEONATAL PULMONARY HYPERTENSION

Neonatal pulmonary hypertension differs from pediatric and adult pulmonary hypertension in that it resolves in the majority of patients and has not been associated with genetic factors. A notable exception is alveolar capillary dysplasia with misalignment of lung vessels (ACD/MPV), a rare but universally lethal cause of pulmonary hypertension in the newborn (Boggs et al, 1994; Sen et al, 2004). Affected infants typically present shortly after birth with cyanosis and respiratory distress refractory to all known therapies including extracorporeal support, although later presentations (at several weeks or months of life) are increasingly recognized. Currently, the diagnosis can only be made by direct examination of lung tissue. Characteristic findings include simplification of lung architecture, widened and poorly developed cellular septa with a paucity of capillaries, and strikingly muscularized small arterioles accompanied by pulmonary veins within the same connective tissue sheath. Approximately 10% of alveolar capillary dysplasia cases have been reported to have a familial association, indicating a potential genetic component. Although the search for a candidate gene has proven difficult, a recent report showed an association with haploinsufficiency for the forkhead (FOX) transcription factor gene cluster and ACD/MPV associated with additional congenital heart defects and/or gastrointestinal anomalies (Stankiewicz et al, 2009).

Recently, mutations in the gene encoding the transporter ABCA3 have been reported as a cause of severe neonatal lung disease. Infants with ABCA3 mutations lack typical lamellar bodies, indicating that ABCA3 is critical for surfactant function at birth (Wert et al, 2009). Although ABCA3 deficiency is typically associated with parenchymal lung disease, a recent report of an infant with severe pulmonary hypertension due to ABCA3 deficiency described a presentation with relatively clear lung fields on chest radiographs (Kunig et al, 2007). Infants with prolonged, severe pulmonary hypertension out of proportion to the degree of lung disease may therefore benefit from a lung biopsy and/or targeted genetic evaluations to determine the etiology of their respiratory failure.

In preterm infants, there is increasing recognition that chronic lung disease may be associated with significant pulmonary hypertension. In the United States alone, it is estimated that up to 10,000 babies develop bronchopulmonary dysplasia (BPD) each year, a disease characterized by developmental abnormalities of lung structure, including impaired alveolarization and vascularization. Although the incidence of pulmonary hypertension associated with BPD is not known, it is clear that altered pulmonary vascular growth and significant pulmonary hypertension frequently complicate the course of BPD (Kinsella et al, 2006; Mourani et al, 2009). Moreover, severe or prolonged pulmonary hypertension increases the risk of late morbidity and death (Khemani et al, 2007). The pathogenesis of pulmonary hypertension associated with BPD is complex: antenatal factors such as growth restriction, oligohydramnios, or fetal inflammation appear to play a role, and postnatal injury due to ventilator-induced lung injury and/or oxidant stress is also important. Similar to the reduction in alveolarization associated with BPD, work in animal models indicates that impaired angiogenesis is a component of abnormal lung development, which leads to decreased vascular growth and abnormal vascular structure. Identifying pulmonary hypertension in infants with BPD requires a high index of suspicion and careful longitudinal evaluation. Echocardiography is currently the most practical screening tool and should be considered in infants who continue to require oxygen supplementation at 36 weeks' corrected gestational age. In infants with evidence for significant pulmonary hypertension by echocardiogram, cardiac catheterization will allow for more accurate quantification of the severity of disease, as well as allow for vasoreactivity testing (Mourani et al, 2008).

CLINICAL EVALUATION OF INFANTS WITH PPHN

Clinically, PPHN is most often recognized in the term or near-term neonate, but may infrequently occur in premature neonates as well. PPHN typically manifests as respiratory distress and cyanosis within hours of birth and may be associated with a variety of lung and/or cardiac disorders (Box 52-1). Although PPHN is often associated with signs of perinatal distress, such as asphyxia, low Apgar scores, or meconium staining, idiopathic PPHN can present without signs of acute perinatal distress.

PPHN is characterized by hypoxemia that is poorly responsive to supplemental oxygen. An important goal for the initial clinical evaluation is to determine whether a hypoxemic infant has PPHN-type physiology (Abman and Kinsella, 1995). Because a PFO and PDA are normally present early in life, elevated pulmonary vascular resistance in the newborn will produce extrapulmonary shunting of blood through these fetal channels, leading to severe and potentially unresponsive hypoxemia. In the presence of right-to-left shunting across the patent ductus arteriosus, "differential cyanosis" is often present, which is difficult to observe by physical exam but may be detected by a gradient in the PaO_2 and/or oxygen saturation between the right radial artery and descending aorta sites. Because the left subclavian artery may have either a preductal or postductal origin from the aorta, it is best to apply the oximeter probe to one of the feet for postductal pulse oximetry monitoring. It is also important to remember that a similar pattern of postductal desaturation may be observed in ductus-dependent cardiac diseases, including hypoplastic left heart syndrome, coarctation of the aorta, and interrupted aortic arch.

In many infants, intrapulmonary shunt or ventilation-perfusion mismatch resulting from parenchymal lung disease is the predominant abnormality, rather than shunting of blood flow across the PDA and PFO. In this setting, hypoxemia is related to the amount of pulmonary arterial blood perfusing the nonaerated lung regions. Although PVR is often elevated in hypoxemic newborns without PPHN, high PVR does not contribute significantly to hypoxemia in these cases. Rapid improvement in response to supplemental oxygen suggests ventilation/perfusion

BOX 52-1 Disorders Associated With Neonatal Pulmonary Hypertension

PULMONARY

Meconium aspiration syndrome
Respiratory distress syndrome (term and preterm newborns)
Lung hypoplasia—primary
Congenital diaphragmatic hernia
Pneumonia/sepsis
Idiopathic
Transient tachypnea of the newborn
Alveolar-capillary dysplasia
Associated abnormalities in lung development:
- Congenital lobar emphysema (rare association)
- Cystic adenomatoid malformation (rare association)
- Idiopathic, with impaired distal alveolarization
- Others

CARDIOVASCULAR

Myocardial dysfunction (asphyxia; infection; stress)
Structural cardiac diseases:
- Mitral stenosis, cor triatriatum
- Endocardial fibroelastosis
- Pompe's disease
- Aortic atresia, coarctation of the aorta, interrupted aortic arch
- Transposition of the great vessels
- Ebstein's anomaly, tricuspid atresia

Hepatic arteriovenous malformations (AVMs)
Cerebral AVMs
Total anomalous pulmonary venous return
Pulmonary vein stenosis (isolated)
Pulmonary atresia

ASSOCIATIONS WITH OTHER DISEASES

Neuromuscular disease
Metabolic disease
Polycythemia
Thrombocytopenia
Maternal drug use or smoking

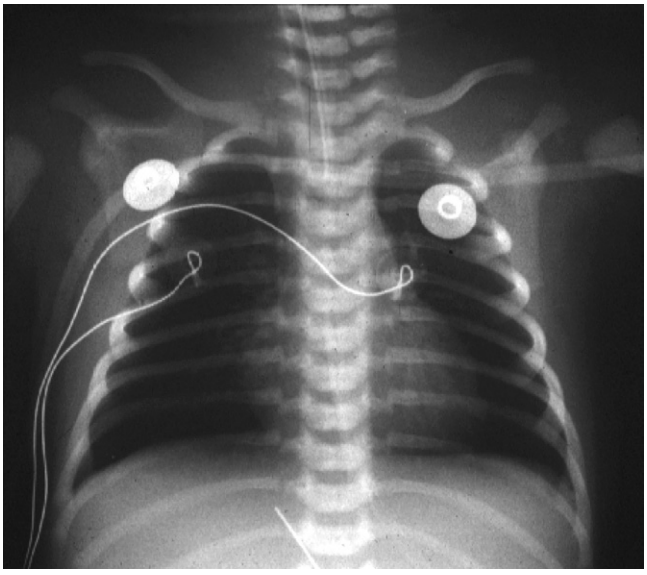

FIGURE 52-4 Typical chest radiograph of an infant with persistent pulmonary hypertension, showing mild hyperexpansion and oligemic lung fields.

mismatch due to primary lung disease, although this may not be obvious with severe parenchymal lung disease. Further, most infants with PPHN have at least a transient improvement in oxygenation in response to interventions such as high inspired oxygen and/or mechanical ventilation. Therefore, these clinical findings can only suggest, and not confirm, the diagnosis.

Radiographic findings are variable, depending on the primary disease associated with PPHN. Classically, the chest x-ray in idiopathic PPHN is oligemic, normally or slightly hyperinflated, and lacks parenchymal infiltrates (Figure 52-4). In general, the degree of hypoxemia is disproportionate to the severity of radiographic lung disease. Laboratory findings may include hypoglycemia, hypocalcemia, polycythemia, or thrombocytopenia.

The echocardiogram plays an essential diagnostic role and is an important tool for managing newborns with PPHN. The initial echocardiographic evaluation rules out structural heart disease causing hypoxemia or ductal shunting (e.g., coarctation of the aorta or total anomalous pulmonary venous return), determines the predominant direction of shunting at the PFO and PDA, and assesses ventricular function. As stated earlier, not all term newborns with hypoxemia have true PPHN physiology. Although elevated pulmonary artery pressure is commonly found in association with neonatal lung disease, the diagnosis of PPHN is not certain without evidence of bidirectional or predominantly right-to-left shunting across the foramen ovale or ductus arteriosus. Echocardiographic signs such as increased right ventricular systolic time intervals and septal flattening are suggestive, but less definitive in making a diagnosis. In addition to demonstrating the presence of PPHN physiology, the echocardiogram is critical for the evaluation of left ventricular function. Although right-to-left shunting at the ductus arteriosus and foramen ovale is typical for PPHN, in some infants predominant right-to-left shunting at the ductus associated with left-to-right shunt at the foramen ovale may reveal that left ventricular dysfunction is contributing significantly to the underlying pathophysiology. High pulmonary venous pressure due to left ventricular dysfunction will elevate pulmonary arterial pressure, causing right-to-left shunting with little vasoconstriction. When severe left ventricular dysfunction accompanies pulmonary hypertension, pulmonary vasodilation alone may be ineffective in improving oxygenation and must be accompanied by targeted therapies to increase cardiac performance and decrease left ventricular afterload. Thus, careful echocardiographic assessment provides invaluable information about the underlying pathophysiology and will help guide the course of treatment.

At present, there is no single biochemical marker that has emerged with sufficient sensitivity and specificity for the diagnosis and management of PPHN. However, brain-type natriuretic peptide (BNP), an endogenous peptide hormone secreted by the cardiac ventricles in response to increased wall stress, may have some utility. A recent report suggests that high BNP levels (particularly those >850 pg/mL) may help differentiate infants with PPHN physiology from those with pulmonary causes of respiratory failure (Reynolds et al, 2004). Because BNP levels are widely used for rapid assessment of cardiac failure in adults, they can be easily and rapidly measured in most hospitals. However, the

correlation between BNP levels and hypoxemia was weak, indicating that this test should not be used alone to gauge the severity of PPHN, but rather in combination with other clinical and echocardiographic data.

GENERAL MANAGEMENT FOR PPHN

General management principles for the newborn with PPHN include maintenance of normal temperature, electrolytes (particularly calcium), glucose, hemoglobin, and intravascular volume. Mechanical ventilation is almost always required to improve oxygenation, to achieve normal lung volumes, and to avoid the adverse effects of high or low lung volumes on pulmonary vascular resistance. The goal of mechanical ventilation should be to optimize lung volumes, and care should be taken to avoid settings that may induce ventilator-induced lung injury, which can lead to inflammatory changes, pulmonary edema, and decreased lung compliance. Some newborns with parenchymal lung disease associated with PPHN physiology demonstrate marked improvements in oxygenation as well as decreased right-to-left extrapulmonary shunting after lung recruitment during high-frequency ventilation (Kinsella and Abman, 2000).

The use of surfactant therapy to recruit the lung remains variable between centers (Fliman et al, 2006). Single-center trials have shown that surfactant improves oxygenation, reduces airleak, and reduces need for ECMO in infants with meconium aspiration (Findlay et al, 1996). A multicenter trial showed benefit in infants with parenchymal lung diseases such as meconium aspiration syndrome and sepsis, and also demonstrated that the benefit was greatest for infants with relatively mild disease (Lotze et al, 1998). However, this trial also failed to show a reduction in ECMO utilization in the subset of newborns with idiopathic PPHN. Therefore, the use of surfactant should only be considered for infants with parenchymal lung disease.

Acidosis can act as a pulmonary vasoconstrictor and should be avoided. However, variability exists between centers regarding the use of hyperventilation to achieve alkalosis in order to improve oxygenation. The use of alkalosis was frequent before the approval of inhaled nitric oxide (iNO) based on studies that found transient improvements in PaO_2 after acute hyperventilation (Drummond et al, 1981). However, no studies have demonstrated long-term or safety benefit. The pulmonary vascular response to alkalosis is transient, and prolonged alkalosis may paradoxically worsen pulmonary vascular tone, reactivity, and permeability edema (Laffey et al, 2000). Further, alkalosis produces cerebral constriction, reduces cerebral blood flow and oxygen delivery to the brain, and may be associated with worse neurodevelopmental outcomes (Ferrara et al, 1984). Similarly, there is currently no evidence to suggest that the use of sodium bicarbonate infusions to induce alkalosis provides any short-term or long-term benefit (Walsh-Sukys et al, 2000).

Systemic hemodynamics should be optimized with volume and cardiotonic therapy (dobutamine, dopamine, and milrinone), to enhance cardiac output and systemic O_2 transport. Systemic hypotension may worsen right-to-left shunting, impair oxygen delivery, and worsen gas exchange in patients with parenchymal lung disease. However, the goal is more complex than simply increasing blood pressure, and careful attention should also be paid to right and left ventricular function. For instance, the level of systemic arterial pressure is the major component of afterload for the left ventricle, and marked increases in systemic pressure have the potential to worsen left ventricular dysfunction. Some clinicians advocate increasing systemic blood pressure to prevent right-to-left shunting across the ductus arteriosus. Although this strategy may improve oxygenation, if it is not accompanied by a reduction in pulmonary vascular resistance, the right ventricle will also be presented with substantial increases in afterload. Because the right ventricle of the fetus and young neonate exhibits a high degree of sensitivity to afterload (Reller et al, 1987), this approach should be used with caution and accompanied by careful longitudinal assessment of biventricular function.

Infants who fail to respond to medical management, as evidenced by failure to sustain improvement in oxygenation with good hemodynamic function, may require treatment with extracorporeal membrane oxygenation or ECMO (UK Collaborative ECMO Trial Group, 1996). The oxygenation index (OI; calculated as [mean airway pressure × FiO_2 × 100]/PaO_2) is often used to gauge the severity of disease, with OI >40 used as an indication for evaluation for ECMO. ECMO remains an effective and potentially life-saving rescue modality for severe PPHN, although it is also costly, labor intensive, and associated with potential adverse effects, such as intracranial hemorrhage and ligation of the right common carotid artery.

Even with all available therapies, the mortality rate for PPHN remains between 5% and 10%. In addition, approximately 25% of infants with moderate or severe PPHN will exhibit significant neurodevelopmental impairment at 12–24 months (Clark et al, 2003; Konduri et al, 2007; Neonatal Inhaled Nitric Oxide Study Group, 2000). This important observation may indicate that the underlying disease, antenatal factors, and/or early therapeutic approaches are associated with early neurological injury.

INHALED NITRIC OXIDE FOR PPHN

The primary goal of PPHN therapy is selective pulmonary vasodilation. iNO therapy (5 to 20 ppm) improves oxygenation and decreases the need for ECMO therapy in patients with diverse causes of PPHN (Clark et al, 2000; Davidson et al, 1998; Kinsella et al, 1997; Neonatal Inhaled Nitric Oxide Study Group, 1997; Roberts et al, 1997). Inhaled NO is well suited for the treatment of PPHN: it is a rapid and potent vasodilator, and because nitric oxide is a small gas molecule, it can be delivered as inhalation therapy to airspaces approximating the pulmonary vascular bed. In contrast, intravenous dilators such as prostacyclin, tolazoline, and sodium nitroprusside may produce nonselective effects on the systemic circulation, leading to hypotension as well as increased right-to-left shunting and impaired oxygenation. Large placebo-controlled trials enrolled infants with an oxygenation index of >25 and provided clear evidence that iNO significantly decreases the need for extracorporeal life support in newborns with diverse causes of hypoxemic respiratory failure and PPHN,

TABLE 52-1 Summary of the Large, Multicenter Randomized Trials of Inhaled NO in Term Newborns With Hypoxemic Respiratory Failure and/or PPHN, Showing the Effect of iNO on ECMO Utilization and Mortality

			% ECMO		% Mortality	
	n	OI	Control	iNO	Control	iNO

*Indicates significantly different than control group

as shown in Table 52-1 (Clark et al, 2000; Neonatal Inhaled Nitric Oxide Study Group, 1997). These studies also showed that doses of 5 to 20 ppm were effective, and that increasing the dose beyond 20 ppm in nonresponders did not improve outcomes (Neonatal Inhaled Nitric Oxide Study Group, 1997). Further, sustained treatment with 80 ppm NO increased the risk of methemoglobinemia (Davidson et al, 1998). Weaning can generally be accomplished in 4 to 5 days, and prolonged need for inhaled NO therapy without resolution of disease should lead to a more extensive evaluation to determine whether other underlying anatomic lung or cardiovascular disease is present, such as pulmonary venous stenosis, alveolar capillary dysplasia, or severe lung hypoplasia (Goldman et al, 1996).

Although well-controlled trials led to the U.S. Food and Drug Administration (FDA) approval of iNO for therapy of PPHN, it is important to note that iNO did not reduce the mortality, length of hospitalization, or risk of neurodevelopmental impairment associated with PPHN (see Table 52-1) (Clark et al, 2003; Neonatal Inhaled Nitric Oxide Study Group, 2000). Moreover, beginning iNO at a milder or earlier point in the disease course (for an oxygenation index of 15 to 25) did not decrease the incidence of ECMO and/or death, or improve other patient outcomes, including the incidence of neurodevelopmental impairment (Konduri et al, 2004, 2007). Finally, although preterm infants (<34 weeks' gestation) may exhibit pulmonary hypertension as a component of their respiratory failure, there is less evidence to indicate whether iNO benefits this population.

These clinical trials have also revealed that as many as 40% of infants will not respond or sustain a response to iNO. The reasons for an inadequate response are diverse and require the clinician to carefully analyze the relative roles of parenchymal lung disease, pulmonary vascular disease, and cardiac dysfunction for each infant. For instance, if severe airspace disease is associated with PPHN, strategies such as high-frequency ventilation that optimize lung expansion are likely to be effective, and the two therapies used together are more effective than either used individually (Kinsella et al, 1997). Cardiac function should also be carefully assessed longitudinally. In particular, infants with severe left ventricular dysfunction are likely to have pulmonary venous hypertension and are unlikely to respond to pulmonary vasodilation unless there is also optimization of cardiac performance.

Because iNO is usually delivered with high concentrations of oxygen, these therapies could interact and lead to enhanced production of reactive oxygen and reactive nitrogen metabolites, both of which may contribute to vasoconstriction and/or inadequate responses to iNO. Although hyperoxic ventilation is used to promote pulmonary vasodilation in PPHN, we know surprisingly little about what oxygen concentrations will maximize benefits and minimize risk, and there is little to indicate that increasing oxygen concentrations beyond 50% to 60% further enhances pulmonary vasodilation in the normal or remodeled pulmonary circulation (Lakshminrusimha et al, 2007, 2009b; Rudolph and Yuan, 1966). Furthermore, studies in newborn lambs with pharmacologic or anatomic pulmonary hypertension indicate that even brief (30-minute) exposures to 100% O_2 blunt subsequent responsiveness to NO (Farrow et al, 2008a; Lakshminrusimha et al, 2006a, 2007, 2009b). High concentrations of oxygen may be toxic to the developing lung through formation of reactive oxygen species, such as superoxide anions (Lakshminrusimha et al, 2006a). Superoxide may react with arachidonic acid to increase concentrations of isoprostanes and may also combine with NO to form peroxynitrite (Lakshminrusimha et al, 2006b). Both are potent oxidants with the potential to produce vasoconstriction, cytotoxicity, and damage to surfactant proteins and lipids.

NEW INSIGHTS INTO PPHN PATHOPHYSIOLOGY AND TREATMENT

Alterations in downstream signaling mechanisms in pulmonary vascular smooth muscle cells may also lead to inadequate vascular responses to iNO. NO mediates vasodilation by stimulating soluble guanylate cyclase (GC) in vascular smooth muscle cells, which then converts guanosine triphosphate to cGMP (see Figure 52-1). cGMP is the central and critical second messenger that regulates contractility of the smooth muscle cell by modulating the activity of cGMP-dependent kinases, phosphodiesterases, and ion channels. Therefore, there are multiple critical points in the pathway downstream from NO production that serves as attractive targets for manipulating cellular cGMP concentrations. For example, expression and activity of soluble guanylate cyclase are decreased in the abnormally remodeled pulmonary vessels of the PPHN lamb model, which could potentially diminish responses to both endogenous and exogenous NO. This finding would indicate that new compounds that directly stimulate sGC at a NO-independent but heme-dependent site may be helpful, a hypothesis that appears to be promising in pre-clinical testing (Deruelle et al, 2006).

Recent evidence indicates that the low cGMP concentrations associated with PPHN may also be due in part to increased activity of cGMP-specific phosphodiesterases (PDE5). Inhibition of PDE5 activity would thus be expected to increase cGMP concentrations (see Figure 52-1), dilate the pulmonary vasculature, and/or increase the efficacy of iNO. Recently approved by the FDA for the treatment of adult pulmonary hypertension, sildenafil

is a potent and highly specific PDE5 inhibitor that has been used in several preclinical studies of animal models of pulmonary hypertension. For example, in lambs with experimental pulmonary hypertension, both enteral and aerosolized sildenafil dilated the pulmonary vasculature and augmented the pulmonary vascular response to iNO (Ichinose et al, 2001; Weimann et al, 2000). Intravenous sildenafil was found to be a selective pulmonary vasodilator with efficacy equivalent to inhaled nitric oxide in a piglet model of meconium aspiration, although hypotension and worsening oxygenation resulted when sildenafil was used in combination with iNO (Shekerdemian et al, 2002, 2004). Data have now begun to emerge on the use of sildenafil in human infants with PPHN. A recent report of a small cohort of human infants with PPHN demonstrated that enteral sildenafil improved oxygenation and survival compared to placebo (Baquero et al, 2006). More recent findings from a multicenter, dose-range study of intravenous sildenafil for infants with severe pulmonary hypertension indicate that the drug was generally well tolerated, with improvements in oxygenation noted in the cohorts that received higher infusion doses (Steinhorn et al, 2009). It is interesting to note that systemic administration of sildenafil improved oxygenation, but had little effect on systemic blood pressure. Seven infants received sildenafil before initiation of iNO and showed similar improvements in oxygenation. Of these, six survived to discharge without need for additional therapy with iNO or ECMO. These data suggest that sildenafil has the potential to independently decrease pulmonary vascular resistance and improve oxygenation in human infants with PPHN.

Similar to cGMP, cAMP also stimulates the cascade that leads to smooth muscle relaxation, and amplification of the cAMP signaling pathway could therefore enhance pulmonary vasodilation. Prostacyclin is a second central vasodilator that is upregulated after birth, primarily in response to ventilation of the lung. Prostacyclin stimulates adenylate cyclase to increase intracellular cAMP levels, which, similar to cGMP, produce vasorelaxation through a decrease in intracellular calcium concentrations. Intravenous PGI_2 is standard therapy for older children with pulmonary hypertension, but the use of systemic infusions of PGI_2 may be limited by systemic hypotension and/or ventilation-perfusion mismatch in neonatal PPHN populations. Inhaled PGI_2 has been shown to have vasodilator effects limited to the pulmonary circulation, and its efficacy has been reported to be similar to that of iNO (Khan et al, 2009). The actions of inhaled PGI_2 and iNO appear to be additive in humans and even synergistic in some studies. Reports of inhaled PGI_2 use in neonates with PPHN are limited, but case reports indicate it may enhance oxygenation in infants who are poorly responsive to iNO (Kelly et al, 2002). New agents are being developed specifically for inhalation (e.g., iloprost), and it will be interesting to learn if they also promote pulmonary vasodilation in neonatal populations (Ivy et al, 2008). Inhibition of phosphodiesterase type 3 (PDE3), which metabolizes cAMP, might also enhance cAMP signaling in PPHN (Chen et al, 2009). Milrinone, a PDE3 inhibitor, has been shown to decrease pulmonary artery pressure and resistance and to act additively with iNO in animal studies (Thelitz et al, 2004). A recent report indicates that the addition of intravenous milrinone to neonates with severe PPHN and poor iNO responsiveness was associated with improvements in oxygenation without compromising hemodynamic status (McNamara et al, 2006).

There is mounting evidence that oxidant stress plays an important role in the pathogenesis of PPHN. An increase in reactive oxygen species such as superoxide and hydrogen peroxide in the smooth muscle and adventitia of pulmonary arteries has been demonstrated in the PPHN lamb model (Brennan et al, 2003; Lakshminrusimha et al, 2006b; Wedgwood et al, 2005), as well as in postnatal models induced by chronic hypoxia (Fike et al, 2008). Possible sources for elevated concentrations of reactive oxygen species include increased expression and activity of NADPH oxidase and "uncoupled" nitric oxide synthase activity (Aschner et al, 2007; Konduri et al, 2003), as well as a reduction in endogenous superoxide dismutase activity (Brennan et al, 2003). Elevated concentrations of reactive oxygen species promote vascular smooth muscle cell proliferation in PPHN and produce abnormal vascular reactivity through mechanisms that blunt cGMP accumulation. Interestingly, one of the mechanisms may be through oxidant-mediated activation of cGMP-specific phosphodiesterases (Farrow et al, 2008a).

If reactive oxygen species promote vasoconstriction, it is possible that scavengers of reactive oxygen species will augment responsiveness to both endogenous and exogenous NO and promote pulmonary vasodilation. Superoxide dismutase scavenges and dismutates the superoxide radical to hydrogen peroxide, which is subsequently converted to water by catalase and glutathione peroxidase. Administration of recombinant human superoxide dismutase (rhSOD) has been tested in preterm infants without adverse effects and with trends toward decreased pulmonary morbidity (Davis et al, 2003). In lambs with pulmonary hypertension, rhSOD was found to dilate the pulmonary circulation and enhance responsiveness to inhaled NO (Steinhorn et al, 2001). A recent study examined the effects of rhSOD on oxygenation over a 24-hour period in ventilated PPHN lambs (Lakshminrusimha et al, 2006b). A single dose of rhSOD improved oxygenation to a degree similar to that observed for iNO. Further, rhSOD treatment appeared to block formation of oxidants such as peroxynitrite and isoprostanes and restore activity of endogenous nitric oxide synthase (Farrow et al, 2008b). Thus, an antioxidant therapeutic approach may have multiple beneficial effects: Scavenging superoxide may increase the availability of both endogenous and inhaled NO and may also reduce oxidative stress and limit lung injury (Firth and Yuan, 2008).

SUMMARY

Persistent pulmonary hypertension complicates the course of up to 10% of neonates with respiratory failure. It is associated with a diverse set of cardiopulmonary conditions, and its pathophysiologic mechanisms are characterized by vascular dysfunction, injury, and remodeling that occurs before and after birth. In the past 20 years, experimental work on basic mechanisms of vascular regulation of the developing pulmonary circulation has improved the range of therapeutic approaches to neonates with PPHN.

In particular, inhaled NO has proved to be a selective and effective pulmonary vasodilator for infants with PPHN, although successful clinical management requires meticulous care of all aspects of the associated lung and cardiac disease. Current research is focused on developing a better understanding of cellular responses in the remodeled vasculature that will likely elucidate additional signaling pathways and lead to new therapeutic strategies. More work is needed to further improve the survival and neurodevelopmental outcomes of sick newborns with pulmonary hypertension, especially in patients with lung hypoplasia and advanced structural vascular disease.

CHAPTER 53

Fetal and Neonatal Echocardiography

Margaret M. Vernon and Mark Lewin

Echocardiography is the application of ultrasound to the evaluation of the cardiovascular system. Over the past several decades, echocardiography has become the gold standard for the determination of congenital and acquired cardiac malformations. Echocardiography provides reliable and reproducible information on cardiovascular form and function. Detailed cardiac structures can be identified, with differentiation of abnormal from normal anatomy, using high-resolution two-dimensional echocardiography. Accurate measures of myocardial thickness and cavity dimensions can be obtained via M-mode echocardiography. Components of hemodynamics, such as blood flow velocity and spatial direction, can be used to derive pressure measurements by the use of Doppler echocardiography.

Echocardiography is important not only in the diagnostic evaluation of congenital heart disease but also in the overall assessment of the cardiovascular system in disorders unique to the fetus and newborn infant. The information obtained is real-time, noninvasive, and acquired at the patient's bedside. Physiologic data points can be measured in a serial manner, which can be of great value in managing the fetus or sick neonate as conditions are explored and responses to management strategies are gauged. This chapter reviews the basic principles of echocardiography and their applications in the prenatal and newborn setting.

APPLICATION OF ULTRASOUND TO CARDIAC IMAGING

PHYSICS OF ULTRASOUND

Ultrasound energy is generated by the stimulation of piezoelectric crystals housed in a unit called a transducer. When ultrasound energy is transmitted into biologic tissue, the majority is absorbed; however, a small amount is reflected back to the transducer. Reflected energy is processed and an image created on a screen. Ultrasound scatter is greatest at the interfaces between biologic tissues of disparate densities. Hence, bone and air, when adjacent to soft tissues such as the heart, create poor acoustic windows for ultrasound transmission. Soft tissue and fluid are excellent media for ultrasound transmission and provide clear windows for cardiac imaging (Weyman, 1994).

The range of frequencies used for diagnostic assessment of biologic tissue is 2 to 12 MHz (1 MHz = 1 million cycles per second). Low-frequency ultrasound energy penetrates tissue better than high-frequency ultrasound; however, higher-frequency ultrasound provides for greater spatial resolution of fine structures. This principle is dictated by a fundamental law of physics that defines the relation between ultrasound frequency and wavelength:

$$\text{velocity of sound in biologic tissue} = \text{ultrasound frequency} \times \text{wavelength}$$

An ultrasound wavelength distance is the physical limit beyond which two structures in space cannot be distinguished. Hence, the smaller the wavelength (i.e., the higher the frequency), the greater the ability to distinguish two points in space that are very close to each other.

Let us look at the following example. Two structures exist in space 0.5 mm apart. The velocity of sound in biologic tissue is a constant at approximately 1540 meters/second. Applying a frequency of 2 MHz of ultrasound energy will result in a wavelength of 0.77 mm, whereas applying a frequency of 8 MHz of ultrasound energy will result in a wavelength of 0.19 mm. Hence, to the operator using the 2-MHz transducer, the two structures will not be distinguishable from each other and will appear as one (in that the distance between them is less than the ultrasound wavelength), whereas the operator using the 8-MHz transducer will be able to differentiate between the structures with ease. Accordingly, higher frequencies, at a minimum 5 MHz and more typically 8 to 12 MHz, are used in the neonatal setting because penetration is less important in the small subject and the objective is to maximize fine structure resolution.

BASIC IMAGING COMPONENTS

Two-Dimensional Imaging

Development of phased-array transducers has allowed for sector scanning and the display of two-dimensional (2D) images. This is the most commonly applied modality of echocardiography and is used primarily for determination of anatomic structure.

M-Mode

The earliest form of echocardiographic imaging, M-mode echocardiography, displays fine detail of cardiac structure along a time line. A single thin plane of ultrasound energy is focused onto a targeted region of the heart. All structures within the targeted plane of insonation are then displayed in real time as they change during various portions of the cardiac cycle.

M-mode echocardiography is commonly used for measurement of myocardial wall thickness and cavity dimensions and is useful in estimating ventricular cavity size for calculation of the ventricular *shortening fraction*—an estimate of ventricular function. By angling the plane of insonation through the short axis of the left ventricle at the level of the tips of the papillary muscles, one can obtain an M-mode display of the change in ventricular cavity dimension over time (Figure 53-1). The ratio of the difference between left ventricle end-diastolic dimension (LVEDD) and left ventricle end-systolic dimension (LVESD) to the left ventricle end-diastolic dimension is

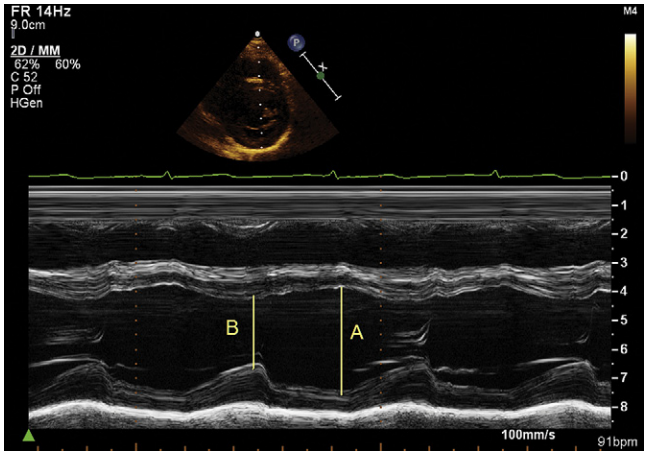

FIGURE 53-1 M-mode tracing of the left ventricular dimensions over time obtained in the short-axis view. The electrocardiographic tracing helps identify the timing of the cardiac cycle as systolic or diastolic. Measurement A demonstrates the left ventricle end-diastolic dimension, and measurement B, the left ventricle end-systolic measurement. The shortening fraction is calculated at 35%.

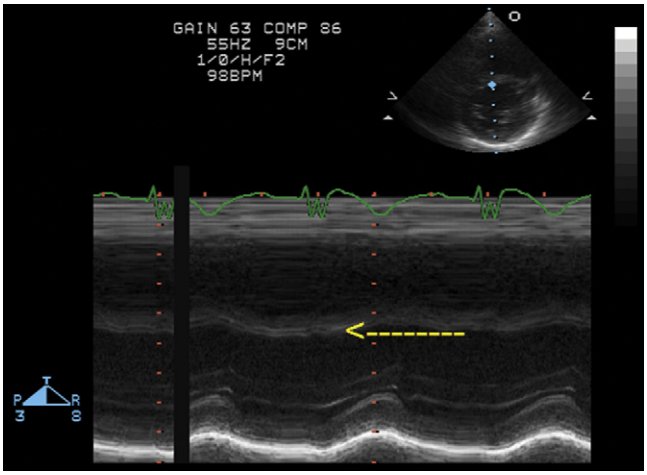

FIGURE 53-2 M-mode tracing of the left ventricular dimensions over time obtained in the short-axis view. The electrocardiographic tracing helps identify the timing of the cardiac cycle as systolic or diastolic. The interventricular septum moves paradoxically (*arrow*) because of elevated right ventricular pressure. Therefore, a shortening fraction cannot be calculated accurately.

the shortening fraction [(LVEDD – LVESD)/LVEDD × 100 = %SF]. The normal range is 28% to 38%, which correlates with a ventricular volumetric ejection fraction ratio of 55% to 65%, suggesting normal ventricular function. Interpretation of the %SF must also take into account the overall dimensions of the left ventricle. For example, an infant with a volume load due to mitral regurgitation or a large patent ductus arteriosus (PDA) may have a normal %SF but may have a dilated, enlarged left ventricle when normalized for body surface area. The %SF also can be helpful in investigating the cause of hypotension in infants. With hypotension due to myocardial dysfunction, the infant will have a dilated left ventricle and diminished %SF. With hypotension due to vasodilatation, such as is seen in various conditions of sepsis, the infant may have a normal or hyperdynamic %SF, often exceeding 40%. Volume-depleted infants will exhibit a normal %SF but a small left ventricular cavity size.

Although it is the most commonly used technique for determination of ventricular function, the M-mode measurement of %SF has a number of limitations. It provides for only a single-plane assessment of ventricular contraction and is invalid in conditions in which there is wall motion abnormality. Paradoxical movement of the ventricular septum away from the posterior wall during systole may create a spuriously low %SF value. Hence, %SF measures may be difficult to interpret in the presence of right bundle branch block, right ventricle dilatation due to atrial septal defect, or right ventricular hypertension due to either a congenital cardiac lesion (for example, tetralogy of Fallot) or pulmonary hypertension (Figure 53-2).

Doppler

Application of the Doppler principle allows for determination of the velocity and direction of moving objects. Because blood and myocardial tissue both are in motion throughout the cardiac cycle, either can be assessed by Doppler echocardiography. Doppler imaging can be performed in a number of ways. In pulsed-wave Doppler echocardiography, transducer crystals alternately fire pulses of energy and then "listen" for reflected signal return. This mode allows for determination of spatial signal position but limits the ability to measure blood traveling at higher velocities. In continuous-wave Doppler echocardiography, half of the transducer crystals fire continuously while the other half "listen" continuously. This mode allows for unambiguous assessment of increased velocities but limits the ability to pinpoint the precise location at which the velocity is obtained. In combination, pulsed-wave and continuous-wave Doppler modes provide a complete picture of blood flow direction and velocity.

Color Doppler echocardiography uses pulsed-wave principles to create a 2D sector display of all velocities within a given region of interest. A sector within a 2D image is identified and pixels of color are displayed overlying the area of interrogation. Each color pixel reflects the direction of motion; the shade of color reflects the velocity. By convention, "warm" colors such as red and orange designate direction of flow toward the transducer, and "cold" colors such as blue and white designate flow away from the transducer (Figure 53-3). When flow velocities exceed the characteristics of the transducer, the smooth, laminar color pattern changes to a speckled color pattern, suggesting a region of more turbulent flow. Whether this represents a pathologic velocity change requires pulsed Doppler interrogation. Doppler techniques are also applied to tissue motion of the myocardium, yielding information helpful in ascertaining parameters of myocardial function. Although tissue signals move at much lower velocities than blood signals, determination of Doppler-derived tissue velocities can aid in understanding complex states of systolic and diastolic dysfunction (Mertens and Friedberg, 2009). Distinct patterns of normal and abnormal motion of various myocardial segments have been described.

Data derived from Doppler echocardiography are used to provide physiologic information. Using the principles of flow hydraulics across a tubular system with

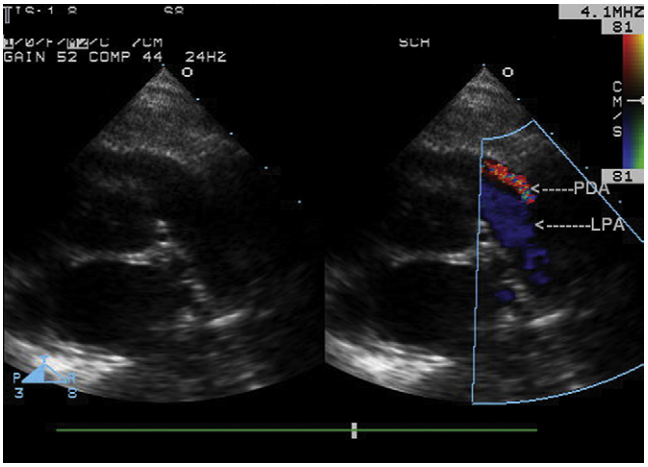

FIGURE 53-3 *(Supplemental color version of this figure is available online at www.expertconsult.com.)* **Side-by-side two-dimensional and color Doppler echocardiographic images of a ductus arteriosus.** Flow in the PDA is red, indicating flow toward the transducer (in this case left-to-right) and is directed toward the MPA from the aorta. The PDA color signal is speckled, indicating a more turbulent region of flow. High velocity in the PDA is the normal state, indicating appropriately elevated pressures in the aorta as compared to the lower pressures in the pulmonary artery. The flow in the LPA is blue, indicating flow away from the transducer. The LPA color flow signal is laminar (smooth), indicating a lower velocity of flow. Turbulent flow at this portion of the LPA in a neonate is most commonly associated with physiologic branch pulmonary artery stenosis, a transient phenomenon associated with neonatal transitional physiology. *PDA*, Patent ductus arteriosus; *LPA*, left pulmonary artery.

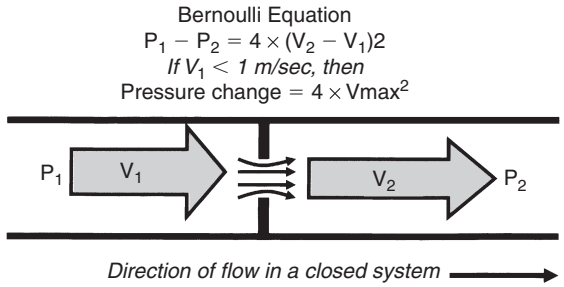

FIGURE 53-4 Bernoulli equation of flow dynamics describes the relationship between pressure differences and velocity differences across an area of narrowing in a closed fluid system. P_1, proximal pressure; P_2, downstream distal pressure; V_1, proximal velocity; V_2, distal downstream velocity.

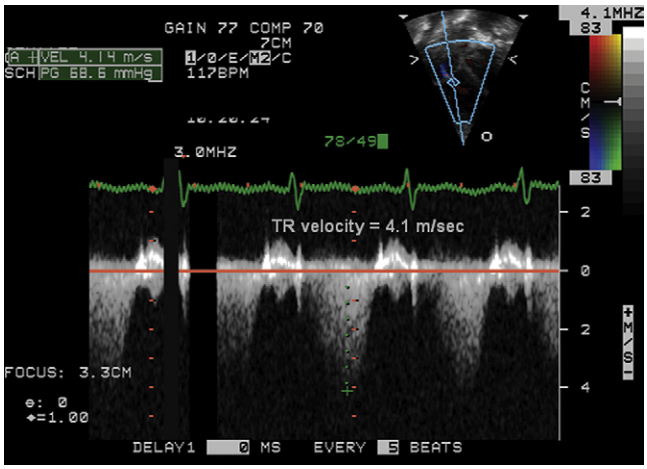

FIGURE 53-5 **Example of a Doppler signal.** Time is on the *x*-axis, and velocity is in meters/second on the *y*-axis. The Doppler signal is obtained by positioning a marker just proximal to the tricuspid valve annulus in order to sample the tricuspid regurgitant *(TR)* jet flow. In this example the TR peak velocity measures 4.1 m/sec. Using the modified Bernoulli equation, the predicted right ventricular pressure is $4 \times (4.1)^2 = 68$ mm Hg + right atrial pressure. This predicts elevated right ventricular pressure (normal is typically in the range of 20 mm Hg). In the absence of obstruction to flow through the pulmonary artery, the right ventricular pressure is equivalent to pulmonary artery pressure. We can therefore quantify pulmonary artery pressure based on the velocity of the TR jet.

discrete narrowing, velocity data can be translated into pressure data via modification of the Bernoulli equation (Figure 53-4):

$$P_1 - P_2 = 4 \times (V_2 - V_1)^2$$

Normal velocities in the heart are rarely greater than 1 meter/second. Velocities proximal to areas of narrowing are typically less than 1 meter/second and can often be ignored. Hence, the equation can be simplified to:

$$\text{pressure change} = 4 \times Vmax^2$$

This principle can be applied in a variety of clinical settings. For example, in the presence of tricuspid regurgitation (TR), the peak right ventricle pressure (which will equal the pulmonary artery pressure in the absence of pulmonary outflow obstruction) can be estimated by measuring the regurgitant jet peak velocity. A TR peak velocity of 2 meters/second suggests a pressure difference between the right atrium and the right ventricle of 16 mm Hg ($4 \times (2)^2$). We express this as a right ventricular pressure of 16 mm Hg + right atrial (or central venous) pressure. In infants and children, right atrial pressure is estimated to be between 3 and 10 mm Hg, with 5 mm Hg typically chosen as an estimated guess. Hence, in the preceding example, the patient would have a right ventricle pressure of 21 mm Hg, which is within normal limits. Alternatively, an infant with severe chronic lung disease may have a TR peak jet of 4.1 meters/second (Figure 53-5). This would translate to a pressure estimate of 64 mm Hg ($4 \times (4.1)^2$); 68 mm Hg added to the estimated right atrial pressure of 5 mm Hg gives a right ventricle pressure of 73 mm Hg, which suggests pulmonary hypertension. The Bernoulli equation also is commonly used to assess pressure gradients across stenotic valves or vessels, for example valvular aortic stenosis or coarctation of the aorta. Using the maximum velocity, we derive the "peak instantaneous" gradient across the site of obstruction.

FETAL IMAGING TECHNIQUES

Fetal echocardiography is the ultrasonic evaluation of the fetal cardiovascular system. Echocardiography is the main diagnostic modality used to evaluate the fetal heart. Cardiac formation is complete by 8 weeks after conception, and ventricular contraction can be detected by ultrasound imaging at that time. The optimal timing for performance of a comprehensive transabdominal fetal echocardiogram is 18 to 20 weeks' gestation; however, as resolution has improved, earlier diagnosis and reassurance may be possible late in the first trimester (Smrcek et al, 2006).

Similar to a pediatric transthoracic echocardiogram, a fetal echocardiogram involves assessing cardiac anatomy in a sequential fashion. Initial imaging establishes fetal position in utero (vertex, breech, or transverse). Once fetal

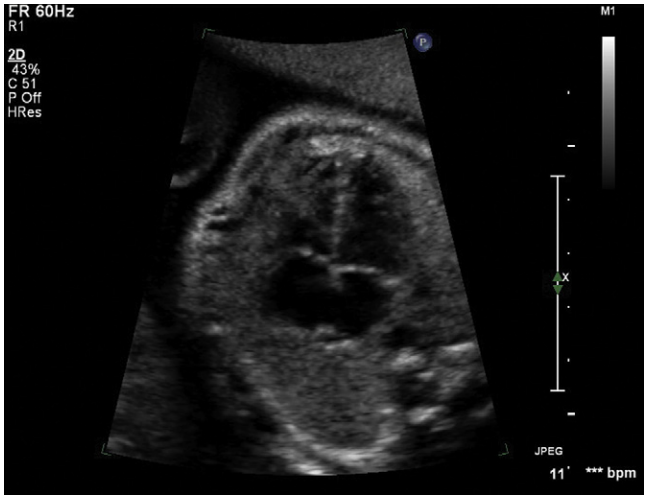

FIGURE 53-6 Four-chamber view of a normal fetal heart. All four chambers are visible with relative symmetry in size between the ventricles and atria. The right ventricle is identified by the presence of the moderator band and increased myocardial trabeculations in comparison with the left ventricle. The descending aorta is seen directly behind the left atrium.

FIGURE 53-7 Four-chamber view of the fetal heart with complex congenital heart disease. There is a large ventricular septal defect as well as a large primum atrial septal defect. There is size discrepancy between the two ventricular chambers. This fetus was diagnosed with an unbalanced complete atrioventricular canal defect (CAVC).

left and right are established, the fetal abdominal situs is confirmed as well as the position of the heart within the thorax. Although uncommon as a whole, congenital heart disease and abnormalities of laterality (heterotaxy syndrome) are commonly found together. The cardiovascular system is then evaluated beginning below the diaphragm in the abdomen and ending at the thoracic inlet as a series of imaging planes. The four-chamber view (Figure 53-6) is the most important in a comprehensive examination of the fetal heart. In this view, cardiac position, size, rate and rhythm, and qualitative contractility can all be assessed. Additionally many congenital heart defects can be detected (Figure 53-7). After a four-chamber view is obtained, attention turns to visualization of the left and right ventricular outflow tracts and an assessment of ventriculoarterial concordance. Establishing the origin of the main pulmonary artery from the right ventricle and the aorta from the left ventricle is mandatory. Finally, the systemic and pulmonary venous return is evaluated.

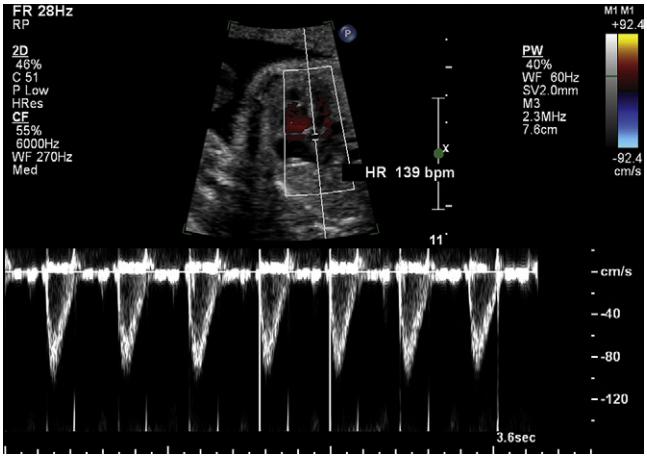

FIGURE 53-8 The fetal heart rate is documented using aortic valve Doppler. The time between successive beats is measured and a heart rate per minute calculated.

Structures are evaluated in orthogonal imaging planes in order to form a composite picture of the heart including any identified malformation. In addition to obtaining clear pictures of each structure, flow is evaluated with color Doppler and pulsed Doppler. Valve regurgitation and/or stenosis can be detected and valve leaflet motion observed. From 2D images, structures can be measured and compared with established normals for varying gestation ages.

Once a comprehensive assessment of the cardiac anatomy is complete, the heart rate is documented (Figure 53-8). The rate and rhythm of the fetal heart are evaluated by mechanical surrogate events, specifically the movement of atria and ventricles or blood flow across valves.

NEONATAL IMAGING TECHNIQUES

A systematic and standardized approach is important in performing the echocardiogram in the neonate. Follow-up echocardiographic studies may be curtailed and limited in scope; however, initial evaluation should be complete and include investigation of all aspects of the heart and great vessels using 2D, Doppler, color Doppler, and M-mode imaging. Standard imaging locations are used to create a complete picture of the heart and great vessels (Figure 53-9). These include images obtained mid-chest (parasternal imaging plane), four-chamber views (apical imaging), and abdominal views through the liver and diaphragm (subcostal imaging) and between the clavicles (suprasternal notch views). 2D imaging "sweeps" result in acquisition of tomographic cuts of the heart as the transducer is fanned through an imaging plane. This allows for "mental reconstruction" in the development of a three-dimensional understanding of cardiac structure, function, and structural relationships. Subcostal imaging is unique to neonates and pediatric patients: The liver acts to enhance acoustic transmission, and the proximity of the transducer to the heart optimizes image resolution.

Although echocardiography is considered a noninvasive diagnostic test, care should be taken during the performance of the echocardiogram, particularly in small, premature infants. In the older, less cooperative child, sedation is

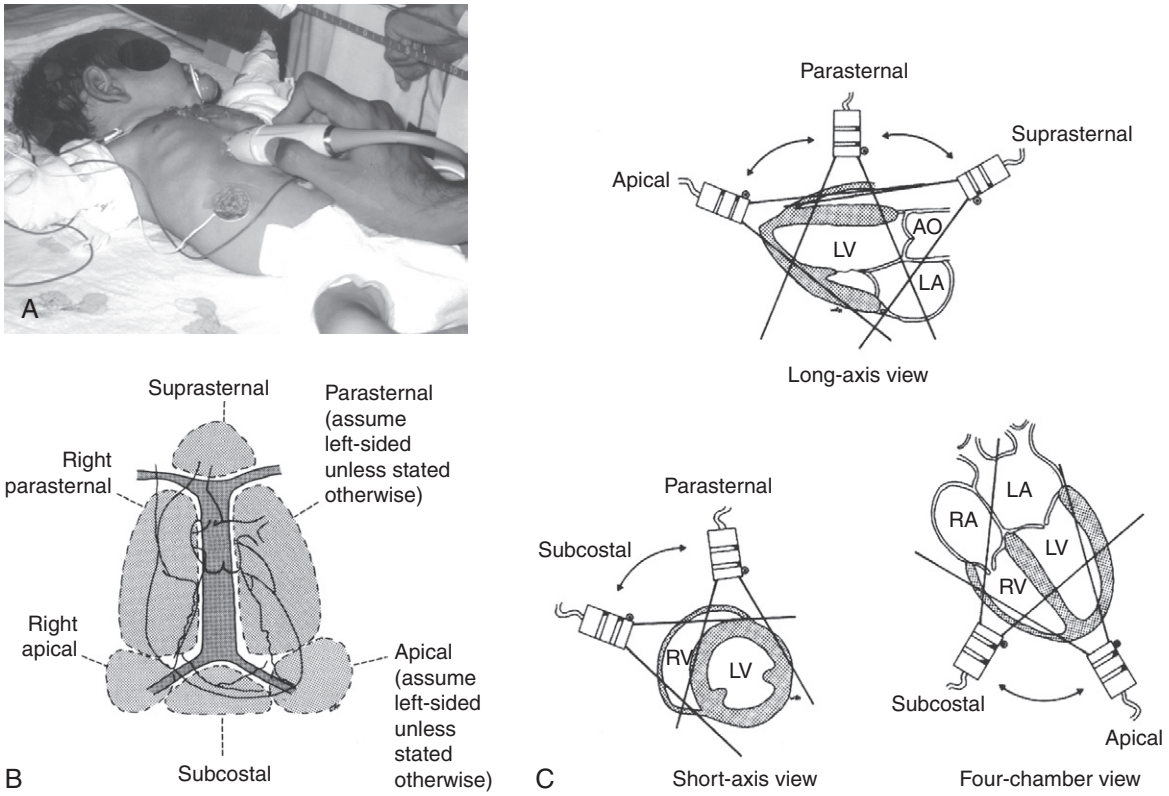

FIGURE 53-9 **A,** Demonstration of position of ultrasound transducer using the subcostal approach in a neonate. **B,** By moving the transducer to multiple windows surrounding the heart, echocardiographic two-dimensional tomographic imaging provides for a three-dimensional look at the heart via "mental reconstruction" once each of the corresponding windows has been examined. **C,** Long-axis, short-axis, and four-chamber views of the heart contribute to visualization of the overall detail of complex cardiac anatomy. *(**B** and **C,** Courtesy American Society of Echocardiography.)*

necessary to obtain patient compliance, and therefore continuous assessment during the procedure and monitoring thereafter are essential. Application of cold ultrasound gel and environmental exposure may cause temperature instability. Applying pressure on the abdomen during subcostal imaging or extending the neck during suprasternal imaging may cause destabilization of the patient due to either cardiac or pulmonary compromise. Either the person performing the echocardiogram or another assigned person should monitor heart rate, blood pressure, and ventilatory parameters during the procedure in unstable, ill infants.

FETAL ECHOCARDIOGRAPHY: GOALS OF IMAGING

Congenital heart disease, which refers mainly to anatomic malformations of the heart, constitutes one of the most common congenital anomalies. The reported incidence rate per 100 liveborn infants is 0.3 at birth and nearly 1 by the end of the first year of life (Botto et al, 2001).

Technical advances in ultrasound imaging have improved the antenatal detection of congenital heart disease (CHD); however, cardiac anomalies continue to be one of the most frequently overlooked lesions during prenatal obstetrical ultrasound examination.

The ultimate goal of fetal echocardiography is the accurate definition of any anatomic abnormality of the heart during the prenatal time period. Although a variety of maternal or fetal disorders may result in abnormality of the fetal cardiovascular system (Table 53-1), a majority of children diagnosed with congenital heart disease are born with no known risk factors. Currently, however, a comprehensive cardiovascular evaluation is recommended only in those with identified risk factors.

TABLE 53-1 Indications for Fetal Echocardiography

Maternal Indications	Fetal Indications
Family history of CHD including prior child or pregnancy with CHD	Abnormal obstetrical screening ultrasound
Metabolic disorders (e.g., diabetes)	Extracardiac abnormality
Exposure to teratogens	Chromosomal abnormality
Exposure to prostaglandin synthetase inhibitors (ibuprofen)	Arrhythmia
Infection (rubella, Coxsackie, parvovirus B19)	Hydrops
Autoimmune diagnosis (e.g., Sjögren's, SLE)	Increased first-trimester nuchal translucency
Familial inherited disorder (Marfan, Noonan syndromes)	Multiple gestation and suspected twin-twin transfusion syndrome
In vitro fertilization	

CHD, Congenital heart disease; *SLE*, systemic lupus erythematosus.

Fetal diagnosis depends on the ability to obtain standard views. The components of a comprehensive evaluation are listed in Table 53-2, although not all may be visualized in every fetus at every examination. In addition, some lesions can evolve in utero.

Once a diagnosis is established, the secondary goal of fetal echocardiography, parental counseling, can begin. Complete parental counseling includes not only a discussion of

TABLE 53-2 Components of the Fetal Echocardiogram

Overview	Fetal number and position Stomach position and abdominal situs Cardiac position
Biometric examination	Cardiothoracic ratio Biparietal diameter and head circumference Femur length Abdominal circumference
Cardiac imaging	Four-color view LVOT RVOT Great arteries Three-vessel view Bicaval view Ductal arch Aortic arch
Doppler examination	Inferior and superior vene cavae Pulmonary veins Ductus venosus Foramen ovale Atrioventricular valves Semilunar valves Ductus arteriosus Transverse aortic arch Umbilical artery Umbilical vein

Examination of rate and rhythm	M-mode study of atrial and ventricular wall motion Doppler examination of atrial and ventricular flow patterns

LVOT, Left ventricular outflow tract; *RVOT*, right ventricular outflow tract.

TABLE 53-3 Indications for Echocardiographic Evaluation in the Neonate

Conditions Associated With Congenital Heart Defects	
Syndromes	**Nonsyndromes**
Trisomies 13, 18, 21	Congenital diaphragmatic hernia
22q11 microdeletion syndromes:	Gastroschisis
DiGeorge	Omphalocele
Velocardiofacial	Tracheoesophageal fistula
VACTER association	
CHARGE association	
Holt-Oram syndrome	
Goldenhar's syndrome	
De Lange's syndrome	
Turner's syndrome	
Noonan's syndrome	
Williams syndrome	
Infantile Marfan syndrome	
Conditions Associated With Impact on Cardiovascular System	
Congenital diaphragmatic hernia	
Chronic lung disease	
Gestational diabetes mellitus	
Sacrococcygeal teratoma	
Twin-twin transfusion syndrome	
Arteriovenous malformation	
Perinatal asphyxia	
Severe anemia	

CHARGE, Coloboma, heart disease, retarded growth/development and/or central nervous system anomalies, genital hypoplasia, ear anomalies and/or deafness; *VACTER*, vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula and/or esophageal atresia, renal agenesis/dysplasia.

the abnormality identified, but also the frequently increased risk for extracardiac anomalies and chromosomal abnormalities and long-term outcome. Prenatal management plans need to be discussed, including local laws regarding termination of a pregnancy. Finally, perinatal management plans can be created to smooth the transition to the postnatal time period. Prenatal detection of CHD has been shown to improve outcome by reducing postnatal acidosis and mortality (Tworetzky et al, 2001; Verheijen et al, 2001).

NEONATAL ECHOCARDIOGRAPHY: GOALS OF IMAGING

Echocardiography is considered the gold standard in the diagnosis of congenital heart lesions. In addition, noninvasive cardiac imaging provides diagnostic support for the management of a variety of neonatal conditions. The indications for the performance of an echocardiogram in the nursery or newborn intensive care unit include the assessment of the neonate with a presumed syndromic or genetic condition that is at high risk for cardiac disease (e.g., trisomy 21), the infant with a noncardiac lesion where there is an increased risk of associated congenital heart disease (e.g., omphalocele), and the neonate with a condition that may adversely affect hemodynamics (e.g., arteriovenous malformations). These are summarized in Table 53-3. The goals of neonatal cardiac imaging are similar to that of the fetal echocardiogram. Cardiac and abdominal situs are assessed, a complete evaluation is made of the anatomic structure of the heart and proximal vasculature, and a determination is made as to the functional (systolic and diastolic) properties of the myocardium.

For an accurate determination to be made as to the dimensions of chambers, valves, and vessels, a normative data set is required. The most common methodology involves normalizing measurements to body surface area. A number of data sets are available for comparison; in order to achieve consistency, each pediatric echocardiography laboratory must decide which of these data sets will be used. Various normative (Z-score) calculators are also available online (www.parameterz.com) with references and descriptors included for ease of use. The identification of a pathologically large or small structure is especially troublesome when the patient is markedly premature. Comparative data for such children are scant and are often based on data collected from a very small number of "normal" patients. Determination of dimensions (e.g., left ventricle, aortic valve, or pulmonary artery) in such premature patients is therefore subject to a fair bit of interpretation; in these cases, consultation with the pediatric cardiologist is imperative in order to make appropriate management decisions.

Serial echocardiographic evaluations are often necessary in order to care for the neonate. This is particularly the

case when changes are occurring in the patient's clinical condition. We follow left atrial and left ventricular chamber dimensions as pulmonary vascular resistance drops in order to determine the left-to-right shunt impact in the face of a patent ductus arteriosus. We follow interventricular thickness and left ventricular outflow tract obstruction in the infant of a diabetic mother to determine if serial improvement occurs over time. The neonatal cardiopulmonary system is a highly fluid system, subject to perturbation from numerous outside influences and thus requires close monitoring in the labile child. Echocardiography is but one tool in the armamentarium of the neonatologist and cardiologist to assist with this monitoring.

FETAL-TO-NEONATAL TRANSITION PHYSIOLOGY: ECHOCARDIOGRAPHY-DERIVED ASSESSMENT

During fetal life, the placenta serves as the organ of gas exchange. This fundamental difference between the fetal and neonatal circulations is behind the complex physiological transition that occurs following birth and the clamping of the umbilical cord. With the initiation of respiration and expansion of the lungs, oxygen is brought to the alveoli. This results in a dramatic fall in pulmonary vascular resistance (PVR) and increase in pulmonary blood flow. Simultaneously, the umbilical cord is clamped, resulting in a sudden increase in systemic vascular resistance (SVR). The combination of this sudden increase in SVR and decrease in PVR leads to a reversal of flow through the ductus arteriosus. In utero flow was from right to left (pulmonary artery to descending aorta) and now flow reverses, becoming left to right (from descending aorta to pulmonary artery). Finally, because of the marked increase in pulmonary blood flow, venous return to the left atrium increases and left atrial pressure exceeds right atrial pressure. The redundant flap of tissue of the foramen ovale is pressed against the septum and closes the foramen.

Echocardiography is a very useful tool in the evaluation of a newborn. The information obtained is real-time, noninvasive, and acquired at the bedside. It is the primary imaging modality used when clinical events such as tachypnea, tachycardia, or persistent cyanosis suggest an abnormality in transitional physiology. Anything increasing the pulmonary vascular resistance or delaying the fall in pulmonary vascular resistance, such as acidosis, hypoxemia, polycythemia, lung disease, or immaturity, may impair the normal neonatal transition. Additionally, it is the uniqueness of the fetal circulation that allows many complex lesions to be tolerated silently in utero only to unmask themselves during the transitional period. Alterations from normal are most frequently associated with persistent patency of the ductus arteriosus, persistently elevated pulmonary vascular resistance, or the presence of congenital heart disease.

SUSPECTED CONGENITAL HEART DISEASE

Confirmation of the absence of structural heart disease or alternatively the identification of a significant congenital heart defect can be extremely helpful to the team caring for an ill neonate, particularly one with a recognized extracardiac anomaly. In those in whom congenital heart disease is confirmed, high-quality 2D images combined with color and pulsed- and continuous-wave Doppler are frequently sufficient for development of a comprehensive management strategy, including a surgical plan if necessary (Tworetzky et al, 1999).

ASSESSMENT OF THE DUCTUS ARTERIOSUS

Before the routine use of echocardiography, a hemodynamically significant PDA was diagnosed clinically by the presence of a murmur, hyperdynamic precordium, bounding and palmar pulses, increased ventilatory support, and radiographic evidence of cardiomegaly with increased pulmonary vascular markings. In the present era, a complete transthoracic echocardiogram is recommended before medical treatment of a presumed PDA.

The echocardiographic assessment of a PDA documents not only the size of the ductus but also the direction of flow across the ductus. Additionally, pulsed- and continuous-wave Doppler can be used to establish flow velocity and predict the pressure difference between the aorta and pulmonary artery. It is important not only to confirm the presence of a PDA, but also to ensure the absence of structural heart defects. In addition, the determination of aortic arch sidedness or branching pattern is important should surgical ligation be required (Murdison et al, 1990). Typically the aortic arch is a left aortic arch with a left-sided ductus, but a right aortic arch with a right-sided ductus can occur and alters the surgical approach to ductal ligation.

EVALUATION OF PERSISTENT PULMONARY HYPERTENSION

Persistent pulmonary hypertension of the newborn (PPHN), occasionally referred to as persistent fetal circulation, results when there is severe vasoconstriction of the pulmonary vasculature resulting in elevation of pulmonary arterial pressure and right ventricular pressure. Blood continues to bypass the lungs by shunting across the foramen ovale and ductus arteriosus. Several factors may disrupt the normal decrease in pulmonary vascular resistance and increase in pulmonary blood flow at birth, including apnea and parenchymal lung disease, both of which interfere with ventilation. Meconium aspiration and severe respiratory distress syndrome are the major parenchymal lung diseases. Pneumonia and asphyxia can cause PPHN as well.

In infants with PPHN, transthoracic echocardiography confirms the absence of structural heart disease, demonstrates atrial- and ductal-level shunting, and provides an estimate of pulmonary arterial pressure by measuring the velocity of the tricuspid regurgitation jet, if present. The Doppler pattern of flow in the ductus establishes flow direction as well as velocity. From flow velocity a pressure gradient (or lack thereof) between the aorta and pulmonary artery can be estimated by applying the Bernoulli equation (Musewe et al, 1990). The appearance of the Doppler pattern sampled in the branch pulmonary arteries may also provide information about the pulmonary vascular resistance and response to therapy.

In addition, echocardiography may be used to assess ventricular function in an infant with PPHN (Figure 53-10).

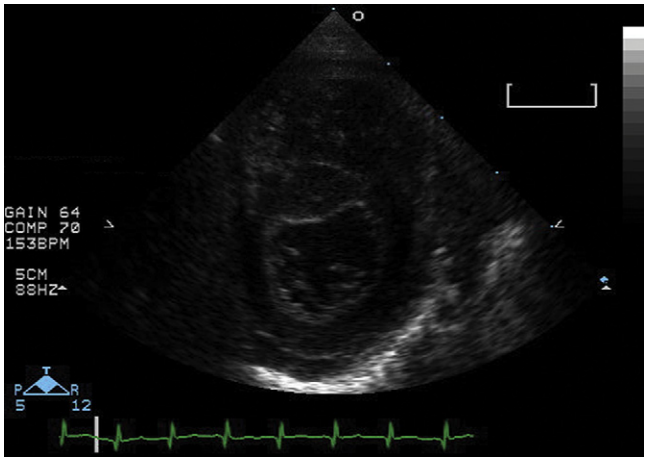

FIGURE 53-10 Short axis imaging of the ventricles. Normally the left ventricular pressure exceeds the right resulting in bowing of the ventricular septum into the right ventricular cavity. In PPHN, the right ventricular pressure (RVp) may be equivalent or even exceed the left ventricular pressure (LVp), altering the ventricular septal position, as seen in this image where the septum bows abnormally into the left ventricle. This septal position suggests the RVp exceeds the LVp.

Neonates with PPHN typically have right ventricular dysfunction (Valdes-Cruz et al, 1981). Although the etiology of cardiac dysfunction in PPHN is unclear, prenatal constriction of the ductus arteriosus has been suggested as a possible mechanism (Morin, 1989).

Extracorporeal membrane oxygenation (ECMO) is frequently used in infants with severe PPHN whose hypoxemia does not respond to mechanical ventilatory support and pulmonary vasodilators such as oxygen and nitric oxide. Echocardiography can be used to document improvement or causes of difficulties in circuit flow. Additionally, an echocardiogram is often crucial to rule out congenital heart defects that may mimic PPHN, including total anomalous pulmonary venous return with obstruction.

LIMITATIONS OF ECHOCARDIOGRAPHY

Although an extremely useful tool that has revolutionized the approach to diagnostic evaluation of the cardiovascular system in the neonate, echocardiography has a number of limitations:

- *Discrepancy between "echo-derived" and "catheter-derived" gradients*. Doppler echocardiography measures the "peak instantaneous" pressure difference at any point in time during flow across a stenotic valve. In the case of a stenotic aortic valve, this may occur during the upstroke of systole, not at the peak of systole. Catheter-based measures of pressure are taken at the peak of systole; hence, echo-derived pressure gradients do not equal, and usually exceed, catheter-derived measures. This discrepancy does not invalidate the measures of either modality but rather highlights the point that they are measures of gradients occurring during two different points in systole. Historically, clinical decision making has been based on catheter-derived information; therefore, echocardiographically derived data should be interpreted in this light. Other factors that may have an impact on differences in echocardiographic versus catheter-based gradients are level of sedation, hydration status, medications (inotropes), and ventilatory strategy.
- *Stress of the test*. Lengthy environmental exposure, temperature instability, and pressure application on the chest or abdomen during transducer contact may result in stress for the premature or hemodynamically unstable infant, often necessitating termination of the procedure or limiting the scope of the ultrasound evaluation.
- *Inadequate visualization of structures*. Lung disease can cause acoustic impedance, limiting the ability to visualize structures. Air within the thorax due to air trapping, pneumothorax, or pneumopericardium can result in a dramatic deterioration in image clarity.
- *Inadequate Doppler signal for velocity measurement*. Small blood volumes traveling at low velocity may be difficult to identify with echocardiography. Examples are coronary arteries in the very small, premature infant and pulmonary vein flow in patients with severe lung disease in whom pulmonary blood flow may be limited. Identification of pulmonary venous anatomy and flow in infants on extracorporeal membrane oxygenation also may be difficult as a result of reduced pulmonary circulation. Transesophageal echocardiography may be indicated in these patients because of the enhanced imaging resolution of this modality.

OTHER CARDIOVASCULAR IMAGING MODALITIES

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Technologic advancements in miniaturization have allowed for the development of tiny transducer housings and small footprints for the performance of surface echocardiography in the neonate. Similar technology has allowed for the development of transesophageal echocardiography (TEE), in which a small transducer can be introduced into the esophagus of an infant typically weighing as little as 2.5 to 3.0 kg. Newer technology has become available that expands the size range for TEE such that premature infants as small as approximately 1 kg can be safely imaged. TEE is helpful in elucidating structures in the posterior mediastinum, such as pulmonary veins, and in overcoming acoustic impediments at the surface such as air and bone (Randolph et al, 2002). Most important, TEE has allowed for imaging to take place during interventional procedures in the operating room or catheterization laboratory (Figure 53-11). This eliminates the need to place a transducer directly on the chest or abdomen, thereby avoiding potential contamination of the operative field. Interventional procedures can be guided by TEE imaging, yielding immediate feedback to the proceduralist that has been well validated as a means of improving overall outcomes.

INTRACARDIAC ECHOCARDIOGRAPHY

Recently, ultrasound transducer technology has been incorporated into the tips of catheters, allowing for intracardiac imaging (Hijazi et al, 2009). This is primarily of use in the cardiac catheterization laboratory for the imaging of

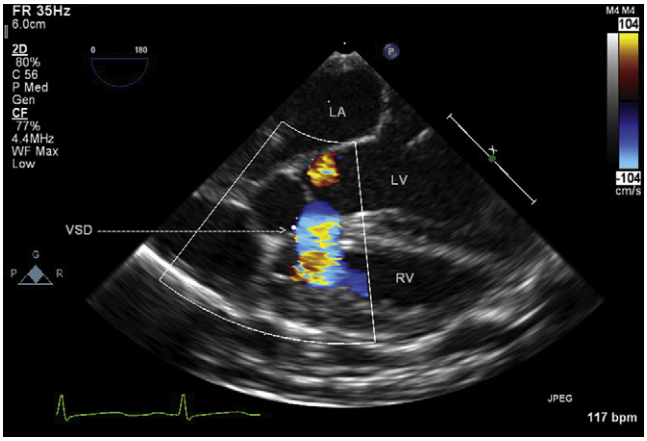

FIGURE 53-11 *(Supplemental color version of this figure is available online at www.expertconsult.com.)* Color Doppler image obtained during transesophageal imaging in the operating room preceding surgical closure of a moderate sized membranous ventricular septal defect. The color signal is blue, indicating flow away from the transducer, in this case left-to-right. *LA*, Left atrium; *LV*, left ventricle; *RV*, right ventricle; *VSD*, ventricular septal defect.

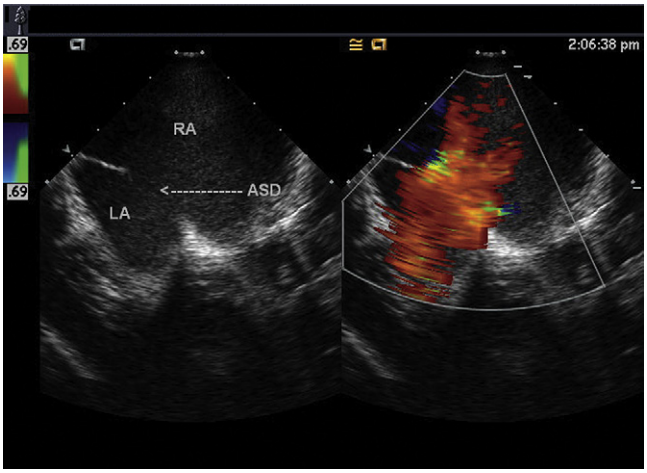

FIGURE 53-12 *(Supplemental color version of this figure is available online at www.expertconsult.com.)* Side-by-side two-dimensional and color Doppler imaging of a large secundum atrial septal defect *(ASD)* obtained by intracardiac echocardiographic (ICE) imaging. The color signal is red and laminar, indicating low velocity, left-to-right flow through the ASD. The right atrium *(RA)* is dilated in comparison with the left atrium *(LA)* because of the volume load on the right heart caused by this shunt lesion.

structures and devices during interventional procedures. In the pediatric interventional laboratory, the primary use is for the percutaneous device closure of atrial septal defects (Figure 53-12). Although these catheters provide an additional imaging modality, because of the currently available technology the size of these catheters (8F) precludes their use in the femoral veins of younger children (less than approximately 10 kg). Additionally, in most cases small children yield excellent transthoracic images, thus obviating the need for direct intracardiac assessment.

THREE-DIMENSIONAL ECHOCARDIOGRAPHY

Integration of multiplanar image data into a real-time three-dimensional (3D) display has been a goal of echocardiography. The earliest methods required acquisition of

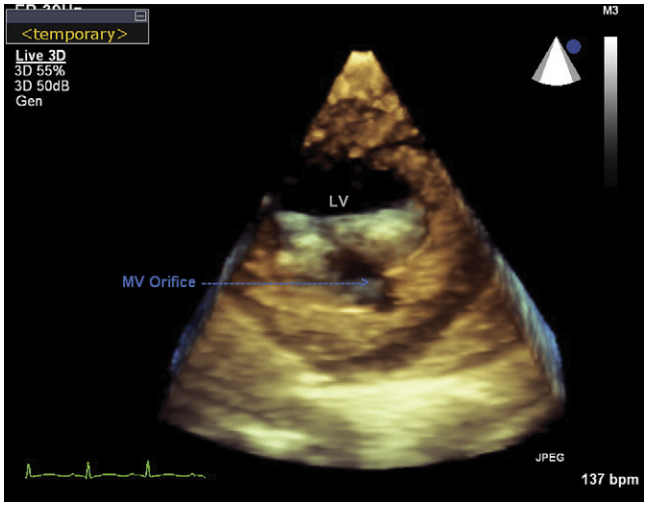

FIGURE 53-13 Three-dimensional echocardiographic image of a pathologic mitral valve. Using this imaging technique, a view of the mitral valve position within the left ventricular cavity is obtained that allows for a more thorough understanding of the nature of the anomaly. In this case the mitral valve is seen in a cross-sectional, short-axis view peering into the left ventricular cavity. The mitral orifice is hypoplastic, resulting in obstruction to inflow. *LV*, Left ventricle; *MV*, mitral valve.

data that then required offline 3D image rendering. Over the past several years systems have been made available that are capable of displaying "live" 3D echocardiographic images (Figure 53-13). This has resulted in our ability to interpret data as it is being obtained, making possible real-time bedside feedback. 3D echocardiography allows for enhanced identification of spatial relationships and structural malformations (Marx and Su, 2007). 3D echocardiographic technology has been miniaturized such that it is now available in an adult-sized TEE transducer. This allows for the benefits of TEE (improved image resolution and ease of image acquisition during procedures) to be combined with the enhanced data available from 3D imaging. In the foreseeable future, 3D TEE should be available in small transducers amenable to imaging the newborn and small child. 3D echocardiography will continue to evolve and promises to become an important modality as technologic advances continue.

SUMMARY

Echocardiographic assessment has become inseparable from effective management of the ill neonate. The ability to use noninvasive cardiac evaluation not only aids in the identification of congenital cardiac lesions but, just as important allows for a thorough understanding of the newborn physiologic state. Pharmacologic, ventilatory, and surgical decision making are by necessity based on clarity surrounding how these management strategies affect, and are affected by, cardiac status. In addition, the understanding of prenatal cardiac issues (e.g., anatomic anomalies, rhythm disturbances, myocardial function) can only be performed via fetal echocardiographic imaging. Neonatal outcomes are therefore dependent on both accurate fetal and postnatal echocardiographic diagnosis and the application of these data to overall multidisciplinary newborn care.

ACKNOWLEDGMENTS

CHAPTER 54

Patent Ductus Arteriosus in the Preterm Infant

Ronald I. Clyman

The ductus arteriosus represents a persistence of the terminal portion of the sixth branchial arch. During fetal life, the ductus arteriosus serves to divert blood away from the fluid-filled lungs toward the descending aorta and placenta. After birth, constriction of the ductus arteriosus and obliteration of its lumen results in separation of the pulmonary and systemic circulations. In full-term infants, obliteration of the ductus arteriosus takes place through a process of vasoconstriction and anatomic remodeling. In the preterm, the ductus arteriosus frequently fails to close. The clinical consequences of a patent ductus arteriosus (PDA) are related to the degree of left-to-right shunt through the PDA with its associated change in blood flow to the lungs, kidneys, and intestines. Although the magnitude of shunt flow plays a significant role in creating neonatal morbidity, equally important factors are the duration of exposure to the shunt and the infant's ability to compensate for the shunt.

DIAGNOSIS

Two-dimensional echocardiography and color Doppler flow mapping are the gold standards for assessing the magnitude and direction of PDA shunting. Ductus diameter ≥1.5 mm, left atrial-to-aortic root (LA:Ao) ratio ≥1.5, reversal of forward blood flow in the descending aorta during diastole, and end-diastolic flow velocity in the left pulmonary artery ≥0.20 m/s are signs consistent with a moderate-to-large PDA shunt (Table 54-1) (El Hajjar et al, 2005).

Clinical signs of a PDA (systolic murmur, hyperdynamic precordial impulse, full pulses, widened pulse pressure, and/or worsening respiratory status) usually appear later than echocardiographic signs and are less sensitive in determining the degree of left-to-right shunt. Certain signs such as continuous murmur or hyperactive left ventricular impulse are relatively specific for a PDA but lack sensitivity; conversely, worsening respiratory status, although a sensitive indicator, is relatively nonspecific for a PDA. Tachycardia is not a useful or reliable indicator of a PDA in preterm infants. Infants with large left-to-right shunts may have evidence of cardiomegaly and increased pulmonary arterial markings on their chest radiographs; however, in general, the chest radiograph and electrocardiogram are not useful in diagnosing a PDA. Although elevated plasma concentrations of brain natriuretic peptide (BNP) correlate with the presence of a moderate sized left-to-right PDA shunt (El-Khuffash and Molloy, 2007), changes in BNP concentrations have poor sensitivity and specificity in predicting increases or decreases in PDA shunt magnitude (Chen et al, 2010).

INCIDENCE

Pulsed Doppler echocardiographic assessments of full-term infants indicate that functional closure of the ductus has occurred in almost 50% by 24 hours, in 90% by 48 hours, and in all by 72 hours. The rate of ductus closure is delayed in preterm infants; however, essentially all healthy preterm infants (and 90% of those with respiratory distress syndrome) who are ≥30 weeks' gestation will close their ductus by the 4th day after birth. Preterm infants of <30 weeks' gestation, with severe respiratory distress, have a 65% incidence of persistent ductus patency beyond the 4th day of life. Even among these infants, spontaneous closure can occur during the neonatal period. Sixty-seven percent of very low-birthweight (VLBW) infants (weighing between 1000 and 1500 g at birth) will spontaneously close their ductus by 7 days after birth (94% will close before hospital discharge) (Nemerofsky et al, 2008). On the other hand, spontaneous, ductus closure only occurs in 30% to 35% of infants weighing <1000 g at birth during the neonatal period (Koch et al, 2006; Nemerofsky et al, 2008). Among VLBW infants who are discharged from the hospital with a persistent PDA, 14% will still have a persistent PDA or have had coil occlusion of their PDA at 1 year of age (Herrman et al, 2009).

Infants who are small for gestational age (Cotton et al, 1981; Del Moral et al, 2007; Rakza et al, 2007), develop late-onset septicemia (Gonzalez et al, 1996), or receive excessive fluid administration during the first days of life also are more likely to develop a clinically symptomatic PDA (Bell and Acarregui, 2001). On the other hand, nonwhite infants and infants who receive antenatal glucocorticoids have a reduced risk of PDA (Chorne et al, 2007a; Clyman et al, 1981a; Furzan et al, 1985). Administration of exogenous surfactant can alter both the incidence and presentation of a PDA. Although surfactant has no effect on the contractile behavior of the ductus, its effects on pulmonary vascular resistance lead to an earlier clinical presentation of the left-to-right shunt in preterm animals (Clyman et al, 1982; Shimada et al, 1989) and humans (Alpan et al, 1995; Kaapa et al, 1993; Reller et al, 1991, 1993). Similarly, lowering the "tolerable" range of oxygen saturations in preterm infants has led to an increased incidence of PDA (see later discussion of effects of oxygen on the ductus) (Noori et al, 2009).

REGULATION OF DUCTUS ARTERIOSUS PATENCY

In the full-term infant, closure of the ductus arteriosus occurs in two phases: (1) "functional" closure of the lumen within the first hours after birth by smooth muscle constriction, and (2) "anatomic" occlusion of the lumen over the next several days due to extensive neointimal thickening and loss of smooth muscle cells from the inner muscle media.

TABLE 54-1 Echocardiographic Characteristics Associated With Different Degrees of PDA Left-to-Right Shunts

PDA Shunt	Ductus Diameter (mm)		LA:Ao Ratio		LPA Diastolic Velocity (m/s)		DAo Flow Reversal	
	>1.5 (%)	<1.5 (%)	>1.5 (%)	<1.5 (%)	>0.2 (%)	≤0.2 (%)	*Yes* (%)	*No* (%)
Closed	0	100	0	100	0	100	0	100
Small	33	67	26	74	12	88	8	92
Moderate	86	14	56	44	53	47	60	40
Large	98	2	74	26	93	7	95	5

BALANCE BETWEEN VASOCONSTRICTION AND VASORELAXATION

Ductus arteriosus patency, therefore, is determined by the balance between dilating and constricting forces. The factors known to play a prominent role in ductus arteriosus regulation involve those that promote constriction (oxygen, endothelin, calcium channels, catecholamines, and Rho kinase) and those that oppose it (intraluminal pressure, prostaglandins, nitric oxide, carbon monoxide, potassium channels, cyclic adenosine monophosphate [cAMP] and cyclic guanosine monophosphate [cGMP]). The relative importance of each of these factors depends on the intrauterine and extrauterine environment, the degree of ductus maturation, and the genetic background and species being studied.

In Utero Regulation

The fetal ductus normally has a high level of intrinsic tone (Kajino et al, 2001). The intrinsic tone is due to mechanisms that both depend on and are independent of extracellular calcium (Kajino et al, 2001). The contractile proteins (smooth muscle myosin, calponin, and caldesmon) are more differentiated in the ductus than they are in adjacent fetal arteries (Colbert et al, 1996; Sakurai et al, 1996; Slomp et al, 1997). In addition, the fetal ductus arteriosus is more sensitive to the contractile effects of calcium than are the aorta and the pulmonary artery (Crichton et al, 1997). This may be due in part to increased Rho kinase activity in the ductus (Clyman et al, 2007). Endothelin-1 also appears to play a role in producing the elevated basal tone of the fetal ductus arteriosus (Coceani et al, 1999). Although catecholamines can constrict the ductus arteriosus (Tomita et al, 1996), there is little information about their role or the role of ductus innervation in regulating ductus tone. The presence of catecholamine-containing nerves varies with the species being studied (Bergwerff et al, 1999). The presence of high circulating catecholamine concentrations during the transition to extrauterine life suggests a role for catecholamines in ductus closure (Padbury et al, 1985).

The factors that oppose ductus arteriosus constriction in utero are better understood. The elevated vascular pressure within the ductus lumen (due to the constricted pulmonary vascular bed) plays an important role in opposing ductus constriction (Clyman et al, 1989a). The fetal ductus also produces several vasodilators that maintain its patency. Vasodilator prostaglandins (PGs) appear to be the dominant vasodilators that oppose ductus constriction in the later part of gestation (Momma et al, 1999). Inhibitors of prostaglandin synthesis constrict the fetal ductus both in vitro and in vivo. PGE_2 is the most potent prostaglandin produced by the ductus (Clyman et al, 1978; Coceani et al, 1978) and appears to be the most important prostanoid to regulate ductus patency. The response of the ductus to PGE_2 is unique among blood vessels because it is extraordinarily sensitive to this vasodilating substance. Prostaglandin E_2 produces ductus relaxation by interacting with several of the prostaglandin E receptors (EP_2, EP_3, and EP_4) (Bouayad et al, 2001). In contrast with other blood vessels, all of the EP receptors in the ductus can activate adenylate cyclase and relax the vessel (Bouayad et al, 2001). The increased cAMP concentrations inhibit the sensitivity of the contractile proteins to calcium (Crichton et al, 1997). Inhibitors of phosphodiesterase (the enzyme that degrades cAMP) relax the ductus in utero (Toyoshima et al, 2006). Low phosphodiesterase levels in the fetal ductus account for its increased sensitivity to PGE_2 (Liu et al, 2008). In addition, one of the EP receptors (EP_3) also relaxes the ductus by opening K_{ATP} channels and hyperpolarizing the smooth muscle cells (Bouayad et al, 2001).

Both isoforms of the enzyme responsible for synthesizing prostaglandins (cyclooxygenase [COX]-1 and COX-2) are expressed in the fetal ductus (Takahashi et al, 2000). Depending on the species, both nonselective (e.g., indomethacin and ibuprofen) and selective cyclooxygenase inhibitors constrict the ductus. In the fetal mouse, COX-2 appears to be the COX isoform responsible for producing the prostaglandins that regulate the ductus (Loftin et al, 2001), whereas in the fetal sheep, both COX-1 and COX-2 play a role in ductus patency (Takahashi et al, 2000).

In addition to the prostaglandins that are made within the ductus wall, circulating PGE_2 concentrations also regulate fetal ductus tone. Circulating concentrations of PGE_2 appear to be of placental origin (Thorburn, 1992). In the late-gestation fetal lamb, the circulating concentrations of PGE_2 (approximately 1 nM) are close to those that produce maximal relaxation of the ductus (Clyman et al, 1980). Circulating PGE_2 is cleared primarily by the pulmonary endothelium. Decreased pulmonary blood flow in the fetus results in reduced pulmonary clearance and contributes to the elevated fetal plasma PGE_2 concentrations (Clyman et al, 1981b).

Nitric oxide (NO), formed mainly by endothelial nitric oxide synthase (eNOS), is made by the fetal ductus arteriosus. NO appears to play an important role, early in gestation, in maintaining ductus patency in rodent fetuses (Momma et al, 1999). PGE_2 and NO appear to be preferentially coupled for reciprocal compensation because cyclooxygenase inhibition upregulates NO (Sodini et al, 2008). Although NO is also made in the ductus of larger species, its importance in maintaining ductus patency under normal in utero conditions has not been conclusively demonstrated (see later discussion of the role of NO in fetuses exposed to indomethacin tocolysis and in premature newborns) (Fox et al, 1996).

Carbon monoxide relaxes the ductus arteriosus, and both hemoxygenase-1 and -2 (the enzymes that make carbon monoxide) are found within the endothelial and smooth muscle cells of the ductus. Under physiologic conditions, the amount of carbon monoxide made by the ductus does not seem to affect ductus tone; however, in circumstances where its synthesis is upregulated, such as in endotoxemia, it may exert a relaxing influence on the ductus (Coceani et al, 1997). There is little evidence to suggest that adenosine or β-adrenergic stimulation play a significant role in ductus patency (Friedman et al, 1983).

Although the initial response to, pharmacologic inhibition of prostaglandin synthesis and signaling is to constrict the ductus in utero (Momma et al, 2005), chronic inhibition of prostaglandin synthesis (Loftin et al, 2001; Reese et al, 2006) and signaling (Nguyen et al, 1997) produces the opposite effect: namely, a persistent patent ductus in utero and a newborn mouse that fails to close its ductus after birth (Loftin et al, 2001; Nguyen et al, 1997). The exact mechanisms responsible for the persistent ductus patency that follows chronic inhibition of prostaglandin signaling have yet to be elucidated. Inhibition of prostaglandin production leads to increased nitric oxide production (Baragatti et al, 2003, 2007); however, inhibition of nitric oxide production does not appear to increase the rate of ductus closure in the COX-null mice (Reese et al, 2006). Inhibition of prostaglandin signaling may also contribute to delayed closure by inhibiting hyaluronic acid production and intimal cushion formation in the ductus (Yokoyama et al, 2006a). Intimal cushions play an important role in permanent ductus closure after birth (see later discussion). In addition to its function as a vasodilator, PGE_2 also plays a significant role in the development of ductus contractility (Reese et al, 2009). PGE_2 is necessary for the expression of several genes that control postnatal oxygen-induced ductus constriction (see later discussion). Specifically, PGE_2 increases the expression of CaL- and K^+-channel genes (CaLalpha1c, CaLbeta2, Kir6.1, and Kv1.5), which regulate calcium entry, without affecting genes that regulate calcium sensitization (Rho kinase–associated genes). Chronic inhibition of prostaglandin synthesis decreases the expression of CaL- and K^+-channel genes. Phosphodiesterase expression, which decreases the ductus's sensitivity to cAMP- or cGMP-dependent vasodilators, is also decreased by chronic COX inhibition (Reese et al, 2009).

It is interesting to note that pharmacologic inhibition of prostaglandin synthesis in human pregnancy also is associated with an increased incidence of patent ductus arteriosus after birth (Norton et al, 1993). However, this appears to be due to indomethacin's ability to produce ductus constriction in utero. In utero constriction produces ischemic hypoxia, increased nitric oxide production, and smooth muscle cell death within the ductus wall. These factors prevent the ductus from constricting after birth and make it resistant to the constrictive effects of postnatal indomethacin (Clyman et al, 2001; Goldbarg et al, 2002).

Postnatal Regulation

There are several events that promote ductus constriction in the full-term newborn after delivery: (1) an increase in arterial PO_2, (2) a decrease in blood pressure within the ductus lumen (due to the postnatal decrease in pulmonary vascular resistance), (3) a decrease in circulating PGE_2 (due to the loss of placental prostaglandin production and the increase in prostaglandin removal by the lung), and (4) a decrease in the number of PGE_2 receptors in the ductus wall (Bouayad et al, 2001). Although the newborn ductus continues to be sensitive to the vasodilating effects of NO, it loses its ability to respond to PGE_2 (Abrams et al, 1995; Clyman et al, 1983). All of these factors promote ductus constriction after birth.

The postnatal increase in arterial PaO_2 plays an important role in ductus constriction. Normoxic contraction can be demonstrated in the absence of the ductus endothelium (Fay, 1971), and in the presence of inhibitors of prostaglandin, nitric oxide, and endothelin signaling. This suggests that these vasoactive substances are not essential for normoxic constriction. In most species, oxygen appears to constrict the ductus arteriosus (1) through a mechanism that involves smooth muscle depolarization and (2) through a mechanism that is independent of changes in membrane potential (Roulet and Coburn, 1981). Oxygen depolarizes the ductus smooth muscle cells by inhibiting K^+ channels (Michelakis et al, 2000; Reeve et al, 2001). Following the depolarization of the membrane, calcium enters the ductus smooth muscle through L-type (Clyman et al, 2007; Nakanishi et al, 1993) and T-type (Akaike et al, 2009; Yokoyama et al, 2006b) voltage-dependent calcium channels. Several O_2-sensitive K^+ channels have been found in the fetal ductus (including Kv1.5 and Kv2.1). These vary with species and gestational age and may account for the differing sensitivity of the ductus to oxygen (Hayama et al, 2006; Wu et al, 2007). Oxygen also appears to have a direct effect on the CaL-channels themselves (Thebaud et al, 2008) and on the store-operated calcium channels (Hong et al, 2006). In addition, oxygen may increase smooth muscle sensitivity to calcium by activating Rho kinase–mediated pathways (Hong et al, 2006; Kajimoto et al, 2007; Keck et al, 2005; Roulet and Coburn, 1981).

The unique oxygen sensors within the ductus wall are still not clearly elucidated and may vary by species. The mitochondrial electron transport chain may act as an oxygen sensor by generating reactive oxygen species that constrict the avian, rabbit, and human ductus (Cogolludo et al, 2009; Michelakis et al, 2002; Reeve et al, 2001). This does not appear to be the mechanism in the ovine ductus (Clyman et al, 1989b), where reactive oxygen species dilate the ductus, and where the oxygen-induced events appear to involve a cytochrome P450 hemoprotein (Coceani

et al, 1989a, 1994). Preterm infants treated with cytochrome P450 inhibitors have an increased incidence of PDA (Cotton et al, 2009).

Elevated oxygen tensions can also increase the formation of the potent vasoconstrictor endothelin-1 (Coceani et al, 1989b). The exact role of endothelin-1 in postnatal ductus closure is still unclear (Coceani et al, 1999; Fineman et al, 1998; Michelakis et al, 2000; Shen et al, 2002; Taniguchi and Muramatsu, 2003). This is due, in large part, to the marked species variation in its contribution to ductus constriction. Endothelin receptor stimulation accounts for 44% of the oxygen-induced constriction in the rat, but only 13% in the rabbit (Shen et al, 2002). In the human ductus, inhibition of endothelin production does not inhibit oxygen-induced constriction (Michelakis et al, 2000).

Although the contractile effects of oxygen play an important role in postnatal ductus constriction, they may not be essential for postnatal ductus closure. Mice lacking the endothelin A receptor have diminished oxygen-induced ductus constriction; however, their ductus closes normally after birth (Coceani et al, 1999). The postnatal increase in PaO_2 also has profound modulatory effects on other vasoactive systems (Smith, 1998). Elevated oxygen tensions can increase the ductus's contractile response to neural mediators (Ikeda et al, 1973) and can decrease the formation of vasodilator prostaglandins (Kajino et al, 2001). Although neural and hormonal factors contribute to ductus closure, they do not appear to mediate the oxygen-induced constriction itself.

Developmental Regulation

Gestational age has a marked effect on the rate of ductus closure after birth. In contrast with the full-term ductus, the premature ductus is less likely to constrict after birth. This is due to several mechanisms. The intrinsic tone of the extremely immature ductus (<70% of gestation) is decreased compared to the ductus at term (Kajino et al, 2001). This may be due to the presence of immature smooth muscle myosin isoforms, with a weaker contractile capacity (Brown et al, 2002; Colbert et al, 1996; Reeve et al, 1997; Sakurai et al, 1996) and to decreased Rho kinase expression and activity (Clyman et al, 2007; Cogolludo et al, 2009; Kajimoto et al, 2007). Calcium entry through L-type calcium channels appears to be impaired in the immature ductus (especially under hypoxic conditions) (Clyman et al, 2007; Cogolludo et al, 2009; Thebaud et al, 2008). The potassium channels that promote ductus relaxation also change during gestation (switching from K_{Ca} channels, which are not regulated by oxygen tension, to K_V channels, which can be inhibited by increased oxygen concentrations) (Thebaud et al, 2004; Waleh et al, 2009; Wu et al, 2007). Reduced expression and function of the putative oxygen-sensing K_V channels appear to contribute to ductus patency in the preterm rabbit, sheep, baboon, mouse, and chicken (Cogolludo et al, 2009; Thebaud et al, 2004; Waleh et al, 2009). In contrast, a decrease in K_V channel expression occurs with advancing gestation in the rat, which suggests that in that species DA closure may occur by eliminating K_V channels (Wu et al, 2007).

Although circulating catecholamine concentrations are elevated during the transition to extrauterine life (Padbury et al, 1985), immature animals are less responsive to circulating catecholamines than are animals near term (Agren et al, 2007; Padbury et al, 1985).

Premature infants have elevated circulating concentrations of PGE_2, which may play a significant role in maintaining ductus patency during the first days after birth. This is due to the decreased ability of the premature lung to clear circulating PGE_2 (Clyman et al, 1981b). In the preterm newborn, circulating concentrations of PGE_2 can reach the pharmacologic range during episodes of bacteremia and necrotizing enterocolitis and are often associated with reopening of a previously constricted ductus arteriosus (Gonzalez et al, 1996).

In most mammalian species, the major factor that prevents the preterm ductus from constricting after birth is its increased sensitivity to the vasodilating effects of PGE_2 and NO (Clyman et al, 1998). The preterm ductus's increased sensitivity to PGE_2 is due to increased cAMP signaling. There is both increased cAMP production, due to enhanced prostaglandin receptor coupling with adenyl cyclase, and decreased cyclic AMP degradation by phosphodiesterase in the preterm ductus (Liu et al, 2008; Waleh et al, 2004). As a result, inhibitors of prostaglandin production (e.g., indomethacin, ibuprofen, and mefenamic acid) are usually effective agents in promoting ductus closure in the premature infant. It follows that drugs interfering with NO synthesis or function also could become useful adjuncts, especially in situations where indomethacin has proven to be ineffective (Keller et al, 2005; Seidner et al, 2001).

Increased prostaglandin sensitivity can also contribute to delayed ductus closure in some late gestation newborns. Among infants ≥37 weeks' gestation with a persistent PDA, approximately 30% will close their PDA after indomethacin treatment and another 30% will develop partial ductus constriction (Takami et al, 2007).

The factors responsible for the changes that occur with advancing gestation are currently unknown. Prenatal administration of vitamin A has been shown to increase both the intracellular calcium response and the contractile response of the preterm ductus to oxygen (Wu et al, 2001). However, vitamin A administration does not improve the rate of ductus closure in preterm infants (Ravishankar et al, 2003). Thyroid hormones may play a role in ductus arteriosus maturation because full-term infants with congenital hypothyroidism have an increased incidence of PDA that appears to respond to thyroid hormone replacement therapy (Guarnieri et al, 2008). Similarly, a lower occurrence of PDA has been found in thyroid hormone–treated preterm infants (Osborn and Hunt, 2007; van Wassemaer and Kok, 2008). Elevated cortisol concentrations in the fetus also foster ductus maturation by decreasing the sensitivity of the ductus to the vasodilating effects of PGE_2 (Clyman et al, 1981c). Prenatal administration of glucocorticoids significantly reduces the incidence of PDA in premature humans and animals (Clyman et al, 1981a, 1981c; Collaborative Group on Antenatal Steroid Therapy, 1985; Momma et al, 1981; Thibeault et al, 1978; Waffarn et al, 1983). Postnatal glucocorticoid administration also reduces the incidence of PDA (Group VONSS, 2001). However, postnatal glucocorticoid treatment also increases the incidence of several other neonatal morbidities (Watterberg et al, 2004).

Genetic Regulation

Both species and genetic background play a significant role in determining the relative importance of ductus regulatory pathways. There is a marked species difference among several of these pathways: Although endothelin receptor stimulation may account for 44% of the oxygen-induced contraction in the rat, it contributes to only 13% of the contraction in the rabbit (Shen et al, 2002) and plays a negligible role in the human ductus (Michelakis et al, 2000). Oxygen depolarizes the ductus smooth muscle cells by inhibiting K channels (Michelakis et al, 2000; Reeve et al, 2001). In the rabbit, an increase in the expression of K_V channels appears to be responsible for the developmental increase in the oxygen-induced contraction (Thebaud et al, 2004). In contrast, in the rat, K_V channel expression decreases with advancing gestation (Wu et al, 2007). Ductus patency is critically dependent on vasodilator prostaglandins in most species; however, notable exceptions exist in the guinea pig, chicken, and emu ductus, where locally derived prostaglandins do not appear to play a role in patency (Agren et al, 2007; Bodach et al, 1980; Dzialowski and Greyner, 2008).

Several genes have been identified (from mouse mutation models and from human genetic syndromes) that are associated with PDA in the full-term neonate. These include homeobox genes (Prx1 and Prx2) (Bergwerff et al, 2000); chromosomal region 12q24, designated PDA1 (Mani et al, 2002); the Noonan's syndrome gene, PTPN11 (Ko et al, 2008); and genes that regulate myosin heavy chains (Morano et al, 2000; Zhu et al, 2006), filamin 1 (Anderson et al, 2009), prostaglandin signaling (COX2 and EP4) (Loftin et al, 2001; Segi et al, 1998), gap junctions (connexin 43) (Huang et al, 1998), and neural crest transcription factors (TFAP2B and myocardin) (Huang et al, 2008; Zhao et al, 2001).

Although Bhandari et al (2009) found that familial factors accounted for 76% of the variance in risk for persistent PDA in preterm twins, they attributed most of the effect to shared environmental rather than genetic factors. On the other hand, several single nucleotide polymorphisms (SNPs) in candidate genes have been identified that are associated with PDA in preterm infants: ATR type 1 (Treszl et al, 2003), interferon (IFN)-γ (Bokodi et al, 2007), estrogen receptor-alpha PvuII (Derzbach et al, 2005), TFAP2B, PGI synthase, and TRAF1 (Dagle et al, 2009). Recent studies suggest that an interaction between preterm birth and TFAP2B may be responsible for some of the PDAs that occur in preterm infants: TFAP2B is uniquely expressed in ductus smooth muscle (Ivey et al, 2008); it regulates other genes that are important in ductus smooth muscle development (Ivey et al, 2008); mutations in TFAP2B produce PDA in mice and humans (Zhao et al, 2001); and TFAP2B polymorphisms are associated with preterm PDAs (especially those that are unresponsive to indomethacin) (Dagle et al, 2009).

ANATOMIC CLOSURE: HISTOLOGIC CHANGES

In the full-term newborn there is progressive intimal thickening and fragmentation of the internal elastic lamina after delivery. As the intima increases in size, it ultimately forms mounds that occlude the already constricted lumen. The increase in intimal thickening is due (1) to migration of smooth muscle cells from the muscle media into the intima and (2) to proliferation of luminal endothelial cells. The process of intimal cushion formation starts with the accumulation of hyalurona (HA) below the luminal endothelial cells. This is accompanied by the loss of laminin and collagen IV from the basement membrane of the endothelial cells and their subsequent separation from the internal elastic lamina. Laminin and collagen IV ultimately reform under the detached endothelial cells, but HA continues to accumulate in the subendothelial space. The hygroscopic properties of HA cause an influx of water and widening of the subendothelial space; this creates an environment well suited for cell migration. Accompanying the increase in HA is an increase in fibronectin (FN) and chondroitin sulfate (CS) in the neointimal space (de Reeder et al, 1988). The endothelial and smooth muscle cells of the ductus arteriosus differ from those of the adjacent vessels in their ability to form neointimal cushions. Isolated endothelial cells of the ductus arteriosus have an increased rate of HA, FN, and CS accumulation compared with those of the aorta or pulmonary artery (Boudreau et al, 1992). Hyaluron makes ductus smooth muscle cells migrate faster. The potentiating effect of HA on ductus smooth muscle cells is mediated through a hyaluron-binding protein (RHAMM). After delivery, there is a marked increase in ductus arteriosus transforming growth factor (TGF)-β expression, which accentuates the accumulation of HA within the neointima. Prostaglandins, acting through the EP4 receptor, also appear to play a critical role in HA production in the ductus (Yokoyama et al, 2006a). Fibronectin plays an important role in facilitating ductus smooth muscle cell migration. When fibronectin production in the ductus is inhibited, intimal cushion formation is blocked (Mason et al, 1999). CS appears to have no direct effect on ductus smooth muscle cell migration (Boudreau et al, 1990).

Ductus arteriosus smooth muscle cells use a family of cell surface receptors, called integrins, to interact with, adhere to, and migrate through the extracellular matrix that surrounds them. When ductus smooth muscle cells of the inner muscle media begin to migrate into the subendothelial space, two new integrin complexes appear on their cell surface: the αvβ3 and the α5β1 receptors. The αvβ3 integrin is essential for migration of ductus smooth muscle cells in vitro. The α5β1 integrin binds exclusively to fibronectin and mediates the potentiating effects of fibronectin on ductus smooth muscle cell migration. During the process of migration, ductus smooth muscle cells secrete laminin, which also has an important promigratory role.

Intimal cushion formation in the ductus is also associated with striking alterations in elastin fiber assembly. In contrast to the aorta, where formation of well-developed elastic laminae is seen between layers of muscle cells, smooth muscle cells of the ductus muscle media are surrounded by thin and fragmented elastin fibers. Smooth muscle cells in the neointima are surrounded by even fewer elastin fibers (de Reeder et al, 1990). The disruption of normal elastin fiber assembly in the ductus does not appear to be due to increased elastase activity or decreased tropoelastin production. Rather, it appears to be due to a developmental mechanism that reduces insolubilization of elastin and

prevents formation of intact elastic laminae (Hinek et al, 1991; Hinek and Rabinovitch, 1993; Zhu et al, 1993). The exact relationship between impaired elastin assembly and smooth muscle migration into the neointima is still open for speculation. Impaired assembly of thick elastic laminae might facilitate smooth muscle cell migration by removing a physical barrier to which they might attach. The elastic laminae of the ductus appear abnormally well developed and similar to those in the aorta in some genetic forms of PDA; when this occurs, intimal cushions fail to develop (de Reeder et al, 1990).

RELATIONSHIP BETWEEN VASOCONSTRICTION AND ANATOMIC CLOSURE

In full-term animals, loss of responsiveness to PGE_2 shortly after birth prevents the ductus arteriosus from reopening once it has constricted (Abrams et al, 1995; Clyman et al, 1983). This is due, in part, to decreased synthesis of PGE_2 receptors in the ductus after birth. Both the loss of vasodilator regulation and the anatomic events that lead to permanent closure appear to be controlled by the degree of ductus smooth muscle constriction. Experimental models that alter the ability of the ductus to constrict at term also prevent the normal histologic changes that occur after birth (Clyman et al, 1989a; Fay and Cooke, 1972; Jarkovska et al, 1992; Loftin et al, 2001; Mason et al, 1999; Nguyen et al, 1997). Constriction produces ischemic hypoxia of the vessel wall (Clyman et al, 1999). In the full-term newborn ductus, the ischemic hypoxia that accompanies constriction is due to loss of intramural vasa vasorum blood flow, which occurs even before luminal blood flow has been eliminated (Kajino et al, 2002). With advancing gestation, the thickness of the ductus wall increases to a dimension that requires the presence of intramural vasa vasorum to provide nutrients to its outer half. These collapsible, intramural vasa vasorum provide the ductus with a unique mechanism for controlling the maximal diffusion distance for oxygen and nutrients across its wall. In the full-term newborn, the intramural tissue pressure that develops during ductus constriction obliterates vasa vasorum flow to its muscle media; this turns the entire thickness of the muscle media into a virtual avascular zone. The profound ischemic hypoxia that follows the compression of the vasa vasorum inhibits local production of PGE_2 and NO, induces local production of hypoxia inducible factors such as HIF1α and vascular endothelial growth factor (VEGF), and produces smooth muscle apoptosis in the ductus wall. VEGF plays a critical role in the migration of the ductus smooth muscle cells into the neointima and in the proliferation of intramural vasa vasorum (Clyman et al, 2002). After postnatal ductus constriction, several genes known to be essential for vascular remodeling (TGF-β, VCAM-1, E-selectin, IL-8, MCSF-1, CD154, IFN-γ, IL-6, and TNF-α) are increased in the ductus wall. In addition, VLA4-positive monocytes/macrophages (CD68- and CD14-positive) adhere to the ductus wall. The inflammatory response that follows postnatal ductus constriction may be as necessary for ductus remodeling, because the extent of neointimal remodeling is significantly correlated with the degree of mononuclear cell adhesion (Waleh et al, 2005).

In preterm infants, the ductus frequently remains open for many days after birth, preventing it from developing profound hypoxic ischemia. Although alterations in prostaglandin signaling appear to be responsible for as many as 60% to 70% of the delayed ductus closures, cyclooxygenase inhibitors (such as indomethacin and ibuprofen) become less effective in closing the ductus with increasing postnatal age. A number of factors conspire to make the postnatal preterm ductus increasingly resistant to indomethacin- and ibuprofen-induced closure. After delivery, COX-2 expression and PGE_2 production increase in the ductus wall (Guerguerian et al, 1998). However, in contrast to the full-term ductus, where all of the PGE_2 EP receptors are downregulated after birth, in the preterm ductus, the dominant PGE_2 receptor, EP_4, continues to be synthesized after birth and the ductus continues to relax with prostaglandin stimulation. In addition, despite the presence of persistent ductus luminal blood flow, there is a progressive decrease in ATP concentrations within the preterm newborn ductus smooth muscle cells. The decreased ATP concentrations limit the preterm newborn ductus's ability to constrict (Levin et al, 2005). Similarly, the mild degrees of hypoxia that develop within the postnatal preterm ductus induce the production of other vasodilators within its wall that do not depend on prostaglandin signaling to affect contractility (e.g., nitric oxide, TNF-α, and IL-6) (Clyman et al, 2002; Waleh et al, 2005). These "other" vasodilators produce a change in the vasodilator-balance that maintains ductus patency. Ductus patency becomes less dependent on prostaglandin generation and more dependent on other vasodilators during the first weeks after birth. These postnatal changes may explain why the effectiveness of indomethacin wanes with increasing postnatal age (Clyman, 1996; Schmidt et al, 2001). In premature animals and humans, the combined use of a nitric oxide synthase inhibitor and indomethacin produces a much greater degree of ductus constriction than indomethacin alone (Keller et al, 2005; Seidner et al, 2001). It follows that drugs that interfere with NO synthesis could become a useful adjunct, especially in situations where indomethacin has been found to be ineffective.

Even when it does constrict, the premature ductus frequently fails to develop the same degree of profound hypoxia and anatomic remodeling that occurs in the full-term newborn ductus. The preterm ductus requires a greater degree of constriction, and a more complete degree of luminal closure, than the full-term ductus in order to develop a comparable degree of hypoxia. This is due to the thinness of the preterm ductus wall. In contrast with the full-term ductus, the thin-walled preterm ductus can extract all of the oxygen and nutrients it needs from its luminal blood flow. The preterm ductus does not need intramural vasa vasorum to provide oxygen and nutrients to its wall, and, as a result, before 26 weeks' gestation, intramural vasa vasorum are absent from the ductus wall. The absence of intramural vasa vasorum leaves the preterm ductus without a mechanism to rapidly increase the diffusion distance across its wall during postnatal constriction. As long as there is any degree of luminal patency and flow, the thin-walled preterm ductus fails to become profoundly hypoxic and fails to undergo anatomic

remodeling. The preterm ductus requires that the lumen be completely obliterated before it can develop the same degree of hypoxia found at term. Once the preterm ductus develops profound ischemic hypoxia, it will undergo most of the anatomic changes seen at term (Kajino et al, 2001; Seidner et al, 2001). However, if the premature ductus does not develop the degree of ischemic hypoxia needed to induce cell death and anatomic remodeling, it will continue to be responsive to vasodilators and continue to be susceptible to vessel reopening.

HEMODYNAMIC AND PULMONARY ALTERATIONS

The pathophysiologic features of a PDA depend both on the magnitude of the left-to-right shunt and on the cardiac and pulmonary responses to the shunt. There are important differences between immature and mature infants in the heart's ability to handle a volume load. Immature infants have less cardiac sympathetic innervation. Before term, the myocardium has more water and less contractile mass. Therefore, the immature fetal ventricles are less distensible than at term and generate less force per gram of myocardium (even though they have the same ability to generate force per sarcomere) (Friedman, 1972). The relative lack of left ventricular distensibility in immature infants is more a function of the ventricle's tissue constituents than of poor muscle function. As a result, left ventricular distention secondary to a large left-to-right PDA shunt may produce a higher left ventricular end-diastolic pressure at smaller ventricular volumes. The increase in left ventricular pressure increases pulmonary venous pressure and causes pulmonary congestion.

Studies in preterm animal and human newborns (Clyman et al, 1987; Shimada et al, 1994) have shown that despite these limitations, preterm newborns are able to increase left ventricular output, and maintain their "effective" systemic blood flow, even with left-to-right PDA shunts equal to 50% of left ventricular output. With shunts >50% of left ventricular output, "effective" systemic blood flow falls, despite a continued increase in left ventricular output. The increase in left ventricular output associated with a PDA is accomplished not by an increase in heart rate, but by an increase in stroke volume (Clyman et al, 1987; Shimada et al, 1994). Stroke volume increases primarily as a result of the simultaneous decrease in afterload resistance on the heart and the increase in left ventricular preload. Despite the ability of the left ventricle to increase its output in the face of a left-to-right ductus shunt, blood flow distribution is significantly rearranged. This redistribution of systemic blood flow occurs even with small shunts (Clyman et al, 1987). Blood flow to the skin, bone, and skeletal muscle is most likely to be affected by the left-to-right ductus shunt. The next most likely organs to be affected are the gastrointestinal tract and kidneys because of a combination of decreased perfusion pressure and localized vasoconstriction. Mesenteric blood flow is decreased in both fasting and fed states in the presence of a PDA (McCurnin and Clyman, 2008). Significant decreases in organ blood flow may occur before there are signs of left ventricular compromise (Meyers et al, 1990; Shimada et al, 1994) and may contribute to the decreased feeding tolerance and decreased glomerular filtration rate (Cassady et al, 1989; Clyman, 1996; Patole et al, 2007) that have been observed with ductus patency.

The decreased ability of the preterm infant to maintain active pulmonary vasoconstriction (Lewis et al, 1976) may be responsible in part for the earlier presentation of a "large" left-to-right PDA shunt (Gersony et al, 1983; Jacob et al, 1980). Dopamine can increase systemic blood pressure and systemic blood flow in preterm infants with hypotension and a PDA, by increasing pulmonary vascular resistance and decreasing the left-to-right shunt across the ductus (Bouissou et al, 2008). Therapeutic maneuvers, such as surfactant replacement, or prenatal conditions, such as intrauterine growth retardation, that lead to a rapid drop in pulmonary vascular resistance can exacerbate the amount of left-to-right shunt and lead to pulmonary hemorrhage (Alpan et al, 1995; Raju and Langenberg, 1993; Rakza et al, 2007). Randomized, controlled trials have shown that early ductus closure decreases the incidence of significant pulmonary hemorrhage (Al Faleh et al, 2008; Clyman and Chorne, 2008; Domanico et al, 1994). Although phototherapy has been associated with the persistence of a PDA, a recent randomized controlled trial found that chest shielding did not alter the incidence or severity of PDA (Travadi et al, 2006).

The factors responsible for preventing plasma fluid and protein from moving into the lung interstitium and from the interstitium into the air spaces have been described elsewhere. In premature animals, a wide-open PDA increases hydraulic pressures in the pulmonary vasculature; this, in turn, increases the rate of fluid transudation into the pulmonary interstitium (Alpan et al, 1991). Any increase in microvascular perfusion pressure in premature infants with respiratory distress syndrome may increase interstitial and alveolar lung fluid because of their low plasma oncotic pressures and increased capillary permeability. Leakage of plasma proteins into the alveolar space inhibits surfactant function and increases surface tension in the immature air sacs (Ikegami et al, 1983), which are already compromised by surfactant deficiency. The increased FiO_2 and mean airway pressures required to overcome these early changes in compliance may be important factors in the development of chronic lung disease (Brown, 1979; Clyman, 1996; Cotton et al, 1978). Depending on the gestational age and the species examined, changes in pulmonary mechanics may occur as early as 1 day after birth or not before several days of exposure to a PDA left-to-right shunt (McCurnin et al, 2008; Perez Fontan et al, 1987). Although it is true that preterm animals with a PDA have increased fluid and protein clearance into the lung interstitium, because of an increase in pulmonary microvascular filtration pressure, a simultaneous increase in lung lymph flow appears to eliminate the excess fluid and protein from the lung (Alpan et al, 1991). This compensatory increase in lung lymph acts as an "edema safety factor," inhibiting fluid accumulation in the lungs. As a result, there is no net increase in water or protein accumulation in the lung and there is no change in pulmonary mechanics (Alpan et al, 1989; Clyman, 1996; Krauss et al, 1989; Perez Fontan et al, 1987; Shimada et al, 1989). This delicate balance between the PDA-induced

fluid filtration and lymphatic reabsorption is consistent with the observation, made in human infants, that closure of the ductus arteriosus within the first 24 hours after birth has no effect on the course of the newborn's hyaline membrane disease. However, if lung lymphatic drainage is impaired, as it is in the presence of pulmonary interstitial emphysema or fibrosis, the likelihood of edema increases dramatically. After several days of lung disease and mechanical ventilation, the residual functioning lymphatics are more easily overwhelmed by the same size ductus shunt that could be accommodated on the 1st day after delivery. As a result, it is not uncommon for infants with a persistent PDA to develop pulmonary edema and alterations in pulmonary mechanics at 7 to 10 days after birth. In these infants, improvement in lung compliance occurs after closure of the PDA (Clyman, 1996; Gerhardt and Bancalari, 1980; Johnson et al, 1978; Naulty et al, 1978; Stefano et al, 1991; Szymankiewicz et al, 2004; Yeh et al, 1981a).

Recently, a premature baboon model of PDA has been used to examine the factors responsible for the alteration in pulmonary mechanics that occur in the presence of a PDA (McCurnin et al, 2008). Animals delivered at 67% term gestation (equivalent to 26 weeks' human gestation) were given surfactant and mechanically ventilated for 2 weeks. One group was treated with a cyclooxygenase inhibitor to close the ductus; the other group had a persistent PDA. Exposure to a persistent PDA for 2 weeks did not appear to alter surfactant secretion, pulmonary epithelial protein permeability, or presence of surfactant inhibitory proteins. Nor did it alter the expression of genes that regulate inflammation and tissue remodeling. The animals with an open ductus had an increased amount and altered distribution of water in their lungs. In contrast with the full-term lung, which mobilized fluid rapidly after birth, the preterm lung mobilized lung fluid much more slowly. A persistent PDA led to a small but significant increase in lung water at 2 weeks after delivery. In addition, closure of the PDA with a cyclooxygenase inhibitor, such as indomethacin or ibuprofen, produced increased expression of alveolar epithelial sodium channels, which facilitate fluid removal from the alveolar compartment. This finding may account for the decreased incidence of significant pulmonary hemorrhage in infants who are treated with prophylactic indomethacin after birth (Al Faleh et al, 2008; Clyman and Chorne, 2008; Domanico et al, 1994).

Pharmacologic closure of the PDA was also associated with improved lung development in the preterm baboons. In contrast to the animals with an open ductus, where an arrest in alveolar development (the hallmark of the new "BPD") was noticeable by 2 weeks after birth, pharmacologic closure of the PDA led to improved alveolarization (McCurnin et al, 2008).

Not all of the changes associated with a PDA are necessarily detrimental to the immature infant with respiratory distress syndrome. The recirculation of oxygenated arterial blood through lungs that are not fully expanded can lead to improved arterial PaO_2 (Clyman et al, 1987; Dawes et al, 1955). Decreases in systemic arterial O_2 content have been observed after PDA closure, despite the absence of any alterations in pulmonary mechanics.

TREATMENT

TREATMENT OPTIONS FOR CLOSING A PDA

Surgical ligation produces definitive ductus arteriosus closure; however, it is associated with its own set of morbidities: thoracotomy, pneumothorax, chylothorax, scoliosis, and infection (Roclawski et al, 2009). The incidence of unilateral vocal cord paralysis (which increases the requirements for tube feedings, respiratory support, and hospital stay) has been reported to be as high as 67% in extremely low birthweight (ELBW) infants, after PDA ligation (Clement et al, 2008; Smith et al, 2009). Between 30% and 50% of infants with birthweights ≤1000 g will require inotropic support for profound hypotension during the postoperative period (Moin et al, 2003). In addition, neonatal transport to another facility may be required if surgical expertise is not readily available. Early surgical ligation of the PDA has recently been shown to be an independent risk factor for the development of bronchopulmonary dysplasia (Chorne et al, 2007b; Clyman et al, 2009). Studies in premature baboons support the concept that surgical ligation may produce detrimental effects on lung function and growth. Although pharmacologic ductus closure minimizes the postnatal arrest in alveolar development that occurs in preterm infants (see earlier discussion) (McCurnin et al, 2008), no benefit for alveolar growth has been observed after surgical ligation (Chang et al, 2008; McCurnin et al, 2005). This raises the possibility that ductus ligation, while eliminating the detrimental effects of a PDA on lung development, may create its own set of problems that counteract any of the benefits derived from ductus closure (Chorne et al, 2007b; Clyman et al, 2009).

Inhibition of prostaglandin synthesis with nonselective inhibitors of COX-1 and COX-2 (e.g., indomethacin and ibuprofen) appears to be an effective alternative to surgical ligation (Gersony et al, 1983). In most intensive care nurseries, indomethacin and ibuprofen have replaced surgery as the preferred therapy for closing a persistent PDA. However, both have been associated with several potential adverse effects in the newborn. Indomethacin produces significant reductions in renal (Pezzati et al, 1999; Rennie et al, 1986), mesenteric (Coombs et al, 1990; Van Bel et al, 1990), and cerebral blood flow (Austin et al, 1992; Edwards et al, 1990; Laudignon et al, 1988; Patel et al, 2000; Pryds et al, 1988; Van Bel et al, 1989). Indomethacin also reduces cerebral oxygenation (McCormick et al, 1993; Patel et al, 2000). Alterations in creatinine clearance and oliguria (that are minimally responsive to dopamine or furosemide therapy [Barrington and Brion, 2002; Brion and Campbell, 2001]) are common problems with the initial doses of indomethacin. Renal function returns toward normal after the initial doses of indomethacin or after drug discontinuation (Seyberth et al, 1983). Indomethacin's action on these organ systems may not be due entirely to its inhibition of prostaglandin synthesis (Chemtob et al, 1991; Malcolm et al, 1993; Speziale et al, 1999). Indomethacin also has effects on lipoxygenase activity and histamine and endothelin release (Docherty and Wilson, 1987; Konig et al, 1987; Therkelsen et al, 1994), although the relevance of these effects to any neonatal morbidity is still unknown.

Although indomethacin produces significant physiologic alterations, none of the controlled, randomized trials that have examined the relationship between indomethacin and neonatal morbidity have found an increase in the incidence of necrotizing enterocolitis, gastrointestinal perforation, retinopathy of prematurity (ROP), chronic lung disease, or cerebral white matter injury after indomethacin treatment (Fowlie and Davis, 2002). Although indomethacin, by itself, has not been shown to increase the incidence of gastrointestinal perforations, the combination of indomethacin *and* postnatal steroids, administered simultaneously, has been shown to increase the incidence of gastrointestinal perforations/necrotizing enterocolitis (Peltoniemi et al, 2005; Watterberg et al, 2004).

Indomethacin's cerebral vasoconstrictive effects are frequently cited as a concern for neonatologists (Edwards et al, 1990; Leffler et al, 1985); however, a Cochrane systematic review found that indomethacin prophylaxis is more likely to decrease rather than increase the incidence of periventricular leukomalacia (Fowlie and Davis, 2002). There is no evidence that prophylactic indomethacin has any adverse effect on neurodevelopmental outcome at 18 months (Schmidt et al, 2001); in fact, there is evidence that it may have long-term benefits at 4.5 and 8 years (Ment et al, 2000, 2004; Vohr et al, 2003).

Although there may be general consensus on the efficacy of indomethacin for treatment of a PDA, questions about proper dosage, treatment duration, and optimal timing of treatment remain quite controversial. Indomethacin's plasma clearance depends on postnatal age (Brash et al, 1981; Smith et al, 1984; Thalji et al, 1980; Yaffe et al, 1980; Yeh et al, 1989). Therefore, a dosage regime recommended for infants at the end of the 1st week (when the half-life of the drug is 21 hours) (Yaffe et al, 1980; Yeh et al, 1989) may lead to elevated and prolonged plasma concentrations when used in infants on day 1 (when the half-life is 71 hours) (Smith et al, 1984). Conversely, a single loading dose of indomethacin (0.2 mg/kg), without subsequent maintenance doses, can be effective in closing a PDA when administered within the first 24 hours after delivery (Krueger et al, 1987).

Many variations in dosage regimens have been evaluated (Gork et al, 2008; Herrera et al, 2007). A prolonged low-dose course of indomethacin (0.1 mg/kg every 24 hours for 5 to 7 days) may increase the rate of permanent closure, especially in infants who still have residual ductus flow after completing the standard short course (2 to 3 doses over 24 hours) (Hammerman and Aranburo, 1990; Quinn et al, 2002; Rennie and Cooke, 1991; Rhodes et al, 1988). This dosage regimen still needs further evaluation because in some reports (Rennie and Cooke, 1991; Rhodes et al, 1988) a higher mortality rate was observed in the infants receiving prolonged maintenance indomethacin. Although some have suggested that the dose of indomethacin be increased when conventional dosing fails to produce ductus closure (Gal et al, 1990; Shaffer et al, 2002; Sperandio et al; 2005), a randomized controlled trial examining this issue found that the rate of ductus closure was not substantially improved despite a nearly threefold increase in serum indomethacin concentrations. More worrisome was the fact that the higher indomethacin concentrations produced significant increases in the incidence of moderate to severe ROP and late renal dysfunction (Jegatheesan et al, 2008).

The postnatal age at which indomethacin is administered plays an important role in determining its effectiveness. Even when indomethacin concentrations have been maintained in the "desired" range, the drug's ability to produce ductus closure remains inversely proportional to the postnatal age at the time of treatment (Achanti et al, 1986; Brash et al, 1981; Rennie et al, 1986; Rheuban et al, 1987; Thalji et al, 1980). With advancing postnatal age, dilator prostaglandins play less of a role in maintaining ductus patency (see earlier discussion). As a result, indomethacin becomes less effective in producing PDA closure (Achanti et al, 1986). It appears that in some situations, prostaglandins may not be the dominant factor maintaining ductus patency (Chorne et al, 2007a; Cotton et al, 1991).

Recurrence of a symptomatic PDA can occur after initial successful treatment. The rate of reopening, which is greatest among the most immature infants, appears to be related to the timing and completeness of ductus closure after the treatment course (Clyman, 1996; Narayanan et al, 2000). Permanent anatomic closure requires tight constriction of the ductus lumen and the development of ductus wall hypoxia (see earlier discussion). Of infants delivered at <28 weeks' gestation in whom clinical ductus closure was achieved after indomethacin treatment, 80% will reopen their ductus and develop clinical symptoms if there is any evidence of luminal patency on the Doppler examination performed at the end of indomethacin treatment (Narayanan et al, 2000). Unfortunately, there are limitations in the Doppler's ability to detect complete luminal closure. Even when there is no evidence of ductus patency on the Doppler/echocardiogram, a significant number of preterm infants will still have a tiny patent ductus lumen. The more immature the ductus (i.e., the thinner the ductus wall), the greater the likelihood that profound hypoxia and anatomic remodeling will not occur. These vessels will reopen at a later date: 23% of those born before 26 weeks reopen in spite of echocardiographic evidence of closure; in contrast, only 9% of those born between 26 and 27 weeks will reopen if the ductus is found to be closed by echocardiography. Early treatment produces a tighter degree of ductus constriction and, as a result, higher rates of ductus wall hypoxia and permanent closure (Narayanan et al, 2000).

Ibuprofen, another nonselective cyclooxygenase inhibitor, has been shown to close the ductus in animals (Coceani et al, 1979) and preterm infants. It appears to be as effective as indomethacin in producing PDA closure in VLBW infants (at least in infants with a mean gestational age of 28 weeks) (Van Overmeire et al, 2000). In contrast with indomethacin, ibuprofen does not appear to affect mesenteric blood flow (Malcolm et al, 1993; Pezzati et al, 1999; Speziale et al, 1999) and has less of an effect on renal perfusion, oliguria (Malcolm et al, 1993; Pezzati et al, 1999; Speziale et al, 1999), and cerebral blood flow (Chemtob et al, 1990; Mosca et al, 1997; Patel et al, 2000; Speziale et al, 1999). Animal studies suggest that ibuprofen may have some cytoprotective effects in the intestinal tract (Grosfeld et al, 1983). However, aside from its renal sparing effects, comparison trials have not found ibuprofen to be superior to indomethacin in the prevention of other neonatal morbidities (necrotizing enterocolitis, gastrointestinal

perforation, and bronchopulmonary dysplasia) (Ohlsson et al, 2008). In addition, ibuprofen does not appear to have the same intracranial hemorrhage sparing effects that are seen with indomethacin (see later discussion). The optimal age-appropriate dosing schedule for ibuprofen is still under consideration (Hirt et al, 2008). Ibuprofen's effects on total and free serum bilirubin concentrations (Ahlfors, 2004; Zecca et al, 2009) raise concerns about the safety of some of the higher dose options.

INDOMETHACIN AND INTRACRANIAL HEMORRHAGE

Previous studies have shown that indomethacin can decrease the incidence of intracranial hemorrhage (ICH) in preterm infants and experimental animals (this has not been the case with ibuprofen). The effects of indomethacin on ICH do not appear to be due to its effects on ductus patency (Ment et al, 1985, 1988). Indomethacin decreases cerebral blood flow, decreases reactive postasphyxial cerebral hyperemia, and accelerates maturation of the germinal matrix microvasculature (Dahlgren et al, 1981; Ment et al, 1983, 1992). Because most intracranial hemorrhages occur within the first 3 days after birth, one would expect to see beneficial effects only when indomethacin is given in a prophylactic strategy (within the first 18 hours after birth). When prophylactic indomethacin is given to infants with normal echoencephalograms, there is a significant reduction in both the incidence of all grades (I–IV) as well as the most severe grades (III, IV) of ICH. Because 30% to 50% of infants who develop an ICH have evidence of an ICH on their screening pre-indomethacin echoencephalogram, the beneficial effects of prophylactic indomethacin are less dramatic when it is administered to populations where the prior ICH status is unknown. When indomethacin is administered prophylactically, without knowledge of prior ICH status, there is no longer a difference in the overall incidence of ICH; however, there is still a significant reduction in the incidence of severe (grade III, IV) ICH (Clyman, 1996). Although randomized controlled trials have not shown an effect of prophylactic indomethacin on neurodevelopmental outcome at 18 months (Schmidt et al, 2001), there is evidence for long-term benefits at 4.5 and 8 years (Ment et al, 2000, 2004; Vohr et al, 2003).

PDA AND NEONATAL MORBIDITY: TO TREAT OR NOT TO TREAT

A persistent PDA increases pulmonary hyperemia and pulmonary edema and decreases renal, mesenteric, and cerebral perfusion; however, clear evidence is lacking for or against many of the approaches to PDA treatment (Bose and Laughon, 2006; Clyman and Chorne, 2007; Laughon et al, 2004). Although a prolonged, persistent left-to-right shunt through a PDA shortens the life span of animals and humans (Brooks et al, 2005; Campbell, 1968; Loftin et al, 2001; Van Israel et al, 2003), there has been growing debate in recent years about whether or not to treat a persistent PDA during the neonatal period (Laughon et al, 2004). Preterm infants have a high rate of spontaneous PDA closure during the first 2 years. Therefore, early treatment runs the risk of exposing infants to drugs or procedures they might not need.

Published randomized controlled trials (RCTs) provide only a limited amount of information to help guide current PDA treatment choices. Most of these have focused on the timing of treatment and the risks and benefits of prophylactic versus early indomethacin treatment. Numerous RCTs (and their metaanalyses) have shown that indomethacin prophylaxis decreases (1) the incidence of severe early pulmonary hemorrhages, (2) the occurrence of severe grades of intraventricular hemorrhage, (3) the risk of developing a symptomatic PDA, and (4) the need for surgical PDA ligation (Al Faleh et al, 2008; Bandstra et al, 1988; Clyman and Chorne, 2008; Domanico et al, 1994; Fowlie and Davis, 2002; Ment et al, 1994; Schmidt et al, 2001). On the other hand, indomethacin prophylaxis results in overtreatment of infants who would normally close their ductus spontaneously (Koch et al, 2006).

Even less information exists about the consequences of a persistent, symptomatic, moderate-to-large PDA shunt on neonatal morbidity. To date, only two small RCTs, performed about 30 years ago, have specifically examined the role of a persistent untreated symptomatic PDA on neonatal morbidity (Cotton et al, 1978; Kaapa et al, 1983). Both studies found that a persistent PDA increased pulmonary morbidity and prolonged the need for respiratory support. Whether these findings are still applicable in the setting of modern neonatal treatment is a matter for controversy among neonatologists.

The role of a PDA in the development of necrotizing enterocolitis is even more controversial. Although some retrospective, population-based studies have reported an association between PDA and NEC (Cassady et al, 1989; Dollberg et al, 2005; Sankaran et al, 2004), there is little evidence from RCTs to either support or refute the idea that a PDA plays a role in the development of necrotizing enterocolitis. At this time, there are no RCTs in the medical literature that address this issue. Nor is there information about the advisability of continuing or stopping enteral feeding in the presence of a PDA.

Although indomethacin has been shown to be effective in producing ductus closure (Gersony et al, 1983), its long-term benefits on chronic lung disease, necrotizing enterocolitis, or survival have yet to be established (Clyman and Chorne, 2007; Cooke et al, 2003; Knight, 2001; Yeh et al, 1981a, 1981b). These uncertainties have resulted in several areas of controversy regarding PDA management: (1) whether or not to use indomethacin prophylaxis, (2) when to treat a moderate-to-large PDA, and (3) whether or not enteral feeding should be stopped in the presence of a PDA or during treatment of a PDA (Amin et al, 2007; Bose and Laughon, 2006; Clyman and Chorne, 2007; Knight, 2001; Laughon et al, 2004). At this time, 95% of U.S. neonatologists believe that a moderate-to-large PDA should be treated if it persists in ELBW infants who still require mechanical ventilation; in contrast, only 30% use indomethacin prophylactically (Jhaveri et al, 2009). The number of neonatologists who treat a persistent PDA when it occurs in infants who do not require mechanical ventilation varies significantly by geographic region. Marked differences in neonatologists' willingness to feed infants in the presence of a PDA appears to account

for the large geographic variations in indomethacin use and rates of PDA ligation. Of interest, 70% of U.S. neonatologists believe that enteral feedings need to be stopped in the presence of a PDA. In contrast, non-U.S. neonatologists have exactly the opposite opinion: 70% believe that enteral feedings should continue in the presence of a PDA (Jhaveri et al, 2009).

A PERSONALIZED APPROACH

Prolonged exposure to the left-to-right shunt can ultimately lead to congestive failure, pulmonary hypertension, and death. Therefore, our recommended approach has been to use early pharmacologic treatment of a PDA in the newborn period, because pharmacotherapy has not been shown to produce increased morbidity and early treatment is more likely to result in successful ductus closure. In certain settings (where ICH, pulmonary hemorrhage, and PDA ligations are frequent occurrences), indomethacin prophylaxis may even be a preferred alternative. On the other hand, ductus ligation, while eliminating one potential cause for neonatal morbidity, may introduce its own set of problems. Further investigations will be needed to determine which infants are most likely to benefit from surgical ligation and which infants might best be left untreated when pharmacologic approaches are no longer an option.

CHAPTER 55

Congenital Heart Disease

Thomas D. Scholz and Benjamin E. Reinking

Congenital heart disease (CHD) is the most common birth defect encountered in the clinical setting. The prevalence of all forms of congenital heart lesions is approximately 1% of live births, although estimates in the newborn are likely to be compromised by underdiagnosis of some lesions such as bicuspid aortic valve and overdiagnosis of normal structures that are in transition, including the foramen ovale and ductus arteriosus. The presentation of the newborn with CHD can range from absence of symptoms to complete cardiovascular collapse. Most commonly, neonates with CHD present with a murmur, cyanosis, and/or congestive heart failure. Lesions that result in each of these clinical findings are considered separately here, although considerable overlap exists among the three groups.

GENERAL CONSIDERATIONS

FETAL-TO-POSTNATAL TRANSITION

The hemodynamic state of the fetus is much different from that of the newborn. In the fetus, a relatively low systemic resistance exists because of the presence of the placenta, and the pulmonary vasculature maintains a high resistance. Central shunts exist that provide alternate routes on the venous side (ductus venosus), within the heart (foramen ovale), and on the arterial side of the circulation (ductus arteriosus).

The ductus venosus predominantly collects oxygen- and nutrient-rich blood from the placenta via the umbilical vein and delivers this blood directly to the right atrium, largely bypassing the hepatic and portal venous systems. As indicated by based on studies in fetal sheep, less than one half of the umbilical venous return enters the left lobe of the liver and reaches the ductus venosus near its insertion into the inferior vena cava (IVC), returning as relatively nutrient-rich blood (Edelstone et al, 1978). The lateral position of the IVC within the right atrium results in streaming of this nutrient-rich blood across the foramen ovale and into the left atrium. The most desaturated blood to return to the right atrium comes from the coronary sinus, which combines with the venous return from the superior vena cava and is directed across the tricuspid valve into the right ventricle.

In the fetus, the presence of the ductus arteriosus, which is nonrestrictive, results in the subjection of both ventricles to a comparable afterload. Compared with that in the postnatal heart, this results in an increase in right ventricular workload and some restriction to filling of the right ventricle. The nutrient-rich blood from the umbilical vein that has crossed the foramen ovale to enter the left side of the heart predominantly supplies the heart and brain. Output from the right ventricle supplies the lungs (less than 8% of the combined cardiac output) and flows right to left through the ductus arteriosus to supply the remainder of the body.

At birth, several important transitions take place that allow the fetus to adapt to extrauterine life. First, the gradual decline in pulmonary vascular resistance that was occurring during the last trimester of pregnancy undergoes an abrupt drop with the first breath taken by the newborn (Figure 55-1). The decline in pulmonary vascular resistance results in a more than 20-fold increase in pulmonary blood flow and reversal of flow (left to right) in the ductus arteriosus before its closure (Teitel, 1988). Second, the central shunts present in the fetus undergo closure such that blood flows in series through the body. The ductus venosus closes largely because of lack of flow after separation of the placenta, although some contractile elements may be present in the vessel wall (Adeagbo et al, 2004). The foramen ovale becomes occluded as the flap of the septum primum abuts the septum secundum following the increased pulmonary blood flow that increases filling of the left atrium. Small residual left-to-right shunts at the foramen ovale may persist, although these will generally decrease with time (see later discussion of atrial septal defects). Closure of the ductus arteriosus is mediated by a variety of pathways, although patency of the ductus can usually be maintained by exogenous prostaglandin administration. The third important transition at birth is an increase in the combined ventricle output as the metabolic demands of the body increase at birth.

The dramatic hemodynamic changes that occur at birth continue to evolve over the first few months of life. There is a continued decline in pulmonary vascular resistance for the first 6–8 weeks of life. In addition, the right ventricle remodels to a thinner and more compliant ventricle. Probe patency of the foramen ovale may persist for years, although in most individuals the septa become adherent.

NOMENCLATURE

The complete description of any heart requires more than a description of the presence or absence of a specific congenital heart defect. Each heart has a specific set of structures and connections that may be normal or abnormal. Although the terminology used for the various lesions that affect the heart is relatively consistent among pediatric cardiologists, various nomenclatures have been developed to completely define the cardiac anatomy. The various systems that have evolved are based on surgical approaches, embryologic origins, or spatial relationships and have hampered communication between individuals and institutions. A common method of describing cardiac anatomy would be a benefit but seems unlikely to be agreed on in the near future. Although the brief summary of nomenclature that is given here is based on the segmental approach of Anderson's group (Anderson et al, 1984), the embryologic approach of Van Praagh is equally valid and used by several institutions (Van Praagh, 1972).

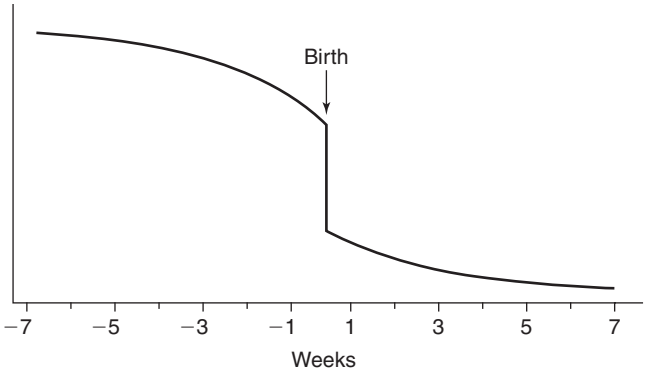

FIGURE 55-1 Change in pulmonary vascular resistance. A gradual decline in pulmonary vascular resistance is seen during the latter part of gestation followed by an abrupt decline at birth. A gradual decline occurs postnatally over the next 6 to 8 weeks.

The segmental approach to describing cardiac anatomy includes the following elements:

1. Cardiac position
2. Visceral sidedness
3. Systemic and pulmonary venous connections
4. Atrial sidedness and atrial connections
5. Atrioventricular (AV) valves
6. Ventricle sidedness
7. Ventriculoarterial connections
8. Great vessel number and position

The description of cardiac position in the chest can be separated into where the heart is located and the direction in which the apex of the heart is pointed. Normally, the heart is in the left chest with the apex pointed to the left. Dextro- (right) or meso- (midline) position of the heart can occur with decreased right lung volume, severe scoliosis, or an elevated left diaphragm. Typically, the position of the heart in the chest is determined by chest radiography. The normal leftward-pointing apex of the heart (levocardia) can vary to mesocardia (in various heterotaxy syndromes) or dextrocardia (in situs inversus). The orientation of the apex of the heart is usually defined by echocardiography.

Visceral sidedness is often defined separately for the abdominal organs, the cardiac structures, and the lungs, although they frequently share the same destination. Sidedness is referred to as solitus (normal), inversus (mirror image), or ambiguus (isomerism or indeterminate). In the last situation, effort is made to define whether the organs that appear on both sides are right-sided (liver, right atrium, and trilobed lung) or left-sided (stomach/spleen, left atrium, bilobed lung) structures, because this can have prognostic and therapeutic importance. For instance, patients with bilateral right-sidedness typically lack a spleen, require lifelong prophylactic antibiotics for encapsulated organisms, and have malrotation of the intestine.

Venous connections of the superior and inferior venae cavae must also be delineated. The usual connection of the superior vena cava (SVC) to the right atrium may also be accompanied by a persistent left SVC to the coronary sinus, with or without a bridging brachiocephalic vein. The inferior vena cava is derived from various embryologic vessels and can have its suprahepatic segment interrupted, in which case the normal connection of the IVC to the right atrium does not occur. In this case, lower extremity blood flow is routed to the SVC through the azygous or hemiazygous systems. Various pulmonary venous connections are described next.

Atrial sidedness can be solitus with the morphologic right atrium on the right (normal), inversus, mirror-image, common, or, rarely, indeterminate. The right atrium is typically identified by its venous connections (in particular, the coronary sinus), the presence of the crista terminalis, the large sail-shaped appendage, and the coarse pectinate muscles of the free wall. The left atrium is characterized by its smooth walls and narrow, finger-shaped appendage. Atrial morphology can typically be discerned by echocardiography, although angiography may also aid in their distinction. When the morphologic right atrium connects to the morphologic right ventricle (and similarly on the left), the connection is concordant. A discordant connection occurs when the morphologic right atrium connects to the morphologic left ventricle, as in corrected transposition of the great arteries. When both atria connect to one ventricle (as in double-inlet left ventricle) or a single ventricle, the type of connection is referred to as univentricular. An ambiguous connection occurs in cases of atrial isomerism.

The AV valves usually travel with their ventricle. Thus, the tricuspid valve, when present, connects to the morphologic right ventricle and the mitral valve connects to the morphologic left ventricle. The tricuspid valve has three leaflets and is distinguished from the mitral valve by the septal attachments of its papillary muscles and the slight, inferior position of the septal leaflet of the tricuspid valve relative to the anterior leaflet of the mitral valve. When the AV valves fail to undergo septation, a common AV valve is found, as in children with a complete AV septal defect. The position of the AV valves and their chordal attachments are used to define whether the valves are malaligned or straddling. A malaligned AV valve is not completely positioned over its respective ventricle, which is sometimes referred to as overriding. If the chordal attachments of an AV valve cross the septum and connect to the other ventricle, an AV valve is referred to as straddling.

The morphology of the ventricles, the associated AV valve, and the outflow portion of the ventricle can generally be used to identify the right and left ventricles. The right ventricle, besides being associated with the tricuspid valve, is more heavily trabeculated at its apex and anterior free wall than the left ventricle. In addition, an infundibular or conus ring exists in the right ventricle that separates the tricuspid and semilunar valves. The left ventricle, besides being more smooth-walled with finer trabeculations at its apex than the right ventricle, demonstrates fibrous continuity between the mitral and semilunar valves. When the ventricular morphology is uncertain, the ventricles are said to be indeterminate. A *c*ommon ventricle is defined by virtual absence of the interventricular septum.

The great vessels are largely defined by their branching pattern. The pulmonary artery bifurcates shortly after exiting the heart into the right and left pulmonary arteries, which undergo subsequent branching to supply the segments of the lung. The right pulmonary artery is positioned anterior to the right upper bronchus, whereas the left pulmonary artery is posterior to the left upper bronchus. The pulmonary arteries typically follow the situs of the lungs such that mirror-image pulmonary artery branching is

seen in situs inversus, bilateral branch pulmonary arteries anterior to the upper bronchus are seen in right isomerism, and branch pulmonary arteries posterior to the upper bronchus are seen in left isomerism. The aorta is normally left-sided, traveling to the left of the main bronchus, and gives rise to the three arch vessels. A right aortic arch passes to the right of the main bronchus before crossing back to the left side of the spine in the thorax and gives rise to mirror-image arch vessels such that the first arch vessel, the brachiocephalic artery, bifurcates to give rise to the right subclavian and right carotid. Although the aorta is typically posterior and rightward to the main pulmonary artery, the relative position of the vessels can vary greatly. Most commonly, in d-transposition of the great arteries, the aorta is anterior and rightward to the main pulmonary artery. In situations where only a single semilunar valve is present, a truncus arteriosus (or common truncal artery) is found that gives rise to both the aorta and pulmonary artery.

The ventriculoarterial connections are said to be concordant when the right ventricle connects to the pulmonary artery and the left ventricle gives rise to the aorta. The ventriculoarterial connection is discordant when the opposite occurs. The ventriculoarterial connection can also be double, single, or common. If both great arteries arise from one ventricle, a double outlet occurs. The definition of a double-outlet connection is somewhat controversial. For example, in the case of double-outlet right ventricle (DORV) with normally related great vessels, some clinicians have proposed basing the definition on whether greater than 50% of the aorta overrides the right ventricle, whereas others define the double outlet on the basis of presence of a subaortic conus exists that results in mitral-aortic discontinuity. From a clinical management perspective, both situations are relevant for either placement of the ventricular septal defect (VSD) patch or the potential for development of subaortic obstruction, respectively. A single outlet results when severe pulmonary hypoplasia occurs such that no main pulmonary artery segment is present. A common outlet occurs in truncus arteriosus.

CLINICAL EVALUATION OF THE NEWBORN

Even with the technologic advances in pre- and postnatal echocardiography and genetic testing, a careful history and physical examination is needed in every newborn with suspected congenital heart disease. Birth history including complications during pregnancy, labor, and delivery is important to document. Often, the child with cyanosis due to structural heart disease has an unremarkable birth history. A difficult labor or delivery may point toward noncardiac causes of cyanosis such as persistent fetal circulation, infection, or pneumothorax. For the child with poor systemic perfusion, a history of premature rupture of membranes or maternal fever may suggest sepsis as a cause for the diminished cardiac function. Hematologic abnormalities that may cause cardiovascular dysfunction in the neonate, such as polycythemia or anemia, may be suggested by a history of placental abruption or twin-twin transfusion.

Family history is critical to review with the biologic parents. There is a genetic basis for a growing number of congenital heart defects (see later discussion). CHD in a sibling more than doubles the risk of CHD in future children (Nora and Nora, 1988). A history of congenital heart disease in either of the parents also increases the chance of developing a congenital heart lesion (Nora and Nora, 1987; Whittemore et al, 1994).

Physical examination of the newborn should initially include a general assessment looking for dysmorphic features and the degree of distress of the infant. The child with cardiac obstructive physiology may have shallow, rapid respirations with intercostal and suprasternal retractions. Cyanosis may or may not be seen, depending on the degree of hemoglobin desaturation (roughly 5 g of hemoglobin must be desaturated to be clinically evident). Vital signs, including four extremity blood pressures, should be determined along with pre- and postductal oxygen saturation measurement. Palpation of the precordium may identify an overactive or displaced cardiac impulse or the sensation of a thrill due to turbulent flow. Palpation of the abdomen for a liver edge or spleen tip can often provide an indication of volume overload or neonatal infection. Assessment of femoral and upper extremity pulses is essential. Simultaneous palpation of the right brachial and right femoral pulses allows assessment of comparable timing and intensity of the pulsations. Perfusion and capillary refill of the extremities is also important to determine.

Auscultation is often challenging in the sick neonate. However, characterizing the presence, timing, intensity, position, and radiation of murmurs that are present may provide a clue to the underlying diagnosis. In the tachypneic and tachycardic child, it is critical to listen over the head and liver for a continuous murmur that may indicate an arteriovenous malformation. The presence of a click or gallop over the precordium may indicate valvular disease or cardiac failure. Assessment of the second heart sound is particularly important. It has been suggested that the presence of physiologic splitting of the second heart sound nearly always suggests a structurally normal heart (El-Segaier et al, 2007).

Signs of congestive heart failure in the newborn may be subtle and include resting tachypnea with no periodic variation, sinus tachycardia, and enlarged liver. Tachypnea may be accompanied by nasal flaring and inter- and subcostal retractions, particularly if elevated pulmonary venous pressures are present. Grunting respirations are a particularly concerning sign in a newborn that often accompanies severe heart failure and decreased systemic perfusion.

LABORATORY ASSESSMENT OF THE NEONATE

As mentioned earlier, initial laboratory assessment should include measurement of preductal (right hand) and postductal (foot) oxygen saturations. Values less than 93% are considered abnormal. The oxygen challenge test is performed by increasing the inspired oxygen concentration to 100% for at least 5 minutes. Oxygen saturation values that increase into the normal range may be useful to distinguish an admixture, cyanotic heart lesion from lung disease, although this test does not discriminate perfectly.

TABLE 55-1 Electrocardiogram Standards

Age Group	QRS Axis	PR1	QRSD	QV6 (mm)	RV1 (mm)	SV1 (mm)	RV6 (mm)	SV6 (mm)	SV1+RV6
<1 day	59–163	0.08–0.16	.031–.075	2	5–26	0–23	0–11	0–9.5	28
1–2 days	64–161	0.08–0.14	.032–.066	2.5	5–27	0–21	0–12	0–9.5	29
3–6 days	77–163	0.07–0.14	.031–.068	3	3–24	0–17	0.5–12	0–10	24.5
1–3 weeks	65–161	0.07–0.14	.036–.08	3	3–21	0–11	2.5–16.5	0–10	21
1–2 months	31–113	0.07–0.13	.033–.076	3	3–18	0–12	5–21.5	0–6.5	29
3–5 months	7–104	0.07–0.15	.032–.08	3	3–20	0–17	6.5–22.5	0–10	32
6–11 months	6–99	0.07–0.16	.034–.076	3	1.5–20	0.5–18	6–22.5	0–7	32
1–2 years	7–101	0.08–0.15	.038–.076	3	2.5–17	0.5–21	6–22.5	0–6.5	39
3–4 years	6–104	0.09–0.16	.041–.072	3.5	1–18	0.2–21	8–24.5	0–5	42
5–7 years	11–143	0.09–0.16	.042–.079	4.5	0.5–14	0.3–24	8.5–26.5	0–4	47
8–11 years	9–114	0.09–0.17	.041–.085	3	0–12	0.3–25	9–25.5	0–4	45.5
12–15 years	11–130	0.09–0.18	.044–.087	3	0–10	0.3–21	6.5–23	0–4	41
Adult	–30–90	0.12–0.2	0.05–0.1		0–10	0.5–23	4–23	0–4	35

Normal ranges of electrocardiogram measurements (made at full standard) are given. The values vary throughout childhood, because the in utero right ventricular dominance decreases postnatally.

History and physical examination should be included and guide the need for further evaluation. A decrease in postductal oxygen saturations compared to preductal values suggests right-to-left shunting due to an increase in pulmonary vascular resistance. The unusual situation where the preductal saturation is less than the postductal reading occurs with transposition of the great arteries and pulmonary hypertension with a patent ductus arteriosus (PDA).

An electrocardiogram (ECG) should be obtained in the initial evaluation of the newborn with suspected CHD although, in the absence of an arrhythmia, it rarely provides a specific diagnosis. The neonatal ECG demonstrates prominent rightward forces and may have an upright T wave in the right precordial leads in the first few days of life and still not be diagnostic of right ventricular hypertrophy. Age-dependent standards are available and should be referred to when evaluating the ECG (Table 55-1). Certain lesions may be associated with distinctive findings on ECG such as extreme right axis deviation and q waves in leads I and aVL (complete AV canal), preexcitation and right atrial enlargement (Ebstein's anomaly), and q waves in leads V1 to V3 (corrected transposition of the great arteries).

A chest radiograph should also be obtained in every newborn who is evaluated for CHD. The chest radiograph may help to determine if lung disease is contributing to cyanosis. The heart size, shape, and border contours should be evaluated on the chest radiograph along with pulmonary vascular markings. A prominent thymic shadow in the newborn may make identification of classic chest radiography findings difficult (such as the "boot-shaped" heart in tetralogy of Fallot (TOF), the "egg on a string" in transposition, and the "snowman" appearance in supracardiac total anomalous pulmonary venous return), although the massively increased heart size typically found with Ebstein's anomaly (see later discussion) will not be missed. An absent thymic shadow may suggest DiGeorge syndrome (22q11 deletion), although genetic testing is still required. Increases in pulmonary vascular markings typically found in left-to-right shunt lesions may not be immediately apparent in the newborn because of the relatively high pulmonary vascular resistance and may take days or weeks to evolve. Often, decreased pulmonary vascular markings in lesions with diminished pulmonary blood flow, such as tricuspid or pulmonary atresia, will be apparent in the newborn period. Presence of a PDA, however, will improve pulmonary blood flow in these lesions.

Echocardiography is truly the mainstay in the diagnosis of congenital heart disease in the neonate (described in detail in Chapter 53). Although we encourage complete cardiovascular evaluation and consultation with a pediatric cardiologist in all children with suspected CHD, more programs are performing echocardiograms in neonates without direct evaluation of the newborn by a pediatric cardiologist. In such instances, it is critical to have the echocardiographic examination reviewed by a pediatric cardiologist with some knowledge of the clinical condition of the child. Furthermore, the pediatric cardiologist reading the echocardiogram should discuss the findings directly with the caregivers in order for the team to define relevant therapy and follow-up.

GENETICS AND CONGENITAL HEART DISEASE

Our understanding of the genetic basis of CHD is progressing at a rapid pace. The early identification of the association of specific syndromes with CHD suggested that it would be possible to identify genes relevant to abnormal cardiac morphogenesis. With the completion of the Human Genome Project and the availability of large-scale sequencing techniques, it is expected that genetic causes for CHD will continue to become more highly refined, as will the identification of novel gene-environment interactions that alter cardiac development. A child with suspected CHD should be carefully evaluated for dysmorphic features that may indicate an associated syndrome. The converse is also true in that if a newborn is suspected to have a syndrome, careful cardiac evaluation, including an echocardiogram, should be considered.

Screening for chromosomes is an important initial step in the genetic evaluation of the newborn with a presumed syndrome. Well-described associations of congenital cardiac lesions with chromosome abnormalities include trisomy 21 with complete AV septal defect, Turner's syndrome (45 XO) with coarctation of the aorta, Williams syndrome (7q11 deletion) with valvar and supravalvar pulmonic stenosis, and DiGeorge or velocraniofacial syndrome (22q11 deletion) with conotruncal anomalies. These syndromes, and others, make karyotype analysis with fluorescence in situ hybridization (FISH) analysis an important initial step in the workup of infants with these lesions.

A number of single-gene disorders that are associated with CHD have now been defined using direct sequencing of chromosome regions associated with specific syndromes, linkage analysis based on data for large kindreds with a congenital heart lesion, and genome-wide association studies using microarrays or single-nucleotide polymorphisms (SNPs). Included in this list of syndromes and cardiac lesions due to single-gene defects are Noonan's syndrome (pulmonic stenosis), Holt-Oram syndrome (atrial septal defect), Alagille syndrome (peripheral pulmonic stenosis), Ellis-van Creveld syndrome (common atrium), and CHARGE syndrome (embodying variety of lesions). Syndromes and single-gene disorders and their associated CHD have been well tabulated, and the reader is referred to these references for complete listings (Allen et al, 2008).

Genetic testing should be done in all newborns with suspected syndromes whether or not CHD is present. FISH studies for 22q11 deletions should be performed in all infants with conotruncal anomalies such as tetralogy of Fallot, truncus arteriosus, and interrupted aortic arch. Other FISH studies can be specifically ordered at most institutions, although the maximum number of fluorescent probes is typically four or five because of detection limitations of the range of wavelengths available. Genome-wide chromosome microarray screening is now also available that can detect deletions and duplications across the genome, although results take approximately 1 week to generate, and the amount of blood needed for the study may be a limitation in some infants.

The usefulness of genetic testing is not only to help to provide prognostic information for a specific patient, but to provide counseling for the family. Consulting genetics faculty should be considered whenever a karyotype, FISH study, or genome-wide chromosome microarray is found to be abnormal. Consideration of services available to the infant, screening of additional family members, and risk to future pregnancies should be reviewed during the genetics consultation that will affect the overall care of the patient.

MURMURS IN THE NEWBORN: CONGENITAL CARDIAC LESIONS

PATENT DUCTUS ARTERIOSUS AND AORTOPULMONARY WINDOW

As discussed earlier, every child is born with a PDA that typically closes within the 1st week of life. Prematurity is a risk factor for a persistent PDA and is covered in Chapter 54. Persistent PDA in term infants occurs more commonly in females and, in some patients, may have a genetic component, as suggested by an animal model of inbred poodles (Knight et al, 1973) and linkage to chromosome 12 (Mani et al, 2002).

The pathophysiology of a PDA largely depends on the degree of shunting from the aorta to the pulmonary artery, which is determined by the inner diameter and length of the PDA and the relative pulmonary and systemic resistances. If the PDA diameter is small, the ductus itself will provide the primary site of resistance to flow and the shunt will be small. In the case of a larger PDA, low pulmonary vascular resistance may allow for a significant shunt that places the patient at risk for developing heart failure and, eventually, pulmonary vascular occlusive disease. The low-resistance pathway through the lungs provides a route for diastolic runoff from the aorta that can result in decreased coronary perfusion pressure. The diastolic steal by the pulmonary artery can lead to myocardial ischemia.

Clinically, patients with a small shunt will be asymptomatic. With a larger PDA shunt, the progressive decline in pulmonary vascular resistance postnatally will cause an increase in left-to-right shunt flow with signs of increasing heart failure. The murmur in a child with a PDA is generally continuous and has been described as a "machinery" murmur in the left infraclavicular region. The character of the murmur, however, varies greatly, although the continuous nature is generally present once the pulmonary vascular resistance has declined. Examination of the patient with a PDA will also include a wide pulse pressure due to decreased diastolic pressure and bounding pulses.

The diagnosis of PDA, when suspected on examination, can nearly always be confirmed by echocardiography. Even in the face of high pulmonary vascular resistance with limited left-to-right shunting, differences in the pulse waveforms between the aorta and pulmonary artery will allow left-to-right and/or right-to-left shunting to be observed by color Doppler imaging. Echocardiography can also provide information regarding the degree of left-to-right shunting as the dimensions of the left atrium and left ventricle are increased, and the left atrium–to–aorta ratio is increased. In addition, retrograde flow will be seen in the proximal descending aorta when a large shunt is present. Cardiac catheterization is rarely needed unless coil closure of the PDA is considered.

The prognosis for small PDAs is quite good, and debate exists as to whether closure of "silent" PDAs incidentally identified by echocardiography should be undertaken (Giroud and Jacobs, 2007). With the most recent recommendations from the American Heart Association suggesting that PDAs do not require subacute bacterial endocarditis prophylaxis (Wilson et al, 2007), the need to close these small vessels is low.

Because of long-term concerns with pulmonary overcirculation and the development of pulmonary vascular occlusive disease, closure of PDAs by 1 year of age is recommended when a significant left-to-right shunt is present. Surgical ligation and division can readily be performed through a lateral thoracotomy. However, coil or device closure in the catheterization labratory has a lower morbidity and success rates equal to those with surgery (Arora, 2005). As a result, catheter closure of PDAs has become the preferred method in nonpremature infants.

Aortopulmonary (AP) window occurs when there is direct communication between the aorta and main pulmonary artery and is a rare lesion that can readily be confused with

PDA on both physical and laboratory evaluation. Nearly half of patients with an AP window have an associated cardiac anomaly. These lesions nearly always result in a large degree of left-to-right shunting. Patients will show signs of congestive heart failure on examination, and physical and laboratory findings will be similar to those with a large PDA. Generally, all AP windows should be closed when they are identified. Closure of an AP window must be done surgically, with patch closure from the pulmonary artery side generally being the preferred technique.

VENTRICULAR SEPTAL DEFECT

VSDs are the most common type of congenital heart disease (excluding bicuspid aortic valve). Generally, VSDs are classified into four types (Figure 55-2):

- Perimembranous
- Muscular
- Inlet
- Outlet

The perimembranous VSD is the most common of the four types and has variably been referred to as membranous, paramembranous, and infracristal. From the right ventricular side of the heart, these defects lie under the septal leaflet of the tricuspid valve below the crista supraventricularis and posterior to the papillary muscle of the conus. Muscular VSDs can occur in isolation or as multiples ("Swiss cheese septum") and, as the name implies, can occur anywhere in the muscular septum. Apical muscular VSDs are the most common and are sometimes difficult to accurately size by echocardiography because of the heavy trabeculations at the apex of the right ventricle. Inlet VSDs are located posterior and inferior to perimembranous defects; although the nomenclature is controversial, this is the location of the defect in patients with complete AV septal defects (see later discussion). The location of the VSD in patients with outlet defects is above the crista supraventricularis and typically undermines the right aortic valve leaflet. A variety of synonyms have been used for outlet VSDs, including subarterial, subaortic, supracristal, and conal VSD.

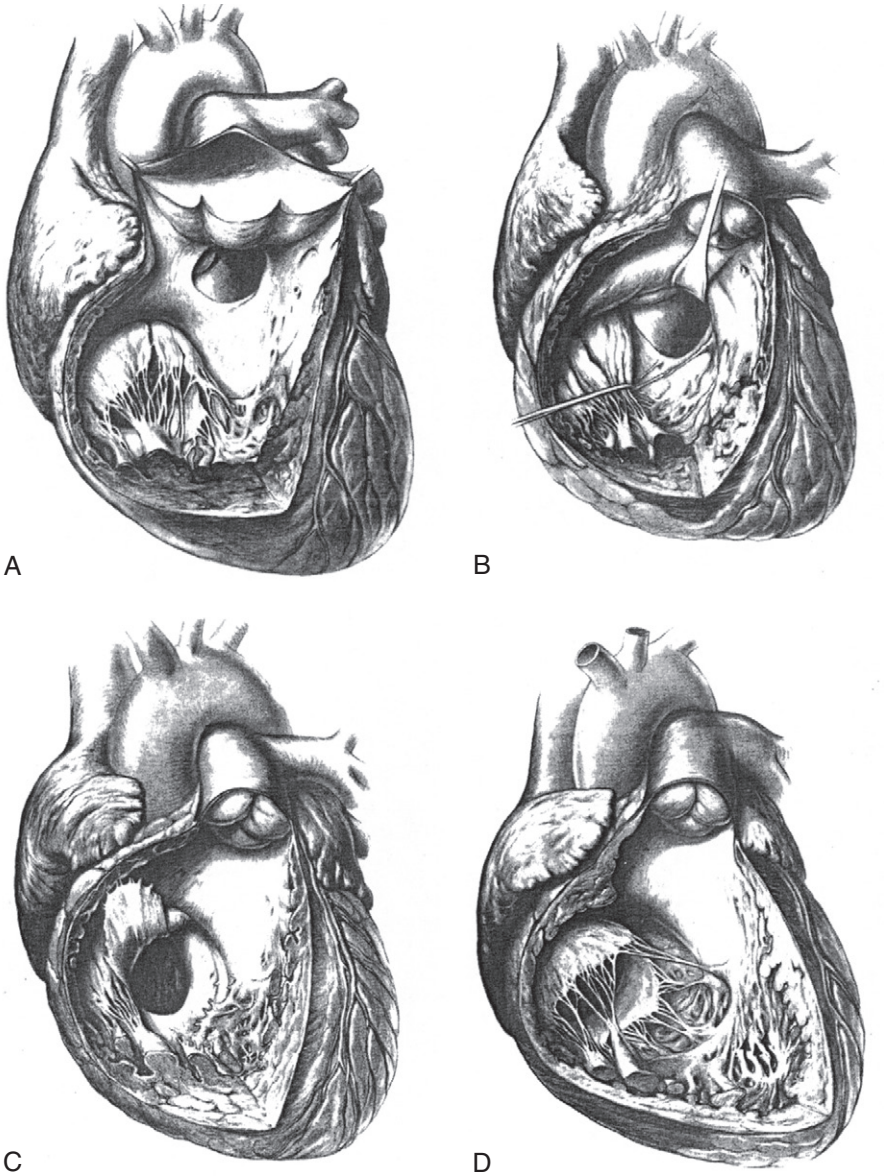

FIGURE 55-2 Anatomic varieties of ventricular septal defect. A, Subpulmonary defect; **B,** membranous defect; **C,** inlet (atrioventricular septal defect type) defect; **D,** apical muscular defects. *(From Mavroudis C, Backer CL:* Pediatric cardiac surgery, *St. Louis, 1994, Mosby-Year Book.)*

The clinical importance of any VSD is dependent on the size of the defect and the relative pulmonary-to-systemic vascular resistance, which together determine the degree of left-to-right shunting. An additional consideration with outlet VSDs is the degree to which the right coronary cusp of the aortic valve prolapses into the defect and results in aortic insufficiency. Defects whose cross-sectional area is equal to or greater than the cross-sectional area of the aortic valve will not restrict flow leaving the left ventricle and entering the right ventricle. In this case, the degree of shunting will be determined by the relative resistance to flow in the pulmonary and systemic vascular beds. The normal postnatal decline in pulmonary vascular resistance will result in a progressive increase in left-to-right shunting and signs of congestive heart failure. A small percentage of children do not experience the usual postnatal decline in pulmonary vascular resistance and may never develop signs of pulmonary overcirculation and heart failure despite the presence of a large VSD. As discussed later, this is an indication for early surgical closure of the defect.

When the VSD is small relative to the aortic valve, the defect itself will be the primary point of resistance to shunt flow. In this case, changes in pulmonary vascular resistance will have little impact on the degree of left-to-right shunting.

An important associated lesion that is critical to rule out is coarctation of the aorta. The coarctation results in a fixed, elevated systemic vascular resistance that can lead to important left-to-right shunting even in the presence of a small VSD. In this case, medical therapy is often unable to control congestive heart failure symptoms, and surgery is needed.

The volume of shunted blood is most accurately quantitated at cardiac catheterization based on step-up in oxygen saturation from the right atrium (mixed venous) to the pulmonary artery and is represented as the ratio of pulmonary-to-systemic blood flow (Qp:Qs). Generally, a Qp:Qs <1.5 is considered below the threshold for surgery, whereas a Qp:Qs >2.0 is an indication for surgery. The Qp:Qs can also be estimated by echocardiography and by magnetic resonance imaging.

The examination of the patient with a VSD depends on the magnitude of the shunt. Small defects that provide considerable restriction to flow often have the loudest murmur. The rapid drop in pulmonary vascular resistance immediately after birth allows VSD murmurs to often be heard in the newborn nursery, although the full extent of the murmur, and perhaps a thrill at the lower left sternal border, may not be appreciated for several weeks. The murmur may have a more ejection quality in the newborn nursery in the face of high pulmonary vascular resistance and somewhat elevated right ventricular pressure. The more typical holosystolic murmur will be more apparent as the pulmonary vascular resistance falls.

With large VSDs, little or no murmur may be heard, depending on the pulmonary vascular resistance. With low pulmonary vascular resistance, signs of heart failure will likely be present, including tachypnea with nasal flaring and retractions, tachycardia, diaphoresis, poor feeding, and diminished weight gain. A systolic murmur at the lower left sternal border (due to flow across the VSD) or upper left sternal border (due to increased flow across the right ventricular outflow tract [RVOT]) may be heard along with a diastolic inflow rumble (an absence of silence) at the apex. If pulmonary vascular resistance is high, the pulmonic component of the second heart sound may be increased, although difficult to appreciate. Occasionally, large defects may allow transient right-to-left shunting to occur, particularly when the infant is crying.

In patients with an outlet VSD, the holosystolic murmur is often present, but the murmur is located higher on the left sternal border. Care should be taken to listen for the diastolic decrescendo of aortic insufficiency at the mid-left sternal border or at the apex.

The laboratory evaluation of the infant with a suspected VSD should include an ECG, chest radiograph, and echocardiogram. In infants, the ECG may not be distinctive unless an inlet VSD is present (see later discussion). The chest radiograph, even in the neonate, is important to obtain to assess heart size and pulmonary vascular markings. The chest radiograph can be an important tool in the follow-up of newborns with VSDs to assess progression in left-to-right shunting as the pulmonary vascular resistance declines. Echocardiography is the definitive diagnostic modality for characterizing the location and size of the VSDs. Associated lesions, such as coarctation of the aorta, can also be readily assessed by echocardiography. Doppler studies can estimate the degree of restriction by calculating the pressure drop at the defect (see Chapter 53). M-mode measurements can be used to determine left ventricular dimensions, which will be increased when a significant left-to-right shunt is present. As mentioned earlier, cardiac catheterization can accurately quantitate the degree of shunting but is rarely needed in the initial assessment of the newborn with VSD.

Up to 80% of small, muscular VSDs and 30% to 50% of perimembranous defects will close spontaneously. It is uncommon for these defects to increase in size, although the degree of left-to-right shunting can increase as pulmonary vascular resistance drops. Occasionally, inlet VSDs will undergo closure secondary to chordal attachments of the AV valves, but closure is generally present at birth if it is going to occur. Outlet VSDs virtually never close and have the associated risk of progressive aortic insufficiency due to prolapsing of the right coronary cusp into the defect.

The short-term consideration in following patients with VSDs is the management of congestive heart failure if the left-to-right shunt is excessive. Medications that are used include furosemide (typically 1 mg/kg/dose bid), digoxin (5 μg/kg/dose bid), and afterload reduction with enalapril (initial dose of 0.05 mg/kg/dose bid up to 0.25 mg/kg/dose bid—monitoring blood pressure). The primary goal in controlling congestive heart failure is to allow the newborn to grow adequately and, it is hoped, allow progressive closure of the VSDs. Weight gain is a useful and objective measure to follow.

The long-term goal of therapy or intervention is to prevent the development of irreversible pulmonary vascular occlusive disease. Shunts with a Qp:Qs >2 are at long-term risk for development of Eisenmenger's syndrome, and closure of the defect is warranted beyond 2 to 4 years of age when further decline in defect size is unlikely.

If medical therapy fails to control heart failure and the infant has failure to thrive, surgical closure of the defect

in the first 6 months of life is needed. Surgical closure is also indicated in the 6- to 12-month-old child with a large VSD who has not demonstrated signs and symptoms of congestive heart failure due to lack of decline in pulmonary vascular resistance. In these infants, irreversible changes in the pulmonary vasculature may occur if the pressure load is not taken off the lungs. As mentioned earlier, defects with a Qp:Qs >2 and outlet defects also require closure. The use of pulmonary artery banding is falling out of favor for palliation of patients with VSDs unless the patient's clinical condition makes complete repair untenable. There is growing use of hybrid procedures where the surgeon and interventional cardiologist work together to close defects in small children (Contrafouris et al, 2009). This combined approach has successfully been applied to the closure of muscular VSDs in infants that are positioned in a location that is difficult for the surgeon to visualize from a right atrial approach. Additional indications for the hybrid approach to VSD closure will likely be determined in the coming years.

ATRIAL SEPTAL DEFECTS

Although atrial septal defects (ASDs) rarely produce a murmur in the neonatal period, the systolic murmur they generate later in life makes them appropriate for this section. As discussed previously, atrial-level shunting through the foramen ovale in utero allows the nutrient-rich placental blood to gain access to the left ventricle and ascending aorta. In the immediate postnatal period, careful echo examination of the interatrial septum will usually identify residual left-to-right or bidirectional shunting through the foramen ovale. Measurement of the size of the shunt provides an indication of whether there will be a persistent septal defect. An opening less than 6 mm in a term infant will most likely close and is referred to as a patent foramen ovale in order to distinguish it from a true atrial septal defect. Atrial septal defects that represent congenital lesions are classified as follows:

- Secundum
- Primum
- Sinus venosus
- Coronary sinus

Secundum defects are the most common and, when present in the neonate, allow for left-to-right or bidirectional shunting. The direction of the shunt, and the reason an ASD murmur is typically not heard in the neonate, is that right ventricular compliance remains low until the right ventricle remodels postnatally. The reduced right ventricular compliance increases right atrial pressure and limits the amount of left-to-right atrial-level shunting. Secundum ASDs are associated with Holt-Oram syndrome (abnormal radii, first-degree AV block, and ASD). Primum ASDs are in the spectrum of AV septal defects and are considered in the next section. Sinus venosus defects occur when the wall separating the upper or lower right pulmonary vein is deficient so that pulmonary venous return from either or both veins spills into the right atrium. This results in a left-to-right shunt. This variant of anomalous pulmonary venous return is considered in greater detail later. Coronary sinus defects result from an "unroofing" of the coronary sinus so that the coronary sinus enters at the left-right atrial junction where the septum is deficient. Often, this lesion is associated with a persistent left superior vena cava that enters into the coronary sinus.

In later childhood when the compliance of the right ventricle increases and left-to-right shunting through an ASD increases, the classic physical findings of fixed splitting of S2, a systolic ejection murmur at the left upper sternal border, and a diastolic right ventricular inflow murmur at the lower left sternal border become apparent in lesions with a Qp:Qs >2. Electrocardiography will often demonstrate an rsR′ pattern in the right precordial leads with evidence of right ventricular hypertrophy. Cardiomegaly with a prominent pulmonary artery segment and increased vascular markings will be seen on chest radiograph. Echocardiogram remains the gold standard for identifying and sizing the defects.

It is uncommon for infants and children with an isolated ASD to develop heart failure. Typically, intervention for a significant ASD is performed to prevent the long-term sequelae of pulmonary vascular occlusive disease. Thus, closure is rarely performed before the age of 3 or 4 years. Device closure of secundum ASDs is now routinely performed in the catheterization laboratory in children weighing more than 15 kg, although surgical closure is still performed when lesions are large or the rim of tissue between the ASD and aorta is deficient.

ATRIOVENTRICULAR SEPTAL DEFECTS

A variety of terms have been used to describe AV septal defects including AV canal defect, endocardial cushion defect, and common AV orifice. In addition, there is a spectrum of AV septal defects:

- Complete: a common AV valve is present along with a significant primum ASD and inlet VSD
- *Intermediate*: a common AV valve annulus although separate AV valves along with a primum ASD and inlet VSD
- Transitional: completely separate AV valves along with a primum ASD and inlet VSD
- Partial: separate AV valves with a primum ASD and no VSD

These four groups have some therapeutic relevance with regard to the degree of AV valve abnormality that must be considered at surgery, although each has a cleft between the anterior bridging leaflet and the lateral leaflet of the left-sided (mitral) valve that must be addressed. In infants with a complete AV septal defect, it is important to assess whether the right and left ventricles are *balanced*, that is, equally developed so that a two-ventricle repair is possible, and also to determine the degree of AV insufficiency, which has prognostic importance in the surgical outcome. The association of AV septal defects with Down syndrome has been addressed previously.

In the immediate postnatal period, variations in pulmonary vascular resistance that occur, particularly in infants with Down syndrome, can result in a right-to-left shunt through a nonrestrictive primum ASD and/or inlet VSD and result in systemic desaturation. Many infants with complete AV septal defects will develop heart failure in the first 2 months of life as pulmonary vascular resistance falls. A small percentage of infants will not have a decline in pulmonary vascular resistance, making the lack of heart

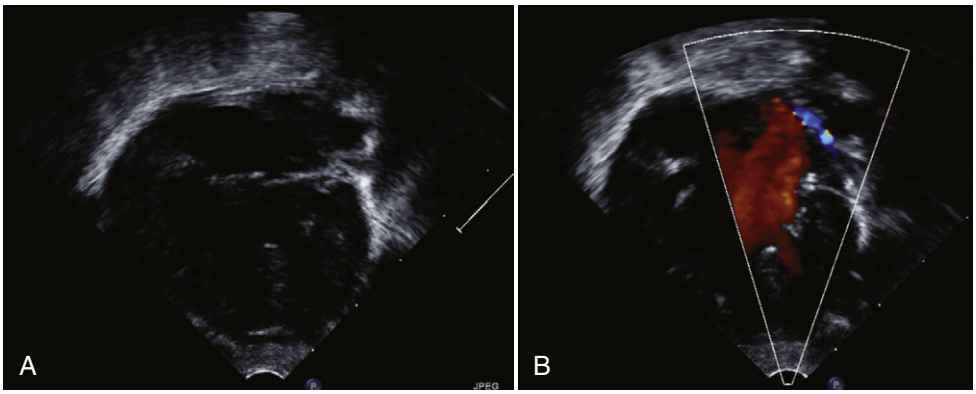

FIGURE 55-3 *(Supplemental color version of this figure is available online at www.expertconsult.com.)* **Echocardiographic view of complete atrioventricular septal defect.** **A,** Four-chamber view showing the common AV valve that separates the atria and ventricles (RV, right ventricle; LV, left ventricle) which in this patient are well balanced. The large primum ASD and inlet VSD are seen. **B,** With color Doppler, inflow across the AV valve is seen.

failure a troubling sign and an indication for early surgical repair.

Although diagnosis largely rests on the echocardiogram, AV septal defects can be suspected on ECG with the presence of a superior frontal QRS axis (ranging from –30 to –120 degrees), evidence of right ventricular hypertrophy, and Q waves in leads I and aVL. Echocardiography is used to define the type of AV septal defect and identify associated anomalies (Figure 55-3). As mentioned earlier, critical assessment of relative ventricular sizes and the degree of AV valve insufficiency is necessary. Interrogation of the right ventricular outflow tract (RVOT) is also needed due to the associated pulmonic stenosis or tetralogy of Fallot that can occur with complete AV septal defects.

Correction of complete AV septal defects is done surgically at 4 to 6 months of age. While awaiting surgery, care must be taken not to treat minor desaturation episodes with excessive oxygen because oxygen-induced lowering of pulmonary vascular resistance can rapidly worsen heart failure and lead to further desaturation, a spiral that can be difficult to reverse. Furosemide, digoxin, and afterload reduction are often needed to control heart failure, and some cardiologists will start these medications in the immediate postnatal period because of the high likelihood of infants developing congestive heart failure. Complete repair (septation of atrial, AV valves, and ventricles) is preferred. It is very rare that palliative banding of the pulmonary artery is needed to control heart failure symptoms. As mentioned previously, early repair should be considered in the infant who does not have a decline in pulmonary vascular resistance and the development of heart failure because of the concern of early development of irreversible increases in pulmonary vascular resistance, particularly in non–Down syndrome complete AV septal defect patients.

PERIPHERAL PULMONIC STENOSIS

Peripheral pulmonic stenosis (PPS) can range widely in its severity. In many instances, mild narrowing of the branch pulmonary arteries occurs in the neonate and produces a murmur that is heard widely throughout the chest. The murmur due to this mild PPS is considered by some to be an "innocent murmur" of infancy and usually resolves by 2 to 4 months of age. This lesion likely reflects mild hypoplasia of the branch pulmonary arteries due to decreased in utero pulmonary blood flow and the postnatal transition where these vessels must accommodate the entire cardiac output.

More severe PPS is seen in cases of congenital rubella syndrome or in association with Williams or Noonan's syndrome. Branch pulmonary artery stenoses can also occur with tetralogy of Fallot. In these cases, multiple levels of obstruction may exist that require catheterization or surgical intervention.

In isolated or mild PPS, minimal right ventricular pressure overload occurs. With increasing stenosis, right ventricular pressure overload will result in right ventricular hypertrophy and, in later stages, right atrial enlargement on ECG. Echocardiography can interrogate the proximal pulmonary arteries, but more distal lesions require other imaging modalities such as magnetic resonance imaging or cardiac catheterization.

Intervention to treat severe branch stenoses should be considered when right ventricular pressure is greater than 75% of systemic pressure or any clinical or laboratory evidence of right ventricular dysfunction is present. Surgical management is possible for proximal areas of stenosis, although the treatment preferred by most clinicians is balloon dilation or expandable stent placement in the cardiac catheterization laboratory. Repeated interventions may be needed to enlarge vessels as the patient grows or to dilate other areas of stenosis that develop.

PULMONIC STENOSIS

Isolated pulmonary valve stenosis is a common cause of a systolic ejection murmur in the neonatal period. Although cases typically occur sporadically, more than 50% of infants with Noonan's syndrome will have pulmonic stenosis, and thus the pulmonary valve should be evaluated in all these children.

The degree of pulmonic stenosis determines the pathophysiology of the disease process. As the stenosis of the valve worsens, right ventricular pressure increases along with the degree of right ventricular wall stress. Right ventricular hypertrophy will develop if the stenosis is left untreated. In severe, or critical, pulmonic stenosis (discussed later), heart failure can develop in the neonate accompanied by cyanosis due to right-to-left shunting at the atrial level.

The degree of stenosis is generally classified based on the pressure drop across the pulmonic valve, with mild stenosis defined as a gradient <30 mm Hg, moderate stenosis as a gradient of 30 to 60 mm Hg, and severe stenosis as >60 mm Hg. Although these definitions were initially based

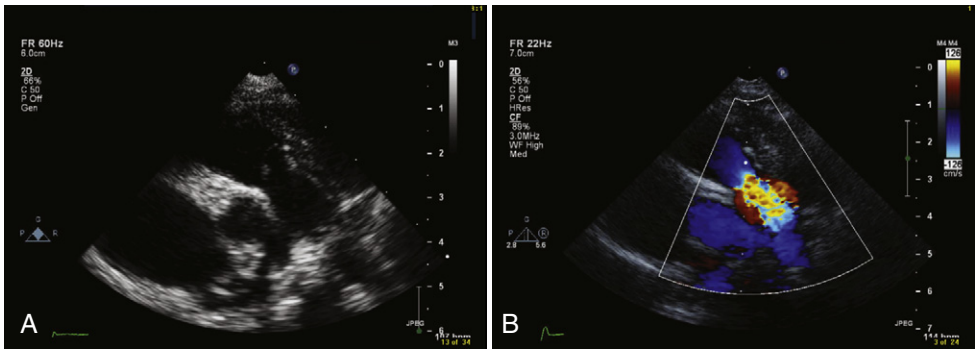

FIGURE 55-4 *(See also Color Plate 22.)* **Pulmonic stenosis. A,** Short-axis view of pulmonic stenosis with a thickened appearing pulmonic valve (PV). **B,** Using color Doppler imaging, turbulence in the main pulmonary artery is seen above the pulmonic valve.

on cardiac catheterization, current follow-up of patients with pulmonic stenosis utilizes echocardiogram, which overestimates the gradient compared to direct hemodynamic measurement at catheterization. Thus, some use an *echo gradient* of <40 mm Hg as mild pulmonic stenosis.

Consideration of the valve gradient is critical because of the prognostic significance of the value. In older children, mild stenosis rarely progresses (Nugent et al, 1977). In infants, however, follow-up of patients with echo gradients <40 mm Hg found that 29% developed progressive valve stenosis, with half of those showing an increase in the first 6 months of life (Rowland, 1997). Neonates with moderate valve stenosis may face an even greater likelihood of developing progressive stenosis, although limited data exist.

A systolic ejection murmur of pulmonic stenosis can be heard in the neonatal period at the upper left sternal border. Typically, although the fast heart rate in the neonate may make it difficult to appreciate, a systolic ejection click just after the first heart sound (S1) can be heard in most of these infants and is an important feature to distinguish pulmonic stenosis from other lesions. Much as in PPS (see earlier discussion), the murmur of pulmonic stenosis radiates throughout the lung fields. As the gradient across the valve worsens, a thrill may be palpable at the upper left sternal border. As the degree of stenosis progresses further and becomes severe, the murmur and click will diminish and may even be absent as right ventricular dysfunction worsens. Of note is that while progressive pulmonic stenosis may be able to be estimated on the basis of the murmur, the clinical condition of the infant may not change appreciably until the degree of stenosis becomes severe.

The findings on laboratory studies in infants with pulmonic stenosis will vary depending on the degree of stenosis. Electrocardiogram will demonstrate right ventricular hypertrophy in most patients with moderate stenosis, although the study may be normal when mild stenosis is present. Chest radiography is often normal unless poststenotic dilation of the main pulmonary artery has developed. Echocardiography will be diagnostic. The valve will have varying degrees of dysplasia that is characterized by thickened, poorly mobile leaflets that dome during systole. Turbulence distal to the valve will be seen by color Doppler imaging (Figure 55-4), while pulsed-wave Doppler is used to determine the degree of stenosis. As discussed earlier, Doppler echo generally gives a value of stenosis that is 20% to 30% higher than the peak-to-peak pressure gradient measured as cardiac catheterization.

Treatment of isolated pulmonic stenosis, even in the neonate, can readily be performed by balloon valvotomy in the cardiac catheterization laboratory. The exception may be in infants with Noonan's syndrome where the degree of valvar dysplasia may prevent an adequate result, although most will initially attempt a balloon valvotomy before progressing to surgery. Valvotomy should be considered in infants with more than mild stenosis. Mild or moderate pulmonary insufficiency, should it develop after balloon valvotomy, is usually well tolerated. Recurrent stenosis and more significant pulmonic insufficiency are found more often when valvotomy is needed in the neonatal period (Garty et al, 2005).

AORTIC STENOSIS

Like stenosis of the pulmonic valve, aortic valve stenosis can produce a murmur in the neonatal period. However, aortic stenosis is more likely to be progressive than pulmonic stenosis. Levels of obstruction of the left ventricular outflow tract can also occur at the subvalvar and supravalvar levels. Subvalvar stenosis is rarely diagnosed in the neonatal period, but often progresses later in life as a fibromuscular ridge beneath the aortic valve. Supravalvular stenosis can present in the newborn period and is often associated with Williams syndrome.

As with pulmonic stenosis, the pathophysiology and physical findings associated with aortic valve stenosis depend on the degree of obstruction. Certainly the most common aortic valve abnormality addressed in the neonatal period is critical aortic stenosis associated with decreased left ventricular function. This medical emergent situation is addressed in detail later. Mild (aortic valve gradient <30 mm Hg) and moderate (valve gradient of 30 to 60 mm Hg) aortic valve stenosis is not commonly encountered in the neonatal period. When it is, these milder forms of stenosis are generally associated with a bicuspid aortic valve and tend to progress with age. The rate of change of progression throughout infancy and childhood is quite variable and necessitates frequent follow-up of these patients.

The murmur in the newborn with aortic stenosis may be difficult to localize to the upper right sternal border as in older children. A thrill is usually palpable at the suprasternal notch with even mild aortic valve stenosis with a precordial thrill felt as the degree of stenosis increases. Usually a click from the stenotic aortic valve is heard at the apex or lower left sternal border.

Electrocardiography may be of limited benefit in the newborn with mild or even moderate aortic valve stenosis, although some degree of left ventricular hypertrophy may be seen. Chest radiograph is of limited benefit in following these patients, with the focus of the diagnostic assessment being the echocardiogram. On echocardiogram, the aortic valve can be characterized. Fused leaflets that are thickened and domed are seen. Pulsed Doppler is used to determine the gradient across the valve; color Doppler imaging can define the presence of aortic insufficiency.

Initial management of moderate aortic valve stenosis is balloon valvotomy in the cardiac catheterization laboratory. The balloon is sized in an effort to limit aortic insufficiency, which is much less well tolerated than insufficiency of the pulmonic valve. If significant aortic valve insufficiency is present or develops, surgical repair or valve replacement is needed. In neonates and infants, the Ross procedure is usually the procedure of choice (Elkins et al, 1994). In this procedure, the pulmonary valve is removed intact from the patient and sewn into the aortic position, and a homograft is placed in the pulmonic position. Interestingly, the pulmonary autograft generally demonstrates good growth and excellent function in the aortic position. Although the child will outgrow the pulmonary homograft, replacing it and managing progressive pulmonic stenosis is much easier than addressing the aortic valve.

CYANOSIS IN THE NEWBORN

Congenital heart defects that present with cyanosis do so because of a right-to-left shunt. The shunt results in mixing of the systemic and pulmonary venous returns that can occur between the atria and ventricles or great vessels. Defects manifesting predominantly with cyanosis can be further subclassified by the amount of associated pulmonary blood. If there is no restriction to pulmonary blood flow, cardiac output to the lungs will increase as the normal postnatal drop in pulmonary vascular resistance occurs. Clinically, this results in tachypnea, poor feeding, hepatomegaly, and pulmonary edema. Much of the neonatal management is aimed at balancing the ratio of systemic to pulmonary blood flow. Defects with restriction to pulmonary blood flow typically present with cyanosis without associated symptoms of congestive heart failure. If the restriction is severe, pulmonary blood flow may be dependent on a left-to-right shunt through the ductus arteriosus. These patients typically have some degree of right ventricular hypertension. If the ductus closes, profound cyanosis results. Lesions presenting primarily with cyanosis in the newborn period are discussed below.

TRANSPOSITION OF THE GREAT ARTERIES

Transposition of the great arteries (TGA) accounts for 5% of all cases of cyanotic congenital heart disease and is the most common cyanotic cardiac defect in the newborn. There is a strong male predominance (60% to 70%), but no other clear association between TGA and maternal conditions, teratogen exposure, or genetic abnormalities. TGA is typically an isolated defect, with <10% of cases associated with extracardiac malformations.

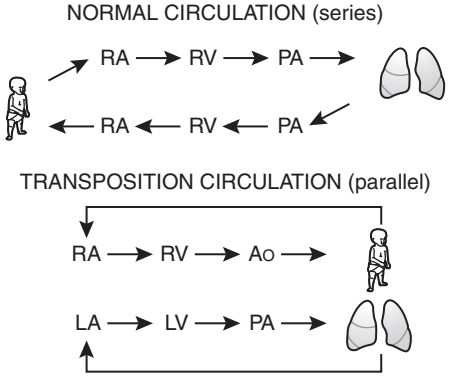

FIGURE 55-5 Series and parallel circulations. The series circulation in the normal newborn is compared with the parallel circulation in transposition of the great arteries (TGA). In TGA, survival after birth is dependent on mixing at either the atrial, ventricular, or great vessel level. *(From Wernovsky G: Transposition of the great arteries. In Allen HD, Gutgesell HP, Clark EB, et al, editors:* Moss and Adams' heart disease in infants, children, and adolescents: including the fetus and young adult, *ed 6, Philadelphia, 2001, Lippincott Williams & Wilkins, pp 1027-1084.)*

In the most common form of TGA (d-TGA, complete transposition, or simple transposition), the aorta arises from the right ventricle anteriorly and slightly rightward of the pulmonary artery, which arises from the left ventricle. Desaturated blood returns to the right ventricle and is recirculated to the body via the aorta, while oxygenated blood returns to the left ventricle and is recirculated to the lungs. The end result is separate, parallel circulations (Figure 55-5). Survival is dependent on communication between the two circulations, typically in the form of bidirectional shunting at the patent foramen ovale (PFO) and PDA. With absent or small communications between the circulations, severe systemic acidosis and hypoxia develop after birth, resulting in death.

Cyanosis is apparent within the first few hours of life and is not responsive to oxygen. Cardiac examination is typically normal with the exception of a loud single S2. Because of the arrangement of the great vessels, the louder closure of the anterior aortic valve obscures closure of the more posterior pulmonary valve. Chest radiograph may be normal or reveal a narrow mediastinum with slight predominance of the right ventricle resulting in an "egg on a string" appearance. Pulmonary vascular markings are normal to slightly increased. ECG is typically normal but may reveal right ventricular hypertrophy. Echocardiogram reveals the transposed great vessels and is used to determine the size of the PFO and PDA and to define any associated cardiac defects.

Initial management of infants with TGA is aimed at maintaining communication between the systemic and pulmonary circulations. Prostaglandin E_1 is started to maintain patency of the ductus arteriosus (dose of 0.05 to 0.1 μg/kg/min). In patients with a restrictive patent foramen ovale, or with persistent hypoxia and acidosis despite a PDA, a balloon atrial septostomy is performed within the first 24 to 48 hours of life to encourage mixing at the atrial level. In the setting of adequate mixing, pulmonary overcirculation may develop as pulmonary vascular resistance drops. Surgical treatment is the arterial switch procedure (Figure 55-6), typically performed within the 1st week of life (Castaneda et al, 1989; Prifti et al, 2002).

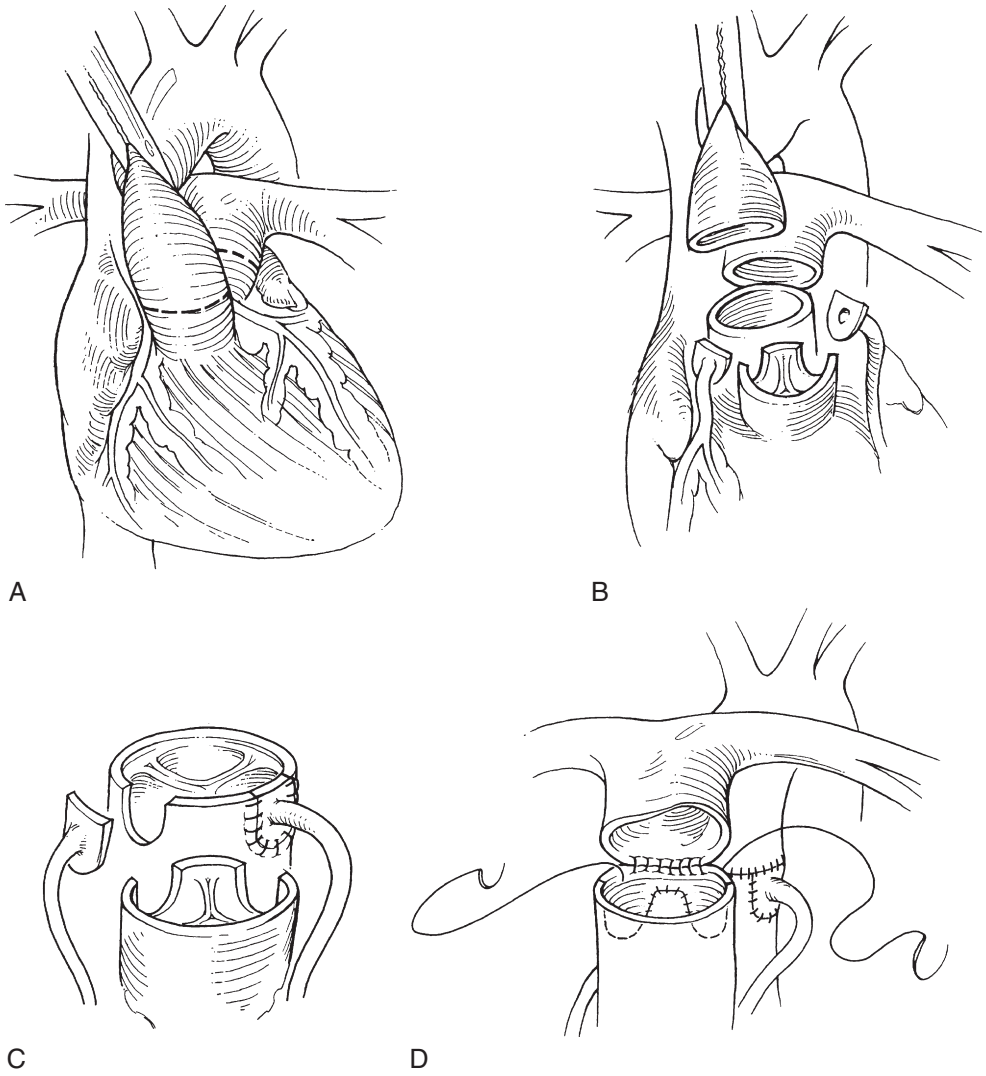

FIGURE 55-6 Arterial switch operation for d-transposition of the great arteries. A, The *dashed lines* depict the planned location of transection of the great vessels. **B,** The coronary arteries are removed with surrounding aortic wall as "buttons." **C,** The coronary buttons are translocated to the posterior neoaortic root. **D,** The Lecompte maneuver brings both pulmonary arteries anterior to the neoaorta. The aortic suture line is completed, incorporating the coronary buttons. The coronary donor sites are filled in with patches of autologous pericardium, and the pulmonary anastomosis is completed. *(From Wernovsky G, Jonas RA: Transposition of the great arteries. In Chang AC, Hanley FL, Wernovsky G, et al, editors:* Pediatric cardiac intensive care, *Baltimore, 1998, Williams & Wilkins, pp 289-301.)*

Although TGA is usually an isolated lesion, 40–45% of patients have an associated ventricular septal defect, 10% have a ventricular septal defect with left ventricular outflow tract obstruction, and 5% have left ventricular outflow tract obstruction alone. In addition, there is a wide variety in coronary artery anatomy in patients with TGA. The clinical presentation of patients with TGA and VSD depends on the size of the VSD. Those with a restrictive VSD present like patients with TGA and intact ventricular septum. Those with a large VSD may not experience any symptoms initially. As pulmonary vascular resistance drops, symptoms of pulmonary overcirculation develop. Patients with restricted pulmonary blood flow (TGA with VSD and pulmonic stenosis) appear clinically similar to patients with tetralogy of Fallot. The timing and type of surgical repair in patients with complex TGA is variable and beyond the scope of this chapter.

DOUBLE-OUTLET RIGHT VENTRICLE

Double-outlet right ventricle (DORV) is relatively rare and consists of a diverse group of lesions characterized by the origination of both great vessels from the right ventricle and by the persistence of the subaortic and subpulmonary conus. There are multiple anatomic variations of this lesion, which are commonly classified by the relationship of the great vessels to one another and/or by the location of the ventricular septal defect to the great vessels (Figure 55-7) (Anderson et al, 1983; Mahle et al, 2008; Stellin et al, 1991). Accordingly, there are four types of DORV, each with a slightly different neonatal presentation and surgical management.

DORV of the tetralogy type typically has normally related great vessels with a subaortic VSD. Because the subaortic conus is pulled anteriorly, the subpulmonary conus is typically smaller, resulting in variable obstruction

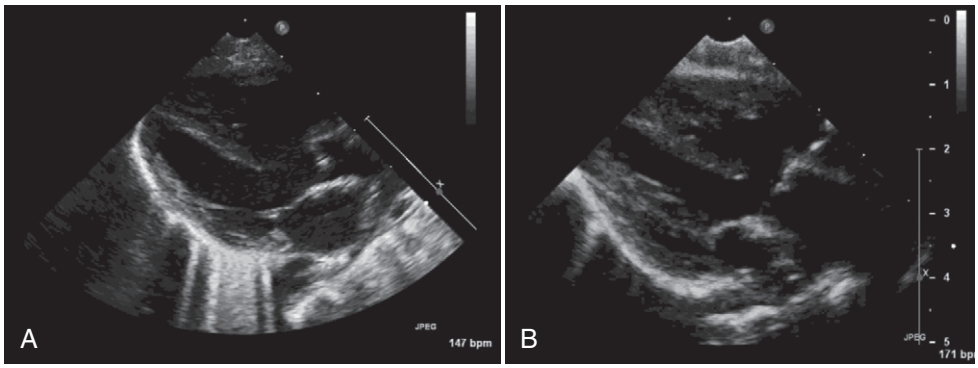

FIGURE 55-7 Echocardiographic views of double outlet right ventricle. A, The aorta is committed to the right ventricle and the ventricular septal defect is below the aortic valve. **B,** The great vessels are transposed in this patient with the pulmonary artery overriding the ventricular septal defect.

to pulmonary blood flow. The clinical presentation and surgical management are similar to those of tetralogy of Fallot.

DORV of the transposition type typically has malposed great vessels with the aorta located either anterior to or rightward of the pulmonary artery. The ventricular septal defect is subpulmonary and directs flow into the pulmonary artery, resulting in transposition-like physiology. This lesion is frequently associated with variable obstruction to aortic blood flow and coarctation of the aorta. Surgical repair consists of baffling the VSD to the pulmonary valve and performing an arterial switch. In the setting of coronary artery anomalies that prevent an arterial switch, the left ventricle is baffled to both the aortic and pulmonary valves and a right ventricle to pulmonary artery conduit is placed. Arch obstruction is corrected if needed.

In DORV with a "doubly committed" VSD, the VSD is below both great vessels. The physiology and clinical presentation are variable, depending on the size and orientation of the VSD and the degree of outflow tract obstruction. Surgical repair is directed at closing the interventricular communication without obstructing either ventricular outflow.

The least common variety of DORV is that in which the VSD is remote from both great vessels. Because of the distance between the VSD and the great vessels, a two-ventricle repair is difficult and often impossible. Pulmonary banding is frequently performed in the newborn period to limit pulmonary blood flow, delaying attempts at a biventricular repair or single ventricle palliation until several months of age. Recently, there has been increasing interest in biventricular repair for this lesion through creation of intracardiac baffles (Lacour-Gayet, 2002).

TRUNCUS ARTERIOSUS

In truncus arteriosus, a single arterial trunk gives rise to the pulmonary, systemic, and coronary circulation. The arterial trunk typically overrides a ventricular septal defect. Truncus is classified by the origin of the pulmonary arteries (Figure 55-8). In type I, a small pulmonary artery arises from the arterial trunk and bifurcates in the right and left branch pulmonary arteries. The right and left pulmonary arteries can also arise from separate ostia that are either close to one another (type II) or some distance apart (type III) (Collett, 1949). Type IV is similar to tetralogy of Fallot with pulmonary atresia (see later discussion). The truncal valve has between one and six cusps. It is occasionally

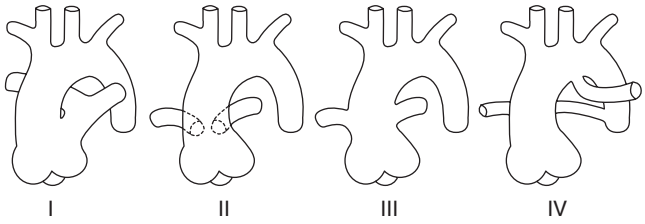

FIGURE 55-8 Types of truncus arteriosus. The classification of truncus arteriosus is determined by the origin of the pulmonary arteries (see text for details).

insufficient, but rarely stenotic. Truncus usually occurs as an isolated cardiovascular defect, although it has been associated with microdeletion of chromosomal region 22q11 (McElhinney et al, 2003).

As the pulmonary vascular resistance drops over the first several weeks of life, increased shunting from the arterial trunk to the pulmonary arteries occurs, and pulmonary overcirculation develops. If left untreated, symptoms of heart failure develop. Long-term pulmonary vascular obstructive disease occurs.

The clinical presentation of truncus changes with the pulmonary vascular resistance. Initially, infants are minimally cyanotic and do not appear to be in distress. As pulmonary overcirculation occurs, symptoms of heart failure develop. Cardiac examination reveals a hyperdynamic precordium and a loud single S2. As pulmonary vascular resistance drops, the pulses become bounding and the pulse pressure widens because of runoff into the pulmonary arteries. A low-pitched diastolic inflow rumble may be heard at the apex. In addition, a systolic ejection murmur may be present, and a medium- to high-pitched diastolic murmur may be heard from truncal valve insufficiency. Chest radiograph typically reveals cardiomegaly with pulmonary vascular markings that increase over the first few weeks of life. ECG demonstrates right, left, or biventricular hypertrophy. Echocardiography is used to demonstrate the anatomy and evaluate for associated cardiac defects such as right aortic arch, coronary artery anomalies, interrupted aortic arch, and secundum atrial septal defects.

Initially, heart failure symptoms are managed with anticongestive medications. Surgical repair is typically performed within the first 2 months of life because of difficulty in controlling heart failure. The usual repair involves closure of the ventricular septal defect so that the arterial trunk arises from the left ventricle. A right ventricle–to–pulmonary artery conduit is then placed

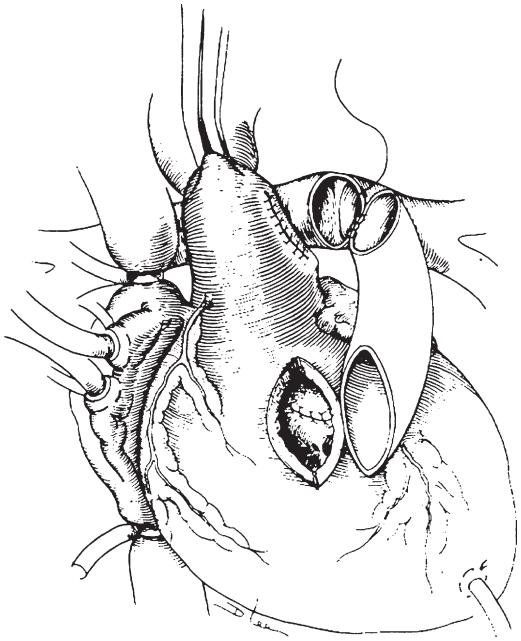

FIGURE 55-9 Anatomy and repair of truncus arteriosus. After the branch pulmonary arteries are removed from the common trunk (and the resulting aortic defect is closed), a ventriculotomy is performed. The ventricular septal defect is closed through this incision, and a conduit is placed from the right ventricle to the pulmonary arteries. *(From Behrendt DM, Dick M: Truncus repair with a valveless conduit in neonates,* J Thorac Cardiovasc Surg *110:1148-1150, 1995.)*

(Figure 55-9). This conduit needs to be replaced several times over the course of the patient's life.

TOTAL ANOMALOUS PULMONARY VENOUS RETURN

In total anomalous pulmonary venous return (TAPVR) the pulmonary veins return to a systemic vein or directly to the right atrium, rather than the left atrium. Both systemic and pulmonary venous return pass through the right atrium, right ventricle, and pulmonary artery, creating pulmonary overcirculation and right heart volume overload. An atrial septal defect is present in all cases. The right atrium–to–left-atrium shunt supplies the systemic cardiac output. If the atrial septal defect is restrictive, then systemic output will be limited.

Several common patterns of anomalous pulmonary venous return are seen (Figure 55-10) (Edwards and Helmholz, 1956). Most commonly, the anomalous veins drain in a supracardiac fashion, entering the left innominate vein or superior vena cava via a vertical vein, and draining into the right atrium via the superior vena cava. Cardiac drainage occurs when the anomalous veins drain into the right atrium via the coronary sinus. Alternatively, a descending vein may pass through the diaphragmatic hiatus and enter the hepatic or portal venous system, resulting in infracardiac drainage. Rarely, a mixed pattern of drainage may exist, or the anomalous veins may drain directly to the right atrium. Drainage directly into the right atrium occurs almost exclusively in patients with heterotaxy.

The clinical presentation of TAPVR varies, depending on the degree of obstruction to pulmonary venous flow.

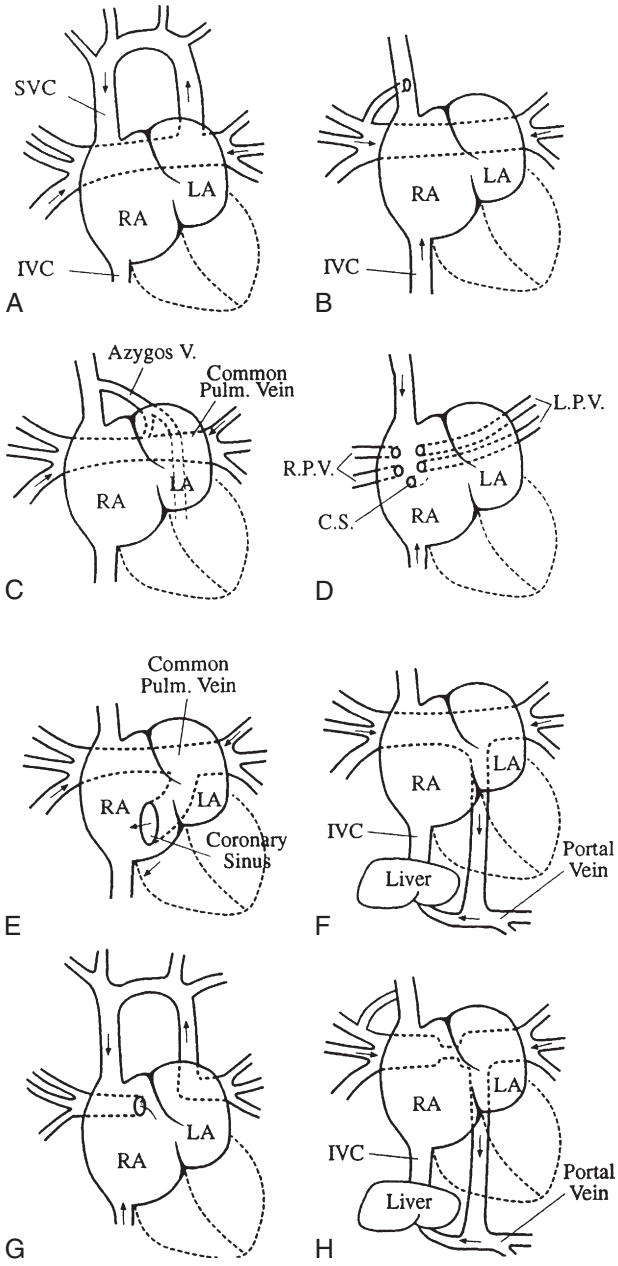

FIGURE 55-10 Anatomic varieties of total anomalous pulmonary venous return: **A** to **C,** Supracardiac; **D** and **E,** cardiac; **F,** infracardiac; **G** and **H,** mixed. See text for details. *CS*, Coronary sinus; *IVC*, inferior vena cava; *LA*, left atrium; *LPV*, left pulmonary vein; *RA*, right atrium; *RPV*, right pulmonary vein; *SVC*, superior vena cava. *(From Eimbcke F, Enriquez G, Gomez O, et al: Total anomalous pulmonary venous connection. In Moller JH, Hoffman JIE, editors:* Pediatric cardiovascular medicine, *Philadelphia, 2000, Churchill Livingstone, pp 409-420.)*

Patients with unobstructed pulmonary venous flow will have minimal symptoms in the newborn period, and cyanosis is usually not apparent. Symptoms of right heart failure develop over time owing to the progressive right heart volume overload. Physical examination may reveal a right ventricular heave, fixed split S2, and a soft systolic ejection murmur in the pulmonic area. Chest radiograph may demonstrate cardiomegaly due to an enlarged right atrium, right ventricle, and main pulmonary artery. Pulmonary vascular markings increase over time. ECG reveals

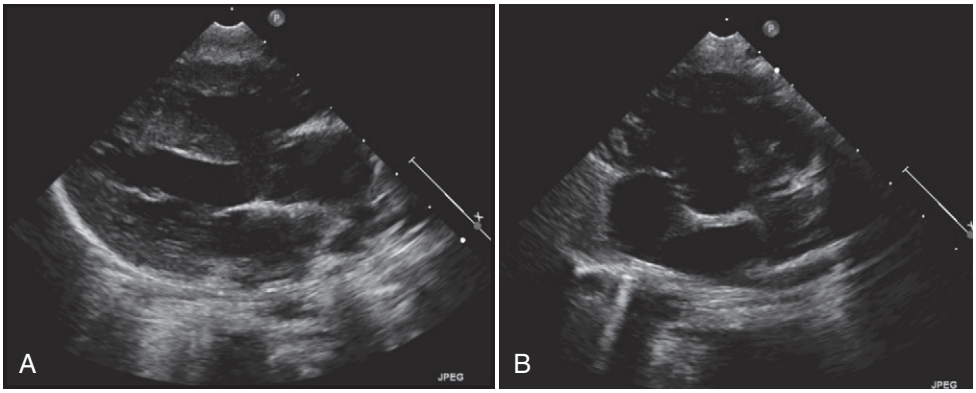

FIGURE 55-11 Echocardiographic view of tetralogy of Fallot. A, Some of the anatomic features of tetralogy of Fallot are readily demonstrated on the long-axis echocardiographic view including the hypertrophy of the right ventricle, the ventricular septal defect (VSD), and the aorta overriding the VSD. **B,** The short-axis view on echo shows the infundibular or right ventricular outflow tract stenosis.

peaked p waves and right ventricular hypertrophy. Patients with moderate restriction to pulmonary blood flow are typically cyanotic in the newborn period. There is usually adequate mixing of venous return to allow for oxygen delivery to tissues. These patients may, however, benefit from supplemental oxygen, mechanical ventilation, and sedation to decrease oxygen consumption. The presentation of patients with obstructed pulmonary blood flow is discussed later in this chapter under obstructive lesions.

Treatment of TAPVR is surgical. In most cases, a pulmonary venous confluence is seen near the left atrium. Cardiac catheterization is used to define pulmonary venous anatomy if the pulmonary veins are not well seen by echocardiography. During surgery, the pulmonary venous confluence is anastomosed to the left atrium, the atrial septal defect is closed, and the connections to systemic veins are ligated. In the absence of pulmonary venous obstruction and in the setting of uncomplicated anatomy, surgical mortality is low and long-term results are good. Late pulmonary venous obstruction occurs in approximately 20% of cases, with relatively poor surgical and interventional cardiac catheterization results.

TETRALOGY OF FALLOT

Tetralogy of Fallot (TOF) consists of a ventricular septal defect, overriding aorta, RVOT obstruction, and right ventricular hypertrophy (Figure 55-11). The severity and location of the RVOT obstruction are variable. Infundibular hypertrophy, a small, frequently bicuspid pulmonary valve, and small main pulmonary artery can jointly or independently create obstruction at the subvalve, valve, or supravalve level, respectively. Complete obstruction of the right ventricular outflow tract (pulmonary atresia) with a ventricular septal defect is an extreme form of TOF. TOF is associated with a right aortic arch in 20% of cases and aberrant coronary arteries in 5–10% of cases, both of which can affect surgical planning. The etiology of TOF is heterogeneous. Maternal diabetes, phenylketonuria, and retinoic acid exposure have been associated with TOF. In addition, genetic syndromes including 22q11 deletion, Alagille syndrome, and VACTERL/VATER sequence have been associated with TOF.

The pathophysiology and clinical presentation of TOF are directly tied to the severity of the RVOT obstruction. With mild RVOT obstruction, the predominant shunt through the VSD is left to right. Cyanosis is minimal, and symptoms of heart failure are the typical presenting manifestations. The main and branch pulmonary arteries are usually of normal size. With moderate RVOT obstruction, the shunt through the VSD is right to left but the prograde flow through the RVOT is adequate, resulting in mild cyanosis. The main and branch pulmonary arteries may have areas of focal stenosis or be diffusely small. With severe RVOT obstruction, there is minimal or no prograde flow across the RVOT. Pulmonary blood flow is thus dependent on left-to-right shunt through the PDA. Patients are severely cyanotic. PDA closure leads to cardiovascular collapse. The main and branch pulmonary arteries may be confluent and small. With pulmonary atresia (pulmonary atresia VSD or tetralogy pulmonary atresia), the pulmonary vascular bed is variable. The pulmonary arteries can be confluent, normal-sized, and fed entirely by the ductus arteriosus; confluent, small, with a small ductus; or virtually absent with pulmonary blood flow supplied by multiple aortopulmonary collateral vessels (MAPCAs).

Initial management depends on the amount of pulmonary blood flow. Patients without significant symptoms or hypoxemia undergo a complete repair in the first 6 months of life. Complete repair consists of VSD closure and relief of RVOT obstruction through a combination of infundibular muscle resection, pulmonary valvotomy, or RVOT patch that can extend out to the branch pulmonary arteries as needed (Figure 55-12). In patients with significant cyanosis or ductal dependent circulation, management options include palliation with a systemic–to–pulmonary artery shunt in the newborn period (modified Blalock-Taussig shunt) and complete repair at a later date or a complete anatomic correction in the newborn period. The recent trend has been toward earlier complete correction in symptomatic infants (Ooi et al, 2006; Reddy et al, 1995; Tamesberger et al, 2008).

TETRALOGY OF FALLOT WITH ABSENT PULMONARY VALVE

ToF with absent pulmonary valve (APV), or APV syndrome, is a spectrum of disorders with a rudimentary pulmonary valve. The resultant pulmonary valve stenosis and insufficiency cause dilation of the right ventricle and main and branch pulmonary arteries that is apparent in utero (Figure 55-13). The vast majority of cases also have a malalignment ventricular septal defect. Presumably secondary to airway compression by the dilated pulmonary

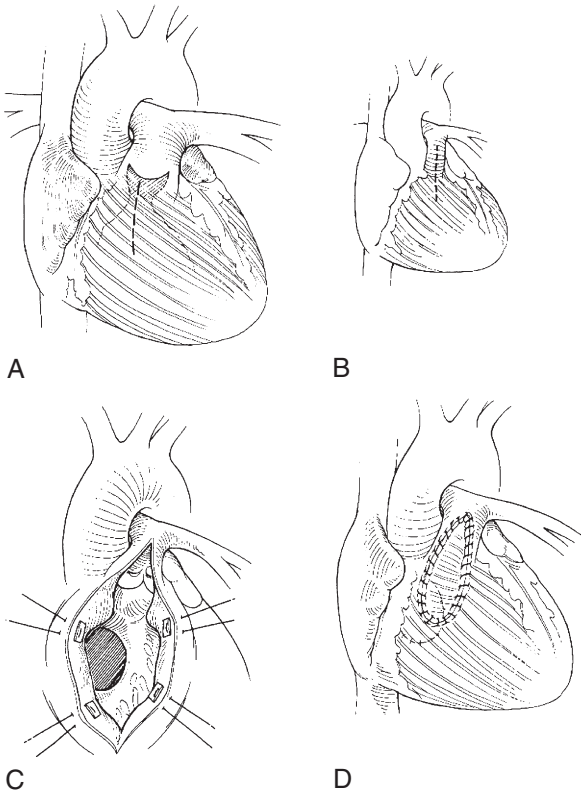

FIGURE 55-12 Repair of tetralogy of Fallot. A, *Dashed line* depicts nontransannular incision, used when the pulmonary valve and annulus are of adequate size. **B,** A transannular incision *(dashed line)* is used when there is annular hypoplasia. **C,** An example of transventricular exposure of the ventricular septal defect (VSD). Alternatively, the VSD may be closed via a right atriotomy through the tricuspid valve. **D,** External view of patch closure of the transannular incision. *(From Spray TL, Wernovsky G: Right ventricular outflow tract obstruction. In Chang AC, Hanley FL, Wernovsky G, et al, editors:* Pediatric cardiac intensive care, *Baltimore, 1998, Williams & Wilkins, pp 257-270.)*

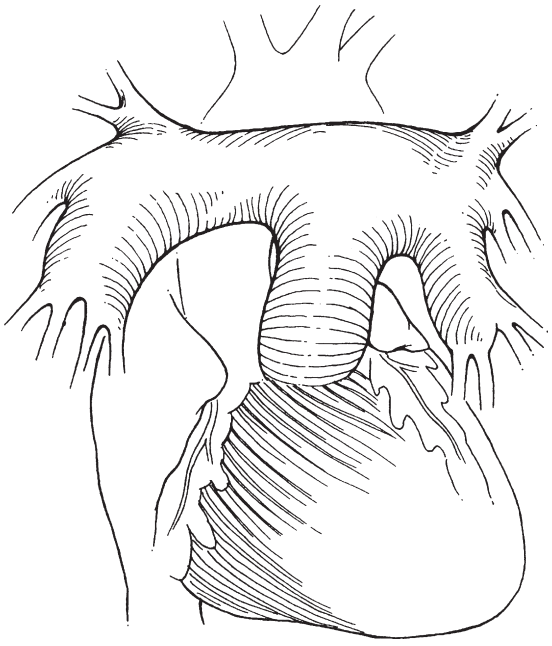

FIGURE 55-13 Tetralogy of Fallot with absent pulmonary valve. Severe dilatation of the main and branch pulmonary arteries is seen and is frequently with associated bronchial compression and large and small airway disease. The intracardiac anatomy is usually similar to that in standard tetralogy of Fallot. *(From Spray TL, Wernovsky G: Right ventricular outflow tract obstruction. In Chang AC, Hanley FL, Wernovsky G, et al, editors:* Pediatric cardiac intensive care, *Baltimore, 1998, Williams & Wilkins, pp 257-270.)*

vasculature, this syndrome is commonly associated with airway anomalies. There is a high prevalence of 22q11 deletion among patients with APV.

Physical examination reveals a characteristic to-and-fro murmur of pulmonary stenosis and insufficiency. A prominent right ventricular heave and hepatomegaly are present secondary to the right ventricular volume overload. There is a wide range of symptoms, depending on the degree of right ventricular volume overload and degree of airway disease. At one end of the spectrum is an asymptomatic neonate with mild cyanosis and the gradual development of heart failure symptoms during the normal postnatal decline in pulmonary vascular resistance. At the other end of the spectrum is a critically ill infant with severe cyanosis and respiratory failure due to the combination of right-to-left shunt through the VSD and underlying airway disease. Mechanical ventilation is necessary and occasionally unsuccessful because of airway compression by the dilated pulmonary vasculature. Urgent surgery is required in these infants.

Surgery consists of VSD closure, pulmonary artery plication, relief of RVOT obstruction, and insertion of a valve or homograft in the RVOT position. There is significant variation in surgical technique between centers (Alsoufi et al, 2007; Tissot et al, 2007). The surgical mortality and short- and long-term outcomes are related primarily to the severity of pulmonary artery dilation and airway compression. More severely affected infants have a higher surgical mortality and need for prolonged postoperative ventilation. Those with less significant pulmonary artery dilation have low postoperative mortality and long-term outcomes similar to those with TOF.

PULMONARY ATRESIA WITH INTACT VENTRICULAR SEPTUM

In pulmonary atresia with intact ventricular septum, the pulmonary valve leaflets are fused or fail to form. Without egress from the right ventricle, systemic venous return passes through the patent foramen ovale and mixes with pulmonary venous return. Pulmonary blood flow is dependent on the PDA, with the left ventricle providing cardiac output to both the systemic and pulmonary circulations. Tricuspid valve and right ventricular size vary, ranging from nearly normal-sized structures to a nearly atretic tricuspid valve and diminutive right ventricular chamber. The latter patients may have sinusoidal channels in the right ventricular myocardium that communicate with the coronary circulation. The high right ventricular pressure results in retrograde perfusion of the coronary arteries, resulting in right ventricle-dependent coronary circulation (Figure 55-14).

Pulmonary atresia with intact ventricular septum presents with cyanosis. Cardiac examination reveals a single loud second heart sound. A murmur is typically not present, other than from the PDA. ECG typically reveals a relative lack of right-sided forces with a QRS axis between 0 and 90 degrees. The p wave is peaked from right atrial

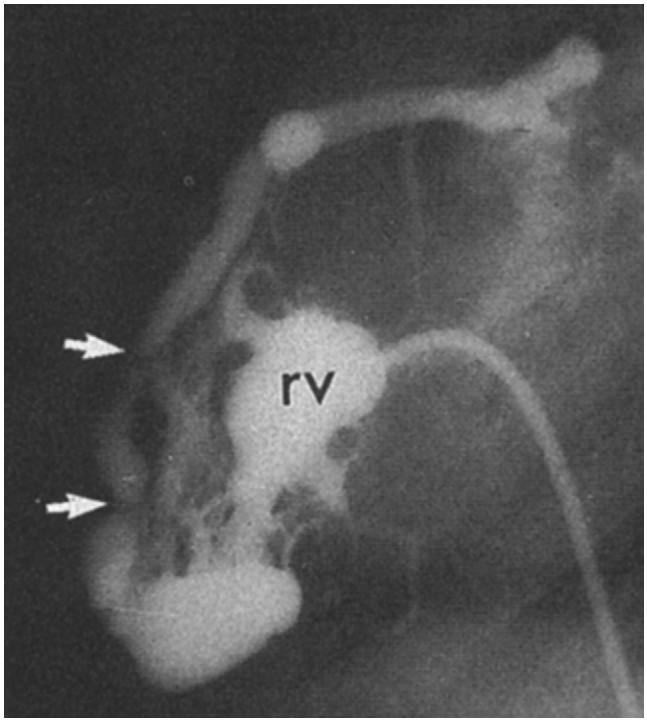

FIGURE 55-14 Lateral angiogram from a newborn with pulmonary atresia and intact ventricular septum. After injection of contrast through the hypertrophied and diminutive right ventricle *(rv)*, there is retrograde filling of tortuous coronary arteries through sinusoidal connections to the right ventricle *(arrows)*.

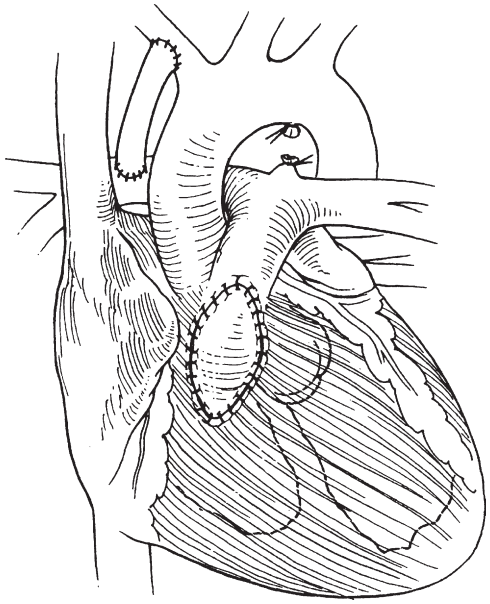

FIGURE 55-15 Newborn surgical palliation for pulmonary atresia with intact ventricular septum and normal coronary arteries. A right ventricular outflow tract patch is placed, the ductus is ligated and divided, and a modified Blalock-Taussig shunt is placed. *(From Wernovsky G, Hanley FL: Pulmonary atresia with intact ventricular septum. In Chang AC, Hanley FL, Wernovsky G, et al, editors:* Pediatric cardiac intensive care, *Baltimore, 1998, Williams & Wilkins, pp 265-270.)*

enlargement. Pulmonary vascular markings on chest radiograph are typically decreased. Echocardiography confirms the diagnosis and can be used to look for coronary sinusoids. Cardiac catheterization is performed in patients where coronary sinusoids are known or suspected to completely define the extent and connections of the sinusoids.

Initially, prostaglandin E_1 (PGE_1) is used to maintain ductal patency until a more permanent source of pulmonary blood flow is provided. In patients with right ventricle-dependent coronary circulation, the outcome of surgical repair is often poor. A systemic-to-pulmonary shunt followed by staged single-ventricle palliation may be tried, but proceeding directly to heart transplantation may be appropriate. In patients without right ventricular coronary-dependent circulation, an egress from the right ventricle to pulmonary arteries is created by surgical valvotomy or RVOT augmentation, or valve perforation and valvuloplasty are performed in the catheterization lab (Figure 55-15) (Justo et al, 1997). At times, additional pulmonary blood flow is provided by a modified Blalock-Taussig or other systemic-to-pulmonary shunt. The postoperative course can be complicated by low cardiac output or a circular shunt.

TRICUSPID ATRESIA

In tricuspid atresia, there is no outlet from the right atrium to the right ventricle. Systemic venous return passes from the right atrium, through a PFO or ASD, to the left ventricle. More than 90% of patients with tricuspid atresia have an associated VSD, allowing blood to pass from the left ventricle to the pulmonary arteries (Figure 55-16). The size of the ventricular septal defect determines the amount of pulmonary blood flow. Patients with a small or absent VSD have a very hypoplastic right ventricle and pulmonary artery. The major portion of pulmonary blood flow passes through the PDA. If a large VSD is present, pulmonary blood flow is prograde through the pulmonary valve, and the ductus is not necessary. A variant of tricuspid atresia is associated with transposition of the great vessels. Pulmonary blood flow is derived from the left ventricle, and systemic blood flow must pass through the VSD. There may be an associated coarctation or hypoplastic aortic arch in these patients.

Clinically, cyanosis is present at birth, the degree of which is dependent on the degree of restriction to pulmonary blood flow. A holosystolic murmur consistent with a VSD and a prominent left ventricular impulse are present on examination. Electrocardiography is nearly diagnostic and reveals left axis deviation and left ventricular hypertrophy. Chest radiography reveals variable pulmonary vascular markings, depending on the size of the VSD and relationship of the great vessels. Echocardiography demonstrates a fibromuscular plate in place of the tricuspid valve and a variably small right ventricle and pulmonary valve. The relationship of the great vessels can also be determined by echo. The degree of obstruction at the VSD or across the RVOT can be evaluated.

PGE_1 is used initially to maintain a PDA. If there is restriction to flow at the atrial level, a balloon septostomy is performed. Further management depends on the amount of pulmonary blood flow and the relationship of the great vessels. Patients with ductal dependent pulmonary blood flow have a systemic-to-pulmonary-artery shunt placed (modified Blalock-Taussig shunt).

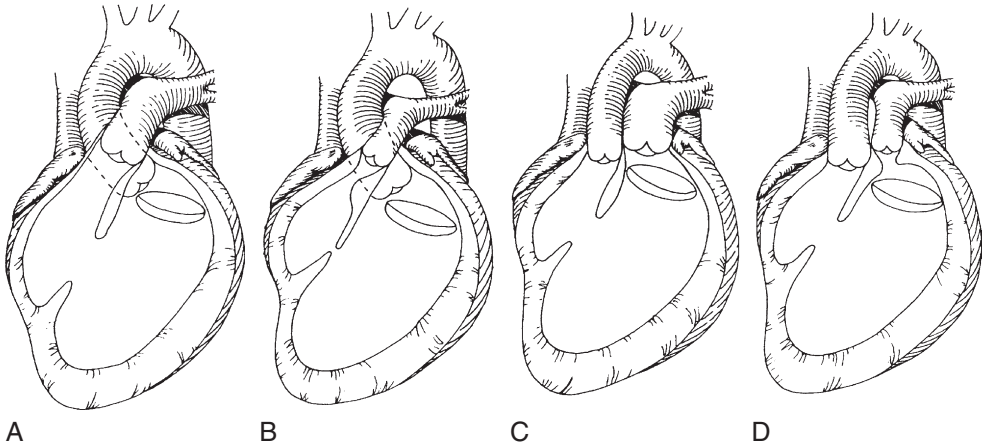

FIGURE 55-16 Anatomic variants in tricuspid atresia. A, Normally related great vessels with a large ventricular septal defect (VSD) and normal-sized pulmonary arteries (PAs). **B,** Normally related great vessels with a small VSD and PAs. **C,** Transposed great arteries (left ventricle aligned with the PA, right ventricle with the aorta) with a relatively small VSD and aorta. Many patients with this variant have coarctation as well (see text). **D,** Transposed great vessels with a VSD, subpulmonary obstruction, and small PAs. *(From Fyler DC: Tricuspid atresia. In Fyler DC, editor:* Nadas' pediatric cardiology, *Philadelphia, 1992b, Hanley & Belfus, pp 659-667.)*

Those with adequate pulmonary blood flow undergo a superior vena cava–to–pulmonary artery anastomosis (bidirectional Glenn) at approximately 6 months of age, with completion of the Fontan procedure around 3 years of age. Patients with transposition, or more complex anatomy, undergo more extensive palliative procedures initially, but continue down the pathway to Fontan palliation.

EBSTEIN'S ANOMALY OF THE TRICUSPID VALVE

Ebstein's anomaly is a rare form of congenital heart disease with variable presentation. Dysplasia of the tricuspid valve, with downward displacement of the septal and posterior leaflets, is the defining feature (Figure 55-17). The anterior leaflet, although normally positioned in the valve annulus, frequently has abnormal chordal attachments and is large and redundant. The tricuspid valve abnormality can be accompanied by tricuspid regurgitation, right atrial dilation, abnormal right ventricular myocardium, and an increased risk for Wolf-Parkinson-White syndrome. In addition, functional and true pulmonary atresia can occur with severe Ebstein's malformation. With displacement of the tricuspid valve, a significant portion of the right ventricle becomes atrialized, making it an ineffective pumping chamber. In this setting, it can be difficult to differentiate functional pulmonary atresia from true pulmonary atresia. Severe Ebstein's anomaly of the tricuspid valve is associated with heart failure in utero (Tongsong et al, 2005).

The clinical presentation is variable and depends on the degree of displacement of the tricuspid valve and severity of RVOT obstruction. In many patients, symptoms are mild and do not manifest until later in life. In more severe disease, cyanosis results when a right-to-left shunt occurs at the atrial level, secondary to the tricuspid regurgitation and elevated right atrial pressures. Cardiac examination reveals a holosystolic murmur at the lower left sternal border with associated gallop and clicks. Neonates with severe Ebstein's anomaly present with marked cyanosis, cardiomegaly, and ductus dependent pulmonary blood flow. Chest radiograph appearance is characteristic in severe cases, with massive cardiomegaly evident at birth (Figure 55-18). Death can occur from the significant heart failure and hypoxemia. Clinical improvement may occur as the pulmonary vascular resistance drops, improving the right ventricle's ability to contribute to pulmonary blood flow.

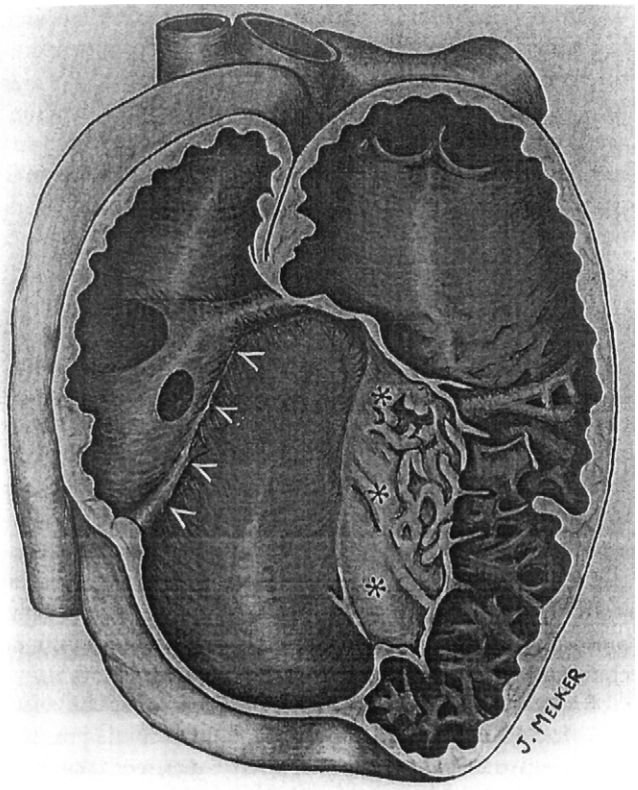

FIGURE 55-17 Inferior displacement of tricuspid valve leaflet (*) into the right ventricular cavity. The *white arrowheads* indicate the normally positioned tricuspid valve annulus. The area between the true annulus and the displaced valve leaflet is considered "atrialized." *(From Epstein ML: Congenital stenosis and insufficiency of the tricuspid valve. In Allen HD, Gutgesell HP, Clark EB, Driscoll DJ, editors:* Moss and Adams' heart disease in infants, children, and adolescents: including the fetus and young adult, *ed 6, Philadelphia, 2001, Lippincott Williams & Wilkins, pp 810-819.)*

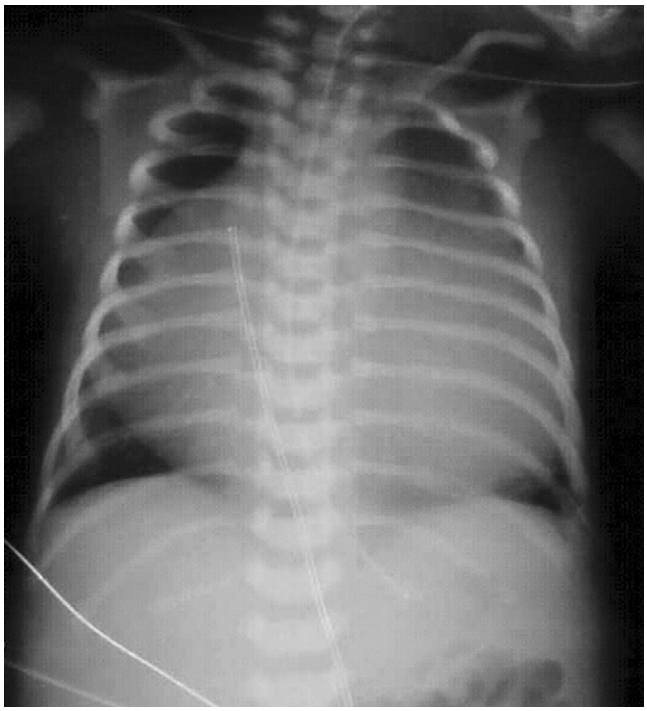

FIGURE 55-18 Chest radiograph in a 1-day-old newborn with Ebstein's anomaly of the tricuspid valve. Note the massive cardiomegaly and relative pulmonary oligemia and hypoplasia.

Initially, management of the severely cyanotic infant is aimed at promoting pulmonary blood flow. PGE_1 is used to maintain ductal patency. Supplemental oxygen, inhaled nitric oxide, and mild respiratory alkalosis can have marginal success in improving pulmonary blood flow by lowering pulmonary vascular resistance. After several days, attempts are made at weaning from the PGE_1. If this is unsuccessful, surgical options are considered. Options include tricuspid valve repair or replacement, 1½ ventricle repair, or other palliative procedures such as right ventricular exclusion with a fenestrated patch and placement of a modified Blalock-Taussig shunt (Reemtsen et al, 2007). Although surgical outcomes have improved, a neonatal repair for symptomatic disease remains a risk factor for death (McElhinney et al, 2005; Sarris et al, 2006).

LESIONS THAT MANIFEST PRIMARILY WITH HEART FAILURE

HYPOPLASTIC LEFT HEART SYNDROME

Hypoplastic left heart syndrome (HLHS) is an anatomically heterogeneous lesion characterized by a variable degree of underdevelopment of the left ventricle, hypoplasia or atresia of the aortic and mitral valves, and hypoplasia of the aortic arch. Although HLHS accounts for only 1.4% to 3.8% of all congenital heart defects, it accounts for 23% of cardiac deaths in the 1st week of life and 15% of cardiac deaths in the 1st month of life (Samanek, 2000). HLHS likely is multifactorial in etiology. There is a slight male predominance. Although there is no clear genetic etiology, familial clustering of various left heart obstructive lesions has been noted.

It is theorized that the growth of developing vascular structures is dependent on flow. HLHS probably results from in utero obstruction of left ventricular inflow or outflow. The fetal left ventricle is predominantly filled with blood that passes through the foramen ovale. Restriction to flow or reversal of flow through the foramen ovale could then result in decreased flow to the left heart and its underdevelopment. Similarly, several studies have documented the progression of severe aortic stenosis to hypoplastic left heart syndrome in utero (Danford and Cronican, 1992; Hornberger et al, 1995). The progressive left ventricular hypertrophy, dilation, and fibrosis associated with severe aortic stenosis can lead to decreased ventricular compliance, elevated left atrial pressures, and reversal of flow through the foramen ovale in utero. Prenatal cardiac intervention is still in its infancy, but recent successes with in utero balloon dilation of the aortic valve suggest that the progression to HLHS can be altered (Makikallio et al, 2006).

Because of the underdevelopment of the left heart structures, pulmonary venous return must exit the left atrium through the foramen ovale. Pulmonary venous blood then mixes with systemic venous return in the right atrium and enters the right ventricle. Right ventricular output then passes either to the pulmonary circulation or through the ductus arteriosus to the systemic circulation. That is, the pulmonary and systemic circulations are in parallel. The ratio of systemic to pulmonary blood flow is determined by the relative resistances of the vascular beds. As the normal postnatal drop in pulmonary vascular resistance occurs, pulmonary flow increases at the expense of systemic flow. Thus, the management of HLHS is dependent on an adequate egress from the left atrium and balancing the resistances of the pulmonary and systemic vascular beds.

Most cases of HLHS are now diagnosed prenatally when an abnormal four-chamber view is noted on a screening obstetric ultrasound examination. Ideally, delivery is planned and occurs at a tertiary care center. Postnatally, prostaglandins are immediately started to maintain ductal patency and an echocardiogram is obtained to confirm the diagnosis. The cardiothoracic surgeon and the interventional cardiologist should be made aware and available at the time of delivery.

In the absence of prenatal diagnosis, postnatal presentation is somewhat variable and dependent on ductal patency and the degree of restriction to flow at the atrial septum. The infant with an unrestrictive atrial septum and PDA is largely asymptomatic at birth and may be missed in the newborn period. Cyanosis is minimal and pulmonary overcirculation is mild whereas pulmonary vascular resistance is high. Cardiac exam is relatively unremarkable. The second heart sound is single and loud. A third heart sound becomes apparent as heart failure develops. As pulmonary vascular resistance drops and ductal closure occurs, feeding difficulties and respiratory distress become apparent with rapid progression to cardiovascular collapse. Physical exam after ductal restriction is significant for lethargy, pallor, and diminished or absent pulses. Chest radiograph typically reveals relatively normal-sized heart and pulmonary edema. ECG is nonspecific but may reveal relative lack of left-sided forces.

The patient with a restrictive atrial septum presents with tachypnea and profound cyanosis shortly after birth. The elevated left atrial and pulmonary venous pressures result in pulmonary venous congestion that is apparent on chest radiograph.

The preoperative management of patients with HLHS is directed at balancing the ratio of pulmonary-to-systemic blood flow (Qp:Qs) to allow for sufficient oxygenation of blood while maintaining adequate systemic cardiac output. Prostaglandins should be started immediately postnatally to ensure ductal patency. Echocardiography is utilized to confirm cardiac anatomy and determine the degree of restriction to flow through the foramen ovale. If the atrial-level shunt is restrictive with profound cyanosis and metabolic acidosis, a balloon atrial septostomy, surgical septectomy, or emergent stage I palliation should be performed (see later discussion). If the restriction was present in utero, pathologic fibrosis and arterialization of the pulmonary veins and medial hypertrophy of the pulmonary arterioles occurs. Even after atrial septostomy, lung disease can persist and pulmonary vascular resistance can remain high. Oxygen may be needed to maintain saturations in an appropriate range. This subset of patients has a high mortality rate.

A small group of patients will have adequately balanced pulmonary and systemic blood flow at the time of presentation. A small degree of restriction to flow through the foramen ovale may be associated with slight cyanosis but has the beneficial effect of restricting pulmonary blood flow. In the absence of acidosis or end organ dysfunction, this state is generally tolerated until stage I palliation is performed.

An unrestrictive atrial septal defect allows increased pulmonary blood flow as the pulmonary vascular resistance falls. Because of the parallel arrangement of the circulations, increasing pulmonary flow decreases systemic flow. In this setting, there is increasing oxygen saturation associated with inadequate oxygen delivery to the tissues. Worsening metabolic acidosis and end-organ dysfunction ensue. The ratio of pulmonary to systemic blood flow is balanced by manipulating the resistances of the pulmonary and systemic vascular beds. The success of these therapies is monitored using oxygen saturation, mixed venous saturation, lactate, and arterial blood gases.

Pulmonary vascular resistance can be manipulated through mechanical ventilation and alteration in the amount of oxygen delivered. Mechanical ventilation with high positive end-expiratory pressure (PEEP) can limit pulmonary blood flow. Pulmonary vascular resistance can also be increased by adding CO_2 ($FiCO_2$ 0.03) or nitrogen (FiO_2 0.17) to the ventilator circuit (Riordan et al, 1996; Shime et al, 2000). Both CO_2 and nitrogen have been shown to decrease the Qp:Qs and decrease oxygen saturations. Only hypercarbia has been shown to improve systemic oxygen delivery (Tabbutt et al, 2001). The goal of this therapy is to maintain normal lactate, systemic oxygen saturation at 75–85%, and mixed venous oxygen saturation approximately 25 percentage points lower than systemic saturations.

Vasoactive medications can be used to alter systemic vascular resistance and improve ventricular function. Use of these medications is determined by clinical presentation and echocardiographic findings. Milrinone can be used to provide some afterload reduction, if tolerated by blood pressure. The inotropic effects of milrinone are also an advantage if ventricular function is poor. In addition to decreasing pulmonary blood flow, afterload reduction has the added benefit of decreasing tricuspid valve regurgitation if it is present. Milrinone also dilates the pulmonary vascular bed, so care should be taken when it is used. Although counterintuitive, when faced with an unoperated patient with high oxygen saturations and low peripheral blood pressure, the gentle addition of milrinone may improve blood pressure simply by increasing systemic blood flow.

The immediate goal of surgical palliation is to provide stable unrestricted systemic and coronary blood flow and reliably restricted pulmonary blood flow. There are several strategies for stage I palliation. Traditionally, aortic arch reconstruction was performed using pulmonary artery tissue and pulmonary blood flow was supplied using a modified BT shunt (Norwood procedure) (Figure 55-19). A recent modification of a right ventricle-to-pulmonary artery conduit has been used to supply pulmonary blood flow — the Sano modification; Figure 55-20). The Sano modification has the presumed benefit of providing pulsatile flow to the pulmonary arteries without aortopulmonary diastolic run off and coronary steel. The downside of this procedure is the need for a ventriculotomy. A hybrid procedure that combines stent placement in the ductus arteriosus by the cardiologist and pulmonary artery banding by the surgeon is an approach being taken by a number of institutions that provides a relatively noninvasive stage I palliation for hypoplastic left heart syndrome (Caldarone et al, 2007). Each of these procedures has its pros and cons and its advocates and detractors (Caldarone et al, 2007; Ghanayem et al, 2006; Malec et al, 2003). Longer-term prospective studies are needed to determine the optimal approach to stage I palliation. In the low-risk patient, survival after the first stage nears 80–90%.

The remaining palliative surgeries occur outside the newborn period. Stage II palliation unloads the right ventricle and begins to separate the pulmonary and systemic circulations. The superior cavopulmonary anastomosis (bidirectional Glenn) is usually performed between 4 and 6 months of age. During this procedure, the conduit providing pulmonary flow is removed and the superior vena cava is anastomosed to the pulmonary artery.

Stage III palliation completely separates the pulmonary and systemic circulations. An inferior cavopulmonary anastomosis (Fontan completion) is performed by one of several techniques.

OBSTRUCTED TOTAL ANOMALOUS PULMONARY VENOUS RETURN

Obstructed total anomalous pulmonary venous return (TAPVR) represents one of the few remaining neonatal surgical emergencies in pediatric cardiology. Although obstruction can occur with any type of TAPVR, it is most common in infradiaphragmatic TAPVR. Physiologically, obstruction to pulmonary venous flow results in pulmonary venous hypertension that is transmitted to the pulmonary capillary bed, resulting in pulmonary edema.

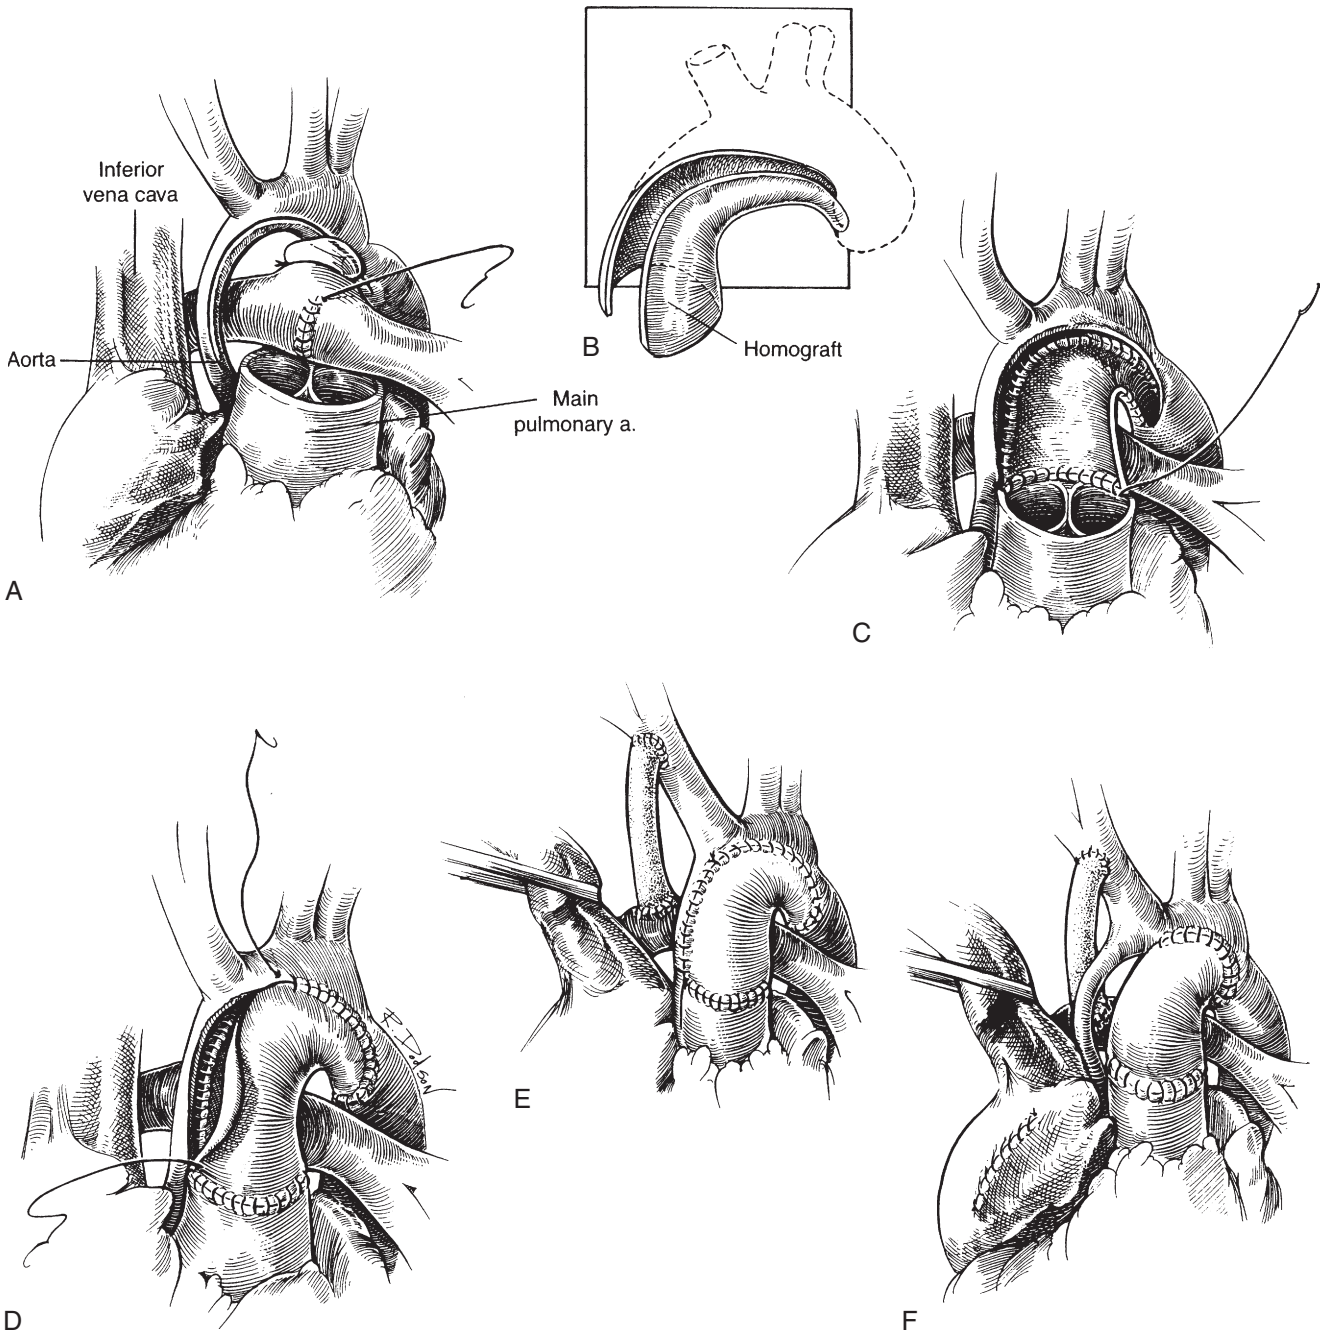

FIGURE 55-19 **Stage I palliation for hypoplastic left heart syndrome: classic Norwood procedure. A,** The main pulmonary artery is transected, and the distal end oversewn. The ductus arteriosus is ligated, and an incision is made from the proximal ascending aorta around the aortic arch to the level of the ductus. **B,** A pulmonary homograft is utilized to create a patch to reconstruct the neoaorta. **C** and **D,** This homograft patch is used to connect the proximal main pulmonary artery and pulmonary (neoaortic) valve to the ascending aorta and transverse arch. **E,** A modified Blalock-Taussig shunt is placed from the base of the innominate artery to the right pulmonary artery. **F,** An alternative technique utilizing a circumferential tube graft from the proximal main pulmonary artery to the distal transverse aortic arch. *Not shown*: Atrial septectomy is performed to provide unobstructed egress from the pulmonary veins to the right ventricle. *(From Castañeda AR, Jonas RA, Mayer JE Jr, et al:* Cardiac surgery of the neonate and infant, *Philadelphia, 1994, WB Saunders.)*

Pulmonary blood flow is severely limited. Newborns thus present with profound cyanosis and respiratory distress that is not responsive to medical management. Prostaglandins may help minimize the obstruction by maintaining patency of the ductus venosus, but patency of the ductus arteriosus does not improve the clinical picture, because the limitation to pulmonary blood flow is not due to insufficient antegrade flow, but rather obstructed outflow. Chest radiograph reveals a normal cardiac silhouette with pulmonary venous congestion that may be interpreted as interstitial pneumonia (Figure 55-21). Echocardiography can be challenging in these patients. The pulmonary veins can be small because of limited flow, making them difficult to detect by two-dimensional and color Doppler imaging. Surgical treatment is the same as for unobstructed TAPVR. The postoperative course is frequently marked

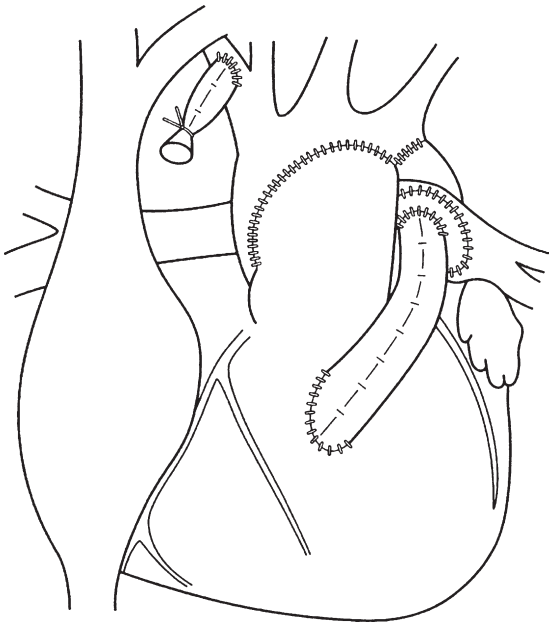

FIGURE 55-20 Right ventricle-pulmonary artery, or Sano, modification of stage I reconstruction. The arch reconstruction is similar to that shown in Figure 57-20. The Blalock-Taussig shunt is replaced with a Gore-Tex tube inserted from the right ventricle to the main pulmonary artery. *(From Sano S, Ishino K, Kawada K, et al: Right ventricle-pulmonary artery shunt in first-stage palliation of hypoplastic left heart syndrome*, J Thorac Cardiovasc Surg *126:504-510, 2003.)*

FIGURE 55-21 Chest radiograph in a 1-day-old infant with obstructed total anomalous pulmonary venous return.

by pulmonary vascular resistance lability, right ventricular hypertension, and low cardiac output syndrome.

COR TRIATRIATUM

Embryologically, the pulmonary veins enter a common pulmonary vein that initially has no connection to the left atrium (Neill, 1956). During normal development, the common pulmonary vein becomes incorporated into the left atrium, resulting in the usual pattern of two right and two left pulmonary veins entering the left atrium. Abnormal incorporation of the common pulmonary vein can result in cor triatriatum, a condition in which the common pulmonary vein joins the left atrium through a single opening. If the opening is small and restrictive, the clinical presentation is similar to that in obstructed TAPVR. If the opening is nonrestrictive, no symptoms are present. Surgical resection of the membrane that separates the left atrium and common pulmonary vein is an effective treatment. Significant preoperative pulmonary venous obstruction increases surgical mortality.

MITRAL STENOSIS

Congenital mitral stenosis is a rare form of congenital heart disease with several subtypes. The stenosis can occur in the supravalvular region, at the valve annulus, or within the mitral valve support apparatus. Typical congenital mitral stenosis is characterized by thickened leaflets, short or absent chordae tendineae, obliteration of interchordal spaces, and two separate papillary muscles. Supravalvar mitral ring occurs when there is connective tissue outgrowth on the atrial surface of the mitral valve leaflets, leading to a decreased mitral valve orifice. The mitral valve orifice can also be stenotic secondary to a parachute mitral valve, when most or all chordae tendineae insert onto only one papillary muscle. Another form of obstruction occurs with a double orifice mitral valve, where a tongue of tissue connects the anterior and posterior mitral valve leaflets. A mitral arcade or hammock occurs when the leaflets are connected directly or by short chordae to the papillary muscles. Congenital mitral stenosis frequently occurs in conjunction with other left-sided obstructive lesions.

Symptoms from mitral stenosis usually occur in the first 2 years of life and may consist of shortness of breath, respiratory distress or wheezing, cyanosis, and pallor. Cardiac exam reveals a rumbling apical diastolic murmur, loud first heart sound, and loud split second heart sound. Opening snap of the mitral valve may be heard. Chest radiograph reveals left atrial enlargement and pulmonary venous congestion. ECG reveals right ventricular hypertrophy with normal, bifid, or spiked P waves suggesting left atrial enlargement. Echocardiogram is used to define mitral valve anatomy and localize the area of obstruction. Doppler can be used to determine valve gradient and estimate right ventricular pressure.

Treatment options for congenital mitral valve stenosis include balloon mitral valvuloplasty, surgical mitral valvuloplasty, and mitral valve replacement. Despite recent improvements in outcomes, intervention and mitral valve replacement have relatively poor short-term outcomes (McElhinney et al, 2005). Patients with additional left-sided obstructive lesions or associated defects frequently require single-ventricle palliation.

CRITICAL AORTIC STENOSIS

Patients with critical aortic stenosis have severe left ventricular outflow tract obstruction that limits systemic cardiac output (Figure 55-22). The result is ductus dependent systemic perfusion. Although the obstruction can occur

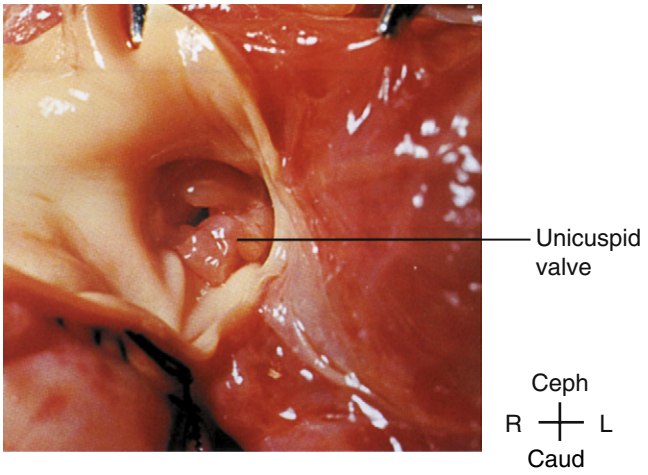

FIGURE 55-22 Congenital aortic stenosis. Frontal view through opened aorta demonstrates stenotic and dysmorphic aortic valve with commissural fusion. *(From Litwin SB:* Color atlas of congenital heart surgery, *St. Louis, 1996, Mosby.)*

below the valve, at the valve, above the valve, or a combination of these, this section focuses on outflow tract obstruction resulting from morphologic problems of the aortic valve. Severe aortic valve stenosis is defined as a Doppler-derived pressure gradient greater than 60 mm Hg. Moderate stenosis is defined as gradient of 30 to 60 mm Hg, whereas mild stenosis is a peak gradient less than 30 mm Hg. In the setting of depressed left ventricular function, the Doppler echo-derived gradient may be significantly lower and underestimate the severity of the stenosis.

Aortic valve stenosis is detectable in utero. The long-standing pressure overload on the left ventricle causes left hypertrophy and left ventricular scarring (endocardial fibroelastosis). In some cases, as discussed earlier, the disease progresses to hypoplastic left heart syndrome. Attempts have been made to identify fetuses at high risk for progressing to hypoplastic left heart syndrome and then perform an in utero valvuloplasty with the hope of alleviating the obstruction and altering the course of the disease (Makikallio et al, 2006). Although initial results with this procedure are promising, more work is needed in this area.

Clinically, critical aortic stenosis manifests in the newborn period with signs of decreased systemic perfusion: pallor, decreased pulses, and prolonged capillary refill. A harsh ejection-quality murmur is heard on exam in the aortic area. The volume and quality of the murmur correlate with the severity of stenosis in the setting of normal left ventricular function. If left ventricular function is depressed, the murmur may be soft despite severe stenosis. Electrocardiogram reveals left ventricular hypertrophy with possible T-wave abnormalities. Heart size is typically normal on chest film, although the aortic knob may be prominent and pulmonary congestion may be present. Echocardiogram is used to define the location and severity of the left ventricular outflow tract obstruction. Aortic stenosis is commonly found with other left-sided obstructive lesions, with possible underdevelopment of left heart structures. These findings may alter the treatment plan and lead to single-ventricle palliation. Published models have attempted to identify echocardiographic findings that predict the suitability of a two-ventricle repair in neonates with critical aortic stenosis (Colan et al, 2006; Lofland et al, 2001; Rhodes et al, 1991).

Initial management of infants with critical aortic stenosis is directed at the treatment of cardiogenic shock. Intubation, mechanical ventilation, stable vascular access, inotropic support, sedation, and paralysis are all frequently necessary. PGE_1 maintains ductal patency and provides systemic output. A small patent foramen ovale must be present for pulmonary venous return to cross the atrial septum and enter the systemic vasculature via the right ventricle and ductus arteriosus. A balloon septostomy may be necessary to decompress the left atrium.

Further management depends on left ventricular size and the presence of other left heart obstructive lesions. Patients with multiple levels of left heart obstruction, a small mitral valve, hypoplastic aortic arch, or small left ventricle may be best suited for single-ventricle palliation. Options for two-ventricle palliation include balloon valvuloplasty in the cardiac catheterization lab, surgical valvotomy, or neonatal Ross procedure (Figure 55-23) (Alsoufi et al, 2007). Outcomes of all procedures depend, in part, on relief of obstruction, presence of aortic valve regurgitation, associated cardiac lesions, and severity of end-organ dysfunction at the time of initial presentation. The mortality of each of the interventions is relatively high. Regardless of the treatment chosen, critical aortic stenosis is a lifelong illness. Patients require close follow-up and multiple procedures throughout their lifetimes.

COARCTATION OF THE AORTA

Coarctation may occur anywhere from the transverse aortic arch to the bifurcation of the iliac arteries. Most commonly, there is a discrete narrowing distal to the left subclavian artery, across from the aortic insertion of the ductus arteriosus in a *juxtaductal* position. Conversely, there can be long-segment narrowing of the transverse aortic arch, otherwise referred to as a hypoplastic aortic arch. A bicuspid aortic valve occurs in 70% of cases. Other left-sided obstructive lesions tend to occur with coarctation of the aorta. There is a 2:1 male-to-female preponderance and an association with Turner's syndrome.

In neonates with a discrete juxtaductal narrowing, the PDA widens the narrowed area and provides relief from the obstruction. The net shunt through the PDA is left to right. These patients have equal oxygen saturations in the upper and lower extremities. In patients with a severe coarctation or a diffusely hypoplastic arch, descending aortic flow originates from a right-to-left shunt through the ductus arteriosus. Differential upper and lower extremity oxygen saturations occur in these patients, with the upper extremities having greater saturation than the lower extremities.

The clinical presentation of coarctation of the aorta depends on the severity of the narrowing. Mild coarctation often does not manifest in infancy. Detection typically occurs when upper extremity hypertension and diminished or absent femoral pulses are noted on exam. Infants with more severe coarctation or aortic arch hypoplasia present with diminished lower extremity perfusion after ductal closure. Physical exam reveals an infant in extremis with

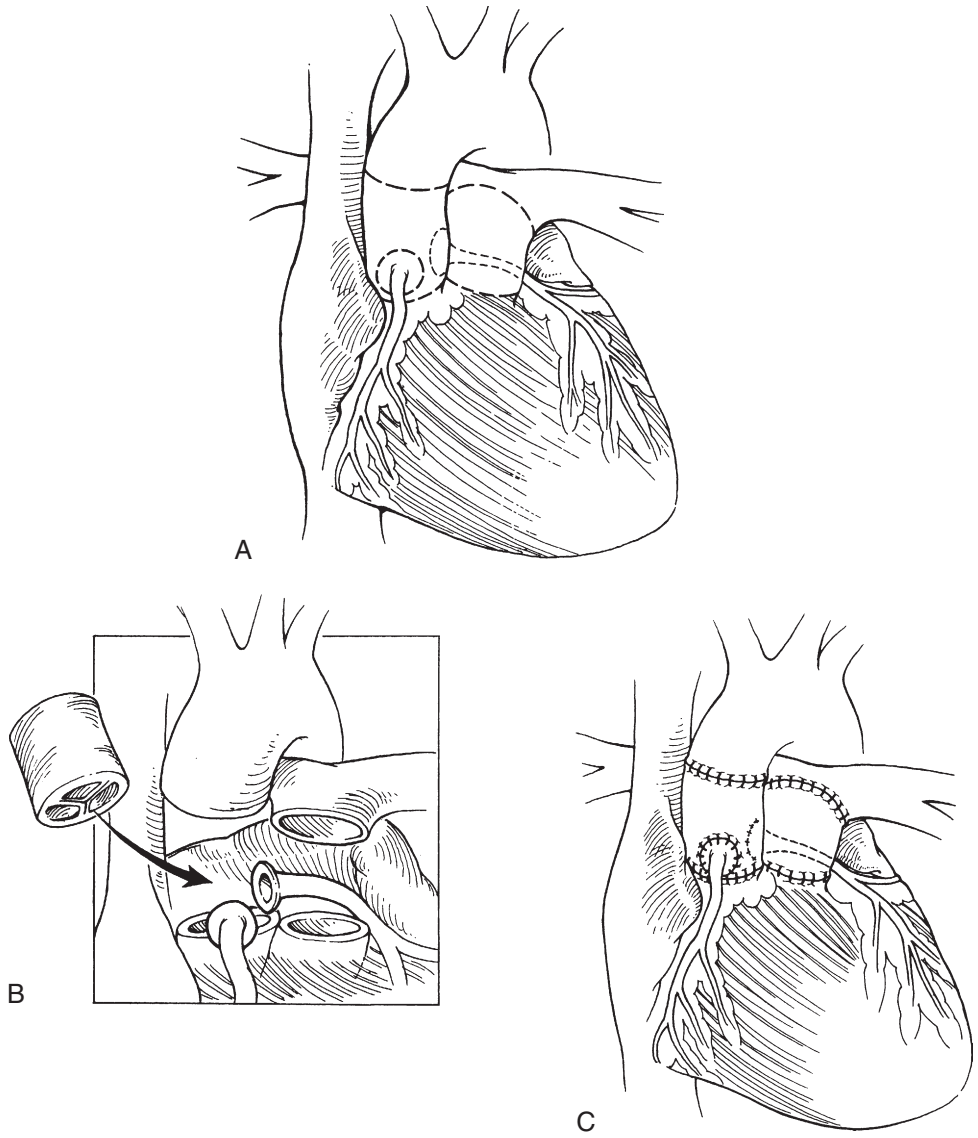

FIGURE 55-23 Ross procedure: "Autograft" aortic valve replacement. A, *Dotted lines* depict surgical incisions around coronary arteries, aorta, and pulmonary artery. **B,** After removal of the coronary arteries and adjacent "buttons" and the diseased aortic valve, the patient's native pulmonary valve ("autograft") is positioned in the aortic root. **C,** Completed repair with reimplanted coronary arteries and a cadaveric homograft valve inserted in the pulmonary position. *(From Chang AC, Burke RP: Left ventricular outflow tract obstruction. In Chang AC, Hanley FL, Wernovsky G, et al, editors:* Pediatric cardiac intensive care, *Baltimore, 1998, Williams & Wilkins, pp 233-256.)*

poor perfusion and absent femoral pulses. Cardiac exam may reveal a systolic ejection click if a bicuspid aortic valve is present. A systolic ejection-quality murmur is heard that radiates to the back and left infraclavicular area. Chest radiograph demonstrates a large heart with increased pulmonary vascular markings. ECG reveals right ventricular hypertrophy. Echocardiography is used to define the location and extent of aortic narrowing. Additional left-sided obstructive lesions are ruled out. Right ventricular hypertrophy and right ventricular hypertension are also frequently noted.

Treatment of the infant presenting with coarctation of the aorta is similar to that of infants with aortic stenosis. Intubation and mechanical ventilation are necessary. Vascular access is obtained for inotropes. PGE_1 is started to open the ductus arteriosus. Metabolic derangements are corrected. Ideally, the infant is stabilized before surgery. Surgery is typically indicated at the time of diagnosis, even in relatively asymptomatic patients. In most cases, a lateral thoracotomy is performed, the area of coarctation is excised, and an end-to-end anastomosis is performed. If long-segment narrowing is present, patch material may be used to augment the arch and a more extended end-to-end anastomosis is performed. Balloon angioplasty of native coarctation is not typically performed in infancy because of the risk of aneurysm, recoarctation, and vascular injury at the site of access.

Surgical mortality is slightly greater than 5% (Gutgesell et al, 2001). Recoarctation occurs in 10% to 15% of children and is successfully managed with balloon angioplasty. If a ventricular septal defect is present, this is typically closed at the time of surgery.

INTERRUPTED AORTIC ARCH

Interrupted aortic arch is a relatively rare anomaly that is defined simply as complete separation of the ascending and descending aorta. Interrupted aortic arch can be classified by the location of the interruption relative to the head and neck vessels (Figure 55-24): type A, distal to the left subclavian artery; type B, between the left subclavian and left carotid arteries; and type C, between the left carotid and innominate arteries. All types of interruption occur in conjunction with posterior malalignment of the infundibular septum; this results in a ventricular septal defect and

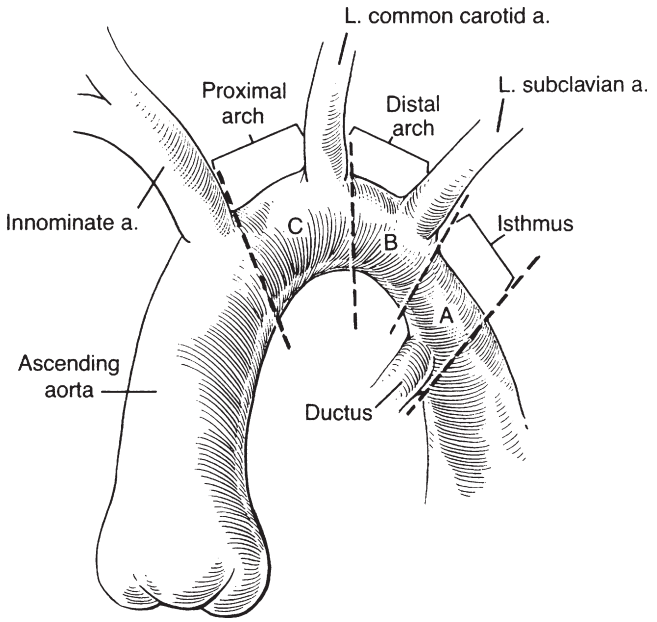

FIGURE 55-24 Anatomic classification of interrupted aortic arch. *Dashed lines* indicate the potential areas of discontinuity (interruption) in the aortic arch. See text for details. *(From Castañeda AR, Jonas RA, Mayer JE Jr, et al:* Cardiac surgery of the neonate and infant, *Philadelphia, 1994, WB Saunders.)*

various degrees of left ventricular outflow tract obstruction. Aberrant arrangements of the head and neck vessels are common, with 50% of patients with type B interruption having an aberrant right subclavian artery that arises from the descending aorta. Interrupted aortic arch is associated with 22q11 deletion.

The clinical presentation of interrupted aortic arch is similar to that of other left-sided obstructive lesions. Descending aortic flow is entirely dependent on right-to-left shunting through the PDA. Ductal closure causes cardiovascular collapse. Initial management is as described for coarctation of the aorta. PGE_1 should be started as soon as possible, because all other resuscitative efforts will have no benefit until postductal circulation is established.

Surgical repair is performed after metabolic acidosis resolves and end-organ function is improved. Continuity is established between the ascending and descending aorta via end-to-end anastomosis, homograft insertion/patch augmentation to connect the two segments, or jump grafts (Figure 55-25). The ventricular septal defect is typically closed. In patients with severe left ventricular hypoplasia, a two-ventricle repair may not be possible and a staged repair or single-ventricle palliation is performed (Tchervenkov et al, 2005). Surgical mortality is less than 10%, but higher in patients with additional anomalies (Brown et al, 2006). Repeat operation due to left ventricular outflow tract obstruction and balloon angioplasty for recurrent arch obstruction are both common.

ANOMALOUS ORIGIN OF THE LEFT CORONARY ARTERY FROM THE PULMONARY ARTERY

When the left coronary artery arises from the pulmonary artery, inadequate oxygen delivery to the left ventricle results. Coronary artery perfusion occurs primarily during diastole. As pulmonary artery pressures drops postnatally, perfusion pressure of the left coronary artery falls, resulting in ischemia and infarction of the left ventricle. If collateral vessels connect the right and left coronary circulations, flow in the left coronary artery reverses. A left-to-right shunt occurs, resulting in coronary artery steal. Mitral valve regurgitation secondary to papillary muscle ischemia and left ventricular dilation develops.

Clinically, symptoms typically develop in the 1st month of life. If adequate collateral vessels and myocardial oxygen delivery exist, the patient may present later in life with angina-like symptoms. In the infant, attacks of irritability, pallor, and diaphoresis with feeds are a common presentation. Cardiac examination reveals a displaced point of maximum impulse, gallop rhythm, and nonspecific murmur. If mitral regurgitation is present, a holosystolic, regurgitant-quality murmur is heard. Chest radiograph reveals massive cardiomegaly. The ECG demonstrates a QR pattern and inverted T waves in leads I and aVL. Leads V_5 and V_6 may also show deep Q waves, inverted T waves, and ST segment depression. Echocardiography may suggest the diagnosis but is not always reliable, because the left coronary occasionally appears to arise from the aorta. Color Doppler may demonstrate retrograde flow in the left coronary with flow into the pulmonary artery. Cardiac catheterization is diagnostic.

Symptoms of congestive heart failure are managed medically. Surgical reimplantation of the left coronary artery to the aorta restores normal coronary perfusion pressure. If the usual two-vessel coronary blood supply is reestablished, there is gradual normalization of left ventricular size and function by echocardiography (Kuroczynski et al, 2008; Lange et al, 2007). If myocardial damage is severe or the left coronary artery is unable to be reimplanted surgically, cardiac transplantation is performed.

SYSTEMIC ARTERIAL MALFORMATIONS

Vascular anomalies are placed in two major groups: hemangiomas and malformations. Hemangiomas are tumors that demonstrate endothelial hyperplasia and undergo a period of proliferation and involution. Malformations result from abnormal vascular morphogenesis. They have normal endothelial cell turnover and grow accordingly with surrounding structures. Vascular malformations are further subcategorized by the type of vascular tissue involved (arterial, venous, and lymphatic). Because of their association with high output failure in the newborn period, two types of systemic vascular malformations are discussed further: arteriovenous malformations (AVMs) and arteriovenous fistulas (AVFs). An AVM results from multiple microfistulas between small arteries and veins. An AVF results from a connection between a large artery and vein.

Hemodynamically significant AVFs and AVMs manifest with high-output heart failure and cyanosis in the newborn period. An effective large left-to-right shunt occurs through the direct arterial-venous connections. Heart rate, stroke volume, plasma volume, and cardiac output are increased. The fistulous connection lowers systemic vascular resistance, promoting a right-to-left shunt through the ductus arteriosus, particularly if the normal postnatal

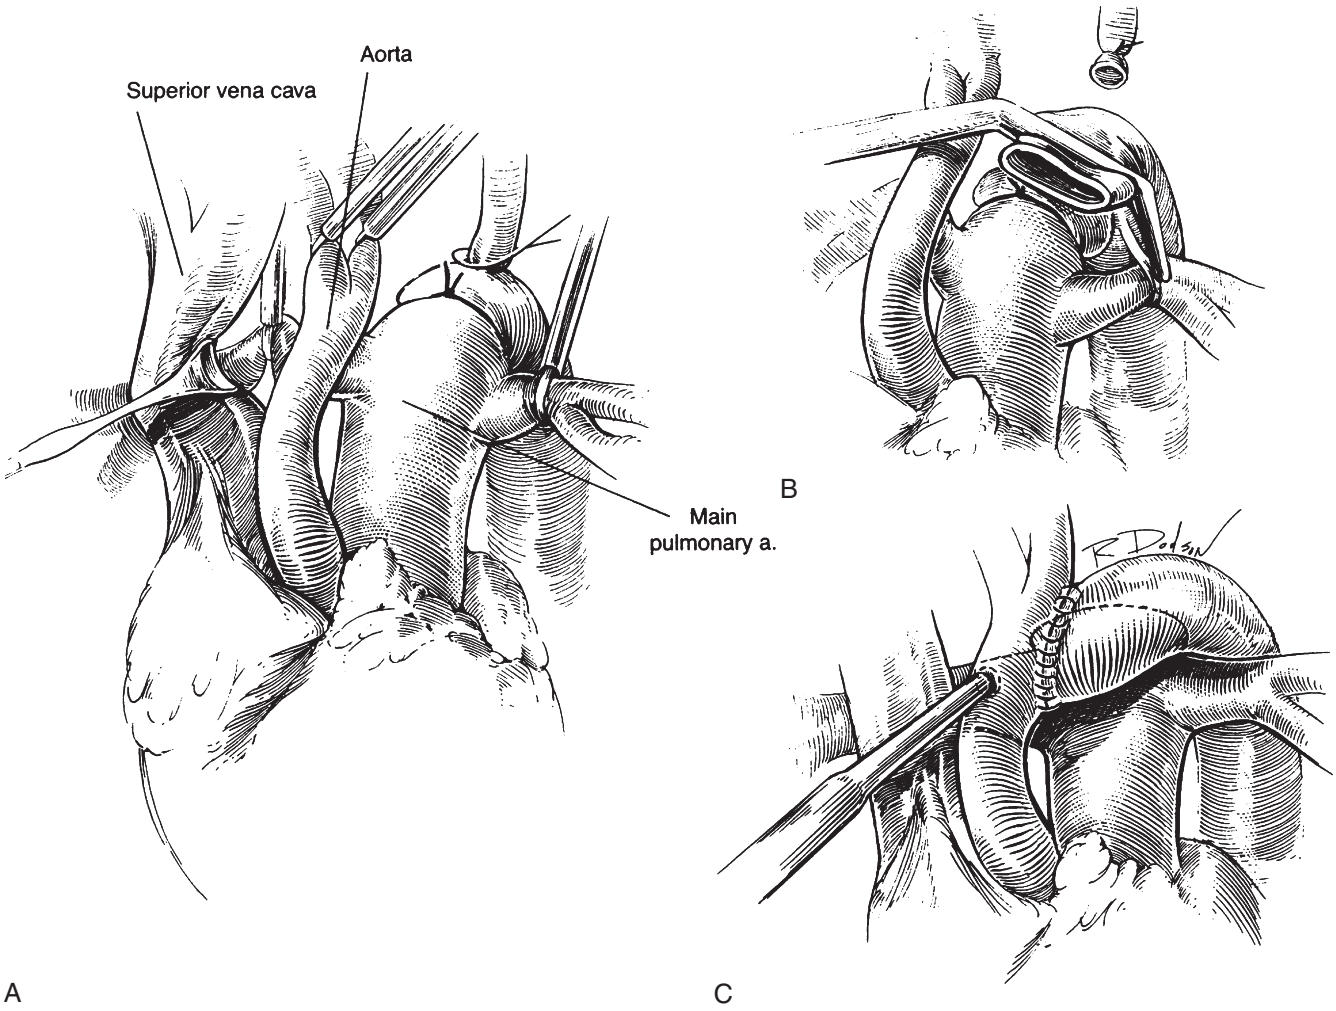

FIGURE 55-25 Surgical repair of interrupted aortic arch, type B. A, The branch pulmonary arteries and arch vessels are snared, and a ligature is placed around the ductus arteriosus. **B,** The proximal descending aorta is controlled with a clamp. To adequately mobilize the descending aorta, the left subclavian artery may need to be divided (as shown). After resection of the ductus arteriosus, the proximal (pulmonary artery) end is oversewn. **C,** The descending aorta is anastomosed directly to the ascending aorta. An alternative strategy is anastomosis of the left subclavian and left common carotid arteries combined with homograft patch augmentation of the inferior surface of the arch. Ventricular septal defect closure, when present, is also performed (not shown). *(From Castañeda AR, Jonas RA, Mayer JE Jr, et al:* Cardiac surgery of the neonate and infant, *Philadelphia, 1994, WB Saunders.)*

drop in pulmonary vascular resistance has not occurred. The increased systemic venous return increases right atrial pressures and promotes right-to-left shunting through the foramen ovale.

Cardiac examination reveals a hyperdynamic precordium. A prominent second heart sound, S3, and S4 may be heard. Systolic murmurs may be present secondary to tricuspid valve regurgitation or increased flow across the pulmonary valve. Increased tricuspid valve flow may create a diastolic sound. Bruits may be heard over the vascular malformation. When a malformation is suspected, care must be taken to auscultate areas where malformations are likely, such as the head, liver, and chest. Arteries proximal to the malformation are typically dilated with bounding pulses, whereas those distal are small with diminished pulses. ECG is nonspecific and may demonstrate right atrial and right ventricular enlargement. Chest radiograph reveals cardiomegaly with increased pulmonary vascular markings. Echocardiography demonstrates generalized cardiomegaly. Treatment, if necessary, requires interventional closure or surgical ligation of the anomalous vascular connections.

CARDIOMYOPATHY

A large body of literature exists describing the diagnosis and management of structural congenital heart disease in the fetus and newborn. There is a paucity of information, however, regarding the diagnosis and management of fetal and newborn cardiomyopathy. In evaluating a newborn infant with signs of congestive heart failure, structural heart disease should be ruled out. In the absence of structural problems, the diagnosis of cardiomyopathy should be considered. The etiology of neonatal cardiomyopathy includes prenatal infections (with cytomegalovirus, human immunodeficiency virus, enterovirus, or parvovirus); familial or genetic causes; maternal autoimmune disease with anti-Ro or anti-La antibodies; prenatal drug exposure; arrhythmia-induced cardiomyopathy; and twin-twin transfusion. Postnatal evaluation should include a search for the underlying cause.

Data from the Organ Procurement and Transplant Network Database (http://optn.transplant.hrsa.gov/).

Initial management is similar to that for other types of heart disease. Initial stabilization may require mechanical ventilation, the use of ionotropes, afterload reduction, and diuresis. Long-term treatment is dependent somewhat on the specific cause of the cardiomyopathy, because some forms may be reversible. Cardiac transplantation should be considered if cardiac function is poor or improvement is not noted.

HEART TRANSPLANTATION

The first heart transplant procedure in an infant was reported in 1968 (Kantrowitz et al, 1968). Since then, improved understanding of transplant immunology and medical management has made heart transplantation in infants and children an important option in inoperable patients or those with end-stage cardiac disease. In a recent scientific statement from the American Heart Association, the indications for pediatric heart transplantation were defined (adapted from Canter et al, 2007):

1. Need for ongoing intravenous inotropic or mechanical circulatory support
2. Complex CHD not amenable to conventional surgical repair or palliation or for which the surgical procedure carries a higher risk of mortality than transplantation
3. Progressive deterioration of ventricular function or functional status despite optimal medical care
4. Malignant arrhythmia or survival after cardiac arrest unresponsive to medical therapy, catheter ablation, or an automatic implantable defibrillator
5. Progressive pulmonary hypertension that could preclude future transplantation
6. Growth failure secondary to severe congestive heart failure unresponsive to conventional medical therapy
7. Unacceptably poor quality of life

There are a variety of lesions in the neonate for which cardiac transplantation has been used as primary palliation. These have included hypoplastic left heart, pulmonary atresia with intact ventricular septum and presence of coronary sinusoids, complex heterotaxy or unbalanced complete AV canal with poor common AV valve function, and single-ventricle hearts in which the dominant semilunar valve is severely insufficient. In considering transplantation in these patients, there is a balance between the success of palliative surgery and the availability of organs for transplantation. For example, over the past decade, survival of patients undergoing surgical palliation of hypoplastic left heart syndrome has continued to improve (Alsoufi et al, 2007; Gordon et al, 2008). With the availability of infant donors increasing only slightly over this period of time (Table 55-2), the balance for treatment of these newborns has shifted toward surgical palliation with the Norwood or hybrid Norwood procedures.

Patients with the other lesions just noted continue to have relatively poor surgical outcomes, suggesting that palliation with heart transplantation may be the best approach. Given the limited availability of organs, however, it should be recognized that some of these infants will not survive to transplantation (Kirklin et al, 2006). The long-term survival of infants who undergo heart transplantation is quite good. The calculated "half-life" of transplant recipients younger than 1 year of age was 15.8 years, 14.2 years for children between 1 and 10 years, and 11.4 years for children over the age of 10 years (Boucek et al, 2007).

It is interesting that there appears to be a survival advantage in newborns who receive their transplant before 1 month of age versus those between 1 and 12 months (del Rio, 2000). Although the mechanism of the improved survival in the younger neonates is not known, it may reflect an immunologic window where in graft rejection and transplant coronary artery disease are limited.

CHAPTER 56

Arrhythmias in the Newborn and Fetus

Jeremy P. Moore, Gary M. Satou, and Thomas S. Klitzner

Advances in both electrophysiology and fetal echocardiography over the past two decades have substantially enhanced our ability to diagnose and treat arrhythmias in the fetus and newborn. This chapter outlines many of the advances and can serve as a guide to the most modern approaches to the issue of rhythm disturbances in the perinatal period. After a brief introduction to the pathophysiology of arrhythmias, the chapter is divided into sections on the neonate and fetus. Each section is organized to describe the various types of arrhythmias occurring in that period, along with the corresponding management strategies. Of necessity, there is some overlap between the neonatal and fetal sections, which is highlighted when appropriate. Although advances in the field occur frequently, the basic understanding of arrhythmia pathogenesis and the overall principles of treatment outlined here have remained relatively constant for the last 5 to 10 years.

In this chapter, fetal tachycardia is considered a persistent elevation in the heart rate above 180 beats/min and fetal bradycardia is defined as a persistent heart rate below 100 beats/min. After birth, these same definitions apply to the neonate (Davignon et al, 1980).

PATHOPHYSIOLOGY OF ARRHYTHMIAS IN THE NEONATE AND FETUS

Three general mechanisms of arrhythmogenesis have been described and are presumed to be responsible for the majority of tachycardias seen in the fetus and neonate with tachycardia:

- Reentry
- Abnormal automaticity
- Triggered activity

Reentry classically requires several conditions for initiation and maintenance, including multiple pathways for impulse conduction, an area of slow conduction in at least one of these pathways, block in one pathway, and recovery of tissue excitability at the site of origin. These rhythms involve anatomically defined circuits of electrical activity and therefore tend to behave predictably with a stable cycle length and paroxysmal initiation and termination. Reentrant rhythms may be altered or interrupted by premature beats that enter the reentry circuit.

Abnormal automaticity is the result of spontaneous depolarization of a group of myocardial cells known as the automatic focus. Automatic rhythms tend to accelerate on initiation and show variation in rate with changes in external influences, most significantly autonomic tone. However, premature beats do not alter automatic rhythms unless they depolarize the automatic focus, which is unusual.

Triggered activity is due to small, spontaneous depolarizations of the myocardial cell membrane that result in repetitive electrical activity when they reach threshold. Conditions that predispose to triggered arrhythmias are intrinsic myocardial disease, ischemia, digitalis toxicity, and metabolic disturbances.

NEONATAL RHYTHMS

TACHYCARDIAS

Although a host of neonatal tachycardias may be seen in clinical practice, only a few are seen commonly. These more common tachycardias include orthodromic reciprocating tachycardia (ORT) and atrial flutter.

The substrate of ORT is a reentrant circuit that includes the atrium, the atrioventricular (AV) node, and His-Purkinje system in the antegrade direction, and the ventricular myocardium and an accessory pathway in the retrograde direction back to the atrium (Figure 56-1). This is the most common arrhythmia in the newborn period. ORT manifests as a narrow-complex tachycardia with a P wave that occurs more than 70 ms (just under 2 "little" boxes on a standard electrocardiogram [ECG]) after the QRS complex. The heart rate tends to be in the range of 240 to 260 beats/min in the newborn. A large percentage of the accessory pathways responsible for ORT will spontaneously become nonfunctional during the course of infancy as the heart matures.

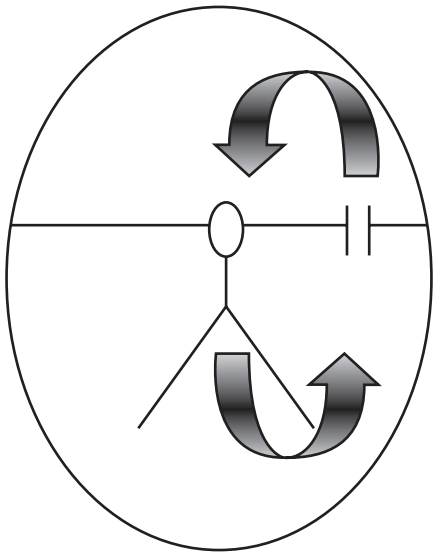

FIGURE 56-1 Mechanism of orthodromic reciprocating tachycardia. The electrical impulse travels down the normal conduction system by way of the AV node and His-Purkinje system to the ventricle, where it returns to the atrium by the accessory pathway (in this case, a left-sided pathway).

Atrial flutter is a reentrant rhythm that requires only the atrium to complete the circuit, with conduction to the ventricles occurring passively over the AV node. Typical circuits travel in a counterclockwise direction around the tricuspid valve annulus, which is responsible for the characteristic appearance on the 12-lead ECG. Features include sawtooth P waves in the inferior leads and positive, generally more discrete, P waves in lead V1. Atrial rates tend to be greater than 300 beats/min, resulting in various degrees of aberrancy (bundle-branch block) and physiologic AV block. In the neonate, classic flutter waves may be absent. Consequently, the atrial rate tends to be the most important clue to the diagnosis (Figure 56-2). After conversion to sinus rhythm, recurrence of atrial flutter is rare in the neonate without structural heart disease (Wren, 2006).

Other tachycardias in the newborn are much less common, but are important to recognize in order for therapy to be administered in a timely manner. They are considered next in their relative order of frequency.

Atrial ectopic tachycardia (AET) is often an incessant rhythm that displays warm-up periods and variable functional AV block at higher rates. The most characteristic feature on the surface ECG is the p-wave axis, which is almost always abnormal. Most foci originate from remnants of embryonic myocardium that insert on extracardiac structures, such as the superior vena cava (SVC), pulmonary veins, coronary sinus, and atrial appendages. The location of these foci tends to dictate the resultant p-wave axis. Incessant tachycardia due to AET carries the associated risk of tachycardia-mediated cardiomyopathy if the rhythm goes undiagnosed for extended periods of time. In patients with AET tachycardia, AV node–blocking medications may result in high-grade AV block with little effect on the underlying atrial rhythm but may be diagnostic (Figure 56-3). This distinction may be especially useful for ectopic tachycardias that originate near the SVC, which otherwise can appear very similar to sinus tachycardia on the surface ECG.

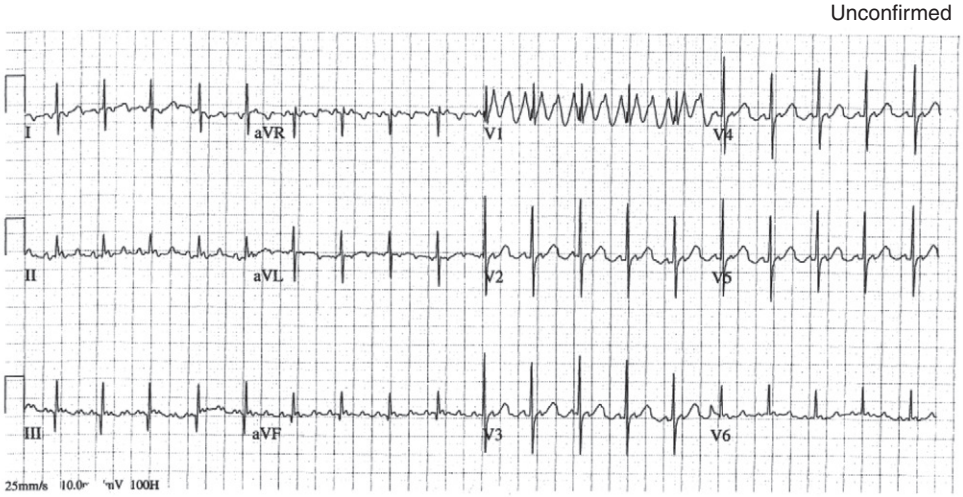

FIGURE 56-2 12-lead electrocardiogram demonstrating atrial flutter. The atrial rate is approximately 360 beats/min. Note that the atrioventricular conduction demonstrates 3:1 AV block, resulting in the slower ventricular rate of only 120 bpm. P waves appear discrete and are positive in the inferior leads, as opposed to the classic "sawtooth" pattern seen in older children and adults. *AV*, Atrioventricular; *ECG*, elecrocardiogram.

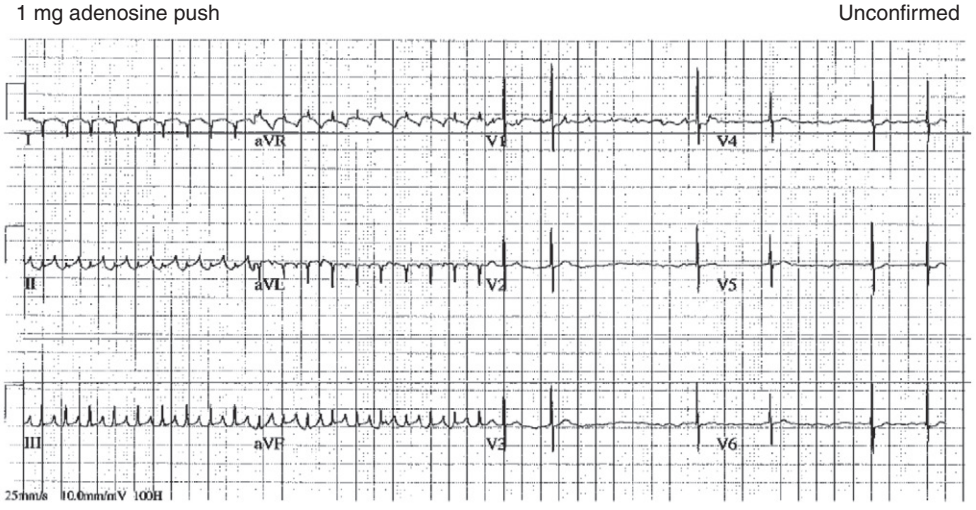

FIGURE 56-3 12-lead ECG in a patient with atrial ectopic tachycardia. The P-wave axis suggests a posterior and slightly leftward focus. Note that the ectopic rhythm (best seen in lead V1) is not perturbed by the administration of a bolus of adenosine. *AET*, Atrial ectopic tachycardia; *EGG*, electrocardiogram.

The permanent form of junctional reciprocating tachycardia (PJRT) is a rare reentrant rhythm that uses the AV node and His-Purkinje system as the antegrade pathway and a slowly conducting accessory pathway in the region of the posterior septum of the heart as the retrograde limb. This rhythm often manifests with heart rates in the upper range of normal for the neonate but is typically incessant with frequent interruptions and spontaneous reinitiations. Consequently, PJRT also can result in a progressive cardiomyopathy if it goes unnoticed over extended periods of time. The hallmarks of this rhythm are its sudden onset and termination, as well as the characteristically inverted P-wave axis (sometimes quite large) on the 12-lead ECG (Figure 56-4).

Congenital junctional ectopic tachycardia (JET) is extremely rare, and there are only a few case series describing experience with this rhythm (Coumel et al, 1976; Villain et al, 1990). The arrhythmia is due to abnormal automaticity in the region of the AV junction. The nature of the rhythm results in simultaneous depolarization of atria and ventricles, with subsequent loss of AV synchrony. The rhythm tends to be very resistant to medical management, with the net effect being a predisposition to tachycardia-mediated cardiomyopathy over time.

Ventricular tachycardia (VT) is defined as a ventricular rhythm greater than 20% faster than the underlying sinus rhythm. It is characterized by a wide QRS complex (more than 80 ms, or 2 "little" boxes on the neonatal ECG). It is considered sustained if lasting longer than 30 seconds and incessant if present more than 10% of the time on continuous monitoring. Clues to the diagnosis of VT in the neonate are as follows (Batra and Silka, 2000):

1. The QRS complex has abnormal axis and morphology as compared with sinus rhythm.
2. The first QRS complex occurs earlier than expected and is not preceded by an atrial depolarization.
3. Ventriculoatrial (VA) dissociation or fusion complexes occur.

Not all wide complex tachycardia is VT, however. The differential diagnosis also includes supraventricular tachycardia (SVT) with aberrancy as well as some forms of SVT utilizing an accessory pathway in the antegrade direction. The preceding criteria are often helpful in making the correct diagnosis.

VT has several diverse causes in the neonate. The most common inherited cause of neonatal VT is the long QT syndrome (LQTS). The reported prevalence of this

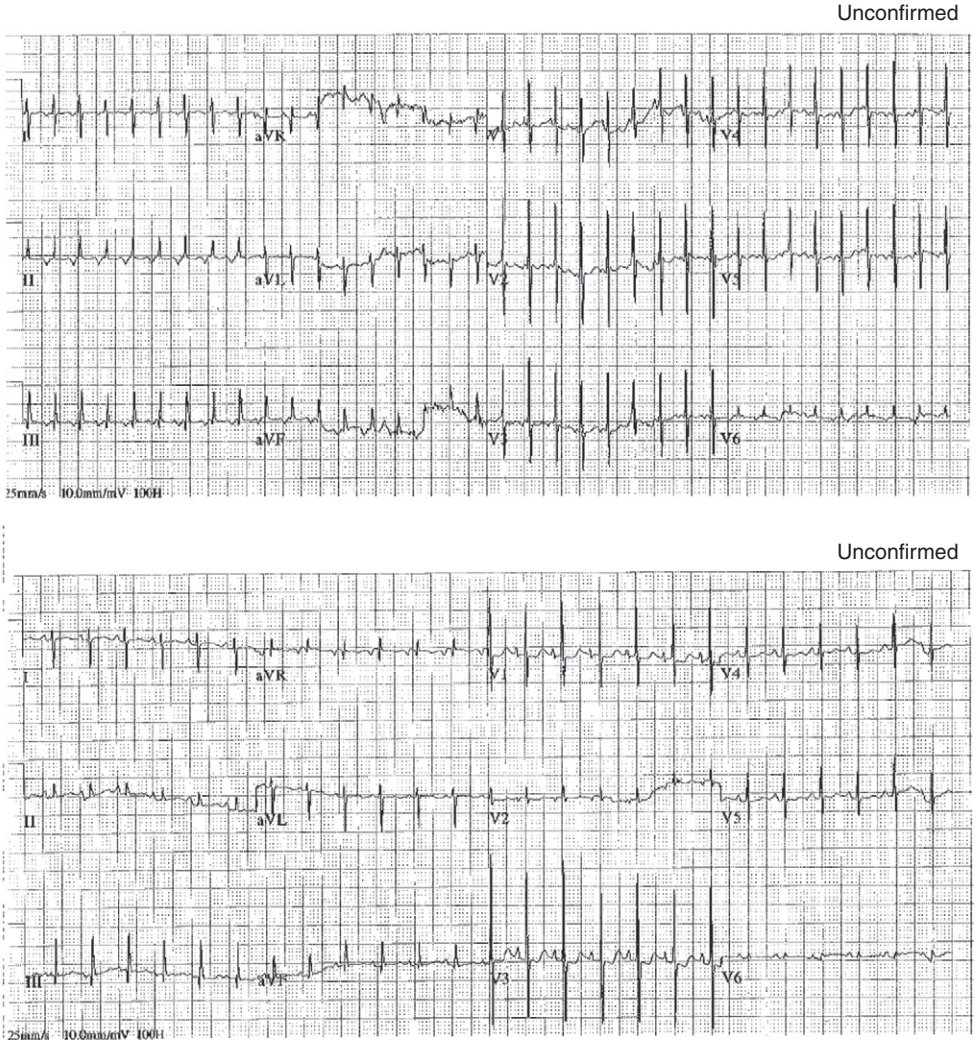

FIGURE 56-4 12-lead electrocardiogram in a neonate with permanent form of junctional reciprocating tachycardia before and after adenosine administration. During tachycardia, the p wave axis is directed superiorly and rightward, consistent with an origin near the "crux" of the heart.

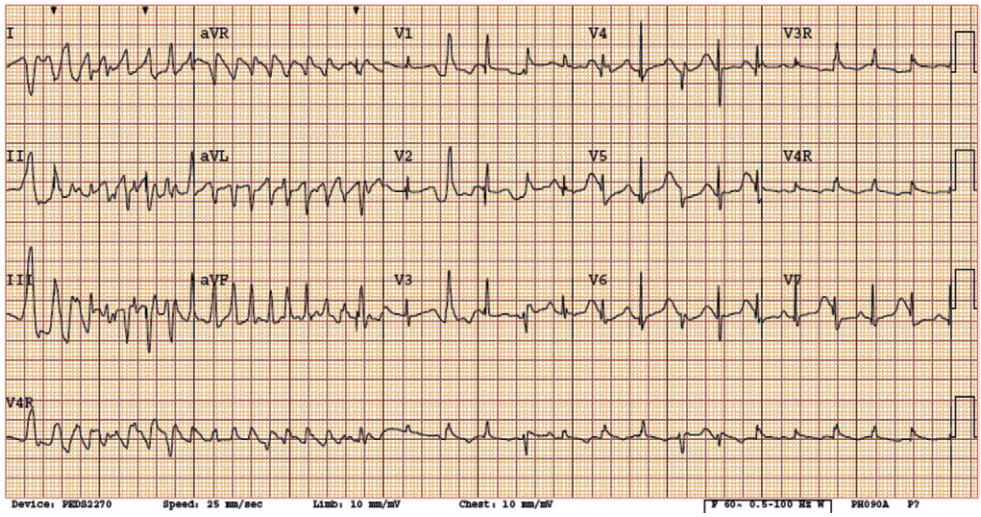

FIGURE 56-5 15-lead electrocardiogram (ECG) and rhythm strip recording of torsades de pointes type ventricular tachycardia in a neonate with congenital long QT syndrome. Note the "twisting" pattern of the QRS complex during tachycardia. The rhythm spontaneously terminates with resumption of sinus rhythm at the beginning of the ECG.

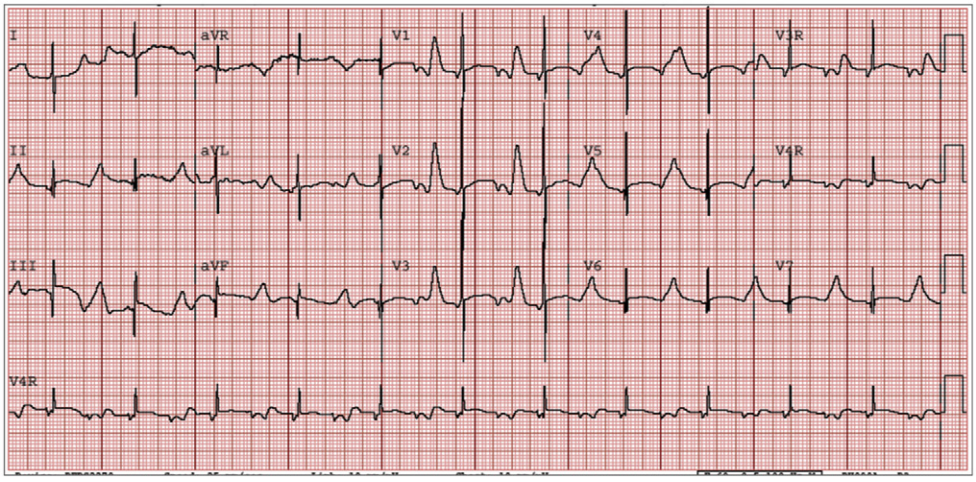

FIGURE 56-6 15-lead electrocardiogram and rhythm strip in the same neonate as in the previous figure. Note the very long QT interval and 2:1 atrioventricular block, owing to the functional refractoriness of the ventricle during the prolonged QT interval.

condition in the general population is approximately 1 in 2500, but prevalence may be higher in the neonate (Collins and Van Hare, 2006). The arrhythmias associated with this condition are related to prolongation of repolarization in the epicardial layer of the heart leading to early afterdepolarizations (a form of triggered activity) and subsequent polymorphic VT (Yan et al, 1998). In patients with LQTS, the VT is described as torsades de pointes (TdP) which literally means "twisting of the points" and displays a classic ECG appearance (Figure 56-5). In any patient presenting with this type of ventricular tachycardia, the diagnosis should be strongly suspected and the baseline 12-lead ECG should be examined for prolongation of the QT interval. In the neonate, the corrected QT interval should be less than 440 ms, regardless of gender (Schwartz et al, 1998). Unfortunately, during the first days to week of life the QTc tends to be highly variable, making this measurement unreliable (Walsh, 1963). Rarely, severely affected neonates may present with 2:1 AV block and bradycardia related to functional refractoriness of ventricular tissue due to the long QT interval (Figure 56-6).

Prolongation of the QT interval can also be acquired, in which case it can be secondary to factors such as medication administration, electrolyte abnormalities, or neurologic injury. Just as with the congenital LQTS, acquired QT prolongation can predispose the neonate to TdP.

Another source of VT in the neonate is the presence of intramyocardial tumors. The most common tumors seen in the newborn period are rhabdomyomas, which typically are multiple and involve the ventricular muscle directly, but occasionally can involve the conduction system as well. VT related to rhabdomyomas may be difficult to control, but typically improves with time because these tumors tend to spontaneously regress. More rarely, neonates may be affected by a disease entity known as histiocytoid cardiomyopathy. This is a genetic disorder characterized by macroscopic yellow-tan nodules, which are Purkinje fibers and scattered clusters of histiocytoid myocytes (Finsterer, 2008). These abnormal cell collections can be the focus of VT in affected neonates and infants.

Neonatal VT may also be a nonspecific response to a variety of systemic insults that include electrolyte

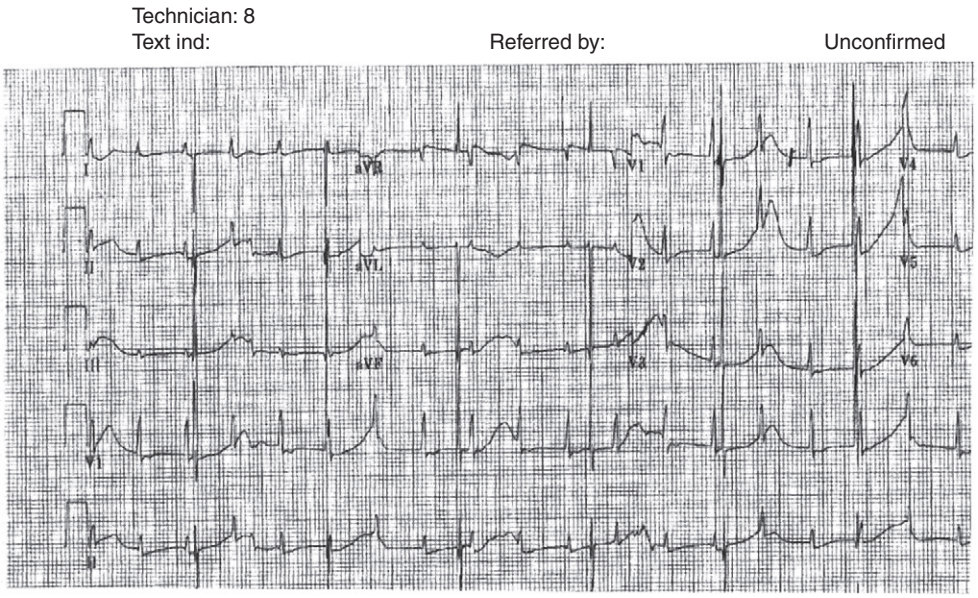

FIGURE 56-7 Congenital AV block. The atrial rate is 130 beats/min and the ventricular rate is just under 50 beats/min. There is complete dissociation between the atrial and ventricular rhythms. The very tall P waves represent right atrial enlargement.

TABLE 56-1 Echocardiographic Diagnosis of Fetal Tachycardia Subtype Based on the Ventriculoatrial Interval/Duration

VA Relationship	Tachycardia Diagnosis
Short VA (VA<AV)	ORT
Long VA (VA > AV)	AET

derangements, acidosis, hypoxia, sepsis, and myocardial ischemia. Correction of the underlying problem usually ameliorates the tachycardia.

Myocarditis is an important cause of neonatal VT, but usually manifests with hemodynamic instability and shock rather than isolated tachycardia. Other electrocardiographic clues to the diagnosis include decreased precordial voltages, various conduction abnormalities, and frequent atrial and/or ventricular ectopy.

Noninfectious cardiomyopathies may manifest with VT, but as with myocarditis, other signs and symptoms are often present to assist in the diagnosis. These may include respiratory distress with inspiratory crackles, cardiomegaly, thready pulse with narrowed pulse pressure, and hemodynamic instability.

Benign forms of "idiopathic VT" can affect healthy neonates with structurally normal hearts. These include idiopathic right ventricular outflow tract (RVOT) tachycardia and left ventricular posterior fascicular VT. Last, accelerated idioventricular rhythm (AIVR) refers to a ventricular rhythm that is not more than 10–20 beats/min faster than the underlying sinus rate. The QRS axis is most commonly a left bundlebranch block with an inferior axis. This rhythm is generally benign and most often self-limiting.

BOX 56-1 Pathologic Causes of Neonatal Bradycardia

Left atrial isomerism
LQTS with 2:1 block
Sick sinus syndrome
Blocked atrial bigeminy

BRADYCARDIAS

Neonatal bradycardia is defined as a persistent heart rate <100 beats/min. Noncardiac causes are most common and are typically transient. These usually involve situations associated with high vagal tone. Bradycardia in the neonate may also represent a nonspecific response to hypoxia and acidosis, in which case it may be more sustained.

Cardiac causes of fetal and neonatal bradycardia are diverse. The most common is congenital AV block, which occurs in approximately 1:20,000 live births (Michaelsson and Engle, 1972) (Figure 56-7). Other, less frequent cardiac etiologies are listed in Box 56-1. Congenital AV block is generally divided into two broad categories based on the underlying pathophysiology.

Congenital Atrioventricular Block Associated with Structural Heart Disease

The congenital heart defects that are most frequently accompanied by congenital heart block include heterotaxy syndrome (with left atrial isomerism), congenitally corrected transposition of the great arteries, and AV canal

defects. Congenital AV block associated with structural heart disease has the highest mortality of the two subtypes, with fetal loss rates as high as 75%. Large clinical studies evaluating the incidence of fetal and neonatal congenital AV block have shown that in utero, the causes of heart block are initially evenly distributed, with 50% of cases due to structural heart disease and 50% due to immune-mediated mechanisms (Machado et al, 1988; Schmidt et al, 1991). Postnatally, however, the incidence of congenital AV block associated with structural heart disease decreases to 30% of cases with the remaining cases related to immune-mediated mechanisms, reflecting the high in utero mortality of the former. Outcomes for a fetus with the combination of congenital AV block, complex congenital heart disease, and hydrops fetalis is particularly dismal, with extremely high rates of fetal loss (Anandakumar et al, 1996).

Immune-Mediated Congenital Atrioventricular Block

The presence of maternal anti-Ro (SSA) or anti-La (SSB) antibodies have been demonstrated in most cases of *isolated* congenital AV block, with the presumed mechanism being that of immunecomplex deposition with specific damage to the fetal cardiac conduction system. Ro-52 specific antibodies have shown a very close association to immune-mediated congenital AV block in recent studies (Salomonsson et al, 2004). The risk of heart block in mothers with anti-SSA and anti-SSB antibodies is approximately 2% to 3%, with recurrence rates after one affected child as high as 14% to 17%. Autopsy specimens typically reveal progressive fibrosis of the AV nodal structures in affected fetuses. The process typically spares the His-Purkinje system, however, so that the slower "escape rhythm" tends to be fairly reliable. In addition, damage to the conduction system is variably accompanied by damage to contractile elements of the heart (Assad et al, 1994; Horsfall et al, 1996; Schmidt et al, 1991; Walkinshaw et al, 1994). Less frequently, a progressive cardiomyopathy develops, unrelated to the heart block, and is marked by sustained high levels of maternal autoantibodies in the affected fetus and neonate (Moak et al, 2001; Taylor-Alber et al, 1997). The risk of transfer of maternal autoantibodies to the fetus seems to be highest between 16 and 26 weeks' gestation (Buyon et al, 1998; Waltuck and Buyon, 1994), and it usually is at this point that affected fetuses will demonstrate manifestations of conduction system disease.

An uncommon cause of neonatal bradycardia is blocked atrial bigeminy, which is a pattern of atrial ectopic beats closely coupled to the preceding QRS complex, in which the AV node is refractory. This results in failure of conduction to the ventricle (Figure 56-8). In most cases, this phenomenon results in bradycardia, but it also predicts a higher risk for progression to sustained tachycardia (Simpson et al, 1996). The underlying pathophysiology is of ten times reentry from the ventricle to the atrium over an accessory pathway (Kleinman and Nehgme, 2004). In other cases, atrial bigeminy may be caused by a redundant flap of the foramen ovale, which comes in contact with the free wall of the atrium during ventricular systole when the membrane moves away from the septum (Pernot et al, 1984; Phillipos et al, 1994).

NEONATAL MANAGEMENT

NEONATAL TACHYCARDIA MANAGEMENT

The management of neonatal supraventricular tachycardia (SVT) is based on the presumed mechanism of the tachyarrhythmia, with ORT and atrial flutter being most common (Figure 56-9 shows a proposed treatment algorithm and drug dosing). Cases of ORT can often be terminated with vagal maneuvers or adenosine. Digoxin remains first-line therapy for treatment and prevention of both ORT and atrial flutter in many institutions after preexcitation has been excluded on the 12-lead ECG. Digoxin can be administered orally or by the intravenous (IV) route (with IV administration of digoxin being 80% of the enteral dose). The surface electrocardiogram is followed for evidence of PR prolongation, and serum potassium levels are kept in the normal range. Whereas some institutions use propranolol as a first-line agent for neonatal tachycardia, many others reserve propranolol and flecainide for refractory cases of ORT. Atrial flutter responds well to electrical cardioversion if initial therapy with digoxin fails. This is more likely to occur if the rhythm is less organized and resembles atrial fibrillation. In cases of successful electrical cardioversion, flecainide may be used to prevent recurrence. Regardless of the drug chosen, therapy is generally continued for 6 months, after which time recurrence rates decrease significantly (Wren, 2006). Some centers follow a "wait and see" policy after conversion of neonatal atrial flutter to sinus rhythm, given that recurrence rates are low (Jaeggi et al, 1998).

In contrast with neonatal ORT and atrial flutter, atrial ectopic tachycardia is less effectively treated with digoxin and often requires the administration of flecainide or sotalol. In more refractory cases, combination therapy with both agents is required. Alternatively, amiodarone can be used. IV administration of amiodarone is avoided whenever possible, given rare reports of neonatal "gasping

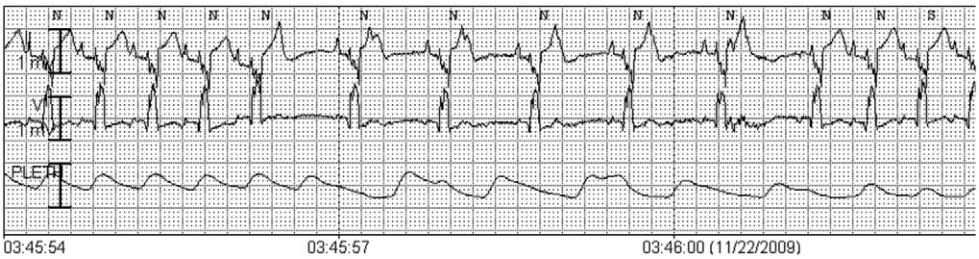

FIGURE 56-8 Two-lead rhythm strip and arterial line trace demonstrating blocked atrial bigeminy in a newborn with intermittent episodes of bradycardia. The blocked atrial extrasystoles can be seen superimposed on the T waves preceding the pauses.

syndrome" and leaching of plasticizers from IV tubing (Centers for Disease Control, 1982; Gershanik et al, 1982; Sabex, 2001). However, it has been used safely in this form when required for more refractory arrhythmias (Perry et al, 1996). Amiodarone is administered with loading doses and is continued at this dose until the atrial rate is in the normal range, or for 10 days, whichever comes first. At this point, the dose of amiodarone is decreased to the maintenance range. If monotherapy is successful, a trial of discontinuation of the drug is attempted at 6 months of age. With combination therapy, a staggered wean is best. For example, one drug can be discontinued at 6 months, and then a trial period discontinuing the remaining medication can be performed several months later.

Congenital JET tends to be a refractory arrhythmia and often does not respond to the usual drug therapies. Amiodarone is the drug most likely to be successful for the treatment of JET. However, in exceptional cases, biventricular pacing and high-dose antiarrhythmic therapy with two separate agents may be required to achieve arrhythmia suppression.

The two ventricular rhythms relevant to the neonatal period are AIVR and VT. In general, AIVR does not require therapy and resolves during infancy. The treatment of VT should be based on the underlying mechanism, but patients with hemodynamically unstable VT/ventricular fibrillation should undergo immediate cardiac defibrillation according to American Heart Association (AHA) guidelines.

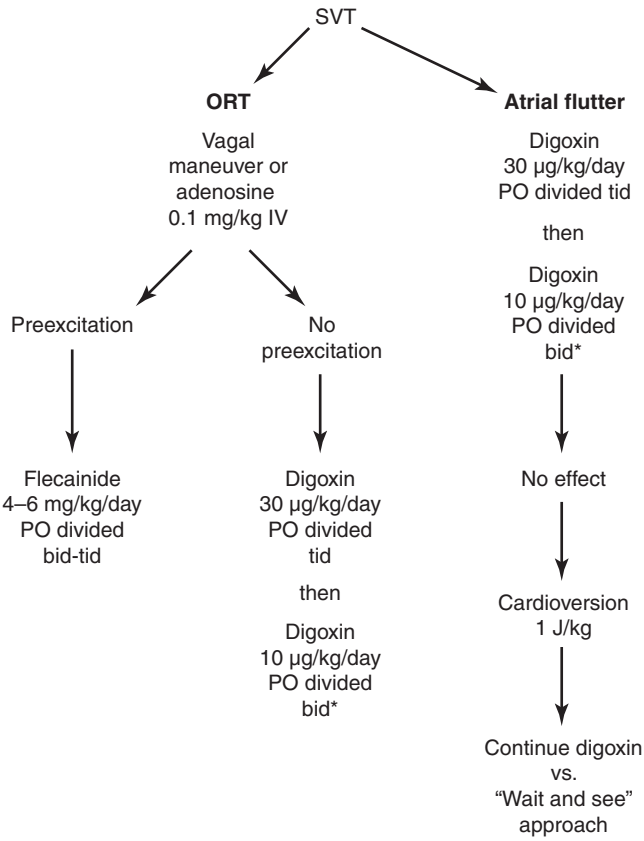

FIGURE 56-9 Suggested neonatal management scheme for the two most common types of Supraventricular tachycardia. Orthodromic reciprocating tachycardia is usually treated medically, whereas atrial flutter may require electrical cardioversion. See text for further details. *Digoxin dose reduction is required in preterm neonates.

In cases in which cardiac defibrillation has been performed, further therapy of TdP consists of IV magnesium. Once rhythm control has been achieved, a continued search should be made for exacerbating factors. Drug-induced TdP usually responds well to removal of the offending medication in addition to aggressive correction of electrolyte disturbances. If the etiologic disorder is determined to be congenital LQTS, therapy relies heavily on the use of beta-blockers, the most common of which is propranolol. Neonates with suspected or proven LQTS should have all QT-prolonging medications stopped. Electrolytes should always be kept in the normal range with special attention to serum potassium levels. Other LQTS-specific treatment modalities for severely affected neonates who experience breakthrough episodes despite beta-blocker therapy include left stellate ganglionectomy as well as implantable cardioverter-defibrillator (ICD) placement (Berul, 2000, Progress Pediatr Cardiol). ICD implantation is typically used only as secondary preventive measure after aborted sudden cardiac death, particularly because ICD shocks have been implicated in creating incessant tachycardia.

Management of VT related to intracardiac tumors often begins acutely with a lidocaine drip. Long term suppression often involves beta-blocker therapy with class Ic agents or amiodarone for more refractory cases. The acute treatment for VT in the setting of myocarditis and dilated cardiomyopathies similarly relies on lidocaine for rapid arrhythmia suppression, whereas amiodarone is often the drug of choice for more long-term suppression.

The management of idiopathic VT in the neonate usually does not require therapy, because these tend to be benign rhythms. Right ventricular outflow tract (RVOT) tachycardia is usually well controlled with beta-blocker therapy if needed.

NEONATAL BRADYCARDIA MANAGEMENT

Congenital AV block in the otherwise healthy neonate with good ventricular function and average heart rates greater than 55 beats/min is generally well tolerated, and follow-up can be performed as an outpatient. Close observation should include serial history and physical examinations, echocardiography, and Holter monitoring. Evidence of an unreliable escape rhythm and progressive cardiac dysfunction suggest the need for pacemaker placement. Consensus guidelines have been published recently regarding indications for pacing (Hui et al, 2008). In infancy, class I indications include the following (Epstein et al, 2008):

1. A wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction
2. An average ventricular rate less than 55 beats/min with isolated heart block
3. An average ventricular rate less than 70 beats/min with associated congenital heart disease

At the time of delivery, any significant pleural effusions related to hydrops fetalis should be drained and medical therapy with isoproterenol can be started if there is evidence of hemodynamic compromise. Epicardial pacing is generally feasible in infants who weigh more than 2 kg, and temporary transvenous pacing can be instituted via an umbilical or femoral venous approach on an emergent basis.

Blocked atrial bigeminy as a cause of bradycardia is generally a benign neonatal rhythm. Treatment is indicated in

the occasional neonate in whom the extrasystoles serve as a trigger for recurrent episodes of supraventricular tachycardia. In these cases, conservative management with digoxin is recommended (Fish and Benson, 2001). Because several studies have described an association with these rhythms and the future occurrence of SVT, outpatient follow-up is also warranted.

FETAL RHYTHMS

IRREGULAR RHYTHMS

One of the most common reasons for referral to the fetal cardiologist is irregular fetal heart rhythms, noted in 1–3% of pregnancies (Strasburger, 2005). The causes of these irregular rhythms are often isolated premature atrial beats (Srinivasan and Strasburger, 2008). Rarely, they may be ventricular in origin. Occasionally, they may be related to intermittent disturbances in AV conduction due to primary AV nodal disease or secondarily related to abnormalities in ventricular repolarization. The vast majority of these ectopic beats are benign. Only a very small subset of cases represent underlying cardiac pathology or progress to persistent, sustained tachyarrhythmias.

Investigation of the fetus referred for an abnormal rhythm should focus on causes of impaired AV conduction and causes of abnormal atrial or ventricular ectopy. Etiopathologic disorders include various degrees of AV block, congenital LQTS, myocarditis, and intracardiac tumors, among others. LQTS is suggested by a combination of bradycardia alternating with tachycardia at different times in the same fetus (Strasburger, 2005). The association of an irregular rhythm with one of the foregoing pathologic entities has been described in 2.6% of fetuses referred for cardiac evaluation (Cuneo et al, 2006). In addition to indicating a specific pathologic diagnosis, the occurrence of frequent benign ectopy such as premature atrial contractions in the fetus has been associated with the subsequent development of sustained tachycardia in 2–3% of affected fetuses (Simpson et al, 1996; Wakai et al, 2003). The presence of cardiomegaly, systolic ventricular dysfunction, AV valve regurgitation, or hydrops suggests the diagnosis of either frequent episodes of SVT or fetal myocarditis. In this circumstance, frequent ultrasound evaluation is required until the ectopy has resolved (Hornberger and Sahn, 2007). Because frequent ectopy may trigger the future occurrence of SVT given the incidence of accessory pathways in the immature heart (Ko et al, 1992; Perry and Garson, 1990; Silver et al, 1973), many institutions recommend providing continued monitoring of the fetal heart on a weekly or biweekly basis (Fouron et al, 2004).

FETAL TACHYCARDIAS

The two most common mechanisms of SVT in utero are ORT in approximately 70% of cases, followed by atrial flutter (AFL) in 20% (Strasburger, 2005) (see Figures 56-10 and 56-11). Less frequent mechanisms make up the remainder. A convenient classification scheme to determine the type of SVT in utero (see Box 56-1) uses the echocardiographic measurement of the interval between the ventricular contraction (V) and the subsequent atrial contraction (A). With this approach, tailored management and prognosis can be assessed for a given fetus based on the suspected type of SVT (Table 56-1). As well, the

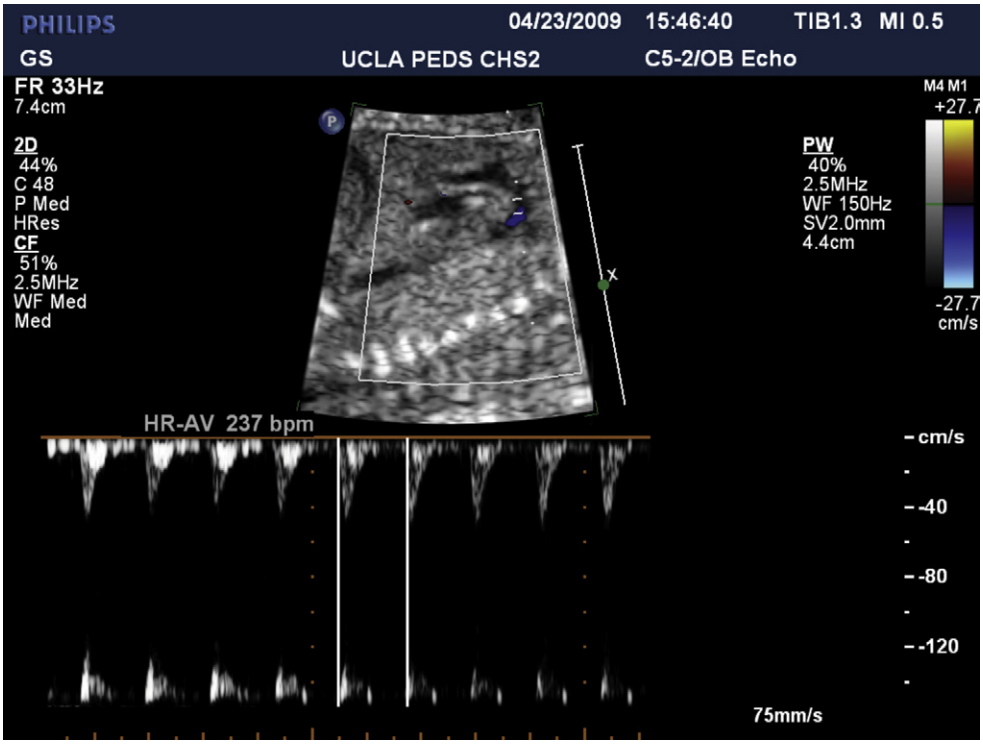

FIGURE 56-10 Doppler echocardiography recording performed in a fetus with Supraventricular tachycardia. The pulse Doppler pattern, measured in the aortic arch, demonstrates an elevated ventricular contraction rate at 237 beats/min. Note that the atrial rate is not apparent in this interrogation.

echocardiographic examination can be used serially to monitor treatment outcomes and to detect impaired myocardial function that may develop with sustained tachyarrhythmias.

Because the immature fetal myocardium is intrinsically less compliant than the mature myocardium (Friedman, 1972), persistent tachycardias are not well tolerated and, in protracted cases, can lead to the development of nonimmune hydrops fetalis. Risk factors for the development of hydrops fetalis include early gestational age (<32 weeks) (Hornberger and Sahn, 2007; Naheed et al, 1996) and prolonged duration of tachycardia (Naheed et al, 1996). As the fetal myocardium is challenged by a further reduction in diastolic filling in the setting of tachycardia, atrial pressures increase, with the pulsations of atrial contraction being ultimately transmitted to the umbilical veins (Gudmundsson et al, 1991). Hepatic venous congestion may then result in decreased synthesis of albumin and decreased serum oncotic pressure. When the elevated hydrostatic pressure of myocardial dysfunction exceeds oncotic pressure, extravasation of fluid into the extravascular space ensues, leading to the clinical manifestation of hydrops fetalis (Grossman et al, 1990). This syndrome is defined by the accumulation of fluid in more than two of the following locations: abdomen, skin, pericardium, or pleural space. At the same time, increased placental venous pressure can lead to polyhydramnios and increased risk of premature delivery with its attendant risks of complications (Maxwell et al, 1988). Poor placental transfer of oxygen to the fetus through a congested placental circuit can be a terminal event in this scenario.

In the fetus, ORT usually presents with intermittent or sustained heart rates in the range of 240 to 260 beats/min and a 1:1 AV relationship. Similar to the situation in the newborn and infant, this rhythm results from conduction down the AV node to the ventricles and back up an accessory pathway to the atrium to complete the circuit. In general, ORT presents at an earlier age than AFL, usually at weeks 28 to 33 of gestation (Hornberger and Sahn, 2007). Progression to hydrops is not uncommon, with risk factors being tachycardia duration, fetal immaturity, and concurrent structural heart disease (Hornberger and Sahn, 2007; Naheed et al, 1996). It has also been suggested that pathway location on the left side is a risk factor for progression to hydrops fetalis due to changes in intracardiac hemodynamics (left atrial pressure is transiently elevated above right atrial pressures, thereby restricting flow across the foramen ovale) (Kannankeril et al, 2003).

The second most common mechanism of fetal tachycardia is AFL, which is characterized by atrial rates of 300–500 per minute and slower ventricular rates due to physiologic block in the AV node. This rhythm is more likely to manifest later in pregnancy than ORT, predominantly at 31 to 34 weeks' gestation. (Jaeggi et al, 1998; Strasburger, 2005). A unique feature of the fetal atrium in the latter part of gestation is its ability to sustain high atrial rates and thereby permit this type of tachycardia (Til et al, 1992). The most common presentation of AFL in the fetus demonstrates ventricular rates of 150 to170 per minute. Because the rhythm usually occurs in the more mature fetus and with lower ventricular rates, it is generally a well-tolerated rhythm (Jaeggi et al, 1998). However, the rhythm can go undiagnosed because of the relatively normal ventricular rates (Fouron et al, 2004). In this situation, the lack of variability in heart rate is the primary clue to the diagnosis. An association with accessory pathways has been reported in many fetuses with AFL (Naheed et al, 1996) and ORT has been reported to

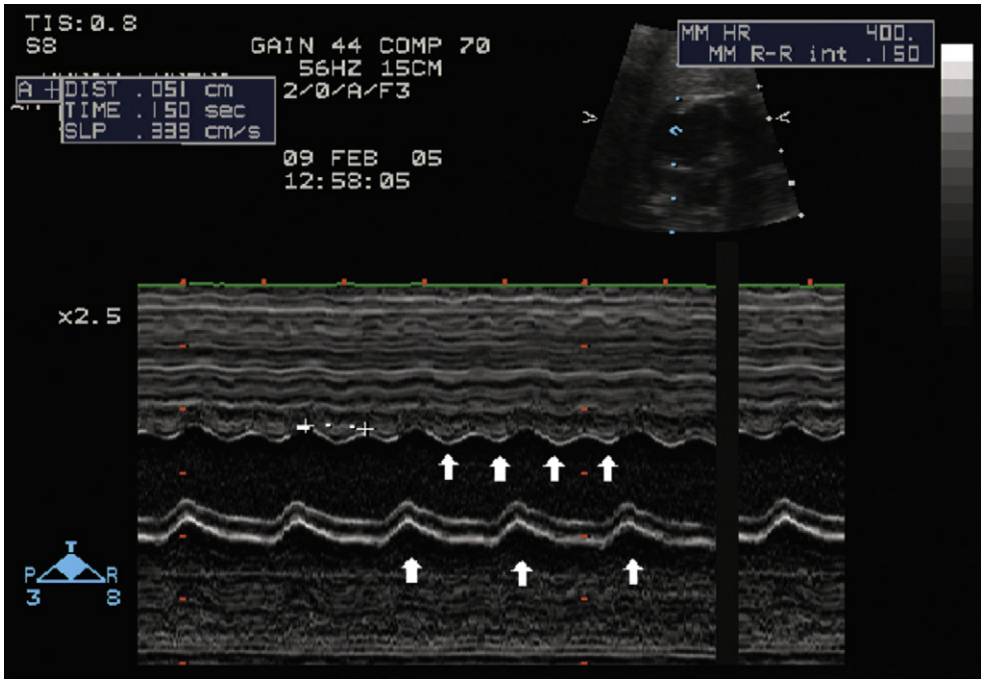

FIGURE 56-11 *(See also Color Plate 23.)* **Fetal M-mode echocardiogram recording of a late second-trimester fetus with atrial flutter.** The ultrasound cursor is positioned through the right atrium, the tricuspid valve, and the right ventricle *(upper right corner)*. The top row of *four arrows* delineates the mechanical right atrial contraction rate, which is faster than the tricuspid valve/right ventricle contraction rate *(bottom three arrows)*.

co-occur spontaneously in 12% to 33% of affected fetuses (Casey et al, 1997; Till and Wren, 1992).

The fetal echocardiogram may suggest less common tachycardias on the basis of an increased fetal heart rate with long ventriculoatrial (VA) times. The differential diagnosis for this group of tachycardias includes AET and PJRT. The latter may be distinguished on the basis of sudden onset, usually triggered by an atrial extrasystole and a consistent heart rate during tachycardia. On the other hand, AET typically demonstrates a gradual warm-up phase with variable physiologic block in the AV node at faster rates. Tachycardia rates with AET are generally on the order of 180 to 250/min (Strasburger, 2005). In general, this class of fetal arrhythmias is the most refractory to treatment both before and after birth.

Occasionally, sinus tachycardia may be confused with AET as noted previously for the newborn. Characteristics specific to sinus tachycardia include a gradual warm-up period, preservation of heart rate variability, and consistently normal conduction through the AV node to the ventricles (Srinivasan and Strasburger, 2008). Causes of fetal sinus tachycardia in excess of 180/min include maternal pyrexia, stimulant medications, and thyrotoxicosis, as well as fetal anemia, distress, and infection (Fisher et al, 1983).

Congenital JET is rare automatic rhythm with a consistent warm-up phase and is generally very resistant to therapy. It has been reported only rarely in utero (Coumel et al, 1976; Villain et al, 1990). As noted previously, JET can be an incessant rhythm that ultimately leads to a secondary cardiomyopathy.

FETAL MANAGEMENT

MANAGEMENT OF IRREGULAR FETAL RHYTHMS

In general, if ectopy is infrequent (i.e., <1 beat per 10 sinus beats), no further investigation is indicated after associated pathologic entities have been ruled out, and follow-up can be handled adequately in the obstetric office (Srinivasan and Strasburger, 2008). With frequent ectopy, however, follow-up auscultation of the fetal heart rate should be performed approximately every 2 weeks, with a repeat echocardiographic examination approximately 4 to 6 weeks to ensure there has been no progression to SVT. Postnatally, an ECG should be obtained to exclude preexcitation (Simpson et al, 1996; Srinivasan and Strasburger, 2008).

FETAL TACHYARRHYTHMIA MANAGEMENT

Management of fetal tachyarrhythmias is generally divided into three categories (Srinivasan and Strasburger, 2008).

1. Observation
2. Transplacental drug therapy
3. Delivery of the fetus

In the situation of intermittent tachycardia (usually defined as lasting less than 12 hours at a time or present during <50% of the echocardiographic examination) (Cuneo et al, 2000; Jaeggi et al, 1998) in a fetus of late gestational age, the rhythm is generally well tolerated and rarely results in myocardial dysfunction. In the absence of hydrops fetalis, many would advocate observation alone (Cuneo et al, 2000; Srinivasan and Strasburger, 2008; Strasburger, 2005). This consists of a brief observation period in the hospital to document arrhythmia duration and frequency and fetal well-being, followed by repeat obstetrical ultrasounds on an initial daily and then biweekly basis to ensure that clinical deterioration does not occur.

At the other extreme, emergent delivery should be reserved for the hydropic fetus who exhibits persistent, difficult-to-treat arrhythmias, in whom both transplacental and direct therapy have failed. If delivery is to be a viable option, however, the fetus should be of a reasonable gestational age (Srinivasan and Strasburger, 2008).

The remaining subgroup of patients are treated with what is referred to as transplacental drug therapy. Multiple treatment algorithms have been proposed, but there is no universal or standard approach. A suggested management algorithm for fetal tachyarrhythmias is presented in Figures 56-12 and 56-13.

The most commonly used and safest antiarrhythmic agent for the treatment of fetal tachycardia remains digoxin, which is associated with a very low mortality per patient treated (Srinivarsan and Strasburger, 2008). Digoxin monotherapy is very effective for the treatment

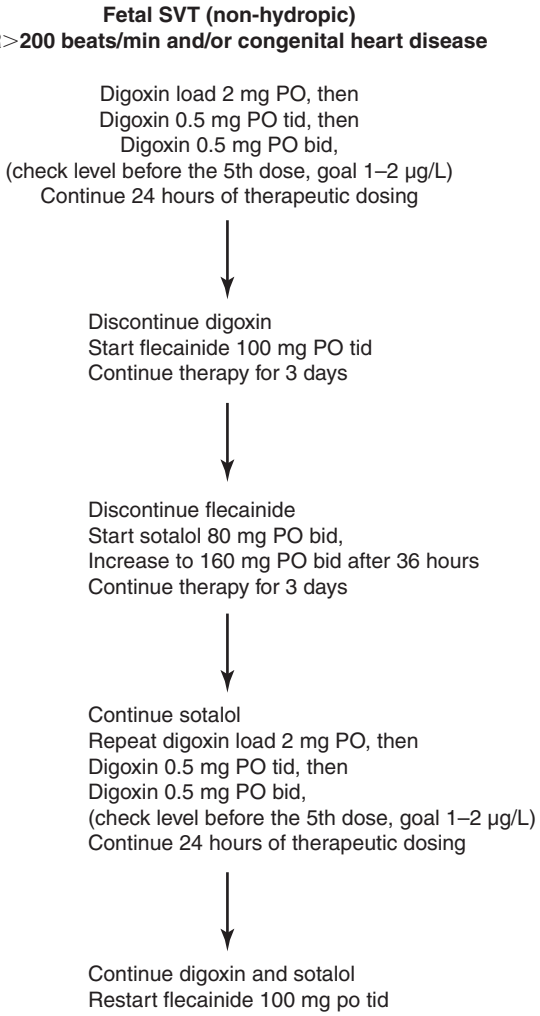

FIGURE 56-12 A suggested management strategy for fetal tachycardia (nonhydropic) with escalation of management for non-responders. *SVT*, Supraventricular tachycardia.

of ORT and, to a lesser degree, AFL. Published series describe an efficacy of 62–100% in the absence of hydrops (Casey et al, 1997; Fouron et al, 2004; Krapp et al, 2003; Simpson and Sharland, 1998). Digoxin is administered to the mother orally or intravenously, depending on institutional preference. Before maternal administration, a maternal 12-lead ECG and cardiology consultation should be obtained to rule out high-risk factors such as preexcitation, or other cardiovascular disease. (This prescreening approach is important when considering any drug for transplacental therapy.) Maternal hypokalemia should also be excluded. Unfortunately, transplacental transfer of digoxin is significantly impaired in the setting of hydrops (Srinivasan and Strasburger, 2008) and efficacy decreases to approximately 25% for hydropic fetuses (Krapp et al, 2003). In this setting, combination therapy is usually required. Of note, some investigators prefer not to use digoxin for the control of fetal arrhythmias unless there is evidence of congestive heart failure because of the very small risk of atrial fibrillation with rapid antegrade conduction across an accessory pathway (Kleinman and Nehgme, 2004).

The most common second-line agent in the treatment of fetal tachycardia is flecainide, a class Ic antiarrhythmic with powerful sodium channel–blocking properties. Flecainide reaches higher concentrations in the placenta in the setting of hydrops fetalis than levels achieved with digoxin and results in cardioversion rate of around 60% of hydropic fetuses with SVT or flutter (Simpson and Sharland, 1998).

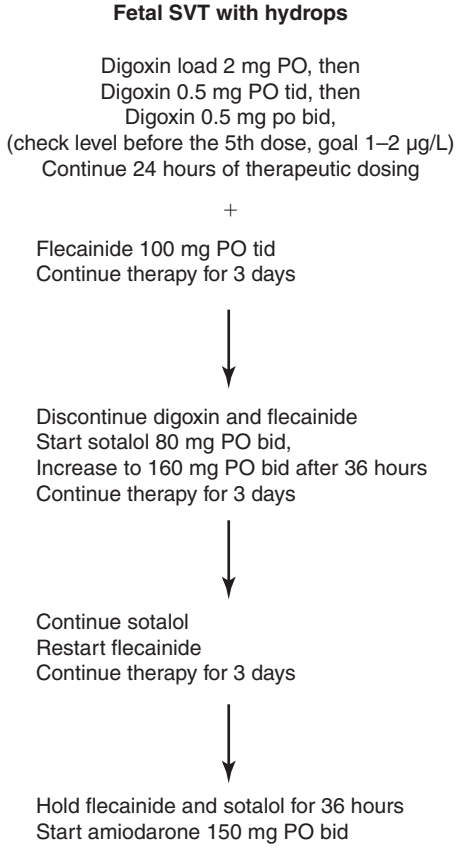

FIGURE 56-13 Suggested management scheme for the fetus with SVT and hydrops fetalis. Combination therapy is recommended up front, because digoxin monotherapy is often ineffective in this setting.

Before initiation of flecainide, the mother should be screened for evidence of structural or ischemic heart disease and a baseline ECG recorded. Renal and hepatic disease should be excluded. The QRS duration should be followed with a decrease in the dosage for >50% increase in duration, or more than 25% if the baseline QRS is >120 ms. Some institutions prefer not to use flecainide because of reports of potential proarrhythmic effects in the neonate (Allan et al, 1991; Fish et al, 1991).

Another second-line agent, sotalol, is the preferred drug at some institutions (Hornberger and Sahn, 2007). Sotalol is a class III antiarrhythmic with beta-blocking properties that has been shown to effectively alter conduction properties in fetal animal models (Houyel et al, 1992). In addition, placental transfer results in a maternal to fetal ratio of nearly 2:1. Maternal renal disease should be excluded before initiating therapy, because this is the major route of elimination, and the maternal ECG should be screened for evidence of QTc prolongation, which can be exacerbated by therapy. If follow-up ECGs demonstrate QTc prolongation >25% above baseline or >500 ms, the drug should be withheld.

One other drug used occasionally in the treatment of fetal tachycardias is amiodarone. Amiodarone has demonstrated safety and efficacy in the control of fetal arrhythmias, but has diminished transplacental transfer and is generally less efficacious. Some centers do not use it at all, whereas others may reserve use for cases in which other pharmacologic approaches have failed.

FETAL BRADYCARDIAS

The pathophysiology and natural history of fetal bradycardia have been discussed earlier. However, the echocardiographic evaluation of the fetus with AV block deserves special mention.

The echocardiographic evaluation of the fetus referred for congenital AV block is based on the search for dissociation of atrial and ventricular contractions with a slow ventricular "escape rhythm." Although scattered case reports and small series have suggested a progressive evolution from first- through third-degree heart block over time, a recent large multiinstitutional retrospective review was unable to demonstrate this pattern in affected fetuses, presumably because of the transient influence of vagal tone as a compounding factor, as well as rapid progression of findings in some cases (Friedman et al, 2008). When congenital AV block is present in a well-compensated fetus, the ejection fraction remains normal with an elevated end-diastolic volume and increased flow across the pulmonary and aortic valves. The cardiothoracic ratio can be determined echocardiographically and followed serially to detect cardiac enlargement and secondary evidence of cardiac decompensation (Paladini et al, 1990). More diffuse sequelae, such as moderate (or greater) tricuspid regurgitation, depressed ventricular systolic function, and atrial endocardial fibroelastosis, as identified in recent studies, are often thought to be secondary to an immune-mediated myocarditis (Friedman et al, 2008). Low fetal heart rate is a well-described risk factor, with values below 55 beats/min associated with increased rates of in utero demise (Schmidt et al, 1991).

FETAL BRADYCARDIA MANAGEMENT

Treatment of immune-mediated congenital AV block is largely empirical and based on fetal hemodynamic status. Although maternal steroid administration has been shown to improve fetal survival (Jaeggi et al, 2004) and even temporarily reverse complete AV block (Jaeggi et al, 2004), multiple adverse effects have been reported, including impairment of postnatal mental development, especially with fluorinated formulations such as dexamethasone (Baud et al, 1999, 2001) and oligohydramnios. Other potential therapies include beta-sympathomimetics (Groves et al, 1995), intravenous immunoglobulin, and plasmapheresis. However, plasmapheresis has generally been found to be ineffective (Buyon et al, 1987). A specific contraindication to beta-sympathomimetics includes congenital LQTS which notably can manifest with 2:1 block. Drug therapy of this type and in this setting can be catastrophic.

Management strategies include surveillance with serial echocardiograms to evaluate the progression of ventricular dysfunction. If decompensation is noted, maternal therapy with betamethasone can be initiated. Fetuses with low or dropping heart rates can be treated with maternal beta-sympathomimetics. Unfortunately, once hydrops fetalis has developed, this latter therapy has not been shown to improve outcomes (Schmidt et al, 1991). Delivery is reserved for cases in which concern for fetal loss is high or if a gestational age of 34–35 weeks has been achieved.

CHAPTER 57

Neurodevelopmental Outcomes in Children with Congenital Heart Disease

Gil Wernovsky

Before the early 1980s, it was uncommon for children with complex congenital heart disease (CHD) to survive into later childhood. The nearly simultaneous advances in congenital cardiac surgery, echocardiography, and intensive care medicine were coupled with the availability of prostaglandins and the developing discipline of interventional cardiology. Together, these factors resulted in a dramatic fall in surgical mortality, with complex repairs taking place at increasingly younger ages. At many large centers, palliative surgery followed by later repair was replaced by primary repair in infancy, while staged reconstructive surgery for various forms of functionally univentricular heart, including those with hypoplastic left heart syndrome (HLHS) was improving with steadily falling rates of surgical mortality. As a result, the early part of the 21st century has seen an increasing number of children with complex CHD entering primary and secondary schooling. Research into their academic and behavioral outcomes has led to some sobering realizations about the outcomes in these children. For the purposes of this chapter, *complex CHD* refers to morphologic abnormalities significant enough to require surgical or catheter intervention as neonates or young infants.

SCOPE OF THE PROBLEM

An estimated 30,000 to 40,000 children are born in North America each year with CHD, and approximately one third require surgical intervention during the 1st year of life. CHD represents a spectrum of anomalies from relatively minor structural defects such as a bicuspid aortic valve or tiny ventricular septal defect through more complex conditions requiring surgical repair in early infancy, such as tetralogy of Fallot (TOF) or HLHS. For this group of children with complex CHD, approximately one half will develop some signs of neurodevelopmental disability as they mature. These typically are mild, but also typically occur in combination, and occasionally they are quite debilitating. Formal evaluations of preschool and school-aged children who were born with complex CHD demonstrate a pattern of neurodevelopmental sequelae that may appear alone or in combination. These include mild cognitive impairment; expressive speech and language abnormalities; impaired visual-spatial and visual-motor skills; attention-deficit/hyperactivity disorder (ADHD); motor delays; and learning disabilities.

The need for early intervention, rehabilitative services, and special education reduces the quality of life for these children and their families, as well as resulting in significant costs to society. As children progress through school, low scores in terms of academic achievement, learning disabilities, behavioral problems, difficulties with social cognition, and ADHD may result in academic failure, development of poor skills both in the classroom and socially, low self-esteem, behavioral disinhibition, and ultimate delinquency. In view of these findings, there is active interest in better understanding the mechanisms of brain injury in these children, in order to design treatment trials and improve long-term outcomes for future patients. In addition, there is active interest in adapting techniques used to treat these disabilities in children without CHD to this growing population (Table 57-1).

MECHANISMS OF INJURY

Central nervous system (CNS) injury in children with CHD is a result of a complex interaction of patient-specific factors and environmental influences including, but not limited to, the effects of various interventions such as cardiac surgery. The risk of a poor developmental outcome varies according to the specific cardiac defect. In addition, there is significant interindividual variation in developmental outcome, even among children with the same cardiac defect. Cerebral ischemia before, during, and after the surgical repair of CHD has been proposed to be a primary mechanism of CNS injury. However, many factors may contribute to neurologic dysfunction. There is growing recognition that the brain is abnormal at birth in many neonates with complex CHD. These recent studies have identified a surprisingly high incidence of white matter injury, stroke, and hemorrhage, as well as brain immaturity such as an underdeveloped operculum (Licht et al, 2009; Mahle et al, 2002; Miller et al, 2007). These findings are due in part to abnormalities of fetal blood flow and substrate delivery leading to immaturity of the developing CNS (Donofrio et al, 2003; Kaltman et al, 2005; Limperopoulos et al, 2010) and in part due to congenital structural CNS abnormalities (Glauser et al, 1990; Mahle et al, 2002).

FETAL CEREBROVASCULAR PHYSIOLOGY AND OXYGEN DELIVERY

Ultrasound studies in the fetus have revealed that cerebral vascular resistance is altered in the presence of congenital cardiac disease. Fetuses with left-sided disease, for example, hypoplastic left heart syndrome, were shown to have decreased cerebral vascular resistance compared with normal fetuses (Donofrio et al, 2003; Kaltman et al, 2005). In patients with aortic atresia, the fetal cardiac output from the arterial duct must deliver flow cephalic to the brain as well as caudal to the low-resistance placenta. It is speculated that cerebral vascular resistance must therefore

TABLE 57-1 The Neurodevelopmental Challenges Seen in Children With Complex CHD

Age Group	Relevant Domains	Findings and Clinical Impact
Infants and toddlers (approximately 0–3 years)	Behavior and temperament	Negative in mood and difficult to soothe, particularly in infants with forms of single ventricle. High incidence of parental anxiety and clinical depression.
	Gross motor	Hypotonia and hypertonia both described. May have delayed rolling, sitting, crawling, walking, running, and stair skills. Likely less active than peers. Decreased prone skills.
	Fine motor	Delays affect abilities to reach toward objects. These include difficulty with grasp and exploration of toys with both hands, limited ability to operate levers or push buttons on toys, and decreased play skills, including stacking and container play. Decreased self-feeding skills and dressing skills.
	Oral motor	Poorly coordinated suck and swallow as infants.
	Language	Delays in expressive language more prevalent than receptive language. Reduced ability to imitate oral movements and speech sounds.
	Cognition	Difficult to assess in infants; standardized testing has limited predictive validity for later intelligence. Individual scores on the Mental Developmental Index of the Bayley Scales of Infant Development are typically in the normal range, although group mean values are frequently below average. Difficulties have been identified with object permanence, cause-effect, and attention to task.
	Visual-perceptual	Delays lead to decreased ability to target, reach toward toys and other objects. Decreased ability to stack and copy block designs and in prewriting skills such as tracing and copying simple shapes.
	Sensory processing	May have sensitivity to touch, position changes, different textures of toys/clothes, sounds, and bathing.
Preschool children (approximately 3–5 years)	Behavior and temperament	Increased incidence of internalizing (anxiety, depression) and externalizing (hyperactivity, impulsivity, disruptive) behaviors.
	Gross motor	Decreased coordination and balance may lead to "clumsiness" with ball skills, stairs, running, etc. May have difficulty keeping up with peers. Postural challenges and fatigue with tabletop activities.
	Fine motor	Decreased coordination with hands and quality of grasp, leading to challenges with school tasks, including the use of writing utensils, prewriting skills, scissor skills. Difficulties with activities of daily living skills including self-feeding, dressing and fasteners (Velcro, zippers, etc.) may be present.
	Language	Apraxia of speech, or difficulty with the motor planning of speech. Reduced intelligibility of connected speech.
	Cognition	Standardized testing typically at or slightly below average; cognitive delays are rarely significant.
	Visual-perceptual	Difficulties in identifying speed of moving objects, ball catching, tracking moving objects, and color differences, noting things as "similar" or "different." May have difficulties with coloring in lines, puzzles, and connect the dots.
	Sensory processing	May have sensitivity to certain materials used in activities of daily living, school and play tasks. May have decreased awareness of body in space. May seek out and/or avoid sensory input.
Children (approximately 5–12 years)	Behavior	Difficulty sustaining attention to tasks, regulating activity level and emotions. Increased incidence of internalizing (anxiety, depression) and externalizing (hyperactivity, impulsivity, disruptive) behaviors.
	Motor	Decreased balance and strength, as well as higher-level coordination skills. Also may have decreased ability to keep up with peers; may be the "last one chosen for sports activities." Decreased fine motor abilities affecting important school tasks such as handwriting skills, scissors ability, and activities of daily living such as shoe-tying, grooming, and self-care.
	Speech and language	Reduced intelligibility of connected speech. Delays in expressive language that may affect higher-level cognitive, memory and executive functioning. Apraxia of speech, or difficulty with the motor planning of speech. Simplistic story-telling. Echolalia and repetition of questions.
	Cognition	Individual scores on standardized IQ and achievement testing are frequently within normal limits, although group mean values lower than expected.
	Visual-perceptual and problem solving	Decreased handwriting skills, speed of note-taking, and ability to copy notes from board/book. Difficulties in checking work. Difficulty with word searches, hidden picture activities, and mazes.
	Executive function and working memory	Difficulty following multistep instructions, organizing materials, and sequencing tasks. Slower processing of incoming information and written output.
	Personal/social	Deficits in adaptive functioning (activities, social relationships, school performance).

TABLE 57-1 The Neurodevelopmental Challenges Seen in Children With Complex CHD—cont'd

Age Group	Relevant Domains	Findings and Clinical Impact
	Sensory processing	May have sensitivity to certain materials used in activities of daily living, school, and play tasks. May have decreased awareness of body in space. May seek out and/or avoid sensory input.
Adolescents and young adults (>12 years)	Behavior	Increased incidence of internalizing (anxiety, depression) and externalizing (hyperactivity, impulsivity, disruptive) behaviors.
	Motor	If easily fatigued and/or decreased strength, may self-limit and choose activities that do not require physical activity. Decreased handwriting skills. Decreased speed of note taking.
	Speech and language	An early history of speech and language delay or disorders will likely affect higher-level cognitive and executive functioning skills.
	Cognition	Individual scores on standardized IQ and achievement testing are frequently within normal limits, although group mean values lower than expected. Increased prevalence of aptitude-achievement discrepancies.
	Visual-perceptual and problem solving	Decreased speed of note-taking from board/book. Decreased ability to read complex graphs/diagrams. Implicated in difficulties in mathematics.
	Executive function and working memory	Difficulty following multistep instructions, organizing materials, and sequencing tasks. Slower processing of incoming information and written output. Limitations to logical hypothesis generation and testing and to applying principles to solve problems.
	Higher-order theory of mind	Weaknesses in higher order "theory of mind," such as social cognition (understanding what another may be thinking or feeling), empathy, cognitive flexibility, and planning.
	Personal/social	Alexithymia (inability to express feelings with words). Difficulty identifying and describing internal state. Strained interpersonal relationships.

Approximately 50% of children with complex CHD have one or more of these domains affected. This has been termed *high prevalence–low severity* disability. However, although many of these findings are mild individually, in combination they may significantly impair school performance and employment opportunities in adulthood.

be lower than normal to allow adequate blood flow to the developing brain. Fetuses with right-sided obstructive lesions, for example, TOF, were also shown to have increased fetal cerebral vascular resistance (Kaltman et al, 2005). In these children, it is speculated that the obstruction to flow into the pulmonary arteries changes the usual delivery from the patent arterial duct caudal to the placenta. In these cases, the left ventricle must contribute to placental blood flow antegrade from the ascending aorta, with a resultant increase in cerebral vascular resistance. The impact of these alterations in fetal cerebral vascular resistance is unclear, but they almost certainly play a role in subsequent neurologic development.

In the normal fetus, the intracirculatory patterns created by the normal fetal connections result in preferential streaming of the most highly oxygenated fetal blood to the developing brain, and the most desaturated blood to the placenta. When significant structural disease exists within the heart, these beneficial patterns are likely to be altered. Although not yet confirmed by fetal magnetic resonance spectroscopy, fetuses with transposition are likely to have the blood with the lowest saturation of oxygen returning to the ascending aorta and brain, while blood with the highest saturation returns to the abdominal organs and placenta. Speculation on the consequences of the transposed fetal circulation as an explanation for the high incidence of macrosomia in these infants dates back almost 50 years (Naeye, 1966), and this pathomechanism has also been offered as an explanation for the increased incidence of relative microcephaly seen in transposition. Complete mixing, as seen in fetuses with functionally univentricular hearts, fetal will produce intermediate values of cerebral saturation of oxygen, but lower than those seen in the normal fetus.

It has long been recognized that the neurologic status of newborns with CHD is frequently abnormal before open heart surgery. Gillon (1973) reported neurologic abnormalities including tone abnormalities, abnormal posturing, weak cry, and poor coordination of suck, swallow, and breathing in many infants before open heart surgery. After birth, cerebral blood flow has been shown to be significantly lower than normal in some patients, because of low cardiac output or a low diastolic blood pressure ("steal") secondary to an open ductus arteriosus (Licht et al, 2004). In some lesions, such as total anomalous pulmonary venous return with obstruction and transposition of the great arteries (TGA) for later profound hypoxemia and acidosis may result immediately after birth secondary to the uncorrected CHD. Certain procedures, such as balloon atrial septostomy, have been linked to an increased risk of stroke by some authors (McQuillen et al, 2006; Mukherjee, 2010) but not others (Applegate and Lim, 2010; Petit et al, 2009). Genetic syndromes, present in a significant proportion of children with complex CHD, play a role in abnormalities of brain structure as well as developmental delays (Andelfinger, 2008). A study from Montreal Children's Hospital evaluated 56 consecutive neonates referred for open-heart surgery (Limperopoulos et al, 1999). Neurobehavioral and neurologic abnormalities, including hypotonia, hypertonia, jitteriness, motor asymmetries, and absence of suck

reflex, were noted in more than 50% of patients before surgery. Preoperative seizures were present in three patients; 35% were microcephalic, and 12.5% were macrocephalic. Finally, all patients with a right-to-left shunt have the potential for air or particulate emboli to reach the brain from intravenous catheters, whether before or after surgery.

Hypoxemia, low cardiac output, and cardiac arrest in patients with uncorrected CHD may result in CNS ischemia and injury. Aisenberg et al (1982) evaluated mental and motor development in 173 infants with uncorrected CHD. Developmental delay was present in 25% and was apparent as early as 2 months of age. Congestive heart failure and hypoxemia were risk factors for developmental delay. Kurth et al (2001), from The Children's Hospital of Philadelphia, used near infrared spectroscopy (NIRS) to evaluate cerebral oxygenation in 93 infants with heart defects before surgery. Decreased cerebral oxygenation was present in many patients, particularly infants with TOF and those with HLHS or other single-ventricle physiology. Very low cerebral oxygen saturations (<38%) were found in 13 patients, suggesting that patients with CHD are at risk for cerebral ischemia and CNS injury in the preoperative period (Box 57-1).

MICROCEPHALY

Head circumference at birth is a surrogate for growth of the brain, and in neonates without congenital cardiac disease, microcephaly is independently associated with later developmental delays and academic difficulties. The incidence of microcephaly at birth is increased in children with complex CHD, approaching a rate of 25% in some reports (Hinton et al, 2008; Mahle et al, 2002; Miller et al, 2007; Shillingford et al, 2007), and persists into later infancy. Although the causes are speculative, and most certainly multifactorial, a recent report in children with HLHS, in whom the median head circumference was at only the 18th percentile, revealed that patients with microcephaly had significantly smaller ascending aortas than those without, suggesting that reduced flow to the brain from the left ventricle secondary to anatomic hypoplasia of the ascending aorta may result in diminished brain growth (Shillingford et al, 2007).

THE OPEN OPERCULUM

The opercular region is that covering the so-called insula and is made up of frontal, temporal, and parietal cortical convolutions. In magnetic resonance and computed tomography imaging studies of neonates with complex CHD, underdevelopment of the operculum may be seen in nearly one quarter of the patients and is a marker for functional immaturity of the brain. This may be a unilateral or bilateral finding and has been termed underoperculinization, or an open operculum. The operculum is thought to be related to oral motor coordination, taste, and speech, particularly to expressive language. In adults who experience a stroke in this area of the brain, the so-called Foix-Chavany-Marie syndrome, deficits include impairment of voluntary movements such as chewing and deglutition, dysarthria, and problems with taste. In macaque monkeys, receptive fields on the tongue, lips, and palate have been mapped to the operculum. Given the high prevalence of problems with feeding, delay with expressive language, and oral-motor apraxia in children with complex cardiac malformations, as well as the increasing recognition of a high prevalence of an open operculum, one can speculate that some patients with these oral-motor developmental disabilities may have a structural underdevelopment of the operculum. Studies are currently under way to test this hypothesis.

BOX 57-1 Patient-Specific Risk Factors for Neurodevelopmental Delays in CHD

- Congenital central nervous system abnormalities
- Genetic syndromes
- Genetic susceptibility to cerebral ischemia-reperfusion injury
- Underlying cardiac diagnosis
- Additional congenital anomalies
- Lower birthweight (prematurity and/or intrauterine growth restriction)

PERIVENTRICULAR LEUKOMALACIA

Injury to the white matter, a common finding in premature infants, has been increasingly recognized in full-term neonates with complex CHD. It has been suggested that decreased blood flow to the brain preoperatively is significantly associated with lesions in the white matter, affecting slightly more than one quarter of neonates before surgery (Mahle et al, 2002). Periventricular leukomalacia was also found in slightly more than half of a cohort of patients who underwent surgery for complex CHD, but was rarely detected in those who underwent surgery between 1 and 6 months of age (Galli et al, 2004). Magnetic resonance imaging has shown not only a high incidence of injury to the white matter but also evidence of immature brain metabolism and microstructure, which are strikingly similar to findings seen in the premature population.

Periventricular leukomalacia is believed to arise from several factors, including the high susceptibility of the immature oligodendrocyte to hypoxic ischemic injury, as well as the watershed distribution of flow of blood to this area between the small arteries that penetrate from the cortex and those that arise centrally and run radially outward. This watershed area is particularly prone to ischemia during decreases in cerebral perfusion pressure. In premature infants, severe degrees of periventricular leukomalacia have been associated with cerebral palsy, whereas mild degrees of injury have been associated with developmental delay, motor difficulties, and behavioral disorders—a developmental "phenotype" remarkably similar to that of school-age children with complex CHD.

THE EFFECT ON THE BRAIN OF CARDIAC SURGERY

Even though there is increasing evidence for congenital and acquired CNS injury in children with CHD before surgery, many investigators still focus on intraoperative management as the primary mechanism of CNS injury. As

opposed to all of the risk factors for abnormal neurologic development discussed thus far, variation in intraoperative support, such as the conduct of cardiopulmonary bypass, is one of the few modifiable risk factors that can be altered to improve long-term neurologic outcomes. Multiple factors may contribute to CNS injury during surgical repair, including hypoxemia, cerebral hypoperfusion, and cerebral embolism (particulate and/or air). Factors that possibly contribute to intraoperative neurologic injury include the type of support during surgery (deep hypothermic circulatory arrest [DHCA] or continuous cardiopulmonary bypass [CPB]), use of hemodilution, the degree of cooling, use of steroids, and type of blood gas management.

Use of CPB exposes the blood to foreign surfaces of the bypass circuit, initiating a systemic inflammatory response characterized by neutrophil activation, complement activation, and increased circulating levels of inflammatory cytokines (du Plessis, 1999). This inflammatory response may result in increased capillary permeability, tissue edema, and organ dysfunction. When continuous CPB is used, perfusion to the body and brain is maintained. When DHCA is used, there is a period of obligate global cerebral ischemia followed by reperfusion. Use of DHCA provides a bloodless surgical field, facilitating meticulous completion of the repair, and decreases the duration of blood exposure to the bypass circuit, but at the cost of a period of global cerebral ischemia. Continuous CPB maintains perfusion to the brain and body but increases the duration of blood exposure to the bypass circuit, which may increase the severity of inflammatory response. Use of continuous CPB avoids the period of cerebral ischemia but results in a greater increase in total body water and more severe dysfunction of other organs, such as the lungs (Skaryak et al, 1996; Wernovsky et al, 1995). These multiple facets of CPB have received considerable attention and have been the subject of active research. Of the many potential modifiable technical features of cardiopulmonary bypass (Box 57-2), there are three that have been most extensively studied, particularly with randomized clinical trials.

BOX 57-2 Procedural and Environmental Risk Factors for Neurodevelopmental Delays in CHD

PREOPERATIVE
- Cardiac arrest
- Low cardiac output
- Profound hypoxemia

OPERATIVE
- Longer duration of cardiopulmonary bypass
- Longer duration of deep hypothermic circulatory arrest
- Air or particulate embolization

POSTOPERATIVE
- Hypoxemia
- Hypotension
- Low cardiac output
- Cardiac arrest
- Postoperative seizures
- Air or particulate embolization
- Longer length of hospital stay

OTHER
- Chronic (preoperative/postoperative) hypoxemia
- Lower socioeconomic status
- Higher parental stress

pH MANAGEMENT

In one very important trial at Children's Hospital, Boston (du Plessis et al, 1997), developmental and neurologic outcomes were evaluated in infants undergoing biventricular repair of a variety of cardiac defects at less than 9 months of age who were randomized to either alpha-stat or pH-stat management during deep hypothermic cardiopulmonary bypass. Although there were some benefits reported with the use of pH-stat management for outcomes in the immediate perioperative period, the use of either strategy was not consistently related to either improved or impaired neurodevelopmental outcomes at 1 to 4 years of age (Bellinger et al, 2001). On the Bayley Scales of Infant Development, there was no effect of treatment on the Psychomotor Development Index (PDI). The Mental Development Index (MDI), in contrast, varied significantly depending on the underlying anatomic diagnosis. For patients with transposition and TOF, use of pH-stat resulted in a slightly higher mental developmental index, although the difference was not statistically significant. In patients with a ventricular septal defect, the effect was opposite, with use of alpha-stat management resulting in significantly improved scores. There was a significant effect of cardiac diagnosis on outcomes. Both scores of the Bayley examinations were significantly higher in those with transposition than in those with the other cardiac defects. Despite the equivocal data in this early report, with no longer-term follow-up yet available, many centers are currently using pH-stat management exclusively in all operations on neonates and infants. Further research in this area, based on additional potential modifiers, for example, cardiac diagnosis, age, and severity of preoperative hypoxemia, should continue.

HEMATOCRIT DURING BYPASS

During cardiopulmonary bypass, hemodilution has been widely applied based on the notion that increased viscosity would be detrimental during periods of profound or even moderate hypothermia. Results in animals suggesting that higher hematocrit levels resulted in better cerebral protection were recently investigated in two randomized clinical trials (Jonas et al, 2003; Newburger et al, 2008). The results of these trials indicated that hematocrit levels during bypass below 24% were associated with lower scores in the PDI of the Bayley Scales of Infant Development, although the improvement was not seen at hematocrit levels of 35% versus 25%. In addition, lower hematocrit levels were associated with a more positive fluid balance after surgery and higher serum lactate levels.

DEEP HYPOTHERMIC CIRCULATORY ARREST

Much has been written on the potentially deleterious effects of prolonged circulatory arrest with profound hypothermia in cardiac surgery for neonates and infants. It

is generally agreed that very prolonged periods of uninterrupted circulatory arrest may have adverse neurologic outcomes. Close inspection of the data shows that the effects of short durations of circulatory arrest are inconsistently related to adverse outcomes, and that the effect of circulatory arrest is not a linear phenomenon. The effects are most likely modified by other preoperative and postoperative factors related to the patient. Some reports, most in an earlier era of cardiac surgery, demonstrate a detrimental effect of circulatory arrest on a variety of outcomes relating to the CNS whereas some demonstrate either an inconsistent effect or no effect. Some have taken the stance that, because a majority of studies suggest a negative effect of circulatory arrest, it should be avoided at all costs. Innovative and challenging strategies have been designed to provide continuous cerebral perfusion during reconstruction of the aortic arch or intracardiac repair. The avoidance of circulatory arrest, however, by necessity requires an increased duration of CPB. This has consistently been shown to have an adverse effect on outcomes in both the short and longer term. A randomized trial comparing circulatory arrest to continuous cerebral perfusion has recently been completed at the University of Michigan (Goldberg et al, 2007). This demonstrated no improvement in developmental scores at 1 year of age. Similar findings were reported in a contemporaneous but nonrandomized study at Children's Hospital of Boston (Visconti et al, 2006). It seems imprudent to change practice based on studies with only short-term developmental assessment. Developmental studies in infants have very limited predictive validity for long-term outcomes, for patients with or without CHD.

Perhaps the best conducted study in this regard, which emphasizes this point, is the Boston Circulatory Arrest Study (Bellinger, 2008; Bellinger et al, 1997, 1999, 2003, 2009; Helmers et al, 1997; Newburger et al, 1993; Rappaport et al, 1998; Wernovsky et al, 1995; Wypij et al, 2003). In this study, a cohort of children with transposition undergoing an arterial switch were randomly assigned to intraoperative support predominantly by DHCA or predominantly by CBP at low flow. Earlier reports suggested that the group as a whole was performing below expectations in many aspects of evaluation, with worse outcomes for those undergoing circulatory arrest in the areas of postoperative seizures and motor skills at 1 year of age, as well as behavior, speech, and language at the age of 4 years. Mean intelligence quotient at the age of 4 was lower than expected, at 93, with no difference according to assignment. Many centers began avoiding even short periods of circulatory arrest based on these and other reports. In 2003, assessments of quality of life and detailed standardized testing were reported. Neurodevelopmental analyses when the patients were aged 8 years revealed that the intelligence quotients for the cohort as a whole were then closer to normal, at 98 versus the population mean of 100. The patients did demonstrate significant deficits in visual-spatial and visual-memory skills, as well as in components of executive functioning such as working memory, hypothesis generation, sustained attention, and higher-order language skills. In other words, the children had difficulty coordinating skills to perform complex operations. Those repaired using circulatory arrest scored worse on motor and speech functioning, whereas those undergoing bypass at low flow demonstrated worse scores for impulsivity and behavior. When compared with a normative sample, parents of the entire cohort reported significantly higher frequencies of attention problems, developmental delay, and problems with learning and speech. More than one third of the population required remedial services at school, and 1 in 10 had repeated a grade. Thus, in this population of patients who underwent the arterial switch operation between 1988 and 1992, there appears to be a correlation between congenital CHD and its surgical repair, with difficulties occurring later with speech and language, behavioral difficulties, and execution planning in childhood. Whether current modifications of techniques will improve the outcomes in the long term remains the subject of ongoing study. This well-designed trial, with superb follow-up, enrolled neonates for whom the management plan included an arterial switch operation between 1988 and 1992. Hence, the results reflect the perioperative and surgical care delivered in that era, and thus may not be generalizable to the current era, or to other congenital cardiac lesions. For example, some features of routine postoperative care in that era, including extension of the anesthetic period for at least 48 hours, active rewarming in the intensive care unit after surgery, and hyperventilation to reduce the risk of pulmonary hypertension, may each independently and adversely affect neurodevelopmental outcomes. In addition, those patients randomized to receive predominantly continuous bypass also underwent a relatively brief period of circulatory arrest. Thus, the study does not compare use of circulatory arrest to no circulatory arrest. The results nonetheless serve to show the multiple factors that influence developmental outcome at school age and show that factors related to poorer outcome, such as use of DHCA, which seem apparent and significant on early testing, may be attenuated or even abolished during longer-term follow-up, as other factors assume a more important role.

POSTOPERATIVE FACTORS

CNS injury may occur or be exacerbated in the postoperative period. Most studies have focused on the operating room as the site of CNS injury; however, events in the cardiac intensive care unit may be equally important. Cerebral ischemia can result from low cardiac output or severe hypoxemia. Postoperative hyperthermia may increase the metabolic needs of the brain, resulting in worsening CNS injury (Shum-Tim et al, 1998). In addition, postoperative cardiac arrest may result in significant CNS injury. After cardiac surgery with CPB with or without DHCA, cerebral autoregulation may be impaired (Bassan et al, 2005). After surgery, especially in neonates and infants, there is a predictable and reproducible fall in cardiac output (Wernovsky et al, 1995). This period of decreased oxygen delivery, usually within the first 24 hours after surgery, represents a particularly vulnerable time for the CNS, especially if associated with increased oxygen consumption (as with fever, pain, seizures, or agitation). At present, studies linking postoperative hemodynamic lability to long-term CNS outcomes are lacking. However, postoperative hypotension has been shown to be related to new or worsened white matter injury (Galli

et al, 2004), especially if combined with hyperventilation (Samanta et al, 2009), which may further reduce cerebral blood flow. Finally, there are a growing number of reports that an increased length of stay in the hospital, and in the intensive care unit in particular, is associated with worse long-term outcomes, and this association is *independent* of the reasons for the prolonged length of stay, such as sepsis or low cardiac output (Fuller et al, 2009; Mahle et al, 2006; Matsuzaki et al, 2010; Newburger et al, 2003).

Thus, it may be very difficult to completely define the etiologic factors leading to CNS injury in individual patients with CHD. The neurologic sequelae of cardiac surgery can be subtle in very young infants. The full extent of an injury is often not fully recognized until long after the event, when certain cognitive and higher executive skills are required. Neurologic examination of neonates and infants is limited, and developmental testing, even at 1 year of age, has imprecise predictive value for long-term neurodevelopmental outcomes. Investigators have evaluated potential surrogate measures such as electroencephalographic monitoring and magnetic resonance imaging of the brain. However, the predictive value of these tests in isolation for long-term neurodevelopmental outcome is uncertain. Examination of preschool- and school-aged children provides greater sensitivity and specificity in determination of neurologic defects and remains the standard for evaluation of the neurologic sequelae of infant cardiac surgery.

GENETIC SUSCEPTIBILITY TO NEUROLOGIC INJURY AND DEVELOPMENTAL DYSFUNCTION

All of the foregoing risk factors do not fully explain either the high frequency or the pattern of neurodevelopmental dysfunction described in children with complex CHD, suggesting that other patient-specific factors may be important determinants of neurologic injury. Intellectual development and cognitive function are highly heritable and probably are dependent on multiple genes, as well as on environmental factors. Numerous inherited defects or syndromes that are associated with compromised mental development and intellectual capacity (e.g., Down syndrome, Williams syndrome, DiGeorge syndrome) may have CHD as one of the phenotypic outcomes. Although the genetic basis for most cardiac defects has not been delineated, specific genetic anomalies have been implicated in the pathogenesis of some defects. For example, microdeletions of chromosome 22 are associated with DiGeorge syndrome and a variety of heart defects, including TOF, truncus arteriosus, and interruption of the aortic arch. Developmental abnormalities are present in children with 22q11 microdeletions, even those with no cardiac abnormalities (Gerdes et al, 1999). Thus, children with cardiac defects and 22q11 microdeletions may be developmentally impaired independent of the cardiac defect and cardiac surgery. It may be difficult to separate the adverse developmental sequelae of an underlying genetic anomaly from those related to CHD and cardiac surgery.

Risk of disease or injury in response to an environmental stimulus is a complex interaction between genetic susceptibility and environmental exposures. Interindividual variation in disease risk and in the response to environmental factors is significant. The risk may be modified by age, gender, ethnicity, and the extent of exposure to environmental factors. Multiple genes are involved in determining an individual's response to a specific environmental factor. Interindividual variation in response to environmental exposures, such as cardiac surgery, probably is due in part to genetic polymorphisms. Common genetic variants, often due to single-nucleotide substitutions, occur with a frequency of greater than 1%. For a child with CHD, environmental factors include cardiac surgery, use of DHCA, need for repeated operations, and socioeconomic status. The role of genetic polymorphisms in determining susceptibility to CNS injury in children with CHD is not known.

Recent studies suggest that polymorphisms of apolipoprotein E may be predictors of adverse neurodevelopmental sequelae after infant cardiac surgery (Burnham et al, 2010; Fuller et al, 2009; Gaynor et al, 2003, 2009), as has been similarly reported in adults (Newman, 1995; Steed et al, 2001; Robson et al, 2002). It is likely that multiple genes modulate the CNS response to CPB, DHCA, and other environmental factors modifying the risk and pattern of injury (Ozbek et al, 2005).

The underlying cardiac diagnosis may have a significant and independent impact on neurodevelopmental outcome and may modulate the effects of neuroprotective strategies. Presence of a ventricular septal defect (VSD) in patients with transposition of the great arteries is a significant risk factor for poor developmental outcome (Bellinger et al, 1995, 1999; Newburger et al, 1993). In the pH study mentioned previously, developmental and neurologic outcomes were evaluated in infants undergoing repair of a variety of cardiac defects before the age of 9 months who were randomized to either alpha-stat or pH-stat blood gas management strategy during deep hypothermic CPB (Bellinger et al, 2001). Children with transposition (TGA) with or without VSD, TOF, isolated VSD, atrioventricular canal defect, truncus arteriosus, and total anomalous pulmonary venous return were enrolled. There was no effect of treatment group on the PDI score of the Bayley Scales of Infant Development. The MDI score, however, varied significantly depending on treatment group and diagnosis. For patients with TGA and TOF, use of pH-stat resulted in a slightly higher MDI, although the difference was not statistically significant. Of interest, in the VSD subgroup, the treatment effect was opposite with use of alpha-stat management, resulting in significantly improved scores. Cardiac diagnosis had a significant effect on outcomes: PDI and MDI scores were significantly higher in the TGA group compared with those noted for the other cardiac defects. A study at The Children's Hospital of Philadelphia evaluated the neuroprotective effect of allopurinol, a scavenger and inhibitor of oxygen free radical production, during infant cardiac surgery using DHCA (Clancy et al, 2001). A total of 318 infants (131 with HLHS) underwent surgery. Allopurinol provided significant neuroprotection only in patients with HLHS; no benefit was found in the non-HLHS patients.

HYPOPLASTIC LEFT HEART SYNDROME

Previous studies have suggested that developmental outcome is worst for patients with complex cardiac defects, such as HLHS, who require multiple operations during

infancy and early childhood (Wernovsky et al, 2000). Rogers et al (1995) at the Children's Hospital of Buffalo evaluated 11 survivors of staged repair for HLHS at a mean age of 38 months. Seven children (64%) had major developmental disabilities and were considered to be mentally retarded. Two had severe cerebral palsy. Gross motor delays were present in 5 children (45%). At follow-up, microcephaly was present in 8 children (73%) and correlated with cognitive delay. More recent studies, however, suggest that developmental outcomes for these children have improved. Kern et al (1998) at Columbia-Presbyterian Medical Center evaluated early neurodevelopmental outcome after stage I reconstruction for HLHS. Twelve patients who had undergone the Norwood procedure and subsequent surgery were evaluated along with a control group of children including siblings and first cousins. DHCA was used for the stage I reconstruction, with a mean duration of 56 minutes. The median scores for Full-Scale IQ were in the lower range of normal. Although scores for control subjects were generally higher than for patients, the differences between the two groups in intelligence testing did not reach statistical significance. The only statistically significant difference was in adaptive behavior, with the controls scoring higher. There was no correlation between neurologic outcome and bypass time, age at surgery, number of operations, or age at testing. Longer duration of DHCA was a risk factor for lower Full-Scale IQ.

Eke et al (1996) from Loma Linda evaluated the neurologic sequelae of DHCA in patients undergoing neonatal cardiac transplantation. The majority of these patients had HLHS. Developmental outcomes were evaluated using the Bayley Scales of Infant Development. There was no correlation between the duration of DHCA and neurodevelopmental outcome. Mahle et al (2000) at The Children's Hospital of Philadelphia evaluated neurodevelopmental outcomes in school-aged survivors of reconstructive surgery for HLHS. A majority of patients had IQ scores within the normal range; however, mean performance for the study group was lower than population norms. In a multivariable analysis, only the occurrence of a preoperative seizure predicted lower Full-Scale IQ. Duration of DHCA was not a predictor of lower IQ, although this lack of correlation may be due to the narrow spread of DHCA time in the study cohort. Scores on achievement tests (mathematics and reading) were lower than expected for the normal population. Nearly two thirds of the cohort had a clinical diagnosis of ADHD.

In another, more recent cohort, cognitive outcomes in school-age children with HLHS were assessed with the Wechsler Preschool and Primary Scale of Intelligence-Revised (Goldberg et al, 2000). Mean scores for the entire cohort were within the normal range for Full-Scale IQ, Verbal IQ, and Performance IQ. Scores for patients with HLHS were lower than for patients with other defects but were not significantly different from scores for the standard population. Use of DHCA was associated with lower scores. Because of the significant mortality previously associated with staged reconstructive surgery for HLHS, most of these studies evaluated relatively small numbers of young patients. In addition, these studies provide conflicting evidence concerning the significance of DHCA as a risk factor for adverse neurodevelopmental outcomes. It is of interest to examine the developmental abnormalities seen in children with HLHS who underwent staged surgical reconstruction (Norwood, Glenn, and Fontan procedures) and compare them to the findings after transplantation for the same disease (Mahle et al, 2006). The patterns of dysfunction are remarkably similar, despite the markedly different therapeutic strategies. This similarity suggests that factors other than the surgical approach and intraoperative support, such as congenital CNS disease and the abnormal fetal physiology, may play a more significant role in long-term outcome for these children. Of importance, outcomes for these complex patients have improved in recent years in terms of both mortality and neurodevelopmental outcome. A recently completed randomized trial of surgical strategies for HLHS has reported data on early mortality (Ohye et al, 2010); long-term neurodevelopmental outcomes are being measured during longitudinal follow-up and are likely to represent the largest and most comprehensive study performed in children with HLHS.

FUNCTIONAL STATUS AFTER REPAIR OF COMPLEX CONGENITAL HEART DISEASE

Most studies have focused on delineating cognitive impairments in children who have undergone repair of CHD; however, the impact on the child's functional status and on the child's caregivers has not been as carefully investigated. Recently, parental stress was assessed early after surgery for complex CHD (Torowicz et al, 2010). The demands of care for infants with CHD were a significant source of parental stress compared with those in control parents, especially related to feeding and medication burden. In addition, infants with single-ventricle palliation were more negative in mood and less distractible than those children who underwent biventricular repair. In childhood, developmental delay after cardiac surgery can impair a child's functional status, resulting in a considerable burden for family and caregiver. Limperopoulos et al (2001) from Montreal Children's Hospital evaluated functional limitations and burden of care in 131 infants after surgical repair of CHD, using the WeeFIM (Functional Independence Measure), a pediatric functional assessment designed to assess and track levels of functional independence, and the Vineland Adaptive Behavior Scale. Only 21% of the patients were functioning within their appropriate age range. Moderate disability was noted in 37% and severe disability in 6%. Functional difficulties in daily living skills were documented in 40% of the patients, and greater than 50% had poor socialization skills. Factors that increased the risk of functional disabilities included microcephaly, longer duration of DHCA, longer length of stay in the intensive care unit, and lower level of maternal education. Finally, essentially all studies conducted in school-aged children suggest that between 25% and 40% of school-aged children will require remedial help in school.

SUMMARY

Although children with mild types of CHD appear to have normal CNS and neurodevelopmental outcomes (Quartermain et al, 2010; van der Rijken et al, 2008),

children with complex CHD constitute an at-risk population with a significant incidence of adverse developmental outcomes. Current techniques for developmental evaluation in neonates and infants are imprecise predictors of late outcomes. Evaluation of preschool- and school-aged children reveals a pattern of neurodevelopmental dysfunction characterized by mild cognitive impairment, motor dysfunction, impaired visual-spatial and visual-motor skills, and attention and academic difficulties in about one-half of the children. There are significant problems with expressive speech and language and a high incidence of learning disabilities.

The factors resulting in CNS injury and developmental dysfunction in these children are not completely understood. Developmental dysfunction results from a complex interaction between patient-specific factors (genetic susceptibility, cardiac diagnosis) and environmental factors (preoperative events; techniques of support during surgical repair, including the use of DHCA; postoperative events; socioeconomic status). Currently, reported risk factors do not adequately explain the pattern or incidence of CNS injury after cardiac surgery in infants, suggesting that other patient-specific factors may modulate the response to CHD and cardiac surgery, increasing the risk of adverse neurodevelopmental sequelae. Children with CHD are at risk for cerebral ischemia before, during, and after cardiac surgery; therefore, factors, that impair CNS recovery after ischemia may be important determinants of long-term neurologic outcome.

PART XII

Neurologic System

CHAPTER 58

Developmental Physiology of the Central Nervous System

Christine A. Gleason, A. Roger Hohimer, and Stephen A. Back

Over the past several decades, numerous important advances have been made in neonatal cardiovascular and pulmonary medicine, that have dramatically improved survival of critically ill term and preterm infants. Attention has now turned increasingly toward improving the neurologic outcome in not only these critically ill high-risk infants but also those born with prenatal brain injuries, brain malformations, or neurodevelopmental disorders. In the first edition of this textbook, limited attention was devoted to neonatal neurology. Beginning with the eighth edition, the book now features a comprehensive neurology section that, in addition to this introductory chapter, includes chapters devoted to neonatal neuroimaging; malformations and deformations of the developing brain; brain injury and neuroprotection; neuromuscular disorders; neonatal seizures; and finally, risk assessment and neurodevelopmental outcomes. This introductory chapter provides an overview of central nervous system (CNS) vascular anatomy and physiology and a discussion of normal principles of regulation of cerebral blood flow (CBF) and energy metabolism. Chapter 60 discusses normal CNS developmental anatomy in the context of the associated major human brain malformations.

CENTRAL NERVOUS SYSTEM VASCULAR DEVELOPMENT

Development of the cerebral vasculature is closely linked with that of neural tissue. Early in development, the CNS is essentially avascular. Blood vessels form as a meshwork in the meninges before growing into the CNS from the pial surface in a caudal-to-rostral progression. The blood-brain barrier is essentially a collection of capillary–endothelial cell tight junctions and develops under the influence of astrocytes. Brain blood vessel formation and blood-brain barrier capacities are present early in the CNS, but maximal capillary sprouting occurs during the period of dendritic growth and glial cell proliferation.

Cerebral vascular development, particularly in the periventricular region, is clinically relevant because the immature infant is susceptible to ischemic injury in the white matter around the ventricles and to hemorrhage in the germinal matrix region (part of the ventricular zone) and into the ventricles (Takashima and Tanaka, 1978a, 1978b). The periventricular white matter has two major blood supplies. Perforating arteries branch from leptomeningeal arteries, penetrate the cerebral cortex, and terminate as capillary beds adjacent to the ventricles. Branches of choroidal and striate arteries project toward the lateral ventricles and then deviate away from the ventricle toward their final termination in vascular capillary beds in the periventricular white matter. It has been proposed that these vascular beds collectively form vascular end zones and border zones that render the periventricular white matter particularly susceptible to ischemia. However, the existence of these border zones remains controversial (Mayer and Kier, 1991; Nelson et al, 1991; Takashima et al, 2009; Volpe, 2008). Recent studies in the preterm fetal sheep measured blood flow in histopathologically defined regions of injury in cerebral cortex and white matter (McClure et al, 2008). Although white matter blood flow is lower than cerebral gray matter, there was no evidence for pathologically significant gradients of fetal blood flow within the periventricular white matter under conditions of ischemia or reperfusion. White matter lesions did not localize to regions susceptible to greater ischemia, nor did less vulnerable regions of cerebral white matter have greater flow during ischemia. An alternative explanation for the topography of cerebral white matter lesions is the distribution of susceptible cell types, particularly late oligodendrocyte progenitors, that are particularly susceptible to hypoxia-ischemia (Back et al, 2005; Riddle et al, 2006).

A current limitation to our understanding of human cerebral vascular development is the lack of approaches that precisely measure regional blood flow in real time in the preterm or term neonate. Magnetic resonance angiography (MRA) has provided structural data on the impact of preterm birth on subsequent vascular development. Preterm survivors studied longitudinally up to 18 months of age demonstrated a persistent reduced tortuosity of proximal segments of all major cerebral arteries (Malamentiniou et al, 2006). Recently, van Kooij et al (2010) assessed the circle of Willis in 72 preterm neonates at term-equivalent age using magnetic MRA. They observed "a high prevalence of variant types of the circle of Willis" with corresponding variations in flow in the internal carotid and basilar artery. The significance of this finding with regard to regional blood flow, brain injury, brain development, or vulnerability to injury later in life is not known.

Venous drainage from the cerebral hemispheres is bidirectional. Cortical and subcortical veins drain in the meningeal direction from cortex and superficial white matter, whereas medullary veins drain in the ventricular direction from the deep white matter. Studies of collagen type 6

immunoreactivity suggested that arterial vessels may be more late-maturing relative to venous development in the deep white matter (Takashima et al, 2009). Characteristics of the developing vasculature, such as the fact that the medullary veins in the deeper cerebral white matter are more developed than the veins in the subcortical white matter, may predispose the developing deep white matter to certain types of injury, particularly periventricular venous infarction that occurs in association with intraventricular hemorrhage (Volpe, 2008).

GERMINAL MATRIX

The germinal matrix is supplied by striatal arteries through a dense capillary network that is particularly susceptible to hemorrhage in the preterm infant. Although the germinal matrix is considerably more vascular than the cerebral cortex or white matter, the increased risk for hemorrhage is related to developmental immaturity of the vasculature and the cellular and extracellular matrix elements that make up the blood-brain barrier. The propensity of the matrix to hemorrhage in premature infants less than 34 weeks' gestational age is thus related to a complex interplay between vascular fragility and disturbances in cerebral blood flow that are particularly prominent in the first 3 to 4 postnatal days (Ballabh, 2010; Ment et al, 1995).

In recent years, the relative contributions of several of the key molecular components of the blood-brain barrier to germinal matrix hemorrhage have been studied. The barrier is composed of astrocytic endfeet, pericytes, basement membrane, and endothelial tight junctions. Pericytes are involved in both the initiation of angiogenesis and the later stabilization of blood vessels via the synthesis of components of the extracellular matrix and regulation of endothelial differentiation. Perivascular coverage by astrocytic endfeet and pericytes is reduced in human preterm germinal matrix relative to other brain regions (Braun et al, 2007; El-Khoury et al, 2006).

Studies of the ultrastructural features of the blood-brain barrier in an animal model initially suggested that postnatal endothelial basal lamina deposition occurs before tight junction formation and glial investiture and that basal lamina induction influences the latter two processes (Ment et al, 1995). Various candidate molecules have been proposed to contribute to the stabilization of the matrix vasculature in the first days of life, including laminin, collagen V (Ment et al, 1991), and fibronectin (Xu et al, 2008), all of which increase significantly with advancing age after birth. Enhanced expression of these molecules in the germinal eminence was promoted by indomethacin (Ment et al, 1991) or low-dose prenatal betamethasone (Xu et al, 2008), suggesting that these agents might stabilize the germinal matrix vasculature.

The biology of vascular maturation is an active research area that raises an alternative strategy for prevention of intraventricular hemorrhage. Endothelial proliferation declines in the 1st week of life in human germinal matrix, which supports the notion that angiogenesis is in an active phase around the time of birth (Ballabh et al, 2007). The pronounced angiogenesis in the preterm matrix coincides with the increased expression of the proangiogenic factors vascular endothelial growth factor (VEGF) and angiopoietin-2 in the matrix relative to cerebral cortex and white matter. Moreover, inhibitors of VEGF activity significantly reduced the incidence of intraventricular hemorrhage in a premature rabbit model. Despite the potential benefits of short-term treatment with antiangiogenesis factors, the potential of these agents to cause hypoxia to the germinal matrix or other tissues remains unclear.

REGULATION OF CEREBRAL BLOOD FLOW AND ENERGY METABOLISM

CBF is regulated by many systemic and local factors, including arterial blood pressure, intracranial pressure, arterial O_2 content, hematocrit, and arterial CO_2 tension. Cerebral O_2 consumption (i.e., cerebral metabolic rate, or $CMRO_2$) is an important determinant of CBF. Responsivity of the cerebral circulation to the aforementioned stimuli also is determined in part by $CMRO_2$.

CBF normally is regulated to maintain adequate oxygen and substrate delivery to the brain. When blood flow regulatory limits and oxygen extraction capabilities of the brain are exceeded, the brain sustains tissue hypoxia. When abnormally low CBF is the primary abnormality, then the brain sustains ischemia. In most clinical situations, both hypoxia and ischemia occur, although one may predominate. It should be emphasized that even under conditions of significant hypoxia-ischemia, cerebral injury is often selective rather than diffuse. The timing of an insult during development is a critical factor that contributes to CNS susceptibility to hypoxia-ischemia. For example, under conditions of prolonged global cerebral ischemia, the cerebral cortex is relatively spared in the preterm fetal sheep, whereas panlaminar cortical necrosis occurs in the term animal (Reddy et al, 1998; Riddle et al, 2006). In a fetal rabbit model of placental insufficiency, significant global fetal hypoxia-ischemia caused minimal preterm cerebral white matter injury, but a similar insult three days later in gestation causes pronounced white matter injury (Buser et al, 2010). The timing of appearance of susceptible oligodendroglial progenitors defined the relative susceptibility of the white matter at these two developmental ages. Hence, the extent of the susceptibility to hypoxia-ischemia is related to both the timing and the regional expression of cellular-molecular factors.

AUTOREGULATION

Cerebral autoregulation refers to the maintenance of constant CBF over a range of changes in arterial blood pressure or cerebral perfusion pressure (Lassen and Christensen, 1976; Paulson et al, 1990). This autoregulatory range has both upper and lower limits; above or below these limits, CBF does not remain constant but instead increases or decreases passively, along with changes in arterial blood pressures. Cerebral autoregulation has been demonstrated in several species and across developmental stages, but the mechanism of this important phenomenon remains elusive. It is believed to be an intrinsic property of arterial smooth muscle cells, in which transmural pressure modifies muscle tone, by affecting the activation state of K^+ and Ca^{2+} channels in muscle cells, thereby affecting the cells' membrane potential (Greisen, 2005). Current thinking

also supports the notion that autoregulation is mediated by a fine balance between endothelial cell–derived constricting and relaxing factors (Iadecola and Nedergaard, 2007). In adults, CBF remains constant over an autoregulatory range of mean blood pressures from 50 to 150 mm Hg (Paulson et al, 1990). In late fetal lambs, the range is lower and narrower (40 to 80 mm Hg), but more importantly, normal blood pressure is at most 5 to 10 mm Hg above the lower limit of the autoregulatory curve (Papile et al, 1985). Preterm fetal lambs show even less autoregulatory capability (Helou et al, 1994).

Autoregulation of CBF is of considerable interest to neonatologists because of the many clinical circumstances under which it may be impaired with risk for tissue hypoxia-ischemia. Impaired cerebral autoregulation in sick and clinically unstable premature infants was initially studied by means of xenon clearance and Doppler studies and more recently by near infrared spectroscopy and spatially resolved spectroscopy (du Plessis, 2008; Greisen, 2009). Severe perinatal asphyxia, hypoxia, head trauma, and hypercapnic acidosis, even when relatively mild, have been shown to attenuate or even abolish autoregulation (Busija and Heistad, 1984; Jones et al, 1988; Tweed et al, 1986). Nevertheless, considerable controversy remains regarding the role of pressure passivity in the pathogenesis of various forms of brain injury in the sick preterm neonate. This is illustrated, for example, by recent studies that failed to support a role for impaired autoregulation in the pathogenesis of intraventricular hemorrhage (Soul et al, 2007; Wong et al, 2008). Hence, basic questions regarding cerebral autoregulation remain unanswered, including determining the optimal clinical practices for blood pressure regulation (Greisen, 2009).

The Cushing phenomenon is characterized by increasing systemic arterial pressure, enough to maintain cerebral perfusion pressure when intracranial pressure rises. Harris et al (1989) have shown that this response is highly developed in fetal sheep, possibly as an adaptation to the rigors of head compression during labor. If the newborn human Cushing response is similarly well developed, then the newborn brain may be better able to preserve cerebral blood pressure when intracranial pressure rises (as with postasphyxial cerebral edema).

RESPONSE TO HYPOXIA

When arterial oxygen content (CaO_2) decreases, the cerebral circulation responds by increasing CBF to maintain oxygen delivery to the brain. This cerebral vasodilatory hypoxic response is directly related to CaO_2 and not to arterial oxygen tension (PaO_2). Increased CBF preserves cerebral oxygen delivery ($CaO_2 \times$ CBF) and cerebral O_2 consumption [($CaO_2 - CvO_2$) $\times$ CBF]. There is a limit beyond which CBF cannot increase, and then O_2 delivery falls. The brain must then increase O_2 extraction to maintain $CMRO_2$. There is a limit to this as well (cerebral venous PO_2), and when this is reached, $CMRO_2$ falls and brain tissue hypoxia results.

Jones and colleagues (1981) studied hypoxic hypoxia in neonatal sheep and found that CBF correlates best with CaO_2; as CaO_2 decreases, CBF increases. Studies have shown similar cerebral hypoxic cerebral vasodilatory responses in fetal (Ashwal et al, 1981) and adult sheep (Koehler et al, 1984). Developmental differences have been noted, however, in the regional brain blood flow responses to hypoxia. Ashwal and associates (1981) demonstrated a hierarchy of responsivity in fetal sheep in which the brainstem is more responsive than the subcortex or cortex. Such a hierarchy has not been noted in more mature sheep. Studies in immature fetal sheep (Gleason et al, 1990) have shown that cerebral O_2 delivery is not maintained during hypoxic hypoxia; therefore, fractional O_2 extraction must increase to maintain $CMRO_2$. This finding suggests that important regulatory mechanisms are not fully developed in the immature brain, thus rendering it more vulnerable to hypoxic injury.

Anemic hypoxia produces a rise in CBF similar to that with hypoxic hypoxia so that oxygen delivery is maintained despite reduced CaO_2 (Jones et al, 1981). Arterial PaO_2 changes little, if at all, in anemic hypoxia, and changes in blood viscosity alone are not sufficient to account for the increase. Patchy areas of tissue hypoxia, with some areas receiving only plasma, could produce cerebral vasodilation (Jones et al, 1988).

HYPEROXIA

Several studies have demonstrated a decrease in cerebral blood flow when PaO_2 is raised to relatively hyperoxic levels. Gleason et al (1988) raised fetal PaO_2 from 20 to 73 mm Hg in fetal sheep and noted a 46% drop in CBF. Kennedy et al (1971) showed a 20% to 30% decrease in CBF during extreme hyperoxia (PaO_2 of 349 mm Hg) in neonatal puppies; this CBF response disappeared by 3 weeks of age. Rahilly (1980) demonstrated a 33% drop in cranial blood flow in term infants breathing 100% O_2, and Leahy et al (1980) showed a 15% drop in CBF in preterm infants who received similar treatment. These results are not surprising when the curve for the CBF response to hyperoxia is placed along the inverse hyperbolic hypoxic response curve previously described by Jones et al (1977) for fetal sheep. This potential decrease in CBF with increased O_2 is certainly an important consideration in the decision to use extracorporeal membrane oxygenation in a hypoxemic neonate, during which the carotid PaO_2 may transiently be as high as 500 mm Hg, or in resuscitation of a newborn using 100% oxygen (Gleason, 1993).

POLYCYTHEMIA/HYPERVISCOSITY

Arterial O_2 content increases when the hemoglobin concentration rises, as does whole blood viscosity. An increase in CaO_2 alone results in decreased CBF. The independent effect of hyperviscosity on decreasing CBF in polycythemic animals was studied by Massik et al (1987). In their study in lambs, methemoglobin was used to dissociate the effects of hematocrit and CaO_2 as the hematocrit was raised. Approximately 50% of the decrease in CBF associated with polycythemia was attributed to hyperviscosity and the remainder to increases in CaO_2. In the perinatal period, a number of factors can result in neonatal polycythemia, both chronically (fetal hypoxia) and acutely (umbilical cord clamping). Although neurologic signs may

be present, a partial exchange transfusion to reduce the hematocrit has not been shown to be of benefit with short-term or long-term neurologic abnormalities (Rosenkrantz, 2003).

ALTERATIONS IN CEREBRAL OXYGEN CONSUMPTION

CBF normally is coupled with $CMRO_2$, such that when clinical conditions alter $CMRO_2$, CBF is adjusted appropriately (Siesjo, 1984). For example, in the preterm sheep, barbiturate coma lowers $CMRO_2$; therefore, CBF is comparably reduced (Hohimer and Bissonnette, 1989). Donegan et al (1985) studied CBF autoregulation and hypoxic responses during pentobarbital-induced coma in newborn lambs. The CBF response to hypoxia was attenuated during coma, but only in proportion to the decrease in $CMRO_2$. Chronic narcotic infusions in ventilated sick preterm infants may induce a similar response.

Cerebral O_2 consumption increases during neuronal excitation such as seizures (Metzger, 1979; Plum and Duffy, 1975). Increased CBF mirrors the increased $CMRO_2$, but there may not be adequate tissue PO_2. If seizure activity is sustained, the high metabolic rate and potentially maximal CBF may increase the brain's susceptibility to additional hypoxic-ischemic injury (Meldrum and Nilsson, 1976).

CARBON DIOXIDE REACTIVITY

Changes in arterial PCO_2 induce significant cerebral vascular responses in developing animals (Rosenberg, 1982). Hypercapnia is a potent cerebral vasodilator, and hypocapnia is a potent vasoconstrictor (Reivich et al, 1971; Volpe, 2008). Hypocapnia may occur clinically secondary to overventilation or may be induced intentionally, in an attempt to decrease pulmonary vascular resistance. Numerous studies have demonstrated a 30% to 40% reduction in CBF after 15 to 30 minutes of moderately severe hypocapnia ($PaCO_2$ of 15 to 25 mm Hg). A gradual increase in CBF during prolonged hypocarbia has been shown by Gleason et al (1989) in newborn lambs, with CBF gradually returning to baseline during 6 hours of hyperventilation. In these hyperventilated lambs, significant cerebral hyperemia was noted after abrupt discontinuation of hyperventilation. Additional animal studies by Delivoria-Papadopoulos and associates (1988) have suggested that severe hypocapnia ($PaCO_2$ <10 mm Hg) results in tissue ischemia. In newborn piglets, hyperventilation increases the expression of Bax, a pro-apoptotic protein, without simultaneous induction of the anti-apoptotic protein bcl-2 (Greisen, 2009; Lasso Pirot et al, 2007). Clinical studies have shown abnormal electroencephalograms, auditory evoked responses, and abnormal neurodevelopmental outcomes associated with significant hypocarbia.

The effect of hypercapnia on the cerebral circulation has been of interest to neonatologists since the "permissive hypercapnia" ventilatory strategy was introduced in an attempt to minimize lung damage in preterm infants. In newborn sheep, increasing PCO_2 from 37 to 78 mm Hg resulted in a 355% increase in CBF, which remained 195% above baseline after 6 hours. An abrupt return to normocapnia resulted in a return to baseline with no adverse effects on cerebral oxygenation throughout the study (Hino et al, 2000). Clinically, Kaiser et al (2005) used Doppler ultrasound to measure cerebral blood flow velocity during and after tracheal suctioning in preterm neonates and noted that the cerebral circulation became progressively pressure passive with hypercapnia. They recommended careful control of $PaCO_2$ (avoiding both hypercapnia and hypocapnia) during the first week of life to limit brain injury.

BRAIN ENERGY METABOLISM

Oxygen and glucose are the brain's primary energy fuels. Although the requirement for oxygen is absolute, other substrates can replace or augment glucose during special circumstances such as hypoglycemia or anoxia (Jones, 1979). When oxygen delivery to the brain is impaired and oxygen extraction capability is exceeded, tissue hypoxia occurs, and brain damage may be the result. The issue of whether or not newborns have decreased vulnerability or "resistance" to anoxic insult continues to be debated. Increased survivability after prolonged anoxia has been demonstrated in immature animals such as newborn rats, and there have been occasional anecdotal reports of this phenomenon in newborn infants, but whether or not such increased survivability reflects resistance of the *brain* to anoxia is debatable. Nevertheless, immature animals do have better survival, and this has been variously attributed to (1) lower cerebral O_2 consumption, (2) predominance of anaerobic metabolism as an energy source, or (3) circulatory adaptations in immature animals, such as greater stores of cardiac glycogen that enable the heart to sustain the cerebral circulation. None of these possible mechanisms accounts for increased survival in all species, and none has been definitively proved to be important exclusively in immature animals (Gleason, 1993; Jones, 1979).

Hypoglycemia occurs quite commonly in sick newborn infants, although the associated physiologic conditions vary considerably. Poor glycogen stores, increased glucose demands, hyperinsulinism, and poor glucose intake are among the more common of these conditions. Cerebral effects of hypoglycemia may depend in part on the cerebral effects of the associated physiologic conditions. Alternative oxidative substrates are available to the brain, including ketone bodies, lactate, amino acids, and lipids. Owen et al (1967) showed that cerebral ketone body consumption accounts for 50% of cerebral O_2 consumption in obese adults who were starved for 5 to 6 weeks. Hypoglycemia is associated with decreased cerebral glucose consumption but no change in cerebral O_2 consumption (Jones, 1979). Whether this response is adaptive or pathologic is not known.

METABOLIC ALKALOSIS/ACIDOSIS

Cerebrovascular resistance is believed to be directly related to brain interstitial pH (Kontos et al, 1977). Biologic membranes are highly permeable to CO_2, so a change in $PaCO_2$ has an almost immediate effect on interstitial pH and, consequently, on CBF. In contrast, hydrogen and bicarbonate ions do not diffuse as easily through membranes. Therefore, induction of acute metabolic acidosis or alkalosis has not been shown to change CBF or autoregulation

(Harper and Bell, 1963; Hermansen et al, 1984). During hypocapnia, addition of metabolic alkalosis does not alter CBF. However, during hypercapnia, bicarbonate infusion causes a significant decrease in CBF (Arvidsson et al, 1981), suggesting that hypercapnia alters the blood-brain permeability to ions. Such alterations in blood-brain barrier may also be associated with neonatal hypoxic/ischemic brain injury.

Sodium bicarbonate is used clinically to correct metabolic acidosis in neonates, but it has been used with caution since a 1974 report that linked its use with hypernatremia, intracranial hemorrhage, and acute secondary changes in arterial PCO_2 (Simmons et al, 1974). Laptook (1985) evaluated the cerebral effects of sodium bicarbonate (2 mEq/kg given over 3 minutes) administered to paralyzed newborn piglets to correct metabolic acidosis associated with hypoxemia. This investigator noted no alterations in brain blood flow or O_2 delivery. Constant $PaCO_2$ was maintained by increasing the ventilator rate during the bicarbonate infusion. In a study of preterm infants with metabolic acidosis, slow infusion (over 30 minutes) of 4% $NaHCO_3$ was associated with less fluctuation in cerebral hemodynamics (primarily, an increase in cerebral blood volume), compared with a rapid bolus (van Alfen-van der Velden et al, 2006). A 2005 Cochrane Review concluded that there was insufficient evidence to determine whether infusion of sodium bicarbonate reduces morbidity and mortality rates in preterm infants with metabolic acidosis (Lawn et al, 2005). Similarly, there is lack of evidence for efficacy and potential for harm when sodium bicarbonate is given during cardiac arrest. This overall lack of evidence for benefit led Aschner and Poland (2008) to conclude, in a review article on sodium bicarbonate, that "clinicians should resist the common impulse to administer bicarbonate to infants with metabolic acidosis, recognizing the risks of immediate worsening of the intracellular milieu."

SUGGESTED GUIDELINES FOR CEREBROVASCULAR AND METABOLIC CARE IN HIGH-RISK NEWBORNS

Guiding principles for the cerebrovascular and metabolic care of critically ill preterm and term infants may include the following:

1. Maintain stable blood pressure. Severe hypotension is clearly detrimental, but so are rapid increases in blood pressure in a pressure-passive circulation.
2. Maintain stable acid-base balance without rapid corrections.
3. Avoid severe hypoxemia.
4. Avoid marked hyperoxemia (i.e., consider effects of resuscitating with 100% oxygen).
5. Avoid major changes in $PaCO_2$, both hypocapnia and hypercapnia.
6. Correct significant anemia or polycythemia; if the condition is chronic, correct slowly.
7. Consider cerebrovascular and metabolic effects of any new (and existing) drug therapies. Use the lowest effective dose for the shortest period of time.
8. Maintain euglycemia, particularly in asphyxiated newborns.

CHAPTER 59

Neonatal Neuroimaging

Sanjay P. Prabhu, P. Ellen Grant, Richard L. Robertson, and George A. Taylor

ULTRASONOGRAPHY

ANATOMIC (GRAY SCALE) SONOGRAPHY

Ultrasonography (US) became a viable tool for imaging the neonatal brain in the late 1970s with the development of real-time capabilities (Pape et al, 1979). Subsequent advances in ultrasound technology have dramatically improved our ability to visualize normal structures and abnormalities in the neonatal brain. As a result, US continues to be an integral part of caring for the critically ill neonate.

Diagnostic US relies on the transmission and reflection of high-frequency sound waves into tissues. The speed and reflectivity of sound differ among various tissues, resulting in acoustic interfaces that can be used to create images of anatomic structures. By convention, tissues with high reflectance, such as clotted blood, are bright, and those with low reflectance, such as cerebrospinal fluid (CSF) or moving blood, are dark. Thick bone and air significantly interfere with the transmission of sound into deeper tissues. Consequently, cranial US requires a coupling agent (gel) between the transducer and the skin to eliminate as much intervening air as possible and most often is performed through an open fontanel.

DOPPLER SONOGRAPHY

Continuous-wave and pulsed-wave Doppler techniques have been used for decades to sample hemodynamics in specific intracranial vessels. The resistive index (RI) and mean blood flow velocity over time (time-averaged velocity) are the most commonly used spectral Doppler measures for monitoring intracranial hemodynamics. The easiest and most reproducible are measures of pulsatility, which are relatively insensitive to differences in angle of insonation and correlate well with acute changes in intracerebral perfusion pressure. As the intracranial pressure rises, arterial flow tends to be more affected during diastole than during systole, resulting in an elevated pulsatility of flow. This phenomenon has been reported in Doppler studies in infants with elevated intracranial pressure (ICP) from a variety of causes including hydrocephalus, cerebral edema, and intracranial hemorrhage. However, elevated ICP may not always be present in infants with abnormal intracranial pressure-volume relationships (decreased cranial compliance). Thus, the RI may be within the normal range in these infants. Doppler examination of the anterior cerebral artery during fontanel compression may be useful in the early identification of infants with abnormal intracranial compliance before the development of increased ICP as shown by elevated baseline RI.

Many factors other than cerebrovascular resistance may affect the RI in an intracranial vessel, including the presence of a patent ductus arteriosus, alterations in heart rate and cardiac output, and the amount of pressure applied on the fontanel during scanning (Perlman et al, 1981; Taylor, 1992a; Taylor et al, 1989, 1996).

Although reproducible and easy to obtain, the RI is only a weak predictor of cerebrovascular resistance under most physiologic conditions. Mean blood flow velocity measures are the most informative indices of cerebral blood flow (CBF). A strong correlation has been demonstrated between mean blood flow velocity and changes in global CBF under a variety of clinical and experimental conditions (Taylor et al, 1990).

The introduction of color Doppler technology in 1989 has made imaging and reliable hemodynamic sampling of the intracranial vasculature routinely possible in the normal newborn (Dean and Taylor, 1995; Mitchell et al, 1988, 1989; Taylor, 1992b). Standard color Doppler sonography is based on an estimate of the mean frequency shift created by the movement of red blood cells at different velocities within the tissue or blood vessel being examined. Flow is generally depicted as variations of red or blue color, depending on the degree of shift from the baseline frequency, and on the direction of the moving red cells.

EQUIPMENT AND SCANNING TECHNIQUE

Transducers

In the premature infant, transducers operating at a higher frequency range (7 to 10 MHz) are recommended because of their higher spatial resolution. Lower-frequency transducers (3.5 to 5 MHz) are often used in larger infants to obtain adequate sound penetration. Sector transducers with a 120-degree imaging field are most useful for imaging through the anterior and posterior fontanels.

Scanning Technique

For sonographic examination of the neonatal brain, standardized coronal and sagittal images are obtained through the anterior fontanel. Coronal images are obtained by placing the transducer transversely across the fontanel and sweeping it in an anteroposterior direction to cover the entire brain (Figure 59-1). The transducer should be carefully held to produce symmetric imaging of both hemispheres.

At least six angled images are obtained. The most anterior image is anterior to the frontal horns of the lateral ventricles at the level of the orbits. The frontal lobes and anterior portion of the interhemispheric fissure can be visualized. The second image is obtained through the anterior horns of the lateral ventricles at the level of the suprasellar cistern. This structure has the appearance of

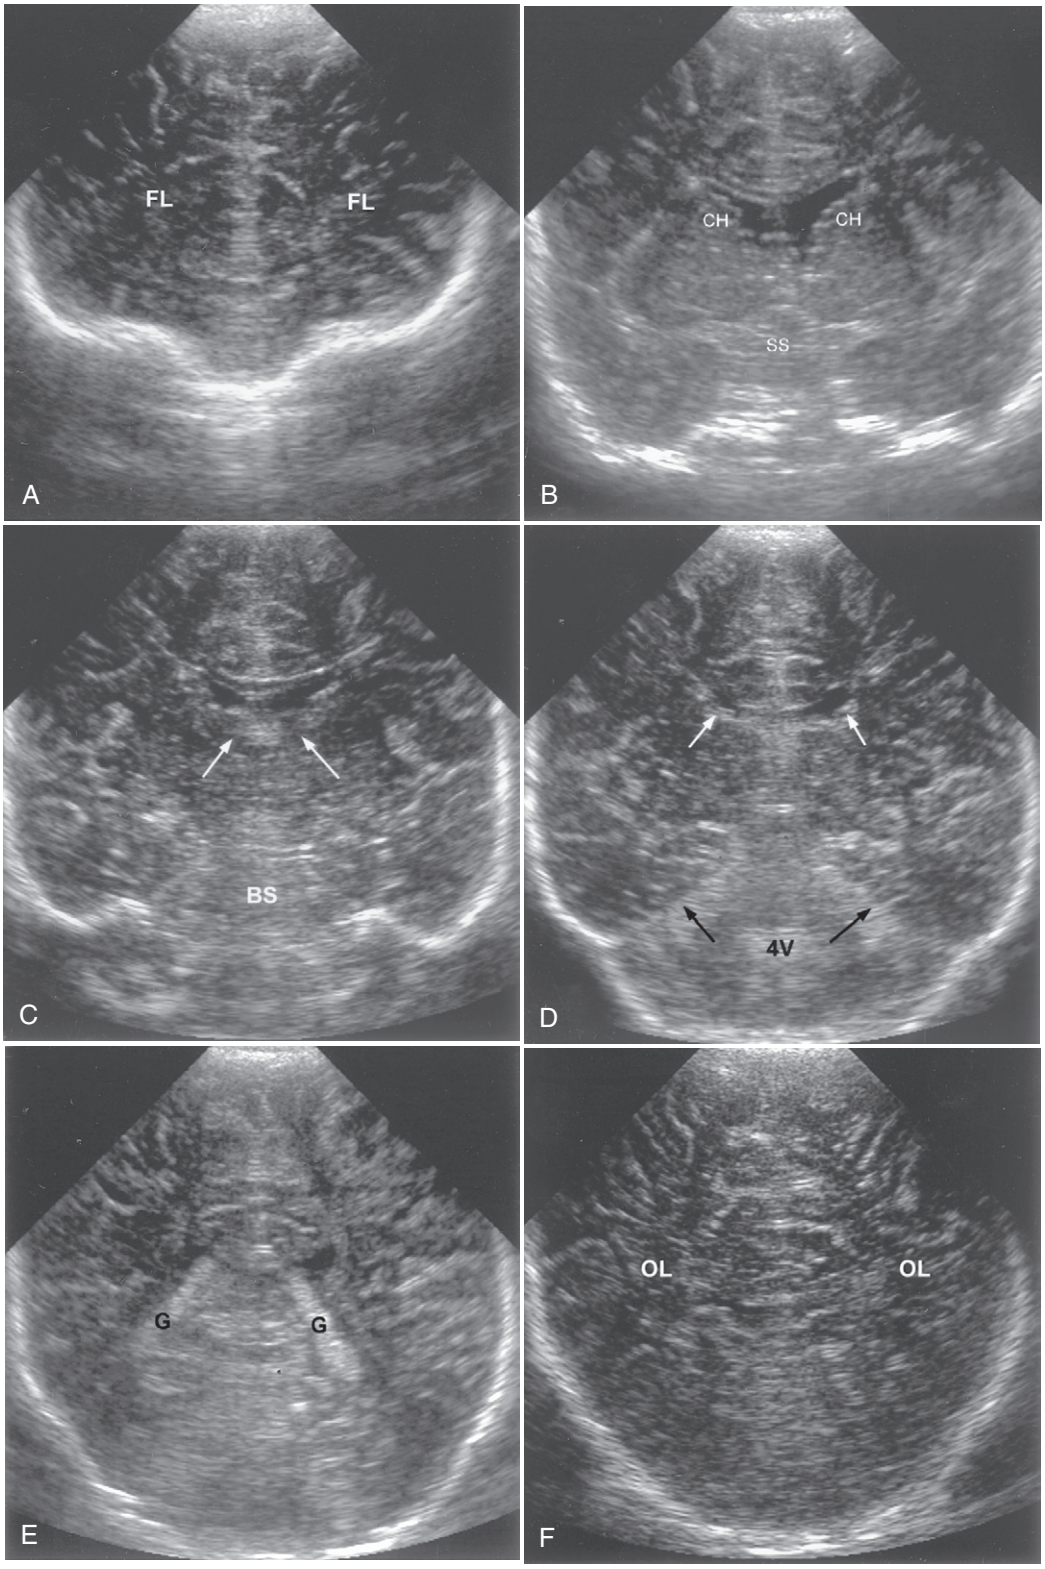

FIGURE 59-1 Standard coronal planes of cranial sonography performed through the anterior fontanel. A, Plane 1 is angled anteriorly to include the frontal lobes (*FL*) and orbits. **B,** Plane 2 demonstrates the caudate heads (*CH*) and the suprasellar cistern (*SS*). **C,** Plane 3 passes through the foramina of Monro (*arrows*) and the brainstem (*BS*). **D,** Coronal plane 4 shows the rounded echogenic choroid plexus within the body of the lateral ventricles (*white arrows*), the fourth ventricle (*4V*), and the tentorium (*black arrows*). **E,** Plane 5 includes the glomus (*G*) of the choroid plexus in the trigones of the lateral ventricles. **F,** Plane 6 is angled posteriorly to include the occipital lobes (*OL*).

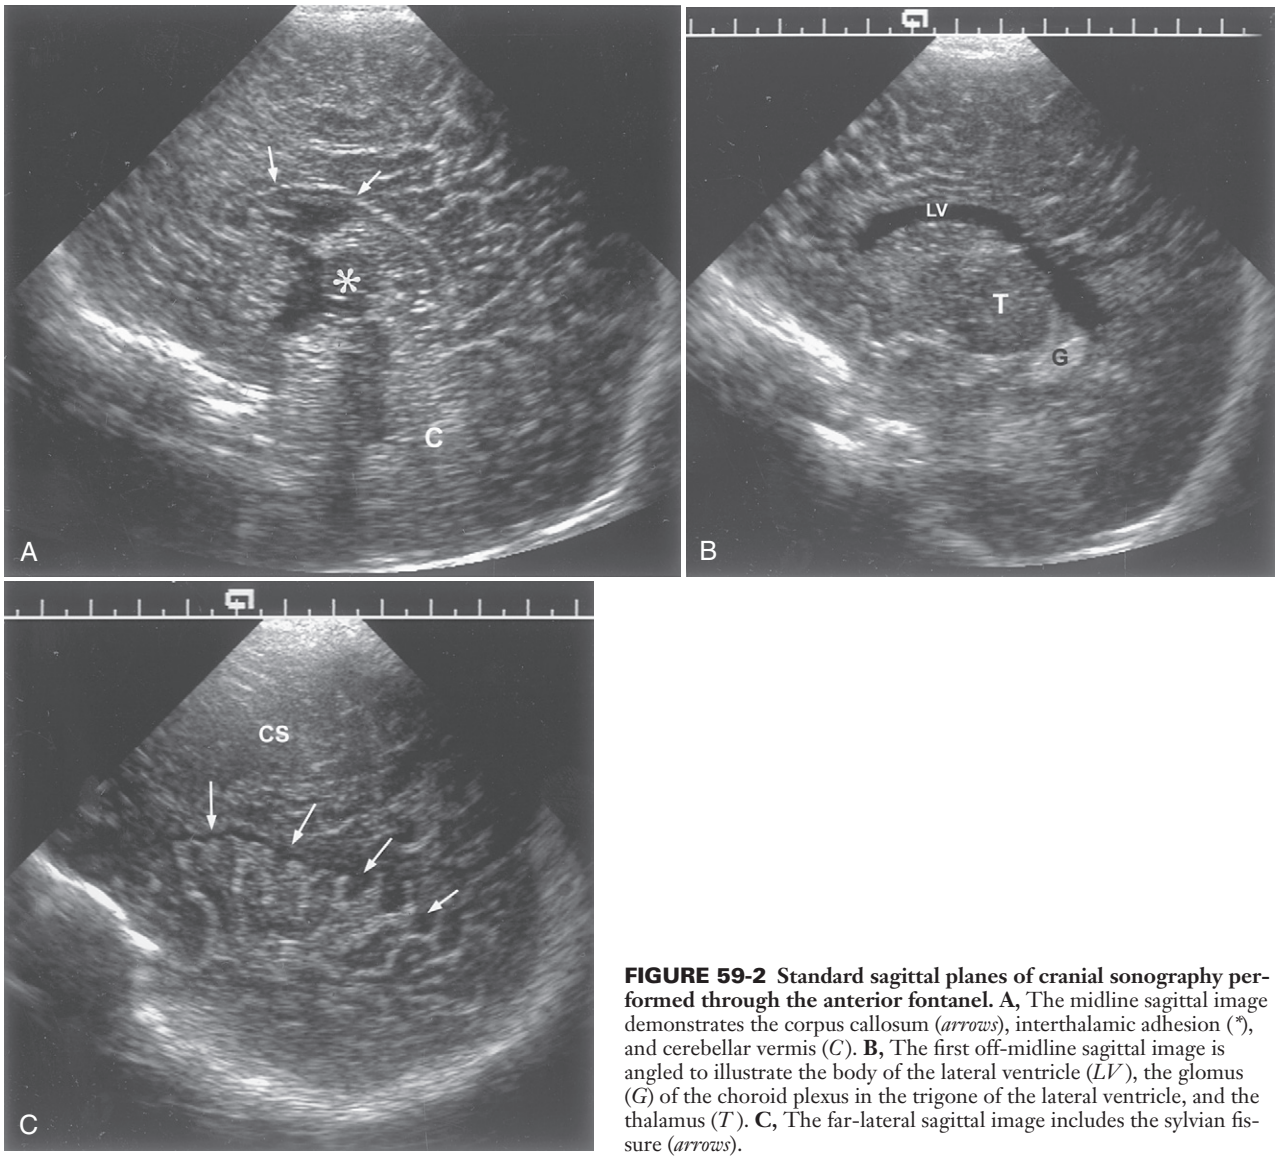

FIGURE 59-2 Standard sagittal planes of cranial sonography performed through the anterior fontanel. A, The midline sagittal image demonstrates the corpus callosum (*arrows*), interthalamic adhesion (*), and cerebellar vermis (*C*). **B,** The first off-midline sagittal image is angled to illustrate the body of the lateral ventricle (*LV*), the glomus (*G*) of the choroid plexus in the trigone of the lateral ventricle, and the thalamus (*T*). **C,** The far-lateral sagittal image includes the sylvian fissure (*arrows*).

an echogenic five-pointed star. The hypoechoic caudate nucleus can be seen inferior and lateral to the comma-shaped lateral ventricles. The ventricles are separated from each other by the centrally positioned cavum of the septum pellucidum. Basal ganglia, frontal and temporal lobes, insula, and T-shaped sylvian fissure can be identified in this plane. The next image is obtained more posteriorly through the body of the lateral ventricles at the level of the paired foramina of Monro and brainstem. The anterior portion of the choroid plexus can identified as three small echogenic structures along the inferomedial aspect of the lateral ventricles, and paired thalami can be seen lateral to the third ventricle. Lateral and superior to the lentiform nuclei is a region of the deep white matter called the centrum semiovale. The fourth image is obtained with the transducer angled slightly more posteriorly. At this level, the lateral ventricles have a more rounded appearance, and the choroid plexus is seen as a more prominent echogenic structure along the floor of the ventricles. The confluence of frontal, parietal, and temporal lobes can be seen as well as the echogenic tentorium cerebelli and the anterior portion of the cerebellum and fourth ventricle. The transducer sweep is continued posteriorly until the prominent paired echogenic structures of the glomus of the choroid plexus are seen in the atrium of the lateral ventricles. The parietal and posterior aspects of the temporal lobe and sylvian fissure can be visualized, along with the echogenic cerebellum inferiorly. The last coronal image is obtained posterior to the lateral ventricles. The posterior aspect of the interhemispheric fissure and the occipital lobes are seen on this view.

Sagittal images are obtained by placing the transducer longitudinally along the anterior fontanel (Figure 59-2). A total of five images are usually obtained, one along the midline and two on each side by angling the transducer laterally. True midline can be established by identifying the curved corpus callosum and echogenic cerebellar vermis on the same imaging plane. The cingulate gyrus can

be seen as an undulating echogenic line superior to the corpus callosum. The medial aspect of the paired thalamic nuclei, the tectum of the midbrain, and fourth ventricle can be identified on this image. The transducer is swept laterally approximately 10 degrees to show the body of the lateral ventricle. Because the lateral ventricles are not located in a straight anteroposterior line, the transducer must be slightly angled so that the posterior aspect of the probe is positioned more laterally than its anterior aspect. The echogenic choroid plexus is C-shaped and cups the thalamus like a baseball in a catcher's mitt. Its superior limb extends anteriorly to the caudothalamic notch immediately posterior to the head of the caudate nucleus. Its inferior limb extends well into the temporal horn. The second angled sagittal image is obtained with the transducer angled lateral to the body of the lateral ventricle. The centrum semiovale is well shown, and the sylvian fissure can be seen separating the parietal and temporal lobes (Naidich and Yousefzadeh, 1986; Siegel, 2001).

Although scans through the anterior fontanel provide adequate views of the cerebral hemispheres, images of the convexities, midbrain and posterior fossa are often limited. Four additional scanning approaches through the midline posterior fontanel, the squamosal suture, the posterolateral or mastoid fontanel, and the foramen magnum can be very useful as additional problem-solving tools in selected patients with suspected or poorly delineated posterior fossa and midbrain lesions (Buckley et al, 1997; Luna and Goldstein, 2000) (Figure 59-3).

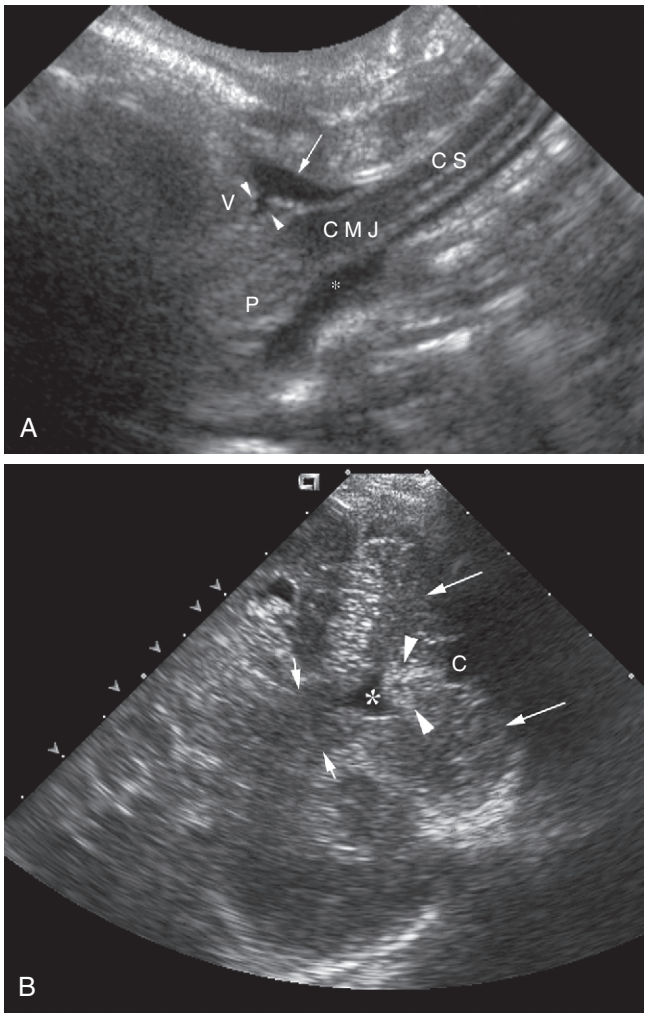

FIGURE 59-3 Cranial sonography performed using alternate imaging approaches. A, Midline sagittal image obtained through the foramen magnum shows the cervical spine (*CS*), cervico-medullary junction (*CMJ*), pons (*P*), cerebellar vermis (*V*), vallecula (*arrowheads*), cisterna magna (*arrow*), and pre-pontine cistern (*). **B,** Oblique axial image obtained through the mastoid fontanel demonstrates the cerebellar lobes (*long arrows*), cerebellar vermis (*arrowheads*), midbrain (*short arrows*), fourth ventricle (*), and cisterna magna (*C*).

COMPRESSION DOPPLER

Color Doppler is used to identify the pericallosal portion of the anterior cerebral artery (ACA) in midline sagittal projection using a 7- to 8-MHz vector transducer. A baseline Doppler spectrum is obtained while no pressure is exerted over the fontanel. The fontanel is then completely depressed with the transducer such that any additional pressure results in no further depression of the fontanel. During compression, the Doppler range gate is repositioned over the same portion of the ACA, and a second Doppler spectrum is obtained. The duration of each pressure episode should not exceed 3 to 5 seconds.

CLINICAL INDICATIONS

The most common indication for cranial US in the newborn is screening for suspected intracranial hemorrhage and periventricular leukomalacia (PVL) in the premature infant. Once either is detected, US is an excellent method for monitoring the progression or resolution of the pathologic process as well as for detecting the attendant complications of ventricular dilatation and progressive hydrocephalus. Sonography also is a very useful tool in the identification of focal infarction and hemorrhagic lesions in the term or near-term infant, as well as congenital midline anomalies, cystic lesions, vascular malformations, and intracranial calcifications, and in the definition of extraaxial fluid collections. The portable, noninvasive nature of cranial US allows for the cribside identification of many important lesions on an urgent basis without need for transport of the unstable or critically ill newborn. A more definitive characterization of a sonographic finding or suspected lesion can be performed subsequently with magnetic resonance imaging (MRI) or computed tomography (CT) once the infant is more stable.

COMPUTED TOMOGRAPHY

CT uses a narrowly collimated x-ray beam in conjunction with a digital detector array to produce a cross-sectional anatomic image (Boyd, 1995) (Figure 59-4). Although employing ionizing radiation, current-generation CT scanners effectively limit exposure to the immediate volume of interest (Raj et al, 2000). Tissue contrast in CT is dependent on differential attenuation of the x-ray beam. Tissues with high electron density, such as bone, markedly attenuate the beam, whereas brain and other soft tissues absorb fewer photons. Relative tissue densities on CT images are, by convention, measured in Hounsfield units (HU). After acquisition of the digital data, the images can

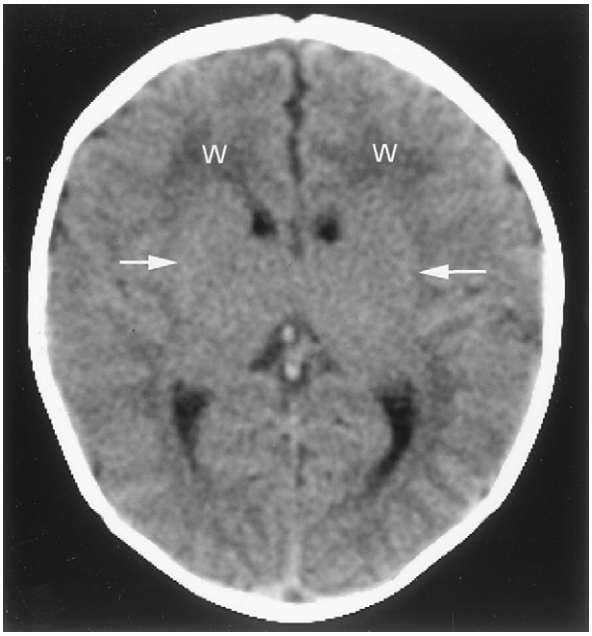

FIGURE 59-4 Axial computed tomographic image in a normal term newborn. Unmyelinated white matter is characterized by low density (*W*), whereas cortex and deep gray matter (*arrows*) are slightly denser.

be adjusted to emphasize different tissues such as bone or soft tissue.

TECHNIQUES

CT images are typically acquired in the axial plane. In most systems, the patient lies supine on a specialized scan table while the x-ray tube and detector array are rotated through a 360-degree arc. The scan table is then advanced several millimeters, and the next image slice is obtained. With current-generation scanners, the images are often acquired in a spiral (helical) or volumetric fashion with continuous rotation of the x-ray tube-detector array and uninterrupted scan table advancement.

Brain CT in the newborn is usually performed without the administration of intravenous contrast. Intravenous contrast may be used in CT for the evaluation of blood-brain barrier breakdown and as a blood pool agent for vascular imaging. Most often, however, the relevant clinical questions regarding the presence of hemorrhage, masses, or infarctions or ventricular dilatation can be answered without the use of contrast or are more fully evaluated with MRI (Cowan and MacDonald, 1999; Haring et al, 1999).

RISKS OF RADIATION

Children are at greater risk than adults from a given dose of radiation. This is explained by the inherent radiosensitivity of their young, developing tissues and because they have more remaining years of life during which a radiation-induced cancer could develop (Brenner and Hall, 2007). Further, although absolute energy imparted from a CT is smaller in children because of the smaller volume of tissues exposed, the effective dose is significantly higher than in an adult, for a similar amount of radiation used (Vock, 2005). Therefore, weight-based protocols to scan neonates to minimize the risks of radiation to the neonate have been suggested. It is important to justify a CT exam, and when one is performed, every attempt must be made to minimize the area scanned and to reduce the radiation dose as much as reasonably acceptable by selecting optimal parameters for age and size of the child and avoiding multiple scanning of the same area.

CLINICAL INDICATIONS

In addition to the dangers of radiation exposure and attendant risks associated with the use of CT and the relatively limited tissue information obtained, there are now few indications for CT of the neonatal brain. Both US and MRI provide imaging of the brain without the use of ionizing radiation. The multiple tissue parameters interrogated with MRI and the ability to generate multiplanar images make it the preferred modality for evaluation of the neonatal central nervous system (CNS). US is sufficient for addressing many causes of an acute change in neurologic status and is a useful tool for evaluating the neonate who is too unstable to undergo MRI. The primary indication for brain CT in a neonate is to evaluate potential causes of neurologic findings, when information from US is insufficient to fully answer the clinical questions and when the child's condition is not stable enough to safely undergo an MRI exam or when MRI is not readily available. CT is particularly useful for the detection of hemorrhage, calcification, or mineralization and delineation of craniofacial osseous anomalies. Although CT can be used for detection of infarction, its sensitivity in the early stages of stroke is significantly limited, and MRI is the investigation of choice in cases of suspected ischemic injury.

CT venography may be used to assess patency of the dural venous sinuses in the neonate; however, MR venography or Doppler sonography provides similar information without the use of ionizing radiation.

MAGNETIC RESONANCE IMAGING

MRI is an established technique based on the principles of nuclear MR. Clinical MRI uses a radiofrequency (RF) pulse to interrogate the properties of water protons in an applied external magnetic field (Balter, 1987; Mulkern and Chung, 2000). The behavior of the protons is determined by both the applied external magnetic field and the local magnetic field produced by neighboring protons. Image signal intensity (brightness) is related to the overall water content of the tissue as well as the inherent tissue properties: T1, T2, proton flow, proton diffusion, paramagnetism, magnetic susceptibility, and chemical shift (Barnes and Taylor, 1998). MR contrast is determined by the relative emphasis (i.e., weighting) placed on these various factors during image acquisition (Figs. 59-5 to 59-8). The manipulation of multiple tissue properties in MRI provides greater flexibility in imaging than is available with the single tissue property used in US (acoustic impedance) or CT (x-ray attenuation). MR images may be obtained in any desired anatomic plane without repositioning the patient. With few exceptions (e.g., Sturge-Weber syndrome, tumor, infection, intra- and extraaxial collections), neonatal brain MRI does not require the use of intravenous contrast.

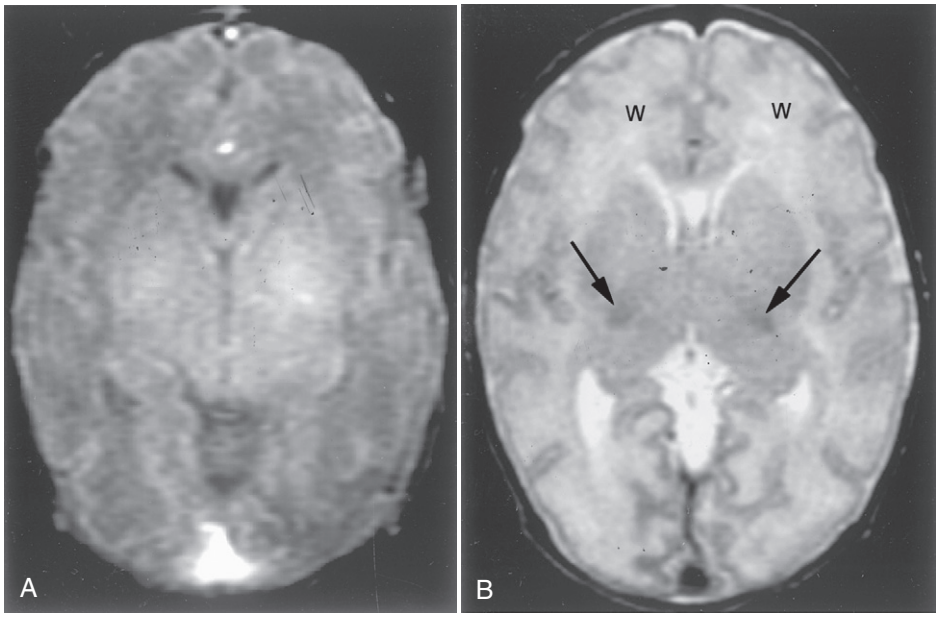

FIGURE 59-5 Axial images in a normal 34-week-gestation preterm neonate. A, Unmyelinated subcortical white matter appears hypointense (dark) on T1-weighted imaging, while the cortical and deep gray matter exhibit higher signal intensity. **B,** Unmyelinated subcortical white matter (*W*) appears markedly hyperintense (bright) on the T2-weighted fast spin echo image, while areas of early myelination, such as in the lateral thalamus (*arrows*), are of lower signal intensity. Loss of this focus of hypointensity is one of the earliest indicators of hypoxic-ischemic injury on T2-weighted images.

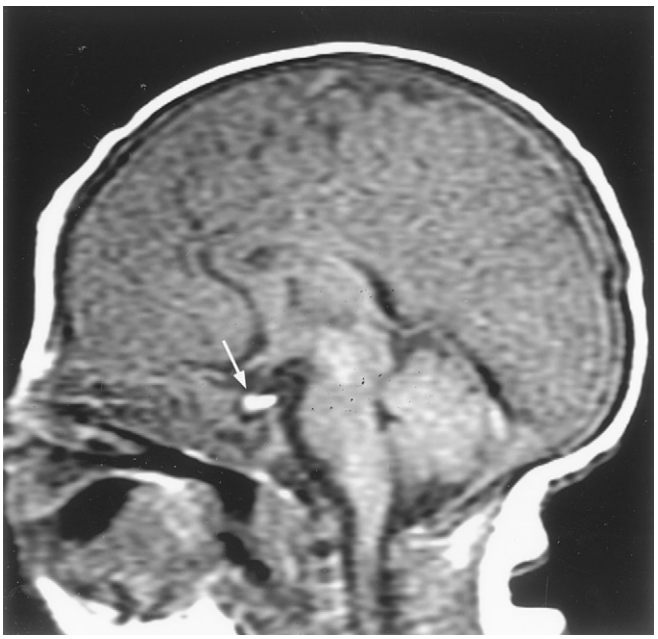

FIGURE 59-6 Midline sagittal T1-weighted image from a normal term neonate. Midline structures such as the corpus callosum, brainstem, and cerebellar vermis are well seen in the newborn. Of note, the anterior pituitary (*arrow*) is diffusely hyperintense because of hormonal activity. Note that the posterior pituitary gland (*arrow*) is intensely bright.

TECHNIQUES

Anatomic Magnetic Resonance Imaging

In general, conventional MR spin echo imaging is not as rapid as US or CT. In recent years, however, a number of fast imaging pulse sequences such as fast spin echo, fast spoiled gradient-recalled imaging have been developed (see Figs. 59-6 and 59-7, *A-C*). The use of these techniques in conjunction with higher-field-strength MR units, parallel imaging, and multichannel coils has helped reduce scan acquisition times significantly. As a result of these developments, imaging can be performed without sedation or anesthesia in the vast majority of neonates. Appropriate patient positioning and immobilization is typically adequate to permit diagnostic imaging, although sedation or anesthesia may still be required in some cases to provide motion-free imaging. More recently, MR-compatible incubators and monitoring systems have been developed to enable imaging studies of critically ill preterm and term neonates, with continued full clinical support while undergoing MR imaging studies. MR-compatible incubators can enable control of airflow, humidity and temperature regulation, monitoring and respiratory devices and can provide a safe and controlled environment for critically ill preterm and term newborns (Panigrahy et al, 2010). Such MRI-compatible neonatal incubators are currently in use in a number of centers in the United States. The use of the integrated RF head and body coils optimized for newborns has also been shown to improve the quality of MR imaging.

MRI has superseded CT in demonstrating features of acute focal cerebral ischemia, hypoxic ischemic brain injury, congenital malformations, vascular anomalies, hemorrhages, infections, and neoplasia.

MR angiography (MRA) and MR venography (MRV) may be used to demonstrate the intracranial arteries and veins of the neonatal brain without the use of intravenous contrast. Vascular imaging is usually performed by exploiting the time-of-flight (TOF) effect that occurs when stationary tissues are repeatedly excited with RF pulses causing their signal to be suppressed. Signal suppression in stationary tissues occurs due to the relatively long T1 of the brain and a consequent inability of protons to regain magnetization between RF pulses. The use of short interval RF pulses leaves only previously unexcited protons in blood moving into the imaging volume free to generate signal. This signal can be used to create a representation of either arterial or venous structures.

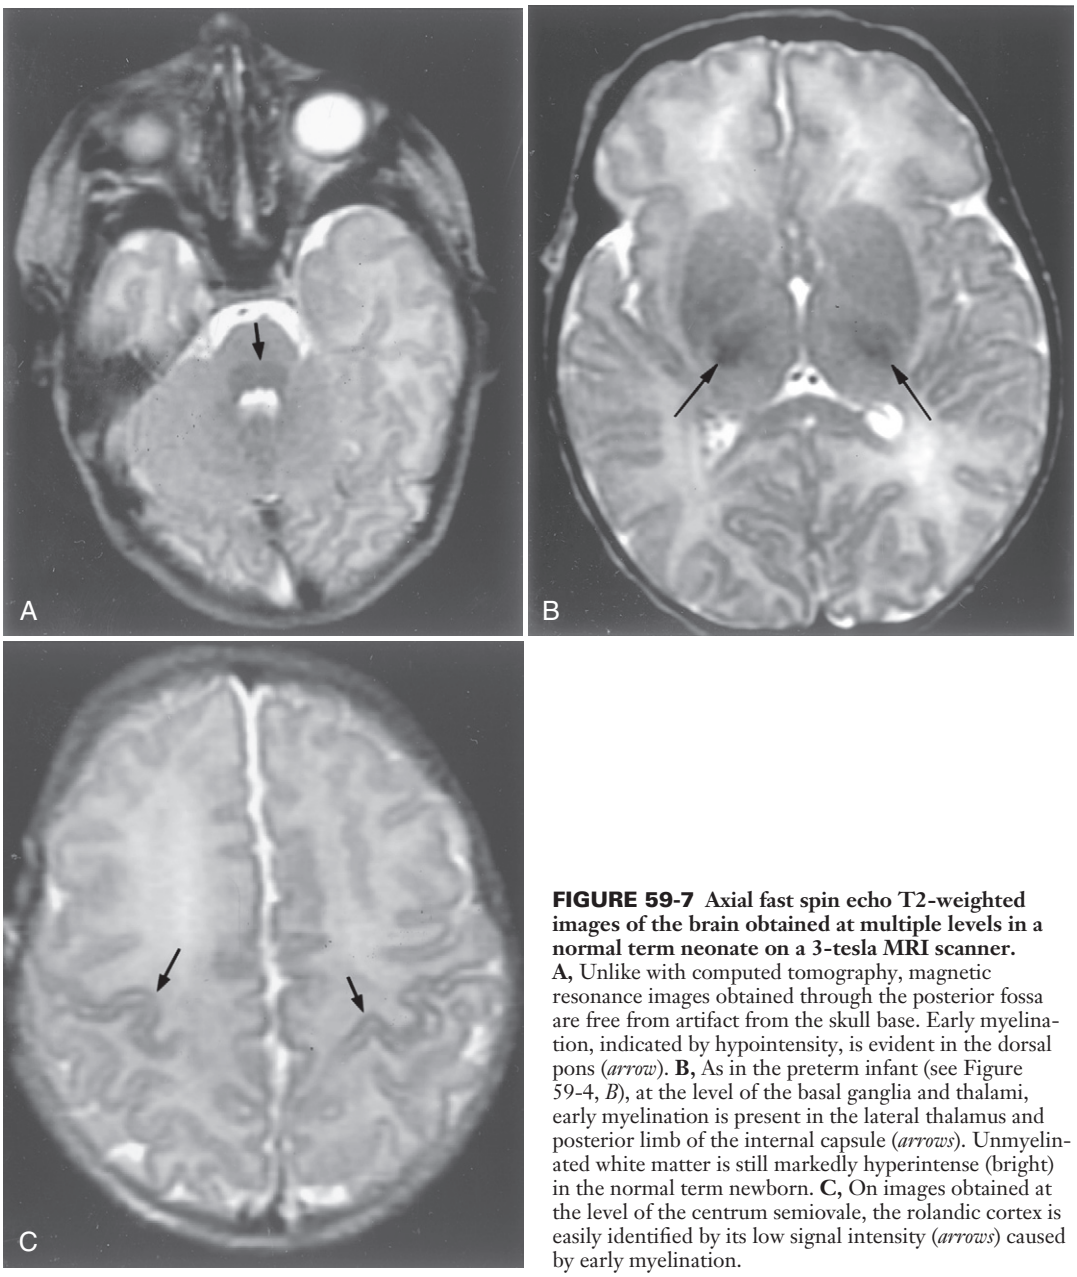

FIGURE 59-7 Axial fast spin echo T2-weighted images of the brain obtained at multiple levels in a normal term neonate on a 3-tesla MRI scanner. **A,** Unlike with computed tomography, magnetic resonance images obtained through the posterior fossa are free from artifact from the skull base. Early myelination, indicated by hypointensity, is evident in the dorsal pons (*arrow*). **B,** As in the preterm infant (see Figure 59-4, *B*), at the level of the basal ganglia and thalami, early myelination is present in the lateral thalamus and posterior limb of the internal capsule (*arrows*). Unmyelinated white matter is still markedly hyperintense (bright) in the normal term newborn. **C,** On images obtained at the level of the centrum semiovale, the rolandic cortex is easily identified by its low signal intensity (*arrows*) caused by early myelination.

Advanced MRI Techniques

Advanced MRI techniques that are useful in evaluating the normally developing or injured neonatal brain include diffusion-weighted and diffusion-tensor imaging (DWI and DTI), arterial spin labeling (ASL), perfusion-weighted imaging and susceptibility-weighted imaging (SWI), and volumetric imaging. Postprocessing of these imaging data often yield additional information about the structure or function of the brain beyond that provided by the image acquisitions themselves. For example, insights into increases in the overall cortical surface area and cortical thickness in the premature period have emerged from the use segmentation algorithms applied to volumetrically acquired imaging data.

These newer sequences have been made possible in large part by the development of ultrafast imaging such as echo planar MRI and the improved uniformity of the magnetic field available with newer MR scanners. Used in adults and older children for several years, functional techniques are also now being applied in the newborn.

DIFFUSION IMAGING

Initially popularized for its usefulness in the evaluation of acute stroke in adults, diffusion imaging (DI) is now widely utilized to provide information about both normal and abnormal processes, in the neonatal brain (Robertson et al, 1999; Rutherford et al, 1995). In DI, supplemental MR gradients are applied during the image acquisition. The motion of protons during the application of these gradients affects the signal in the image, thereby, providing information on molecular diffusion. DI may be performed

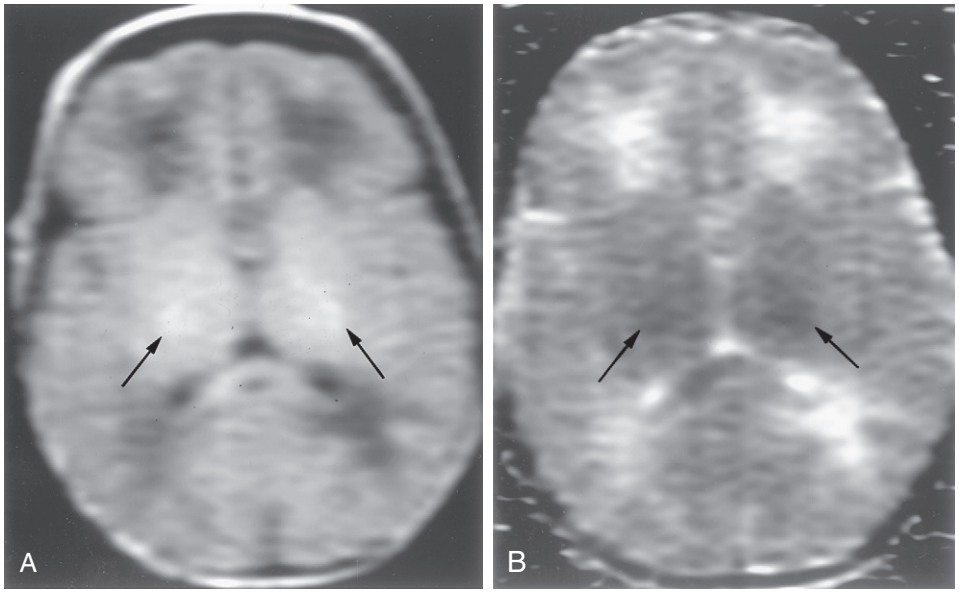

FIGURE 59-8 Axial diffusion-weighted imaging in a normal term newborn. A, Isotropic diffusion-weighted image at the level of the basal ganglia. Unmyelinated white matter has very low signal intensity because of the rapid diffusion of water in these regions, whereas areas that have already begun to myelinate, such as the lateral thalamus and posterior limb of the internal capsule (*arrows*), have more restricted diffusion and increased signal. **B,** Corresponding processed apparent diffusion coefficient (ADC) map. These maps are produced to limit T2 effects in the images. Areas with relatively restricted molecular diffusion are, by convention, depicted as lower pixel values (*arrows*).

using one of several techniques. In diffusion-weighted imaging, the supplemental gradients are employed in one to three directions. DWI is often used to evaluate pathologic processes such as brain infarction but provides limited information on brain structure. In diffusion-tensor imaging, the supplemental gradients are employed in many more directions, typically from 6 to 35 or more. Using DTI, differences in regional diffusion due to inherent brain structure can begin to be resolved and mapped. This information, can, for example, be used to generate images of white matter fiber tracts. A new diffusion imaging technique, diffusion-spectrum imaging (DSI), provides even more information by directly measuring three dimensional-spin diffusion probability. By exploring the orientation contrast information in DSI, it is possible to resolve intravoxel fiber crossing more accurately than with DTI, allowing improved delineation of white matter tracts.

In newborns, DI has been used to study normal brain myelination as well as ischemic and nonischemic CNS disorders. The immature brain is characterized by a high water content and relatively rapid molecular diffusion (Robertson and Robson, 2001; Robertson et al, 1999; Sakuma et al, 1991) (see Figure 59-7). The bulk of the water in the neonatal brain is within the extracellular space (Barlow et al, 1961). As the brain matures, a gradual decline in the extracellular volume fraction occurs because of the hydrophobic nature of myelin. Myelin also impairs the exchange of water molecules across the cell membrane. Because the movement of water within the cell is limited by its interaction with intracellular structures and the cell membrane, the apparent diffusion coefficient (ADC) of intracellular water is lower than that of extracellular water. Consequently, the ADC of myelinated white matter is lower than that of unmyelinated white matter. In addition, because of cellular structure, the direction of movement of intracellular water is preferentially along the length of the axon rather than perpendicular to it. Therefore, the relative anisotropy (RA), a measure of the inequality of diffusibility in different directions, increases as the proportion of intracellular water increases (Takeda et al, 1997; Toft et al, 1996).

Interestingly, there is a striking decrease in the overall diffusion (decreased ADC) in the central white matter between 28 and 40 weeks of postconceptional age. This occurs even though there is very little myelin deposition during this stage of brain development. This reduction in water diffusivity is accompanied by increased directionality of diffusion (increased RA). Factors that are believed to increase RA during this stage of development include neurofilament development, axon alignment, a growing number of membrane barriers, greater cohesiveness and compactness of the fiber tracts, reduced extraaxonal space (i.e., greater packing), and changes in extracellular and intracellular matrix (Huppi et al, 1998).

PERFUSION IMAGING

Cerebral perfusion may be assessed on MR either by imaging during the administration of an exogenous contrast agent in dynamic susceptibility contrast-enhanced perfusion imaging (DSCE) or RF "tagging" of in-flowing protons in ASL. In DSCE, rapid imaging is performed during the bolus administration of a susceptibility contrast agent, such as gadolinium-DPTA. The passage of contrast through the microvasculature leads to decreases in signal intensity proportional to regional tissue perfusion. Analysis of the change in signal intensity over time can provide information on the time to peak contrast concentration, cerebral blood flow, cerebral blood volume, and mean transit time of the contrast (Laswad et al, 2009). Although DSCE can be performed in neonates, successful imaging requires a rapid injection of a relatively large volume of contrast material. The limited, small-gauge intravenous access frequently available in the neonate is not optimal for DSCE perfusion-weighted imaging.

ARTERIAL SPIN LABELING

ASL is a technique assessing cerebral perfusion without the use of intravenous contrast. It is carried out by labeling protons of the intravascular arterial blood using one or two

radiofrequency pulses that invert the longitudinal magnetization of protons in arterial blood just upstream of the region of interest. The measurable magnetization and T1 relaxation time of the labeled blood will thus be modified. During acquisition (ultrafast echo planar type sequences), the signal obtained is the sum of the measurable magnetization of the region of interest and the magnetization from the labeled blood pool present in the explored volume. A second unlabeled acquisition serves as a reference to then calculate the perfusion images. The ability to assess perfusion without use of intravenous contrast medium and the relatively rapid acquisition times make ASL an attractive technique for use in the ill neonate. However, the signal intensity changes associated with perfusion in ASL are relatively modest, making the technique challenging to perform successfully.

SUSCEPTIBILITY-WEIGHTED IMAGING

All MRI techniques are susceptible to signal losses due to static inhomogeneities in the magnetic field. Mineralization and blood products cause local distortions in the magnetic field that can affect the MR image. The relative sensitivity of the MR image to perturbations in the magnetic field varies by sequence type. Gradient echo (GRE) imaging is particularly sensitive to static local magnetic field inhomogeneities and has long been used to detect regions of mineralization or prior hemorrhage. More recently, a newer technique, SWI, has been developed that provides both a greater sensitivity to magnetic field inhomogeneities and an ability to distinguish between blood products and mineralization by capturing information on proton spin phase. Although both paramagnetic substances (e.g., blood products) and diamagnetic substances (e.g., mineralization) alter proton spins, they do so in an opposite manner. Calcification and blood products, both of which cause a loss of signal on the MR image, can be distinguished from one another by evaluating the effect of their presence on proton spin phase images.

FUNCTIONAL MRI TECHNIQUES

Use of functional techniques such as magnetic resonance spectroscopy (MRS) and brain activation functional MRI (fMRI) using the blood oxygen level–dependent (BOLD) technique have increased the understanding of the biochemical and physiologic changes occurring in the neonatal brain in the first weeks to month of life. The following paragraphs discuss the value of some of these techniques.

Magnetic Resonance Spectroscopy

Proton MRS exploits the minute differences in magnetic moments of hydrogen atoms reflecting differences in their local chemical environment to produce spectra characteristic of a variety of metabolites (Keevil et al, 1998) (Figure 59-9). Because of its ability to detect both normal and abnormal metabolites in the brain, MRS is popular in the MR assessment of a number of processes affecting the newborn (Vigneron et al, 2001).

With most proton MRS techniques, the signal from water protons must be suppressed to demonstrate biologically interesting metabolites that are present in very small quantities. This requires a very homogeneous magnetic field that is generally found only in newer and higher-field-strength MR systems. Because of the tiny amount of signal emanating from the metabolites of interest, relatively large voxels (1 to 2 cm^3) must be acquired to obtain adequate signal intensity. MRS may be performed using single voxels, which sample a small region of the brain, or multiple voxels, by which many areas may be interrogated during a single acquisition (Vigneron et al, 2001). Typically, single-voxel MRS provides higher quality spectra than those available with multiple-voxel techniques.

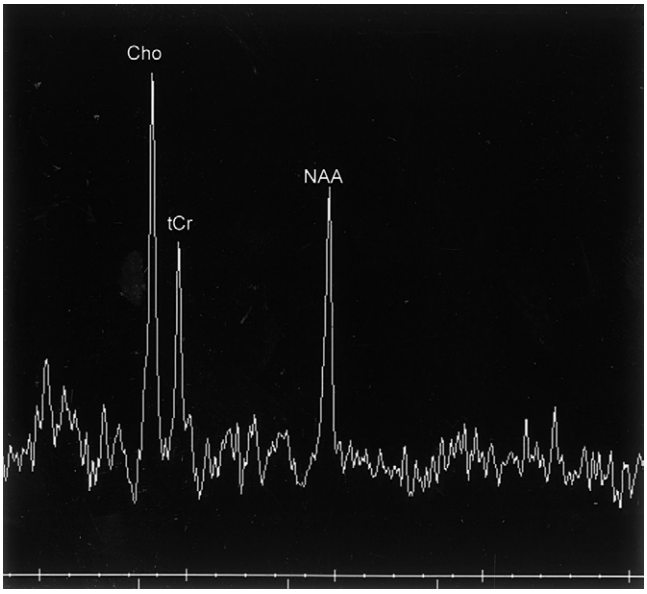

FIGURE 59-9 Single-voxel proton spectroscopy of the brain from a normal term neonate. The spectra were obtained with an echo time of 144 ms. Three prominent peaks are identified: At 3.2 ppm is choline *(Cho)*. Choline compounds are involved in the metabolism of membrane lipids. At 3.0 ppm is total creatine *(tCr)*. Creatine and phosphocreatine are involved in ATP metabolism. At 2.0 ppm is *N*-acetyl aspartate *(NAA)*. NAA is an intracellular compound found primarily in neurons. Note that lactate, which would appear, if present, as an inverted doublet at 1.3 ppm, is not seen in the normal newborn.

Three metabolites are most apparent in the normal neonatal brain proton spectra: choline (3.2 ppm), total creatine (3.0 ppm), and *N*-acetyl aspartate (NAA) (2.0 ppm) (Heerschap and van den Berg, 1994). Choline compounds are central in the metabolism of membrane lipids and tend to be elevated in processes that result in rapid cell turnover. As a consequence of membrane development during myelination, the amount of choline present in the neonatal brain tends to be relatively large. The total creatine peak is composed of creatine and phosphocreatine, which serve as a reserve for high-energy phosphates in neurons and also as an ATP/ADP buffer. Total creatine tends to remain relatively constant in most intracranial processes (Govindaraju et al, 2000). NAA is an intracellular compound found primarily in neurons, although its biologic function is largely unknown (Miller, 1991). NAA is present in smaller quantities in the neonate than in the older child or adult.

Lactate is a terminal product of glycolysis. The tissue concentration of lactate can vary from minute to minute, depending on the status of a number of major metabolic pathways.

Lactate is not demonstrated on proton MRS in the normal newborn brain but may be seen as a prominent doublet at 1.3 ppm in certain pathologic conditions such as energy exhaustion due to ischemia/infarction or certain metabolic disorders. Depending on the parameters chosen for imaging, the lactate peaks may project above or below the baseline.

Brain Activation Function Magnetic Resonance Imaging

MR brain activation studies have been performed successfully in the neonate, albeit in limited scope (Anderson et al, 2001; Benaron et al, 2000; Born et al, 1998). The use of MRI to indirectly demonstrate cortical activation is based on the observation that regional blood flow varies with neuronal activity. That is, in areas of the brain that are activated, there is an increase in blood flow. During brain activation, the oxygen extraction fraction remains constant. Consequently, there is an increase in the local concentration of oxyhemoglobin and a decrease in the local concentration of deoxyhemoglobin in regions of activation (Buchbinder and Cosgrove, 1998). Deoxyhemoglobin has susceptibility effects that cause minor perturbations in the magnetic field, leading to signal loss. The increase in oxyhemoglobin that accompanies brain activation causes a local increase in signal intensity. These changes form the basis of the BOLD MRI technique. Because the signal changes associated with brain activation are quite small, a number of images must be averaged together to demonstrate cortical activation. Typically, therefore, BOLD imaging requires that the subject cooperate with repetitive tasks to demonstrate brain activation. Because the neonate is unable to perform such tasks, only those stimuli that produce an involuntary response, such as visual cortical activation with strobe light flashes, may be tested. Despite these limitations, the use of BOLD MRI to evaluate neonatal brain activation is an active area of research (Anderson et al, 2001; Benaron et al, 2000; Born et al, 1998).

NEAR INFRARED SPECTROSCOPY AND QUANTITATIVE DETERMINATIONS OF OXYGENATED HEMOGLOBIN

NIRS is a noninvasive optical imaging technique used to measure hemoglobin oxygenation in the blood in vivo. It can provide useful information about cerebral hemoglobin oxygen saturation, cerebral blood volume, cerebral blood flow, cerebral venous oxygen saturation, and cerebral oxygen availability and utilization (Franceschini et al, 2007).

The NIRS technique is based on the fact that light in the near-infrared range can pass relatively easily through the skin, bone, and other tissues in a newborn infant, and on the property of hemoglobin to absorb light in the near-infrared range. Appropriate selection of near-infrared wavelengths allows detection of the characteristic changes in light absorption of oxygenated and deoxygenated hemoglobin and oxygenated cytochrome aa_3. This in turn allows quantification of oxygenated and deoxygenated hemoglobin and determines the oxidation-reduction state of cytochrome oxidase. NIRS data is expressed as a percentage of HbO_2 saturation, or absolute changes in HbO_2, deoxyhemoglobin, and total hemoglobin in micromolar concentrations, referenced to an arbitrary baseline. Significant advances in NIRS technique include development of frequency-domain and time-domain (FD-NIRS and TD-NIRS) devices that allow quantification of brain tissue oxygen (StO_2) and total hemoglobin concentration (HbT). Recently, FD-NIRS has been looked at in assessing neonatal brain injury (Grant et al, 2009). The results from early studies indicate that there is no significant difference in measured StO_2 between brain-injured and normal neonates, suggesting that StO_2 alone may be insensitive to evolving brain injury. Combining cerebral blood volume (CBV) and regional cerebral oxygen consumption ($CMRO_2$) has been shown in encouraging sensitivity and specificity values for FD-NIRS for detecting brain injury within the first 2 weeks of life (Grant et al, 2009).

CHOOSING THE APPROPRIATE TEST

Ultrasound is the modality of choice for monitoring and screening for suspected intracranial hemorrhage and PVL in the premature infant, and for detecting the subsequent complications of ventricular dilatation and progressive hydrocephalus. In the hands of skilled operators, it can be a very useful tool in the identification of congenital midline anomalies, cystic lesions, vascular malformations, and intracranial calcifications and in the definition of extraaxial fluid collections.

CT is superior to MRI, and remains the study of choice, for the detection of parenchymal calcification and demonstration of bone abnormalities. However, it is important to note that potential late untoward effects of radiation used for diagnostic CT scanning have been highlighted by a number of studies (Donnelly and Frush, 2001; Hall, 2007). The theoretical risk of malignancy related to exposure to ionizing radiation is highest in the neonate. Given that significant intracranial hemorrhage is detected by MRI as well as by CT, an argument can be made for eliminating CT for the evaluation of the encephalopathic term neonate, thereby avoiding the potential risks of ionizing radiation altogether (Robertson et al, 2003).

In addition to its ability to detect focal cerebral infarcts earlier than CT, MRI is superior to CT in detecting disorders of neuronal migration, abnormal myelination, arteriovenous malformations, venous thrombosis, differentiating hemorrhagic infarction from primary parenchymal hemorrhage, posterior fossa lesions (Figure 59-10), and almost all spinal cord abnormalities (Volpe, 2008).

IMAGING APPLICATIONS

NORMAL PRETERM VERSUS TERM INFANTS

The most obvious difference between the preterm and the term neonatal brain is relative maturation of the sulcal/gyral architecture. As with fetal imaging, the cerebral cortex of the preterm infants studied at 25 weeks of gestational age equivalent has a very smooth cortical mantle with a largely uncovered sylvian fissure and very few developed gyri. At this age, demonstration of lissencephaly and of some localized anomalies of cortical development is not possible with US and may be difficult with more advanced imaging techniques as well. Cortical maturation proceeds in a predictable fashion and should attain a fully developed

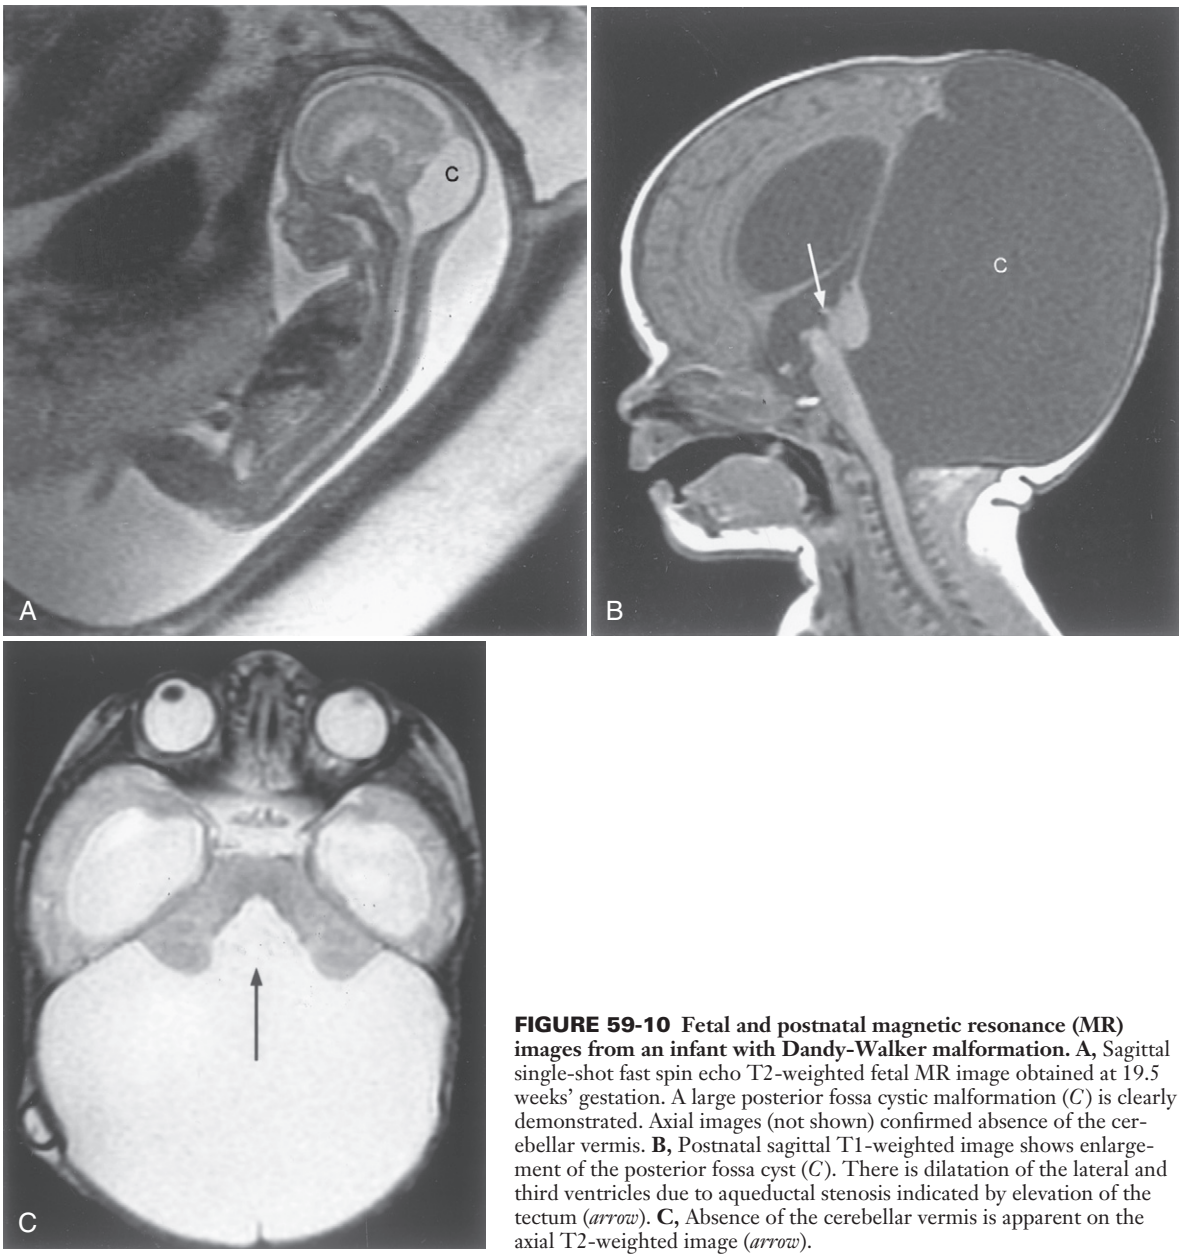

FIGURE 59-10 Fetal and postnatal magnetic resonance (MR) images from an infant with Dandy-Walker malformation. A, Sagittal single-shot fast spin echo T2-weighted fetal MR image obtained at 19.5 weeks' gestation. A large posterior fossa cystic malformation (*C*) is clearly demonstrated. Axial images (not shown) confirmed absence of the cerebellar vermis. **B,** Postnatal sagittal T1-weighted image shows enlargement of the posterior fossa cyst (*C*). There is dilatation of the lateral and third ventricles due to aqueductal stenosis indicated by elevation of the tectum (*arrow*). **C,** Absence of the cerebellar vermis is apparent on the axial T2-weighted image (*arrow*).

secondary sulcal/gyral pattern by 40 to 44 weeks of gestational age (Chi et al, 1977). On US, gyri are depicted as linear echoes that increase in length, undulation, and branching as the infant matures.

A prominent feature of both the preterm and the term neonatal brain is the very high water content of the unmyelinated subcortical white matter. In the premature infant, there is little difference in echogenicity between gray and white matter until 32 to 34 weeks' gestation. In the near-term infant, the cortical ribbon is hypoechoic in relation to the underlying white matter. Beyond 40 weeks' gestation, the overall echogenicity of white matter structures increases markedly, and visualization of deeper structures may become more difficult. On CT, unmyelinated white matter is hypodense relative to cortex and deep central gray matter. On MRI, the high water content of unmyelinated white matter produces marked prolongation of T1 and T2, causing the white matter to be hypointense to gray matter on T1-weighted imaging and hyperintense to gray matter on T2-weighted imaging. This pattern is the inverse of signal intensities of gray and white matter present in the fully myelinated brains of older children and adults (Barkovich, 2000; Barkovich et al, 1988). Because many pathologic processes result in edema, seen as low density on CT studies and resulting in T1 and T2 prolongation on MR images, these lesions are especially difficult to see in the neonatal white matter.

INTRACRANIAL HEMORRHAGE

Acute intracranial hemorrhage in the neonate may be epidural, subdural, subarachnoid, or parenchymal in location. Hemorrhages may be small and noted incidentally on

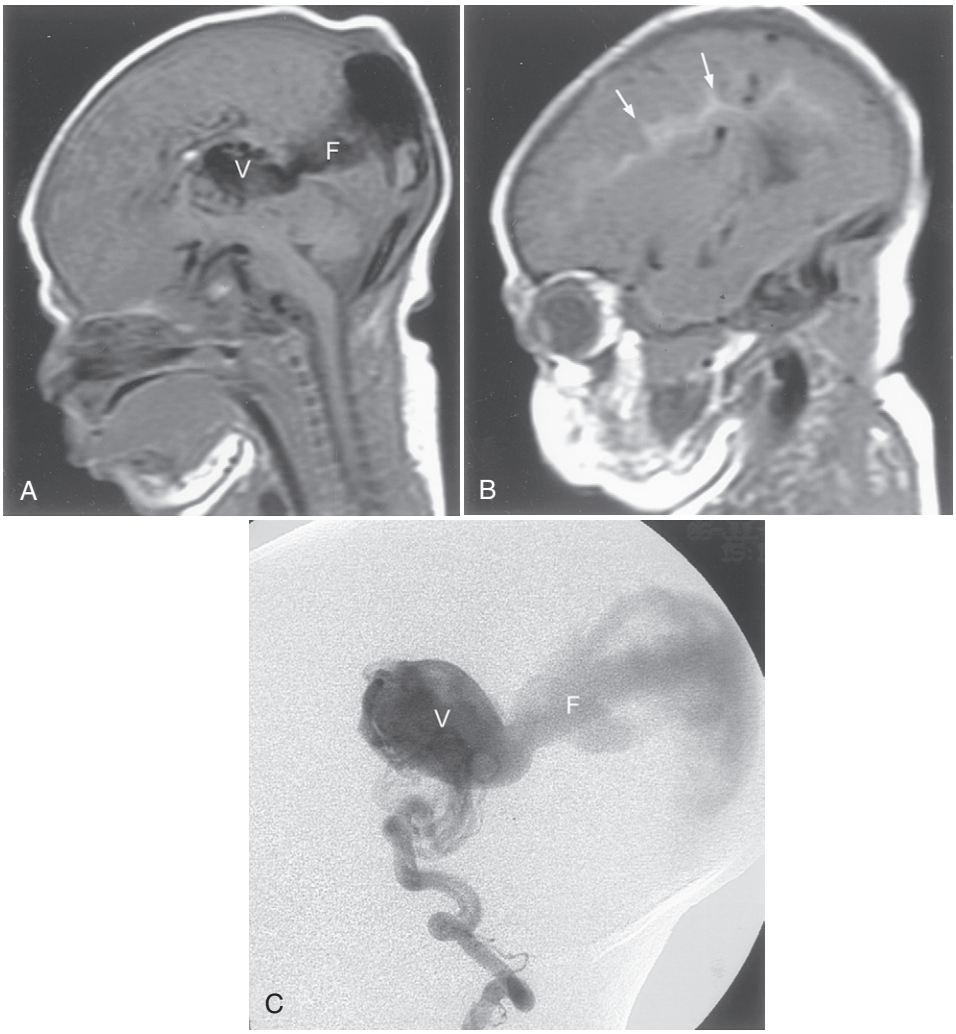

FIGURE 59-11 The patient was a neonate with congestive heart failure due to a Galenic arteriovenous malformation (also called vein of Galen aneurysm). A, Midline sagittal T1-weighted magnetic resonance (MR) image shows a signal void within the median prosencephalic vein (*V*), the embryologic precursor to the vein of Galen, and the persistent falcine sinus (*F*). **B,** Parasagittal T1-weighted MR image shows hyperintensity of the subcortical white matter (*arrows*) due to chronic ischemic injury. **C,** Selective vertebral artery conventional angiogram performed as part of a transcatheter therapeutic procedure shows flow within the varix (*V*) and draining sinus (*F*). Note that although the feeding arteries are markedly dilated because of the massive intracranial flow that is present, all of the blood flow is diverted through the fistulas, and there are no brain parenchymal branches filling. This "steal" phenomenon produces the ischemic changes that can be demonstrated with computed tomography and MR imaging.

imaging performed for other reasons or may be large and produce acute neurologic symptoms.

Small parturitional subdural hemorrhages are common even in the absence of a traumatic birth history and are often asymptomatic (Holden et al, 1999). Significant subdural hemorrhages are most frequently encountered in the setting of traumatic delivery, accidental trauma or, occasionally, nonaccidental trauma. Laceration of the falx cerebri or the tentorium cerebelli may produce large or rapidly expanding subdural hematomas. Larger subdural hematomas may be associated with acute or progressive symptoms due to intracranial mass effect.

A small amount of parturitional subarachnoid bleeding is not uncommon. Subarachnoid hemorrhage with larger amounts of bleeding may occasionally occur in conjunction with vascular malformations. The most common symptomatic intracranial vascular malformation in the newborn is the vein of Galen malformation (Figure 59-11). Although most newborns with vein of Galen malformations present with cardiopulmonary distress due to high-output cardiac failure resulting from arteriovenous shunts, massive subarachnoid bleeding may occasionally occur from either spontaneous or iatrogenic perforation of the varix or feeding arteries.

Parenchymal hemorrhage in the preterm infant occurs most often in or around the highly cellular, gelatinous, and highly vascularized subependymal germinal matrix. Although its pathogenesis is multifactorial (Volpe, 2008), a common final pathway seems to be microscopic perivenular hemorrhage in the highly vascular germinal matrix (Ghazi-Birry et al, 1997).

The classification originally proposed by Papile and colleagues remains the most widely accepted method of grading the severity of germinal matrix hemorrhage in the preterm infant (Papile et al, 1983). Grade I consists of subependymal hemorrhage only (Figures 59-12 and 59-13). On US, grade I hemorrhages appear as bright echogenic foci in the subependymal area typically located in or

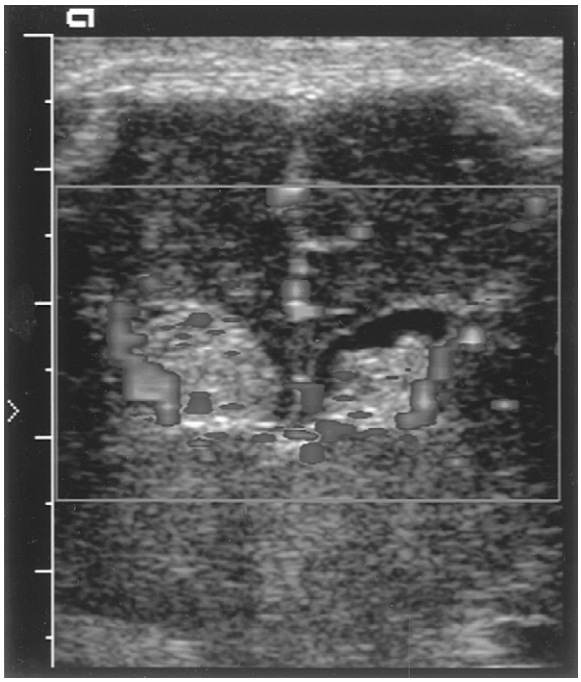

FIGURE 59-12 *(See also Color Plate 24.)* **Coronal color Doppler image of bilateral grade I germinal matrix hemorrhages.** The hemorrhages are echogenic. Although flow is confirmed within the terminal veins (*blue*), the veins are laterally displaced by the subependymal hemorrhages.

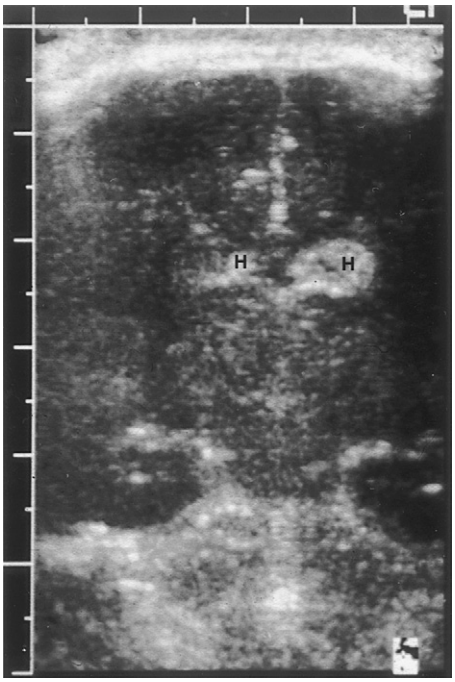

FIGURE 59-14 Coronal ultrasound study of bilateral grade II intracranial hemorrhage in the preterm neonate. Echogenic subependymal hemorrhages (*H*) are seen extending into the lateral ventricles. There is no hydrocephalus.

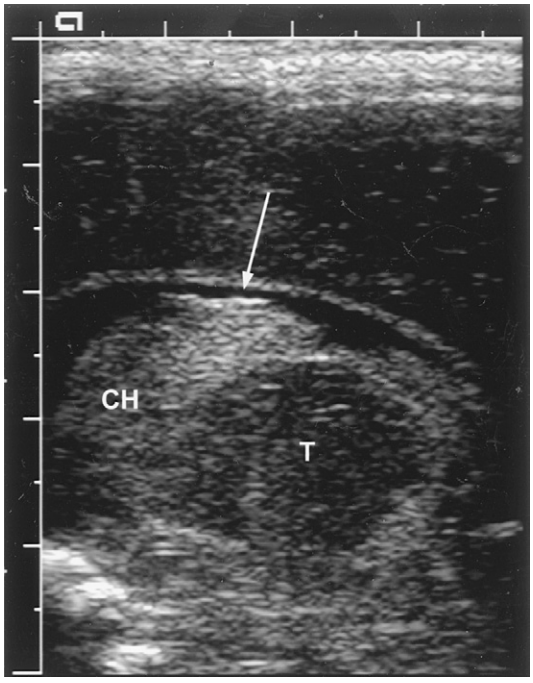

FIGURE 59-13 Sagittal ultrasound study of grade I germinal matrix hemorrhage. Echogenic hemorrhage (*arrow*) is seen at the caudothalamic notch situated between the caudate head (*CH*) anteriorly and the thalamus (*T*) posteriorly.

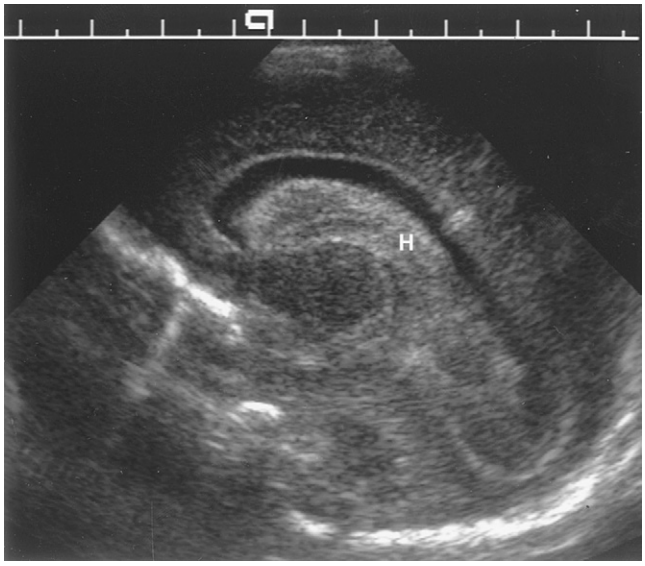

FIGURE 59-15 Sagittal ultrasound study of grade III intracranial hemorrhage. The lateral ventricle is moderately dilated and filled with echogenic blood (*H*).

anterior to the caudothalamic notch. Grade II is defined as subependymal and intraventricular hemorrhage without ventricular dilatation (Figure 59-14). Grade III is the combination of subependymal and intraventricular hemorrhage with ventricular dilatation by clot (Figure 59-15). Small choroid plexus hemorrhages may be difficult to distinguish from a normal "lumpy bumpy" choroid plexus, because both are brightly echogenic. Larger, acute intraventricular clots can be identified as echogenic irregular and asymmetrical masses. Poorly clotted blood will often result in a fluid-debris level within the ventricle that disappears or is redistributed when the baby is repositioned and blood is remixed with CSF. In critically ill premature infants it is important to distinguish progression of a grade II hemorrhage to grade III from the development of

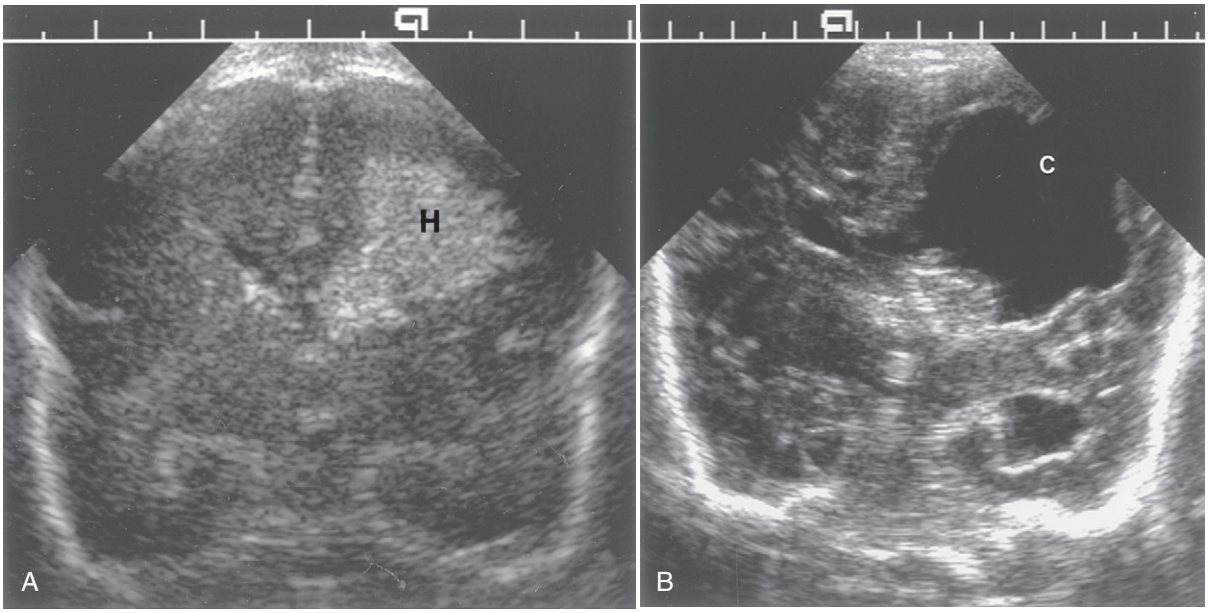

FIGURE 59-16 Coronal ultrasound study of intraparenchymal hemorrhage. A, Initially the parenchymal hemorrhage (*H*) is echogenic. **B,** As the hematoma ages, liquefaction occurs and the hematoma becomes echolucent with the development of a porencephalic cyst (*C*).

posthemorrhagic hydrocephalus. Both entities are associated with intraventricular clot and dilatation of the ventricular system. However, in grade III hemorrhage, the ventricle is almost completely distended by clot, whereas the ventricle in posthemorrhagic hydrocephalus is often primarily distended with CSF. The size of the obstructing intraventricular clot may be relatively small. The distinction is important because ventricular dilatation caused by increasing hemorrhage may have therapeutic implications different from those associated with posthemorrhagic hydrocephalus.

Destruction of the germinal matrix and the precursor glial cells within it is the most consistent consequence of the periventricular hemorrhage. This destruction of glial cells has an adverse effect on subsequent brain development (Volpe, 2008).

Up to 15% of very low birthweight infants with intraventricular hemorrhage develop hemorrhagic necrosis in the periventricular white matter. A number of neuropathologic studies have shown that simple extension of blood into the periventricular white matter does not account for this periventricular hemorrhagic necrosis. Instead, this finding is now believed to be a hemorrhagic infarction, resulting from venous congestion of the terminal medullary veins in the region of residual germinal matrix at the caudothalamic groove (see Figure 59-11). This hemorrhagic venous infarction can be depicted with color Doppler techniques (Taylor, 1995, 1997). The most common result of the periventricular hemorrhagic infarction is a large porencephalic cyst, either alone or in combination with other smaller cysts.

Periventricular hemorrhagic infarction (PVHI), formerly described as a grade 4 germinal matrix hemorrhage (GMH) in the original classification, is now thought to be caused by pressure of the GMH on the periventricular terminal medullary veins that drain the cerebral hemispheres (Volpe, 1998). This leads to venous congestion in the periventricular white matter and subsequently to ischemia and hemorrhage (see Figure 59-15). PVHI, or venous infarction, is now considered a complication of the GMH instead of an extension of the GMH. PVHI is seen in 10% to 15% of preterm infants with germinal matrix hemorrhage and is, on occasion, documented in the fetus on obstetrical sonography or fetal MRI.

In the term infant, lobar parenchymal and subpial hemorrhages are occasionally encountered (Koenigsberger, 1999) (Figure 59-16). These hemorrhages appear to occur spontaneously in the first few days of life in otherwise healthy babies.

Spontaneous superficial parenchymal and leptomeningeal hemorrhage occurs in otherwise healthy term neonates (Figure 59-17). The hemorrhage is most often in the temporal lobe and in proximity to sutures, often accompanied by minor overlying soft tissue swelling and subjacent decreased diffusion in the brain parenchyma. This pattern suggests the possibility of local trauma with contusion or venous compression or occlusion as contributing to the development of these hemorrhages (Huang and Robertson, 2004).

Color Doppler US may be used to characterize extracerebral fluid collections as subarachnoid, subdural, or combined. Because superficial cortical blood vessels lie within the pia-arachnoid, fluid in the subarachnoid space lifts the cortical vessels away from the brain surface, whereas fluid in the subdural space approximates cortical vessels to the brain surface and is separated from these vessels by a thin membrane (Figure 59-18). Correlation with MRI and CT suggests that color Doppler is reliable in making this differentiation (Chen et al, 1996).

Suspected intracranial hemorrhage remains one of the most common indications for brain CT in the neonate. On CT, acute hemorrhage appears hyperdense relative to the brain parenchyma (see Figure 59-18). Of note, the dural venous sinuses and cortical veins appear relatively dense during the first few days of life as a result of high hematocrit levels. This normal density of the venous structures

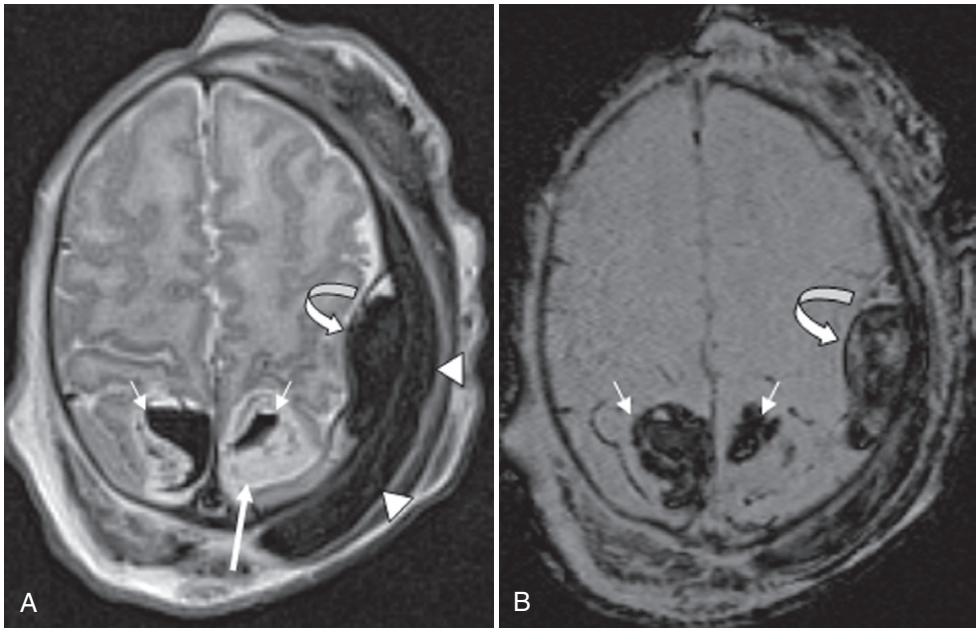

FIGURE 59-17 The patient is a term neonate scanned on day 2 after a failed forceps delivery and low Apgar scores and acidosis at birth. A, Axial T2-weighted image shows bilateral parasagittal right and left subpial hemorrhages (*arrows*) with surrounding edema (*long arrow*). There is a left frontoparietal epidural hematoma (*curved arrow*) and a large subgaleal hematoma (*arrowheads*) as well. **B,** Corresponding susceptibility-weighted image shows large areas of susceptibility corresponding to the areas of subpial (*arrows*), epidural (*curved arrow*), and subgaleal hemorrhage (*arrowheads*).

should not be mistaken for subdural bleeding or dural venous sinus thrombosis on CT. As blood ages, the density of the clot will decrease. In the chronic phase, sites of extraaxial or parenchymal hemorrhage have decreased density relative to the brain parenchyma. Parturitional subdural hemorrhages are typically completely resolved by 6 to 8 weeks of life.

Until recently, MRI was considered to be less sensitive for the detection of acute intracranial hemorrhage than CT. However, if either gradient echo sequences or the more recently described SWI technique is used, all significant intracranial hemorrhages in the newborn are reliably demonstrated by MRI (Blankenberg et al, 2000; Robertson et al, 2003). On MRI, the signal intensity of blood varies with age.

Although the timing for the development of the various stages of hemorrhage in the neonate may differ from that in the adult, the signal intensity changes are similar. With hyperacute hemorrhage, unclotted blood appears similar to free fluid (i.e., low signal intensity on T1-weighted images and high signal intensity on T2-weighted images). Within hours, oxyhemoglobin is converted to deoxyhemoglobin. Deoxyhemoglobin within the red blood cells causes susceptibility artifact that produces low signal intensity on T2-weighted images (Figure 59-19). Over the first several days, deoxyhemoglobin is converted to methemoglobin, which results in high signal intensity on T1-weighted images and low signal intensity on T2-weighted images. Subsequently, the red blood cells lyse, and an increase in signal intensity is observed on the T2-weighted images. Chronically, hemosiderin staining occurs, which appears dark on both T1-weighted and T2-weighted images.

The administration of contrast agent is not usually required in the MRI investigation of hemorrhage, except in the rare case of suspected underlying tumor. When tumor is present, it is imperative that spinal imaging also be performed because most brain tumors discovered in the newborn period have a propensity to seed the CSF.

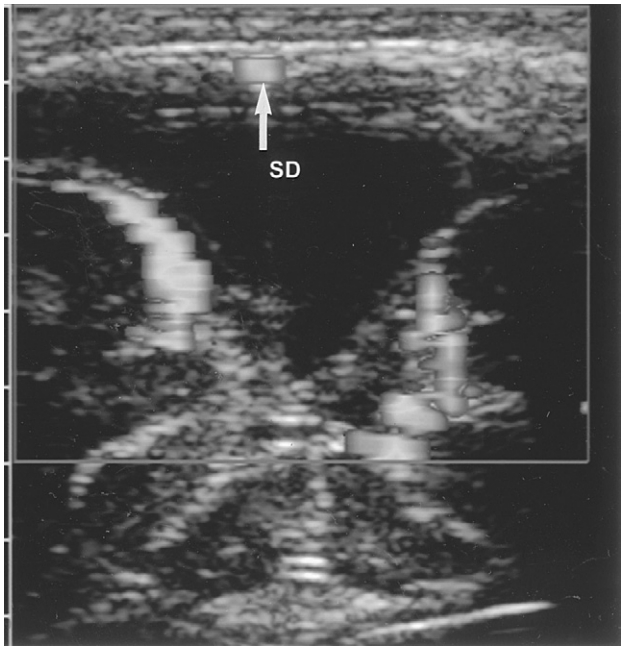

FIGURE 59-18 *(See also Color Plate 25.)* Coronal color Doppler ultrasound study shows that the vessels (color) are displaced toward the brain parenchyma by the subdural fluid (*SD*). Note flow in the superior sagittal sinus (*arrow*).

NEONATAL CEREBRAL INFARCTION

Neonatal cerebral infarction is a common cause of infant morbidity and mortality (Rivkin, 1997; Volpe, 2008). Infarctions in the newborn may be due to global transient decreases in blood flow or in oxygen delivery to the brain (hypoxic-ischemic injury) (Figure 59-20) or to focal arterial or venous occlusions (Figures 59-21 to 59-23). Hypoxia-ischemia tends to produce bilaterally symmetric lesions, whereas arterial or venous occlusions are associated with focal or asymmetric multifocal areas of

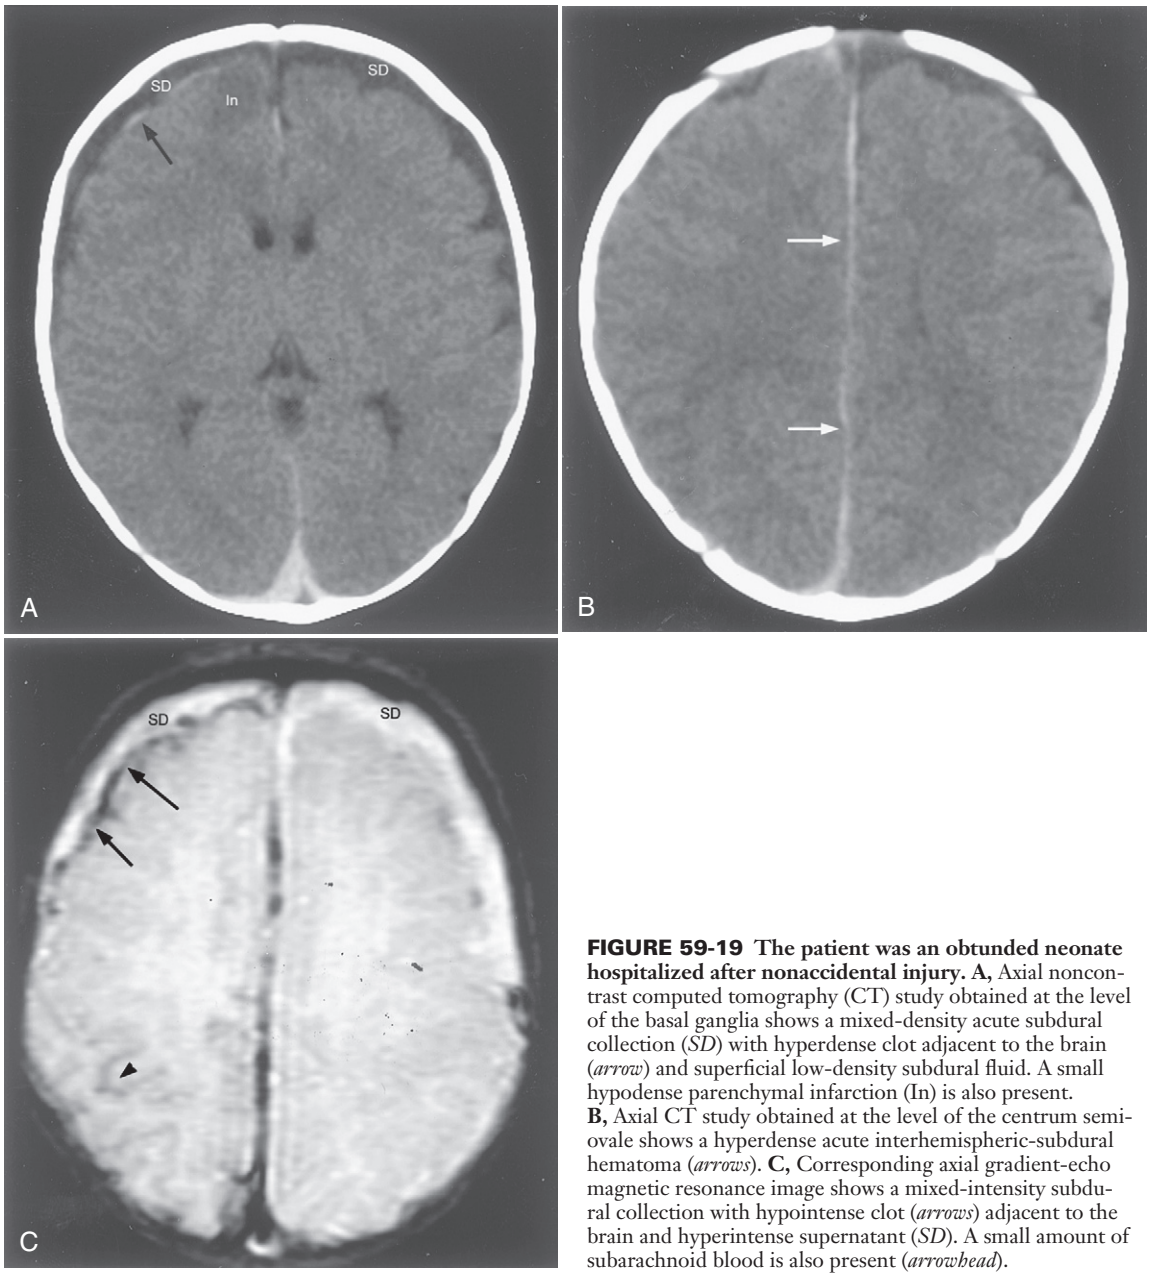

FIGURE 59-19 The patient was an obtunded neonate hospitalized after nonaccidental injury. A, Axial noncontrast computed tomography (CT) study obtained at the level of the basal ganglia shows a mixed-density acute subdural collection (*SD*) with hyperdense clot adjacent to the brain (*arrow*) and superficial low-density subdural fluid. A small hypodense parenchymal infarction (In) is also present. **B,** Axial CT study obtained at the level of the centrum semiovale shows a hyperdense acute interhemispheric-subdural hematoma (*arrows*). **C,** Corresponding axial gradient-echo magnetic resonance image shows a mixed-intensity subdural collection with hypointense clot (*arrows*) adjacent to the brain and hyperintense supernatant (*SD*). A small amount of subarachnoid blood is also present (*arrowhead*).

infarction. A variety of imaging appearances of infarction may be observed at a given postnatal age, and lack of specificity in the clinical presentation may further complicate the interpretation of the imaging (Robertson and Robson, 2001).

In the term infant, the vascular border-zone territories are in a parasagittal location, anteriorly between the major branches of the anterior and middle cerebral arteries and posteriorly between the branches of the anterior, middle, and posterior cerebral arteries. In our experience, border-zone ischemic injury in the term neonate most often occurs in conjunction with deep central gray and white matter injury in cases of profound hypoxia-ischemia.

Profound hypoxia-ischemia in the preterm or term infant tends to affect those regions of the brain with the greatest metabolic requirements. These include areas with high concentrations of excitatory neurotransmitters or regions that are actively myelinating (Rivkin, 1997; Volpe, 1997). The dorsal brainstem, thalami, posterior portions of basal ganglia, posterior limb of internal capsule, corona radiate, and mesial temporal lobes are especially susceptible to injury (see Figure 59-19). The medial portions of the cerebellar hemispheres and cerebellar vermis are also commonly affected. Areas of the brain with lower energy requirements, such as unmyelinated white matter and cortex, tend to be relatively spared unless the ischemia is particularly severe. After severe hypoxia-ischemia, the pattern of tissue injury is variable. In some infants, a deep central gray matter distribution of injury with relative preservation of the cortex and subcortical white matter is present (Roland et al, 1998). In other infants, there is widespread necrosis, ultimately producing a pattern of cystic encephalomalacia.

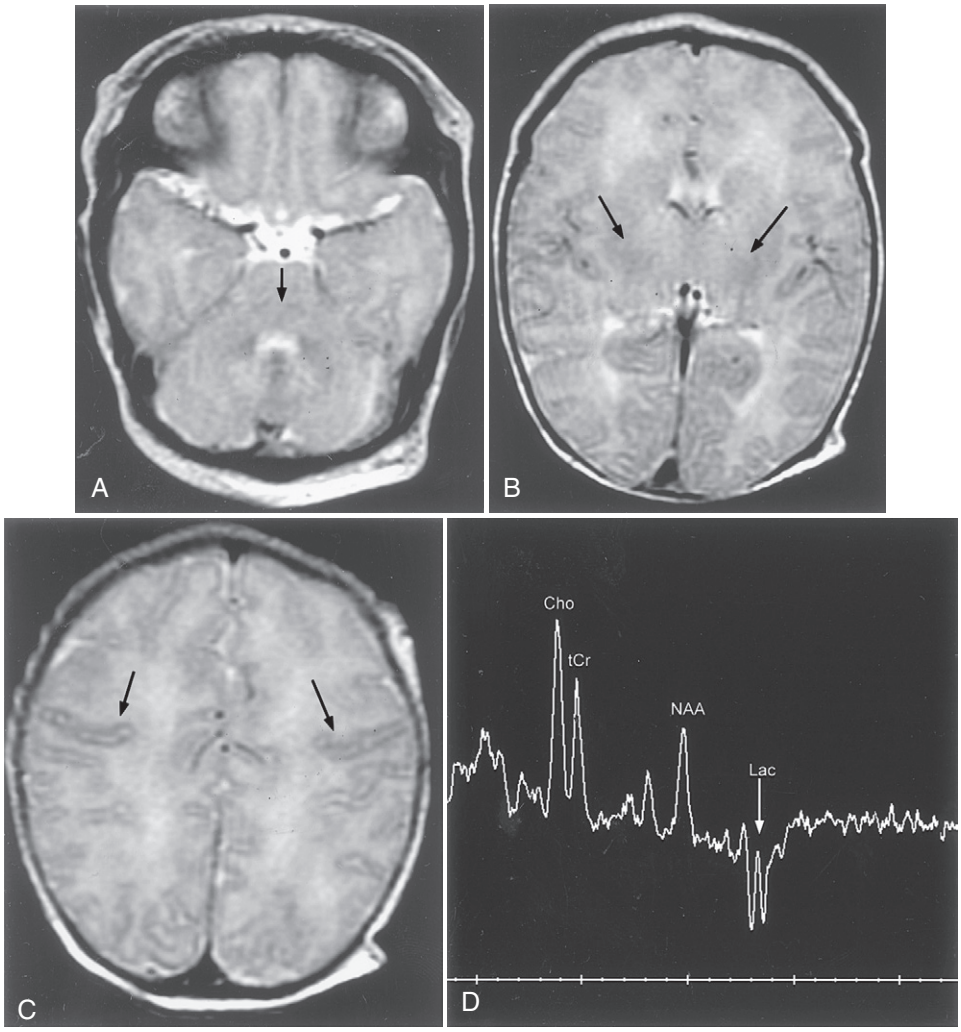

FIGURE 59-20 Magnetic resonance images obtained at 24 hours of life in a neonate with profound hypoxic-ischemic brain injury. Compare with normal T2-weighted and diffusion images (see Figures 59-6 and 59-7). **A** to **C,** T2-weighted images demonstrate edema with loss of normal hypointensity in the dorsal pons (*arrow*) **(A)** and the lateral thalami and internal capsule (*arrows*) **(B)**. Markedly decreased diffusion is seen in the lateral thalami and internal capsule on the apparent diffusion coefficient maps (*arrows*) **(C)**. **D,** Single-voxel spectroscopy obtained from the left basal ganglia demonstrates a prominent lactate doublet (*Lac*). The peaks project above the baseline because of the echo time used (TE = 270 ms). *Cho*, Choline; *NAA*, *N*-acetyl aspartate; *Cr1* and *Cr2*, two peaks of creatine.

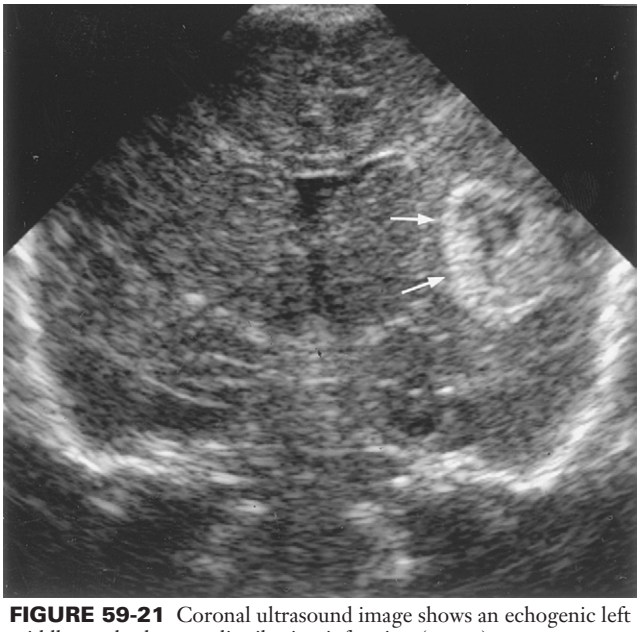

FIGURE 59-21 Coronal ultrasound image shows an echogenic left middle cerebral artery distribution infarction (*arrows*).

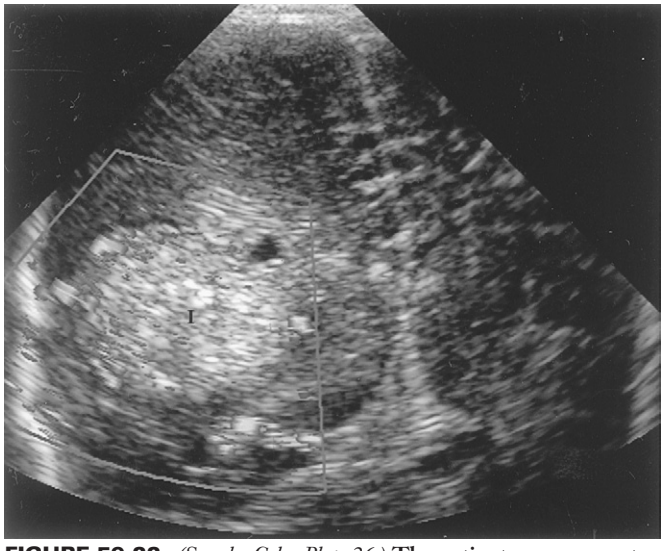

FIGURE 59-22 *(See also Color Plate 26.)* **The patient was a neonate with a focal right occipital infarction with surrounding "luxury perfusion."** A coronal ultrasound image obtained through the anterior fontanel shows a hyperechoic right occipital infarction (*I*) surrounded by increased flow on color Doppler examination.

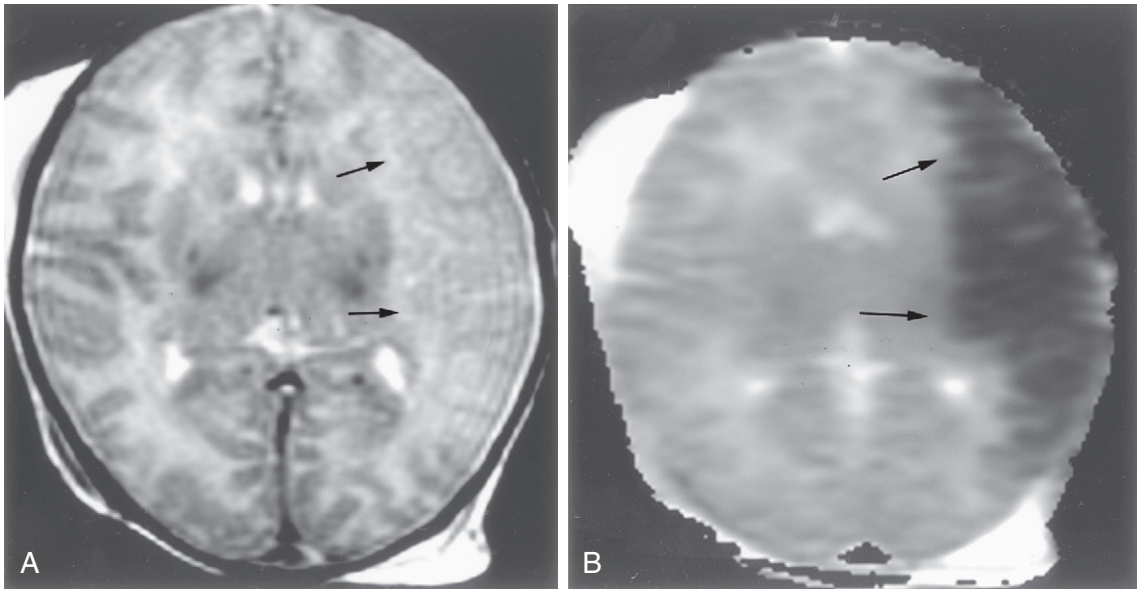

FIGURE 59-23 **Magnetic resonance imaging of a focal left middle cerebral artery infarction in a 6-day-old neonate. A,** Axial T2-weighted image shows edema and loss of the cortical ribbon in the left middle cerebral artery territory (*arrows*). **B,** Apparent diffusion coefficient (ADC) map shows markedly restricted diffusion (hypointensity) in the area of infarction (*arrows*).

The deep central pattern of injury is associated with a variable outcome, whereas widespread encephalomalacia more consistently portends a poor prognosis.

On cranial US, ischemic areas of thalamus and basal ganglia may appear focally or diffusely echogenic. US findings may be quite variable in time of onset and are insensitive to the extent of injury compared to CT or MRI.

In the first few hours after hypoxia-ischemia, brain CT findings are usually normal. Depending on the severity of the insult, changes may begin to be apparent in 24 to 48 hours. In severe hypoxia-ischemia, the thalami and basal ganglia develop low density. The cortical ribbon may become indistinct or even indistinguishable from the subcortical white matter. A subset of babies with hypoxia-ischemia will develop mineralization and hypermyelination in the deep gray matter structures, producing hyperdensity in these structures, an appearance termed status marmoratus.

Although there is considerable variability in the MR appearance of hypoxia-ischemia, some general trends may be observed (Johnson et al, 1999; Robertson et al, 1999; Rutherford et al, 1995; Wolf et al, 2001). Up to 15 to 18 hours after the ischemic event, the diffusion-weighted imaging is often normal. At this time, T1- and T2-weighted sequences typically also fail to show any abnormality. Some studies indicate that measuring the ADC values in visibly normal appearing brain, particularly in the basal ganglia and brainstem, may correlate with outcome (Liauw et al, 2009). Progressively over the next 24 to 48 hours, restricted diffusion develops within the regions of the brain with the highest metabolic requirements (Robertson and Robson, 2001). During this time, the T1- and T2-weighted images also become abnormal (Barkovich et al, 1995). Toward the end of the 1st week, it is not uncommon to demonstrate decreased diffusion in the subcortical white matter in areas that on early examinations showed normal or even increased diffusion (Robertson et al, 1999). These white matter regions typically show hyperintensity on T2-weighted sequences in advance of the development of decreased diffusion. By 10 to 14 days, the diffusion abnormalities typically normalize, and ultimately, increased diffusion may be present. Chronically, T1-weighted and T2-weighted sequences show areas of signal abnormalities related to gliosis, mineralization, or hypermyelination associated with variable tissue loss.

MRS also has been used to evaluate neonates with hypoxia-ischemia (Barkovich et al, 1999; Cady, 2001). The observed changes on MRS in newborns with hypoxia-ischemia include the presence of lactate, indicating energy failure, and a decrease in NAA, suggesting decreased neuronal density or activity (see Figure 59-19). The demonstration of lactate requires the use of a long echo sequence (e.g., echo time [TE] of 135 ms or 270 ms). On the 135-ms TE acquisition, lactate is seen as a doublet peak projecting below the baseline at 1.3 ppm (lactate peaks project above the baseline at the 270-ms TE). Lactate is evident within the first few hours after onset of hypoxia-ischemia. The amount of lactate slowly diminishes over the ensuing several days. Occasionally, elevation of lactate levels will recur several weeks after the insult (Hanrahan et al, 1998). The etiology of this delayed appearance of lactate is uncertain, but it may be due to the production of lactate by macrophages moving into the area of infarction as part of the reparative process. Studies have shown that the presence of lactate within the basal ganglia or as a delayed finding is associated with an abnormal neurologic outcome at 1 year of age (Barkovich et al, 1999; Hanrahan et al, 1998).

Focal infarctions most often occur in a middle cerebral artery distribution (de Vries et al, 1997, 1999; Sreenan et al, 2000) (see Figures 59-20 and 59-21). Focal infarcts may be small and involve the cortex only, or they may involve the subcortical white matter, internal capsule, and basal ganglia. Infarcts that are confined to the cortex tend to carry a relatively good prognosis. Lesions also involving

the internal capsule and basal ganglia are usually associated with a persistent hemiparesis (de Vries et al, 1999; Mercuri et al, 1999).

Sonographically, focal infarcts initially manifest as geographic areas of increased echogenicity, followed by progressively increased echogenicity and loss of gyral and sulcal definition (see Figure 59-21). Mass effect and effacement of the ventricular system are often present. Initially there is diminished flow demonstrated on duplex and color Doppler US. Over time, increased flow in the surrounding tissues consistent with "luxury perfusion" can be seen on color Doppler US (see Figure 59-22) (Hernanz-Schulman et al, 1988; Taylor, 1994).

On CT, focal infarcts appear as localized regions of hypodensity with loss of the cortical ribbon. Hemorrhagic conversion of an arterial infarction in the newborn is uncommon.

On MRI, focal infarcts are seen as regions of low signal intensity on T1-weighted sequences and high signal intensity on T2-weighted sequences (see Figure 59-23). Signal alterations occur earlier and more consistently on both diffusion and conventional MRI in focal infarctions than in hypoxia-ischemia (Robertson et al, 1999).

Unlike imaging in hypoxia-ischemia, even on the first day of life, the diffusion and the conventional imaging will typically demonstrate focal infarctions (Robertson et al, 1999). Also unlike hypoxia-ischemia, focal infarctions in the neonate do not usually show an increase in extent on follow-up imaging. The diffusion abnormality tends to normalize by 10 to 14 days. Atrophic changes are generally apparent on follow-up T1- and T2-weighted images; however, the degree of accompanying gliosis is variable. At times, chronic infarcts may appear simply as focally prominent sulci.

Venous infarction resulting from thrombosis of the internal cerebral veins and perimedullary veins must be considered in neonates presenting with hemorrhagic infarcts, particularly around the thalamus (Figure 59-24).

FIGURE 59-24 The patient was a newborn with sagittal sinus, straight sinus, and right internal cerebral vein thrombosis and right thalamic hemorrhagic venous infarction. An axial, non–contrast-enhanced CT scan shows high-density clot (*arrowheads*) in the right internal cerebral vein and a small hemorrhagic infarction (*arrow*) in the right thalamus.

PERIVENTRICULAR LEUKOMALACIA

Periventricular leukomalacia is the most common form of white matter injury of prematurity (Inder et al, 1999; Volpe, 1997). PVL is characterized by focal necrotic lesions in the periventricular white matter, optic radiations, and acoustic radiations and less prominent, more diffuse cerebral white matter injury. In the premature infant, these sites have in common their location in vascular border zones, lying between the long penetrating branches of the middle, anterior, and posterior cerebral arteries that pierce the cortex from the pial surface and the basal penetrating vasculature suggesting an ischemic origin of the lesions (e.g., lenticulostriate and choroidal vessels) (Shuman and Selednik, 1980; Volpe, 2008). As the fetus or infant approaches term, there is a gradual shift in these border zone territories toward a parasagittal location. Neuropathologically, PVL is characterized in the acute phase by coagulation necrosis and neuroaxonal swelling (Volpe, 2008). A variable amount of hemorrhage may be present. In the subacute stage, cysts may form in the larger lesions. Ultimately, astrogliosis develops and the cysts become less apparent.

The US appearance of the brain may be normal within the first 2 weeks after the inciting event. After 10 to 14 days, the echogenicity of affected areas of deep white matter increases. These areas of abnormality may be focal or diffuse, symmetrical or asymmetrical. They are typically located along the trigones of the lateral ventricles but can involve extensive areas of white matter. PVL is seldom associated with mass effect and displacement of surrounding structures. Cystic encephalomalacia appears in the areas of increased echogenicity within 2 to 3 weeks after the initial insult (Figure 59-25). These are characterized by cysts ranging between 1 mm and 2-3 cm in size. They may be single or multiple and may occasionally communicate with the ventricular system. Focal or hemispheric atrophy is the final stage of PVL and is characterized by dilatation of the ipsilateral ventricle and prominence of the sulci and interhemispheric fissure (Schellinger et al, 1984).

White matter lesions, including those due to PVL, are difficult to detect in the neonate using either CT or MRI because of the inherent high water content of unmyelinated white matter. On CT, even relatively large cysts may be inapparent. Occasionally, the cystic areas may appear slightly more lucent (hypodense) than the surrounding parenchyma. Acute hemorrhagic lesions are hyperdense. The cystic phase of PVL is also difficult to identify on MRI, because the cysts are characterized by long T1 (hypointensity) and long T2 (hyperintensity), similar to normal unmyelinated white matter. Hemorrhagic lesions appear as foci of hyperintensity on T1-weighted sequences and hypointensity on T2-weighted sequences (Figure 59-26). PVL has been reported to show decreased diffusion in the acute phase (Inder et al, 1999).

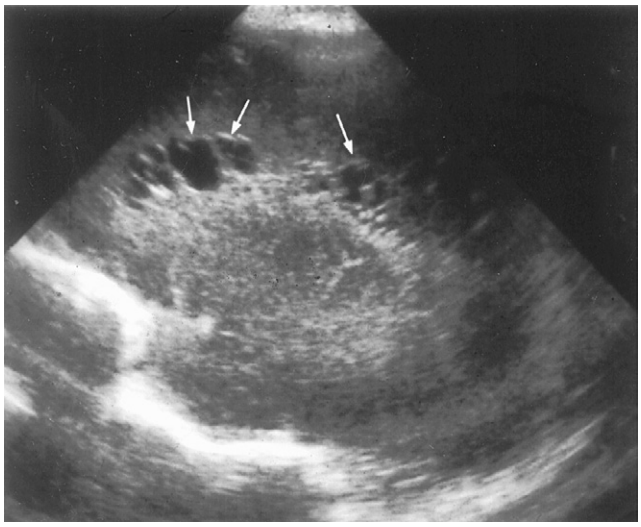

FIGURE 59-25 Sagittal ultrasound image of cystic periventricular leukomalacia demonstrates multiple echolucent periventricular cysts (*arrows*) involving the frontal, parietal, and occipital white matter.

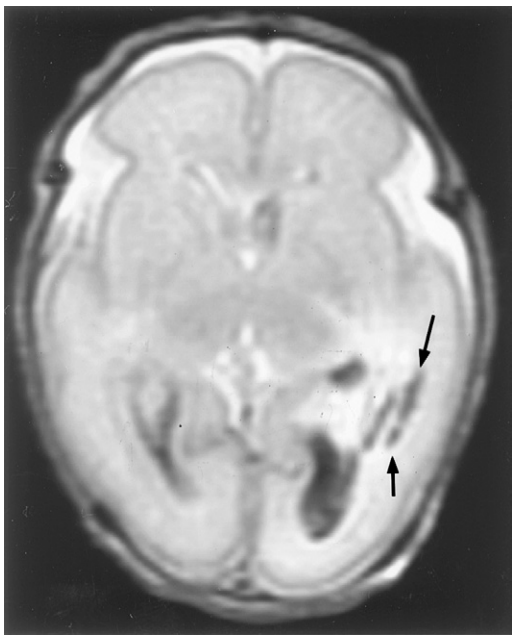

FIGURE 59-26 Axial T2-weighted magnetic resonance image from a 26-week-gestation premature infant. Hemorrhagic PVL is indicated by periventricular hypointensity (*arrows*). Intraventricular hypointense hemorrhage is also present in this neonate.

CONGENITAL MALFORMATIONS

Although use of cranial sonography is limited by the available acoustic windows, many structural anomalies of the brain can be well characterized by this portable technique. However, for most congenital anomalies, MRI has become the most definitive imaging examination (Barkovich, 1988). The multiplanar capability and inherent high tissue contrast of MRI make it superior to CT for the delineation of most congenital malformations. Additionally, unlike CT, MR images are not degraded by artifact from bone. Therefore, MRI is able to provide a detailed evaluation of the regions of the supratentorial brain near the skull base and the posterior fossa.

For most congenital brain malformations, standard T1-weighted and T2-weighted images are sufficient to characterize the anomaly with MRI. Multiplanar conventional imaging is usually all that is required to characterize disorders of structural development including the holoprosencephaly spectrum, malformations of the corpus callosum, leptomeningeal malformations, and posterior fossa malformations (Dodge and Dobyns, 1995; Lena et al, 1995; Rubinstein et al, 1996; Smith et al, 1996) (see Figure 59-9). Thin-section, high-resolution volumetric images may be reformatted in multiple planes to show structural relationships. Intravenous contrast is not usually required for the MR evaluation of congenital brain anomalies.

Although CT is not considered the imaging modality of choice for most congenital brain malformations, it may be used to assess bone integrity and to search for parenchymal calcifications. CT is useful in the assessment of scalp lesions and for calvarial or skull-base defects in the setting of certain intracranial lesions such as cephaloceles and dermoids (Ruge et al, 1988). Sutural synostosis, although only occasionally presenting in the newborn, is best assessed with three-dimensional CT. Cutis aplasia may require CT evaluation to determine the extent of underlying bone deficiency (Madsen et al, 1998).

High-resolution CT is useful for anatomic delineation of facial and temporal bone lesions (Vanzieleghem et al, 2001). Choanal atresia, especially if bilateral, may require urgent CT assessment. Nasal pits or dermoids are typically evaluated using a combination of high-resolution CT for bone detail and MRI for soft-tissue extent of the lesion (Lusk and Lee, 1986). Most temporal bone anomalies do not require intervention during the neonatal period; therefore, CT studies are usually deferred until later in infancy.

VASCULAR MALFORMATIONS

Vascular malformations are classified on the basis of hemodynamics as high-flow or low-flow anomalies (Meyer et al, 1991). High-flow lesions include arteriovenous fistula, with direct, macroscopic connections between arteries and veins, and arteriovenous malformation, with a meshwork of dysplastic vessels termed a *nidus* interposed between the supplying artery and the draining vein. Low-flow vascular malformations include cavernous malformation, developmental venous anomaly, and capillary telangiectasia. Both high- and low-flow intracranial vascular malformations may be present in the newborn; however, it is typically the high-flow lesions that are likely to be symptomatic during the neonatal period.

Many high-flow vascular malformations are now diagnosed in utero using fetal US or MRI. A majority of high-flow vascular malformations manifest in the neonate with symptoms related to high-output cardiac failure (Lasjaunias et al, 1986). CT and postnatal MRI are not typically required to diagnose the presence of the malformation but may provide useful information with respect to prognosis. In high-flow lesions, blood flow is diverted away from the brain parenchyma and through the shunt(s), so that ischemic brain injury may result (see Figure 59-11).

The presence of encephalomalacia and parenchymal calcification on CT indicates chronic ischemic injury and

is associated with a poor neurologic outcome (Brunelle, 1997). CT angiography (CTA) and CT venography (CTV) may occasionally be performed to characterize the arterial supply and size of shunts before intervention.

MRI will show changes similar to those seen with CT including parenchymal ischemic changes (see Figure 59-11, *B*). MRA/MRV can be used in a similar fashion to that for CTA/CTV to characterize the vascular anomaly. However, MRA/MRV is prone to signal loss related to turbulent flow and may therefore be less reliable than CTA/CTV in high-flow lesions.

Conventional catheter angiography is usually performed as a part of a planned endovascular approach to therapy. Subselective vascular injections are used to carefully define the anatomy of the arteriovenous shunts. The choice of embolic material employed depends on the nature and location of the shunts. Sonography with color and duplex Doppler techniques may be used as an adjunct to monitor changing cerebral hemodynamics and complications during endovascular procedures.

Low-flow intracranial vascular anomalies are occasionally encountered as incidental findings on brain CT and MRI in the newborn. Hemorrhage due to low-flow vascular anomalies is exceedingly rare in the neonate.

HYDROCEPHALUS

Hydrocephalus is one of the most common reasons to perform brain imaging in the newborn. Hydrocephalus is nearly always due to an obstruction of CSF resorption. The blockage may occur within the ventricles or in the extracerebral CSF spaces. Hydrocephalus due to the overproduction of CSF is exceedingly rare but may occasionally occur with choroid plexus papilloma or choroid plexus hyperplasia (Figure 59-27).

Hydrocephalus may be either congenital or acquired. Congenital causes of hydrocephalus include Chiari II malformation, aqueductal stenosis, encephalocele, universal craniosynostosis, and skull base dysplasia with jugular venous stenosis as in Crouzon syndrome (McLone and Naidich, 1992; Naidich et al, 1992; Robson et al, 2000). Acquired hydrocephalus may be due to hemorrhage, infection, mass effect from tumor, or venous hypertension (Brann et al, 1990; Hedlund and Boyer, 1999).

Sonography plays an important role in the evaluation of posthemorrhagic hydrocephalus (Figure 59-28). The goals of the US examination are to determine the presence and severity of ventricular dilatation, to identify the location and cause of obstruction (ependymitis vs. clot), to monitor the adequacy of treatment, and to identify potential complications of therapy. The evaluation of the ventricular system in the neonate should include standardized measurements of the lateral ventricles. Although the atria dilate early in the course of ventriculomegaly, measurements of the lateral ventricles on parasagittal images are the most variable in clinical practice (Shackleford, 1986). We use the maximal width of the frontal horns measured at the level of the foramen of Monro to follow ventricular size. This measurement was chosen because it uses reproducible landmarks that are not affected by angulation of the transducer and provide independent measures of each lateral ventricle. In our experience, it provides the most useful measurement for monitoring change in ventricular size.

In general, dilatation tends to be greatest in the ventricle just proximal to the point of obstruction to flow. For example, the normal aqueduct of Sylvius is a narrow passage and often not clearly visible on US. It typically does not become distended by clot. However, when an obstruction to CSF flow exists at the level of the fourth ventricle or beyond, the aqueduct may become markedly distended and is then easily depicted (Taylor, 2001) (Figure 59-29). Early detection of a dilated fourth ventricle may have important therapeutic implications, especially when accompanied by clot or absence of CSF in the cisterna magna. This combination of findings strongly suggests the presence of a blockage to CSF flow into the spinal subarachnoid space (Hall et al, 1992) and the probable failure of serial lumbar punctures as a therapeutic option.

As the ICP rises, arterial flow tends to be more affected during diastole than during systole, resulting in an elevated pulsatility of flow. Seibert and colleagues (1989) have shown that increasing RI on pulsed Doppler interrogation correlates well with elevation in ICP in an animal model of acute hydrocephalus. They and others also have shown a significant drop in pulsatility following ventricular tapping and shunting in infants with hydrocephalus (Bada et al, 1982). However, elevated ICP may not always be present in infants with ventricular dilatation, and the RI may be well within the normal range. Doppler examination of the anterior or middle cerebral artery during fontanel compression may be useful in the early identification of infants with abnormal intracranial compliance before the development of increased ICP as shown by elevated baseline RI (Taylor et al, 1994). According to the Monro-Kellie hypothesis, the volume of brain, CSF, blood, and other intracranial components is constant (Bruce et al, 1977). During graded fontanel compression in normal infants, CSF or blood can be readily displaced to compensate for the small increase in volume delivered by compression of the anterior fontanel, resulting in no increase in ICP. In infants with hydrocephalus, however, the increase in intracranial volume with fontanel compression is translated into a transient increase in ICP and an acute increase in arterial pulsatility (Figure 59-30). Serial examinations using this technique can also be used to follow an individual infant's ability to compensate for minor changes in intracranial volume and thus serve as a noninvasive indirect measure of intracranial compliance (Taylor and Madsen, 1996).

In our experience, transient (3 to 5 seconds) fontanel compression is a safe and well-tolerated procedure, even in critically ill premature infants. However, prolonged compression of the fontanel should be avoided. Pressure should be immediately released if heart rate significantly decreases during Doppler examination. In addition, the presence of reversed flow during diastole in a Doppler study obtained without fontanel compression is strongly suggestive of elevated ICP, and fontanel compression is not necessary or recommended in these patients.

Imaging of hydrocephalus is carried out before shunting to determine the cause of ventricular dilatation, to identify the site of obstruction, and to differentiate hydrocephalus from other intracranial abnormalities, such as holoprosencephaly and hydranencephaly, that may mimic severe

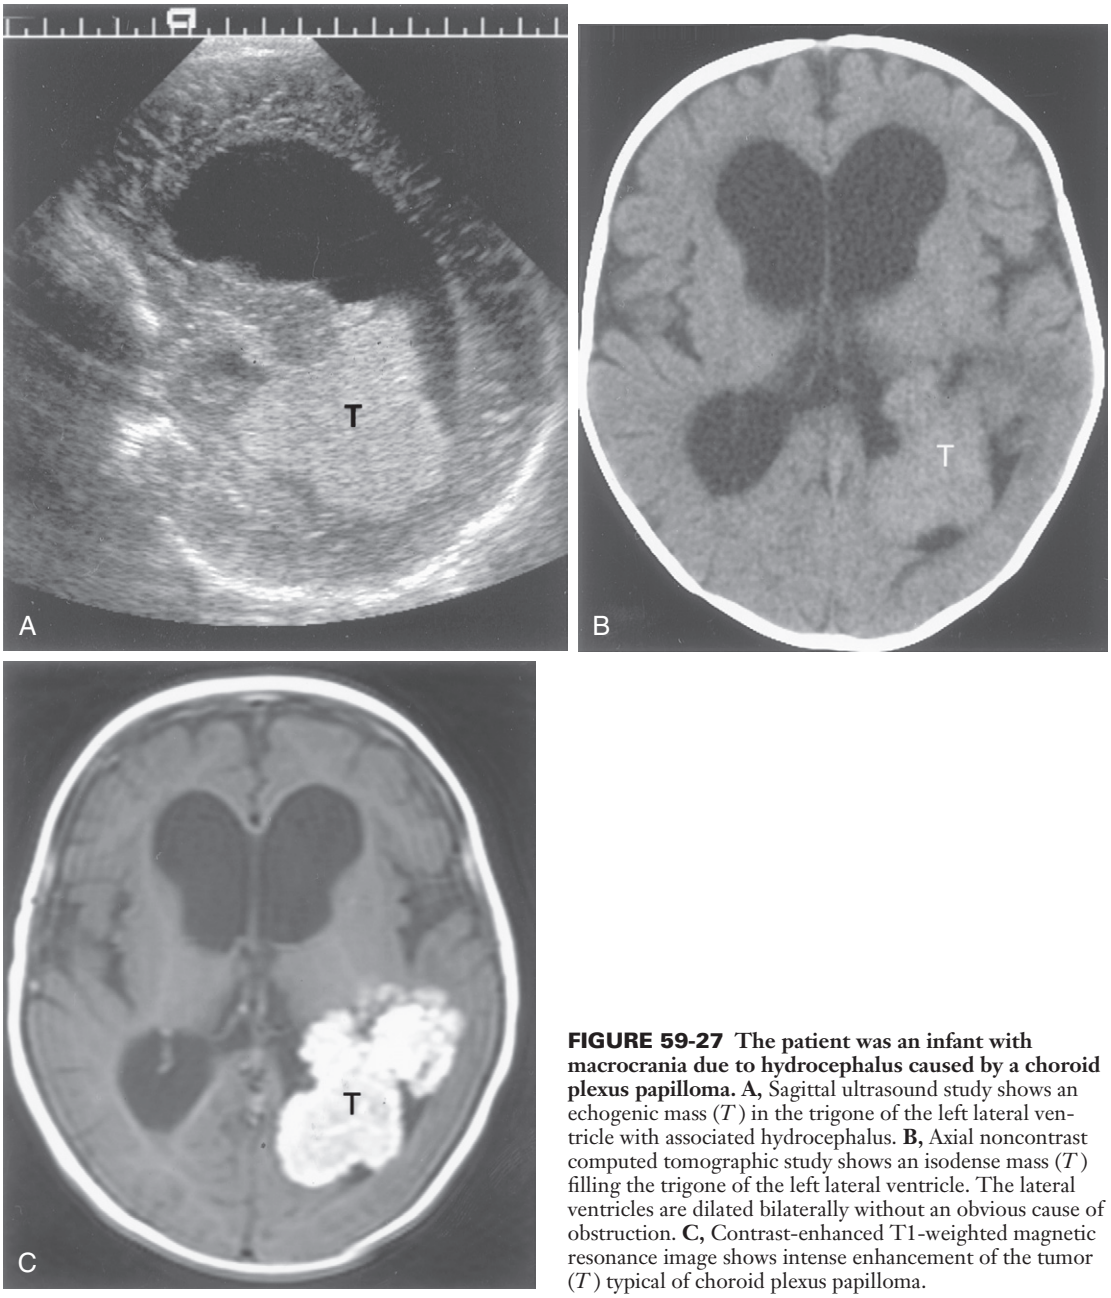

FIGURE 59-27 The patient was an infant with macrocrania due to hydrocephalus caused by a choroid plexus papilloma. A, Sagittal ultrasound study shows an echogenic mass (*T*) in the trigone of the left lateral ventricle with associated hydrocephalus. **B,** Axial noncontrast computed tomographic study shows an isodense mass (*T*) filling the trigone of the left lateral ventricle. The lateral ventricles are dilated bilaterally without an obvious cause of obstruction. **C,** Contrast-enhanced T1-weighted magnetic resonance image shows intense enhancement of the tumor (*T*) typical of choroid plexus papilloma.

hydrocephalus. After shunt placement, imaging is carried out to evaluate ventricular decompression and shunt position, and to assess for the presence of surgical complications and for the development of extraaxial collections.

MRI is the preferred examination for preoperative assessment of hydrocephalus. Thin-section T1- or T2-weighted images, three-dimensional constructive interference in steady-state (3D-CISS) or three-dimensional fast imaging employing steady-state acquisition (3D FIESTA) sequences provide excellent CSF-to-aqueduct contrast. We have found these sequences especially useful in assessing the aqueduct and obstructive membranes in CSF pathways, especially in the fourth ventricular exit foramina and the basal cisterns. By revealing these obstructive membranes, use of these sequences can alter patient treatment and prognosis (Dincer et al 2009).

On MRI, the findings in aqueductal stenosis include loss of the normal signal void within the aqueduct and elevation of the superior tectal plate (see Figure 59-9). Occasionally, high signal intensity suggesting gliosis is seen in the periaqueductal gray matter. Tectal tumors are rarely encountered in neonates. CSF flow studies may be performed to corroborate lack of flow within the aqueduct in equivocal cases. Use of contrast media may be required to evaluate congenital tumors causing hydrocephalus and to search for leptomeningeal metastases.

NEONATAL INFECTION

Congenital cytomegalovirus (CMV) infection is associated with anomalies of cortical development, diminished white matter volume, delayed myelination, variably small

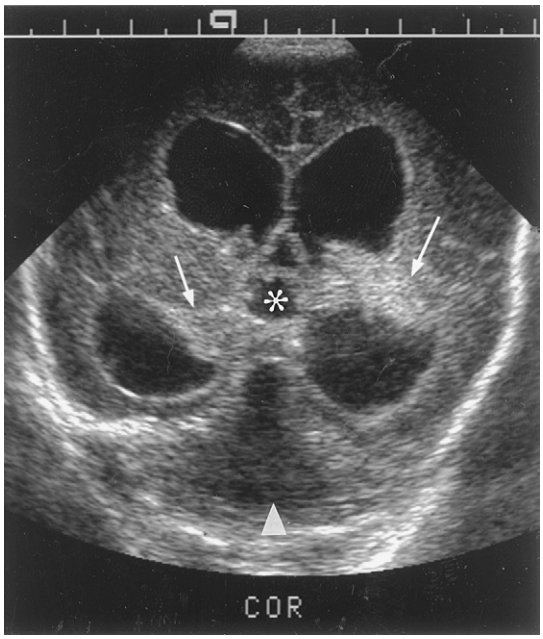

FIGURE 59-28 Coronal ultrasound study of posthemorrhagic hydrocephalus obtained through the anterior fontanel. Adherent, nondependent echogenic clot (*arrows*) is present within the dilated lateral ventricles. The absence of positional change in location of the echogenic material helps to differentiate blood clot from debris in ventriculitis. Note the dilated third ventricle (*) and fourth ventricle (*arrowhead*).

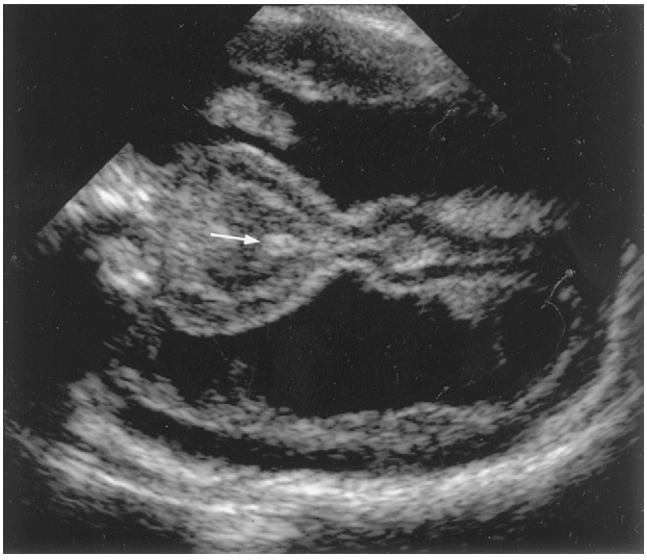

FIGURE 59-29 Axial ultrasound image from an infant with posthemorrhagic hydrocephalus. Due to obstructing clot at the level of the aqueduct of Sylvius (*arrow*), the lateral ventricles and upper aqueduct are distended.

cerebella, parenchymal calcification, and mild ventriculomegaly (Barkovich and Lindan, 1994).

Whereas both CT and US may demonstrate parenchymal calcifications, multiplanar MRI provides superior delineation of the anomalies associated with congenital CMV infection of the CNS. Conventional imaging including coronal T2-weighted images is useful in defining the anatomic abnormalities. We have noted increased diffusion in the regions of delayed myelination. DI findings have otherwise been unremarkable. Findings on high-resolution temporal bone MRI performed in infants with associated hearing loss are typically normal. One recent study in patients with CMV infection demonstrated increased diffusion in the white matter, decreased fractional anisotropy and reduced concentrations of total *N*-acetyl aspartate and choline-containing compounds and slightly increased myoinositol concentration on MRS (Van der Voorn et al, 2009). It has been suggested that the pathology of the white matter lesions in congenital CMV infections is characterized by axonal losses, lack of myelin deposition due to oligodendrocytic losses, and astrogliosis and is similar to the changes seen in PVL: Both congenital CMV infection and PVL affect the cerebral white matter in the same developmental period when immature oligodendrocytes are particularly vulnerable.

Neonatal herpes simplex virus (HSV) infection may involve any region of the brain and is typically multifocal (unlike HSV infection in adults, which has a predilection for the temporal lobes) (Baskin and Hedlund 2007).

Brain CT in HSV infection usually shows multifocal low density in the cortex and subcortical white matter. Occasionally, petechial hemorrhage may occur. Conventional MRI demonstrates multiple areas of cortical and deep gray matter of low signal intensity on T1-weighted images and high signal intensity on T2-weighted images (Figure 59-31). Hemorrhage produces shortening of T1 (hyperintensity) and T2 (hypointensity). On DI, sites of involvement typically have decreased diffusion during the acute phase of the illness. The decreased diffusion is presumably due to necrosis.

Congenital human immunodeficiency virus (HIV) infection remains prevalent in regions including many Asian countries, sub-Saharan Africa, and parts of Latin America. The number of children diagnosed with HIV has decreased significantly. However, despite the fact that more than 90% of all childhood HIV infections are due to in utero transmission, neurologic and imaging manifestations of HIV infection in the immediate neonatal period are rare (Volpe, 1995). Neuroimaging abnormalities develop mainly after the neonatal period, with atrophy and white matter changes seen on MRI and cerebral and basal ganglia calcifications seen on CT (Volpe, 2008).

Neonatal bacterial CNS infections are rarely associated with imaging abnormalities. However, some bacteria such as *Citrobacter* species, *Serratia marcescens*, *Proteus*, *Pseudomonas aeruginosa*, and members of family Enterobacteriaceae may produce parenchymal necrosis and abscess formation (Figure 59-32). Thrombosis of cortical and subependymal veins may also occur. By both CT and MRI, leptomeningeal enhancement may be seen after the administration of intravenous contrast. If cerebritis develops, the cortex and subcortical white matter are seen as areas of low density on CT and of increased signal intensity on T2-weighted MRI. Abscesses are demonstrated as rim-enhancing lesions on both CT and MRI. These lesions, along with the surrounding hyperemia, can also be well demonstrated by cranial US. Widespread malacic changes may be seen on late follow-up imaging after necrotizing CNS infections.

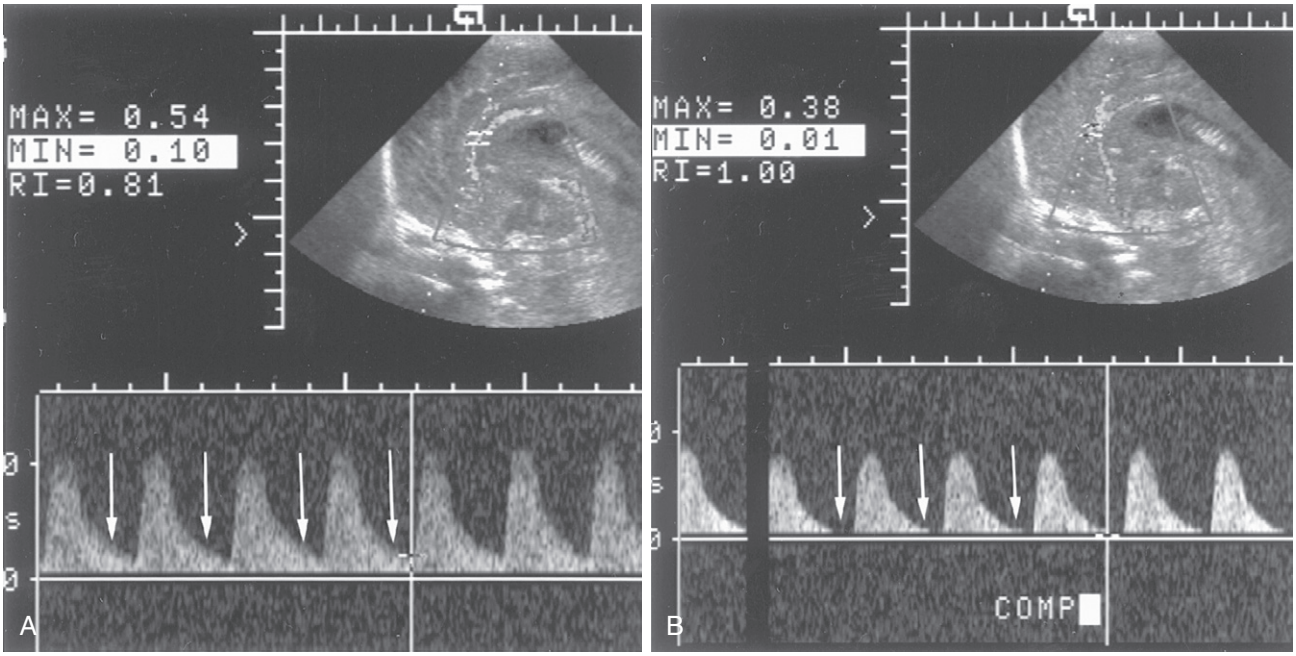

FIGURE 59-30 Positive Doppler ultrasound compression study in hydrocephalus. A, Baseline examination of blood flow within the anterior cerebral artery without fontanel compression shows a low resistance pattern with flow during both systole and diastole (resistive index = 0.81). **B,** Examination during transient compression of the anterior fontanel using the ultrasound transducer results in a loss of diastolic flow resulting from increased intracranial pressure (resistive index = 1.0).

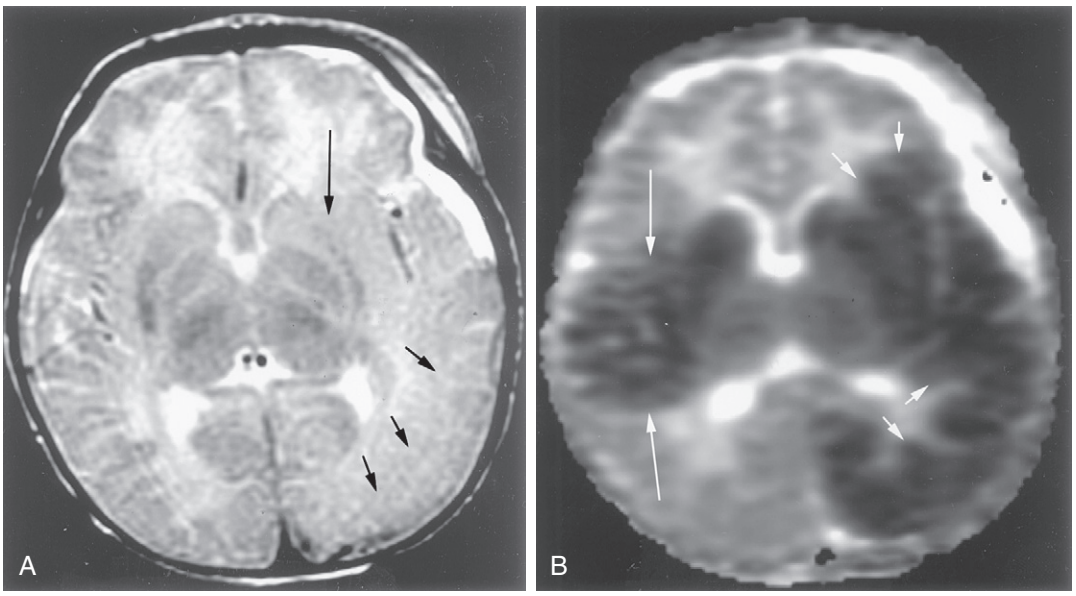

FIGURE 59-31 Magnetic resonance images from a term neonate with herpes simplex virus (HSV) encephalitis. A, Axial T2-weighted image shows high signal intensity in the left basal ganglia (*long arrow*) and loss of the cortical ribbon in the left cerebral hemisphere (*short arrows*). Unlike HSV infection in adults, neonatal herpes is not confined to the temporal and subfrontal lobes, and basal ganglia involvement is common. **B,** Apparent diffusion coefficient (ADC) map from the same examination shows extensive restricted diffusion (hypointensity) involving the areas on the left seen on the T2-weighted images (*short arrows*) and additional right hemispheric cortical (*long arrows*) and deep gray matter involvement.

NEONATAL BRAIN TUMORS

Brain tumors are rare in the newborn. When they occur, they are most often supratentorial, large, high-grade lesions such as primitive neuroepithelial tumors and choroid plexus carcinoma (Figure 59-33).

The imaging appearance of brain tumors is variable depending on the cellularity of the lesion and the presence or absence of necrosis (Klisch et al, 2000) (see Figure 59-32). Low-grade, less cellular tumors tend to have low density on CT, high signal intensity on T2-weighted MRI, and increased diffusion relative to normal brain. High-grade, densely cellular tumors generally are hyperdense on CT and of low signal intensity on T2-weighted MRI and have decreased diffusion relative to normal

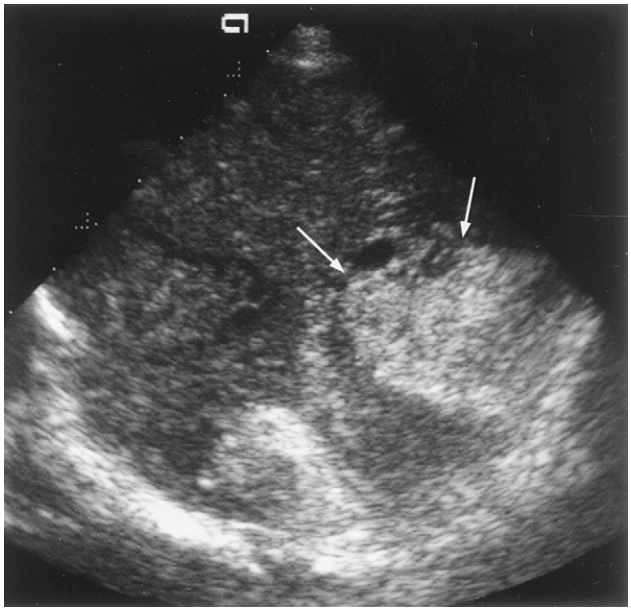

FIGURE 59-32 Ultrasound study of abscess due to *Citrobacter* infection. A large echogenic mass/abscess (*arrows*) is clearly demonstrated. Abscess formation is most often associated with bacterial infections, such as that due to *Citrobacter* species, that cause parenchymal necrosis.

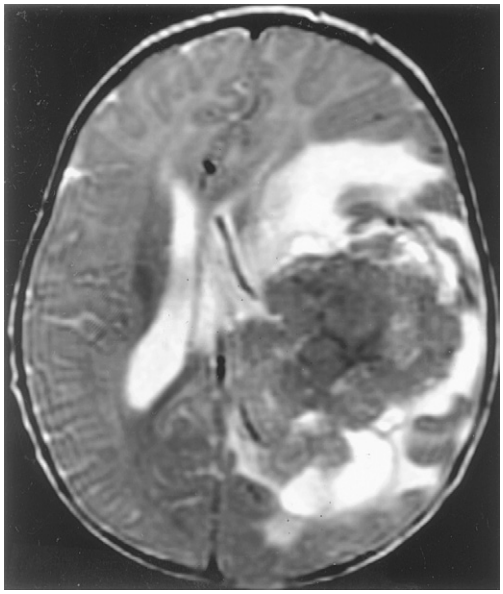

FIGURE 59-33 The patient was a 1-month-old infant with choroid plexus carcinoma. A large left hemispheric mass with regions hypointensity densely cellular tumor is evident on T2-weighted magnetic resonance image.

brain. Enhancement of the tumors is variable but tends to increase with increasing malignancy of the tumor. Important exceptions to this general rule are pilocytic astrocytoma and choroid plexus papilloma (see Figure 59-33), which, despite their low grade, tend to avidly enhance after contrast administration.

Malformative masses such as dermoid, epidermoid, and teratoma are occasionally detected in the neonate (Figure 59-34) (Haddad et al, 1991). These lesions may be associated with other markers of cerebral dysgenesis such as anomalies of the corpus callosum or pericallosal lipoma.

FIGURE 59-34 The patient was a neonate with a pineal region teratoma. Sagittal T1-weighted image shows a large cystic lesion (*C*). The mass contains a small amount of high signal intensity (*arrow*) due to the presence of fat, which strongly suggests the diagnosis of teratoma.

A dermal sinus tract is often present in association with midline cysts.

Malformative masses often have a characteristic appearance on imaging as a result of the presence of fat and/or calcification within the lesion (Smirniotopoulos and Chiechi, 1995). Both dermoid and epidermoid tend to be of low density on CT. Calcification is sometimes seen within the cyst wall. Teeth formed within a teratoma will produce dense calcification on CT, whereas foci of fat have very low density, comparable to that of subcutaneous fat. CT is also used to document associated bone defects that accompany dermal sinus tracts.

On MRI, epidermoids tend to be similar to CSF in signal intensity on T1- and T2-weighted sequences and usually show increased signal (decreased diffusion) relative to CSF on DI. Occasionally, the cyst wall may enhance after intravenous contrast administration. Dermoid cysts containing fat have high signal intensity on T1-weighted sequences. High-resolution MRI may occasionally be required to demonstrate an associated dermal sinus tract. Teratomas may have foci of fat that produce high signal intensity on T1-weighted sequences. Calcifications appear as rounded signal voids on both T1-weighted and T2-weighted sequences.

HYPOGLYCEMIA

Severe perinatal hypoglycemia may result in energy exhaustion and parenchymal infarction in the neonate. In severe hypoglycemia, diffuse cortical and subcortical white matter damage may be evident, with the parietal and occipital lobes most severely affected (Barkovich et al, 1998). Globus pallidus injury has been observed in patients with the most severe cortical injury (Barkovich et al, 1998). Initially,

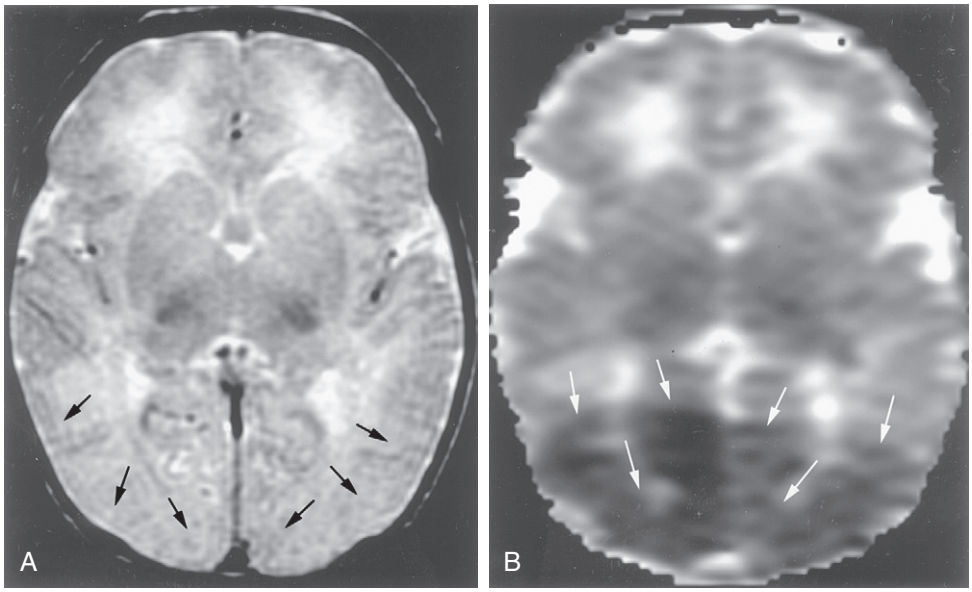

FIGURE 59-35 Term newborn with marked hypoglycemia and seizures. A, Bilaterally symmetric loss of the cortical ribbon is apparent in the parietal and occipital lobes on T2-weighted imaging (*arrows*). **B,** Decreased ADC values are present in corresponding regions of the parietal and occipital cortex (*arrows*).

on CT and MRI, cortical edema is present within the parietal and occipital regions of the cortex (Figure 59-35). As with other causes of infarction, decreased diffusion is usually observed acutely (Barkovich et al, 1998). Chronically, tissue loss is present in the areas that earlier showed edema and abnormal diffusion (Sugama et al, 2001).

HYPERBILIRUBINEMIA

In newborns, severe hyperbilirubinemia and consequent kernicterus may develop. The findings on brain MRI in patients with kernicterus are characteristic. Unlike hypoxia-ischemia, which tends to primarily affect the putamen and thalamus, hyperbilirubinemia selectively affects the globus pallidus. Recently, it has been suggested that the high resting neuronal activity in the globus pallidus might make it more vulnerable to less intense, subacute oxidative stresses from mitochondrial toxins such as bilirubin (Johnston and Hoon, 2000). The imaging findings in kernicterus are most apparent on MRI, with hyperintensity at the posterior margin or throughout the globi pallidi on T2-weighted sequences (Sugama et al, 2001).

NEUROCUTANEOUS DISORDERS

Of the phakomatoses, the two for which imaging is most commonly required in the neonate are tuberous sclerosis and Sturge-Weber syndrome. Because the outwardly apparent clinical features of tuberous sclerosis, such as adenoma sebaceum, are not usually apparent until late childhood or adulthood, early brain imaging is most often requested when cardiac tumors are identified on prenatal US or when there is a positive family history. The intracranial manifestations of tuberous sclerosis include cortical tubers, subependymal hamartomas, subependymal giant cell tumors, and abnormal neuronal and glial cells in the white matter.

On brain CT in the neonate, there is variable calcification of subependymal nodules that appear as small nodular densities projecting into the lateral ventricles (Griffiths and Martland, 1997) (Figure 59-36). The appearance may be similar to that of periventricular calcifications seen with congenital infections such as with CMV but can be differentiated from the latter on the basis of the projection of the lesions into the lateral ventricles and demonstration of cortical tubers. White matter abnormalities are extremely difficult to demonstrate because of the normal low density of unmyelinated neonatal white matter. Likewise, cortical tubers, which are not usually calcified in the newborn, may be difficult to demonstrate with CT, because the affected gyri may simply appear mildly broadened.

On brain MRI in the newborn, subependymal hamartomas may be quite subtle in appearance and must be carefully searched for. The cortical lesions of tuberous sclerosis have variable signal intensity. Cortical tubers appear may appear hyperintense or hypointense to unmyelinated white matter on T1-weighted images. The cortical tubers may be difficult to identify on T2-weighted images in the neonate, because their signal intensity is often similar to that of the unmyelinated subcortical white matter (see Figure 59-36).

Sturge-Weber syndrome (SWS) (i.e., encephalotrigeminal angiomatosis) is a neurocutaneous disorder comprising a facial capillary malformation in the distribution of branches of the trigeminal nerve and an intracranial leptomeningeal capillary-venous malformation. Clinically, patients present with a "port-wine facial nevus" and seizures (Pascual-Castroviejo et al, 1993). Intracranial manifestations of SWS are found in only a small minority of patients with facial capillary malformations.

On brain CT, SWS in the newborn may be difficult to detect. Gyral calcification, a radiographic hallmark of this disorder, may or may not be present. Even when present, the extent of the calcification may not reflect the entire distribution of the vascular malformation. Because of the abnormal development of the cortical venous drainage system, the medullary veins that serve as collateral venous pathways are enlarged and the ipsilateral choroid plexus is engorged and appears enlarged. Hemiatrophy of the brain and overgrowth of the skull are manifestations of long-term ischemic brain injury due to impaired tissue

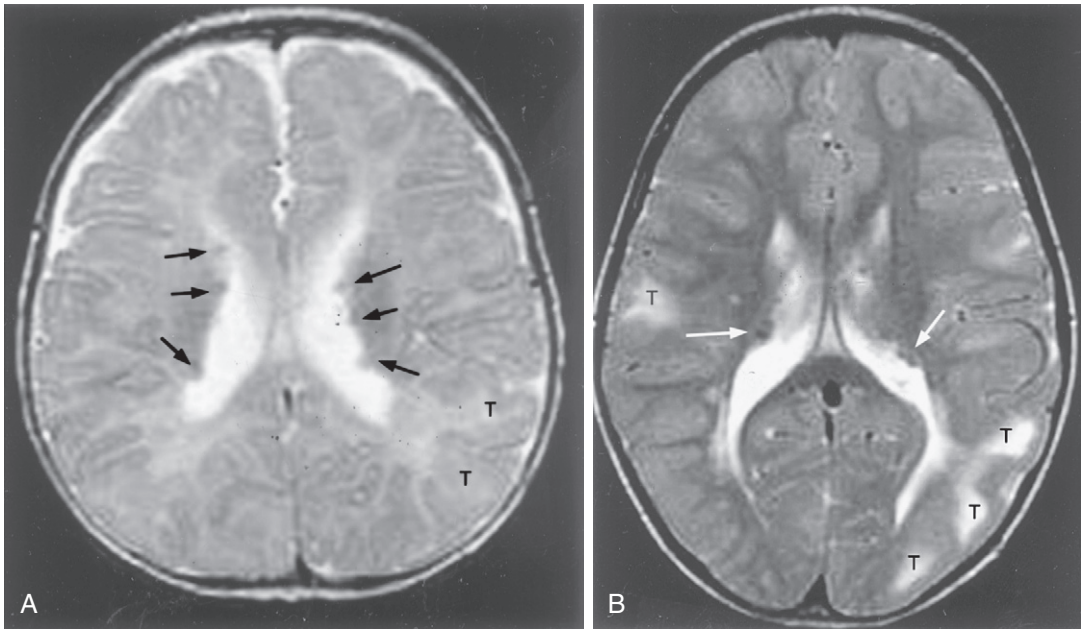

FIGURE 59-36 The patient was a term neonate with cardiac rhabdomyomas. A, Axial T2-weighted magnetic resonance (MR) image obtained at 2 weeks of age shows subependymal nodules (*arrows*) indicative of tuberous sclerosis. Note that the cortical tubers (*T*) may be difficult to see in the newborn. **B,** Follow-up T2-weighted MR image in the same child at 5 years of age shows hypointense subependymal nodules (*arrows*). The cortical tubers (*T*) are now much more obvious.

perfusion and are a hallmark of SWS in older infants or children but are usually not apparent in the newborn.

Contrast-enhanced brain MRI is considered the imaging modality of choice for evaluation of SWS (Elster and Chen, 1990; Pascual-Castroviejo et al, 1993). T1-weighted imaging after the administration of intravenous gadolinium provides the best depiction of the extent of the leptomeningeal vascular anomaly (Figure 59-37). Although gradient echo MRI may be less sensitive than CT for the demonstration of gyral calcification, it is often useful in demonstrating the presence of cortical mineralization. More recently, we have found that SWI can provide useful and unique information complementary to conventional contrast-enhanced T1-weighted MRI for characterizing SWS. We advocate the incorporation of the SWI sequence into routine clinical MRI protocols for suspected SWS. Recent studies have suggested that SWI is superior to gadolinium-enhanced T1 images in identifying the enlarged transmedullary veins, abnormal periventricular veins, cortical gyriform abnormalities, and gray matter–white matter junction abnormalities. Conversely, the gadolinium-enhanced T1 images were found to be better than SWI in identifying enlarged choroid plexus and leptomeningeal abnormalities (Hu et al, 2008).

ADVANTAGES AND DISADVANTAGES OF NEUROIMAGING TECHNIQUES

ULTRASONOGRAPHY

The most significant advantages of US are its portability, lack of ionizing radiation, relative availability and affordability, and ability to depict hemodynamics of blood flow in real time. The most serious disadvantages are its relative lack of spatial resolution compared with CT and MRI, the need for an acoustic window, its operator dependence, and the nonspecificity of many US findings. In addition, the differentiation between bland and hemorrhagic lesions is often difficult, and it is an insensitive tool for the diagnosis of neuronal migration disorders and diffuse neuronal injury.

COMPUTED TOMOGRAPHY

Advantages of CT include availability, compatibility with life support systems, rapid image acquisition, and relative lack of operator dependency.

Unfortunately, CT offers more limited soft tissue contrast than that provided by MRI and is prone to beam-hardening artifact from the skull base such that there is limited detail of the posterior fossa and temporal lobes. In addition, imaging can be acquired only in the axial or coronal plane. The risks associated with exposure to ionizing radiation from CT have come under increased scrutiny as described in an earlier section (Brenner et al, 2001; Huda et al, 2001). It appears that the long-term risk of malignancy due to x-ray exposure may be greatest in the newborn and gradually diminishes with age (Brenner et al, 2001; Brenner and Hall, 2007). The decision to perform CT for neonatal brain imaging should be made on a case-by-case basis, with recognition of the potentially significant medical benefit of performing the study compared with a small theoretical risk of the development of malignancy over the patient's lifetime. When appropriate, it may be prudent to consider using MRI or US, because neither employs ionizing radiation.

Although most brain CT studies in the neonate do not require the administration of intravenous contrast, occasionally, as with suspected dural venous sinus thrombosis, contrast may be of benefit. Because the primary route of

FIGURE 59-37 The patient was a term neonate with seizures and facial capillary nevus. Axial T1-weighted post-gadolinium magnetic resonance image demonstrates asymmetric leptomeningeal enhancement (*arrowheads*) in the right parietal and occipital lobes due to the presence of the leptomeningeal capillary-venous malformation that defines Sturge-Weber syndrome. The choroid plexus ipsilateral (*arrow*) to the leptomeningeal anomaly is typically enlarged. Note that the brain is not yet atrophic in the area of the malformation.

contrast excretion is via the kidney, the renal status must be considered in the newborn, just as in the older child or adult. Typically, nonionic contrast is used, to decrease the risk of side effects related to the high osmolality of the ionic agents.

MAGNETIC RESONANCE IMAGING

Advantages of MRI include superior image detail compared with CT and US and the possibility of evaluating multiple tissue parameters. As with US, MRI does not carry the theoretical risks associated with the use of ionizing radiation. In addition, both anatomic and functional information may be obtained from MRI during the same examination. Moreover, MRI offers improved delineation of the posterior fossa structures without significant artifact from the skull base as occurs with CT, and without the need for an appropriate acoustic window as is essential with US.

The single biggest disadvantage of MRI is the requirement for a strong magnetic field. As a result, the MRI examination room must be magnetically shielded, and all equipment entering the room must be nonferromagnetic. For these reasons, the imaging of the ill neonate can be difficult. Additionally, because of the relatively long time for image acquisition, sedation or anesthesia is often required. However, generally, the additional information obtained with MRI over CT warrants the added inconvenience of the examination, provided that the imaging suite and personnel are equipped to handle the unique requirements of neonatal brain MRI.

SUMMARY OF NEUROIMAGING PRACTICE GUIDELINES

A multidisciplinary group reviewed the literature and established guidelines for neuroimaging in the neonate (Ment et al, 2002). This practice parameter is endorsed by the American Academy of Pediatrics, the American Society of Pediatric Neuroradiology, and the Society for Pediatric Radiology and was subsequently reaffirmed in 2005. The practice parameter recommendations for imaging of the preterm neonate are that routine cranial US screening be performed in all infants born at less than 30 weeks of gestational age once between days 7 and 14 of life and repeated between 36 and 40 weeks of postmenstrual age. For term infants, the recommendations are that noncontrast CT be performed to detect hemorrhagic lesions in the encephalopathic newborn with a history of birth trauma, low hematocrit, or coagulopathy. If CT is inconclusive, then MRI should be performed between days 2 and 8 of life to assess the location and extent of injury.

We emphasize that these practice parameters reflect a review of available literature that was examined by the panel in 2005. With the increased availability of 3-tesla MRI scanners and the newer techniques described earlier, the algorithm for imaging the sick neonate may need revision in the near future.

CHAPTER 60

Congenital Malformations of the Central Nervous System

Stephen A. Back and Lauren L. Plawner

Throughout fetal gestation, the sequence of events that direct the formation of the central nervous system CNS may be interrupted by deleterious intrinsic events or extrinsic insults that result in malformations. This chapter examines those disorders that are more commonly encountered in neonatology. An understanding of the origins and consequences of these disorders are considered within the context of normal CNS development. The peak timing of these events during fetal gestation is summarized in Table 60-1 together with some of the more commonly associated CNS malformations. Remarkable progress in basic developmental neurobiology in the past decade has translated into rapid advances in our understanding of the molecular and genetic basis of many of these previously perplexing disorders. Although a majority of these disorders arise from adverse events that occur during the early phases of pregnancy, these new insights begin to provide a more rational basis for the assessment of prognosis, as well as for the management of future pregnancies.

A true CNS malformation may be multifactorial in origin and results when a disruption occurs in an intrinsic developmental process. Acquired defects occur when an already normally formed brain is injured by a secondary process, such as vascular compromise, hypoxia ischemia, infection, toxic exposure, physical compression or trauma. The nature of acquired malformations is closely related to the stage of development at which the injury occurs, as well as the duration of the insult. Although acquired lesions are usually *encephaloclastic* in nature, which means that destruction of normal brain tissue has occurred, they can resemble primary developmental lesions in some cases (Roessmann, 1995).

PRIMARY AND SECONDARY NEURAL TUBE FORMATION (NEURULATION)

The earliest developmental stages include the one celled embryo, the cleaving embryo, the blastocyst, the process of implantation and development of the amniotic cavity, the formation of chorionic villi, and the formation of axial features (right and left sides, rostral and caudal ends). All of these events occur during the first 14 postconceptual days. At 16 days, the site of the future neural plate can be defined by autoradiographic means, and at about 18 days, the neural groove can be seen (England, 1988; O'Rahilly and Muller, 1994).

Neural tube formation (neurulation) occurs through an inductive process that stimulates the dorsal aspect of the embryo to form the brain and spinal cord. Initial events involve formation of the brain and much of the spinal cord, with the exception of the sacral-coccygeal segments (primary neurulation). Later in embryogenesis, the lower sacral segments of the spinal cord are formed (secondary neurulation). Disruption of primary and secondary neurulation results in distinctly different malformations that are considered separately.

PRIMARY NEURAL TUBE FORMATION

This process forms the brain and spinal cord, with the exception of the most caudal (sacral-coccygeal) segments of the spinal cord. Primary neurulation spans from approximately 18 days' gestation to the end of the 4th gestational week. It involves a complex series of morphogenetic events directed by cell proliferation and apoptosis as well as changes in cell shape and adhesion that regulate cell migration. As discussed later, mutations in the genes that regulate these processes underlie a variety of neural tube defects. During gastrulation, an area of thickened neuroectoderm, the neural plate, is initially formed via induction by the underlying axial mesoderm (notochord and prechordal plate (Figure 60-1, *A*).The nascent neural plate is induced by fibroblast growth factor-8 (FGF-8) activity derived from the primary endoderm (Stern, 2005). It now appears that the ectodermal cells of the neural plate are intrinsically programmed to differentiate along neural lineages. In fact, suppression of this differentiation by various members of the bone morphogenetic proteins (BMPs) is required to generate epidermis from the lateral ectoderm. Hence, endoderm-derived FGFs and lateral ectoderm-derived BMPs, as well as BMP-inhibitory factors from Hensen's node, interact to establish the initial dorsoventral polarity and anterior-posterior regionalization of the neural plate (reviewed in Vieira et al, 2010). At 20 to 21 days, the neural groove forms in the midline with a neural fold on either side (see Figure 60-1, *B*). Elevation of the neural folds coincides with formation of a midline medial hinge point and paired dorsolateral hinge points. Areas destined to become the forebrain, midbrain, and hindbrain can be identified at this early stage. By day 22, the neural folds are beginning to fuse to form the neural tube and central canal (England, 1988; O'Rahilly and Muller, 1994).

The fusion of the neural tube coincides with further planar segregation of the tube into dorsal and ventral domains (Vieira et al, 2010). Central to this process are two key signaling molecules that establish the dorsoventral plane of the neural tube: BMPs derived from the roof plate in the dorsal midline and Sonic hedgehog (Shh) derived from the floor plate in the ventral midline (see Figure 60-1, *B*). Thus, gradients of BMP and Shh induce the formation of the alar and basal plates, respectively, which comprise the future brainstem and spinal cord. In broadest terms, the alar plate gives rise to neurons that are mainly related to sensory functions whereas the basal plate gives rise to motor neurons and interneurons.

TABLE 60-1 Timing of the Major Gestational Events in Human Brain Development and Representative Examples of Significant Related Disorders

Major Developmental Event	Window in Development
Primary Neurulation	**3–4 weeks**
Craniorachischisis totalis Anencephaly Encephalocele Myeloschisis Myelomeningocele/Arnold-Chiari malformation	
Prosencephalic Development	**4–8 weeks**
Holoprosencephaly Agenesis of the corpus callosum Agenesis of septum pellucidum/septo-optic dysplasia	
Hindbrain Development	**3–12+ weeks**
Dandy-Walker malformation Malformations associated with cerebellar vermis hypoplasia Malformations associated with the molar tooth sign (Joubert's syndrome)	
Neuronal Proliferation	**8–12 weeks**
Micrencephaly (micrencephaly vera, radial microbrain) Human autosomal recessive primary micrencephaly types 1–5 Macrencephaly Hemimegalencephaly	
Neuronal Migration	**8–16 weeks**
Schizencephaly Polymicrogyria Lissencephaly/pachygyria Lissencephaly with cerebellar hypoplasia Cobblestone complex syndromes Neuronal heterotopias Cortical dysplasia	

NEURAL TUBE CLOSURE AND NEURAL CREST MIGRATION

Primary neurulation concludes with a series of critical events that result in closure of the neural tube. The neural folds fuse first in the nascent occipitocervical region. Current studies no longer support the "zipper" concept of closure of the neural tube. Rather, fusion occurs at three major sites, with the closure of the cranium being the most complex. Closure site 1 is located at the junction of the hindbrain and spinal cord. Closure site 2 resides at the junction of the midbrain and forebrain and site 3 is at the most rostral extent of the forebrain. At each site, closure proceeds simultaneously both rostrally and caudally. Inbred strains of mice show differences in the timing of the various closure sites and in the exact locations and sequences of closure, all of which are dependent on specific genes (Harris and Juriloff, 2007; Van Allen et al, 1993; Vieira et al, 2010; Zohn and Sarkar, 2008). Analysis of the locations where human anterior neural tube defects occur further supports the notion that anterior neural tube closure proceeds simultaneously at multiple sites (Golden and Chernoff, 1995). Disturbances in human neural tube closure appear to occur by failure of closure at one or more sites or by defective fusion adjacent to sites of closure.

By days 24 to 25, fusion progresses rostrally to the level of the colliculi, and fusion continues rostrally and caudally until only the anterior neuropore and the posterior neuropore are open (Figure 60-2). By day 24, the anterior neuropore has closed; by day 26, the posterior neuropore has closed at the site corresponding to around S2 (O'Rahilly and Muller, 1994). The skull, vertebrae, and dura form through interactions between the neural tube and the adjacent mesoderm. As the rostral parts of the neural folds fuse, the neural crest is formed from ectodermal cells on both sides of the neural tube. The neural crest cells migrate shortly after neural tube closure. They give rise to sensory, sympathetic, and parasympathetic ganglia; chromaffin cells of the adrenal medulla; skin melanocytes; enteric neurons in the gastrointestinal tract; and facial connective tissue (Hall, 2008; O'Rahilly and Muller, 1994).

SECONDARY NEURAL TUBE FORMATION AND CAUDAL REGRESSION

The process of secondary neural tube formation occurs approximately between gestational days 30 to 50, during which vacuoles form in a caudal cell mass that surrounds the lower neural tube. The vacuoles coalesce and connect with the central canal of the already present neural tube. At postconceptual days 41 to 51, the caudalmost part of the neural tube and central canal begins to regress as the tail of the embryo disappears. Atrophy of the caudal neural tube results in formation of a fibrous strand called the filum terminale, which is present throughout life. As the vertebral bodies grow, the end of the central canal (the conus medullaris) becomes placed higher in the vertebral column, eventually reaching the L1-2 level (usually by 2 weeks postnatally). This may be caused by proportionately greater lengthening of the spinal vertebrae compared with the spinal cord (England, 1988; O'Rahilly and Muller, 1994). Disorders of secondary neurulation give rise to several clinically significant occult dysraphic states, discussed later.

NEURAL TUBE DEFECTS

Neural tube defects result from a failure of primary neural tube closure during the 4th week of human gestation (Roessmann, 1995). Most of these defects are related to some degree of failure of anterior or posterior neuropore closure. The clinical spectrum of brain malformations associated with disrupted anterior neuropore closure are, in order of decreasing severity: anencephaly and the encephaloceles. Myeloschisis and myelomeningoceles with the associated Arnold-Chiari malformations encompass the spectrum of spinal cord defects associated with failure of posterior neuropore closure. In addition, craniorachischis totalis is a severe malformation of the brain and spinal cord, which essentially involves complete failure of neural tube closure, and usually results in spontaneous abortion during embryogenesis or early fetal development. Similarly, myeloschisis commonly results in stillbirth, as a result of extensive malformation of large portions of the spinal cord. The remainder of the neural tube defects to be discussed result in malformations of the CNS and the overlying axial skeleton, meninges, and skin that are associated with varying degrees of viability in the newborn period.

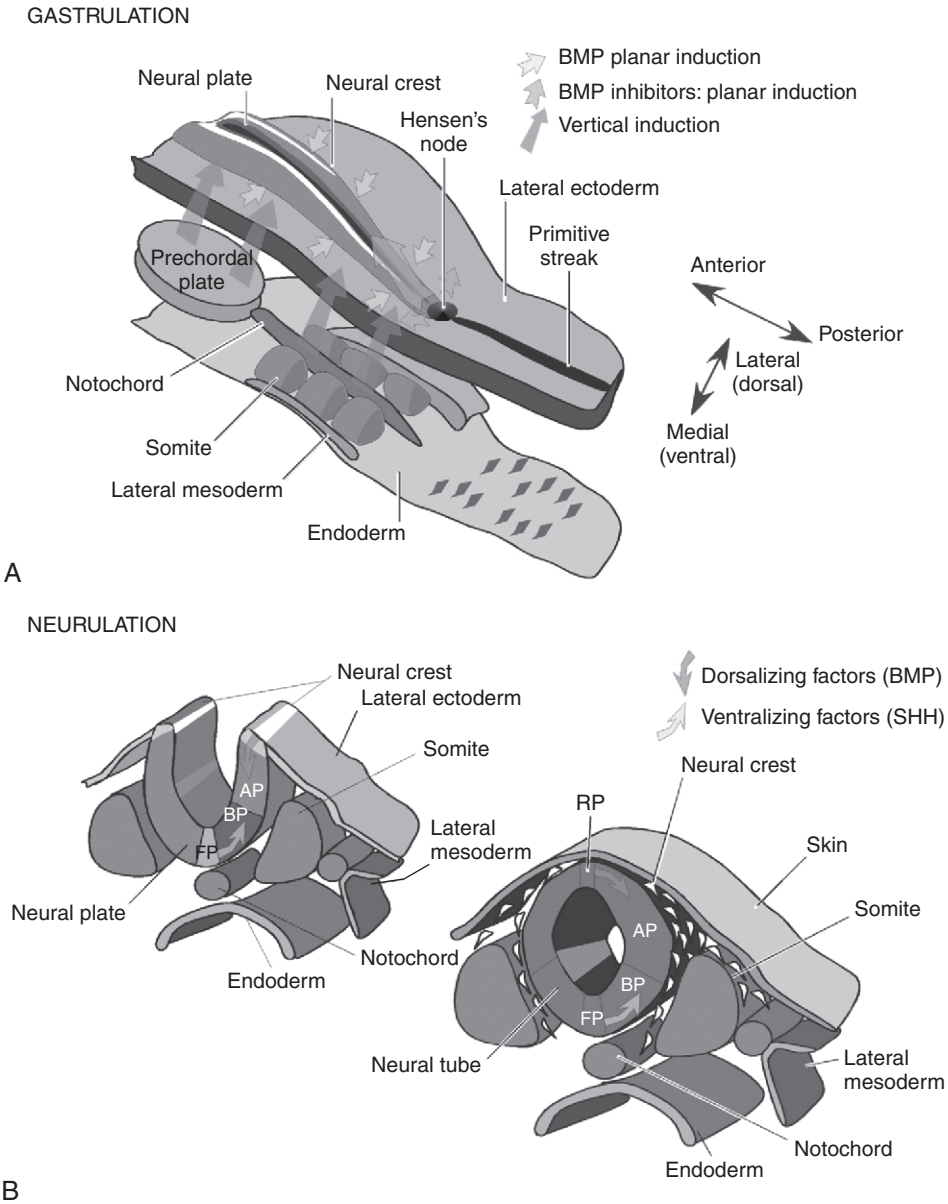

FIGURE 60-1 *(See also color plate 27.)* **Formation of the neural tube. A,** During gastrulation, at the neural plate stage, dorsoventral polarity and early anteroposterior regionalization is defined by a process of vertical induction by fibroblast growth factor-8 (FGF-8) and other factors (*long gray arrows*) derived from mesendoderm (notochord and prechordal plate). Planar induction occurs via BMPs and BMP inhibitors that are derived from lateral ectoderm (*short light gray arrows*) and Hensen's node (*short dark gray arrows*), respectively. **B**, The process of neurulation proceeds with the approximation of the neural folds toward the dorsal midline. Before closure of the neural tube, neural crest cells delaminate and migrate from the neural folds. Dorsalizing factors (BMPs; *dark gray arrow*) derived from the dorsal midline roofplate (RP) and ventralizing factors (SHH; *light gray arrow*) from the floor plate (FP) establish dorsal-ventral gradients of these key signaling molecules that induce formation of the alar plate (AP) and the basal plate (BP) from the lateral wall of the neural tube. *(From: Vieira C, Pombero A, Garcia-Lopez R, et al: Molecular mechanisms controlling brain development: an overview of neuroepithelial secondary organizers,* Int J Dev Biol *54:7-20, 2010; courtesy Dr. Salvador Martinez, Institute of Neuroscience, Universidad Miguel Hernandez, San Juan de Alicante, Spain.)*

EPIDEMIOLOGY

Neural tube defects remain one of the most common congenital malformations encountered in newborns. Despite a recent decline in prevalence, 0.5 to 2 per 1000 pregnancies are affected worldwide (Au et al, 2010; Mitchell, 2005). Because many congenital malformations occur during embryonic development, incidence data are essentially impossible to ascertain. Nevertheless, the prevalence of neural tube defects varies widely and is particularly influenced by race, ethnicity, geographical area, and socioeconomic status (Frey and Hauser, 2003). In the United States, for example, the risk for neural tube defects is higher for Hispanics but lower for African Americans. Geographically, one of the higher prevalence rates occurs in the United Kingdom; distinct geographic gradients also exist within this region. For unclear reasons, after the first affected pregnancy, the risk of recurrence increases at a disproportionately higher rate with each subsequent pregnancy and remains markedly higher than the baseline risk for the relevant general population. In fact, the risk may

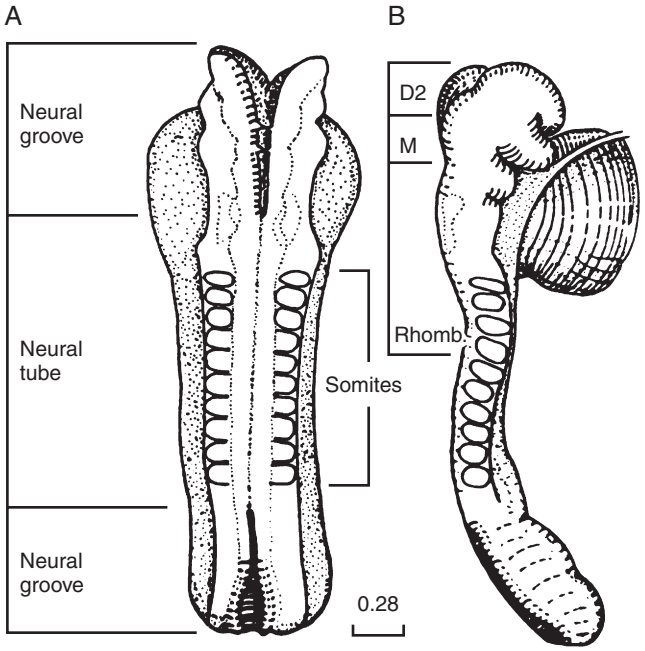

FIGURE 60-2 Positions of anterior and posterior neuropores. *(From O'Rahilly R, Muller F:* The embryonic human brain, *New York, 1994, Wiley-Liss, p 45.)*

nearly triple after each subsequent pregnancy (Elwood et al, 1992).

There has been a marked decline in prevalence at birth of both anencephaly and spina bifida. In 1960, the prevalence for England and Wales was about 6 in 1000 births; in 1990, this rate dropped to about 1 in 1000. The lower rates reflect two major interventions: in utero diagnosis with termination of affected pregnancies and maternal periconceptional folate therapy. The latter is estimated to prevent ~60–70% of neural tube defects (Castilla et al, 2003; Czeizel and Dudas, 1992; Frey and Hauser, 2003; Mills and Signore, 2004; MRC Vitamin Study Research Group, 1992; Oakley et al, 1994; Smithells et al, 1981; Wolff et al, 2009). The mechanisms by which folate prevents defects in neural tube closure remain unclear. There are approximately 200 known genes required for neurulation, many of which are involved in folic acid metabolism or transport (Juriloff and Harris, 2007). Folate deficiency does not cause neural tube defects in mice that lack genetic predisposition (Burren et al, 2008). Although the basis for folate-resistant neural tube defects is unclear, inositol deficiency can trigger neural tube defects in rodents, and inositol supplementation prevents a significant proportion of spinal defects in a mutant mouse model (Copp and Greene, 2009). However, only folate supplementation (0.4 to 0.8 mg daily) is currently recommended for women of childbearing age in the United States (U.S. Preventive Task Force, 2009).

ETIOLOGY

The etiology of neural tube defects is complex and clearly multifactorial. Genetic and environmental factors operate independently to determine individual and population risk. The majority of defects occur sporadically. Although numerous genetic syndromes are associated with familial forms of neural tube defects, they uncommonly come to term and appear to comprise a very small percentage of all cases (Au et al, 2010; Blom, 2009; Hall and Solehdin, 1998). Such defects have been informative, however, in the identification of many human gene defects that have been confirmed to disrupt key neurulation events in mouse models (Harris and Juriloff, 2007). For example, multiple human gene defects have recently been identified in a noncanonical Wnt signaling pathway shown to regulate cell polarity (Zohn and Sarkar, 2008). Mutations in this pathway disrupt neural tube closure in lower vertebrates via a failure of axial elongation or inability of the neural folds to merge in the dorsal midline. Defects range from severe craniorachischisis to spina bifida and exencephaly. One widely studied mouse model is the curly tail (*ct*) variant. The responsible *ct* gene localizes to the distal arm of chromosome 4 and has at least three modifier loci that influence the incidence of neural tube defects (Neumann et al, 1994). An important concept to emerge is that individual gene defects may cause mild or insignificant neurulation defects, whereas compound mutations result in highly penetrant severe defects (Zohn and Sarkar, 2008).

Among the numerous environmental risk factors that have been linked to neural tube defects, the most prominent include maternal febrile illness, maternal heat exposure in the first trimester (e.g., sauna or hot tub use), hyperglycemia from maternal diabetes mellitus or obesity, lower socioeconomic status, dietary factors (prenatal tea but not caffeine consumption), and prenatal exposure to a number of drugs including antiepileptic medications (Au et al, 2010; Blom, 2009; Frey and Hauser, 2003). Valproate and carbamazepine are both associated with an increased risk of neural tube defects (Jones et al, 1989; Yerby, 2003).

DISORDERS OF PRIMARY NEURULATION

Anencephaly

Anencephaly accounts for roughly more than half of all human neural tube defects, which have a worldwide incidence that ranges from 1.0 to 10.0 per 1,000 live births (Au et al, 2010). As an early neurulation defect, it occurs no later than 24 days of gestation. Anencephaly is the most severe and common of the disorders of anterior neural tube closure (Figure 60-3). Both anencephaly and occipital encephaloceles (discussed later) affect girls more than boys. A majority of infants are stillborn. Moreover, it is uniformly lethal within the first 2 months of life in the roughly 25% of cases that survive into the neonatal period (Baird and Sadovnick, 1984; Peabody et al, 1989). The duration of survival is critically related to intensive care support. Without intensive care, survival has not been reported beyond 14 days of life. Survival is related in part to persistence of rudimentary brainstem function. This finding is inconsistent with the diagnosis of brain death in the United States, which is a requirement for organ donation (AAP Committee on Bioethics, 1992; McAbee et al, 2000).

Anencephaly most commonly involves the forebrain and upper brainstem, which accounts for the devastating outcome. It is characterized by absence of the calvaria,

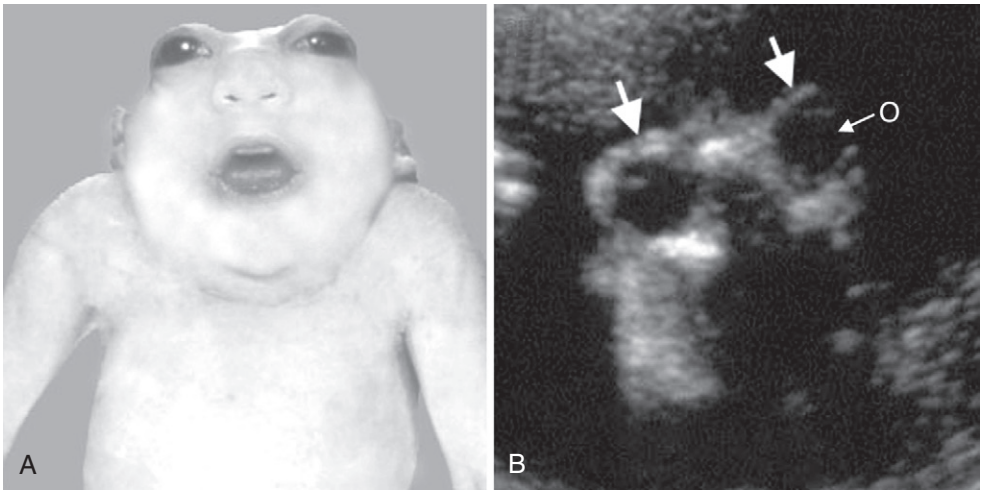

FIGURE 60-3 **A,** An anencephalic infant. **B,** Ultrasonogram of anencephaly. Note the absence of the normal cranial structures (*large arrows*) superior to the orbits *(O). (Courtesy Dr. Marjorie Grafe, Department of Pathology, Oregon Health and Science University.)*

and the intracranial contents are replaced by vascularized, disorganized glial tissue (area cerebrovasculosa) (Menkes, 1991; Roessmann, 1995). The hypothalamus and cerebellum are usually malformed, the anterior lobe of the pituitary is present, and the internal carotid arteries are hypoplastic, which may be secondary to abnormal brain formation. Because the anencephalic infant has a period of exencephaly, in which the brain tissue extrudes through the unformed calvaria and then is degraded by exposure to the amniotic fluid, some investigators have hypothesized that the primary defect is the abnormal skull formation. There are some cases in which remnants of calvarial bones are present, with normal brain under the protective bones (Roessmann, 1995).

Anencephaly can be diagnosed by fetal ultrasound examination (see Figure 60-3, *B*) in the second trimester of gestation (Crane, 1992; Goldstein and Filly, 1988). Polyhydramnios is frequently associated. Anencephaly is also suspected by measurement of alpha-fetoprotein (AFP) in maternal serum. AFP is the major serum protein in the early embryo and is fetus specific. It normally passes from the fetal serum into fetal urine and then into amniotic fluid; in the amniotic fluid, it is swallowed by the fetus and metabolized in the fetal gastrointestinal tract (Brock, 1976). In anencephaly, open spina bifida, and open encephalocele, there is leakage of fetal serum directly into the amniotic fluid, and the level of AFP is elevated in the amniotic fluid, as are maternal serum protein levels. By contrast, when a neural tube defect is closed (i.e., covered by intact skin), the AFP level is not elevated. This occurs in about 5% of neural tube defects (Milunsky et al, 1980).

Encephalocele

In contrast to anencephaly, encephalocele appears to arise from a restricted rather than diffuse failure of anterior neuropore closure around 26 days' gestation. Encephaloceles typically present as a cranial defect through which brain tissue protrudes. Less severe defects may occur with later onset. These include cranium bifidum, where there is a failure of midline fusion of the skull, and cranial

FIGURE 60-4 Newborn infant with a large occipital encephalocele. *(Courtesy Dr. Marjorie Grafe, Department of Pathology, Oregon Health and Science University.)*

meningoceles that contain meningeal but not neural tissue. In up to 80% of cases, encephaloceles occur in the occipital region (Figure 60-4), with the remainder in the parietal, frontonasal, intranasal, or nasopharyngeal regions. Although the precise pathogenetic mechanism remains unclear, geographical or ethnic-genetic factors appear to influence the location of the lesion. Frontal encephaloceles are more prevalent in Southeast Asia, for example, whereas lesions that involve the occipital lobe are more common in Western populations (Mahapatra and Agrawal, 2006). A role for genetic factors is supported by a number of autosomal recessive syndromes where encephalocele is present (e.g., Meckel's syndrome and Walker-Warburg syndrome). Overall, about one half of infants with encephaloceles have other major congenital anomalies that include microcephaly, arhinencephaly, anophthalmia, cleft lip or palate, craniosynostosis, complex congenital heart disease, and other systemic abnormalities (Brown and Sheridan-Pereira, 1992).

Encephaloceles are also associated with various other CNS defects that influence the severity of the outcome as well as the surgical management. These include anomalous draining veins, as well as hydrocephalus, which is

observed in up to 50% of cases (Diebler and Dulac, 1987; Menkes, 1991). The occurrence of lower occipital lobe encephalocele with skull base defects and malformations of the cerebellum and lower brainstem characterizes Chiari type III malformations (see later discussion of Chiari type II malformations that occur in association with myelomeningocele). Partial or complete agenesis of the corpus callosum and subependymal nodular heterotopias are other frequently associated CNS malformations, as discussed later.

Evaluation of the infant with an encephalocele can be aided by transillumination, skull radiographs, cranial ultrasound, computed tomography (CT) scan, and magnetic resonance imaging (MRI). Decisions about the appropriate modality depend on the individual cases and whether other cerebral anomalies or hydrocephalus is suspected. Frontonasal encephaloceles pulse or bulge with brief bilateral jugular vein compression, indicating communication with the subarachnoid space. Nasal *gliomas*, dermoids, and teratomas can all occur in the same region. Intranasal encephalocele should be suspected when an intranasal mass is found in a child with a broad nasal bridge and widely spaced eyes. Some of these children may also present with recurrent meningitis (Menkes, 1991). Basal encephaloceles are not usually diagnosed until childhood and can be located in the nasopharynx, sphenoid sinus, or posterior orbit.

In the majority of patients, neurosurgical management is indicated early in life. However, large lesions or other severe CNS anomalies may preclude intervention. Early intervention is imperative for those infants at high risk for meningitis caused by lesions that externally communicate and leak CSF. Encephaloceles can trigger medically intractable seizures, which may be responsive to surgical resection (Faulkner et al, 2010). Survival and outcome remain difficult to predict because of the variability of presentation and surgical selection bias. One study of a series of children with encephaloceles reported overall mortality at 29% (45% in infants with posterior defects; 0% in infants with anterior defects) (Brown and Sheridan-Pereira, 1992). Neurologic deficits were severe in 33% of survivors with anterior defects and in 33% of survivors with posterior defects. Mild neurologic deficits were found in 17% of survivors of anterior defects and in 50% of survivors of posterior defects.

Myeloschisis

Myeloschisis may be regarded as being at the more severe end of the spectrum of malformations of the spinal cord that arise from failure of posterior neuropore closure no later than 24 days' gestation. Hence, myeloschisis arises from an extensive failure of posterior neuropore closure, whereas myelomeningocele (see next section) arises from more restricted disturbances in posterior neuropore closure. Myeloschisis manifests as a severely malformed spinal cord with an exposed primitive neural plate–like structure that lacks overlying vertebrae and skin. At the level of the malformed upper cervical cord, there may often be associated malformations of the base of the skull that result in retroflexion of the head on the cervical spine (iniencephaly). Not unexpectedly, a majority of infants with myeloschisis are stillborn.

Myelomeningocele

Myelomeningocele and other associated malformations of the spinal cord arise from restricted failure of posterior neuropore closure probably no later than day 26 of gestation. The incidence of myelomeningocele has fallen substantially since the recognition that maternal folate plays a critical role in neural tube closure. Consequently, in the United States, the prevalence of spina bifida was reported in 2005 to be 2 in 10,000 live births and fell approximately 23% between 1995 and 2003 (Au et al, 2010). The spectrum of these spinal cord malformations includes myelomeningocele and meningocele. Myelomeningocele is characterized by herniation of the meninges and spinal cord at the site of the defect. Myelomeningoceles are usually exposed lesions on the back without vertebral or dermal covering (Figure 60-5), unless a lipoma overlies the defect (i.e., a lipomyelomeningocele) (Menkes, 1991). A meningocele is a restricted herniation of the meninges at the defect site. It is usually covered by skin, and neurologic function is often normal. Myelomeningoceles are about 4 times more common than meningoceles (Friede, 1989; Menkes, 1991). These lesions most often occur in the lumbar or lumbosacral regions (69% of cases), which supports the concept that the site of final closure of the posterior neuropore is in the lumbar region.

Myelomeningocele is rarely an isolated malformation, but is usually accompanied by other clinically significant CNS abnormalities. Of major importance is hydrocephalus, which is frequently associated with the Arnold-Chiari II malformation, discussed later (Del Bigio, 2010). Hydrocephalus is not universal, and its development in myelomeningocele correlates with the site of the lesion. Sixty percent of patients with occipital, cervical, thoracic, or sacral lesions develop hydrocephalus, whereas 90% of those with thoracolumbar, lumbar, or lumbosacral lesions do so (Lorber, 1961). Increased intracranial pressure is present in about 15% of newborns with myelomeningocele. In some infants, there are no signs of increased pressure because of decompression due to leakage of cerebrospinal fluid (CSF) from the myelomeningocele (Stein and Schut, 1979). In these infants, hydrocephalus and increased pressure may become evident later after surgical closure of the myelomeningocele. Most infants with hydrocephalus develop an abnormal increase in head circumference within a month after birth (Stein and Schut, 1979).

As in anencephaly, fetal diagnosis of an open myelomeningocele is suspected by detection of an elevation in AFP in maternal serum and can be confirmed by fetal ultrasound or MRI (see Figure 60-5, *A*) (Cameron and Moran, 2009). Screen for AFP is usually performed in the second trimester together with three additional markers (human chorionic gonadotropin [hCG], unconjugated estriol [ue(3)], and inhibin A) that collectively comprise the "quadruple screen." This screen is designed to detect open neural tube defects and Down syndrome (Anderson and Brown, 2009). A false-positive AFP result occurs with misdating of the fetus (older than predicted) and multiple gestation pregnancy (Brock, 1976). Other causes of a high maternal serum AFP include contamination of the amniotic fluid by fetal blood, which may occur in cases of esophageal and duodenal atresia, annular pancreas, omphalocele, gastroschisis, congenital nephrosis, polycystic kidneys, renal

agenesis, or fetal demise. The optimal time for determination in maternal serum is 16 to 18 weeks' gestation and in amniotic fluid at 14 to 16 weeks' gestation.

Clinical management of the newborn with a neural tube defect must be individualized. In the past, selective aggressive treatment was instituted for infants anticipated to have a better outcome. At present, aggressive surgical therapy is advocated for most infants; to date, this has resulted in patients with increased cognitive abilities, increased ambulation, a lower incidence of incontinence, and lower mortality (Hunt and Holmes, 1975; McLone 1992; Stein et al, 1975).

Prenatal fetoscopic surgical repair of myelomeningocele is under active investigation as a means to reduce direct injury that is suspected to occur as a result of chronic exposure of neural tissue to amniotic fluid (Hirose and Farmer, 2009). Preliminary studies found no consistent evidence for improved urologic or neurologic function and identified concerns for maternal safety. An ongoing multicenter trial seeks to identify a subset of patients for whom there is potential benefit (Hirose and Farmer, 2009).

Arnold-Chiari Malformation

The Arnold-Chiari malformation occurs in at least 95% of children with a myelomeningocele that includes a lumbar lesion (Figure 60-6). This malformation results in two types of serious complications (hydrocephalus and brainstem dysfunction) that are a significant cause of morbidity and mortality in infants with a myelomeningocele. The clinical sequelae of this class of malformations are best understood in the context of the principal types of associated anatomical abnormalities (Juranek and Salman, 2010). Hindbrain malformations involve both the brainstem and the cerebellum. Brainstem abnormalities include downward displacement of the medulla and the fourth ventricle through the foramen magnum into the upper cervical canal, which results in obstruction of the fourth ventricle and compression of the upper cervical cord. The resultant downward stretch of the cervical roots causes them to project cranially to their foramina rather than to follow their normal lateral or descending course. The caudal displacement of the brainstem thins and elongates the lower pons and upper medulla, which may compress brainstem nuclei as well as compromise the roots of the cranial nerves (Blaauw, 1971; Friede, 1989; Naidich et al, 1980). The herniation of the cerebellar tonsils through the foramen magnum and flattening of the lower cerebellar hemispheres are frequently associated with the caudal displacement of the brainstem. A variety of bony malformations are observed that include enlargement of the foramen magnum, defects of the occiput, and anomalies of the cervical vertebrae. Finally, cortical neuronal migration abnormalities (cerebral cortical dysplasia or polymicrogyria) are frequently associated with Chiari malformations and may account for cognitive deficits and epilepsy seen in some patients.

FIGURE 60-6 Sagittal magnetic resonance image (T2) of a child with myelomeningocele and a Chiari II malformation with downward displacement of the cerebellar tonsils (*large asterisk*) and a low position of the torcula (*small asterisk*). Note the pronounced hydrocephalus and ventriculomegaly *(V)*, dysplastic corpus callosum (*white arrows*), and the beaked tectum (*black arrow*). *(Courtesy Dr. Dianna M. E. Bardo, Department of Radiology, Oregon Health and Science University.)*

It follows from this constellation of hindbrain abnormalities that hydrocephalus is commonly associated with Chiari malformations (Del Bigio, 2010). The hydrocephalus may arise from compression of the fourth ventricle or obstruction of CSF outflow through the foramen magnum. In addition, many patients also have aqueductal stenosis or uncommonly, aqueductal atresia (Gilbert et al, 1986; Peach, 1965; Stein and Schut, 1979). A less well recognized but potentially fatal complication of hindbrain abnormalities is primary dysfunction of the brainstem. This can manifest as apneic episodes with cyanosis, vocal cord paralysis with laryngeal stridor, or feeding disturbances that result in aspiration related to reflux. Ventilatory disturbances may be either obstructive or central and, thus, prominent during sleep. These disturbances may be identified by polysomnography and pulmonary function studies (Kirk et al, 1999).

Occult Spinal Dysraphisms

Occult spinal dysraphic states are the result of defects in caudal neural tube formation (i.e., secondary neurulation). As discussed previously, development of the sacral and coccygeal segments of the spinal cord involves a process of canalization and caudal regression of the distal neural tube. In contrast to defects in primary neural tube formation, these defects thus uniformly localize to the distal cord and are closed defects with an intact dermal covering. In some instances, these defects are truly occult without any overlying abnormalities of the skin and may go undetected until symptomatic. However, in the majority of newborn infants a lumbosacral midline cutaneous lesion may indicate an occult spinal dysraphism (Figure 60-7). These lesions include abnormal hair tufts, hemangiomas, pigmented spots, skin tags, aplasia cutis congenita, cutaneous dimples or tracts, or a subcutaneous mass (Albright et al, 1989; Hall et al, 1981; Scatliff et al, 1989).

The spinal cord lesions associated with occult dysraphisms include myelocystocele; diastematomyelia-diplomyelia; meningocele-lipomeningocele; lipoma, teratoma, and other tumors; dermal sinus with or without dermoid or epidermoid cyst formation; and tethered cord (Anderson, 1975; Menkes, 1991) (Figure 60-8). More severe lesions include neurenteric cyst, anterior meningocele, and the findings of the caudal regression syndrome (dysraphia of sacrum and coccyx, atrophy of muscles and bones of the legs, fusion of spinal nerves and sensory ganglia, or agenesis of the distal spinal cord) (Towfighi and Housman, 1991). Infants of diabetic mothers are at increased risk for these lesions as well as for more severe neural tube defects (Becerra et al, 1990).

Regardless of the caudal neural tube malformation, an almost invariate feature is an abnormal conus and a thickened filum. A symptomatic tethered cord is a common presentation after surgical repair of myelomeningocele (Bowman et al, 2009). The movement of the filum is commonly restricted or "tethered" by fibrous bands or masses (e.g., a lipoma or teratoma) that can be diagnosed prenatally (Sohaey et al, 2009). Consequently, during growth of the lower spinal cord, progressive functional impairment can occur as the cord is stretched against the fixed filum (Lew and Kothbauer, 2007). Neurologic impairment rarely presents in the newborn period (Hertlzer et al, 2010). Deficits related to these lesions, which occur in infancy and childhood, include delay in walking, disturbed sphincter control, anatomic abnormalities of the feet or legs, and pain in the back or legs. Gait and sphincter abnormalities, foot deformities, and scoliosis are more common in older patients. Recurrent meningitis and rapid loss of function are rare but serious presentations. In the newborn period, a diagnostic evaluation of occult dysraphisms is indicated because early surgical intervention now carries a low risk of morbidity and can preclude sudden neurologic deterioration and the development of permanent deficits (Gower et al, 1988; Hertzler et al, 2010; Scatliff et al, 1989). In neonates, this evaluation may be facilitated by spinal radiographs or CT, which may detect vertebral anomalies; spinal ultrasonography, which permits a dynamic evaluation of lower spinal cord mobility; and MR imaging to define structural anomalies of the cord. After the age of 3 to 4 months, the ossification centers of the spine interfere with visualization of the conus medullaris and its normal motion by ultrasonography. Hence, high-resolution MRI with thin slices (2.5 to 3.0 mm) is the preferred study to evaluate tethered cord and lipomas of the filum. MRI is currently under investigation to evaluate movement-dependent changes in position of the conus medullaris in relation to the dorsal dural surface of the thecal sac.

DISORDERS OF NEURAL CREST MIGRATION

As the neural tube begins to fuse, the neural crest forms as a distinct region of neuroectoderm at the junction between the neural plate and the lateral ectoderm (see

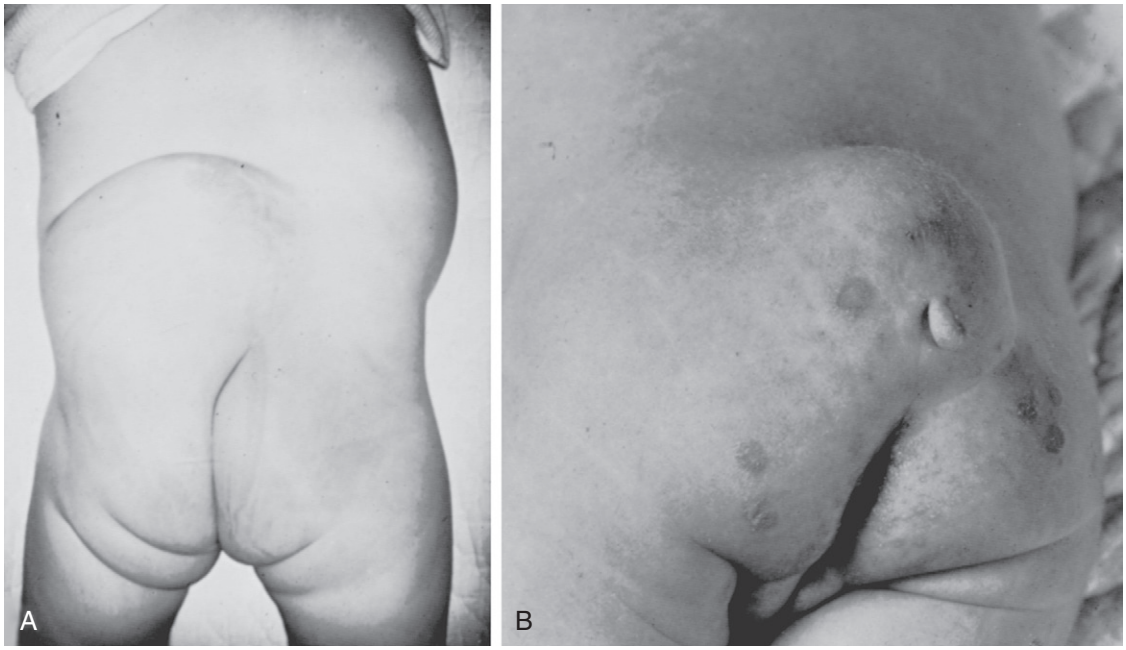

FIGURE 60-7 A and **B, Two examples of lipomeningocele.** Each presented in the left buttock as a firm, well-circumscribed, lobulated tumor that became tense when the infant cried. **B** shows macular erosions and a congenital skin tag and dimple over the surface. This last feature may be a pilonidal dimple displaced by the tumor.

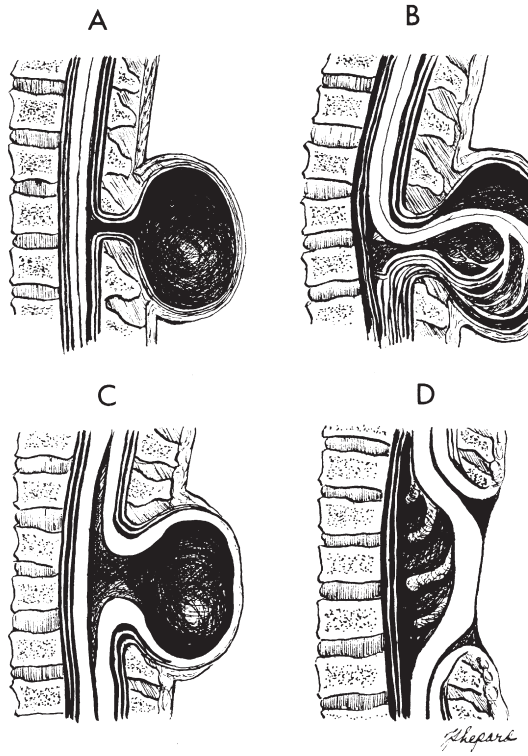

FIGURE 60-8 Diagram of meningoceles. A, Meningocele: Through the bony defect (spina bifida), the meninges herniate and form a cystic sac filled with spinal fluid. The spinal cord does not participate in the herniation and may or may not be abnormal. **B,** Myelomeningocele: Spina bifida with myelomeningocele; the spinal cord is herniated into the sac and ends there or may continue in an abnormal way further downward. **C,** Myelocystocele or syringomyelocele: The spinal cord shows hydromyelia; the posterior wall of the spinal cord is attached to the ectoderm and undifferentiated. **D,** Myelocele: The spinal cord is araphic; a cystic cavity is in front of the anterior wall of the spinal cord. *(From Benda CE:* Developmental disorders of mentation and cerebral palsies, *New York, 1952, Grune and Stratton.)*

Figure 60-1, *B*). This special population of cells gives rise to a remarkably large and diverse number of structures within and outside of the nervous system. There are four major derivatives of the neural crest: the cranial, the vagal and sacral, the truncal, and the cardiac (Hall, 2008). Neural crest derivatives that contribute to the nervous system include the sensory ganglia of cranial nerves V, VI, IX, and X (cranial neural crest); parasympathetic ganglia (vagal neural crest); dorsal root ganglia; sympathetic ganglia (truncal neural crest); and celiac, mesenteric, and aorticorenal ganglia (cardiac neural crest). The truncal neural crest becomes fragmented along with the truncal somites. After the neural crest anlage are formed, neural crest cells migrate throughout the entire embryo. Migration is rostrocaudal, along the medial axis of the embryo (LeDouarin, 1982). After migration is complete, the neural crest cells contributes to five major systems: (1) nervous system: meningioblasts, Schwann cells, ganglia (including enteric ganglion cells of the digestive tract); (2) endocrine system: chromaffin cells of the adrenal medulla and several types of endocrine and paraendocrine cells; (3) melanoblasts in all tissues except the retina; (4) the skeletal system of the head, face, and neck; and (5) cardiac system: connective tissue of the great vessels, aorticopulmonary septum, and smooth muscle of the great arteries.

Abnormalities thus can arise in the migration or differentiation of the neural crest cells, or neural crest derivatives may develop tumors (Jacobson, 1991; Reznik and Pierard, 1995). Disorders related to abnormalities of neural crest formation, migration, proliferation, or differentiation include the LEOPARD syndrome, multiple lentigines syndrome, NAME syndrome, LAMB syndrome, Peutz-Jeghers-Touraine syndrome, and Treacher–Collins syndrome (Reznik and Pierard, 1995). Tumors derived from neural crest cells include those arising from Schwann cells, perineural cells, or fibrocytes; from neural sense

organs; from ganglionic or neuroendocrine cells; or from melanogenic cells (Louis and von Deimling, 1995; Reznik and Pierard, 1995). Neuroblastoma is a neuroectodermal tumor that occurs mostly in children. It usually arises from the adrenal gland but can arise from sympathetic ganglia, the neuroendocrine system, or the ovary (Maris, 2010). It is sometimes seen in association with neurofibromatosis. Cutaneous metastases from neuroblastoma can occur as multiple skin nodules and have been seen in the newborn.

Hirschsprung's disease is a disorder of neural crest stem cells that occurs in 1 in 5000 births (Mundt and Bates, 2010). It is characterized by absence of hindgut intramural ganglion cells, which causes intestinal obstruction in the neonatal period. A gene associated with some cases of Hirschsprung's disease has been mapped to chromosome 10 and localized to the *RET* proto-oncogene (Edery et al, 1994; Moore and Zaahl, 2008; Romeo et al, 1994; Yin et al, 1994). Mutations that affect the RET protein also occur in patients with multiple endocrine neoplasia type 2A (Donis-Keller et al, 1993; Moore and Zaahl, 2008; Mulligan et al, 1993).

PROSENCEPHALIC CLEAVAGE AND RELATED EVENTS

NORMAL PROSENCEPHALIC DEVELOPMENT

The prosencephalon refers embryologically to the telencephalon and the diencephalon, the future forebrain. The telencephalon gives rise to the cerebral hemispheres; the diencephalon gives rise to the thalamus and hypothalamus. Prosencephalic development begins shortly after the closure of the anterior neuropore. The prosencephalon arises through developmental processes that induce the bifurcation of the rostral extent of the fluid-filled neural tube to form the right and left forebrain structures (Rubenstein and Beachy, 1998). This process thus involves the duplication of structures along the midline. The inductive processes that direct forebrain development also control craniofacial development. Hence, disruption of prosencephalic development is frequently associated with midline anomalies of both the forebrain and the face.

During the 5th to 6th weeks of development, the ultimate structure of the forebrain is defined by the sequential cleavage of the forebrain along three major planes. As the anterior neuropore is closing, the first major event is formation of the optic vesicles and nasal placodes, separated along the *horizontal* plane, which will give rise to the neural and craniofacial structures of the visual and olfactory systems, respectively. Shortly thereafter, when the embryo has reached a length of about 5 mm, both neuropores have closed, thus isolating the developing ventricular system from the amniotic fluid. At this time, the retinal and lens placodes are developing. Concurrently, in the brainstem, the cerebellum begins to form, as well as some somatic and visceral efferent nuclei, the common afferent tract, and the ganglia for most of the cranial nerves.

At about day 32 of gestation, when the embryo is 5 to 7 mm long, the second major event in forebrain development occurs when the forebrain is cleaved in the *sagittal* plane to give rise to the paired cerebral hemispheres, lateral ventricles, and basal ganglia. Specific areas, such as the hypothalamic, amygdaloid, hippocampal, and olfactory regions, can be defined. Shortly thereafter, the third major event in forebrain development occurs when the forebrain is cleaved in the *coronal* or *transverse* plane to separate the telencephalon from the diencephalon, thus defining the epithalamus, subthalamus, and hypothalamus.

During the remainder of the 2nd and 3rd months of gestation, the subsequent events in forebrain development occur along the midline to generate three major structures: the corpus callosum, the optic nerve/chiasm, and the hypothalamus. Disturbances in the formation of these midline structures, in particular the corpus callosum and the optic chiasm, are reflected in abnormal axon "pathfinding" to the midline and the failure of hemispheric and optic fibers to cross to the opposite hemisphere.

DISORDERS OF STRUCTURES DERIVED FROM THE PROSENCEPHALON

Holoprosencephaly

Holoprosencephaly (HPE) is the most common brain malformation (Barr and Cohen, 1999; Norman et al, 1995a) in that it has a prevalence of 1 in 250 in the developing embryo. However, many of these conceptuses do not survive to term, resulting in a live birth prevalence of 1 in 10,000 to 1 in 20,000 (Croen et al, 1996; Croen et al, 2000; Orioli and Castilla, 2010; Rasmussen et al, 1996). The abnormality in HPE is a variable degree of incomplete separation of the prosencephalon along one or more of its three major planes. HPE represents a continuum of prosencephalic nonseparation that is traditionally divided into alobar, semilobar, and lobar types (Figure 60-9). In *alobar* HPE (Figure 60-10), the most severe type, a single anterior ventricle is contained within a holosphere (i.e., there is a complete lack of separation of the prosencephalon into two distinct hemispheres, which manifests as the absence of the interhemispheric fissure). There is complete agenesis of the corpus callosum, the thalami usually are fused, and the basal ganglia are a single mass. Milder presentations involve partially formed hemispheres—*semilobar* HPE—and *lobar* forms, in which the distinct hemispheres can be distinguished and a portion of the posterior corpus callosum is present. In addition to these traditional HPE categories, a "middle hemispheric variant" has been described in which the posterior frontal and parietal lobes (i.e., the "midsections" of the brain) fail to separate, with absence of the body of the corpus callosum but presence of the genu and splenium (Barkovich and Quint, 1993; Lewis et al, 2002).

Associated with this midline brain malformation in HPE are often midline craniofacial anomalies. This may range from cyclopia (a single central eye) with a noselike structure (proboscis) above the eye, to cebocephaly (a flattened single nostril situated centrally between the eyes), to median cleft lip. Mildly affected infants may display a single central incisor or hypotelorism. It is often stated that "the face predicts the brain," referring to the fact that more severe facial malformations are often associated with more severe brain malformations. There are exceptions to this rule, however, with patients with lobar HPE having normal facies, and those with alobar HPE having

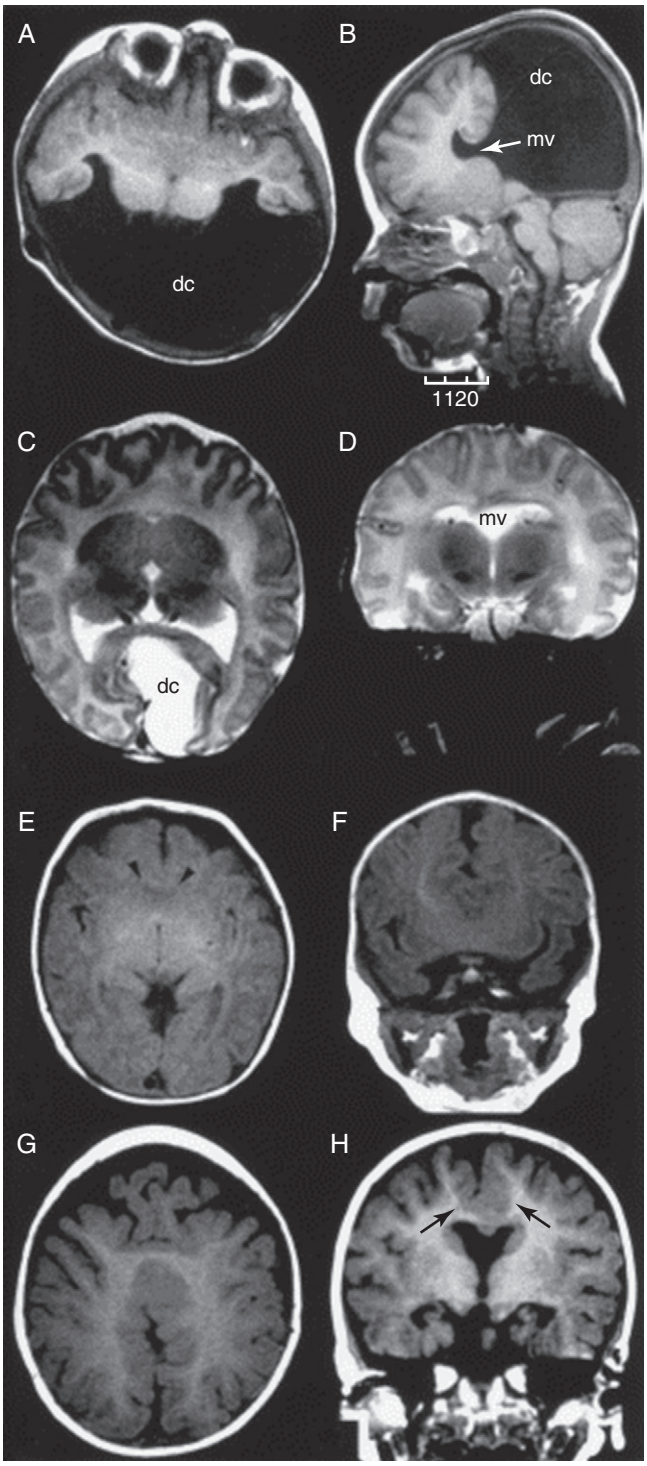

FIGURE 60-9 The spectrum of holoprosencephaly as demonstrated by magnetic resonance imaging. A and **B,** Magnetic resonance images of the brain in a patient with alobar HPE. T1-weighted axial image **(A)** reveals lack of separation of the two hemispheres and deep gray nuclei. Large dorsal cyst (dc) is observed posteriorly. T1-weighted sagittal image **(B)** reveals a midline ventricle, a monoventricle (mv), that communicates posteriorly with the dorsal cyst *(dc)*. **C** and **D,** Magnetic resonance imaging of a patient with semilobar HPE. T2-weighted axial image **(C)** indicates separation of the hemispheres posteriorly but not anteriorly. Anterior horns of the lateral ventricles are absent, whereas the posterior horns are well formed and separated. There is also an incomplete separation of the basal ganglia. T2-weighted coronal image **(D)** reveals a lack of interhemispheric fissure and a monoventricle *(mv)*. **E** and **F,** Magnetic resonance imaging of the brain in a patient with lobar HPE. T1-weighted axial image **(E)** reveals that two hemispheres are fairly well separated as manifested by the presence of an interhemispheric fissure both anteriorly and posteriorly. Note that the frontal horns of the lateral ventricles are only rudimentary (*arrowheads*). T1-weighted coronal image **(F)** documents incomplete separation of the inferior frontal lobes near the midline. **G** and **H,** Magnetic resonance imaging of the brain in a patient with the middle interhemispheric variant of HPE. T1-weighted axial **(G)** and coronal **(H)** images demonstrate the continuity of gray matter in the posterior frontal lobes across the midline (*arrows*). For T1-weighted images, TR of 600–630 ms and TE of 10–16 ms were used. For T2-weighted images, TR of 3000 ms and TE of 120 ms were used. *(From Hahn JS, Plawner LL: Evaluation and management of children with holoprosencephaly*, Pediatr Neurol *31:79-88, 2004.)*

more severely abnormal facies (Cohen, 1989; DeMyer et al, 1964; Plawner et al, 2002).

Clinical Features

Early literature indicated that children with HPE uniformly died during infancy. This statement may have been due to identification of only the most severe cases. Early death is typical for most cytogenetically abnormal children (Croen et al, 1996). However, of cytogenetically normal patients with all types of HPE, more than 50% are alive at 12 months (Barr and Cohen, 1999; Olsen et al, 1997). Survival into late adolescence and adulthood has been reported (Levey et al, 2010; Plawner et al, 2002).

Children with HPE face many medical and neurologic problems. The severity of their symptoms is often correlated with the degree of brain malformation. Microcephaly is the rule, except when hydrocephalus results (Hahn and Plawner, 2004). It has been hypothesized that hydrocephalus results from the blockage of CSF flow through the fused thalami, and the development of a large dorsal cyst (Simon et al, 2001). If there is clinical evidence that these fluid collections are under pressure, placement of ventriculoperitoneal shunts can improve symptoms (Levey et al, 2010).

As with other midline brain defects, endocrinologic abnormalities are very common. Diabetes insipidus occurs in up to 70%, with hypothyroidism, hypoadrenocorticism, and growth hormone deficiency being much less common (Hahn et al, 2005). Diabetes insipidus should be screened for intermittently because it may develop over time. Hypothalamic dysfunction also may cause irregularities of sleep, temperature regulation, appetite, and thirst.

Despite the significant brain malformations in HPE, only about 40% of children will have epilepsy; about one third of these will have intractable epilepsy (Plawner et al, 2002; Levey et al, 2010). Seizures may also be provoked by endocrinologic abnormalities such as hypernatremia or hypoglycemia. Abnormal muscle tone and motoric dysfunction are very common in children with HPE. Hypotonia is most common during infancy, with the development of spasticity and dystonia as the child develops. The motor dysfunction also causes poor oromotor function, and about two thirds of children with HPE will require gastrostomy tube placement.

Delayed development and cognitive disability are very frequent in HPE and are related to the degree of brain

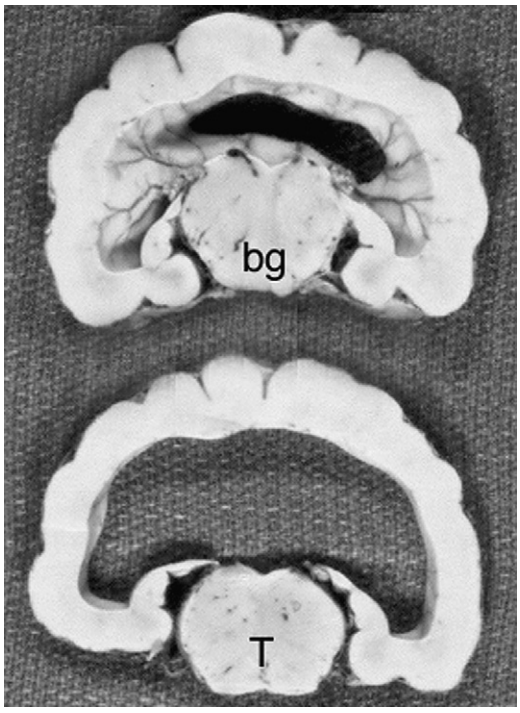

FIGURE 60-10 Alobar holoprosencephaly. Coronal views demonstrate a single anterior ventricle. Note the complete lack of separation of the forebrain into two distinct hemispheres. There is agenesis of the corpus callosum, the basal ganglia are a single mass *(bg)*, and the thalami *(T)* are usually fused. *(Courtesy Dr. Marjorie Grafe, Department of Pathology, Oregon Health and Science University.)*

malformation. Alobar HPE patients are nonambulatory. Patients with lobar HPE may ambulate, have functional hand use, and some degree of verbal communication. In all types of HPE there are relative strengths in receptive language and socialization (Kovar et al, 2001).

Etiology and Epidemiology

The etiology of HPE clearly is multifactorial, and both genetic and environmental factors appear to contribute to the extremely variable spectrum of forebrain and craniofacial malformations (Golden, 1998; Muenke and Beachy, 2000; Norman et al, 1995a). It has been appreciated for over a century that a wide variety of environmental insults (e.g., ethanol, vitamin A toxicity related to elevated retinoic acid levels) applied experimentally can produce cyclopia during the early phase of gastrulation in vertebrate embryos. Maternal diabetes mellitus increases the risk for HPE about 200-fold, to approximately 1% to 2% of all pregnancies. Cholesterol-lowering agents have recently been associated with HPE, by a mechanism described later (Edison and Muenke, 2003).

The genetic basis of HPE has been an area of very active and fruitful research. HPE may be caused by an abnormality in chromosome number, or a single-gene mutation. Abnormalities in single genes may causes either "syndromic" (i.e., associated with multiple other congenital anomalies), or "nonsyndromic" HPE. The most common disorders of chromosomal number that manifest with HPE are triploidy and trisomies 13 and 18. These abnormalities often result in pregnancies that do not survive to term, so the incidence is higher in studies looking at conceptuses rather than live births. Approximately 18% to 25% of HPE result from a mutation in a single gene, which causes syndromic HPE such as the Smith-Lemli-Opitz, Rubenstein-Taybi, Kallman, and Pallister-Hall syndromes (Muenke and Beachy, 2000). Six genes have been well established to cause nonsyndromic HPE: *Shh*, *ZIC2*, *SIX3*, *TGIF*, *GLI2*, and *PTCH1*). Shh was the first identified, best studied, and accounts for up to 40% of familial cases of HPE (Nanni et al, 1999; Roessler et al, 1996). Several of the other genes just listed are involved in the Shh pathway (see later discussion). Five other genes have been associated with HPE, but they are rare, and putative pathophysiologic pathways have not been well established.

HPE is characterized by extreme intrafamilial variability. Asymptomatic or mildly affected family members may carry a deletion for a gene associated with HPE, whereas in a subsequent generation, offspring with the same gene may be severely affected. One explanation for these paradoxical observations comes from studies supporting that the mode of inheritance for HPE may be multigenic transmission (Ming and Muenke, 2002). Mouse models of HPE exist in which mutations in two distinct genes are required to cause HPE. Several affected patients have been identified in whom abnormal alleles for two separate genes were identified. In these cases, a phenotypically normal parent carried a mutation for one gene but not the other (Nanni et al, 1999; Roessler et al, 1996). Hence, the severity of expression of the HPE phenotype throughout a given family may be influenced by the additive contributions from multiple environmental/teratogenic and genetic factors, which may be weighted differently in each affected family member.

Despite the wide intrafamilial variability, some genotype-phenotype correlations have emerged. For example, patients with ZIC2 mutations can have a characteristic facial appearance consisting of bitemporal narrowing, upslanting palpebral fissures, large ears, and a short nose with anteverted nares. ZIC2 mutations also appear to be the most common de novo mutation and have a high penetrance (Solomon et al, 2009, 2010).

Related Molecular Genetic Events

It was recognized decades ago that experimental ablation of the prechordal mesoderm, a mesodermal cell group under the ventral forebrain, disrupted the formation of the chiasmatic plate and optic vesicles and produced cyclopia. It was proposed that the prechordal plate induced the formation of ventral forebrain structures and directed the segmentation of the developing optic fields. Only recently has this complex picture begun to be clarified by the identification of multiple genes expressed in the prechordal plate that directly or indirectly regulate the development of the ventral forebrain. Many of these genes were identified in chromosomal regions with known deletions associated with HPE.

Shh is a signaling molecule secreted in the prechordal mesoderm that directs early embryonic patterning of the ventral forebrain. Mutations of the gene for Shh were the first identified to cause human HPE (Nanni et al, 1999; Roessler et al, 1996). Subsequently, mutations in other genes in the Shh signaling pathway also were identified, underscoring the importance of defects in Shh signaling

in the pathogenesis of HPE (Muenke and Beachy, 2000). These include mutations in the receptor for Shh, PTCH1 (Patched), in GLI2, which is a zinc finger transcription factor that mediates Shh signaling, and in ZIC2, which may mediate the response to Shh protein signaling (Warr et al, 2008).

Cholesterol is necessary for Shh functioning, which has implications for both genetic and environmental causation of HPE. Smith-Lemli-Opitz syndrome arises from a defect in the terminal step in cholesterol biosynthesis (7-dehydrocholesterol reductase); approximately 5% of cases of this syndrome manifest with HPE. Additionally, two plant alkaloids—cyclopamine and jervine—have been identified that caused epidemics of cyclopia in sheep that ingested plants rich in these compounds. Both compounds disrupt the Shh signaling pathway via inhibition of cholesterol biosynthesis. A recent study of cholesterol synthesis in patients with HPE showed that 10% had abnormalities in cholesterol production. About a quarter of these also had a mutation in one of the known HPE genes (Hass et al, 2007). Such findings support that the interactions of multiple environmental/teratogenic and genetic variables are likely to account for the considerable heterogeneity in the phenotypic expression of HPE within families and populations.

Agenesis of the Corpus Callosum

The corpus callosum is the largest of the cerebral commissures and consists of 190 million axons. The formation of the corpus callosum is a complex, multistep process that involves cellular proliferation, cellular migration, axonal growth, and midline patterning. This process is mediated by many genes and takes at least 11 weeks to complete. Thus, there are many genetic as well as environmental factors that can affect callosal formation and result in complete callosal agenesis (ACC) or callosal hypoplasia (Figure 60-11). At least 12 genomic loci are consistently associated with ACC, many of which appear to confer susceptibility to other brain malformations such as cerebellar hypoplasia, microcephaly, and polymicrogyria (O'Driscoll et al, 2010).

Agenesis of the corpus callosum may be difficult to distinguish from conditions in which dysgenesis, hypoplasia, or destructive lesions have occurred. The anatomic features of true agenesis of the corpus callosum include abnormal gyration of the medial portion of each hemisphere, eversion of the cingulate gyri, and sulcation that is perpendicular to the long axis of the hemisphere (Barkovich and Norman, 1988). The external angles of the lateral ventricle are oriented parallel and upward, toward the vertex, and the fornices are widely separated (Figure 60-12). When present, a useful distinguishing feature is Probst's bundles, which are fiber bundles that run parallel to the ventricle and carry callosal fibers in an anterior-to-posterior direction. Agenesis of the corpus callosum can be total or partial; when it is partial, the splenium is involved, and the genu remains intact (Roessmann, 1995; Schaefer, 1991).

Agenesis of the corpus callosum is a feature of dozens of different disorders. It is a primary feature of several important genetic syndromes such as Mowat-Wilson, Aicardi's syndrome, and X-linked lissencephaly with ACC and ambiguous genitalia (XLAG). It can also be seen as a nonspecific finding, such as in Sotos' or Wolf-Hirschhorn syndromes (Table 60-2). A recent population-based study (Glass et al, 2008) found that callosal anomalies were associated with a chromosomal abnormality 17% of the time, commonly aneuploidy (chromosomes 13, 18, 21). Environmental influences (e.g., teratogens or in utero infections) have also been implicated in the causation of ACC. Ethanol exposure has the strongest association with ACC and is seen in 7% of children with fetal alcohol syndrome (Roebuck et al, 1998).

ACC is associated with other CNS malformations 29 to 80% of the time and with musculoskeletal and cardiac abnormalities 34% and 28% of the time, respectively (Glass et al, 2008; Jeret et al, 1987; Parish et al, 1979). The concurrent CNS malformations seen with ACC are diverse and include heterotopia, abnormal sulcation, commissural

TABLE 60-2 Partial List of Syndromes Associated With Agenesis of the Corpus Callosum (ACC)

Syndrome	Gene	Features
Mowat-Wilson syndrome	*ZEB2*	ACC, mental retardation, Hirschsprung's disease, heart defects, genitourinary defects
X-linked lissencephaly with ambiguous genitalia (XLAG)	*ARX*	ACC, lissencephaly, epilepsy, abnormal genitalia
L1 syndrome	*L1CAM*	ACC, spastic paraparesis, mental retardation
Andermann syndrome	*SLC12A6*	ACC, progressive neuropathy
FG syndrome	*MED12*	ACC, hypotonia, mental retardation, dysmorphisms, constipation
Acrocallosal syndrome	Unknown	ACC, polydactyly, mental retardation
Aicardi's syndrome	Unknown	ACC, chorioretinal lacunae, infantile spasms, mental retardation
Fryns syndrome	Unknown	Dysmorphisms, congenital diaphragmatic hernia, pulmonary hypoplasia
Sotos' syndrome	*NSD1*	Somatic overgrowth, learning disabilities, dysmorphisms, ACC
Pyruvate decarboxylase deficiency	Specific gene unknown	Lactic acidosis, mental retardation, ACC
Wolf-Hirschhorn syndrome	On chromosome 4p16	Growth deficiency, dysmorphisms, mental retardation, seizures, ACC
Opitz G	Unknown	Dysmorphisms, laryngotracheoesophageal defects, genitourinary defects, ACC

and white matter abnormalities, and malformations of the posterior fossa (Hetts et al, 2006).

Consistent with the broad range of genetic factors and other concurrent malformations, the neurologic and developmental consequences of ACC are varied. Shevell (2002) found in his practice-based retrospective study that almost one third of patients with ACC were either developmentally normal or had mild developmental delay. Factors predictive of adverse developmental outcome were microcephaly, epilepsy, cerebral palsy, and cerebral dysgenesis. The outcome of isolated ACC is less clear. Prognosis is generally good, but neuropsychologic testing shows cognitive and behavioral deficits in many. IQ is typically normal, but lower than expected based on family history (Chiarello, 1980). Moutard et al (2003) prospectively studied 17 children with prenatally diagnosed isolated ACC through 6 years of age. All had IQs in the normal range, but there was a tendency for the IQ to decrease with age, and behavioral difficulties were common. For example, at 2 years of age attention difficulty was seen in 25%; by 4 years this was a problem in 44%. Neuropsychologic studies have shown specific impairment in abstract reasoning, problem solving, and category fluency (David et al, 1993; Fischer et al, 1992). Word generation is generally normal in patients with ACC, but there is difficulty with higher-level language such as comprehension of syntax and linguistic pragmatics (i.e., understanding idioms and humor) (Banich et al, 2000).

Agenesis of the Septum Pellucidum and Septo-optic Dysplasia

Septo-optic dysplasia (SOD) is the triad of absence of the septum pellucidum, optic nerve hypoplasia, and pituitary dysfunction. The diagnosis is made clinically when two or more features of the triad are present. Only 30% of patients have all three features (Morishima et al, 1986). Frequently, other cerebral abnormalities are present, including schizencephaly and absence of the pituitary infundibulum. The severity of the clinical features is quite variable. Children with SOD may be blind or have reduced vision and nystagmus. Neurodevelopmental prognosis is controversial. In early studies, cerebral palsy was found in 57%, mental retardation in 71%, epilepsy in 37%, and behavior problems in 20% of children with SOD (Acers, 1981; Margalith et al, 1984). A later neurodevelopmental study of seven children with unilateral or bilateral optic nerve hypoplasia, whose only other documented CNS abnormality was absence of the septum pellucidum, found normal cognitive development, intact neurologic status, normal language development, and age-appropriate behavior in six of the seven (Williams et al, 1993). Conversely, a descriptive series of three children with SOD plus cortical dysplasias, showed that all three had abnormal development and neurologic exams (Miller et al, 2000). Thus, the abnormalities found in many patients with SOD are likely caused by other associated brain lesions.

HESX1 is the only gene identified thus far as a likely cause of SOD. *HESX1* is a transcriptional repressor and is a homeobox gene whose mouse homologue has important roles in forebrain, midline, and pituitary development. Mutations in this gene have led to both homozygous and heterozygous forms of SOD. The homozygous mutations are fully penetrant and are associated with more severe disease (Dattani et al, 1998; Thomas et al, 2001). The contribution of mutations in *HESX1* to the cause of SOD appears to be less than 1% (McNay et al, 2007). Mutations in *HESX1* may also cause isolated pituitary dysfunction. In addition to genetic causes, some cases of SOD have been implicated to have antenatal drug and alcohol abuse or a vascular pathogenesis (Lippe et al, 1979; Lubinsky, 1997; Stevens et al, 2004).

The cavum septi pellucidi is an opening formed by the separation of the lamellae of the septum pellucidum; the lamellae fuse as the fetal brain matures. The cavum septi pellucidi may persist into extrauterine life, especially in preterm infants. Mott et al (1992) have documented the presence of a cavum septi pellucidi in all infants born at less than 36 weeks' gestation routinely studied by cranial sonographic examination. A cavum septi pellucidi was

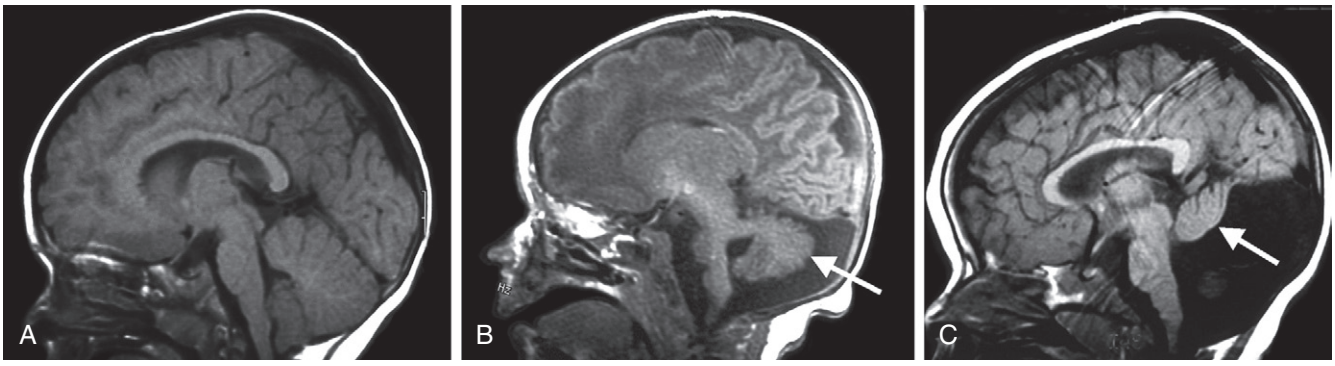

FIGURE 60-13 Dandy-Walker malformation (DWM). Sagittal images of a normal brain **(A),** the brain of a child with Joubert's syndrome **(B),** and the brain of a child with DWM **(C)** illustrate that features of the hindbrain malformations seen in the DWM overlap with that of other disorders. Note the presence of cerebellar vermis hypoplasia (*arrow*) in both **B** and **C**. By contrast, the patient with Joubert's syndrome **(B)** has only a slightly enlarged fourth ventricle, whereas in the DWM **(C)** the fourth ventricle is massively dilated. *(Courtesy Dr. Joseph G. Gleeson, Department of Neurology, University of California, San Diego, School of Medicine, and Dr. William B. Dobyns, The University of Chicago School of Medicine.)*

present in 36% of term newborns in the series reported by these investigators.

MALFORMATIONS OF STRUCTURES IN THE POSTERIOR FOSSA

NORMAL HINDBRAIN DEVELOPMENT

Malformations of the posterior fossa comprise an embryologically diverse group of disorders. Because these disorders are frequently associated with compromise to vital functions of the brainstem, management may focus on concerns for apnea and hydrocephalus, for example. Controversies will undoubtedly persist regarding the appropriate classification of these disorders until such time as the molecular genetic basis is further resolved.

The development of posterior fossa structures begins shortly after closure of the neural tube and coincides with the onset of prosencephalic development (ten Donkelaar and Lammens, 2009). At this time, the primary brain vesicles of the primitive hindbrain (rhombencephalon) emerge distal to the prosencephalon along an anterior-posterior axis. The midbrain derives from the mesencephalon and is embryologically distinct from the rhombencephalon from which the major hindbrain structures derive (cerebellum, pons [metencephalon], and medulla [myelencephalon]). Between 3 and 5 weeks' gestation, the rhombencephalon can be identified between the cranial and cervical flexures of the neural tube. Eight distinct rhombomeres have been defined in the rhombencephalon. The alar plate of rhombomere 1 gives rise to the cerebellum and rhombomeres 2 to 8 to the pons, medulla, and cranial nerves 5 to 10.

MALFORMATIONS WITH MAJOR CEREBELLAR INVOLVEMENT

Acquired malformations typically are unilateral or asymmetric, whereas inherited abnormalities symmetrically involve both cerebellar hemispheres, the vermis, or midline. The involvement of the cerebellum plus pontine hypoplasia comprises a distinct group of malformations (i.e., the pontocerebellar hypoplasias). Global cerebellar hypoplasia may also occur as a consequence of intrauterine insults such as toxins or irradiation and in association with chromosomal syndromes such as trisomy 13, 18, or 21.

Of the cerebellar malformations associated with significant posterior fossa cerebrospinal fluid collections, the prototype is the Dandy-Walker malformation (DWM), discussed later. A number of other posterior fossa malformations share similar embryologic derivatives or similar anatomical features with the DWM (Figure 60-13). These variants of the DWM include several syndromes of cerebellar vermis hypoplasia and dysplasia, syndromes that involve diffuse cerebellar hypoplasia and syndromes with normal cerebellar size and architecture, but with a large posterior fossa fluid collection that does not communicate with the fourth ventricle (e.g., mega cisterna magna or arachnoid cyst) (Altman et al, 1992; Barkovich et al, 2009; Niesen, 2002; Parisi and Dobyns, 2003; Patel and Barkovich, 2002; ten Donkellaar and Lammens, 2009). Moreover, numerous chromosomal anomalies, such as trisomy 9, 13, and 18, present with the DWM.

The DWM has also been described in association with a variety of genetic syndromes. One of these is the Walker-Warburg syndrome, which is characterized not only by extensive brainstem and cerebellar hypoplasia, but also by ocular anomalies, congenital muscular dystrophy, cortical migration abnormalities, and encephalocele. These have led to a variety of attempts to develop unifying classification schemes under the rubric of "DWM and its variants." Because the molecular mechanisms that underlie these malformations are mostly unknown, there is currently no basis for linking them as a spectrum. It should be emphasized that a more unfavorable outcome is related to the extent of other posterior fossa and CNS malformations. Hence, when "DWM" is diagnosed, prenatal and postnatal management and prognosis depend on precise definition of the particular anatomical abnormalities present. Prenatal ultrasound and MRI are increasingly employed, but both have continued challenges for the precise anatomical definition of these malformations (Malinger et al, 2009). Moreover, a number of clinically significant malformations accompany these hindbrain variants, notably agenesis of the corpus callosum and cerebral neuronal migration disturbances (polymicrogyria and heterotopias). Hence, establishing prognosis for DWM and other cerebellar malformations during pregnancy can be difficult.

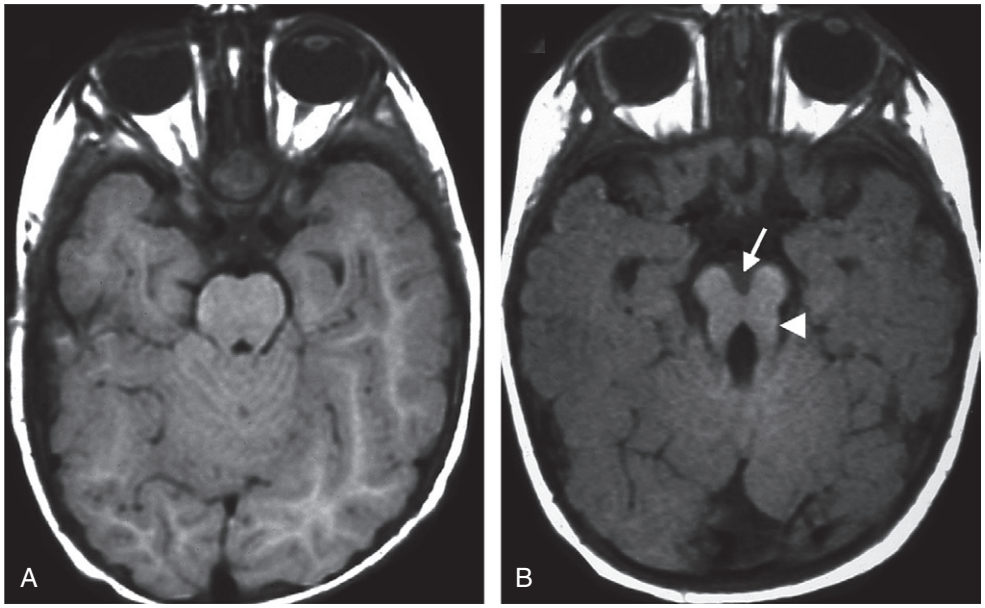

FIGURE 60-14 Molar tooth sign (MTS). Comparison of axial images from a normal brain **(A)** with that of a child with Joubert's syndrome **(B).** Note two key features of the MTS: a deepened interpeduncular fossa (*arrow*) and the elongated superior cerebellar peduncles (*arrowhead*). The third feature, cerebellar vermis hypoplasia, is seen in Figure 60-13, *B. (Courtesy Dr. Joseph G. Gleeson, Department of Neurology, University of California, San Diego, School of Medicine.)*

Children with isolated inferior vermis hypoplasia or mega cisterna magna have better neurodevelopmental outcomes compared with those with DWM or other hindbrain malformations (Bolduc and Limperopoulos, 2009).

Pontocerebellar hypoplasia is a diverse group of largely autosomal recessive disorders characterized by a reduction in pontine volume and a variable degree of cerebellar hypoplasia (for review, see ten Donkellaar and Lammens, 2009). A majority lack a clear etiology. At least five types have been described with associated features such as spinal muscular atrophy or extrapyramidal motor features. Some cases occur in association with congenital disorders of glycosylation, mitochondrial diseases, and congenital muscular dystrophies.

Dandy-Walker Malformation

Precise estimates of the incidence of Dandy-Walker malformation (DWM) are clearly affected by the lack of agreement regarding the definition of DWM. Nevertheless, DWM appears to occur in at least 1 in 5000 liveborn infants (Parisi and Dobyns, 2003). Inheritance is usually sporadic with a low risk of recurrence. The etiology is unknown. Two genetic loci have been identified for DWM. Recently, mutations in the human gene FOXC1 have been associated with DWM as well as cerebellar vermis hypoplasia and mega–cisterna magna (Aldinger et al, 2009). The invariant features of the DWM are aplasia or hypoplasia of the vermis of the cerebellum, cystic dilation of the fourth ventricle, and enlargement of the posterior fossa with upward displacement of the lateral sinuses, tentorium, and torcular (Benda, 1954; D'Agostino, 1963; Friede, 1989; Hart et al, 1972). The enlargement of the posterior fossa and displacement of its contents is related to communication of the fourth ventricle with a retrocerebellar cyst, which may be of considerable size. Communicating hydrocephalus with dilated lateral ventricles is also a common feature that may present in the neonatal period with macrocephaly. In fact, a majority of cases of DWM present with symptoms related to hydrocephalus (Costa and Hauw, 1995; Hart et al, 1972). There is no general agreement regarding the optimal management of hydrocephalus in DWM, which usually involves some combination of ventricular or posterior fossa shunt placement. Other prominent neurologic features include ataxia, nystagmus, apnea, cranial neuropathies, and developmental delay.

Syndromes Associated With the Molar Tooth Sign

The molar tooth sign (MTS) is defined as the triad of cerebellar vermis hypoplasia, and two mid-hindbrain malformations (an abnormally deep interpeduncular fossa and elongated cerebellar peduncles). When viewed on axial MRI images (Figure 60-14), the brainstem malformations have the distinctive appearance of a molar tooth. Abnormalities of the cerebellum are also found in Joubert's syndrome, which is the most extensively studied of several uncommon autosomal recessive cerebello-oculo-renal syndromes associated with the molar tooth sign (MTS) (Parisi and Dobyns, 2002). The cerebellar lesion usually involves complete or partial agenesis of the vermis (see Figure 60-13, *B*), but there may also be dysplasia of the dentate nucleus, cerebellar heterotopias, anomalies of brain stem nuclei, and absence of decussation of the pyramidal tracts (Curatolo et al, 1980).

Joubert's syndrome (JS) is a rare autosomal recessive disorder. It is the prototype for a recently identified group of disorders known as "ciliopathies," in which defects occur in the structure or function of the cellular primary cilium (Lee and Gleeson, 2010; Nigg and Raff, 2009). At least seven genes have been identified for various subtypes

of JS, which subserve signal transduction pathways at the primary cilium. Primary cilia are found in both Purkinje cells and granule cell progenitors. Defective ciliary function is also a feature of retinal dystrophy and fibrocystic renal disease, thus providing a unifying mechanism for many of the multisystem abnormalities seen in patients with JS.

The most prominent clinical features of JS are hypotonia, abnormal eye movements (horizontal nystagmus and oculomotor apraxia), ataxia, abnormal breathing patterns (periods of hyperpnea alternating with apnea) and cognitive delays/mental retardation (Joubert et al, 1969). Variable features of Joubert's syndrome include occipital encephalocele, microcephaly, low-set ears, polydactyly, and pigmentary retinopathy (Egger et al, 1982; Friede and Boltshauser, 1978). Renal disease in Joubert's syndrome includes cystic dysplasia of the kidneys and juvenile nephronophthisis. The latter is a form of medullary cystic renal disease that progresses to chronic renal failure (Satran et al, 1999).

CENTRAL NERVOUS SYSTEM DEVELOPMENT IN THE POSTEMBRYONIC PERIOD

NORMAL DEVELOPMENT OF THE CORTICAL PLATE

Proliferative Events

Four transient tangential layers form during the process of cerebral cortical development. These (from the ventricle to the brain surface) are the ventricular, subventricular, intermediate, and marginal zones. Initially, the nascent cortical plate derives from the ventricular zone (VZ). The VZ is the site of earliest proliferation of neuronal and radial glial progenitor cells in the wall of the neural tube. As the cerebral wall expands, the subventricular zone becomes a secondary site of later neuronal and glial proliferation. These proliferative events occur roughly between 4 and 16 weeks' gestation. Peak cell proliferation occurs around 8 to 16 weeks. This coincides with the expansion of the cortical plate, which appears when the embryo is about 22 to 24 mm long, at about 52 days' gestation.

The initial cycles of neural progenitor proliferation in the VZ result in the symmetrical expansion of the stem cell pool such that each mitotic event results in the generation of two additional stem cells (Caviness, 1995; Rakic, 1995). This process determines the total pool of stem cells, or so-called proliferative units from which the cortical plate will form. Once the generation of this stem cell pool stabilizes, a second phase of proliferation begins during which individual stem cell clones begin to divide asymmetrically. During this phase of clonal expansion, each mitosis generates an additional stem cell and another neuronal cell that withdraws from the cell cycle. The latter postmitotic neuron then begins migration from the VZ to the outer wall of the neural tube. Hence, this second phase of asymmetric cell division results in the expansion of each individual stem cell clone or proliferative unit. Eventually, this phase results in a proportionately larger number of postmitotic cells that all derive from the same proliferative unit.

Migrational Events

Rakic first proposed that the postmitotic neurons that derive from an individual clonal population in the VZ migrate together along the same radial glia fiber to generate individual columns of cells within the cortical plate (Rakic, 1998). The radial glia processes extend from the VZ to the outer wall of the neural tube and serve as a scaffold to guide the migration of individual clones of postmitotic neurons to form the preplate. Migration of neurons from the VZ occurs in an "outside-in" fashion, such that the neurons furthest from the ventricle migrate first and those closest to the ventricle migrate last.

As neuronal migration proceeds, the preplate is split by the arrival of subsequent populations of neuronal progenitors that will form the cortical plate. The cortical plate ultimately gives rise to cortical layers II–VI. The splitting of the preplate results in the formation of the marginal zone (future cortical layer I) and the subplate, which resides between the intermediate zone (the future cerebral white matter) and the bottom of the cortical plate (Marin-Padilla, 1988, 1998). The Cajal-Retzius neurons of the marginal zone and the subplate neurons play critical roles in neuronal migrations, as discussed later.

As neuronal migration progresses, each subsequent group of neurons migrates past the neurons that migrated earlier. Hence, the earliest neurons to migrate eventually reside in the deepest cortical layer. Because the last neurons to migrate reside the closest to layer 1, the cortical layers are thereby formed in an "inside-out" sequence. The major events involved in formation of the cortical layers are occurring between approximately 7 and 11 weeks.

Subplate Neurons and Establishment of Thalamocortical Connections

As emphasized earlier, the cortical plate develops from within the preplate. The preplate consists of the earliest generated neurons and a plexus of nerve fibers. With subsequent waves of neuronal migration, the preplate is split into the marginal zone (i.e., a superplate) and a subplate. Hence, the cells in these layers are among the earliest generated neurons. In the second trimester, two subcortical afferent systems are present in the subplate (Allendoerfer and Shatz, 1994). These are thalamocortical fibers and basal forebrain fibers, which remain in the subcortical region for a period of time before their fibers penetrate the cortical plate. The neurons of layer IV in the cortex receive their predominant ascending inputs from the thalamus. Interestingly, however, the thalamic axons are present in the cortex long before the layer IV neurons have reached the cortical plate. These axons reside in the subplate for a period of weeks in proximity to postmitotic neurons in the subplate. Most of these early maturing subplate neurons undergo programmed cell death after the thalamic axons have grown into the cortical plate (Chun et al, 1987).

Hence, subplate neurons transiently appear during a critical window in development, and few are present in the adult neocortex. In human, the subplate achieves its peak size by 24 weeks' gestation and declines thereafter (Kostovic and Rakic, 1990; Kostovic and Vasung, 2009). The hypothesis that these subplate neurons play a critical role in thalamocortical development by guiding thalamic

axons into the cortical plate has been substantiated by studies that have shown that deletion of the early subplate neurons prevents the thalamic axons from innervating the cortex. Thus, the transient subplate neurons play an important role in establishing both thalamocortical and corticocortical connections (Ghosh et al, 1990; Kanold et al, 2003).

DISORDERS OF NEURONAL PROLIFERATION

Micrencephaly

Micrencephaly is a disorder in which the primary defect is a marked reduction in the size of the brain or of the cerebral hemispheres. Microcephaly denotes a small cranial vault (<-2 standard deviations [SD] below normative curves for age) that is related either to micrencephaly or acquired brain atrophy (e.g., multicystic encephalopathy, hydranencephaly, diffuse cortical atrophy). Until recently, micrencephaly was considered to be an isolated defect of either decreased neuronal proliferation or increased apoptosis (programmed cell death). Representative examples are radial microbrain and micrencephaly vera (Evrard et al, 1989; Rakic, 1988). However, MRI studies have begun to define greater heterogeneity in the types of malformations that are associated with micrencephaly (Barkovich et al, 2001; Tarrant et al, 2009). Associated malformations include simplified gyral patterns, microlissencephaly with thickened cortical gray matter, and polymicrogyria (Barkovich et al, 1998; Peiffer et al, 1999; Sztriha et al, 1998). The association of micrencephaly with features of cortical neuronal migration abnormalities suggests overlap in the mechanisms that direct neuronal proliferation and migration in humans.

Two subgroups of isolated micrencephaly, radial microbrain and micrencephaly vera, provide insight into mechanisms of isolated disturbances of neuronal proliferation. Radial microbrain appears to be related to a reduced *number* of proliferative units. By contrast, micrencephaly vera appears to be related to a reduced *size* of proliferative units (Evrard et al, 1989; Rakic, 1988). Radial microbrain is a rare familial condition characterized by a normal gyral and cortical lamination pattern, but an abnormal number of cortical neuronal columns. The number of cells per column is normal, implying that the defect resides in early neural stem cell division with an impact on the ultimate number of "proliferative units" available to generate the cortical columns.

Micrencephaly vera describes a variety of conditions with small brain size where the underlying etiology may be related to a disturbance in neuronal proliferation. Cases of autosomal recessive micrencephaly vera have a simplified gyral pattern. The number of cortical neuronal columns is normal, but the cell number in each column is reduced (Evrard et al, 1989). This constellation of findings most likely occurs between 6 and 18 weeks' gestation, when later proliferative events occur.

The potential etiologies for microcephaly are diverse. It is associated with hundreds of genetic syndromes. Autosomal dominant, autosomal recessive, and X-linked recessive inheritance patterns have been described (Robain and Lyon, 1972; Warkany et al, 1981). Irradiation before 18 weeks' gestation is a well-known teratogenic agent that can produce micrencephaly. Exposure to alcohol and cocaine during this time can also result in micrencephaly (Gieron-Korthals et al, 1994; Peiffer et al, 1979). Maternal hyperphenylalaninemia has also been associated with these defects in nonphenylketonuric offspring (Lenke and Levy, 1980; Waisbren and Levy, 1990).

A recent large retrospective review found that the prognosis for microcephaly is closely related to the severity of the reduction in head circumference (Ashwal et al, 2009). Developmental disabilities and imaging abnormalities are seen in approximately 80% of children with severe microcephaly defined as a head circumference <-3 SD. The major comorbid conditions are mental retardation (approximately 50%), epilepsy (approximately 40%), cerebral palsy, and ophthalmologic disorders (each approximately 20%).

Eight genetic loci and five genes for human autosomal recessive primary microcephaly have been mapped (Thornton and Woods, 2009). All result in a small but structurally normal-appearing brain and a similar range of mental retardation without other neurologically distinguishing features. Although all the proteins identified to date are ubiquitously expressed and operate in diverse pathways, all are associated with the centrosome, suggesting a common mechanism to regulate neurogenesis.

Macrencephaly

Macrencephaly refers to a diverse group of conditions characterized by a large brain. Although it has been hypothesized that macrencephaly is related to an aberrant increase in neuronal proliferation, quantitative neuropathologic studies are lacking. Macrencephaly manifests most commonly as an isolated finding in familial (autosomal dominant or autosomal recessive) and sporadic cases. Among the other diverse conditions that are associated with macrencephaly are chromosomal disorders (fragile X syndrome and Klinefelter's syndrome) and neuroendocrine disorders related to a generalized disturbance in growth (Beckwith-Wiedemann syndrome, cerebral gigantism, and achondroplasia) (DeMyer, 1972; Dodge et al, 1983).

At birth, the head circumference in about half of cases is greater than the 90th percentile. The diagnosis of autosomal dominant macrencephaly is greatly favored by the finding of a large head circumference (macrocephaly) in either parent. Autosomal dominant inheritance is generally associated with a more favorable outcome, whereas the rare cases of autosomal recessive inheritance are commonly associated with mental retardation and epilepsy. One generally benign form of autosomal dominant macrencephaly is accompanied by extracerebral fluid collections that enlarge the subarachnoid spaces (Alvarez et al, 1986). Erroneously referred to as "external hydrocephalus," there is rarely an indication for placement of a shunt to drain this fluid. Rather, the initial acceleration in head circumference generally arrests spontaneously by around the 1st year of life, and thereafter the fluid collections become smaller. These fluid collections appear to be related to an imbalance in cerebrospinal fluid generation at birth related to developmental immaturity of the subarachnoid granulations that resorb this fluid (Neveling and Truex, 1983; Barlow, 1984).

Hemimegalencephaly (Figure 60-15) refers to a rare malformation of unilateral macrencephaly related to enlargement of some portion of one cerebral hemisphere and accompanied by increased cortical thickness and abnormal

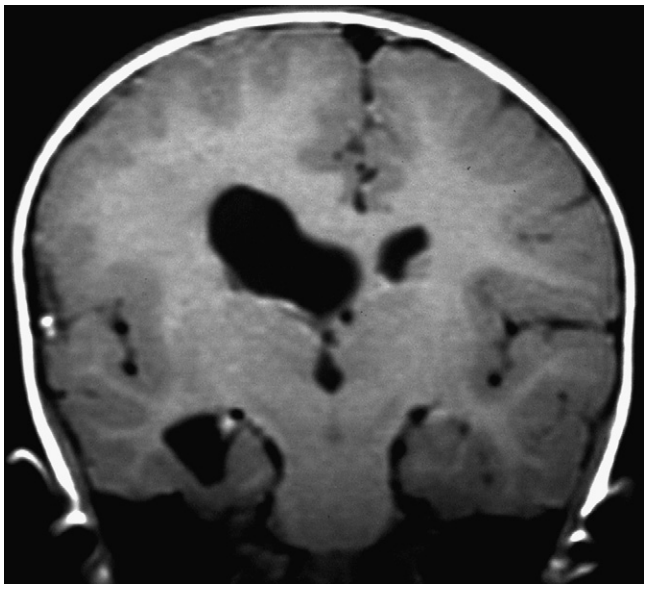

FIGURE 60-15 Magnetic resonance image scan, hemimegalencephaly. Note the marked asymmetry of the two cerebral hemispheres with the pronounced enlargement *on the left. (Courtesy Dr. Martin Salinsky, Department of Neurology, Oregon Health and Science University.)*

cortical gyration (Robain et al, 1972). The pathologic features include apparent disturbances in astroglia proliferation and morphology as well as neuronal heterotopias in subcortical white matter (De Rosa et al, 1992). The usual onset for intractable epilepsy is in the neonatal period (Ohtsuka et al, 1999). A markedly improved outcome may be achieved in selected patients after hemispherectomy as early as the neonatal period (Battaglia et al, 1999). The primary genetic defect is unknown. It has been noted in association with neurocutaneous disorders including the sebaceous nevus syndrome (Dodge and Dobyns, 1995) and hypomelanosis of Ito (Montagna et al, 1991).

DISORDERS OF NEURONAL MIGRATION

Neuronal migration disorders are characterized anatomically by defects in the lamination of the cerebral cortex. Most of these defects are related to some degree of failure of neurons to migrate to their appropriate target positions within the normal six layers of the developing cerebral cortex. The clinical spectrum of brain malformations associated with disrupted neuronal migration ranges from complete focal agenesis of an entire region of the cerebral cortex in schizencephaly to more subtle abnormalities where heterotopic clusters of neurons are retained in abnormal locations within the subcortical white matter (see Table 60-1). In many disorders, there are prominent disturbances in the formation of the cortical surface that manifest as gyral abnormalities. In the extreme, there is a complete absence of gyri and a smooth cortical surface (lissencephaly). At the other extreme is an excess of small gyral convolutions (polymicrogyria). The fact that these gyral abnormalities are often accompanied by other malformations, such as hypoplasia or agenesis of the corpus callosum, points to a complex interplay between the mechanisms that determine neuronal migration and axon pathfinding. This is consistent with the fact that the timing of

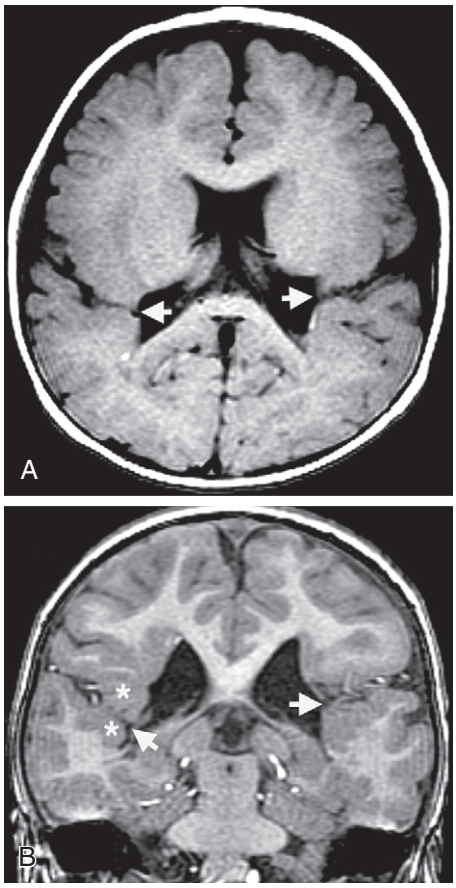

FIGURE 60-16 Magnetic resonance image scan, bilateral open-lip schizencephaly. A, Axial T1 weighted image. James Barkovich, Department of Radiology, University of California, San Francisco, School of Medicine.)*

neuronal migration and midline prosencephalic development overlap. Hence, disturbances in neuronal migration would be anticipated to have a deleterious impact on the axonotropic signaling required for establishment of inter- and intrahemispheric cortical connections.

Schizencephaly

Schizencephaly (i.e., split brain) is characterized by severe focal malformations of the cerebral cortex that result in complete agenesis of all layers of the cortical wall. The resultant defect is a cleft in the cerebral cortex in one or both hemispheres, which thus connects the lateral ventricle with the extracerebral space (Figure 60-16). When the defect is wide (separated-lip or open-lip schizencephaly), the malformation may be confused with a lesion caused by a severe destructive process. However, a feature of schizencephaly that differentiates it from an encephaloclastic lesion (e.g., hydrancephaly, porencephaly) is that on histologic examination, the cleft has features of a migrational disturbance, such as large neuronal heterotopias bordered by adjacent polymicrogyria. When the defect is narrow (closed-lip schizencephaly), it has the appearance of a narrow groove in the cortical mantle. The morphologic features of schizencephalic clefts by neuroimaging are best

delineated by MRI, which has demonstrated the common occurrence of subependymal heterotopias and polymicrogyria and the universal finding of diminished volume of the cerebral white matter (Hayashi et al, 2002a). In addition, a wide range of anomalies related to disturbances of prosencephalic development may occur in association with schizencephaly. These include holoprosencephaly, agenesis of the corpus callosum, and agenesis of the septum pellucidum.

Schizencephaly occurs with a wide range of clinical severity that is related to the size and distribution of the cerebral clefts and the extent of associated malformations (Barkovich and Kjos, 1992; Packard et al, 1997). Significant cognitive impairment is almost universal with bilateral anomalies but occurs in a minority of cases with unilateral lesions. Motor disturbances (spasticity, hemiparesis) are common with both unilateral and bilateral lesions; this finding is likely related to the predilection for frontal lesions. Epilepsy is common in schizencephaly, present in 37% to 65% of patients in case series (as reviewed by Granata et al, 2005). A wide variety of seizure types may manifest, including focal seizures, generalized seizures and infantile spasms. Of interest, some groups have found that the severity of the epilepsy is not correlated with the severity of the brain malformation; patients with unilateral schizencephaly had earlier age of seizure onset and more refractory epilepsy than those with bilateral schizencephaly (Denis et al, 2000; Granata et al, 1996). Hydrocephalus is seen almost exclusively with separated-lip lesions.

The etiology of schizencephaly remains controversial. Many feel that schizencephaly can result from various types of injury to the developing cortex, but the degree to which genetic mutations may cause this defect in neuronal migration is unclear. In utero exposure to toxins and infection is associated with schizencephaly (Iannetti et al, 1998; Takano et al, 1999). It has been suggested that ischemic injury (from toxin, infection, or hypoxia) early in gestation could damage the radial glial fibers resulting in the full-thickness cortical cleft (Barkovich and Kjos, 1992). The possible role of the human homeobox gene *EMX2* in schizencephaly is unclear. Initial reports found some familial cases with *EMX2* mutations (Brunelli et al, 1996; Faiella et al, 1997; Granata et al, 1997). However, further studies have suggested that these mutations were unlikely to be pathogenic, because they did not result in truncation of the protein or a change in protein function, and no mutations in the *EMX2* gene were found in 39 patients with schizencephaly (Merello et al, 2008). Additionally, *EMX2* mutations have not been reported in additional families with schizencephaly. Moreover, the same initially described mutations were seen in unaffected family members, which suggests that the mutation may instead represent a polymorphic variant. Mouse models of *EMX2* deletions also do not result in schizencephaly (Pellegrini et al, 1996; Yoshida et al, 1997).

Polymicrogyria

Polymicrogyria constitutes a heterogeneous group of malformations where an excessive number of small and partially fused gyri are separated by shallow sulci (Figure 60-17). It is thought to result from an injury or genetic disorder that occurs towards the end of neuronal migration or the beginning of cortical organization. Consequently, the normal six-layered cortical lamination pattern is disrupted.

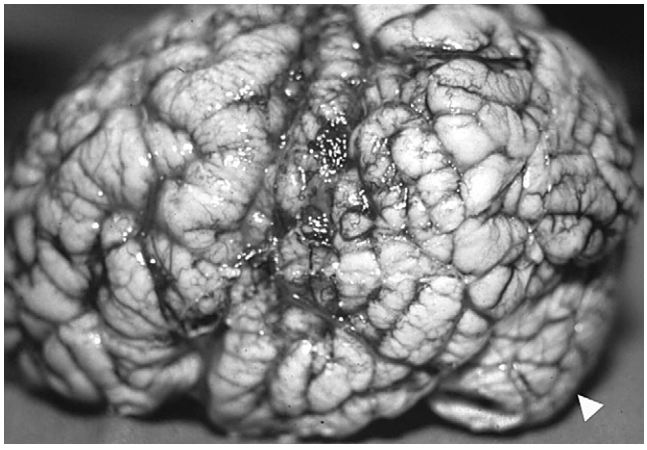

FIGURE 60-17 Polymicrogyria. Much of the cerebral cortex in this photograph shows the irregular, "cobblestone" appearance of polymicrogyria. More normal gyri are present at the frontal pole (*lower left*). The cerebellum is indicated at lower right (*arrowhead*). *(Courtesy Dr. Marjorie Grafe, Department of Pathology, Oregon Health and Science University.)*

Polymicrogyria is diverse both in terms of etiology and histologic features. Causes may be environmental such as intrauterine infection or ischemia (Barkovich and Lindan, 1994; Barkovich et al, 2010), or genetic. Histopathologically, there are two major types of polymicrogyria, layered and unlayered. In *layered polymicrogyria*, four distinct cortical layers form instead of the normal six layers. This "classic" form is not associated with other migrational abnormalities but often is more diffusely localized adjacent to regions of encephalomalacia related to infection (e.g., toxoplasmosis, cytomegalovirus infection) or ischemia with cortical laminar necrosis.

Unlayered polymicrogyria is characterized by a markedly disorganized cortex that lacks distinct cortical layers. The timing of appearance of this form appears to be no later than 4 to 5 months' gestation. Unlayered polymicrogyria is associated with other migrational disturbances, particularly subcortical nodular heterotopias, lissencephaly, and schizencephaly. A genetic basis is suggested by syndromic associations (e.g., Zellweger's syndrome, Miller-Dieker syndrome, DiGeorge syndrome); familial transmission; and sporadic cases with X-linked, autosomal recessive, and autosomal dominant inheritance patterns (Barkovich et al, 1999; Ross and Walsh, 2001).

Delineation of the spectrum of CNS malformations associated with polymicrogyria has been greatly advanced by MRI. Importantly, if thick sections (>4 mm) are acquired, these anomalies may resemble focal pachygyria, abnormally thick large gyri, because of signal averaging from the microgyri. Barkovich (2010) recommends image acquisition in three planes with thinner slice thickness and sequences that provide optimal gray matter–white matter contrast (such as volume 3DFT spoiled gradient acquisition and volume 3DFT fast spin echo images with 1.5-mm slices). Polymicrogyria shows a strong predilection for the

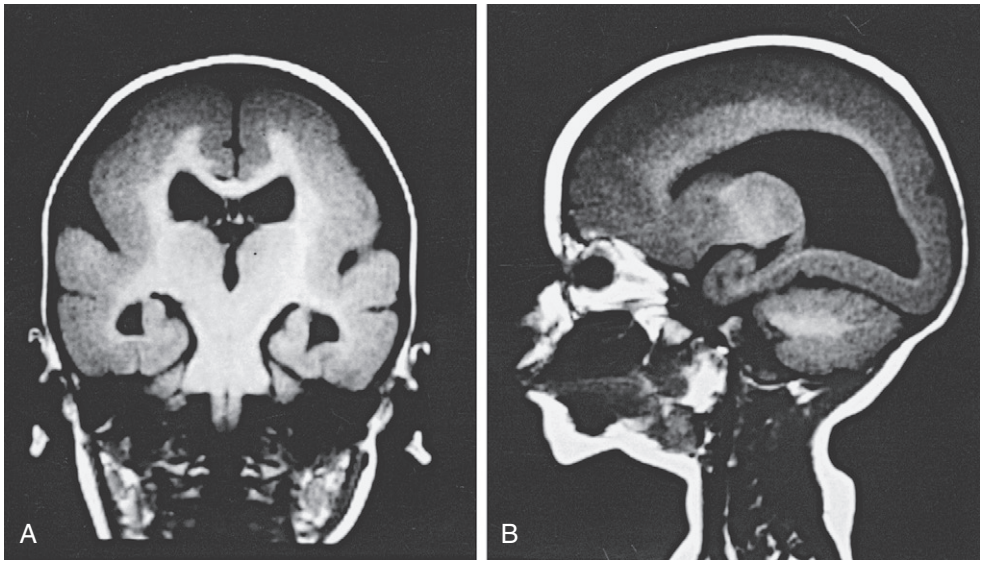

FIGURE 60-18 T1-weighted MR images of the brain of a child with classical lissencephaly. A, Coronal view. **B,** Sagittal view. sylvian fissure and adjacent regions of frontal and parietal cortex (80% of cases), whereas the cingulate cortex, striate cortex, gyrus rectus, and hippocampus are spared. Polymicrogyria is bilateral in 60% of cases (Hayashi et al, 2002b). Often, an additional associated feature is a decrease in cerebral white matter volume adjacent to the dysplastic cortex.

The clinical features of patients with polymicrogyria are variable and relate in part to the extent and distribution of cortical dysplasia. Bilateral polymicrogyria and polymicrogyria that involves more than half of a single hemisphere carry a poor prognosis related to moderate to severe developmental delay and significant motor dysfunction (Barkovich, 2005). Because frontal cortical lesions are common, hemiparesis or quadriparesis is often seen. Epilepsy, notably partial complex seizures, multiple generalized seizure types, or refractory epilepsy, is common but may be delayed in onset beyond the neonatal period.

There are several common syndromes of bilateral symmetrical polymicrogyria. Bilateral perisylvian symmetrical polymicrogyria results in oropharyngeal dysfunction in all patients, because the perisylvian cortex subserves oromotor control and the motor programs of language. Discoordination of suck and swallow is common in the neonate. Epilepsy is seen in 80% of patients and mental retardation in 50–80% (Guerreiro et al, 2000; Guerrini et al, 1992; Kuzniecky et al, 1993). Gene loci linked to this syndrome are Xq21.33, 22q11.2 and Xq28 (Robin et al, 2006; Roll et al, 2006; Villard et al, 2002). In bilateral frontoparietal polymicrogyria, consistent findings include global developmental delay, dysconjugate gaze/esotropia, and bilateral pyramidal and cerebellar motor signs (Chang et al, 2003). Abnormalities in the G protein–coupled receptor GPR56 (16q12.2) have been implicated in this form of polymicrogyria (Chang et al, 2003; Piao et al, 2002). In addition to the polymicrogyria, neuroimaging shows bilateral white matter signal changes, a small brainstem, and a small dysmorphic cerebellum, which is unique for the polymicrogyria syndromes (Barkovich, 2010).

Lissencephaly and Pachygyria

The lissencephalies are a class of neuronal migrational disorders characterized by a paucity or absence of gyri (*agyria*), which gives the cortical surface a smooth or nearly smooth appearance (Kato and Dobyns, 2003). In most patients, lissencephaly is characterized by an abnormally thick cortex and disturbances in the organization of the cortical layers that may be accompanied by diffuse neuronal heterotopias (Figure 60-18). The spectrum of gyral malformations includes *pachygyria*, characterized by regions of cortex with a reduced number of coarse, broadened gyri, and *subcortical band heterotopia* ("double cortex"), where a circumferential band of heterotopic neurons resides within the subcortical white matter directly beneath a relatively normal cortex.

The classification of the lissencephalies has undergone major revision to reflect the rapidly evolving molecular basis of these disorders (Barkovich et al, 2001; Jissendi-Tchofo et al, 2009). A majority of cases are subsumed under the classical lissencephaly/subcortical band heterotopia spectrum (previously type 1). There are currently five genes that cause or contribute to lissencephaly in humans (Kato and Dobyns, 2003). Three genes, *LIS1*, *DCX*, and *TUBA1A*, account for a majority of cases of classical lissencephaly (Kerjan and Gleeson, 2007a). Mutations of the LIS1 gene were first detected in the Miller-Dieker syndrome (severe lissencephaly and distinct craniofacial abnormalities) after identification of chromosome 17p13.3 deletions in over 90% of these patients (Ledbetter et al, 1992). This syndrome is always associated with a more severe lissencephaly phenotype, which appears to reflect the fact that the 17p deletion also contains the 14-3-3ε gene, which is also implicated in neuronal migration. Subsequent studies determined that sporadic cases of isolated lissencephaly were caused by LIS1 mutations, as well. LIS1 encodes a noncatalytic subunit of a ubiquitously expressed enzyme, platelet-activating factor acetylhydrolase. The mechanisms by which LIS1 mutations disrupt neuronal migration relate in part to its roles in cell motility as well

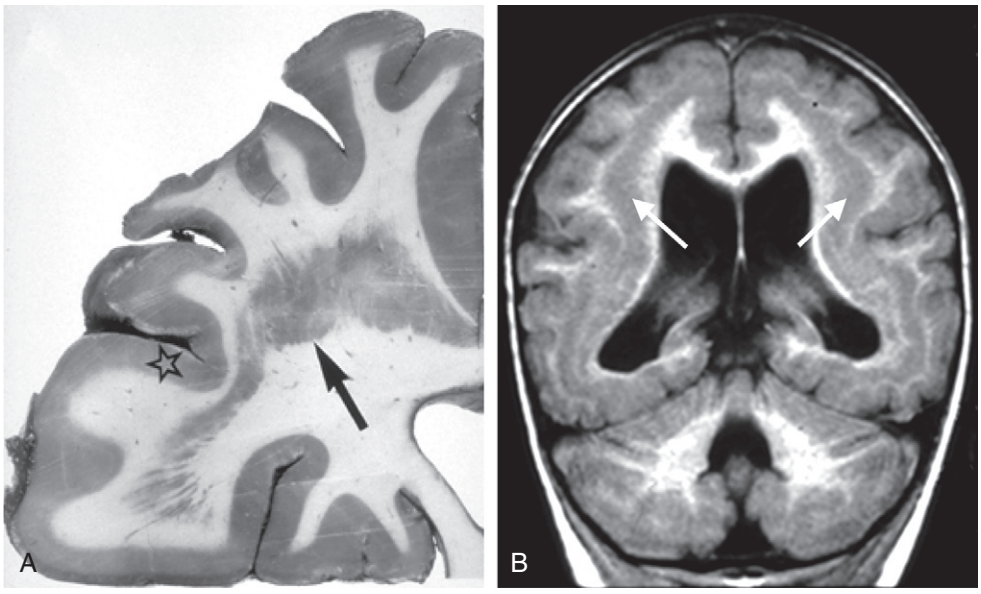

FIGURE 60-19 Subcortical band heterotopia in two female patients diagnosed with a DCX mutation. A, This histologic specimen demonstrates the presence of a broad band of heterotopic gray matter (*arrow*) that is situated within the cerebral white matter and distinct from the cerebral cortex (*star*). **B,** T1-weighted axial magnetic resonance image demonstrates the circumferential nature of the subcortical band heterotopia (*arrows*). *(Courtesy Dr. Joseph G. Gleeson, Department of Neurology, University of California, San Diego, School of Medicine; M. Elizabeth Ross, Department of Neurology, University of Minnesota; Christopher A. Walsh, Department of Neurology, University of Minnesota; and Christopher A. Walsh, Department of Neurology, Harvard Medical School.)*

as mitosis (neurogenesis). The DCX gene was first demonstrated to cause X-linked lissencephaly and subcortical band heterotopia. DCX encodes the doublecortin protein, which is a neuron-specific protein that functions in part in microtubule polymerization and may interact with LIS1 (des Portes et al, 1998; Gleeson et al, 1998). Mutations in the ARX gene result in another form of X-linked lissencephaly with abnormal genitalia and is further characterized by abnormal basal ganglia, often with small cysts, immature white matter, and agenesis of the corpus callosum (Kitamura et al, 2002). ARX is a homeobox gene specifically expressed in forebrain interneurons and the male gonads, where it directs differentiation of the testes. ARX functions in proliferation of neuronal progenitors and in differentiation and migration of interneurons. TUBA 1 encodes alpha-1a tubulin and appears to be the least common of the mutations associated with classical lissencephaly (Morris-Rosendahl et al, 2008). The spectrum of malformations associated with TUBA 1 mutations is broad and commonly includes congenital microcephaly, callosal dysgenesis, and cerebellar hypoplasia.

LIS1, DCX, and other proteins implicated in neuronal migration appear to interact via functionally complex signaling mechanisms to modulate alterations in cell shape at the level of the actin and microtubule-based cytoskeleton (Ross and Walsh, 2001). It is thus not surprising that LIS1 and DCX mutations are associated with considerable variation in the phenotypic expression of classical lissencephaly. Six distinct grades of morphologic severity have been defined that overlap among agyria, pachygyria, and subcortical band heterotopia (Kato and Dobyns, 2003). The most severe form (grade 1) is usually associated with either the Miller-Dieker syndrome or a severe mutation of DCX. Moreover, the gyral malformations associated with LIS1 mutations are more pronounced posteriorly than anteriorly, whereas the gradient of injury is reversed with DCX mutations. The picture is further complicated in X-linked dominant lissencephaly insofar as males and females typically display different phenotypes related to DCX mutations. Because of hemizygosity for DXC on the X chromosome, males often display severe lissencephaly that resembles that seen in LIS1 mutations. Because of lyonization (random X-inactivation), females, however, typically display the subcortical band heterotopia phenotype (Figure 60-19). However, when mosaicism for the aberrant DCX allele predominates, some DCX females can display severe lissencephaly.

Although predictions of genotype are not readily feasible based on the pattern of malformations present, *clinical features* more consistently correlate with the lesions present. Superior definition of malformations is achieved by MRI. In the newborn, the typical presentation of isolated lissencephaly is pronounced hypotonia accompanied by a lack of motor activity. Only later in the first year may spasticity develop. Depending on the nature of the LIS1 mutation on chromosome 17, craniofacial anomalies can be subtle (bitemporal hollowing and a small jaw) or the full expression of the Miller-Dieker syndrome (Dobyns et al, 1984). Head circumference is typically normal at birth, but progressive microcephaly occurs during the first year of life. Although neonatal seizures may occur, severe myoclonic epilepsy typically develops in the latter half of the first year (e.g., infantile spasms or Lennox-Gastaut syndrome) (Guerrini and Carrozzo, 2001). Isolated lissencephaly carries a poor long-term prognosis dominated by mental retardation, spastic quadriparesis, and epilepsy. The severity of clinical deficits is typically less for infants with focal pachygyria. Patients with subcortical band heterotopia are much less affected than those with isolated lissencephaly. Although they may develop seizures

and cognitive impairment, roughly 25% of patients have normal or near-normal intelligence. Neurologic deficits roughly correlate with the thickness and extent of the subcortical band (Dobyns et al, 1996).

Lissencephaly With Cerebellar Hypoplasia

This group encompasses six broad classes (a–f) of malformations that share a lissencephaly spectrum of agyria-pachygyria plus some degree of cerebellar hypoplasia (Barkovich et al, 2001; Jissendi-Tchofo et al, 2009; Kato and Dobyns, 2003; Ross et al, 2001). Individual classes are defined on the basis of additional defining malformations (e.g., brainstem hypoplasia, agenesis of the corpus callosum). The prototype for these disorders is LCHb, in which lissencephaly is accompanied by severe global cerebellar hypoplasia and a very malformed hippocampus. The lissencephaly is characterized by a moderately thick cortex that has an anterior greater than posterior gradient of severity. Several patients with LCHb have proven mutations in the *RELN* gene, which encodes reelin, a large extracellular matrix protein (Hong et al, 2000; Ross and Walsh, 2001). This is notable, because the mouse homologue of the *RELN* gene was shown to account for the phenotype of the reeler mouse, a severely ataxic mutant mouse strain in which the cerebral and cerebellar cortex display an inversion of the normal mammalian "inside-out" laminar organization pattern (Rakic and Caviness, 1995). A role for reelin in neuronal migration is supported by the observation that it is secreted by the Cajal-Retzius cells of the embryonic preplate as well as cerebellar external granule cell layer neurons and pioneering cells of the hippocampus. The distribution pattern of reelin is, thus, consistent with the pattern of malformations seen in LCHb. Functionally, reelin activates a signal transduction pathway via two distinct membrane-associated lipoproteins, the apolipoprotein E2 and the very low-density lipoprotein receptors. These receptors direct the phosphorylation of mDab1, which, on activation, participates in actin polymerization, an integral event in cell migration (Kerjan and Gleeson, 2007b). Of interest, abnormalities very similar to the reeler mouse are observed in mutant mouse strains with disruptions of mDab1 or both lipoprotein receptors.

Cobblestone Complex Syndromes

The cobblestone complex syndromes are included here because they all involve abnormal neuronal migration and were previously classified with type II lissencephaly (Barkovich et al, 2001). Three congenital muscular dystrophy syndromes are represented: Walker-Warburg syndrome, muscle-eye-brain disease, and Fukuyama congenital muscular dystrophy (FCMD). The isolated cobblestone complex malformation without retinal or muscle involvement is rare. The neuronal migration anomaly in the cobblestone complex arises because of failure of early migrating neurons to arrest at the marginal zone (the future layer 1 of the cerebral cortex). Rather, these heterotopic neurons migrate farther through a defective glial limiting membrane into the leptomeninges, which thicken and adhere to the cortical surface—hence the term *cobblestone lissencephaly*. These collections of leptomeningeal neurons can be sufficiently large to obliterate the subarachnoid spaces, with resultant communicating hydrocephalus related to disruption of CSF resorption. The organization of the cerebral cortex is markedly more abnormal than in classical lissencephaly and is characterized by large ectopic clusters of neurons with no discernible lamination pattern.

Walker-Warburg syndrome is the most severe of the three cobblestone complex congenital muscular dystrophy syndromes (Warburg, 1987). Several clinical features distinguish it from those seen with classical lissencephaly. Macrocephaly is commonly present at birth or develops in the 1st year of life. The macrocephaly is typically related to communicating hydrocephalus as well as dilation of the third and fourth ventricles when a retrocerebellar cyst is present (see later discussion). In addition to lissencephaly, cerebellar/hindbrain and oculoretinal malformations and congenital muscular dystrophy are also universal and required for the diagnosis. Cerebellar malformations were discussed earlier, in the context of the DWM, and include midline cerebellar hypoplasia and retrocerebellar cyst. Protrusions of the latter through a skull defect can result in a posterior encephalocele. Ocular anomalies include retinal detachment, optic nerve hypoplasia, microphthalmia, and colobomas. The muscular weakness is typically severe and is associated with elevated serum creatine kinase. The prognosis for survival beyond the 1st year is poor. This complex constellation of features may be recalled by the eponym CHARM ± E (*c*erebellar, *h*ydrocephalus, *a*gyria, *r*etinal, *m*uscle, *e*ncephalocele) (Volpe, 2000).

The spectrum of brain malformations in muscle-eye-brain disease is generally less severe than in Walker-Warburg syndrome. These include milder lissencephaly with frontal pachygyria and less severe occipital gyral dysplasia. Midline cerebellar hypoplasia is more variable, and the retrocerebellar cyst and encephalocele are not seen. Ocular abnormalities include retinal and optic nerve hypoplasia, cataracts and glaucoma. The cobblestone complex malformations are generally least severe in FCMD, and the eye abnormalities are minor or do not occur (Fukuyama et al, 1984). However, the cortical dysplasia in FCMD is sufficiently severe to produce severe mental retardation in at least half of patients. Hence, it can be difficult clinically to distinguish between patients with severe FCMD and those with mild Walker-Warburg syndrome.

Despite overlap in their clinical features, current data support that the cobblestone complex muscular dystrophy syndromes are genetically distinct autosomal recessive disorders (Cormand et al, 2001). These disorders belong to a new class of glycosylation-deficient muscular dystrophies, the dystroglycanopathies that are related to mutations in enzymes that catalyze the post-translational *O*-glycosylation of a small number of mammalian glycoproteins (Grewal and Hewitt, 2003; Toda et al, 2005). Mutations have been described in at least six different genes (Clement et al, 2008). Point mutations in *POMT1*, encoding a putative *O*-mannosyltransferase, account for approximately 20% cases of Walker-Warburg syndrome, which displays reduced glycosylation of alpha-dystroglycan (Beltran-Valero de Barnabe et al, 2002). The defect in muscle-eye-brain disease is *POMGnT1*, the

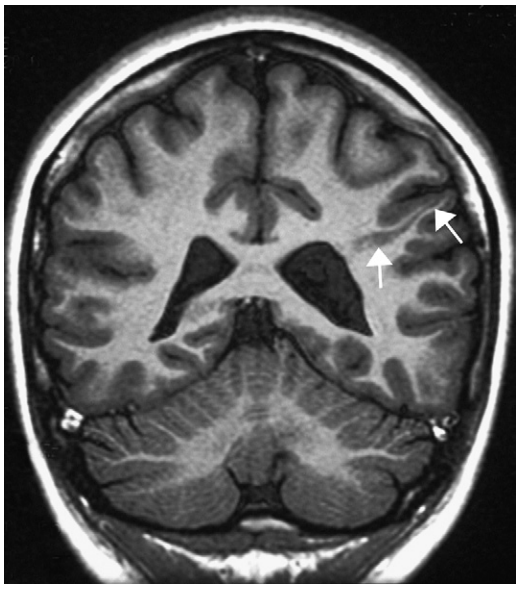

FIGURE 60-21 Magnetic resonance image scan, subcortical white matter heterotopia. This T1-weighted coronal image shows a diffuse stream of heterotopic gray matter (*arrows*) that spans from near the ventricular surface to the cerebral cortex. The appearance of this focal disturbance of neuronal migration suggests that the neurons were "hung up" in their migration from the ventricular surface to the cerebral cortex. *(Courtesy Dr. Martin Salinsky, Department of Neurology, Oregon Health and Science University.)*

gene for a definitive mannosyltransferase, *O*-linked mannose β1,2-*N*-acetylglucosaminyltransferase 1 (Taniguchi et al, 2003). The defect in FCMD resides in the protein fukutin (Kobayashi et al, 2000), a putative phospholigand transferase that shares homology with microbial proteins involved in mannosyl phosphorylation. Hence, the overlapping clinical phenotypes for the three cobblestone complex muscular dystrophies appear to be related in part to defects in a common glycosylation pathway that involves *O*-mannosylation of proteins.

Neuronal Heterotopia

Heterotopias are displaced collections of neurons that have failed to complete their normal migration from the ventricular zone. They are most commonly observed in periventricular white matter, where they comprise nodular collections of cells ("periventricular nodular heterotopia") (Figure 60-20), or in the subcortical white matter, where they may be nodular or diffuse (Figure 60-21). Heterotopias are, in fact, a feature of virtually all of the migrational disorders. In addition, they are often the primary migrational disturbance associated with a wide range of disorders. These include metabolic disorders; fetal toxic exposures; and neurocutaneous, multiple congenital, and chromosomal syndromes (Volpe, 2000). Hence, the clinical significance of heterotopic neurons in these conditions may be as an overt sign of a more serious underlying neurologic condition.

As isolated disorders, the heterotopias are clinically and pathologically less severe than the subcortical band heterotopias, separate disorders that are variously expressed in the spectrum of classic lissencephaly, discussed earlier. The isolated heterotopias are classified with regard to a primary periventricular (subependymal), subcortical white matter, or marginal (superficial cortical/leptomeningeal) site of pathology (Barkovich et al, 2001). Typically, superficial cortical neuronal heterotopias are an incidental finding at autopsy. However, glial-neuronal heterotopias that infiltrate the leptomeninges occur in association with fetal exposure to teratogens such as methylmercury (Choi et al, 1978) or as seen in the fetal alcohol syndrome (Norman et al, 1995b).

The nodules are composed of highly differentiated neurons that can form complex networks and elaborate dense synaptic terminals (Eksioglu et al, 1996). Epileptic discharges have been recorded from the nodules, and it is felt that the seizures that occur in patients with heterotopias originate from the nodules themselves (Li et al, 1997).

Two genes have been identified that cause periventricular heterotopia. The most well-characterized isolated heterotopia syndrome is the bilateral periventricular nodular heterotopia syndrome (Ross and Walsh, 2001), which is caused by mutations in filamin A (FLNA). This is inherited as an X-linked dominant disorder that therefore occurs in females and usually is embryonic lethal in males. FLNA is an actin cross-linking phosphoprotein that appears to function in the actin remodeling required for cell migration out of the ventricular zone (Fox et al, 1998). The usual phenotype of FLNA mutations is a female with seizures and/or psychiatric difficulty with normal or near-normal intelligence. Patients may also have specific difficulty with dyslexia (Chang et al, 2005). There is a suggestion that FLN A mutations may also result in cardiovascular abnormalities, because there have been case reports of individuals with strokes at early ages, aneurysms, and early death (Fox et al, 1998).

Periventricular heterotopia has also been linked to mutations in ARFGEF2 (adenosine diphosphate–ribosylation factor guanine exchange factor 2) (Sheen et al, 2004).

This gene is located on chromosome 20 and inherited in an autosomal recessive fashion. Heterozygous parents are asymptomatic; homozygous offspring have heterotopias, microcephaly, and severe developmental delay. Abnormalities in this gene have thus far been identified only in two consanguineous families. The ARFGEF2 protein (BIG2) regulates vesicular transport. It is hypothesized that BIG2 may affect the vesicle trafficking of adhesion molecules that are required for the movement of neurons from the ventricular zone (Pacheco-Rodriguez et al, 2002; Sheen et al, 2004).

Periventricular heterotopia has also been associated with duplications of 5p, although no specific gene has so far been identified (Sheen et al, 2003). Of all cases of familial periventricular heterotopia, 80% have *FLNA* mutations. Only 20% of sporadic cases have *FLNA* mutations, indicating the importance of environmental influences, or genetic causes not yet identified (Lu and Sheen, 2005).

SUMMARY

Advances in human genetics have led to continued rapid progress toward improved understanding of the cellular and molecular pathogenesis of human brain malformations. These advances are providing a more rational means to approach both prenatal and postnatal diagnosis, which is increasingly allowing for a more realistic assessment of prognosis. Although therapy for brain malformations is still largely focused on treatment of adverse symptoms and sequelae, recent experimental studies suggest that the migration of some populations of neurons may not be permanently arrested. For example, in a rat model of subcortical band heterotopia, some neuronal migration abnormalities were reduced when the doublecortin gene was reexpressed in neurons during a postnatal window during which they were still receptive to reinitiation of migration. This led to diminution of seizures (Manent et al, 2009). Such studies underscore the critical need for ongoing basic research in developmental neurobiology to accelerate progress toward both better diagnosis and treatment of these devastating disorders.

CHAPTER 61

Central Nervous System Injury and Neuroprotection

Sonia L. Bonifacio, Fernando Gonzalez, and Donna M. Ferriero

INJURY AND PROTECTION IN THE DEVELOPING NERVOUS SYSTEM

Injury to the developing brain from a variety of factors (hypoxia-ischemia, infections, inflammation) results in predictable pathologic patterns based on age at the time of insult, and the severity of the insult. This is due to the selective vulnerability of populations of cells undergoing active metabolic change during these time periods. The most common type of injury in the preterm brain is intraventricular hemorrhage (IVH) from germinal matrix bleeding, and white matter injury due to hypoxia-ischemia and infections. In the term brain, the deep gray matter is more likely to be affected by a severe insult. A variety of patterns of cortical and subcortical parenchymal injuries can be seen, depending on how blood flow or metabolism is disrupted. Perinatal arterial ischemic stroke, sinovenous thrombosis and perinatal hemorrhagic stroke occur in both preterm and term newborns. A number of traumatic injuries also can occur in the neonatal period, including damage to the calvaria, cranial nerves, spinal cord, and peripheral nerves. The ability to protect against the adverse sequelae of these varied types of injuries will depend on the timing of injury accurate diagnosis, careful early management, and the development of age-appropriate therapies. New therapies for brain injury in newborns, such as hypothermia for term neonatal encephalopathy, are being implemented, and adjunctive therapies continue to be studied in animal models.

INTRAVENTRICULAR AND PERIVENTRICULAR HEMORRHAGE IN THE PRETERM INFANT

Pathogenesis

IVH is a common injury in the preterm brain, originating in the subependymal germinal matrix. Cortical neuronal and glial cell precursors develop from the germinal matrix and adjacent ventricular germinal zone during the late second and early third trimesters. The subependymal germinal matrix is a highly vascularized region whose arterial supply is derived from the anterior and middle cerebral arteries as well as the anterior choroidal artery. These arteries feed an elaborate capillary network of thin-walled vessels that is continuous with a deep venous system that terminates in the vein of Galen. The terminal, choroidal, and thalamostriate veins course anteriorly to form the internal cerebral vein, which courses posteriorly to join the vein of Galen, thus leading to a U-shaped turn in the direction of blood flow. Involution of the germinal matrix occurs with advancing gestation.

The predisposition of the premature infant to IVH is due to several factors. A pressure-passive state exists due to the lack of autoregulation of cerebral blood flow in the cerebral arterioles in the premature brain. In the presence of a highly vascularized subependymal germinal matrix, the lack of a supporting basement membrane in the blood vessels of the germinal matrix and an increased amount of fibrinolytic activity in the germinal matrix region also predispose to the development of IVH. Extravascular tissue pressure decreases in the first few days of extrauterine life, and in the setting of elevation of venous pressure or an increase in fluctuations in cerebral blood flow velocity from a variety of factors (respiratory distress, pneumothorax, asphyxia, myocardial failure, patent ductus arteriosus, hypotension, hypothermia, hyperosmolarity), IVH may occur (Ment and Schneider, 1993). Fluctuating pressure passivity is common in premature infants and may be associated with IVH (O'Leary et al, 2009; Soul et al, 2007).

IVH has been produced experimentally after hypotension followed by reperfusion (Goddard-Finegold et al, 1982; Ment et al, 1982). These studies support the observation that infants with IVH are more likely to have had an early period of prolonged hypotension followed by an increase in blood pressure (Miall-Allen and Whitelaw, 1987; Miall-Allen et al, 1987). Isolated hypertension associated with seizures, intubation, and suctioning also predispose the brain to IVH. Even gavage feeding and surfactant administration can lead to changes in cerebral hemodynamics as measured by near-infrared spectroscopy (NIRS) that may result in IVH (Baserga et al, 2003; Kaiser et al, 2004; Roll et al, 2000).

Box 61-1 lists the different factors that may interact in an individual case to produce IVH.

Cellular injury in infants with grade III or IV (PVHI) IVH may occur from ischemic injury that may precede the bleed, from a decrease in cerebral blood flow, or from increased intracranial pressure, as well as vasospasm. Posthemorrhagic hydrocephalus is a common sequela of periventricular venous infarction (grade IV). These severe IVH grades are associated with periventricular white matter injury and sometimes pontine neuronal necrosis (Volpe, 2008). In this setting, venous infarction leads to neuronal as well as oligodendroglial cell death (Craig et al, 2003).

Site, Incidence, and Timing of Hemorrhage

In preterm infants, germinal matrix hemorrhage is most commonly seen at the junction of the terminal, choroidal, and thalamostriate veins in the germinal matrix over the body of the caudate nucleus at the level of the foramen of Monro. Parenchymal hemorrhage occurs most commonly

Coagulation disturbances
Increased fibrinolysis

in the frontoparietal region, in approximately 15% of cases, and is thought not to be an extension of the IVH but rather, a separate process—a hemorrhagic infarction. The hemorrhage is more often unilateral or, in less than 30% of cases, asymmetrically bilateral.

The incidence and severity of IVH increase with decreasing gestation. It occurs in approximately 4.6% of term newborns and was previously reported to occur in 40% to 60% of very low-birthweight (VLBW) infants (less than 1500 g birthweight). An overall reduction of IVH in this population to 15% to 25% has been observed in the past two decades (McCrea and Ment, 2008; Paneth et al, 1993; Vohr et al, 2000). Although there has been a gradual decline in the incidence of all grades of IVH, the increased survival of VLBW infants has resulted in an increase in the absolute number of infants with IVH. The risk period for the occurrence of IVH is highest in the first 3 or 4 days of life. Hemorrhage is rarely seen at birth, although it has been reported as early as within the 1st hour of age (Ment et al, 1984). Antenatal hemorrhages can occur, especially in the setting of neonatal alloimmune thrombocytopenia. Twenty-five percent of hemorrhages occur by the 6th hour and 50% of hemorrhages occur during the first 24 hours of life. Less than 5% of infants develop IVH after the 4th or 5th day of life (Ment and Schneider, 1993). Extension of the hemorrhage may occur over the first few days secondary to events leading to alterations in cerebral blood flow.

Clinical Presentation

The clinical presentation of IVH in the newborn depends on the extent of the hemorrhage and may vary from asymptomatic to a sudden and catastrophic deterioration that manifests with neurologic signs such as stupor or coma, seizures, decerebrate posturing, or apnea. A full fontanel along with a sudden drop in hematocrit, hyperglycemia, hyperkalemia, hypotension, and bradycardia all can herald an IVH. Inappropriate secretion of antidiuretic hormone may be present. The more common presentation, however, is that of a gradual clinical deterioration with an altered level of consciousness, hypotonia, abnormal extremity, or eye movements. In 25% to 50% of cases, clinical correlation is lacking (Dubowitz et al, 1998).

Grading of Intraventricular Hemorrhage

Ultrasound examination is a reliable and sensitive technique for evaluating the severity of IVH in the newborn nursery (Pape et al, 1983, 1979). Papile and associates

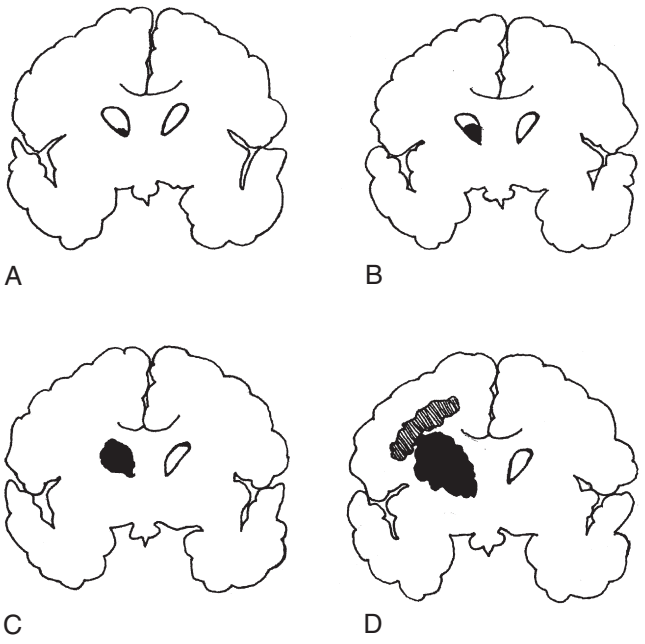

FIGURE 61-1 Illustration of intraventricular hemorrhage (IVH) grades as determined by degree of hemorrhage (see Table 61-1). **A,** Grade I hemorrhage involves less than 10% of the ventricular volume in the lateral ventricles; **B,** grade II hemorrhage involves 10% to 50%; **C,** grade III involves greater than 50% of the ventricular volume and is often associated with some ventricular dilatation; and **D,** grade IV (Papile et al, 1978) or unclassified (Volpe, 2009) is associated with parenchymal echodensities on head ultrasound study, indicating parenchymal infarction.

adapted the standard grading system originally applied to computed tomographic images of IVH to ultrasound images and classified IVH into four different grades of severity depending on the location and extent of the bleed (Papile et al, 1978) (Figure 61-1; Table 61-1). Outcome studies performed over the past two decades use this system for classification. In the preferred grading system used by Volpe (2008), the presence of intracerebral hemorrhage or parenchymal lesions is mentioned separately and not designated as grade IV. This system relies on the head ultrasound examination as the diagnostic measure and more accurately defines IVH based on the extent of the ventricular hemorrhage. Because parenchymal involvement is a distinct process, it is not included in the continuous grading (see Table 61-1). In VLBW infants, 10% to 15% suffer from the more severe hemorrhages (McCrea and Ment, 2008).

Outcome and Prognosis

Grade I hemorrhage and grade II hemorrhage generally are followed by resolution. Grade III hemorrhage evolves over a period of 1 to 3 weeks and in some cases produces a fibrotic reaction that obliterates the subarachnoid space and leads to ventricular dilatation and hydrocephalus. Traditional clinical criteria of increasing ventricular dilatation such as rapid head growth, full anterior fontanel, and separated cranial sutures often appear days or even weeks after the dilatation begins. This delayed appearance is due to the presence of a large subarachnoid space as well as the paucity of myelin in premature infants. In 15% of cases

TABLE 61-1 Grading of Intraventricular Hemorrhage (IVH) by Cranial Ultrasound Findings

Papile Grading System		Volpe Grading System*	
I	Subependymal hemorrhage with minimal or no IVH	I	Germinal matrix hemorrhage <10% IVH
II	Definite IVH without distention of the ventricles	II	IVH 10% to 50%
III	Enlargement of the ventricles secondary to distention with blood	III	IVH >50%, usually with distention of lateral ventricle
IV	Extension of the hemorrhage into the parenchyma along with IVH and enlargement	Separate notation	Periventricular echodensity signifying parenchymal lesion

IVH, Intraventricular hemorrhage.
*By cranial ultrasound.

of IVH, areas of periventricular hemorrhagic involvement are noted (Volpe, 2008). This finding is believed to be due to an independent venous infarct of the periventricular white matter and not a direct extension of the IVH into the parenchyma (Volpe, 2008). Intraparenchymal hemorrhage is followed in 1 to 8 weeks by tissue destruction and formation of a porencephalic cyst. Outcomes vary between studies, but in general, mortality rates are not significantly increased in infants with a grade I or II hemorrhage. Grades III and IV are associated with increased mortality, with mortality rates in neonates suffering hemorrhagic infarction approaching 50% (Brouwer et al, 2008; Sarkar et al, 2009).

Several studies have focused on the relationship between IVH and subsequent neurologic dysfunction. Although grade I and grade II IVH are not associated with significant morbidity, grade III is associated with neurologic sequelae in up to 35% of infants, and grade IV is associated with sequelae in as many as 55% of affected infants (Brouwer et al, 2008). The severity of neurologic sequelae such as seizures, severe motor handicap, and severe hearing and vision impairment increases in infants with grade III or IV hemorrhage in whom persistent ventriculomegaly develops. The presence of hydrocephalus with or without shunting at term increases the odds of a poor neurodevelopmental outcome. Vohr et al (2000), in a longitudinal study of 90 preterm infants with birthweights of less than 1750 g, reported that by 2 years of age, only infants with grade III and grade IV differed in neurologic examination findings from the term control infants. Unlike motor function, cognitive function as assessed by the Bayley scores deteriorates in the first 18 months of life. Infants with grade I and grade II IVH have lower scores than those infants with no IVH or normal term infants. In another study of extremely low-birth weight (ELBW) infants (weight <1000 g at birth), those with grade I or II hemorrhage had an increased risk for major neurodevelopmental impairment (odds ratio [OR] 1.83, 95% confidence interval [CI] 1.11 to 30.03, p <0.05) when compared with those with normal cranial ultrasounds findings (Patra et al, 2006). This increased risk of abnormal outcome may be related to underrecognized white and gray matter injury (Inder et al, 1999b). Follow-up studies have shown that the degree of IVH at birth and the presence of ventriculomegaly are predictors of neurologic status at 24 months' corrected age (Brouwer et al, 2008).

Prevention

Prevention of preterm birth is the most effective method of reducing the incidence of IVH. In the event of preterm labor it is advisable that the infant be born at a center specializing in high-risk deliveries. The risk of IVH is higher in infants who are transported after birth. Adequate management of labor and delivery is essential. Studies of antenatal steroids have demonstrated decreased risk of IVH and cerebral palsy (Leviton et al, 1999). A recent trial of antenatal magnesium sulfate showed a reduction in cerebral palsy but no difference in the rates of IVH (Rouse et al, 2008). Appropriate resuscitation of the preterm infant and vigilance in avoiding hyperventilation and low Pco_2 or hypoxia, maintaining adequate mean arterial pressure, and avoiding elevations in cerebral blood flow by excessive handling or tracheal suctioning are vital. Prevention of pneumothorax and acidosis and avoidance of rapid infusions of sodium bicarbonate or volume expanders also are critical. Because of the increased risk of neurodevelopmental sequelae in infants with IVH, several clinical trials have studied the effects of various pharmacologic interventions to reduce the incidence of IVH. Several clinical trials have been done to evaluate the role of prolonged neuromuscular paralysis in preterm infants. A metaanalysis of five trials concluded that although neuromuscular paralysis with pancuronium may help decrease IVH and pneumothorax in asynchronously breathing infants, its routine use cannot be recommended because of concerns about safety and long-term pulmonary and neurologic effects (Cools and Offringa, 2000).

A low mean arterial blood pressure (MAP) and an increase in fluctuation of blood pressure have been associated with an increased risk of IVH. Close monitoring of the MAP is recommended; however, there is no evidence suggesting that pharmacologic manipulation of the MAP (e.g., with pressors, steroids, or volume expanders) to achieve a set goal (e.g., MAP >30 mm Hg) alters the incidence of IVH or improves neonatal outcome. Phenobarbital administration was shown in early studies to be beneficial by preventing fluctuations in blood pressure (Donn et al, 1981). Subsequently, the results of multicenter trial testing the effect of antenatal administration of phenobarbital (10 mg/kg) to 110 women on the frequency of IVH in infants between 24 and 33 weeks of age showed no decrease in IVH in infants born to mothers treated with phenobarbital (Kaempf et al, 1990). A larger trial confirmed these findings, and long-term follow-up at 18 to 22 months of these infants found no difference in neurodevelopment (Shankaran et al, 1997, 2002). A metaanalysis of 10 trials of postnatal phenobarbital showed no difference in the rates of severe IVH or ventriculomegaly. Therefore, postnatal administration of phenobarbital for reduction of IVH is not recommended (Whitelaw and Odd, 2007).

Pharmacologic doses of vitamin E, an antioxidant, have been associated with a reduction in the incidence of IVH in LBW infants when given intramuscularly (Speer et al, 1984). However, after reports of the association of such large doses of vitamin E with sepsis and necrotizing enterocolitis, its use for prevention of IVH was curtailed (Finer et al, 1984; Johnson et al, 1985). There has been little reported in the literature since these studies.

Indomethacin, a prostaglandin synthetase inhibitor, had originally been shown to decrease the incidence of IVH in infants weighing less than 1250 g (Ment et al, 1985). A recent study on the long-term effects of indomethacin prophylaxis in ELBW infants showed no improvement in the rate of survival without neurosensory impairment at 18 months, despite the reduction in severe IVH (Schmidt et al, 2001). A metaanalysis of 19 trials and 2872 infants found an increased risk of oliguria that was, however, not associated with major renal impairment; no difference in the incidence of necrotizing enterocolitis; a modest reduction in the number of infants with severe IVH; but no difference in long-term neurosensory impairments (Fowlie and Davis, 2002).

Use of antenatal steroids (Canterino et al, 2001; Elimian et al, 2000; Smith et al, 2000) and surfactant replacement therapy have been shown to decrease the incidence of IVH as well as neonatal mortality in LBW infants (Soll and Dargaville, 2000). The increase in IVH reported with surfactant administration may occur as a result of the mode of instillation (Cowan et al, 1991; Hellstrom-Westas et al, 1991, 1992) and the drop in $Paco_2$ with improved ventilation. A significant drop in MAP and cerebral blood flow volume can occur during surfactant administration; attention should be paid to the speed and volume of instillation.

Several studies have been done to evaluate the early use of high-frequency ventilation versus conventional ventilation for infants with respiratory distress syndrome. One of these studies have shown an increased incidence of IVH with high-frequency oscillatory ventilation (HFOV) (HIFI Study Group, 1989, Moriette et al, 2001), whereas another study of jet ventilation did not find an increase in IVH (Keszler et al, 1997). Overall there is no evidence of decreased or increased risk of severe IVH in those treated with high-frequency versus conventional ventilation.

It is important to avoid both hypocarbia (Pco_2 <30 mm Hg) or hypercarbia (Pco_2 >55 mm Hg) because of their significant effects on cerebral blood flow. Hypocarbia is associated with hypotension as well as an acute decrease in cerebral blood flow. Avoiding low Pco_2 has been shown to be neuroprotective in animal studies (Sola et al, 1983; Vannucci et al, 1995). Although the effect of low Pco_2 levels has not been systematically studied in preterm infants, low levels have been shown to be deleterious in term infants with pulmonary hypertension (Ferrara et al, 1984). Hypercarbia leads to increases in cerebral blood flow, which in the presence of other therapies aimed at increasing blood pressure, may be damaging to the central nervous system (CNS).

Free radicals and iron have been shown to be damaging to oligodendrocytes in both cell culture and animal studies (Back et al, 1998; Dommergues et al, 1998). Also, iron-chelating agents such as deferoxamine have been shown to be neuroprotective in animal models (Sarco et al, 2000). It may be wise to prevent iron overload during the period of critical cortical development (Gressens et al, 2002). Similarly, avoiding hyperoxia is important to prevent free radical injury.

Several of the medications that are used frequently in LBW infants may have effects on neurodevelopment. Caffeine therapy for apnea in VLBW infants has been shown in a randomized controlled trial to reduce the incidence of cerebral palsy and neurodevelopmental delay at 18 to 21 months of age (Schmidt et al, 2007). Postnatal steroid use in preterm infants has been found to be associated with an increased risk of periventricular leukomalocia (PVL) and poor neurodevelopment (Merz et al, 1999; Murphy et al, 2001). Pain medications such as morphine, fentanyl, and midazolam are often used for analgesia in ventilated preterm infants. However, there is increasing concern regarding the potential detrimental effects of this practice on the developing brain. Recently, Simons et al (2003) found that routine morphine infusion in ventilated preterm newborns had no measurable analgesic effect and no beneficial effect on neurodevelopment. More controlled studies are needed comparing the efficacy and safety of different analgesic practices in the preterm population.

Management

Infants with birthweights of less than 1500 g or gestational age of less than 32 weeks should have a screening ultrasound performed to detect IVH. A scan on the 4th postnatal day detects 90% of lesions. Because extension of the bleed sometimes occurs over the next few days, a repeat ultrasound examination after 5 days is necessary to establish the extent of the bleed.

The decision to continue intensive care support depends on the severity of the bleed as assessed by head ultrasound examination as well as the infant's gestational age and clinical condition. Parents should be informed regarding the presence of IVH and the prognosis of the infant.

Acute management is mainly supportive and requires control of ventilation, maintenance of a normal metabolic status and optimal nutritional state, and detection and treatment of seizures. Systemic blood pressure should be maintained with cautious attention to the rate of administration of fluid. Consideration of the aforementioned risk factors is important to prevent ischemia.

Of the infants in whom enlargement of the ventricles occurs, approximately 50% develop rapidly progressive ventricular dilatation over the next 4 to 8 weeks. Regular measurement of head circumference and examination of the fontanel and clinical status are recommended in the first 4 weeks in cases of slowly progressive hydrocephalus. Serial lumbar puncture or use of carbonic anhydrase inhibitors has been recommended by some clinicians. A randomized controlled trial of the combined use of furosemide and acetazolamide in 177 infants with posthemorrhagic hydrocephalus concluded that this treatment is ineffective in decreasing the need for shunt placement and is associated with increased risk of a poor neurologic outcome (Kennedy et al, 2001). Use of streptokinase immediately after an IVH with development of posthemorrhagic hydrocephalus has been advocated by some to be beneficial. The studies to date have been too small to allow

reasonable conclusions (Haines and Lapointe, 1999; Luciano et al, 1998, Whitelaw, 2001). One randomized multicenter trial of drainage, irrigation, and fibrinolytic therapy compared with tapping of excess cerebral spinal fluid to prevent shunt dependence showed no benefit (Whitelaw et al, 2007).

In infants with rapidly progressive hydrocephalus that does not respond to serial lumbar punctures, placement of an external ventriculostomy is necessary as a temporizing measure. Placement of a ventriculoperitoneal shunt that diverts cerebrospinal fluid (CSF) from the lateral ventricles to the peritoneal cavity in a premature infant is problematic because of the risk of skin breakdown, shunt obstruction, and/or infection. However, some centers are placing subgaleal shunts as a temporizing measure in these infants; these shunts may be associated with significantly fewer complications (Fulmer et al, 2000).

WHITE MATTER INJURY

In the premature newborn, white matter injury (WMI) consists of discrete (focal) areas of magnetic resonance (MR) signal abnormality. With the increasing use of MR imaging (MRI) in the clinical assessment of brain injury in the premature newborn, "focal non-cystic white matter injury" is recognized as the most common pattern of brain injury in this population (Cornette et al, 2002; Miller et al, 2005a). On conventional MRI, focal noncystic WMI appears as areas of hyperintensity on T1-weighted MR images (Figure 61-2). This type of WMI is distinct from cystic PVL, a more severe abnormality that refers specifically to cystic regions of necrosis in the periventricular white matter that are well detected by brain ultrasound (Volpe, 2009). However, most children who exhibit deficits in motor and cognitive outcomes do not have sonographically-identified PVL (Aziz et al, 1995; Hamrick et al, 2004). As focal non-cystic WMI is observed in half of premature newborns on MRI, this type of white matter injury has been under-recognized (Miller et al, 2003, 2005a).

Premature newborns may have diffuse impairments in the progression and rate of brain development. These acquired developmental brain abnormalities may be even more common than the focal "injuries" identified on MRI and are not limited to the white matter. When severe, these diffuse abnormalities are apparent on MRI by a paucity of white matter, ventriculomegaly, impaired gyral development, or enlarged subarachnoid spaces (Inder et al, 2003). However, most premature newborns do not have these dramatic abnormalities, and up to 20% with adverse outcomes do not have significant qualitative abnormalities on MRI (Boardman et al, 2007; Miller et al, 2005a). One possibility is that the brain is imaged at a time when signal abnormalities have been replaced by tissue loss that is not as easily detected on qualitative MRI.

Clinical Factors Important for White Matter Injury

There is now evidence that the risk of brain injury and abnormal brain development is altered by systemic illness and by critical care therapies. For example, the severity of chronic lung disease predicts cognitive outcome at 8 years of age, even after controlling for birthweight and neurological complications (Short et al, 2003). Postnatal infection in preterm newborns is also associated with impaired neurodevelopmental outcomes (Stoll et al, 2004). Recurrent postnatal infection is an important risk for progressive WMI (Glass et al, 2008). Recent observations suggest that motor impairments seen more commonly in preterm infants with sepsis are mediated by white matter abnormalities (Shah et al, 2008). However, other studies suggest that both postnatal infection and WMI are *independently* associated with adverse neurodevelopmental outcomes (Miller et al, 2005a). In regard to critical care therapies, postnatal exposure to corticosteroids for the prevention and treatment of chronic lung disease may impair brain growth, though this effect may be limited to treatment with dexamethasone (Lodygensky et al, 2005; Murphy et al, 2001). A dramatic decline in the incidence of cystic PVL may be related to a decrease in days of mechanical ventilation (Hamrick et al, 2004), possibly by avoiding hypocarbic alkalosis (Fujimoto et al, 1994). In an observational study, less WMI was seen in premature newborns exposed to prolonged indomethacin therapy for patent ductus arteriosus (Miller et al, 2006). Clinical features of

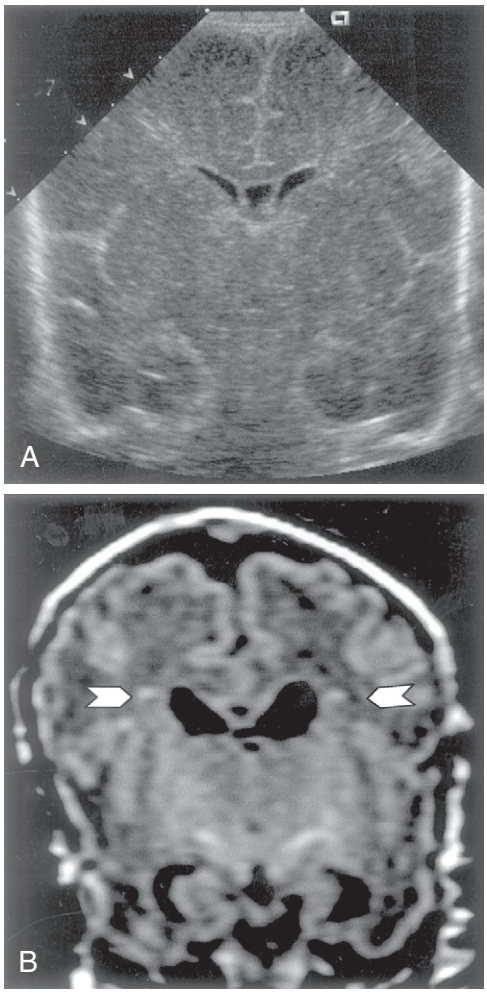

FIGURE 61-2 **A,** Head ultrasound image with no evidence of periventricular leukomalacia. **B,** Abnormalities are well seen on T1-weighted magnetic resonance image (*arrows*) in the same patient.

WMI in the premature infant may involve impairment of gaze and hearing, weakness, or altered muscle tone. Long-term problems may include spastic diplegia and visual and auditory impairment.

Pathogenesis of White Matter Injury

Important work regarding the pathogenesis of WMI has been performed in the last decade. It appears that the late oligodendrocyte progenitors that populate human cerebral white matter during the high-risk period for white matter injury are the major target of ischemic, free radical, or cytokine injury (Back et al, 2001, 2002, 2007). However, recent studies show that injury may be due to lack of oligodendrocyte maturation, resulting in decreased myelination and subsequent axonal injury (Segovia et al, 2008). Some data suggest vulnerability of the subplate neurons as well (McQuillen et al, 2003). Tissue damage is associated with proliferation of astrocytes and microglial cells in areas of subcortical degeneration. Increasingly, injury to the developing gray matter is also being identified in the setting of white matter injury and is recognized both in neuropathologic studies and with advanced imaging techniques (Inder et al, 2005; Pierson et al, 2007). The mechanisms of neuronal injury are likely to be similar to those causing injury of the white matter and the preoligodendrocytes.

IMAGING FOR DIAGNOSIS OF INTRAVENTRICULAR HEMORRHAGE AND WHITE MATTER INJURY

A practice parameter published jointly by the American Academy of Pediatrics, the American Society of Pediatric Neuroradiology, and the Society for Pediatric Radiology recommends routine screening with cranial ultrasonography for all infants of less than 30 weeks' gestation between 7 and 14 days of age. A repeat ultrasound examination is recommended between 36 and 40 weeks of postmenstrual age (Ment et al, 2002c). However, considerable advances in the field of MRI in premature infants have been made recently (Miller et al, 2002). Several studies have focused on determining the spectrum of white matter injury detected by MRI and its effect on neurodevelopment (Groenendaal et al, 1997; Hüppi et al, 1998; Inder et al, 1999a; Maalouf et al, 2001, 1999; Ment et al, 2002; van Wezel-Meijler et al, 1998). Newer techniques such as diffusion tensor imaging (DTI) have been shown to be helpful in defining areas of the brain at risk for damage (Barkovich et al, 2001; Huppi and Inder, 2001). DTI can also be used to monitor normal development of pathways using the apparent diffusion coefficient and anisotropy in certain regions (Miller et al, 2002c). In a comparison of head ultrasound examination with MRI, MRI was more sensitive in identifying PVL (Rijn et al, 2001). Lesions on MRI also show a stronger correlation with school age outcome than lesions on ultrasound (Rademaker et al, 2005). It is now becoming clear that lesions that affect developmental outcome and that are not present on cranial ultrasound images can be detected by MRI (Miller et al, 2005a; Woodward et al, 2006). Given the foregoing studies, MRI should be considered in all ELBW infants at 36 to 40 weeks' postmenstrual age if clinical suspicion for parenchymal brain injury exists. As MRI technology continues to evolve and methods of obtaining scans in this patient population are also improving, including the development of MRI-compatible incubators and specialized neonatal head coils, we will continue to gain insight into injury patterns in the developing brain.

HYPOXIC-ISCHEMIC REPERFUSION INJURY IN THE NEWBORN

Perinatal hypoxic-ischemic reperfusion (HI-R) injury may result in neonatal hypoxic-ischemic encephalopathy (HIE), which is a significant cause of neonatal morbidity and mortality and can lead to severe long-term neurologic deficits. The incidence of HIE is approximately 6 in 1000 term infants, with the incidence of death or severe neurologic deficit being 1 in 1000 (Levene and Evans, 1985).

Etiology

Hypoxic-ischemic brain injury results when the decrease in cerebral perfusion is severe enough to overwhelm the ability of tissue to extract oxygen from the blood, thereby leading to a mismatch between cerebral blood flow and oxidative metabolism. Although the final pathways leading to cerebral brain death are remarkably similar regardless of the instigating event, the extent, location, and evolution of cell death probably are determined by the nature of the insult. The etiology of HIE is multifactorial. In a study of risk factors for neonatal encephalopathy, antepartum risk factors such as maternal hypotension, infertility treatment, and thyroid disease were present in 69% of cases; both antepartum and intrapartum risk factors were present in 24%; and a history of an intrapartum event such as maternal fever, difficult forceps delivery, breech extraction, cord prolapse, or abruptio placentae was present in 5% of cases (Badawi et al, 1998). Postnatal events such as severe respiratory distress or congenital heart disease, sepsis, and shock are responsible for fewer than 10% of cases of HIE.

Clinical Signs and Symptoms

The clinical signs and symptoms depend on the severity, timing, and duration of the insult. The infant's gestational age needs to be taken into consideration in the evaluation. Symptoms usually evolve over a period of 72 hours (Sarnat and Sarnat, 1976) (Table 61-2).

During the first 12 hours after birth, the signs and symptoms are secondary to cerebral hemisphere depression, although signs of brainstem involvement may be present. During this period, the infant is not easily arousable. This alteration in consciousness is attributed to the involvement of the cerebral hemispheres, the reticular activating system, or the thalamus. Periodic breathing with apnea or bradycardia is usually present. The infant has intact pupillary responses and may have spontaneous eye movements, depending on involvement of cranial nuclei 3, 4, and 6. Cerebral cortical or cerebellar cortical involvement may manifest as hypotonia with decreased movement or as jitteriness or seizure activity, which is seen in 50% of severely affected infants by 6 to 12 hours after birth. The Moro, grasp, and suck and swallow reflexes may be absent

TABLE 61-2 Clinical Staging of Hypoxic-Ischemic Encephalopathy

Factor	Stage 1	Stage 2	Stage 3
Level of consciousness	Alert	Lethargy	Coma
Muscle tone	Normal	Hypotonia	Flaccidity
Tendon reflexes	Normal/ increased	Increased	Depressed/ absent
Myoclonus	Present	Present	Absent
Complex reflexes			
Sucking	Active	Weak	Absent
Moro	Exaggerated	Incomplete	Absent
Grasping	Normal/ exaggerated	Exaggerated	Absent
Oculocephalic (doll's eyes)	Normal	Overreactive	Reduced/ absent

Data from Sarnat NB, Sarnat MS: Neonatal encephalopathy following distress, *Arch Neurol* 33:696-705, 1976.

or depressed. In cases of severe asphyxia, seizures may be seen within 2 to 3 hours following the insult. Seizure onset usually occurs within the first 24 hours of life. Seizure activity in a term infant can be multifocal or focal in nature. Subtle seizures may also manifest as ocular movements such as tonic horizontal deviation of the eyes or sustained eye opening or blinking; orolingual movements such as tongue or lip smacking or sucking, or rowing or bicycling movements of the extremities, or as recurrent apnea (Mizrahi and Kellaway, 1987). Electrographic seizures without clinical correlate may also be present, and therefore the newborn with moderate encephalopathy should be monitored for seizures in the form of a complete electroencephalogram (EEG) or amplitude-integrated electroencephalography (EEG) (aEEG). Brainstem release phenomena are common in severely asphyxiated newborns and may be misinterpreted as seizures.

During the 12- to 24-hour period after the injury, there is an apparent increase in the level of alertness, but this is not associated with other signs of improvement in neurologic function. This period is accompanied by seizures in 15% to 20% of infants, apneic episodes in 50%, and jitteriness as well as weakness in the proximal limbs in 35% to 50%. The Moro reflex is exaggerated, the infant's cry is shrill and monotonous, and the deep tendon reflexes are exaggerated.

After 24 to 72 hours, the infant's level of consciousness deteriorates. This is followed by respiratory arrest and signs of brainstem dysfunction such as loss of responsiveness to the doll's eyes maneuver, fixed and dilated pupils, and sometimes death. Infants who survive until 72 hours continue in stupor with disturbed suck, swallow, and gag reflexes; hypotonia; and weakness of the proximal limbs and especially facial and bulbar musculature.

Diagnosis

The diagnosis of HIE is made through a careful history, laboratory studies, and neurologic examination. Metabolic abnormalities, cerebral dysgenesis, and infection can mimic HIE. There is sometimes a history of intrauterine distress, as evidenced by abnormalities on the fetal heart tracing, passage of meconium, or a history of difficult labor or delivery with a decrease in placental or fetal blood flow. A history of a difficult resuscitation that includes the use of cardiopulmonary resuscitation, medications in the delivery room, and intubation and assisted ventilation at birth and low extended Apgar scores after 5 minutes of age are associated with HIE. Excessive jitteriness, seizures, apneic episodes, or abnormal cry are signs of injury.

The neurologic examination provides important information for prognosis. Laboratory tests can be helpful in diagnosing HIE. Metabolic complications such as hypoglycemia, hypocalcemia, hyponatremia, hypoxemia, and acidosis are frequently seen. Several other metabolic parameters such as serum brain-specific creatine kinase (BB fraction), serum hypoxanthine, and serum lactate also are elevated. Lumbar puncture should be performed if the history is not consistent with perinatal distress, to rule out conditions that may mimic HIE. Lumbar puncture should be used to measure cell count, protein and glucose levels, and ratio of lactate to pyruvate, as well as brain-specific creatine kinase. A CSF protein level above 150 mg/dL is considered abnormal. Urinary lactate-to-creatine ratios have been shown to be elevated in asphyxiated infants (Huang et al, 1999). Elevated urinary S100B protein may also serve as a marker of severe perinatal asphyxia (Gazzolo et al, 2004).

Changes on the EEG can be helpful in determining the severity of the insult. The initial change is a suppression of amplitude and frequency. This is followed after 24 hours by a periodic pattern that consists of periods of greater voltage suppression interspersed with bursts of sharp and slow waves. Subsequently, a "burst suppression" pattern with fewer bursts and more severe voltage depression is seen, followed by an isoelectric tracing. The EEG is helpful in supporting the diagnosis of HIE, and amplitude-integrated electroencephalography has been used in both animal and human studies as an aid to identify newborns moderately to severely compromised by hypoxic-ischemic injury (al Naqeeb et al, 1999; Toet et al, 1999). Both aEEG and conventional EEG are useful in monitoring the evolution of encephalopathy, in monitoring for seizures as there can be a high rate of electrographic seizures without clinical correlate, and in predicting outcome. EEG monitoring is critically important after administration of an antiseizure medication, such as phenobarbital, as there is a high likelihood of electroclinical dissociation (Biagioni et al, 1998).

Neuroimaging has become increasingly useful for the accurate diagnosis of HIE. Computed tomography (CT) often is not helpful in making a diagnosis because it is insensitive to changes in water content. Also, especially in the posterior fossa, injury can be obscured by bone artifact. CT is best used to determine the extent of bleeding in an emergency situation when MRI is not available.

MRI has proved to be a sensitive technique to determine injury in the term infant brain. Absence of signal in the posterior limb of the internal capsule is strongly associated with poor neurologic outcome (Rutherford et al, 1995). MRI performed as early as 4 days to as late as 2 to 3 weeks of life, dependent on the techniques used, can be highly

predictive of outcome at 18 months of age, even following hypothermia therapy (Barkovich et al, 2006; Miller et al, 2005b; Rutherford et al, 2010).

Ultrasonography is extremely useful for imaging the unstable patient if performed with high-resolution transducers (de Vries et al, 1997). Injury to the basal ganglia, periventricular echodensities, and presence of focal or multifocal ischemic parenchymal lesions suggest neurologic deficits. Ultrasound is insensitive to cortical damage; therefore, in term infants, ultrasound findings may underrepresent the extent of the lesion.

Proton magnetic resonance spectroscopy (MRS) also has been useful for depicting age-dependent changes in preterm infants and can be a powerful tool for diagnosing early damage in both preterm and term infants (Vigneron et al, 2001). MRS provides a quantitative in vivo measure of brain biochemistry. At long echo times, it can measure resonance intensities for *N*-acetyl aspartate (NAA), creatinine (Cr), phosphocreatine, choline (Cho), and lactate. The measure of NAA in reference to baseline Cr or Cho has provided a sensitive indicator of neuronal integrity, whereas lactate has indicated the presence of oxidative stress or ongoing injury. MRS is now being used more extensively to identify areas at risk in perinatal HIE (Holshouser et al, 2000).

NIRS is a noninvasive technique that holds promise in the future. It can be used at the bedside to provide information regarding cerebral oxygen delivery. However, this modality is not quantitative and is not available at many centers.

Patterns of Injury and Pathology

The mechanism of injury can be one of several types. Different patterns of injury may result, depending on the duration and severity of the insult.

Global hypoxia-ischemia develops when the oxygen requirements for cerebral metabolism are unable to be met by cerebral perfusion pressure, as is seen with a decrease in cerebral arterial pressure or an increase in cerebral venous pressure. Although the injury may be transient, it sets into motion a cascade of events that ultimately lead to neuronal death. The duration of the insult necessary to produce brain injury is inversely proportional to the gestational age of the fetus. The extent and location of the injury can be patchy bilaterally, or diffuse and involve the entire cortex. The latent period to neuronal cell death produced by a global insult can range from hours to days and is determined by a complex interaction among various vascular, cellular, and metabolic factors (see later). In some circumstances, lesions may involve the brainstem (*pontosubicular necrosis*) or the cerebellum. Infants with pontosubicular necrosis have impairment of the cranial nerve nuclei and will exhibit ptosis and facial diparesis.

Focal ischemia occurs when the arterial or venous blood supply to a region is compromised. The degree of injury is dependent on the collateral blood supply to this region. The injured region typically consists of a central dense region of ischemia that undergoes rapid cell death—the core—surrounded by a region of evolving cell injury—the *penumbra*. The cells in the penumbral region initially are sustained by anaerobic glycolysis. However, within hours the injury becomes irreversible, thus bringing the penumbra into the gradually enlarging area of infarction. This period of delay in cell death provides an opportunity for therapeutic intervention and prevention of further cell damage. Partial asphyxia without acidosis, as occurs in response to impairment of placental gas exchange by uterine contractions, maternal hypotension, or impairment in maternal placental circulation, can produce either widespread cerebral cortical necrosis or a more focal injury to the posterior parietal parasagittal regions. Partial asphyxia with acidosis has been shown to cause white matter injury.

Focal and multifocal cerebral necroses occur secondary to an embolus or thrombus (see Perinatal Stroke, later). There are often underlying problems such as thrombophilias, maternal idiopathic thrombocytopenic purpura, vascular maldevelopment, or history of maternal cocaine use. Infants may present with unilateral, focal seizures or display asymmetric motor function, or they may be asymptomatic.

Selective neuronal necrosis can involve specific regions of the cortex, thalamus, brainstem, cerebellum, or hippocampus. An acute global injury such as is seen with uterine rupture or cord prolapse causes injury to the basal ganglia, thalamus, and brainstem, whereas a prolonged partial injury affects mainly the cortex and subcortical white matter. Damage is more extensive in the posterior parietal-occipital region than in the anterior cortical areas. Clinical signs in the infant relate to the site of injury. Seizures are a feature of cortical injury, whereas irritability, posturing, and brainstem dysfunction are seen with infarcts affecting the basal ganglia and thalamus. Long-term sequelae of such an injury include cerebral atrophy and multicystic encephalomalacia. *Status marmoratus* refers to the marbled appearance of the basal ganglia, thalamus, and cerebral cortex in response to the injury. This appearance results from gross shrinkage of the striatum and defects in myelination. It may relate to the type of insult or the density of glutaminergic receptors in the basal ganglia (Johnston, 1995). Although the clinical correlate of this condition in the newborn is not well defined, it is seen in children with choreoathetoid cerebral palsy.

Cerebral blood flow is closely autoregulated over a wide range of systemic blood pressure by either vasoconstriction or dilatation of cerebral arterioles. However, this mechanism is imperfect in the newborn. Therefore, rapid changes in cerebral perfusion pressure can occur in response to changes in systemic blood pressure, as well as changes in cerebral Pao_2 and $Paco_2$. Injury typically tends to occur in the watershed regions, which in the term newborn are located in the parasagittal regions of the cerebral cortex. The periventricular white matter is the most vulnerable region in preterm newborns.

Clinical features of *parasagittal injury* include hypotonia and weakness, especially in the upper trunk. Cortical infarcts usually occur in the watershed region supplied by the most peripheral branches of the anterior, middle, and posterior cerebral arteries.

Spinal cord ischemia is not uncommon after HI-R injury. In patients with hyporeflexia or areflexia, spinal cord pathology should be considered. Ischemic necrosis occurs in spinal cord gray matter (Clancy et al, 1989).

Cellular Mechanisms

The immature brain is more susceptible to hypoxic-ischemic injury for several reasons, including immaturity of vascular regulation, along with maturational differences in metabolic oxidative function between the newborn and adult brain (Ferriero, 2001).

Although overall cerebral O_2 demands are lower in the infant than in the adult, cerebral oxidative metabolism is considerably increased in areas of active neural development that are associated with either synapse formation or activation of enzymes required for ion homeostasis. Glucose is the primary source of energy in cerebral metabolism, and although the newborn brain is capable of utilizing alternative energy substrates such as ketones, lactate, and free fatty acids, glucose uptake mechanisms are relatively underdeveloped (Cremer et al, 1979; Gregoire et al, 1978). Absence of energy stores makes the brain dependent on sustained perfusion. Animal studies have shown that this impaired uptake of glucose can impair cerebral metabolism even before oxygen depletion (Yager et al, 1996).

Vasoautoregulation in response to increased cerebral blood pressure or flow is relatively underdeveloped in the newborn, thus rendering the infant more vulnerable to ischemic events. The gradual increase in vascularity of the developing brain leads to the creation of watershed areas (i.e., areas not well vascularized). These regions are more vulnerable to global ischemic events. These global events lead to patterns of focal injury that are dependent on maturational processes. The similarities between processes essential for brain development and those mediating cellular injury make the immature brain particularly vulnerable to ischemic insult. These similarities include an increased density of glutamate receptors, an increase in glutaminergic synapses in particular regions of the immature brain, and enhanced accumulation of cytosolic calcium after activation of the glutamate receptor. It has been shown that there are proportionately more glutamate receptors in the immature rat brain than in the mature rat brain and that the developing rat brain is much more sensitive to injury than the newborn or adult brain (Yager et al, 1996). HI-R injury triggers a complex series of cellular events that evolve rapidly through amplifying cascades, eventually leading to severe cerebral damage. A gradual or sudden decrease in cerebral oxygen and energy substrates initially leads to synaptic inactivation, which is a reversible and adaptive response to HI-R injury. Decreased cerebral energy stores lead to membrane pump failure and the subsequent inability to maintain normal ion gradients (Figure 61-3). This is followed by neuronal membrane depolarization and release of neurotransmitters such as glutamate, which increase cytosolic calcium and induce destructive enzymes and free radicals. Reoxygenation after the ischemic episode plays a significant role in cellular injury. The pathogenesis of HI-R injury can be divided arbitrarily into four phases (Box 61-2; see also Figure 61-3):

1. A decrease in cerebral energy and membrane depolarization
2. A phase of increased release of neurotransmitters and neuronal damage
3. A period of reperfusion
4. A final phase of irreversible cell death

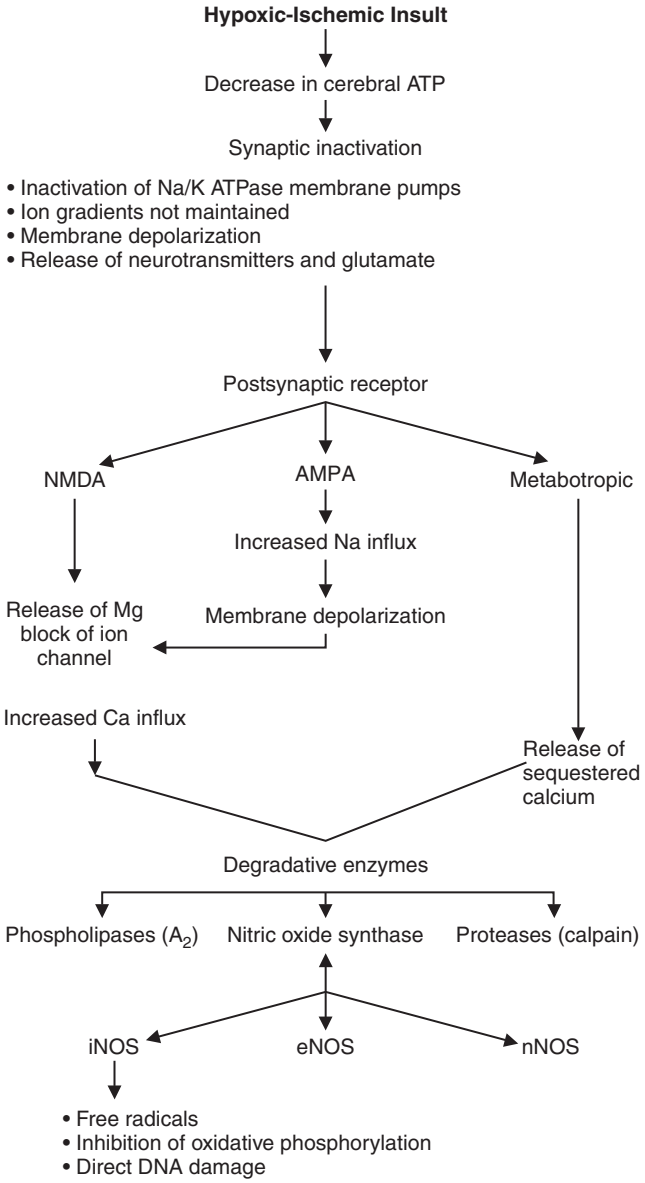

FIGURE 61-3 Flow diagram of events occurring after hypoxic-ischemic/reperfusion injury leading to energy depletion, membrane polarization, neurotransmitter release, calcium influx, and intracellular enzymatic activation leading to cell death.

Decrease in Cerebral Energy and Membrane Depolarization

HI-R injury is followed by a depression of brain function that probably is a protective mechanism to preserve energy. In the normal state, glucose and oxygen are the main requirements for brain energy production, which occurs by oxidative phosphorylation. Glucose is taken up by a carrier-mediated diffusion process and phosphorylated to glucose 6-phosphate, the major portion of which enters the glycolytic pathway to form pyruvate. Pyruvate enters the mitochondria and is converted to acetyl coenzyme A (acetyl CoA); acetyl CoA enters the citric acid cycle and undergoes oxidation to CO_2. The electrons generated get transported through several carrier proteins such as (reduced) nicotinamide adenine dinucleotide (NADH) within the mitochondria. NADH couples to

molecular oxygen and forms ATP through phosphorylation of ADP by adenine kinase. Phosphocreatine also can serve as a store of energy that can transfer phosphorus to generate ATP. HI-R injury is followed by a decrease in brain glucose and ATP. Anaerobic glycolysis is much less efficient at ATP production. Aerobic glycolysis generates 38 moles of ATP per mole of glucose, compared with 2 moles of ATP produced by anaerobic glycolysis.

A decrease in ATP affects the Na/K ATPase pump that helps to maintain the state of polarization of the neuronal membrane. A failure of the pump leads to an influx of sodium into the cell and potassium outside the cell. Associated glial uptake of sodium and water leads to astrocytic swelling that in turn decreases diffusion of oxygen and glucose to the neurons.

Accumulation of lactate secondary to anaerobic glycolysis leads to tissue acidosis, which inhibits both vascular autoregulation and phosphofructokinase, the rate-limiting enzyme in glycolysis. In immature animals, hypoglycemia has been shown to be damaging; pretreating animals with glucose decreases the impact of the injury when given before, but not during, the injury (Sheldon et al, 1992; Vannucci and Vannucci, 2000). This is in contrast with the effect of glucose administration in mature animals.

Excitotoxicity

There is sufficient evidence that excitatory neurotransmitters play a major role in HI-R injury. Excitotoxicity refers to excessive glutamatergic activation that leads to cell injury and death (Olney, 2003). Neuronal injury is initiated by release of glutamate and other excitatory neurotransmitters from the presynaptic neurons. Initially the decrease in energy supply decreases ATP-dependent exocytosis of glutamate and decreases activity of glutamate synthetase, the enzyme responsible for converting glutamate to nontoxic glutamine. Subsequently, glutamate release occurs by both a reversal of normal glutamate uptake mechanisms by the nerve terminals and glia, and membrane leakage. A secondary increase in glutamate occurs during the phase of reoxygenation.

Glutamate receptors are of three subtypes: *N*-methyl-D-aspartate (NMDA), amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and the G protein–associated metabotropic receptor. The NMDA receptor is a postsynaptic receptor that is activated by glutamate and has been shown to play an important role in normal brain development including neuronal survival, differentiation, arborization of dendrites, growth of axons, and development of synapses. The expression of NMDA receptor subtypes as well as the subunit composition of the glutamate receptors changes with maturation (Johnston, 1995; MacDonald and Nowak, 1990). The density of receptors is higher in regions of active development, and the different subtypes vary in different regions of the brain at different gestational ages. Several features in the subunit composition of the immature NMDA receptor result in enhanced opening and influx of calcium into the ion channels (Andersen et al, 1995; Ben-Ari et al, 1988; Morrisett et al, 1990). Activation of any of the three subtypes of glutamate-activated postsynaptic neuron receptors leads to an influx of calcium into the postsynaptic neurons. Activation of the NMDA receptor releases the magnesium block within the ion channel and leads to the entry of calcium into the ion channel. Activation of the AMPA receptor mediates fast excitatory neurotransmission by triggering an influx of sodium. The resulting membrane depolarization opens calcium channels and releases the magnesium block of the NMDA channel, thereby leading to cytosolic accumulation of calcium. Activation of the metabotropic receptor results in the generation of inositol triphosphate, which triggers release of sequestered calcium.

The increase in intracellular calcium sets into motion an irreversible cascade of events that leads to cell injury. Calcium activates several degradative enzymes such as phospholipases, proteases, and endonucleases. Activated phospholipases such as phospholipase A_2 hydrolyze membrane phospholipid, thereby releasing free fatty acids such as arachidonic acid. Arachidonic acid can mediate injury by several mechanisms, including increased release of glutamate, uncoupling of oxidative phosphorylation, and inactivation of membrane Na/K ATPase. Proteases degrade cytoskeletal and other proteins. Cyclooxygenase stimulates production of arachidonic acid and prostaglandins. Enzyme activation as well as activation of xanthine and prostaglandins generates free radicals that perpetuate the injury by lipid membrane peroxidation. Hypoxic-ischemic injury also leads to a change in iron homeostasis. Iron is usually maintained in a nontoxic "ferric" state but is reduced into the injurious "ferrous" form, which can react with oxygen-reactive species to propagate further injury.

Oxidative Stress

Nitric oxide synthase (NOS), one of the enzymes that is released during HI-R injury, has been identified as a mediator of cellular injury. NO causes cellular injury by various mechanisms: combining with superoxide to form a peroxynitrite radical that causes lipid peroxidation, generating free radicals by stimulation of cyclooxygenase activity, direct DNA damage, and participating in the neurotransmitter response by reentering the presynaptic neuron and further increasing release of glutamate.

NO may mediate both the initial reperfusion by vasodilatation and the later mitochondrial enzyme inhibition. During the initial period of reperfusion there is a clearance of glutamate (Takahashi et al, 1997). Several mechanisms that have been proposed to explain the ultimate increase in calcium influx and perpetuation of injury have been the

subject of excellent reviews (Inder and Volpe, 2000, White et al, 2000). Some of the mechanisms proposed include a long-term potentiation of NMDA receptors to low levels of extracellular glutamate, which can then lead to an exaggerated calcium influx, an impairment of the Na/K ATPase pump from delayed energy failure (Obrenovitch and Urenjak, 1997), and enhanced release of glutamate by NO. Generation of free radicals during this phase occurs by two methods: free fatty acids enter the cyclooxygenase pathway and generate arachidonic acid and prostaglandins, and xanthine oxidase converts hypoxanthine to uric acid. Free radicals activate adhesion molecules in platelets and leukocytes, which increases occlusion of the microvasculature, thereby perpetuating injury.

Cell Death

Cell death can occur as necrosis or apoptosis after ischemia. *Apoptosis* refers to programmed cell death, a mechanism that is ongoing during the process of brain maturation. Apoptotic cells are characterized by nuclear shrinkage, chromatin condensation, and DNA fragmentation. Necrotic cells are characterized by cellular swelling, fracture of cell membranes, and an inflammatory cellular reaction. It is hypothesized that a severe insult leads to necrosis, as is seen in the central area of injury, whereas a longer duration of a less severe injury may lead to apoptosis, as seen in the penumbra. In the immature brain, a third pathologic form of injury has been described: the apoptotic-necrotic continuum (Portera-Cailliau et al, 1997). This particular pattern may represent the predominant form of injury (Northington et al, 2001a, 2001b). It has recently been shown in animal models that there is a prolonged period of delayed cell death due to apoptosis (Nakajima et al, 2000; Northington et al, 2001a). This exciting finding suggests that there is a prolonged window of opportunity for interventional strategies.

Management of Hypoxic-Ischemic Encephaolpathy

The immediate management of HIE requires securing an appropriate airway and maintaining adequate circulation. Cerebral edema resulting from hypoxia-ischemia is maximal between 36 and 96 hours and can impair cerebral blood flow secondary to increased intracranial pressure. There is no consensus regarding the need to treat cerebral edema aggressively, because its role in producing neurologic sequelae is debatable. Although steroids have been shown to be beneficial in vasogenic cerebral edema, most investigators agree that corticosteroids are not beneficial for cerebral edema arising from hypoxic-ischemic injury. Attempts to decrease intracranial pressure by controlled hyperventilation ($Paco_2$ of 20 to 25 mm Hg) as well as by the use of furosemide or mannitol may actually be harmful (Collins et al, 2001). Because there is accumulating animal and human evidence of the detrimental effect of seizures, seizure activity should be controlled to limit further compromise of neurologic status, and electroencephalography in the form of aEEG or EEG should be used to monitor for subclinical seizures (Bjorkman et al, 2010; Glass et al, 2009; Miller et al, 2002d; van Rooij et al, 2010). Multiorgan function must be monitored carefully. Maintenance of adequate cerebral perfusion is necessary, and inotropic agents need to be used in patients with evidence of myocardial dysfunction. It is important to avoid both systemic hypotension and hypertension. Infants with hypoxic-ischemic injury can develop hyponatremia from syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Hypoglycemia in an immature animal model during the evolution of HIE has been found to aggravate the insult (Sheldon et al, 1996). Therefore, fluid overload should be avoided, and serum glucose and electrolytes should be monitored closely. Body temperature should be closely monitored and hyperthermia avoided. Moderate hypothermia therapy in the form of whole-body or selective head cooling is being rapidly implemented as part of routine care in many nurseries for infants with moderate to severe encephalopathy and evidence of perinatal asphyxia. Those with moderate to severe encephalopathy should be referred and transferred to an institution with a hypothermia program within the first 6 hours of life. There are currently ongoing studies evaluating whether or not institution of hypothermia, delayed prolonged, or deeper, or hypothermia plus other agents (e.g., xenon, erythropoietin), is neuroprotective for newborns with HIE.

Prognosis

Outcome of HIE depends on the severity of the initial insult and the degree of brain damage. Several factors such as maturity of the infant, placental-fetal blood flow, energy reserves, or presence of cerebral anomalies can affect the final outcome. It is often difficult to determine the duration of the insult because the vast majority of insults occur in utero and because accurate fetal surveillance is difficult. Certain clinical factors as well as the results of brain imaging studies can help identify infants with a poor prognosis (Barkovich et al, 1995; Biagioni et al, 2001). Seizures should be treated, because they have been associated with increased lactate and poor neurodevelopmental outcome. The presence of seizures is perhaps the best clinical indicator of adverse outcome, especially if seizure activity occurs in the first 12 hours of life or if seizures are difficult to control (Miller et al, 2002d).

The Apgar score is not a good predictor of outcome. This measure is affected by the use of maternal drugs or anesthesia, and by the vagal-induced respiratory depression that occurs from the use of suction catheters or from oropharyngeal secretions. There is also considerable variation among personnel in assigning the Apgar score, and all of the five different parameters that make up the Apgar score are not equally weighted for neurologic outcome. Although the Apgar score at 1 minute is not predictive of a poor outcome, the predictive ability does increase with a continued depressed score with increasing age of the infant. It has been shown that infants with Apgar scores of less than 6 at 5 minutes are three times more likely to have abnormalities on neurologic examination than are infants with scores greater than 6 (Levene et al, 1986). However, if the infant shows no neurologic symptoms in the perinatal period, the outcome is often normal. Ekert et al (1997) built a model to predict severe adverse outcome within 4 hours of birth in neonates with HIE and found that delayed onset of breathing, need for chest

compressions, and seizures had a sensitivity of 85% and specificity of 68%. In another predictive model, the following factors were included: the need for chest compressions for >1 minute, delayed onset of respirations >30 minutes, and base deficit >16 within the 1st hour of life, were predictive of poor outcome. When none of the factors were present, the rate of adverse outcome was 46% (95% CI, 33% to 58%) with none of the 3 factors, 64% (95% CI, 54% to 73%) with any 1 factors, 76% (95% CI, 66% to 85%) with any 2 factors, and 93% (95% CI, 81% to 99%) with all of the 3 factors present (Shah et al, 2006).

The duration of the neurologic abnormalities is usually helpful in predicting long-term neurologic disability. In two separate studies, normal examination findings at 1 week and at 2 weeks of age correlated with a good outcome (Robertson and Finer, 1985; Sarnat and Sarnat, 1976). Hypothermia treatment may confound the predictability of level of encephalopathy at the completion of therapy. In a secondary analysis of the Cool-Cap hypothermia trial, the outcomes for newborns after therapy was not necessarily reflected in improvement in the grade of encephalopathy, which may be due to other factors such as the use of morphine or other sedating drugs during cooling (Gunn et al, 2008). Other clinical tools used include the presence of impairment of other organ systems and the Score for Neonatal Acute Physiology–Perinatal Extension (SNAP-PE), a physiologic assessment score done within the first 24 hours of life (Newton et al, 2001). As with other clinical measures, neither of these tools is able to prognosticate outcome in the moderately asphyxiated newborn.

Predicting Outcome With Diagnostic Tests

Electroencephalography

The rate of recovery of the EEG to normal baseline activity and the severity of neonatal encephalopathy can be helpful in establishing the neurologic prognosis (Biagioni et al, 2001).

Amplitude Integrated Electroencephalogram

Amplitude-integrated EEG is a bedside monitor that is useful in assessing the background activity of the brain and in identifying seizures. It is easily interpreted by those with limited training. It is complementary to conventional EEG, may be used as a screening test for those with possible seizures or in monitoring for seizures in an acutely ill or paralyzed neonate, and can help monitor response to antiepileptic medications; also, the rate of recovery of the background in HIE is associated with outcome (Hellstrom-Westas et al, 1995; Toet et al, 1999; van Rooij et al, 2005; van Rooij et al, 2010).

Magnetic Resonance Imaging

MRI has been shown in a variety of studies to be useful in predicting outcome in neonates with HIE (Barkovich et al, 1998; Biagioni et al, 2001; Ment et al, 2002; Rutherford et al, 2006). In particular, absence of the signal in the posterior limb of the internal capsule has been associated with poor neurodevelopmental outcome. A joint statement from the American Academy of Pediatrics, the American Society of Pediatric Neuroradiology, and the Society for Pediatric Radiology recommends that a noncontrast CT study be performed to detect hemorrhagic lesions in term infants with encephalopathy and a birth history of trauma, coagulopathy, or low hematocrit. If the CT findings are inconclusive, MRI is recommended between days 2 and 8 to assess location and extent of injury (Ment et al, 2002). Because the CT scan does not compare favorably with MRI for confirming the diagnosis of hypoxic-ischemic injury or for providing prognostic information, Miller et al (Miller et al, 2002a) recommend that an MRI study be performed in the first week of life for establishing the diagnosis in an encephalopathic newborn (Figure 61-4, *A*).

Magnetic Resonance Spectroscopy

MRS has been shown to correlate with neurologic outcome and may be more sensitive in identifying injury and metabolic disturbances from seizures than standard imaging (Miller et al, 2002d) (see Figure 61-4, *B*). Abnormalities seen on MRS have been significantly associated with both neurologic and cognitive outcomes. Both high lactate and low NAA levels have been associated with persistent injury (Barkovich et al, 2001; Miller et al, 2002b). Study results have varied in accordance with the timing of the scan in relation to the injury. It has been reported that the lactate level of the injured brain increases within the first 24 hours and remains elevated thereafter, presumably because of energy failure and the necessity to metabolize glucose anaerobically (Hanrahan et al, 1996; Penrice et al, 1996). However, the NAA level does not diminish significantly until sometime beyond 48 hours (Penrice et al, 1997). The precise time at which NAA begins to diminish in asphyxiated neonates is not precisely known.

Outcome

The outcome for hypoxic-ischemic brain injury differs substantially for the preterm infant and the term infant. Although more preterm infants survive such an insult than term infants, preterm survivors are more likely to have neurodevelopmental disabilities. In a recent study of extremely preterm children, 49% had disabilities, with 23% meeting criteria for severe disabilities (Wood et al, 2000). In term infants with neonatal encephalopathy, the presence of seizures and the severity and duration of encephalopathic state are predictors of poor outcome (Glass et al, 2009; Robertson et al, 1989; Thornberg et al, 1995). Infants with mild neonatal encephalopathy syndromes usually have no deficits, whereas those with severe encephalopathy die or are severely impaired with spastic quadriparesis, cortical visual impairment, and seizure disorders. Those with moderate degrees of encephalopathy can be normal to severely abnormal, depending on the pattern of injury seen on MRI and MRS and the persistence of EEG abnormalities (Barkovich et al, 2001; Biagioni et al, 2001). The neurologic examination at 3 months may be a good prognostic indicator (Hajnal et al, 1999). In one cohort study, those with predominant injury to the deep grey nuclei experienced more severe outcomes at 30 months compared to those with predominant watershed region injury (Miller et al, 2005b). Using a separate MRI scoring system, in a cohort of 73 neonates with HIE, abnormalities of the posterior limb of the internal capsule were predictive of poor outcome at 1 year of age (Rutherford et al, 1998). Hypothermia is associated with an

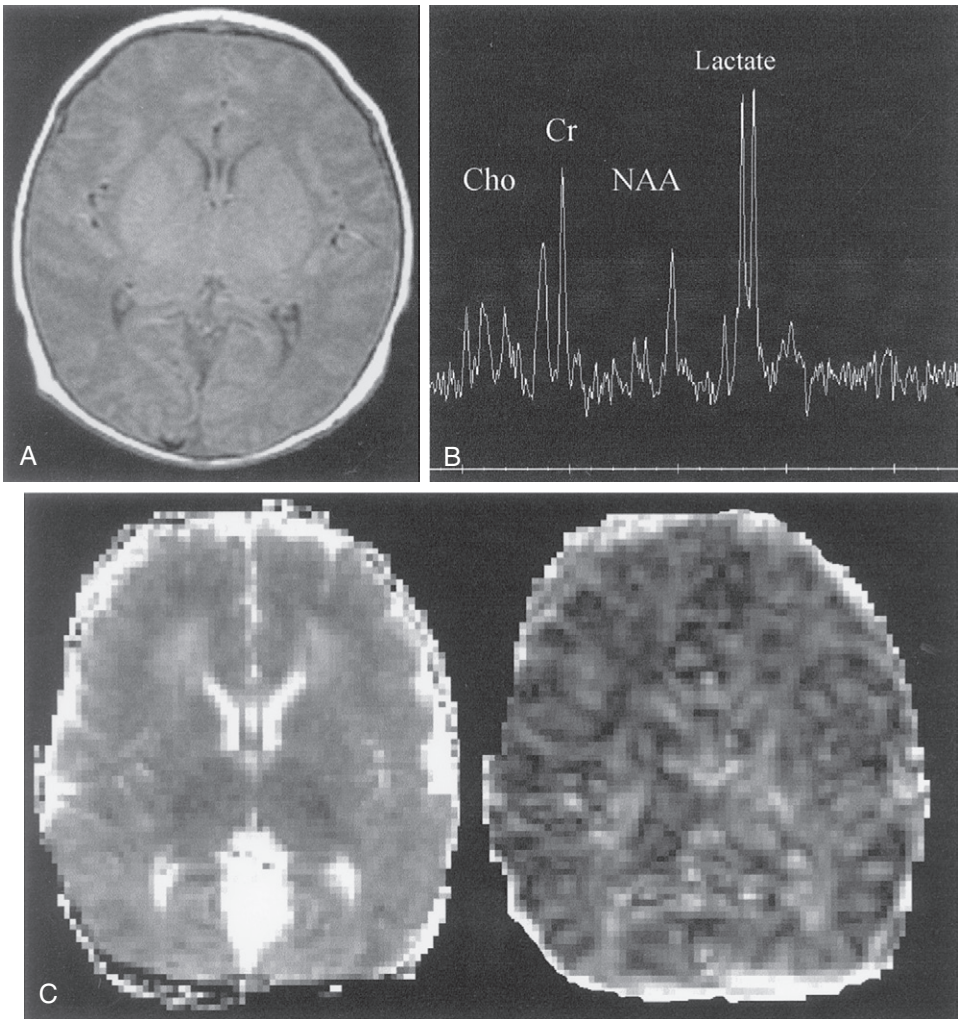

FIGURE 61-4 Magnetic resonance (MR) spectra and diffusion-weighted images obtained on day 2 of life in a term infant with moderate hypoxic-ischemic encephalopathy. **A,** MR image shows loss of signal intensity in the posterior limb of the internal capsule. **B,** The MR spectra show elevated lactate and decreased *N*-acetyl aspartate *(NAA)* peaks in the basal ganglia in that area; **C,** diffusion-weighted images show restricted diffusion on the apparent diffusion coefficient (ADC) image (*left*) and loss of anisotropy (*right*).

increase in number of infants with a normal scan, a reduction in severity or basal ganglia/thalamic and cortical injury, and these findings are still predictive of outcome (Bonifacio et al, 2011; Inder et al, 2004; Rutherford et al, 2005, 2010).

PERINATAL STROKE

Perinatal strokes can be arterial or venous in nature (Figure 61-5). Perinatal stroke is defined as an ischemic event that occurs between 28 weeks' gestation and 7 days of age and includes in utero strokes. The term *neonatal stroke* is reserved for events occurring between birth and the end of the 1st month of life (Raju et al, 2007). It is difficult to establish the exact prevalence of perinatal stroke. Using studies of children with neonatal seizures, prevalence has been estimated to be roughly 12% of neonates greater than 31 weeks' gestation who present with seizures (Lynch et al, 2002). Perinatal stroke is increasingly recognized in full-term infants with an incidence of 1 per 2300 to 4000 liveborn infants (Kirton and deVeber, 2009; Nelson and Lynch, 2004; Schneider et al, 2004; Schulzke et al, 2005). In the newborn period, seizures are the most common presenting symptom. Other symptoms include encephalopathy, abnormalities of tone, feeding problems, or apnea. However, there is a subgroup of neonates who do not present with evidence of injury until late infancy because the neurologic examination findings are normal in the newborn period. This is referred to as presumed perinatal stroke. These infants present later with pathologic early hand preference and/or seizures (Golomb et al, 2001). Stroke in the newborn has a slight male predominance, and there is a tendency toward left-sided lesions (Golomb, 2009; Golomb et al, 2001; Trauner et al, 1993).

The U.S. infant mortality rate for years 1995 to 1998 due to stroke (ICD-9 CM 430-437) is 5.33/100,000 per year, perinatal mortality is 2.21/100,000, and neonatal mortality is 3.49/100,000 live births per year (Lynch and Nelson, 2001). The National Hospital Discharge Survey, from 1980 through 1998, determined that for infants younger than 30 days of age, the in-hospital mortality rate for neonatal stroke was 10.1%, or 2.67/100,000 live births (Lynch and Nelson, 2001; Lynch et al, 2002).

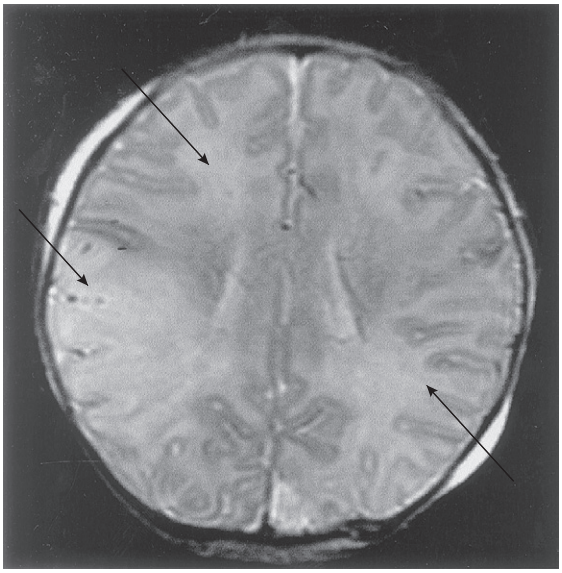

FIGURE 61-5 Brain magnetic resonance T2-weighted image in term neonate who suffered ischemic arterial stroke. Increased signal intensity is seen in the right parietal and frontal areas and the left posterior parietal region.

Cerebral Venous Thrombosis

Sinovenous thrombosis (SVT) is an important cause of stroke in the neonate. It is being increasingly diagnosed in recent years, probably reflecting the use of more sensitive neuroimaging techniques. In a retrospective series of children with abnormal imaging studies suggestive of SVT, 61% were neonates (Carvalho et al, 2001). The Canadian Pediatric Ischemic Stroke Registry (CPISR) identified 0.67 case per 100,000 per year, with neonates the most commonly affected (43%) (deVeber and Andrew, 2001). Most recently in a non–population-based study of 84 neonates with symptomatic SVT, 61% presented within the 1st week of life (Jordan et al, 2010). Risk factors are similar to those for ischemic stroke, with thrombophilias, asphyxial stress, dehydration, and infection being more common in the neonate (Fitzgerald et al, 2006; Kenet et al, 2007). Often, more than one risk factor is present (Wu et al, 2002).

Neonates present with seizures as the most common sign. The head ultrasound examination often reveals an IVH. Further neuroimaging with MRI and MR venography will reveal the site of the venous thrombosis and may also show other parenchymal abnormalities, such as thalamic hemorrhage (Wu et al, 2003b) (Figure 61-6).

Risk Factors

A number of different types of studies of infants with perinatal stroke has found an association with cardiac disorders, blood disorders, infection, trauma, drugs, maternal and placental disorders, catheterization, extracorporeal membrane oxygenation, and perinatal asphyxia. In some studies, the occurrence of multiple risk factors has been noted, especially blood disorders and asphyxial stress (Golomb et al, 2001; Lee et al, 2005).

Outcome

A review of the literature for case reports, series, and case-control studies of perinatal or neonatal stroke, which included 572 infants with perinatal stroke, revealed that 40% of infants with perinatal stroke were neurologically normal, 56% were abnormal (having neurologic or cognitive abnormalities), and 3.0% had died by the outcome evaluation period (Lynch et al, 2002). A similar review concluded that more than 50% of children with neonatal stroke appear normal by 12 to 18 months of age (de Vries et al, 1997). The majority of children did not have recurrent seizures. In the CPISR, the recurrence rate among children with neonatal stroke was 3% to 5%, and among survivors, outcome was normal in 33% (deVeber and Andrew, 2001). In one case series of 24 infants with MRI-confirmed cerebral infarction, 64% of the neonates had neurodevelopmental sequelae. Despite these impairments, most children walk independently by 2 years of age (Golomb, 2009). The presence of prothrombotic disorders, especially presence of factor V Leiden deficiency, was associated with poor outcome in term infants (Mercuri, 2001).

The neurodevelopmental outcome of neonates with SVT is reported to be normal in 77% to 82%. Presence of venous infarction and refractory seizures has been associated with neurologic sequelae (Carvalho et al, 2001; deVeber and Andrew, 2001; Shevell et al, 1989).

Management

There are no randomized trials for acute or chronic therapy following perinatal stroke. The use of anticoagulation therapy for the newborn is based on case series and expert opinion but is still not determined. Recently, guidelines regarding management, diagnostic evaluation, and therapy were published by the American Heart Association Stroke Council (Roach et al, 2008). It is difficult to extrapolate from adult or even nonneonatal pediatric studies. In the acute phase, treatment is mostly supportive. Hydration status, monitoring and treatment of seizures, and antibiotics may be important. Serial imaging may be used to identify extension of thrombi. In neonates with arterial ischemic stroke, anticoagulation may be considered in those with an ongoing cardioembolic source or recurrent stroke. In those with SVT without significant intracranial hemorrhage, the American College of Chest Physicians (ACCP) recommends treatment with unfractionated heparin or low-molecular-weight heparin (LMWH) followed by LMWH or vitamin K antagonists for 6 to 12 weeks (Monagle et al, 2008). Currently a study is being planned for the use of anticoagulation in VST.

PERINATAL TRAUMA

Injuries of the cranial structures and the brain can occur secondary to trauma during the process of birth. Perinatal trauma can result from various causes in utero, during labor, and postnatally. The nature of the trauma can be either mechanical or vascular. Embolism and thrombosis can result from placental infarcts or absorption of material from a macerated twin fetus, or with disorders of

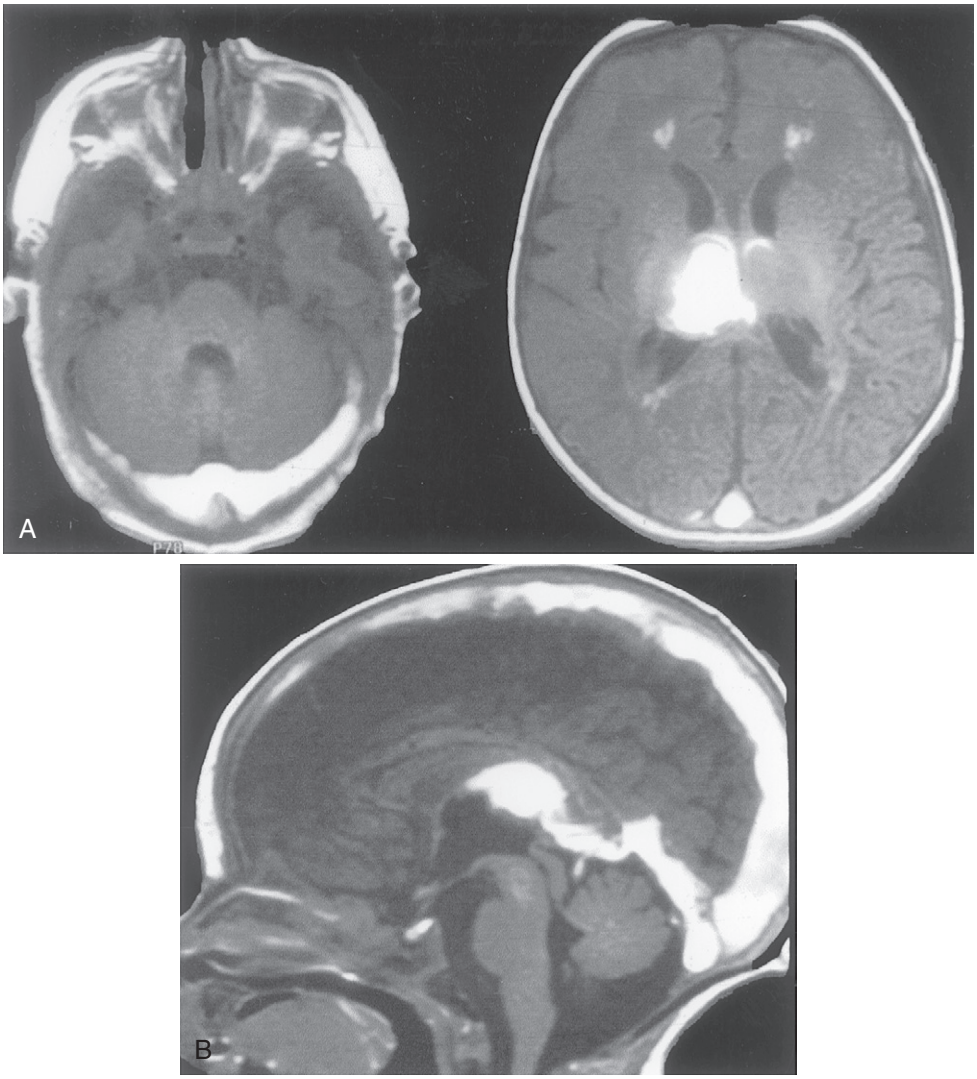

FIGURE 61-6 Brain magnetic resonance (MR) images of sinovenous thrombosis with thalamic infarction in a term neonate. A, Right thalamic infarction and hemorrhage seen on axial T1-weighted MR image; **B,** thrombosis of entire venous system seen on sagittal T1-weighted MR image.

coagulation or sepsis. Mechanical trauma can cause injury to both cranial and extracranial structures as well as the spinal cord and peripheral nerve structures.

Mechanical Trauma

Mechanical trauma can result in damage to extracranial structures, cranial structures, intracranial structures, spinal cord, or peripheral nerves.

Molding of the Head and Caput Succedaneum

Molding of the head is frequently seen in the newborn delivered either vaginally or by cesarean section. It refers to the asymmetrical shape of the head that results from mechanical pressure exerted during passage through the birth canal or during extraction by cesarean section. Caput succedaneum refers to the edematous soft tissue swelling that is often associated with bruising over the molded region. Although this condition is generally benign and resolves with time, abrasions over the area can become infected, and hyperbilirubinemia may develop with resolution of bruising (Figure 61-7).

Subgaleal Hemorrhage

In certain cases the trauma may be severe enough to cause a subgaleal hemorrhage, which consists of extension of the bleeding beneath the scalp aponeurosis to the nape of the neck. This condition needs to be recognized immediately because it can lead to severe blood loss and shock. The coagulation status should be evaluated, because subgaleal hemorrhage may be a presenting sign of hemophilia, hemorrhagic disease of the newborn, or other coagulation disorders. A CT scan or MRI is indicated, especially in conditions associated with an enlarging scalp swelling, altered mental status, and/or decreasing hematocrit with signs of hemorrhagic shock. Maintenance of the circulatory status of the infant is critical and may require use of packed cells or plasma to correct hypovolemia and any coagulopathy. Because of the nature of the subgaleal space, a neonate's entire blood volume can enter this space and lead to significant shock with resulting hypoxic-ischemic brain injury. Occasionally, severe trauma can lead to tearing of either the tentorium or the falx cerebri. A subdural hematoma may occur in cases with venous lacerations.

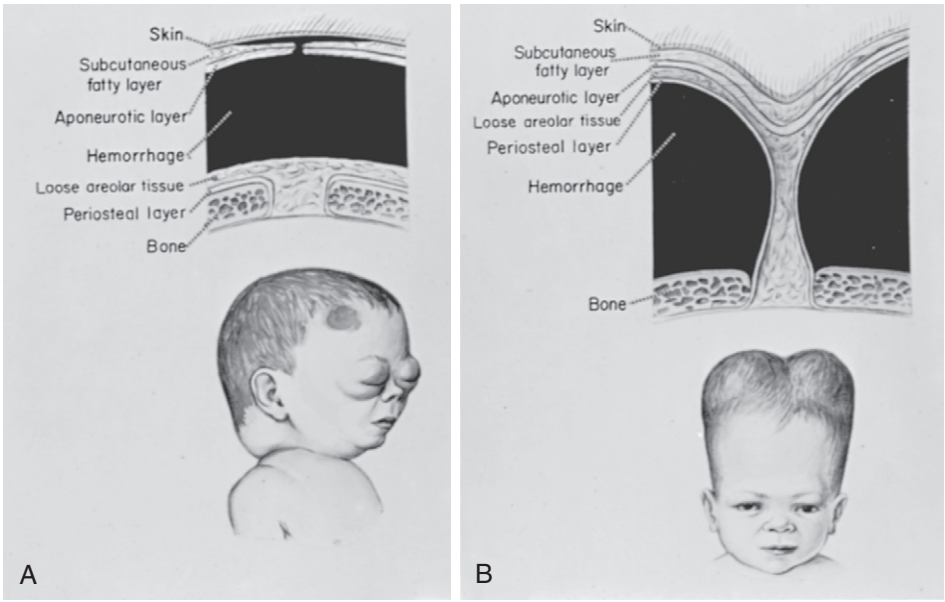

FIGURE 61-7 **A,** Location of edema and hemorrhage seen with a caput succedaneum. **B,** Location of hemorrhage seen with a cephalohematoma.

Cephalohematoma

Hemorrhage beneath the subperiosteum of the scalp leading to an elevation in usually the parietal region of the skull is called a cephalohematoma. It is distinguished from a caput as follows: it does not cross suture lines, it manifests as a firmer swelling that does not transilluminate, and it has a well-defined edge (Figure 61-7). Rarely, it is seen in the occipital region as a soft swelling that needs to be distinguished from an encephalocele. The incidence of cephalohematoma is estimated to be 1.5% to 2.5% of all deliveries. It is seen twice as frequently in male infants and presents bilaterally in 15% of patients. Linear fractures are seen in 5% of unilateral lesions and in 18% of bilateral lesions.

A cephalohematoma generally resolves over a period of 2 to 8 weeks. It often leaves behind a sharp palpable ridge due to calcium deposition. Resorption of the extravasated blood can lead to hyperbilirubinemia, and infants should be observed for jaundice. A severe bleed can lead to anemia. Infection of the mass with formation of an abscess and associated osteomyelitis can occur in rare cases. It should be suspected in the event of an enlarging mass manifesting with fever and laboratory results suggestive of an infection. A skull radiograph or a CT scan is indicated in cases in which a fracture is suspected. Hyperostosis and thickening of the parietal region, calcium deposition, or cystic defects within the hematoma may be seen on neuroimaging studies.

Skull Fractures

Several features of the skull of the newborn make it less likely to sustain fractures, even in the presence of considerable pressure during the process of birth. The presence of unossified sutures and decreased mineralization makes the neonatal skull less rigid and more amenable to temporary distortion. However, fractures do occur in deliveries, especially those associated with forceps or blunt abdominal trauma to the mother. Fractures can also occur simply from pressure of the head against the sacral promontory during delivery from forceful uterine contractions.

Fractures may be linear or depressed and usually occur in the frontal or parietal region. Linear fractures are more common and, if nondisplaced, usually do not pose a problem and do not need treatment. They are seen as a linear region of decreased density on a skull radiograph. Some fractures can be associated with a leptomeningeal cyst when it occurs near suture lines ("growing fracture of the skull").

Depressed skull fractures associated with application of pressure over the parietal region are seen on the anteroposterior skull radiograph as a linear region of increased density. These may not be visualized on the lateral film. A depressed fracture can serve as a focus for seizure activity, and it is therefore recommended that the region be elevated by a surgical procedure.

Subdural Hemorrhage

The dura mater, the outer meningeal layer, lies immediately below the bony layer of the skull and contains several blood vessels. It also encloses the major sinuses between its two layers. Severe compression and stretching can lead to tears of the falx cerebri or the tentorium cerebelli, especially at the site at which the falx meets the tentorium. Risk factors include macrosomia, cephalopelvic disproportion, shoulder dystocia, forceps delivery, and premature delivery. Hemorrhage can occur by injury to the dural sinuses, the major cerebral veins, or the vein of Galen. Injury of the superficial cerebral veins leads to hemorrhage over the cerebrum. Injury to the straight sinus or the vein of Galen can cause extension of a subdural hemorrhage from the base of the brain into the posterior fossa. Damage to the sagittal sinus from overriding parietal bones, and damage to the occipital sinus in conditions leading to separation of the squamous from the lateral parts of the occipital bone, can be seen with breech presentation.

A subdural hemorrhage should be suspected in cases in which there is a history of trauma or a difficult delivery with development of focal cerebral signs such as unequal pupils, deviation of the eyes, or hemiparesis. Symptoms may present over a period of a few hours to days. Often the infant presents with nonspecific signs such as pallor, lethargy, irritability, and a decreased Moro response. A bulging anterior fontanel may be the sign of an acute bleed. Posterior fossa hemorrhages, which can be accompanied by cerebellar hemorrhages or IVH, may manifest later with opisthotonos, apnea and bradycardia, altered mental status, and seizures. Pressure on the fourth ventricle can lead to signs of increased intracranial pressure and apnea.

Ultrasonography is inadequate for demonstrating the presence of a subdural bleed. MRI is a more appropriate imaging study for this purpose and should be undertaken if the diagnosis is suspected.

No surgical treatment is recommended in asymptomatic cases. Evacuation of a posterior fossa bleed can sometimes be lifesaving, although surgical evacuation is not effective in the case of a large subdural hemorrhage. Close monitoring is necessary to detect signs of deterioration in neurologic status. Presence of increased intracranial pressure may require a subdural tap or placement of a subdural shunt.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage occurs as a result of damage to veins traversing the subarachnoid space. This type of injury is fairly common and may manifest as seizures. Diagnosis is suspected when frank blood or blood-tinged fluid is obtained on lumbar puncture. No treatment is needed, because the condition usually resolves spontaneously.

Spinal Cord Injury

Spinal cord injury was first described in the 1800s and is a relatively rare event now because of improved obstetric practices. In a review of studies of cerebral palsy, spinal cord injury was noted to account for just 0.6% of injuries. It is most commonly associated with breech delivery and occurs secondary to either a lateral or longitudinal stretching force or torsion of the neck during delivery. It can also be seen in premature infants as a result of extension of an intracranial hemorrhage. Damage occurs to the cord, the covering meninges, nerve roots, and blood vessels.

The pathologic findings may include laceration of the cord, epidural hemorrhage, laceration of the dura with a subdural hemorrhage, and tears of the nerve roots, as well as focal hemorrhages within the cord.

Most patients with a severe spinal cord injury do not survive. The cervical and upper thoracic segments of the spine are most commonly affected. The condition should be suspected in any infant with a breech presentation who has poor muscle tone and flaccid weakness of the extremities. The presentation in many cases is that of spastic paraparesis with respiratory depression and hypotonia. There is often involvement of both the motor and the sensory systems. Urinary retention and abdominal distention with paradoxical respirations may be present. The neurologic examination is significant for an absence of sensation below the level of the injury. This can manifest as reduced skin temperature and decreased tendon reflexes in the acute phase, followed by the appearance of triple-flexion withdrawal movements.

The differential diagnosis includes neuromuscular disorders such as spinal muscular atrophy, congenital myasthenia gravis, and a tumor of the cervical or lumbar region of the cord. Spinal muscular atrophy is usually not associated with loss of sensation or bladder control. A tumor of the spinal cord is usually associated with midline skin abnormalities such as dimpling, hemangioma, or tufts of hair.

Treatment is usually supportive and may require intubation for respiratory support. No specific treatment is available. Most cases are severe and irreversible, although milder degrees of injury are potentially reversible.

Cranial Nerve Injury

Facial Nerve Injury

Facial nerve injury is the most common cranial nerve injury seen secondary to birth trauma. Contrary to common belief, forceps application is not associated with an increased incidence of facial nerve palsy. The site of injury and the precise timing of injury are controversial. The nerve is most commonly injured at the point where it emerges from the stylomastoid foramen, and the lesion is therefore similar to a lower motor neuron lesion. The signs and symptoms include difficulty in closing the eyelid on the affected side, loss of the normal nasolabial fold, and an asymmetrical crying facies. The forehead is spared, because it is innervated by the opposite facial nerve. The injury occurs as a result of compression of the nerve against the sacral promontory, especially in cases in which presentation of the fetal head leads to compression of the mandible and the neck against the shoulder. Usually, compression of the nerve occurs after it has exited the mastoid canal, although occasionally the portion within the mastoid can also be affected.

Nerve excitability or conduction tests are not usually recommended unless there is no improvement over 3 to 4 days. Most lesions begin to resolve after 1 week. Nerve excitability tests are usually helpful in distinguishing partial from complete denervation. In the case of partial injury, nerve stimulation can lead to some muscular contraction. However, the lack of response to nerve stimulation does not necessarily predict a poor outcome. A neurology consultation should be obtained in cases that do not show resolution within a few weeks. Methyl cellulose eye drops should be used on the affected side to prevent irritation from dryness of the conjunctiva. In severe cases, surgery may be necessary to repair a severed nerve.

Congenital Hypoplasia of the Depressor Anguli Oris Muscle

Congenital hypoplasia of the depressor anguli oris muscle is not due to perinatal trauma but is included here for differential diagnosis purposes. In affected infants, unilateral congenital absence of the depressor anguli oris muscle leads to an inability of contraction and eversion of the lower lip on the same side during crying episodes. The infant thus appears to have an asymmetrical face while crying. The

condition becomes less prominent with age, as episodes of crying are reduced in the older child. This condition can occur as an isolated anomaly or be associated with other anomalies. In a review of data for 41 infants with the condition, 27 had associated genitourinary, respiratory, or cardiovascular abnormalities (Pape and Pickering, 1972). Congenital heart disease, especially a ventricular septal defect, is the most common associated anomaly.

Injury to Other Cranial Nerves

Injury of other cranial nerves secondary to birth trauma is rare. Transient ptosis may be seen as a result of damage to the oculomotor nerve. Unilateral as well as bilateral optic nerve atrophy has been reported to occur from orbital fracture.

Peripheral Nerve Injury

Brachial Plexus Injury

Injury to the brachial plexus usually results from the prolonged vaginal extraction of a macrosomic infant. Traction of the shoulder in a breech presentation as well as turning away of the head in a difficult vertex presentation leads to stretching of the plexus. In most cases, the condition is unilateral; it is located on the right twice as often as on the left. In the mildest cases, nerves C5 and C6 are affected, followed by additional nerves in more severe cases. The nerve is compressed within the nerve sheath from hemorrhage and edema. In severe cases, there may be avulsion of the nerve from the spinal cord. Improvement in obstetric care has resulted in a decrease in incidence of this condition.

Erb-Duchenne paralysis refers to the paralysis of the upper brachial plexus involving nerves C5 and C6. Weakness of the deltoid, biceps, brachioradialis, and supinator muscles leads to the classic clinical picture in which the infant holds the affected arm in a position of tight adduction and internal rotation of the shoulder along with extension and pronation of the elbow. Involvement of C7 can lead to a weakness of the extensors and exaggerated flexion of the wrist. The Moro reflex is asymmetrical and absent on the affected side, and the biceps reflex is weak or absent. The grasp reflex is usually present. The injury may be associated with a fracture of the clavicle or humerus, displacement of the radial head, or shoulder dislocation. Injury of C4 can lead to phrenic nerve paralysis, which manifests as rapid, shallow breathing and decreased movement of the diaphragm on the affected side.

Klumpke paralysis results from injury to the lower brachial plexus and accounts for 2.5% of cases of brachial plexus injury. It is associated with weakness of the flexor muscles of the wrist as well as the intrinsic muscles of the hand. The grasp reflex is absent, and there may be loss of sensation over the hand. Involvement of the cervical sympathetic nerves can lead to unilateral miosis (Horner syndrome). Complete paralysis of the arm is seen in cases in which the entire brachial plexus is damaged.

The diagnosis can be made on the basis of the history of difficult delivery, posture of the affected arm, and the loss of voluntary and reflex movements. Radiographic examination performed with fluoroscopy or ultrasonography can help make the diagnosis of phrenic nerve injury. Radiographic studies can also detect any associated fractures or dislocations. Use of somatosensory evoked potentials may help to distinguish completed avulsion at the spinal cord from a more distal lesion. MRI also can be used to demonstrate root avulsion. The extent of denervation can be demonstrated by performing an EEG 2 to 3 weeks after the injury.

The treatment is mainly supportive and consists of physical therapy to avoid the development of contractures. The arm should be kept in a natural position and not be overimmobilized. Passive exercises should be started 1 week after birth. The timing of recovery is dependent on the extent of the lesion. In mild partial plexus injury and Erb-Duchenne injury, improvement is seen by 1 or 2 weeks after birth, and recovery is complete by 1 to 18 months. Prognosis is poorer in Klumpke paralysis and in cases of complete plexus damage. Recovery is rarely complete in these infants, and sequelae may include muscle atrophy and contractures. Return of neuromuscular function is not always associated with return of normal movements of the extremities due to early deprivation of sensorimotor function.

STRATEGIES FOR NEUROPROTECTION

Considerable advances have been made in recent years in elucidating the cellular and vascular mechanisms of hypoxic-ischemic brain injury. Anticipation and prevention of conditions that cause HIE constitute the best neuroprotective strategy. Many potential strategies have been studied in animal or adult models of disease. Extrapolating the effects of these studies to the human newborn is difficult because the mechanism of injury in experimental animal models is not necessarily similar to that in infants, and several features of the newborn developing brain make it uniquely more susceptible to injury than the adult brain. Therefore, these therapies must be tested in the neonatal population (Box 61-3).

Early identification of infants with a moderately severe insult is necessary in order to initiate appropriate therapy within the narrow therapeutic window, although it is difficult to assess the degree of encephalopathy initially. In addition to our lack of ability to select neonates for neuroprotective therapies, interruption of the injurious events by neuroprotective agents may also simultaneously affect normal developmental processes. Another important issue relates to the route and timing of intervention. Asphyxia in neonates is often associated with multiorgan dysfunction, which can affect the pharmacokinetics of drug therapies. Side effects of these agents can include hypotension and cardiac depression, exacerbating the initial injury by reducing cerebral perfusion pressure.

Several strategies for neuroprotection exert their effects at different stages of the cascade of events that is initiated after injury. These strategies include methods to reduce depletion of ATP stores, both in cases in which hypoxic-ischemic insult is predictable and in the early postinsult phase, to reduce membrane depolarization, to inhibit glutamate release, to inhibit accumulation of intracellular calcium, to block glutamate-responsive NMDA and AMPA receptors, to prevent release of degradative enzymes, to sequester free radicals, to use thrombolytic agents, and to

prevent the reperfusion injury by inhibition of xanthine oxidase. The following discussion examines some of these methods in more detail.

MAINTAINING ENERGY STORES

Prevention of depletion of cerebral energy stores is a strategy that can be utilized in cases in which injury is anticipated (e.g., cardiac surgery requiring placement of the infant on cardiopulmonary bypass). It is recommended that seizures and conditions that exacerbate energy depletion, such as hyperthermia, be avoided in cases of HI-R injury.

HYPOTHERMIA

Mild sustained hypothermia is one of the most exciting and viable neuroprotective strategies for limiting neonatal HI-R injury to emerge from the laboratory in recent years. Cerebral metabolism after the initial phase of energy failure during asphyxia may recover in a latent phase but then deteriorate in a secondary phase of brain injury 6 to 15 hours later. In studies in cell culture and in vivo models of focal and global cerebral ischemias in both adults and immature animals, hypothermia has been shown to have a neuroprotective effect (Coimbra and Wieloch, 1994; Colbourne and Corbett, 1994; Sirimanne et al, 1996). Experimental studies in animal models have shown that moderate hypothermia established within 30 minutes after the HI-R injury is neuroprotective (Edwards et al, 1995; Haaland et al, 1997; Thoresen et al, 1995, 1996; Tooley et al, 2003). These and other studies have shown that hypothermia inhibits early adverse events as well as later events such as secondary energy failure and apoptosis. Studies in fetal sheep have shown that prolonged cerebral cooling starting 5.5 hours but not 8.5 hours after cerebral ischemia may still be associated with neuronal rescue (Gunn et al, 1997).

The possible mechanisms by which hypothermia helps in neuroprotection are inhibition of glutamate release, decreased metabolism and energy conservation, decreased metabolic acidosis, decreased free radical generation, prevention of energy failure and apoptosis, and inhibition of effects of adhesion molecules at the microvascular level, thereby inhibiting the breakdown of the blood-brain barrier and reducing brain edema. Some studies indicate that hypothermia delays but does not prevent the cellular or vascular outcome of HIE. However, even delaying onset of damage can be helpful in prolonging the therapeutic window for other therapies to take effect.

Hypothermia was first reported in the therapy of infants after perinatal asphyxia in 1959, but these experiments did not have a group of control infants (Westin et al, 1959). The adverse consequences of hypothermia and the importance of maintaining infants in a normothermic environment are well known. Metabolic, cardiovascular, pulmonary, coagulation, and immunologic disturbances all have been reported with hypothermia, although the results of the trials demonstrate few complications. A prospective randomized trial conducted to identify the adverse effects of hypothermia showed that selective head cooling was safe, with minimal systemic toxicity (Gunn et al, 1998). Mild hypothermia in this study was induced by application of a water-cooled coil to the infant's head, thereby lowering the cranial temperature to 34.5° C for 72 hours within 2 to 5 hours after the injury. Rectal temperature was maintained up to 35.7° C. The results of this and other studies led to the initiation of several multicenter clinical trials for neuroprotective efficacy.

There have now been four large randomized trials of moderate hypothermia for HIE (Azzopardi et al, 2009; Eicher et al, 2005; Gluckman et al, 2005; Shankaran et al, 2005). Trials of both selective head cooling and whole-body cooling have demonstrated benefit in those with moderate encephalopathy. The therapeutic benefit on those with severe encephalopathy differs between the studies. In a metaanalysis of 8 trials, including 638 infants, hypothermia for moderate/severe neonatal encephalopathy in neonates with evidence of perinatal asphyxia resulted in a significant reduction in mortality or major neurodevelopmental disability to 18 months of age (relative risk [RR] 0.76, 95% CI 0.65, 0.89, number needed to treat [NNT] 7, 95% CI 4, 14) (Jacobs et al, 2007). Cooling also resulted in statistically significant reductions in mortality (typical RR 0.74, 95% CI 0.58, 0.94, NNT 11, 95% CI 6, 50) and in neurodevelopmental disability in survivors (typical RR 0.68; 95% CI 0.51, 0.92), typical RD –0.13, 95% CI –0.23, –0.03, NNT 8, 95% CI 4, 33). Given these findings and because there are currently no other effective therapeutic options, hypothermia is being implemented in many NICUs as a neuroprotective strategy for HIE (Jacobs et al, 2007).

PRECONDITIONING AND GROWTH FACTORS

The response of the neonatal brain to milder forms of injury can help us learn about mechanisms that the brain uses to protect itself from insults. Genes upregulated by stress, such as those that induce growth and differentiation, have been shown to be neuroprotective in animal models (Han and Holtzman, 2000). Animals treated with sublethal stress are protected from subsequent insults that would otherwise be deadly (Bergeron et al, 2000; Sheldon

et al, 2007). Immature rats that are exposed to hypoxia have reduced brain injury following HI that occurs 24 hours after this preconditioning stimulus, with protection that persists 1 to 3 weeks later (Gidday et al, 1994; Vannucci et al, 1998). It is possible that injury may only be delayed, and protection may not be permanent; however, hypoxic preconditioning does provide long-lasting histological and functional protection for up to 8 weeks after neonatal rodent HI (Gustavsson et al, 2005).

Hypoxia-inducible factor 1α [HIF-1α] activation is a key modulator of the protection against subsequent HI injury that is induced by hypoxic preconditioning (Bergeron et al, 2000; Ran et al, 2005). HIF-1α is a neuronal transcription factor that stabilizes during hypoxia by binding to HIF-1β. Following stabilization, it produces a variety of downstream targets that are neuroprotective, including insulin-like growth factor-1 (IGF-1), vascular endothelial growth factor (VEGF), and erythropoietin (EPO).

EPO is a glycoprotein that was originally identified for its role in erythropoiesis. Functions include modulation of the inflammatory and immune responses (Villa et al, 2003), vasogenic and proangiogenic effects through its interaction with VEGF (Chong et al, 2002; Wang et al, 2004b), as well as effects on CNS development and repair. EPO and EPO receptor are expressed by a variety of different cell types in the CNS with changing patterns during development (Juul et al, 1999). EPO plays a key role in neural differentiation and neurogenesis early in development, promoting neurogenesis in vitro and in vivo (Shingo et al, 2001).

Postinjury treatment protocols with exogenously administered EPO has a protective effect in a variety of different models of brain injury in newborn rodents with both short- and long-term histological and behavioral improvement (Sola et al, 2005b). A single dose of EPO given immediately after neonatal hypoxic-ischemic injury in rats significantly reduces infarct volume and improves long-term spatial memory (Kumral et al, 2004). Single- and multiple-dose treatment regimens of EPO following neonatal focal ischemic stroke in rats reduce infarct volume (Sola et al, 2005a) and improve both short-term sensorimotor (Chang et al, 2005) and long-term cognitive (Gonzalez et al, 2009) outcomes, but there may be more long-lasting behavioral benefit in female rats (Wen et al, 2006). EPO treatment initiated 24 hours after neonatal HI also decreases brain injury (Sun et al, 2005). In addition, EPO enhances neurogenesis and directs multipotential neural stem cells toward a neuronal cell fate (Gonzalez et al, 2007; Shingo et al, 2001; Wang et al, 2004b). Following transient ischemic stroke, there is a temporary precursor cell proliferation in the rodent subventricular zone (SVZ), a source of endogenous precursor cells throughout the life of the rodent, with this precursor cell proliferation and differentiation favoring gliogenesis (Plane et al, 2004). EPO has been shown to enhance neurogenesis in vivo in the SVZ after stroke in the adult rat (Wang et al, 2004b). Neurogenesis has also been demonstrated following EPO treatment with an increase in newly generated cells from precursors, and possibly also an effect on cell fate commitment in vitro (Lu et al, 2005; Osredkar et al, 2010; Shingo et al, 2001; Wang et al, 2004b).

In humans, EPO is safely used for treatment of anemia in premature infants (Aher and Ohlsson, 2006). EPO for neuroprotection is given in much higher doses (1000–5000 U/kg/dose) than for anemia to enable crossing of the blood-brain barrier with unknown pharmacokinetics in humans (Chang et al, 2005; Demers et al, 2005; McPherson and Juul, 2007). Recently, ELBW infants tolerated doses between 500 and 2500 U/kg/dose (Juul et al, 2008), and studies are ongoing. There has been one trial of EPO following neonatal HI, showing promising results. Repeated low-dose EPO over the first 2 weeks of life resulted in a reduction in death or moderate/severe disability at 18 months of age (Zhu et al, 2009). Further studies evaluating the safety, optimal dosage, and use in conjunction with hypothermia therapy are needed before implementation. A multicenter safety and pharmacokinetics trial is currently underway.

VEGF is a regulator of angiogenesis and is also involved in neuronal cell proliferation and migration (Zachary, 2005). The endothelial microenvironment establishes a vascular niche that promotes survival and proliferation of progenitor cells, which is tightly coordinated with angiogenesis (Palmer et al, 2000). VEGF-A is the most important member of a family of growth factors and is expressed in cortical neurons during early development, switching to mature glial cells near vessels during maturation. After exposure to hypoxia, there is increased neuronal and glial expression of VEGF-A, directing vascularization and stimulating proliferation of neuronal and nonneuronal cell types (Forstreuter et al, 2002; Jin et al, 2002; Krum and Rosenstein, 1998; Mu et al, 2003). VEGF also has chemotactic effects on neurogenic zones in the brain, increasing migration of stem cells during anoxia (Bagnard et al, 2001; Maurer et al, 2003; Yang and Cepko, 1996). VEGF-knockout mice have severe impairments in vascularization, neuronal migration, and survival (Raab et al, 2004).

Timing of VEGF administrations is important. In adult ischemia models, intravenous VEGF administered 1 hour after insult increases blood-brain barrier leakage and lesion size, but late administration 48 hours after ischemia enhances angiogenesis and functional performance (Zhang et al, 2000). Both topical and intracerebroventricular injection reduced infarct volume, and benefit has been shown in neurodegenerative and traumatic models of injury as well (Harrigan et al, 2003; Hayashi et al, 1998). VEGF overexpression confers direct neuroprotection resulting from inhibition of apoptotic pathways (Zachary, 2005).

Other factors have also shown promise, but given their role in normal neurodevelopment, the effects of treatment are not known. IGF-1 is important for growth and maturation of the fetal brain, as well as differentiation of oligodendrocyte precursors (D'Ercole et al, 1996). IGF-1 has prosurvival properties that can prevent perinatal hypoxic and excitotoxic injury, and it is also effective after intranasal administration (Johnston et al, 1996; Pang et al, 2007; Lin et al, 2009). Brain-derived neurotrophic factor is a neurotrophin that also provides neuroprotection in neonatal HI (Cheng et al, 1997; Cheng et al, 1998; Holtzman et al, 1996; Husson et al, 2005). It prevents spatial learning and memory impairments after injury, but its effectiveness is limited by the stage of development (Husson et al, 2005; Cheng et al, 1998). Although protective in mice when given on postnatal day 5 (P5), it has no effect at later

time points and actually exacerbates excitotoxicity if given on the day of birth (Husson et al, 2005).

ANTIOXIDANTS

Antioxidant defenses such as superoxide dismutase, glutathione peroxidase, catalase, and compounds such as vitamins A, C, and E, as well as beta-carotene, glutathione, and ubiquinones scavenge free radicals (FRs) under normal conditions. Damage occurs when there is an imbalance between their generation and uptake (Fridovich, 1997). Following HI, there is an increase in superoxide and hydroxyl radical production and rapid depletion of antioxidant stores, which leads to cell membrane damage, excitotoxic energy depletion, cytosolic calcium accumulation, and activation of proapoptotic genes that cause damage to cellular components and result in cell death (Taylor et al, 1999).

In an effort to reduce oxidative damage to the neonate, a number of strategies have been employed including reactive oxygen species (ROS) scavengers, lipid peroxidation inhibitors, FR reducers, and nitric oxide synthase (NOS) inhibitors. NOS catalyzes the synthesis of NO from the conversion of arginine to citrulline (Boucher et al, 1999). NO plays an important role in pulmonary, systemic, and cerebral vasodilation and is constitutively produced in response to increased intracellular calcium by endothelial nitric oxide synthase (eNOS) in endothelial cells and by neuronal nitric oxide synthase (nNOS) in astrocytes and neurons. An inducible isoform of nitric oxide synthase (iNOS) also produces NO in response to cellular stress, which initiates neuronal damage when converted to secondary reactive nitrogen species that facilitate nitration and nitrosylation reactions (Beckman and Koppenol, 1996). Early endothelial NO is protective by maintaining blood flow, but early neuronal NO and late inducible NO promote cell death (Iadecola et al, 1997). Selective inhibition of nNOS or iNOS has shown potential as a neuroprotective strategy (van den Tweel et al, 2005). Regions expressing nNOS correspond to those that are susceptible to excitotoxicity, expressing NMDA receptors in vivo and in vitro (Black et al, 1995; Dawson et al, 1993; Ferriero et al, 1996). Destruction of neurons containing nNOS or targeted disruption of the nNOS gene protects animals from HI injury (Ferriero et al, 1995, 1996), but nonspecific blockade of nNOS and eNOS is not protective (Marks et al, 1996). There have been few studies in human newborns examining cerebral NO production. CSF NO levels increase with severity of HIE at 24 to 72 hours after asphyxia (Ergenekon et al, 1999), with increased NO and nitrotyrosine levels in the spinal cord as well (Groenendaal et al, 2008). Initial results in premature infants treated with inhaled NO for prevention of bronchopulmonary dysplasia show reductions in ultrasound diagnosed brain injury and improvements in neurodevelopmental outcomes at 2 years of age, but long-term results are still pending (Ballard et al, 2006; Schreiber et al, 2003).

Other antioxidant strategies that either block FR production or increase antioxidant defenses include melatonin, allopurinol, and deferoxamine. Melatonin is an indoleamine that is formed in higher quantities in adults and functions as a direct scavenger of ROS and NO. It has been found to provide long-lasting neuroprotection in experimental HI and focal cerebral ischemic injury, and human neonates treated with melatonin were also found to have decreased proinflammatory cytokines (Carloni et al, 2008; Gitto et al, 2004, 2005; Koh, 2008). Allopurinol has mixed effects that have shown promise in animal and human studies. Xanthine oxidase–derived superoxide and H_2O_2 react with NO to form damaging reactive nitrogen species. Allopurinol reduces FR production by inhibiting xanthine oxidase while also scavenging hydroxyl radicals. High-dose allopurinol given 15 minutes after HI in P7 rats decreases acute edema and long-term infarct volume (Palmer et al, 1993). Short-term benefits have also been seen in neonates undergoing cardiac surgery for hypoplastic left heart syndrome (Clancy et al, 2001). Early allopurinol in asphyxiated infants improved short-term neurodevelopmental outcomes and decreased serum NO levels after administration; however, there may only be a brief window for benefit, because no improvement in long-term outcomes was seen with later treatment after birth asphyxia (Benders et al, 2006). Deferoxamine (DFO) is an iron chelator that decreases FR production by binding with iron and decreasing the production of OH^- that occurs via the Fenton reaction, while also stabilizing HIF-1α to produce its downstream products VEGF and EPO (Hamrick et al, 2005; Mu et al, 2005). DFO is protective during exposure to H_2O_2 or excitotoxicity in vitro, and in animal models of HI and transient ischemic stroke in vivo (Almli et al, 2001; Mu et al, 2005; Palmer et al, 1994; Sarco et al, 2000). *N*-Acetylcysteine (NAC) is a glutathione precursor and FR scavenger that attenuates lipopolysaccharide-induced white matter injury in newborn rats (Aruoma et al, 1989; Paintlia et al, 2004), but results for other antioxidant compounds, such as vitamin E, have been inconclusive (Brion et al, 2003).

ANTIEXCITOTOXICITY

There has long been a search for agents that decrease brain injury by decreasing excitotoxicity. Dizocilpine (MK801) is a noncompetitive NMDA receptor antagonist that has been studied in humans, but is poorly tolerated and has also been shown to increase apoptosis and decrease neuronal migration in animal models (Ikonomidou and Turski, 2002). Memantine is a low-affinity noncompetitive NMDA receptor antagonist that is well tolerated in adults for Alzheimer's-type dementia (Chen and Lipton, 2006). Post-HI treatment with memantine attenuates acute white matter injury in P6 rats, resulting in long-term histological improvement in vivo and restoring neuronal migration in vitro (Chen et al, 1998; Manning et al, 2008; Volbracht et al, 2006). Another method to decrease excitotoxicity is the use of topiramate, an AMPA-kainate receptor antagonist that is an FDA-approved antiepileptic for patients more than 2 years of age. It has been shown to protect newborn rodents from excitotoxic brain lesions, reducing brain damage and cognitive impairment when administered within 2 hours of the insult (Noh et al, 2006; Sfaello et al, 2005). An intravenous preparation of topiramate does not yet exist for human use, but this treatment shows potential as a therapy for early newborn seizure and injury.

Magnesium sulfate has shown some benefit in preventing white matter damage in animal models, and one

possible mechanism of its neuroprotection is the blockade of NMDA receptors (Khashaba et al, 2006; Marret et al, 1995; Spandou et al, 2007; Turkyilmaz et al, 2002). In a multicenter clinical trial of mothers treated with magnesium who were at risk for preterm delivery, no perinatal side effects were seen, and there was some benefit for the neurodevelopment of survivors (Crowther et al, 2003). However, magnesium administered to asphyxiated term neonates did not result in improvements in aEEG patterns and when given in larger doses was associated with profound hypotension (Groenendaal et al, 2002; Levene et al, 1995).

ANTI-INFLAMMATORY THERAPY

Maternal infection is a known risk factor for white matter damage and poor outcomes, such as cerebral palsy (Dammann et al, 2002; Wu et al, 2003a; Wu and Colford, 2000). The inflammatory response and cytokine production that accompanies infection may play a large role in cell damage and loss (Stirling et al, 2005). Local microglia is activated early and produces proinflammatory cytokines such as TNF-α, IL-1β, and IL-6, as well as glutamate, FRs, and NO. Systemic administration of these cytokines increases excitotoxic lesions (Dommergues et al, 2000), whereas therapies that block microglial activation and cytokine release protect the brain from excitotoxic damage (Dommergues et al, 2003).

Minocycline crosses the blood-brain barrier and has anti-inflammatory effects, including decreasing microglial activation and caspase-3 expression (Chen et al, 2000; Zhu et al, 2002), lipid peroxidation (Pruzanski et al, 1992), and other proinflammatory activity (Machado et al, 2006) while increasing antiapoptotic gene expression (Scarabelli et al, 2004; Wang et al, 2004a). It has shown promise in a number of animal models of neurodegenerative or ischemic disease (Chen et al, 2000; Choi et al, 2007; Du et al, 2001; Popovic et al, 2002; Yrjanheikki et al, 1999). In the neonatal brain, it appears to decrease tissue damage and caspase-3 activation in rodents when given immediately before or after injury, but results are inconsistent (Arvin et al, 2002; Cai et al, 2006; Fox et al, 2005). Low- and high-dose regimens are effective in reducing short-term HI-induced inflammation, protecting developing oligodendrocytes (Cai et al, 2006) and myelin content in neonatal rats (Carty et al, 2008), but this effect was only transient in another study of neonatal rodent stroke (Fox et al, 2005). Delayed therapy has been found to decrease TNF-α and matrix metalloproteinase MMP-12, but efficacy was lost when treatment was extended for a week after stroke (Wasserman et al, 2007). These effects also appear to be species dependent, with an increase in injury in developing C57B1/6 mice (Tsuji et al, 2004).

CELL DEATH INHIBITORS

Although necrosis plays a major role in early neuronal death following injury (Northington et al, 2001b), there is a spectrum of cell death that includes apoptosis (Portera-Cailliau et al, 1997) that may result in heterogeneous responses to antiapoptotic therapies (Northington et al, 2005). It is also probable that apoptosis and cleavage and activation of caspase-3 are responsible for more of the cell death that occurs in delayed phases of injury and neurodegeneration (Hu et al, 2000).

Specific and nonspecific inhibition of caspases or cysteine proteases has been attempted with some success (Blomgren et al, 2001; Feng et al, 2003; Han et al, 2002; Ostwald et al, 1993). For example, calpain or caspase-3 inhibitors such as MDL 28710 and M826 protect neonatal rats after HI (Han et al, 2002; Kawamura et al, 2005). Pretreatment with the hormone 17β-estradiol is neuroprotective in immature rats and appears to work through both antiapoptotic and FR-scavenging pathways (Nunez et al, 2007). In addition, the nuclear enzyme poly(ADP-ribose) polymerase (PARP) is activated during stress and enables DNA repair; however, the PARP-1 isoform also contributes to ischemic neuronal injury by depleting energy stores and activating microglia, leading to cell death. PARP-1 is more abundant in the immature brain, and its blockade protects against excitotoxicity and ischemic injury (Hagberg et al, 2004). The PARP-1 inhibitor 3-aminobenzamide reduces injury after focal ischemia in P7 rats (Ducrocq et al, 2000), but PARP-1 blockade appears to preferentially protect males (Hagberg et al, 2004).

STEM CELL THERAPY

Neural stem cells (NSCs) are multipotent precursors that self-renew and retain the ability to differentiate into a variety of neuronal and nonneuronal cell types in the CNS. They reside in neurogenic zones throughout life, such as the SVZ and the dentate gyrus of the hippocampus. In rodents, NSC transplantation has shown potential as a therapeutic strategy in adult animal models of brain injury. Implanted cells integrate into injured tissue (Park et al, 2002), decreasing volume loss and improving behavioral outcomes (Capone et al, 2007; Hicks et al, 2007; Hoehn et al, 2002; Park et al, 2006a, 2006b). In neonatal models, intraventricular implantation of NSCs after HI results in their migration to injured areas (Park et al, 2006a,b) and differentiation into neurons, astrocytes, oligodendrocytes, and undifferentiated progenitors. These cells promote regeneration, angiogenesis, and neuronal cell survival in both rodent and primate models, and nonneuronal progeny inhibit inflammation and scar formation (Imitola et al, 2004; Mueller et al, 2006). Although complications of implantation have not been noted in these models, efficacy does depend on time of implantation, and the therapeutic window is not known. More recent technology enables labeling of stem cells, which can then be tracked from the site of implantation through their migratory path into the ischemic tissue, making their identification and eventual outcome in humans feasible (Guzman et al, 2007; Modo et al, 2004; Rice et al, 2007).

COMBINATION THERAPY

Therapeutic hypothermia has become common practice in many institutions since showing benefit in moderately to severely encephalopathic newborns; however, it does not completely protect or repair an injured brain, so the search for adjuvant therapies continues. Combinatorial therapy may provide more long-lasting neuroprotection, salvaging

the brain from severe injury and deficits while also enhancing repair and regeneration, possibly providing additive, if not synergistic, protection.

Xenon is approved for use as a general anesthetic in Europe and has shown promise as a protective agent. It is an NMDA antagonist, preventing progression of excitotoxic damage. It appears to be superior to other NMDA antagonists, possibly through inhibition of AMPA and kainate receptors, reduction of neurotransmitter release, or effects on other ion channels (Dinse et al, 2005; Gruss et al, 2004; Ma and Zhang, 2003). In rats, combination xenon and hypothermia initiated 4 hours after neonatal HI provided synergistic histologic and functional protection when evaluated at 30 days after injury (Ma et al, 2005). Hypothermia does reduce glutamate and glycine release (Busto et al, 1989), and NMDA receptor antagonism may explain these effects. More recently, an additive effect was shown after HI in P7 rats that were cooled to 32°C and received 50% xenon, with improvement in long-term histology and functional performance that exceeded the individual benefit of either (Hobbs et al, 2008). More extensive studies on xenon use in human neonates are necessary.

As mentioned earlier, NAC is a medication approved for neonates that is a scavenger of oxygen radicals and restores intracellular glutathione levels, attenuating reperfusion injury and decreasing inflammation and NO production in adult models of stroke (Khan et al, 2004; Sekhon et al, 2003). Adding NAC therapy to systemic hypothermia reduced brain volume loss at both 2 and 4 weeks after neonatal rodent HI, with increased myelin expression and improved reflexes (Jatana et al, 2006). Inhibition of inflammation with MK-801 has also been effective when combined with hypothermia in neonatal rats post HI injury (Alkan et al, 2001). In P7 rats that underwent HI followed by early topiramate and delayed hypothermia, improved short-term histology and function was seen (Liu et al, 2004). This may provide a window for protection if hypothermia is delayed, which is possible given difficulty in initiation of cooling if infants are born at an outside hospital or transport is delayed.

SUMMARY

There continues to be an explosion of information regarding the pathophysiology and possible therapy of ischemic and traumatic injuries to the developing nervous system. The realization that the immature brain exhibits different pathogenetic mechanisms in response to these insults has led investigators to think differently about designing therapies for the immature brain. With continued investigations regarding the mechanisms of cell death in the immature brain, the development of age-appropriate neuroprotective strategies is not far behind.

CHAPTER 62

Neonatal Neuromuscular Disorders

Eugenio Mercuri and Marika Pane

In the past two decades, more than 200 loci responsible for neuromuscular disorders have been identified. This has resulted in new approaches to their classification and in a better definition of phenotype-genotype correlations and of the clinical and histopathologic features for each form. Although by definition all of the genetically inherited disorders should be considered congenital, in clinical practice the term *congenital* is generally applied to the forms with overt clinical signs in the neonatal period or in the first months after birth. These include disorders with primary muscle involvement, such as congenital myopathies and muscular dystrophies, motoneuron disorders, and disorders of the neuromuscular junction, such as neonatal myasthenia.

This chapter reviews the current state of knowledge of the neuromuscular disorders with neonatal onset, providing clinical, pathologic, and, when appropriate, radiologic details for each form. The final part of the chapter summarizes the steps in the diagnostic evaluation of hypotonic neonates in whom a neuromuscular disorder is suspected.

PRIMARY MUSCLE DISORDERS

There are a number of primary muscle disorders with early neonatal onset. These can be broadly subdivided into two groups: muscular dystrophies and congenital myopathies. Congenital muscular dystrophies (CMDs) and congenital myotonic dystrophy are the most common forms of dystrophies with neonatal onset, whereas other dystrophies that are overall more frequent in the pediatric population are, with a few exceptions, generally not clinically symptomatic in the first year. Whereas muscular dystrophies share severe disruption, with a typical "dystrophic pattern" on muscle biopsy, congenital myopathies generally have better preservation of the architecture of muscle fibers and less severe changes such as fiber type dysproportion.

In the past several years there has been increasing evidence that each of these two groups has a quite wide genetic heterogeneity. Although until recently their classification has been based mainly on histopathologic findings, after the recent discoveries of the underlying gene defects, the most recent classifications take into account and combine both histopathologic and genetic findings.

MUSCULAR DYSTROPHIES

Congenital Muscular Dystrophies

Congenital muscular dystrophies represent a heterogeneous group of disorders sharing some features, namely dystrophic changes on muscle biopsy and neonatal or early onset of weakness and often contractures (Dubowitz, 1994). Until recently, classification of CMD was based primarily on the presence or absence of merosin, an extracellular matrix protein found to be missing in approximately 35% to 45% of cases of CMD (Dubowitz, 1994; Tome et al, 1995) or on the presence of associated structural brain abnormalities (Dubowitz, 1994; Mercuri et al, 2001; Muntoni et al, 2002, 2004). In the past few years, the identification of several genes responsible for distinct clinical entities has helped to better classify these forms and to better understand the mechanisms underlying the different disorders.

We now recognize nine forms of CMD for which the genetic defect is known. Several additional forms will likely be discovered, based on their unique clinical and immunohistopathologic features. Table 62-1 shows the classification of the currently identified CMD forms. A comprehensive review of all the CMD forms is beyond the scope of this chapter and we will therefore describe the forms associated with alpha-dystroglycan (α-DG) deficiency and those with merosin deficiency that are the most commonly observed.

Alpha-Dystroglycanopathies

The major contribution to the new classification comes from the identification of a family of genes directly involved in the glycosylation of α-DG. Six of the nine genes identified so far are involved in this process and the forms of muscular dystrophies associated with them are collectively designated as alpha-dystroglycanopathies. These are a clinically and genetically heterogeneous group of autosomal recessive muscular dystrophies with variable neurologic and ophthalmic involvement sharing the common feature of hypoglycosylation of α-DG on skeletal muscle biopsy (Muntoni et al, 2002). To date, mutations in six known or putative glycosyltranferase genes have been identified in these disorders (Beltran-Valero de Bernabe et al, 2002; Brockington et al, 2001a; Kobayashi et al, 1998; Longman et al, 2003; van Reeuwijk et al, 2005a, 2005b; Yoshida et al, 2001).

1. Protein-O-mannosyl transferase 1 (*POMT1;* OMIM 607423)
2. Protein-O-mannosyl transferase 2 (*POMT2;* OMIM 607439)
3. Protein-O-mannose 1,2-N-acetylglucosaminyltransferase 1 (*POMGnT1;* OMIM 606822)
4. Fukutin (OMIM 607440)
5. Fukutin-related protein (*FKRP;* OMIM 606596)
6. LARGE (OMIM 603590)

The phenotypic severity of these forms is extremely variable. At the most severe end of the clinical spectrum are disorders characterized by CMD with severe structural brain and eye abnormalities including Walker-Warburg syndrome (WWS), muscle-eye-brain (MEB) disease, and Fukuyama congenital muscular dystrophy (FCMD). Individuals at the mildest end of the clinical spectrum may present in adult life with limb-girdle muscular dystrophies, with no associated brain or eye involvement (Brockington et al, 2001b).

Recent studies on large populations of patients have reported that known mutations can be detected in only about half the patients with clinical signs suggestive of an alpha-dystroglycanopathy, suggesting that other still-unknown genes are involved (Geodfrey et al, 2007; Mercuri et al, 2009).

As a group, patients with these forms of CMD often have relative hypertrophy of the lower limbs and wasting of the upper limbs and often have structural brain involvement. After the genes were identified, it was initially thought that each gene could be associated with distinct clinical entities, but it is now increasingly obvious that each of the six genes associated with α-DG deficiency may give rise to different phenotypes and, conversely, that each phenotype can be associated with mutations in any of the six genes (Clements et al, 2008; Mercuri et al, 2006, 2009).

We now describe the three forms that have been classically associated with specific structural brain and eye abnormalities (WWS, MEB, FCMD), but other patterns of brain involvement have also been identified (Clements et al, 2008).

Walker-Warburg Syndrome

Walker-Warburg Syndrome (WWS) is the most severe of the congenital muscular dystrophies with central nervous system (CNS) involvement. Severe weakness and neonatal hypotonia, associated with clinical signs of CNS involvement such as poor visual attention and decreased alertness, are invariably present (Dobyns et al, 1989). Ocular abnormalities, such as retinal dysgenesis, microphthalmia, and anterior chamber malformations, are also consistent findings.

Brain magnetic resonance imaging (MRI) (Figure 62-1) shows a type II lissencephaly with the typical micropolygyric cobblestone cortex; the white matter is also severely abnormal, showing dysmyelination or cystic changes (Dobyns et al, 1989). Cerebellar and brainstem hypoplasia is also always present.

Affected infants are often thought have an isolated CNS malformation until a markedly elevated serum creatine kinase (CK) suggests the presence of skeletal muscle involvement as well. The congenital muscular dystrophy diagnosis is then confirmed by pathologic studies.

Initially associated with mutations in the *POMT1* gene (Beltran Valero et al, 2002), the Walker-Warburg phenotype has now been associated with mutations in five of the α-DG genes (Clements et al, 2008; Geodfrey et al, 2007; Mercuri et al, 2006).

Muscle-Eye-Brain Disease

Clinical signs are usually present at birth or in the first months of life with hypotonia and weakness often associated with ocular abnormalities that may be milder than in WWS and may become evident only after the first years of life (Santavuori et al, 1989). Brain MRI shows extensive abnormalities of neuronal migration, such as pachygyria and polymicrogyria and often brainstem and cerebellar hypoplasia and periventricular white matter changes. Initially associated with mutations in the POMGnT1 gene (Yoshida et al, 2001), the muscle-eye-brain (MEB) phenotype has also been associated

TABLE 62-1 Congenital Muscular Dystrophy (CMD) Forms With Known Genetic Defects

Chromosome Locus	Gene	Protein Defect	Disease Phenotype(s)
6q22-23	*LAMA2*	Laminin α2	Primary merosin deficiency (MDC1A)

with mutations in all five of the other α-DG genes (Clements et al, 2008; Geodfrey et al, 2007; Mercuri et al, 2006).

Fukuyama Congenital Muscular Dystrophy

Fukuyama congenital muscular dystrophy (FCMO) is very rare outside of Japan. Clinical features include mild to moderate hypotonia at birth and progressive deterioration with increasing weakness, joint contractures, high CK levels, moderate to severe mental retardation, and frequent association with epilepsy. Ocular abnormalities occur in approximately 70% of these children but are rarely severe. Brain MRI shows structural changes consisting of pachygyria and polymicrogyria and low-density white matter areas. The gene responsible for FCMD is another glycosyltransferase named fukutin (Osawa et al, 1997).

Other Forms of Alpha-Dystroglycanopathies

Some patients with alpha-dystroglycanopathies may have cerebellar hypoplasia or dysplasia that can be present in isolation (Topaloglu et al, 2003) or associated with more diffuse structural brain changes (Clements et al, 2008; Mercuri et al, 2006).

As a rule of thumb, whenever an infant has structural brain abnormalities, especially if associated with eye abnormalities and clinical signs of weakness, it is useful to obtain serum CK levels. With very few exceptions, all reported cases have increased serum CK levels (>5 times the normal levels).

Merosin-Deficient Congenital Muscular Dystrophy

Merosin-deficient congenital muscular dystrophy, classified as MDC1A, is an autosomal recessive form due to mutations in the *LAMA2* gene on chromosome 6, encoding merosin (laminin a2), an extracellular matrix protein (Tome et al, 1994).

Children with merosin deficiency are usually symptomatic at birth or in the first few weeks of life with hypotonia and muscle weakness, weak cry and, in 10–30% of cases, contractures. Weakness often affects upper limbs more than lower limbs. These infants may present with feeding and respiratory problems, although these tend to resolve in the first months. Serum CK levels in these children are always grossly elevated (10 times the normal values). There is severe motor delay, and children never acquire independent ambulation (Philpot et al, 1995).

Brain MRI (Figure 62-2) shows diffuse white matter changes that are a typical feature of merosin-deficient CMD (Philpot et al, 1995). However, these changes become evident only at about 6 months of age. These findings are not obvious on conventional MRI scans performed in the first months of life (Mercuri et al, 1996), though they can be suspected with use of more sensitive T2-weighted images (Mercuri et al, 2000).

Some studies have demonstrated that other patterns of brain lesions, such as cerebellar hypoplasia and/or cortical dysplasia (Sunada et al, 1995), can be observed in approximately 10% of children with merosin-deficient congenital muscular dystrophy.

Congenital Myotonic Dystrophy

The neonatal form of myotonic muscular dystrophy differs from the adult form both clinically and pathologically. Infants with congenital myotonic dystrophy are often born after a pregnancy complicated by polyhydramnios and reduced fetal movements. At birth, clinical signs include weakness, hypotonia, and often severe contractures affecting feet (bilateral equinovarus talipes deformity), knees, and hips, at times dislocated. Marked difficulty in sucking and swallowing is often present in association with striking facial weakness, with a triangular open mouth.

There is also often respiratory muscle weakness, and mechanical ventilation is often required at least in the first weeks of life. Severe neonatal feeding difficulties are also present and require nasogastric tube feeding for several months even in infants who breathe spontaneously.

Both respiratory and feeding difficulties tend to lessen over the first months of life, and gastrostomy tube placement is very rarely needed. The duration and severity of respiratory involvement are important determinants of the long-term survival of these infants. Previous studies have indicated that need for mechanical ventilation for more than 4 weeks in a term infant is a negative prognostic factor for long-term survival (Rutherford et al, 1989).

It is important to recognize that many of the signs invariably present or frequently found in the adult form (such as clinically evident myotonia or cardiac and ocular abnormalities) are often not present in the neonatal period.

The muscle biopsy is not needed in children with congenital myotonic dystrophy. A detailed pedigree and the examination of the mother are generally strongly indicative of the diagnosis because, although myotonic dystrophy is an autosomal dominant trait, the mother is the transmitting parent in 94% of cases (Harper et al, 1992). On detailed examination, the mother generally has features such as facial weakness, mild ptosis, a stiff smile, an inability to bury the eyelashes, and/or or grip myotonia. In most cases, maternal signs are very mild, and the mother is often unaware of being affected.

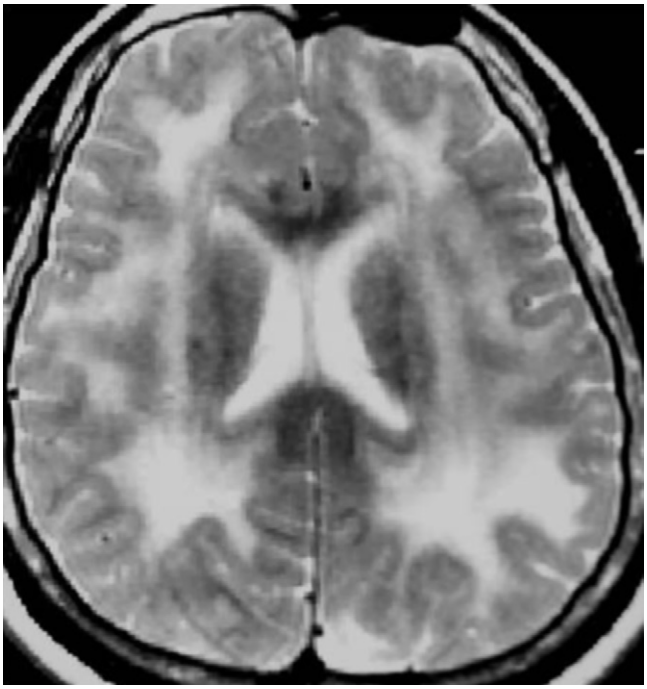

FIGURE 62-2 Brain MRI showing diffuse white matter changes in merosin-deficient congenital muscular dystrophy.

Percussion myotonia on clinical examination and myotonic discharge on electromyography (EMG) will help to further support the diagnosis, which can then be confirmed by molecular genetic testing. This latter is performed by looking at the expansion (increase in the number of CTG trinucleotide repeats) in the *DMPK* gene on chromosome 19. The female locus is more unstable than the male locus—hence the predominance of maternal transmission (Mulley et al, 1993).

Other Forms of Muscular Dystrophies

In the most common forms of muscular dystrophies occurring in pediatric population, such as Duchenne or limb girdle muscular dystrophies, the onset of clinical signs is generally well beyond the 1st year of age. However, it should be mentioned that neonatal or early onset has occasionally been reported in individual cases of specific late-onset forms such as facioscapuloperoneal muscular dystrophy. We and others have found that the dominantly inherited form of Emery-Dreifuss muscular dystrophy, caused by mutations in the LMNA gene, can have a very early presentation with reduced fetal movements and severe hypotonia and weakness at birth with marked involvement of the neck muscles (D'Amico et al, 2005; Mercuri et al, 2004; Quijano-Roy et al, 2008).

An important clinical issue is whether to perform diagnostic screening in an asymptomatic neonate with a positive family history, and if so, when. Performing genetic testing without muscle biopsies makes it easier to have an early diagnosis if the parents are concerned or if this is desired for prognosis, management, or genetic counseling.

CONGENITAL MYOPATHIES

The term *congenital myopathies* refers to a group of genetically inherited primary myopathies characterized by "nondystrophic" changes on muscle biopsies (for a recent review, see Sewry et al, 2008). Unlike muscular dystrophies, these myopathies tend to be relatively nonprogressive even though respiratory muscle weakness may affect prognosis.

This group of disorders is clinically, biochemically, and genetically very heterogeneous. Until recently, the classification of congenital myopathies was based mainly on clinical criteria and histopathologic findings, and the names of these conditions derive from the typical muscle histopathologic findings, which separated those forms with rods from those with cores. However, identification of mutations in different genes has dramatically advanced our understanding of their molecular basis. As with CMDs, there is increasing evidence that the boundaries between defined conditions are often indistinct. Mutations in the same gene can give rise to diverse clinical and histopathologic phenotypes, and conversely, the same phenotype can arise from mutations in a variety of genes (Sewry et al, 2008).

The generic term *congenital myopathy* for the group as a whole is probably a reasonable one, although not all cases are strictly "congenital" with symptoms presenting at birth. Indeed, many cases clinical manifestations may appear much later (Dubowitz, 1995). In order of frequency, the conditions that are more frequent in the neonatal period are nemaline myopathy, central core disease, myotubular myopathy, and minicore disease. Both minicore and central core disease manifest more frequently in early infancy than in the neonatal period, although earlier presentation is possible (Jungbluth, 2004).

Clinically, there are some common presenting features that point to a diagnosis of congenital myopathy, although it is difficult to distinguish among the individual diseases. In neonatal-onset forms, the primary clinical signs are floppiness, often associated with contractures, and weakness that often affects the facial muscles. In nemaline myopathy, minicore disease, and myotubular myopathy, there is a significant tendency to develop progressive respiratory failure, probably related to diaphragmatic involvement. Unlike the muscular dystrophies, the serum CK levels are frequently normal or only mildly elevated. The electromyography (EMG) traces may also be normal or may show mild, nonspecific changes. In all cases, these clinical findings alone will not be enough, and muscle biopsy is the only way to make a definitive diagnosis. It also helps in selecting the most appropriate genetic tests.

Table 62-2 shows a summary of the conditions that have been recognized to date. Generally, the names reflect the underlying structural change.

Nemaline Myopathy

Nemaline myopathy takes the name from the rods observed on muscle biopsy resembling threadlike structures (Greek: *nema*, "thread"). The clinical spectrum of nemaline myopathies is wide, ranging from early-onset neonatal forms to others in which affected individuals develop mild weakness only much later in life. In the neonatal period, there are two main modalities of presentation. In the "classical" congenital form, infants show hypotonia, general weakness predominantly affecting facial and axial muscles, and bulbar and feeding difficulties, requiring frequent suctioning, tube feeding, and gastrostomy. The other form is even more severe: Affected infants have a history of polyhydramnios and, at birth, present with arthrogryposis, severe weakness with complete immobility and respiratory failure, and severe feeding difficulties. Mild dysmorphic features compatible with a fetal akinesia sequence are common. There are cases in between the "classical" variant and this severe form.

The prognosis is always poor for children with the severe congenital form, and fetal akinesia without any improvement of tone, weakness, or bulbar and respiratory function even after several months. The prognosis for the classical form is in contrast much better, with steady improvement most children acquire independent ambulation, even though other signs of the disease such as failure to thrive, scoliosis, and nocturnal hypoventilation are frequent, even in ambulant children.

The serum CK levels are usually normal or only mildly elevated. The muscle biopsy typically shows a well-formed muscle with mild or moderate variability of fiber size, no necrosis or degenerative change, and an abundance of rod-like structures in muscle.

TABLE 62-2 The Most Common Congenital Myopathies With Known Gene Defects

	Gene	Chromosomal Locus	Inheritance*	Protein
Nemaline Myopathy	*ACTA1*	1q42	AD or AR	Skeletal α-actin
	NEB	2q2	AR	Nebulin
	TPM3	1q2	AD	α-Tropomyosin
	TPM2	9p13	AD	β-Tropomyosin
	TNNT1	19q13	AR	Troponin T
	CFL2	14q12	AD	Cofilin-2
Congenital Myopathies With Cores				
Central core disease	*RYR1*	19q13	AD or AR	Ryanodine receptor
Multiminicore disease	*SEPN1*	1P36	AR	Selenoprotein N1
Central Nuclei and Centronuclear Myopathies				
Myotubular myopathies	*MTM1*	Xq28	XLR	Myotubularin
Centronuclear myopathies	*DNM2*	19q13	AD	Dynamin 2
	BIN1	2q14	AR	Amphiphysin
	RYR1	19q13	AR	Ryanodine receptor

**AD*, Autosomal dominant; *AR*, autosomal recessive; *XLR*, X-linked recessive.

Nemaline myopathy is genetically heterogeneous, with at least five genes now implicated in its pathogenesis:

1. Slow α-tropomyosin (*TPM3*) (Laing et al, 1995)
2. Nebulin (*NEB*) (Pelin et al, 1999)
3. Skeletal muscle α-actin (*ACTA1*) (Nowak et al, 1999)
4. β-tropomyosin (*TPM2*) (Donner et al, 2002)
5. Muscle troponin T (*TNNT1*) (Johnston et al, 2000)

Prenatal diagnosis is therefore now available for the genetically defined variants. For example, most of the classical milder congenital forms are due to recessive mutations in the *NEB* gene (Pelin et al, 1999), whereas the great majority of the severe forms have de novo dominant mutations in the *ACTA1* gene (Nowak et al, 1999). Recessive mutations in the slow α-tropomyosin (*TPM3*) gene have been implicated in one homozygous case with early severe presentation (Tan et al, 1999). With few exceptions, the rest do not have mutations in the five known genes and are probably due to mutations in an as yet unidentified gene.

Central Core Disease

Central core disease (CCD) is the most common congenital myopathy. Several hundred cases have now been documented, but this most common form does not always have a neonatal onset. Delayed motor milestones and weakness usually occur in infancy or early childhood, although contractures at birth (equinovarus foot deformity, hip dislocation) are frequently found. However, a number of patients at the severe end of the spectrum have early neonatal presentation with severe arthrogryposis and scoliosis. Severe facial and respiratory muscle weakness and bulbar dysfunction are also present (Sewry et al, 2002).

A novel severe dominant and recessive variant of early-onset central core disease with antenatal onset, fetal akinesia, and, in addition to weakness and severe contractures, severe facial weakness and ptosis has also been reported (Romero et al, 2003).

The prognosis of these forms is variable and often reflects the severity of presentation. In milder forms, the natural course is static or only slowly progressive, with most affected individuals achieving the ability to walk. In the severe form, most affected children die in infancy, although in some patients the long-term outcome can be less severe (Romero et al, 2003).

Serum CK activity is usually normal or only moderately elevated. The biopsy typically shows massive type I myofiber predominance, and predominantly central, corelike areas on oxidative stains; however, these striking abnormalities may develop only after several years despite the congenital onset of muscle weakness. Marked type I predominance or uniformity may be the only abnormal feature in these cases at an early age. CCD is commonly transmitted as an autosomal-dominant trait with variable penetrance, and examination of the parents and a detailed family history may help to clarify the diagnosis.

Malignant hyperthermia susceptibility is a common complication, and all patients should thus be considered at risk. In most affected cases, genetic analysis shows dominant missense mutations in the ryanodine receptor (*RYR1*) gene at 19q13.1, the same genetic mutation as in malignant hyperthermia. The gene encodes a tetramer "ryanodine" receptor to a calcium channel of the sarcoplasmic reticulum within the myofiber (Ferreiro et al, 2002; Jungbluth et al, 2002).

De novo dominant mutations are common and account for a majority of sporadic cases, even though recessive pedigrees have also been reported (Jungbluth et al, 2007).

Minicore Myopathy (Multicore Disease)

Minicore myopathy is a rare condition, that usually does not manifest clinically in the neonatal period. The most common phenotype features marked axial weakness with

spinal rigidity, scoliosis, and respiratory failure in late childhood. At least two genes are responsible for minicore disease: (1) the *SEPN1* gene (the same gene that, when disrupted, can give rise to rigid spine syndrome, suggesting that the two conditions are allelic) and (2) recessive *RYR1* gene mutations (Ferreiro et al, 2002; Jungbluth et al, 2007).

Myotubular (Centronuclear) Myopathy

Myotubular myopathy derives from its muscle biopsy description: numerous centrally placed (centronuclear) nuclei with a surrounding central zone devoid of oxidative enzyme activity. The clinical phenotype of myotubular (centronuclear) myopathy is highly variable, ranging from severe neonatal forms to milder forms with later onset, depending in part on the mode of inheritance. The severe neonatal phenotype is due to the more common X-linked form and is characteristically that of a male infant presenting with polyhydramnios, reduced fetal movement, and, after birth, with marked hypotonia, a variable degree of external ophthalmoplegia, respiratory failure, dysphagia, and often undescended testes (Barth et al, 1975; Sarnat et al, 1990, 1994). The disease is often fatal, but severely affected infants who are ventilator-dependent in the neonatal period may survive if they are maintained on a ventilator, although they will have almost complete lack of motor developmental progress. The autosomal recessive forms are more variable, ranging from early presentation with marked weakness and inability to walk to milder variants. The gene for the X-linked variant is the myotubularin gene (*MTM1*) on chromosome X a q28 (Laporte et al, 1997).

MOTOR NEURON DISORDERS

SPINAL MUSCULAR ATROPHY

The term *spinal muscular atrophy* (SMA) includes a group of disorders characterized by a progressive degenerative disease of spinal and brainstem motoneurons. The most frequent forms of motoneuron involvement in infancy are related to mutations in the survival motor neuron (SMN) gene on chromosome 5. This includes a wide range of clinical forms ranging from severe neonatal-onset forms to those occurring only in adulthood with very mild signs. From a practical standpoint, the classification of SMA takes into account the age at onset and the child's ability to sit unaided and to stand and walk unaided:

1. Severe: Unable to sit unsupported, with onset at birth or in the first months.
2. Intermediate: Able to sit unsupported. Unable to stand or walk unaided.
3. Mild: Able to stand and walk.

This classification is useful in clinical practice (Dubowitz, 1995), but it should be recognized that within each subdivision, there is a wide variability with an overall continuum of severity.

In severe SMA, also called Werdnig-Hoffmann disease or type I SMA, the onset is early, either in utero or within the first 2–3 months of life. In infants who do not show overt clinical signs at birth, the onset may be sudden, and a previously active infant may suddenly lose the ability to move the limbs.

The clinical features in type I SMA are very typical. The posture is characterized by involvement of the internal rotators of the shoulders that gives the arms an internally rotated, "jug-handle" position by the side of the body, with the hands facing outward. This posture is secondary to weakness and not to contractures, because these are not features of severe SMA, even though mild contractures may occur in patients who are not adequately mobilized.

Strikingly, there is no facial weakness, and the child's expression appears normal, this being in contrast with the severe weakness affecting the axial and limb muscles. There is generalized marked hypotonia with almost complete absence of movements and marked weakness that involves both axial and limb muscles (Figure 62-3, *A* and *B*). In the neonatal-onset forms, infants with type I SMA generally do not achieve good head control, although this milestone can be achieved and maintained in a proportion of those who have onset after the neonatal period.

The lower limbs are more affected than the upper, and the proximal muscles more than distal. Very often the movements are restricted to the feet and to the distal part of both upper and lower limbs, with some antigravity movements of fingers and toes. Some infants may also be able to flex and extend the elbows, but without any antigravity movements at the shoulders or upper arm level or in the legs. These infants never achieve the ability to roll over spontaneously. Tendon reflexes are always absent. The intercostal muscles are also severely affected, and

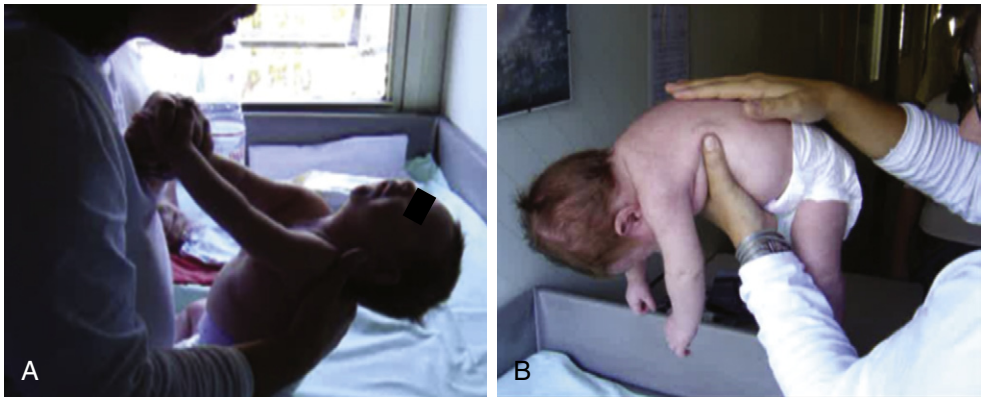

FIGURE 62-3 Severe hypotonia and weakness affecting axial muscles **(A)** and limbs **(B)** in an infant affected by spinal muscular atrophy.

breathing is almost entirely diaphragmatic. This gives the chest a bell-shaped appearance with costal recession and with associated distention of the abdomen with inspiration.

A classic feature of infantile SMA is bulbar weakness with difficulty in sucking and swallowing and an associated accumulation of mucus in the pharynx. These signs may occur at presentation or later during the 1st year and help to distinguish the disease from other neuromuscular disorders presenting in early infancy, which do not have this selective respiratory muscle involvement and frequently have evidence of diaphragmatic weakness. In SMA patients, the cry is often weak and ineffectual, as is any effort at coughing.

The combination of severe weakness and hypotonia, typical posture, absence of tendon reflexes, sparing of the facial muscles, and bell-shaped chest with predominant diaphragmatic breathing pattern are fairly consistent features of SMA and are strongly suggestive of the diagnosis on initial neonatal assessment. EMG shows fibrillation potentials and other signs of denervation of muscle, but findings are often nonspecific in neonates. In the past, when genetic testing was not available, a muscle biopsy was routinely performed, showing a characteristic pattern of peripheral denervation. With genetic testing now readily available and providing reliable results in approximately 95% of cases, muscle biopsy is no longer performed and the diagnosis is made by finding deletions in the SMN gene (Wang et al, 2007).

Until recently, studies of the natural history of type I SMA reported a very poor prognosis with a mean age at death of approximately 8 months. Affected infants are prone to recurrent respiratory infections and rarely survived beyond the first 2 years of life unless tracheotomy was performed. For many years, management of tracheotomy and chronic mechanical ventilation was the only option available to prolong survival. This approach was strongly discouraged by most clinicians because of quality-of-life concerns. However, the natural history of type I SMA has recently changed considerably (Oskoui et al, 2007). In the past few years there has been increasing evidence that infants with type I SMA should be treated with noninvasive ventilator support as early as possible, because this prevents intermittent hypoxia and hypercapnia (especially at night) and also helps to expand the chest muscles. Other measures, such as performing gastrostomy at the onset of swallowing problems or even before their onset, have further decreased the chances of reduced survival related to poor growth and aspiration. Although there are no systematic double-blind studies to establish the long-term effect of these management strategies on survival, they have become routine in many centers. Recent reports have shown clearly increased overall survival rates for these children and improved recovery from acute respiratory infections (Bertini et al, 2005; Wang et al, 2007).

NONSPINAL MUSCULAR ATROPHY MOTOR NEURON DISEASES

Motor neuron diseases that are not linked to mutations in chromosome 5 are rare in neonates. Among these, two often have onset at birth and should be taken into account when dealing with infants with clinical and neurophysiologic signs of motoneuron involvement. In both, there are signs that are different from those found in type I SMA that help in the differential diagnosis. The two forms include *diaphragmatic SMA* (Grohmann et al, 2001; Mercuri et al, 2000) and the form with *pontocerebellar hypoplasia* (Barth et al, 1993).

Diaphragmatic Spinal Muscular Atrophy

Diaphragmatic SMA, also known as spinal muscular atrophy with respiratory distress (SMARD), is also characterized by motoneuron involvement, but unlike the "classical SMA" linked to chromosome 5, in this form there is diaphragmatic weakness, with early onset of life-threatening respiratory failure (Rudnik-Schöneborn et al, 2004). This is due to severe diaphragmatic paralysis with elevation of both hemidiaphragms on chest radiograph. In typical SMA, the diaphragm is spared and the intercostal muscles are more severely affected. The distribution of weakness is another marked difference between the classical SMA, because in SMARD the distal and not the proximal muscles are predominantly involved. SMARD is a clinically and genetically heterogeneous condition. SMARD1 results from mutations in the gene encoding the immunoglobulin-binding protein 2 (*IGHMBP2*) on 11q13 (Groham et al, 2001; Guenther et al, 2007).

Pontocerebellar Hypoplasia

Pontocerebellar hypoplasia is a progressive degenerative disease involving both motoneurons and the CNS, the latter including hypoplasia of the cerebellar vermis and often of the cerebellar hemispheres, associated with a thin brainstem and pons (Barth et al, 1993). In affected infants, clinical signs relate to both motoneuron and CNS involvement. The clinical course is progressive, and respiratory and feeding difficulties, already present at birth or in early infancy, become increasingly severe. This form is not allelic to SMA, and the genetics of these forms have only recently been identified (Budde et al, 2008; Renbaum et al, 2009).

Finally, it should be mentioned that involvement of motor neurons can also be found in the Pena-Shokeir sequences with motoneuron signs associated with arthrogryposis and with normal *SMN* gene expression (Hageman et al, 1987) and in several metabolic diseases of the nervous system, even though the signs of denervation are often obscured by the more prominent CNS or muscle involvement.

MYASTHENIA GRAVIS

TRANSIENT NEONATAL MYASTHENIA

Approximately 20% of infants born to mothers with acquired myasthenia gravis may have transient signs of myasthenia for several days to weeks, as a result of transplacental transfer of maternal antibodies directed against the acetylcholine receptor (AChR). There is no direct correlation between the severity of maternal myasthenia and neonatal clinical signs. In fact, neonatal myasthenia may occur not only in mothers with a known diagnosis but in infants born to undiagnosed mothers who have subclinical

disease but are positive for AchR antibody (Papazian et al, 1992). Onset of clinical signs generally occurs within several hours after birth and always within the first 3 days and include respiratory insufficiency, inability to suck or swallow, and generalized hypotonia and weakness with facial involvement. Ptosis is not always present, but signs of fatigability can be observed, especially during feedings. Ventilatory support and feeding by gavage may be needed during this period. Recovery is anticipated by 2 months in 90% and by 4 months in most infants.

Once the first signs appear, diagnosis can be confirmed by anticholinesterase administration. Positive AchR antibodies in the infant or the mother provide further evidence, but their absence does not rule out the diagnosis. Overall management aims at supporting feeding and ventilation until spontaneous recovery occurs. In symptomatic infants, neostigmine (or pyridostigmine) should be given orally or by nasogastric tube until the infant is no longer symptomatic.

CONGENITAL MYASTHENIC SYNDROMES

Congenital myasthenic syndromes are inherited disorders resulting in neuromuscular transmission dysfunction. These are not related to maternal myasthenia and are nearly always permanent disorders (Engel et al, 2001, 2003). Inheritance is autosomal recessive, except with slow channel syndrome, which is autosomal dominant. Depending on the site and mechanism of the neuromuscular transmission defect, they are classified into presynaptic, synaptic, and postsynaptic categories. Presentation in the early neonatal period is less common and is mainly limited to the forms with episodic apnea (familial infantile myasthenia) and endplate acetylcholinesterase deficiency. Neonates with congenital myasthenia gravis do not experience myasthenic crises or exhibit elevations of AChR antibodies in plasma.

Most of the syndromes will respond to acetylcholinesterase inhibitors. An exception is the slow channel syndrome. Patients with this form do not respond to acetylcholinesterase inhibitors, and in some cases a worsening has been reported after their administration.

INVESTIGATION OF NEUROMUSCULAR DISEASES IN THE NEONATE

The field of inherited muscle disorders has become increasingly complex. The level of genetic heterogeneity is far greater than initially appreciated, and genetically different conditions often share similar clinical and histopathologic phenotypes. For disorders in which the genetic defect is known, a definitive diagnosis can be made by screening for the known genes. However, as the number of proteins and genes that can be potentially screened for enlarges, additional tools for selecting the appropriate genetic and biochemical markers are required. Muscle biopsy generally provides important clues for determining the most appropriate investigations, but clinical examination still plays an important role both in detecting a neuromuscular disorder and in the differential diagnosis with other causes of hypotonia in the newborn infant. Hypotonia is the most typical and common sign of neuromuscular involvement in the newborn infant but can also present in many nonneuromuscular disorders, and, in some cases, the differential diagnosis can be quite difficult.

CLINICAL EXAMINATION

A detailed clinical examination and a good clinical and obstetric history provide in many cases the foundation to distinguish infants with peripheral involvement from those with CNS involvement, and, in some cases, provide important clues for a more specific diagnosis.

In a large cohort of 83 infants referred for evaluation of hypotonia, neuromuscular disorders were identified in 47% of infants. The investigators found that the presence of weakness and contractures had a very high sensitivity and high specificity to detect neuromuscular disorders (Vasta et al, 2005). Other presenting signs of neuromuscular disorders included arthrogryposis, feeding difficulties, sudden episodes of collapse, and unexplained respiratory failure. Reduced fetal movements and polyhydramnios are also frequent in infants with neuromuscular disorders and suggest weakness with onset in utero (Vasta et al, 2005).

CREATINE KINASE

The chances of detecting a neuromuscular disorder further increase if the infant's serum CK levels are increased. However, a normal CK level does not exclude the possibility of a neuromuscular disorder, because the enzymatic levels are normal or only mildly elevated in congenital myopathies such as SMA.

ELECTROMYOGRAPHY

EMG may help at this stage in patients with motor neuron disorders and in other primary myopathies, but it is considered less reliable than at older ages both for technical reasons and because some features may not develop until the pathologic process has progressed further.

MUSCLE BIOPSY AND GENETIC STUDIES: WHICH ONE COMES FIRST?

Muscle biopsy is generally the next step. However, before performing the biopsy, one should exclude disorders that can be suspected from clinical examination and confirmed by genetic analysis, in which case muscle biopsy can be avoided. The two disorders that can be more easily diagnosed on clinical examination are type I SMA and congenital myotonic dystrophy. In SMA, the combination of these clinical signs previously described with evidence of denervation on EMG is a very strong indicator of the disease, which can then be confirmed by genetic analysis (see earlier discussion). Similarly, weakness and hypotonia in an infant with contractures (sometimes associated with facial weakness and respiratory and bulbar involvement) should prompt an investigation of the mother, who may show clinical or EMG signs of myotonia. These cumulative findings may then point to a diagnosis of congenital myotonic dystrophy which can be confirmed by genetic analysis.

In contrast, when the clinical examination, serum CK levels, and possibly the EMG are suggestive of a congenital myopathy or a congenital muscular dystrophy, a muscle biopsy should be done. The biopsy is needed not only to confirm possible muscle involvement but also to detect possible structural changes that may help to define the type of myopathy (e.g., rods, cores, fiber predominance); to study the expression of proteins such as merosin or α-DG; and to ultimately determine the definitive diagnosis and select the most appropriate genetic investigations.

IMAGING STUDIES

In view of all the recent findings on the forms of CMDs associated with CNS involvement, it has become mandatory to perform imaging studies in hypotonic infants in order to detect possible major or minor brain abnormalities that will help determine a diagnosis. Conversely, in infants in whom brain imaging has shown cerebellar hypoplasia or other structural brain abnormalities, it is important to perform appropriate clinical investigations to detect possible signs of weakness and or contractures that may suggest possible muscle involvement. In these patients, the evaluation of serum CK may provide additional information, because with few exceptions, all forms of congenital muscular dystrophies with structural brain involvement reported thus far have very high serum enzymatic levels (Geodfrey et al, 2007; Mercuri et al, 2009).

CHAPTER 63

Neonatal Seizures

Mark S. Scher

Neonatal seizures are one of the few neonatal neurologic conditions that require immediate medical attention. Although prompt diagnostic and therapeutic interventions are needed, multiple challenges impede the physician's evaluation and management of the newborn with suspected seizures (Table 63-1) (Scher, 1997a, 2001b, 2002; Scher and Beggarly, 1989). Clinical and electroencephalographic manifestations of neonatal seizures vary dramatically from those in older children, and seizure recognition remains the foremost challenge to overcome. This dilemma is underscored by the brevity and subtlety of the clinical repertoire of the neonatal neurologic examination. Environmental restrictions in an intensive care setting—the sick infant may be confined to an incubator, intubated, and attached to multiple catheters—limit accessibility by caregivers. Medications alter arousal and muscle tone and limit the clinician's ability to detect clinical neurologic signs reflective of the underlying disease state. Brain injury from antepartum factors may precipitate neonatal seizures as part of an encephalopathic clinical picture during the intrapartum and neonatal periods (Scher, 1994, 2006), well beyond when brain injury occurred. Overlapping medical conditions from fetal through neonatal periods must be factored into the most appropriate etiologic algorithm that explains seizure expression before application of the most accurate prognosis. Medication options that effectively treat seizures remain elusive and may need to be designed and utilized on the basis of the underlying diagnosis (Scher, 2001a, 2006; Silverstein et al, 2008). This chapter presents issues regarding recognition, differential diagnosis, prognosis, and treatment of neonatal seizures, in the context of current neurobiologic and pathophysiologic explanations or causes for neonatal seizures and consequential brain injury.

DIAGNOSTIC DILEMMAS: CLINICAL VERSUS ELECTROENCEPHALOGRAPHIC CRITERIA

Because neonatal seizures are generally brief and subtle in clinical appearance, unusual behaviors may be difficult to recognize and classify. The most common practice in many neonatal intensive care units (NICUs) is to rely on clinical behaviors to identify seizures, without confirmation by electroencephalography (EEG). Motor or autonomic behaviors, however, may represent normal gestational age- and state-specific behaviors in healthy infants or, alternatively, nonepileptic paroxysmal conditions in encephalopathic infants. Medical personnel also vary significantly in their ability to recognize suspicious behaviors; this variability will contribute to overdiagnosis or underdiagnosis. Therefore, confirmation of suspicious clinical events as seizures using coincident EEG recordings is now strongly recommended. Using either routine EEG studies (Glauser and Clancy, 1992) or continuous synchronized video-EEG-polygraphic recordings (Mizrahi and Kellaway, 1998), more reliable start and end points of electrographically confirmed seizures can be established before decisions are made regarding treatment intervention. Rigorous physiologic monitoring of non–central nervous system (CNS) measures also assists in the recognition and management of seizures.

CLINICAL SEIZURE CRITERIA

The International League Against Epilepsy's classification adopted by the World Health Organization still considers neonatal seizures within an unclassified category (Commission, 1981). A more recent classification scheme suggests a stricter distinction of clinical seizure (nonepileptic) events from electrographically confirmed (epileptic) seizures with respect to possible treatment interventions (Mizrahi and Kellaway, 1998). Continued refinement using novel seizure classifications is needed to reconcile disagreements between clinical and EEG criteria, which impede a correct seizure diagnosis.

Several caveats useful in the evaluation for suspected neonatal seizures are listed in Box 63-1.

Clinical criteria for neonatal seizure diagnosis were historically subdivided into five categories: focal clonic, multifocal or migratory clonic, tonic, myoclonic, and subtle seizures (Volpe, 2001). A more recent classification expands these clinical subtypes, adopting a strict temporal occurrence of specific clinical events with coincident electrographic seizures, to distinguish neonatal clinical "nonepileptic" seizures from "epileptic" seizures (Mizrahi and Kellaway, 1998) (Table 63-2).

Subtle Seizure Activity

Subtle seizure activity—now termed *motor automatisms and buccolingual movements*—is the most frequently observed category of neonatal seizures. Before a seizure evaluation is initiated, the normal occurrence of alterations in cardiorespiratory regularity, body movements, and other behaviors during active sleep (rapid eye movement [REM] sleep), quiet sleep (non-REM [NREM] sleep), or waking states should be appreciated (Da Silva et al, 1998; Scher, 1996). In any event, paroxysmal activity that interrupts the expected behavioral repertoire of the newborn infant and appears stereotypic or repetitive should heighten the clinician's level of suspicion for seizures. Repetitive buccolingual movements, orbital-ocular movements, unusual "bicycling" or "pedaling," and autonomic signs are examples of this seizure category (Figure 63-1). Periodic alterations in heart rate, blood pressure, or oxygenation or other autonomic signs are particularly helpful clues to seizure

TABLE 63-1 Dilemmas Regarding Neonatal Seizures

Diagnostic choices	Reliance on clinical vs. electroencephalographic criteria
Etiologic explanations	Multiple prenatal/neonatal conditions with variable times of onset and duration
Treatment decisions	Who, when, how, and for how long?
Prognostic questions	Consider mechanisms of injury based on underlying disorder vs. intrinsic vulnerability of the immature brain to prolonged seizures

BOX 63-1 Caveats Concerning Recognition of Neonatal Seizures

- Stereotypic behaviors occur in association with normal neonatal sleep or waking states, medication effects, and gestational maturity.
- Any abnormal repetitive activity may be a clinical seizure if out of context for expected neonatal behavior.
- Document coincident electrographic seizures with the suspected clinical event.
- Abnormal behavioral phenomena with inconsistent relationships with coincident electroencephalographic seizures suggest a subcortical seizure focus.
- Nonepileptic pathologic movement disorders are independent of the seizure state.

activity during pharmacologic paralysis for ventilatory care. Autonomic expressions, however, also are intermixed with somatic findings. Isolated autonomic signs such as apnea are rarely associated with coincident electrographic seizures (Fenichel et al, 1980). Synchronized video-EEG-polygraphic recordings are now preferred to document temporal relationships between clinical and electrographic events (Mizrahi and Kellaway, 1998; Scher, 1997a, 2001b). Despite the "subtle" expression of this seizure category, affected children may suffer significant brain injuries.

Clonic Seizures

Rhythmic movements of body parts that consist of a rapid flexion phase followed by a slower extensor movement may be *clonic seizures*, to be distinguished from the symmetric "to-and-fro" movements of nonepileptic tremulousness or jitteriness (Scher, 2001b). Gentle flexion of the affected body part easily suppresses the tremor, whereas clonic seizures persist. Clonic movements can involve face, arm, leg, or respiratory or pharyngeal muscles (Figure 63-2, *A* and *B*). Generalized clonic activities also can occur but rarely consist of the classic tonic followed by clonic phases, characteristic of the generalized motor seizure noted in older children and adults. Focal clonic and hemiclonic seizures have been described with localized brain injury, usually from cerebrovascular lesions (Clancy et al, 1985; Levy et al, 1985; Scher et al, 1986), but also can be seen with generalized or multifocal brain abnormalities. As with older patients, focal seizures in the neonate can be followed by transient motor weakness, historically referred to as a transient Todd's paresis or paralysis, characterized by a more persistent hemiparesis over days to weeks. Clonic movements without EEG-confirmed seizures have been described in neonates with normal EEG background rhythms, in whom neurodevelopmental outcome can be normal (Rose and Lombroso, 1970). The less experienced clinician may misclassify myoclonic as clonic movements.

TABLE 63-2 Classification and Clinical Characteristics of Neonatal Seizures

Seizure Class	Characterization
Focal clonic	Repetitive, rhythmic contractions of muscle groups of the limbs, face, or trunk May be unifocal or multifocal May occur synchronously or asynchronously in muscle groups on one side of the body May occur simultaneously but asynchronously on both sides Cannot be suppressed by restraint *Pathophysiology*: epileptic
Focal tonic	Sustained posturing of single limbs Sustained asymmetric posturing of the trunk Sustained eye deviation Cannot be provoked by stimulation or suppressed by restraint *Pathophysiology*: epileptic
Generalized tonic	Sustained symmetric posturing of limbs, trunk, and neck May be flexor, extensor, or mixed extensor/flexor May be provoked or intensified by stimulation May be suppressed by restraint or repositioning *Presumed pathophysiology*: nonepileptic
Myoclonic	Random, single, rapid contractions of muscle groups of the limbs, face, or trunk Typically not repetitive or may recur at a slow rate May be generalized, focal, or fragmentary May be provoked by stimulation *Presumed pathophysiology*: may be epileptic or nonepileptic
Spasms	May be flexor, extensor, or mixed extensor/flexor May occur in clusters Cannot be provoked by stimulation or suppressed by restraint *Pathophysiology*: epileptic
Motor automatisms	
Ocular signs	Random and roving eye movements or nystagmus (distinct from tonic eye deviation) May be provoked or intensified by tactile stimulation *Presumed pathophysiology*: nonepileptic
Oral-buccal-lingual movements	Sucking, chewing, tongue protrusions May be provoked or intensified by stimulation *Presumed pathophysiology*: nonepileptic
Progression movements	Rowing or swimming movements Pedaling or bicycling movements of the legs May be provoked or intensified by stimulation May be suppressed by restraint or repositioning *Presumed pathophysiology*: nonepileptic
Complex purposeless movements	Sudden arousal with transient increased random activity of the limbs May be provoked or intensified by stimulation *Presumed pathophysiology*: nonepileptic

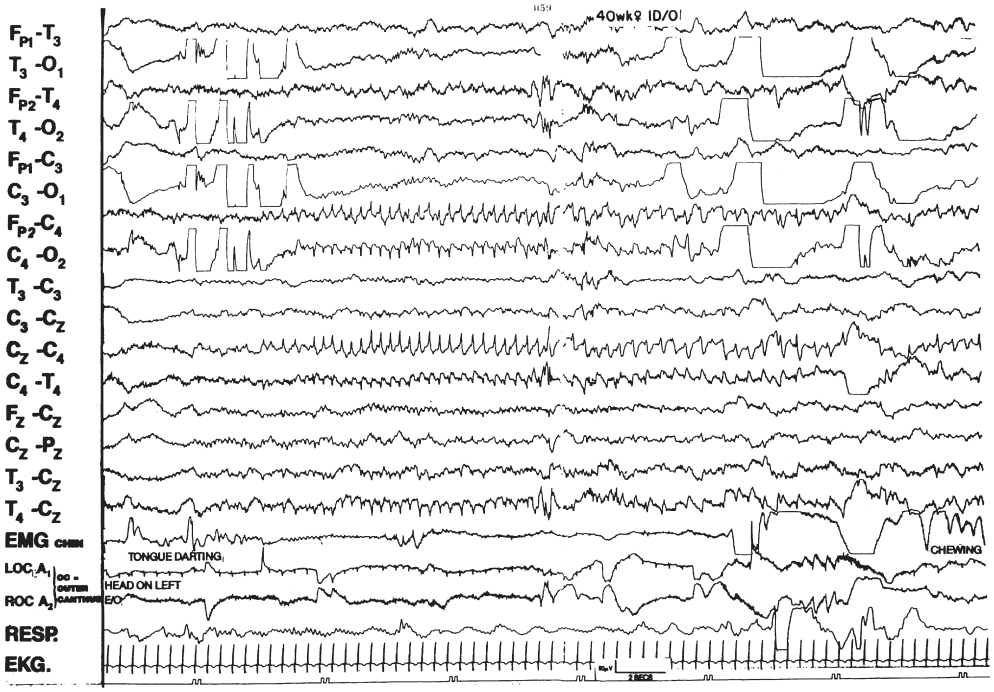

FIGURE 63-1 Segment of electroencephalogram (EEG) from a 40-week-gestation, 1-day-old female infant after severe asphyxia resulting from rupture of velamentous insertion of the umbilical cord during delivery. An electrical seizure in the right central/midline region is recorded coincident with buccolingual and eye movements (see comments and eye channels on record). *(From Scher MS, Painter MJ: Electrographic diagnosis of neonatal seizures: issues of diagnostic accuracy, clinical correlation and survival. In Wasterlain CG, Vert P, editors:* Neonatal seizures, *New York, 1990, Raven Press, p 17.)*

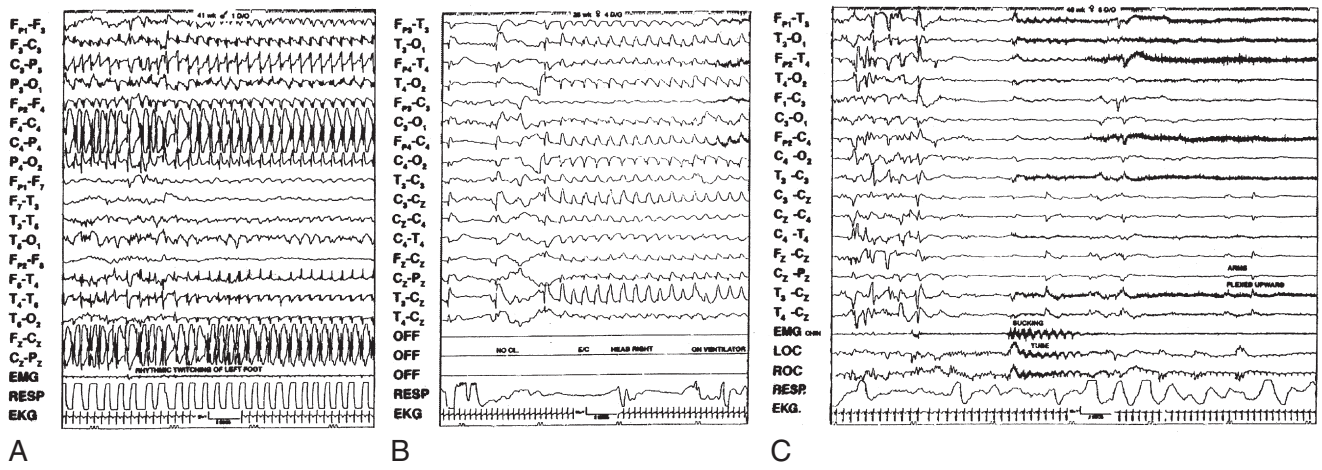

FIGURE 63-2 **A,** Segment of electroencephalogram (EEG) from a 41-week-gestation, 1-day-old male infant with an electroclinical seizure characterized by rhythmic clonic movements of the left foot coincident with bihemispheric electrographic discharges of higher amplitude in the right hemisphere. This seizure was documented before administration of antiepileptic medication. **B,** Segment of EEG from a 25-week-gestation, 4-day-old female infant with an electrographic seizure without clinical accompaniments. **C,** Segment of EEG from a 40-week-gestation, 6-day-old infant with stereotypic flexion posturing in the absence of electrographic seizures (note muscle artifact). *(From Scher MS: Pediatric electroencephalography and evoked potentials. In Swaiman KS, editor:* Pediatric neurology: principles and practice, *St. Louis, Mo, 1999, CV Mosby, p 164.)*

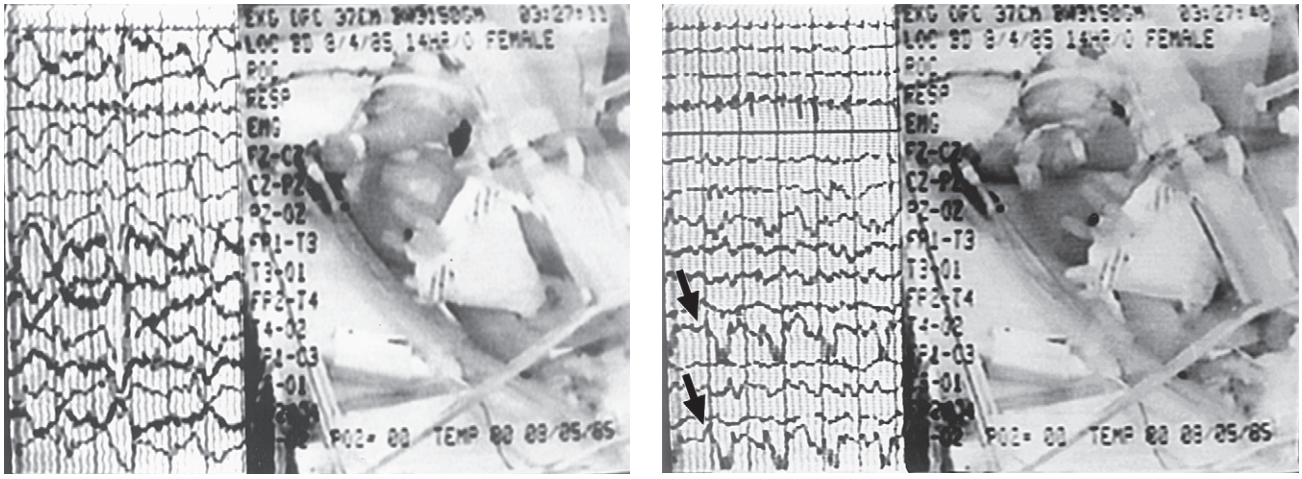
Multifocal (Fragmentary) Clonic Seizures

The word *fragmentary* was historically applied to distinguish multifocal clonic seizures from the more classic generalized tonic-clonic seizure seen in the older child. Multifocal or migratory clonic activities spread over body parts in either a random or an anatomically appropriate fashion. Seizure movements may alternate from side to side and appear asynchronously between the two halves of the child's body. Multifocal clonic seizures may be misclassified as myoclonic seizures, and video-EEG documentation helps with proper identification. Neonates with this seizure description often suffer death or significant neurologic morbidity (Rose and Lombroso, 1970).

Tonic Seizures

Tonic seizure refers to a sustained flexion or extension of axial or appendicular muscle groups (Figure 63-3, *A* and *B*). Tonic movements of a limb or sustained head or eye



A B

FIGURE 63-3 **A,** Segment of a synchronized video-electroencephalographic recording from a 37-week-gestation, 1-day-old female infant who suffered asphyxia demonstrates prominent opisthotonos with left arm extension in the absence of coincident electrographic seizure activity. **B,** Synchronized video-electroencephalographic recording from the same patient as in **A,** documenting electrographic seizure in the right posterior quadrant (*arrows*), after cessation of left arm tonic movements and persistent opisthotonos. *(From Scher MS, Painter MJ: Controversies concerning neonatal seizures. In Pellock JM, editor: Seizure disorders,* Pediatr Clin North Am *36:292, 1989.)*

turning may also be noted. Documentation of tonic activity during coincident EEG recording is needed, because 30% of such movements lack a temporal correlation with electrographic seizures (Kellaway and Hrachovy, 1983). Such nonepileptic activity is referred to as "brainstem release" resulting from functional decortication after severe neocortical dysfunction or damage. Extensive neocortical damage or dysfunction permits the emergence of uninhibited subcortical expressions of extensor movements (Sarnat, 1984). Tonic seizures may also be misidentified when nonepileptic movement disorders consisting of dystonia are more appropriate behavioral descriptions. Both tonic movements and dystonic posturing may simultaneously occur in the same neonate.

Myoclonic Seizures

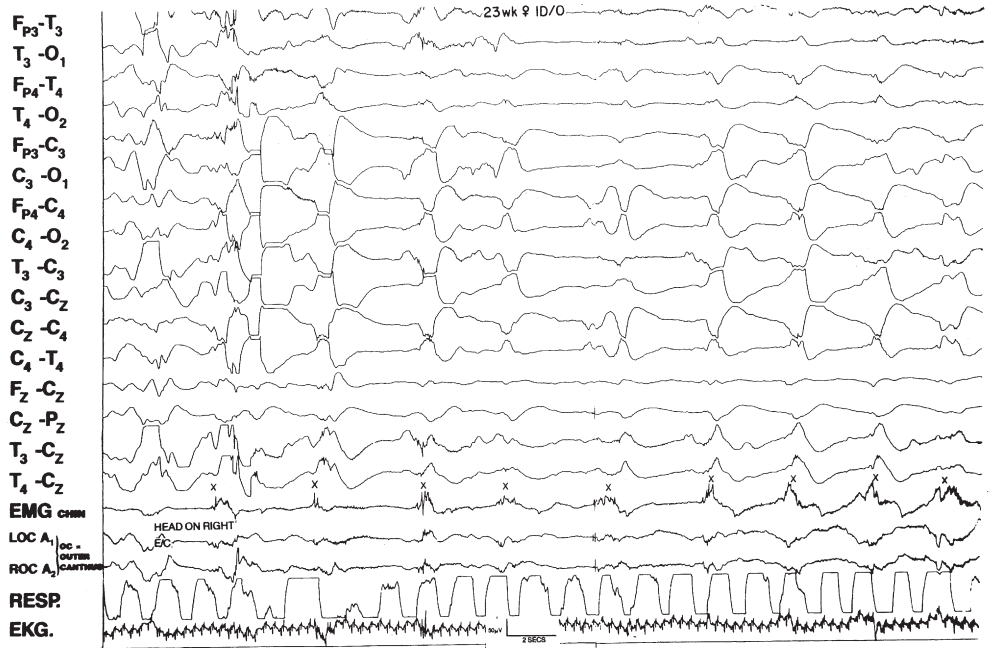
Myoclonic movements are rapid, isolated jerks that can be generalized, multifocal, or focal in an axial or appendicular distribution. Myoclonus lacks the slow return phase of the clonic movement complex. Healthy preterm infants commonly exhibit myoclonic movements without seizures or a brain disorder. An EEG, therefore, is recommended to confirm the coincident appearance of electrographic discharges with these movements (Figure 63-4, *A*). Pathologic myoclonus in the absence of electrographically confirmed seizures also can occur in severely ill preterm or full-term infants after severe brain dysfunction or damage (Scher, 1985). As with older children and adults, myoclonus may reflect injuries at multiple levels of the neuraxis, from spinal cord to brainstem to cortical regions. Stimulus-evoked myoclonus with either single coincident spike discharges or sustained electrographic seizures has been reported (Scher, 1997b). An extensive evaluation must be initiated to exclude metabolic, structural, and genetic causes. Rarely, healthy sleeping neonates exhibit abundant myoclonus that subsides on arousal to the waking state (Resnick et al, 1986); this entity is termed benign *sleep myoclonus of the newborn*.

NONEPILEPTIC BEHAVIORS OF NEONATES

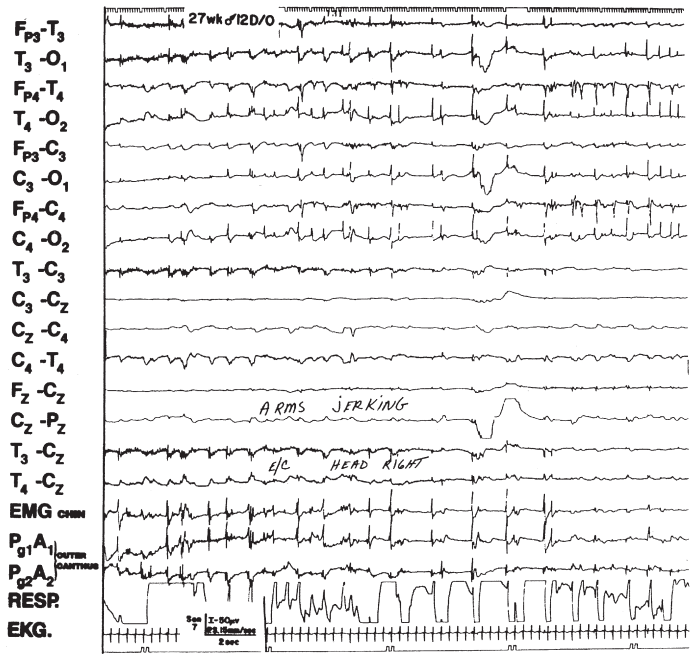
Nonepileptic neonatal movement repertoires continue to challenge the physician's attempt to accurately diagnose seizures. Coincident synchronized video-EEG-polygraphic recordings are now suggested to confirm the temporal relationships between the suspicious clinical phenomena and electrographic expression of seizures (Mizrahi and Kellaway, 1998; Scher 1997a, 2001b).

Tremulousness or Jitteriness Without Coincident Electrographic Seizures

Tremors are frequently misidentified as clonic activity by inexperienced medical personnel. The flexion and extension phases of tremor are equal in amplitude, unlike the unequal phases of clonic movements. Children are generally alert or hyperalert but may also appear somnolent or lethargic as part of an encephalopathy. Passive flexion and repositioning of the affected tremulous body part will diminish or eliminate the movement. Such movements usually are spontaneous but can be provoked by tactile stimulation. This movement may also appear asymmetric, with decreased expression in a weak limb after a brain injury or peripheral neuropathy. Metabolic or toxin-induced encephalopathies, including those due to mild asphyxia, drug withdrawal, hypoglycemia or hypocalcemia, intracranial hemorrhage, hypothermia, and growth restriction, are common clinical scenarios in which tremulous movements occur. Neonatal tremors generally diminish with increasing postconceptional age, spontaneously resolving over days to weeks, with normal neurologic outcome (Parker et al, 1990).



A



B

FIGURE 63-4 **A,** Segment of an electroencephalogram (EEG) from a 23-week-gestation, 1-day-old female infant with grade III intraventricular hemorrhage and progressive ventriculomegaly. An electroclinical seizure is noted coincident with myoclonic movements of the diaphragm (*x marks*). **B,** Segment of an EEG from an encephalopathic 27-week-gestation, 12-day-old male infant with herpes encephalitis who exhibits nonepileptic multifocal myoclonus (myogenic potentials as electroencephalographic artifacts). ***(A,** From Scher MS: Pathological myoclonus of the newborn: electrographic and clinical correlations*, Pediatr Neurol *1:342-348, 1985, with permission.)*

Neonatal Myoclonus Without Coincident Electrographic Seizures

Myoclonic movements can be bilateral and synchronous or asymmetric and asynchronous in appearance. Benign myoclonic activity occurs more frequently during active (REM) sleep and is more predominant in the preterm infant (Hakamada et al, 1981; Scher, 1996), as well as rarely in healthy full-term infants; movements are not stimulus sensitive, have no coincident electrographic seizure correlates, are not associated with EEG background abnormalities, and are suppressed during wakefulness. Benign neonatal sleep myoclonus must be a diagnosis of exclusion.

Infants with severe CNS dysfunction may present with nonepileptic spontaneous or stimulus-evoked pathologic

myoclonus (see Figure 63-4, *B*). Neonates with different forms of metabolic encephalopathies such as glycine encephalopathy, cerebrovascular lesions, brain infections, or congenital malformations can present with nonepileptic pathologic myoclonus (Scher, 1985, 1997b). Encephalopathic neonates may respond to tactile or painful stimulation by isolated focal, segmental, or generalized myoclonic movements. Rarely, cortically generated spike or sharp wave discharges, as well as seizures, also may be noted on the EEG recordings that are coincident with these myoclonic movements. Medication-induced myoclonus and other stereotypic movements also have been described (Sexson et al, 1995); these abnormalities resolve when the drug is withdrawn.

Neonatal Dyskinesias: Dystonia or Choreoathetosis Without Coincident Electrographic Seizures

Dystonia and choreoathetosis are commonly occurring movement disorders that are often misdiagnosed as seizures. These nonepileptic movement disorders are associated with either acute or chronic disease states involving basal ganglia structures or the extrapyramidal pathways that innervate these regions. Dystonia is one of three clinical expressions of neonatal hypertonic states that often reflect antepartum timing to brain injury (Scher, 2008a,b). However, either antepartum or intrapartum adverse events such as severe asphyxia can damage the basal ganglia (i.e., status marmoratus) (Volpe, 2001), as expressed as dyskinesias. Rarely, specific inherited metabolic diseases (Barth, 1992) (e.g., glutaric aciduria) also can injure these structures. Sustained posturing or dystonia often reflects functional disinhibition of subcortical motor pathways due to disease or malformation of the neocortex (Sarnat, 1984) (see Figure 63-2, *C*). Documentation of electrographic seizures by coincident video-EEG-polygraphic recordings will help avoid misdiagnosis and inappropriate treatment of nonepileptic dyskinesias (see Figure 63-3, *A* and *B*).

ELECTROGRAPHIC SEIZURE CRITERIA

Over the past several decades, electrographic/polysomnographic studies have become invaluable tools for the assessment of suspected seizures (Mizrahi and Kellaway, 1998; Pope et al, 1992; Scher, 1999, 2001b). Technical and interpretive skills for assessment of normal and abnormal neonatal EEG sleep patterns must be mastered to develop a confident visual analysis style for seizure recognition. Corroboration with the EEG technologist is always an essential part of the diagnostic process, because physiologic and nonphysiologic artifacts can masquerade as electrographic seizures. The physician also must anticipate expected behaviors for the child for gestational maturity, medication use, and state of arousal, in the context of potential artifacts.

As with the epileptic older child and adult, it is generally accepted that the neonatal epileptic seizure is a clinical paroxysm of altered brain function with the simultaneous presence of an electrographic event on an EEG recording. For assessment of the suspected clinical event in the neonate, synchronized video-EEG-polygraphic monitoring is a useful tool to distinguish an epileptic from a nonepileptic event. Single-channel computerized devices for continuous prolonged monitoring (Hellstrom-Westas, 1992) are useful as screening tools but may fail to detect focal or regional seizures if the single-channel recording is distant from the brain region involved with seizure expression. Neonatal electrographic seizures commonly arise focally from a single brain region. One brain study described 56% of neonatal seizures presenting in a single location, with the remainder occurring in multiple locations (Bye and Flanagan, 1995). In another study, only one third of neonatal EEG seizures displayed clinical signs on simultaneous video recordings, and two thirds went unrecognized or were misinterpreted by experienced neonatal staff (Murray et al, 2008). In the recognition and management of neonatal seizures, clinical diagnosis alone is not enough. Although amplitude-integrated EEG (aEEG) provides simplified bedside monitoring of cerebral functioning, proposed schemes are needed to combine screening with aEEG followed by conventional EEG monitoring (El-Dib et al, 2009).

Ictal Electroencephalographic Patterns: A More Reliable Marker for Seizure Onset, Duration, and Severity

Neonatal electroencephalographic seizure patterns commonly consist of a repetitive sequence of waveforms that evolve in frequency, amplitude, electrical field, and/or morphology. Four types of ictal patterns have been described: focal ictal patterns with normal backgrounds, focal patterns with abnormal backgrounds, multifocal ictal patterns, and focal monorhythmic periodic patterns of various frequencies (Scher, 2001b). It is generally suggested that a minimal duration of 10 seconds for the evolution of discharges is required to distinguish electrographic seizures from repetitive but nonictal epileptiform discharges (Bye and Flannagan, 1995; Clancy and Legido, 1987; Scher et al, 1993) (see Figure 63-1). Clinical neurophysiologists alternatively classify brief or prolonged repetitive discharges that lack this electrographic evolution as nonictal abnormal epileptiform patterns, which does not conform to the seizure definition.

For the older patient, status epilepticus is defined as at least 30 minutes of continuous seizures or two consecutive seizures with an interictal period during which the patient fails to return to full consciousness. This definition, however, does not easily apply to the neonate because levels of arousal are difficult to assess, particularly if sedative medications are given. Neonatal status epilepticus was reported in one third of full-term infant EEG recordings and in 20% of the total cohort of preterm and full-term infant EEG recordings (Scher et al, 1993) using a definition of status epilepticus as continuous seizure activity for 30 minutes or 50% of the recording time. If clinicians relied only on clinical criteria, status epilepticus would be underdiagnosed. Without EEG confirmation, the underdiagnosis of status epilepticus would contribute to brain injury, as discussed later in the section "Effects of Neonatal Seizures on Brain Development: Consequences of Underdiagnosis."

Uncoupling of the clinical and electrographic expressions of neonatal seizures after antiepileptic medication

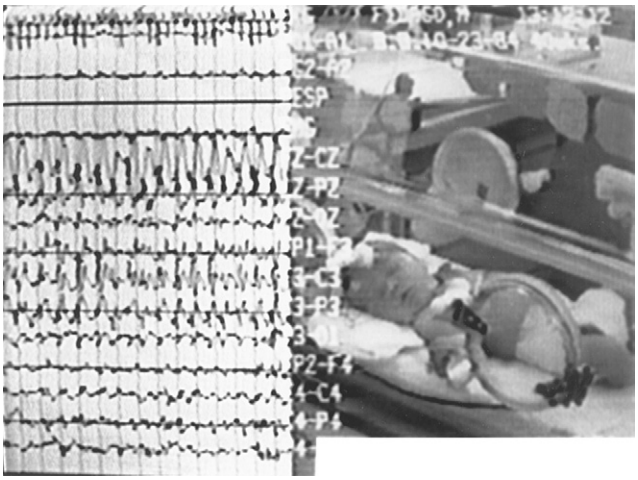


FIGURE 63-5 Segment of a synchronized video-electroencephalographic recording from a 40-week-gestation, 1-day-old male infant with electrographic status epilepticus noted in the left central/midline regions, after antiepileptic medication administration. Focal right shoulder clonic activity was only intermittently noted, while continuous electrographic seizures were documented mostly without clinical expression. This phenomenon of uncoupling of electrical and clinical seizure activities is associated with antiepileptic drug administration (see text). *(From Scher MS, Painter MJ: Controversies concerning neonatal seizures. In Pellock JM, editor: Seizure disorders,* Pediatr Clin North Am *36:290, 1989.)*

administration also contributes to the underestimation of the true seizure duration and frequency of status epilepticus (Figure 63-5). One study estimated that 25% of neonates expressed persistent electrographic seizures despite resolution of their clinical seizure behaviors after receiving one or more antiepileptic medications (Scher, 1994); this phenomenon is termed *electroclinical uncoupling*.

The neonate may alternately express or sustain repetitive or periodic discharges greater than 10 seconds in duration that do not satisfy the electrographic criteria for seizures. The same neonate may express both periodic discharges and electrographic seizures at other times during the same EEG recording (Scher and Beggarly, 1989).

At the opposite end of the spectrum from periodic discharges, brief rhythmic discharges that are less than 10 seconds in duration also do not satisfy electroencephalographic criteria for seizures. Some neonates with electrographic seizures also may exhibit these brief discharges. Both periodic and brief discharges are associated with compromised neurodevelopmental outcome (Oliveira et al, 2000; Scher and Painter, 1989).

Subcortical Seizures versus Nonictal Functional Decortication

Experimental animal models offer conflicting evidence regarding suspicious clinical events for which coincident electrographic confirmation of seizures is absent (Scher, 2001b). Most neurologists prefer documentation of an ictal pattern by surface EEG electrodes before diagnosing a seizure. However, subcortical seizures with or without intermittent propagation to the surface may also occur. Electroclinical disassociation (ECD) is one proposed mechanism by which subcortical neonatal seizures intermittently appear on surface-recorded EEG studies (Biagioni et al, 1998; Weiner et al, 1991). ECD is defined as a reproducible clinical event that occurs both with and without coincidental electrographic seizures, documented in one study as 34% of 51 neonates (Weiner et al, 1991). A clinical seizure precedes the electrographic expression, suggesting a subcortical onset before propagation to the cortical surface.

Some investigators have proposed a nonictal "brainstem release" phenomenon that explains suspicious clinical events that never have coincident EEG seizures expressed on surface recording (Mizrahi and Kellaway, 1998). These authors argue, for example, that motor automatisms have an inconsistent relationship with coincident EEG seizure activity. They alternatively speculate that functional nonictal decortication resulting from neocortical damage best explains these movements, without diagnosing epileptic seizures (Kellaway and Hrachovy, 1983).

This dilemma should encourage the clinician to use the EEG as a neurophysiologic yardstick by which more exact seizure start and end points can be assigned, before offering pharmacologic treatment with antiepileptic drugs (AEDs). Neonates can exhibit electrographic seizures that will go undetected unless EEG studies are utilized (O'Meara et al, 1995; Scher et al, 1993) (Figure 63-6; see also Figure 63-5). For example, in neonates who have been pharmacologically paralyzed for ventilatory assistance or in those who have received AEDs, clinical expression of seizures will be suppressed. In one cohort of 92 infants, 60% were pretreated with antiepileptic medications, and 50% of the cohort had electrographic seizures with no clinical accompaniment. Both clinical and electrographic seizure criteria were noted for 45% of 62 preterm infants and 53% of 30 full-term infants. Seventeen infants were pharmacologically paralyzed when the electrographic seizure was first documented. In a another cohort of 60 infants who were not pretreated with antiepileptic medications, 7% of infants had only electrographic seizures before AED administration, and 25% expressed electroclinical uncoupling after AED use (Scher, 1994).

Both overestimation and underestimation of neonatal seizure incidences are reported, depending on whether clinical or electrical criteria are used. Based on clinical criteria, seizure incidences ranged from 0.5% in term infants to 22.2% in preterm neonates (Lanska et al, 1995; Ronen et al, 1999; Seay and Bray, 1977). Discrepancies in incidence estimates reflect varying postconceptional ages of the study populations chosen, interobserver variability, and the hospital setting in which the diagnosis was made. Hospital-based studies, which will include a greater incidence of high-risk deliveries, generally report a higher seizure incidence. Population studies that include less medically fragile infants from general nurseries report lower percentages. Incidence figures based only on clinical criteria without EEG confirmation include "false positives," consisting of cases in which the neonates had either normal or nonepileptic pathologic neonatal behaviors. Conversely, the lack of electrographic seizures may include a subset of "false negatives," in which the infants express seizures only from subcortical brain regions, without propagation to the cortical surface. Consensus between clinical and EEG criteria, therefore, is still needed to reach the best incidence estimate.

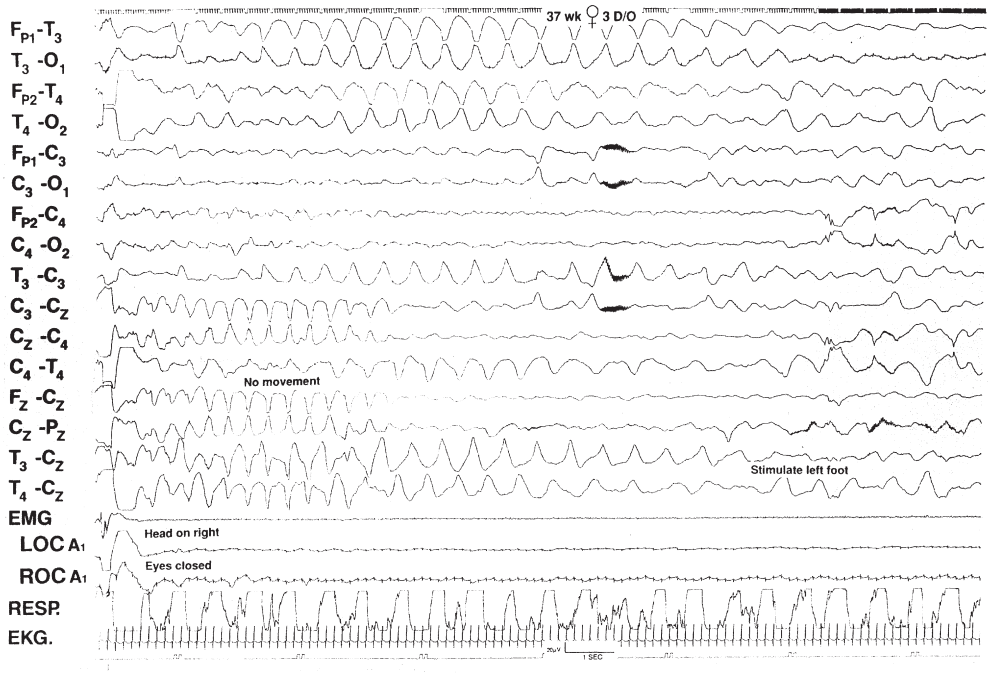

FIGURE 63-6 Segment of a synchronized video-electroencephalographic recording from a 37-week-gestation, 3-day-old female infant who was pharmacologically paralyzed for ventilatory care. A seizure is noted in the right posterior quadrant and midline. *(From Scher MS, Painter MJ: Controversies concerning neonatal seizures. In Pellock JM, editor: Seizure disorders,* Pediatr Clin North Am *36:290, 1989.)*

Interictal Electroencephalographic Abnormalities

Besides use of the EEG to diagnose seizures, documentation of interictal EEG abnormalities is extremely useful for patient management and prognosis. Interictal EEG findings are not pathognomonic for particular etiologic disorders, mechanisms, or timing (Scher, 1994). The clinician must integrate historical, physical examination, and laboratory findings with the electrographic interpretation of both seizure and nonseizure pattern findings for the particular child. The depth and the severity of neonatal brain disorders, as measured by the markedly abnormal interictal findings, help to predict subsequent development of seizures (Laroia et al, 1998). Serial EEG studies help the clinician to predict long-term outcome (see later section on prognosis).

DIAGNOSTIC DILEMMAS: IDENTIFYING CAUSES FOR SEIZURES

Diverse medical conditions in the newborn can be associated with seizure activity (Adamson et al, 1995; Kellaway and Hrachovy, 1983) (Table 63-3). Asphyxia is traditionally introduced as the representative etiologic disorder that exemplifies when seizures may occur. The asphyxial condition, however, encompasses heterogeneous conditions associated with hypoxia-ischemia, which may lead to seizures over a variable timeline encompassing antepartum, intrapartum, and neonatal periods.

Neonatal seizures are not disease-specific and can be associated with a variety of medical conditions occurring before, during, or after parturition. Seizures may occur as part of an asphyxial brain disorder that is expressed after birth (i.e., hypoxic-ischemic encephalopathy). Alternatively, neonatal encephalopathies may represent other etiologic disorders with incidental asphyxia. Finally, seizures can present as an isolated clinical sign secondary to a remote antepartum asphyxial stress without other signs of a postnatal encephalopathy. A logistic model developed to predict seizures emphasizes the accumulation of both antepartum and intrapartum factors that increase the likelihood of neonatal seizure occurrence in the context of asphyxia (Patterson et al, 1989). Although separately these same factors have low positive predictive values, a significant cumulative risk profile results when maternal anemia, vaginal bleeding, asthma, meconium-stained amniotic fluid, abnormal fetal presentation, fetal distress, and shoulder dystocia all are considered. Another study of 40 neonates with clinical seizures indicated that only 37.5% of the seizures were associated with asphyxia, whereas a majority of term infants had early-onset seizures due to malformation, stroke, infection, or hemorrhage (Lien et al, 1995). In a population-based study, several antepartum and intrapartum factors increased the risk of neonatal seizures during the birth admission (Glass et al, 2009b). Infants of women whose age was 40 years and older who were nulliparous, had diabetes mellitus, intrapartum fever, or infection or delivered at greater than 42 weeks had an increased risk of seizures.

HYPOXIA-ISCHEMIA

Hypoxia-ischemia or asphyxia is nonetheless traditionally considered the most common cause of neonatal seizures (Brown et al, 1972, 1974; Sarnat and Sarnat, 1976; Volpe, 2001). However, infants can suffer asphyxia before as well as during parturition, and 10% of neonatal asphyxia cases also result from postnatal causes (Volpe, 2001). When asphyxia is suspected during the labor and delivery

TABLE 63-3 Differential Diagnosis of Neonatal Seizures*

- Metabolic
  - Hypoxia-ischemia (i.e., asphyxia)
  - Hypoglycemia
  - Hypocalcemia
  - Hypomagnesemia
  - Hypoglycemia
  - Glycogen storage disease
  - Galactosemia
- Idiopathic
  - Hypomagnesemia
  - Infant of a diabetic mother
  - Neonatal hypoparathyroidism
  - Maternal hyperparathyroidism
  - High phosphate load
  - Other electrolyte imbalances
  - Hypernatremia
  - Hyponatremia
- Intrauterine growth restriction
- Infant of a diabetic mother
- Intracranial hemorrhage
  - Subarachnoid hemorrhage
  - Subdural/epidural hematoma
  - Intraventricular hemorrhage
- Cerebrovascular lesions (other than trauma)
  - Cerebral infarction (thrombotic vs. embolic causes)
  - Ischemic vs. hemorrhagic lesions
  - Cortical vein thrombosis
  - Circulatory disturbances from hypoperfusion
- Trauma
- Infections
  - Bacterial meningitis
  - Viral encephalitis
- Congenital infections
  - Herpes simplex
  - Syphilis
  - Cytomegalovirus infection
  - Coxsackievirus
  - Meningoencephalitis
  - Toxoplasmosis
  - Acquired immunodeficiency syndrome (AIDS)
  - Brain abscess
- Brain anomalies (i.e., cerebral dysgenesis from either congenital or acquired causes)
- Drug withdrawal or toxins
  - Prenatal exposure to substances of abuse—methadone, heroin, barbiturate, cocaine
  - Prescribed medications—propoxyphene, isoniazid
  - Local anesthetics
- Hypertensive encephalopathy
- Amino acid metabolism
  - Branched-chain amino acidopathies
  - Urea cycle abnormalities
  - Nonketotic hyperglycinemia
  - Ketotic hyperglycinemia
- Familial seizures
  - Neurocutaneous syndromes
  - Tuberous sclerosis
  - Incontinentia pigmenti
  - Autosomal dominant neonatal seizures
- Selected genetic syndromes
  - Zellweger's syndrome
  - Neonatal adrenoleukodystrophy
  - Smith-Lemli-Opitz syndrome

*Etiology independent of timing from fetal to neonatal periods.
Adapted from Scher MS: Neonatal seizures: an expression of fetal or neonatal brain disorders. In Stevenson DK, Benitz WE, Sunshine P, editors: *Fetal and neonatal brain injury: mechanisms, management and the risks of practice*, ed 3, Cambridge, UK, 2002, Cambridge University Press, pp 735-784.

process, biochemical confirmation is required. This metabolic definition of asphyxia represents the cardinal feature of hypoxic-ischemic encephalopathy (HIE).

The American College of Obstetricians and Gynecologists (ACOG) initially published guidelines that suggest four cardinal criteria to define postasphyxial neonatal encephalopathy—that is, HIE—after significant clinical depression noted at birth (ACOG, 2003). These four criteria include:

1. Profound metabolic or mixed acidemia with a pH of less than 7.00 in umbilical cord blood
2. Persistence of an Apgar score of 0 to 3 for longer than 5 minutes
3. Neonatal neurologic sequelae (i.e., seizures, coma, and hypotonia)
4. Multiorgan system dysfunction (i.e., significant cardiovascular, gastrointestinal, hematologic, pulmonary, and renal involvement)

More recent guidelines have been published that suggest stricter criteria, including the four cardinal criteria as well as four collective criteria. Clinicians now recognize that antepartum etiologies from maternal, placental, and/or fetal conditions explain 85% to 90% of HIE, whereas intrapartum etiologies account for a minority of HIE cases, between 10% and 15% (Graham et al, 2008).

OTHER CAUSES OF NEONATAL ENCEPHALOPATHY

Diverse etiologic disorders and conditions occurring in the antepartum, intrapartum, and neonatal periods may cause neonatal encephalopathies, with or without accompanying seizures. Children certainly may exhibit altered arousal and muscle tone, as well as seizures, without meeting the suggested criteria for HIE from intrapartum causes (ACOG, 2003). These children can appear neurologically abnormal based on antepartum conditions involving maternal, placental, or fetal diseases (Adamson et al, 1995).

A case-control study of term infants with clinical seizures reported a fourfold increase in the risk of unexplained early-onset seizures after intrapartum fever (Lieberman et al, 2000). All known causes of seizures were eliminated including meningitis and sepsis. Compared with 152 controls, the 38 newborns experienced intrapartum fever as an independent risk factor on logistic regression analysis that predicted seizures. The authors speculated on the role of circulating maternal cytokines that triggered "physiologic events" contributing to neonatal encephalopathy seizures, which did not occur from asphyxia.

Postnatal medical illnesses also cause or contribute to asphyxia-induced brain injury and seizures without intrapartum HIE. Persistent pulmonary hypertension of the newborn (PPHN), cyanotic congenital heart disease, sepsis, and meningitis are several examples. In one hospital-based study conducted over a 14-year period, 62 of 247 infants presented with EEG-confirmed seizures after an uneventful delivery without fetal distress during labor or neonatal depression at birth. Twenty of these 62 infants (32%) later presented with postnatal onset of pulmonary disease, sepsis, or meningitis (Scher, 1994).

Placental findings may reflect chronic disease states at antepartum time points with or without metabolic acidosis and evolving HIE after birth (Scher, 2002). Although meconium passage more commonly occurs in otherwise healthy newborns, meconium-stained skin also may be associated with meconium-laden macrophages within placental membranes in the depressed newborn. Meconium staining through the chorionic to amnion layers suggests a longer-standing asphyxial stress over a 4- to 6-hour period, which may precede the labor period.

Placental weights below the 10th or above the 90th percentile suggest chronic perfusion abnormalities to the fetus over weeks. Microscopic evidence of lymphocytic infiltration, altered villous maturation, chorangiosis, and erythroblastic proliferation of villi of the placenta support chronic asphyxial stresses to the fetus. In a study of preterm and full-term neonates (23 to 42 weeks of chronologic age) with electrographically confirmed seizures, a significant association between seizures and chronic (with or without acute) placental lesions was noted by calculated odds-risk ratios, increasing to a factor of 12.1 ($P < .003$) by term age. In contrast, odds ratios were not significant

for infants with seizures and exclusively acute placental lesions, presumably from events closer to labor and delivery (Scher et al, 1998).

Clinical examination findings in the depressed neonate with suspected HIE may reflect antepartum disease states rather than evolving HIE (Ajayi et al, 1998). Intrauterine growth restriction, hydrops fetalis, and joint contractures (including arthrogryposis) are findings that suggest intrauterine disease conditions associated with antepartum disease states. Later intrapartum fetal distress with or without asphyxia and neonatal depression also may occur with subsequent neonatal seizures (Scher, 2001a, 2001c). Hypertonicity, often with cortical thumbs (i.e., severely adducted across closed palms), in a depressed child who then rapidly recovers over hours after a successful resuscitative effort also suggests a longer-standing fetal brain disorder. Sustained hypotonia and unresponsiveness for 3 to 7 days constitute the expected clinical repertoire of HIE after an intrapartum asphyxial stress, either with or without coincident brain injury. In encephalopathic newborns, depressed arousal and hypotonia nonetheless also may reflect an antepartum disease process with neonatal dysfunction or superimposed injury after a stressful intrapartum period. For example, this was described in 10 of 20 neurologically depressed infants with electrographic seizures and isoelectric interictal EEG pattern abnormalities, who were comatose and flaccid for days, requiring ventilator assistance after difficult deliveries (Barabas et al, 1993). All children appeared neurologically depressed after asphyxial stress during the intrapartum period (i.e., depressed Apgar scores and metabolic acidosis). Fetal brain injury from preexisting maternal-placental diseases was documented by evidence of chronic brain lesions on neuroimaging studies and/or neuropathologic postmortem findings. Although intrapartum asphyxial stress may worsen brain injury in some children, it was impossible to differentiate the neonatal encephalopathy from preexisting antepartum brain injury for these 10 children.

HYPOGLYCEMIA

Hypoglycemia is generally defined as glucose levels of less than 20 mg/dL in preterm infants and less than 30 mg/dL in term infants (Cornblath and Schwartz, 1967; Milner, 1972). No clear consensus exists concerning a direct cause and effect for hypoglycemia with seizure occurrence (Sencor, 1973). Methods of glucose determination (i.e., point-of-care blood sampling versus laboratory serum sampling) will affect the accuracy of the value. Also, associated disturbances may coexist, such as hypocalcemia, craniocerebral trauma, cerebrovascular lesions, and asphyxia, which may contribute to lowering the threshold for seizures. Infants born to diabetic or preeclamptic mothers, particularly those who were small for gestational age, also are at risk for hypoglycemia. Jitteriness, apnea, and altered tone are clinical signs that may appear in children with hypoglycemia, but they are not representative of a seizure state. Cerebrovascular lesions in posterior brain regions have been reported in children who suffer hypoglycemia (Griffiths and Laurence, 1974). Vulnerability of brain to ischemic insults is enhanced by concomitant hypoglycemia, as reported in mature animals (Siemkowicz and Hansen, 1978) and neonatal infants (Griffiths and Laurence, 1974).

HYPOCALCEMIA

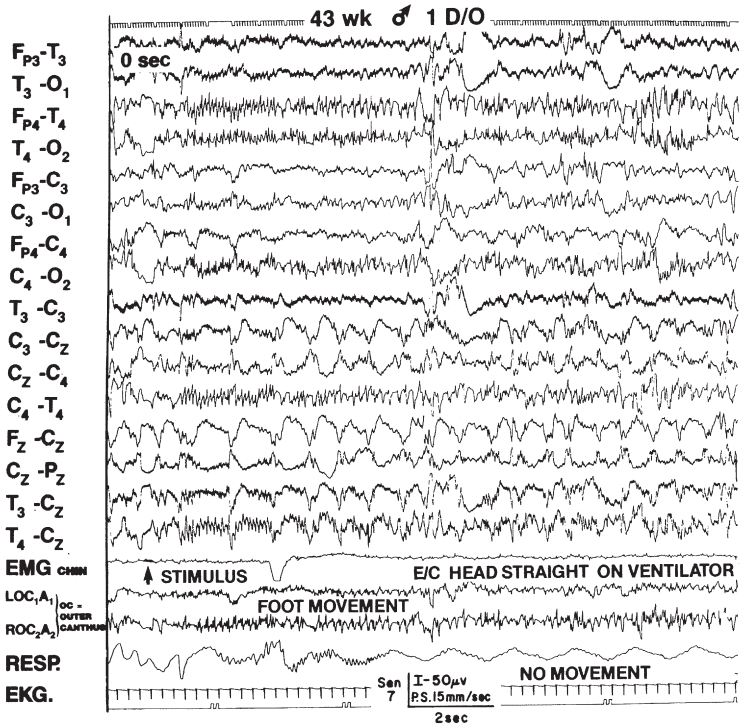
Total serum calcium levels of less than 7.5 mg/dL in preterm and less than 8 mg/dL in the term infant generally define hypocalcemia. The ionized fraction is a more sensitive indicator of seizure vulnerability. As with hypoglycemia, the exact level of hypocalcemia at which seizures occur is debatable. An ionized fraction of 0.6 or less may have a more predictable association with the occurrence of seizures. Late-onset hypocalcemia due to use of high-phosphate infant formula has been previously cited as a common cause of seizures (Keen and Lee, 1973; McInerny and Schubert, 1969; Rose and Lombroso, 1970). However, hypocalcemia now more commonly occurs in infants with trauma, hemolytic disease, or asphyxia and may coexist with hypoglycemia or hypomagnesemia. Rarely, congenital hypoparathyroidism occurring in association with other genetic abnormalities such as DiGeorge syndrome (i.e., velocardiofacial syndrome, with a 22q11 deletion associated with cardiac and brain anomalies) must be considered. Affected infants may have severe congenital heart disease, as well as hypoparathyroid state with hypocalcemia and hypomagnesemia, which precipitates seizures (Lynch and Rust, 1994). Hypocalcemia of unknown etiology in infants also may be the result of maternal hypercalcemia. Ascertainment of the mother's calcium status should be considered, because maternal hypercalcemia can suppress fetal parathyroid development.

HYPONATREMIA AND HYPERNATREMIA

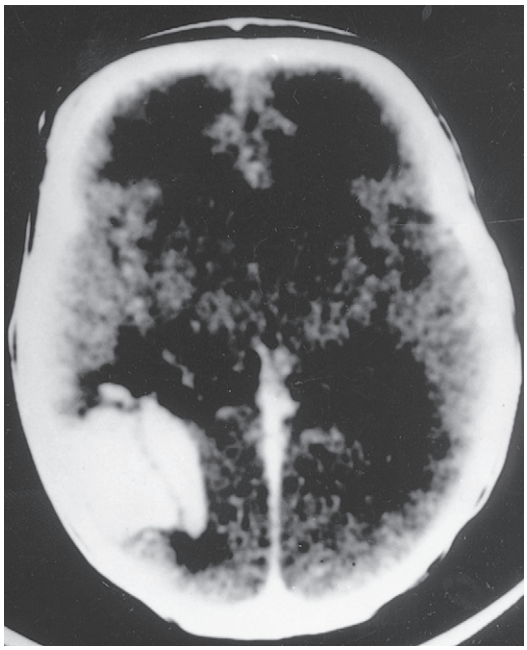
Hyponatremia is a metabolic disturbance that may result from inappropriate secretion of antidiuretic hormone after severe brain trauma, infection, or asphyxia (Volpe, 2001) but is an uncommon isolated cause of neonatal seizures. Hypernatremia also is a rare cause of seizures, usually associated with congenital adrenal abnormalities or iatrogenic disturbance of serum sodium balance, from the use of intravenous fluids with high concentrations of sodium.

CEREBROVASCULAR LESIONS

Hemorrhagic or ischemic cerebrovascular lesions are associated with neonatal seizures, on either an arterial or a venous basis (Clancy et al, 1985; Levy et al, 1985; Ment et al, 1984; Rivkin et al, 1992; Scher and Beggarly, 1989; Scher et al, 1986). Intraventricular or periventricular hemorrhage (IVH or PVH) is the most common intracranial hemorrhagic lesion in the preterm infant and has been associated with seizures in as much as 45% of a preterm population with EEG-confirmed seizures (Scher et al, 1993). In a cohort of newborns with clinical seizures, IVH was the predominant cause of seizures in preterm infants of less than 30 weeks' gestational age (Sheth et al, 1999). Intracranial hemorrhage is usually expected within the first 72 hours of life of the preterm infant. Although IVH-PVH may occur in otherwise asymptomatic infants, the neonate with a catastrophic deterioration of clinical status will exhibit signs of apnea, bulging fontanel, hypertonia, and seizures (Volpe, 2001). Seventeen percent of preterm infants with IVH may have acute seizures during the 1st month of life; 10% of one cohort suffered remote seizures



A



B

FIGURE 63-7 **A,** Segment of an electroencephalographic recording from a 43-week-gestation, 1-day-old male infant with a stimulus-evoked electrographic seizure (*arrow*) in the right temporal region, without clinical accompaniments. The child required ventilatory care for persistent pulmonary hypertension of the neonate (see text). **B,** Computed tomography scan on day 6 from the patient in **A**, documenting a hemorrhagic infarction in the right posterior quadrant with surrounding edema. *(From Scher MS, Klesh KW, Murphy TF, Guthrie RD: Seizures and infarction in neonates with persistent pulmonary hypertension,* Pediatr Neurol *2:332-339, 1986, with permission.)*

(after hospital discharge) (Strober et al, 1997). Full-term infants present less commonly with IVH, which usually originates from the choroid plexus or thalamus.

Another site of intracranial hemorrhage is the subarachnoid space; hemorrhage in this location may result in seizures but generally is associated with a more favorable outcome. Subdural hematoma, whether spontaneous or with craniocerebral trauma, should always be considered, particularly when focal trauma to the face, scalp, or head has occurred; simultaneous occurrences of cerebral contusion and infarction also should be considered.

Cerebral infarction has been described in neonates with seizures and can result from events during the antepartum, intrapartum, or neonatal period. Either preterm or term neonates with infarction also may present without seizure expression (De Vries et al, 1997). Seizures also can occur in otherwise healthy infants, suggesting an antepartum occurrence of cerebral infarction (Mercuri et al, 1995; Scher et al, 1991). Aggressive use of neuroimaging during the antepartum period by fetal sonography or magnetic resonance (MR) techniques, or within the first days after birth, may document remote brain lesions (Scher, 2001a,c). In a group of 62 healthy infants with electrographic seizures after an uneventful delivery, 23 (37%) had cerebrovascular lesions, and 18 of the 23 had ischemic brain lesions (Scher et al, 1993). Destructive lesions such as evolving porencephaly require approximately 5 to 7 days before becoming radiographically evident. The occurrence of injury during more recent intrapartum or neonatal periods can be supported by the presence of early cerebral edema using diffusion-weighted MR images (Forbes et al, 2000). Cerebral infarction also may occur during the postnatal period from asphyxia, polycythemia, dehydration, or coagulopathy.

PPHN with severe and recurrent hypoxia also can be associated with cerebrovascular lesions and seizures (Scher et al, 1986) (Figure 63-7, *A* and *B*). Certain infants with PPHN will require extracorporeal membrane oxygenation (ECMO) to treat severe forms of this pulmonary disease, which does not respond to traditional ventilatory therapy. Radiographic documentation of brain lesions is needed before initiation of ECMO, because the anticoagulation required for ECMO may convert "bland" or ischemic infarctions to hemorrhagic forms, with greater risk for cerebral edema and herniation. Although meconium aspiration syndrome has historically been identified with an intrapartum/neonatal presentation of PPHN, in most affected children this lung disease generally is secondary to antepartum maternal/fetal or placental conditions that predispose the fetus to thickening of the muscular layers of the pulmonary arteries in utero, with resultant sustained increased pulmonary vascular resistance after birth (Benitz et al, 1997).

Cerebral infarction in the venous distribution of the brain may also lead to neonatal seizures (Rivkin et al, 1992; Shevell et al, 1989). Lateral or sagittal sinus thrombosis after coagulopathy can occur secondary to systemic infection, polycythemia, or dehydration. Venous infarction within the deep white matter of the preterm infant's brain also occurs in association with IVH.

INFECTION

Central nervous system infections during the antepartum or postnatal period can be associated with neonatal seizures (Kairam and De Vivo, 1981). A specific group of congenital infections—toxoplasmosis, rubella, cytomegalic inclusion disease, and herpes (the TORCH infections)—can produce severe encephalopathic damage that results in seizures, as well as more diffuse brain disorders. Other congenital infections include those due to enteroviruses and parvoviruses. Specific infections—for instance, neonatal herpes encephalitis—may be associated with severe EEG pattern abnormalities (Mizrahi and Tharp, 1982). Rubella, toxoplasmosis, and cytomegalic inclusion disease each also can lead to devastating encephalitis, usually manifesting with microcephaly, jaundice, body rash, hepatosplenomegaly, and/or chorioretinitis. Increasing lethargy and obtundation with or without seizures may suggest the subacute presentation of encephalitis during the postnatal period. Serial cerebrospinal fluid (CSF) analyses document progressively increasing protein levels and/or pleocytosis.

Bacterial infections from either gram-negative or gram-positive organisms, acquired in utero or postnatally, also are associated with neonatal seizures. Infection with some organisms, such as *Escherichia coli*, group B streptococci, *Listeria monocytogenes*, and *Mycoplasma*, may produce severe leptomeningeal infiltration, with possible abscess formation and cerebrovascular occlusions. A high percentage of survivors suffers significant neurologic sequelae.

CENTRAL NERVOUS SYSTEM MALFORMATIONS

Disorders occurring during the stages of induction, segmentation, proliferation, migration, myelination, and synaptogenesis can contribute to brain malformations. The neonate with such malformations is at increased risk for seizures in association with the stress experienced around the time of birth (Palmini et al, 1994), which presumably lowers seizure thresholds. Brain anomalies may occur as a result of either genetic causes from conception and/or acquired defects early during gestation. Specific dysgenesis syndromes, such as holoprosencephaly and lissencephaly, can be associated with characteristic facial or body anomalies. Cytogenetic studies may document trisomies or deletion defects. Unfortunately, infants may lack physical clues to the presence of a brain malformation. Therefore, a high index of clinical suspicion for this entity is warranted in evaluating neonates with persistent seizures. In one study, 9% of 356 infants who presented with neonatal seizures were found to have brain malformations (Sheth et al, 1999). Neuroimaging, preferably with MR techniques, documents brain dysgenesis in children who may also express severe electrographic disturbances including seizures. Local or regional brain malformations are rare causes of early-onset epilepsy in neonates and young infants (Aicardi, 1985; Ohtahara, 1978). Functional imaging studies such as positron emission tomography scans (Chugani et al, 1994) may identify localized areas of altered brain metabolism, which can assist in a neurosurgical approach to seizure management, even in young children who fail to respond to AED maintenance (Pedespan et al, 1995).

INBORN ERRORS OF METABOLISM

Inherited biochemical abnormalities are rare causes of neonatal seizures (Scher, 2001b). Intractable seizures associated with elevated lactate and pyruvate levels in blood and CSF may reflect specific inborn errors of metabolism. Dysplastic or destructive brain lesions, as documented on neuroimaging, may be associated with specific biochemical defects, such as glycine encephalopathy or branched-chain aminoacidopathies. Pregnancy, labor, and delivery histories for affected infants are commonly uneventful. The emergence of poor feeding and also increasing lethargy, stupor, coma, and seizures are early indications of an inborn metabolic disturbance during the first few days of life. The newborn with an inherited metabolic disorder may initially present as a neurologically depressed and hypotonic child with asphyxia and seizures (Barth, 1992). Some children respond to specific dietary therapies, including vitamin supplementation (Painter et al, 1984), depending on the enzymatic defect. Specific urea cycle defects such as carbamoylphosphate synthetase deficiency may manifest as coma and seizures during the first 2 days of life, with marked elevations in plasma ammonia levels. Affected infants may respond to aggressive treatment with exchange transfusion, dialysis, and appropriate dietary adjustments.

Pyridoxine (vitamin B_6) dependency is an uncommon cause of neonatal seizures. Pyridoxal-5′-phosphate is the cofactor for more than 100 enzymatic reactions, of which several are important for the central nervous system metabolism of various amino acids and neurotransmitters. Infants with pyridoxine-dependent epilepsy (PDE) generally present with anticonvulsant resistant seizures within the first several days of life, frequently associated with signs of encephalopathy including irritability, sleeplessness, and hypotonia (Gospe, 2010). In retrospect, some mothers will occasionally report paroxysmal fetal movements. In this clinical setting, the infant who is unresponsive to conventional antiepileptic medications should promptly receive an intravenous injection of 100 mg of pyridoxine; up to 500 mg administered over 30 minutes may be needed to obtain a clinical response. Although a pathognomonic EEG pattern is not seen in this disorder, concomitant EEG monitoring may be helpful to evaluate the extent of electrographic seizure activity and to aid in following the clinical response to pyridoxine administration (Schmitt et al, 2010). Termination of clinical seizures within minutes to hours as well as improvement in the EEG supports a clinical diagnosis of PDE. For these patients, pyridoxine administered in pharmacologic doses of 15 mg/kg/day is needed to maintain seizure control. PDE is an autosomal recessive disorder due to mutations in the *ALDH7A1* gene, and affected patients have elevated levels of α-aminoadipic semialdehyde in blood and urine. Patients with clinically suspected PDE should have molecular and/or biochemical confirmation of the disorder (Gospe, 2001).

Other rare causes of seizures include disorders of carbohydrate metabolism with coincident hypoglycemia (Scher, 2002) as well as peroxisomal disorders such as neonatal

adrenoleukodystrophy or Zellweger's syndrome. A defect in a glucose transporter protein necessary to move glucose across the blood-brain barrier also has been reported, which results in hypoglycorrhachia and seizures (De Vivo et al, 1991). Affected children may achieve seizure control with a ketogenic diet but nonetheless suffer delayed development.

Molybdenum cofactor deficiency and isolated sulfite oxidase deficiencies are other rare metabolic defects that cause neonatal seizures and associated destructive changes on neuroimaging, which may resemble findings in cerebrovascular disease or asphyxia (Slot et al, 1993).

DRUG WITHDRAWAL AND INTOXICATION

Newborns born to mothers with a history of prenatal substance abuse may be at increased risk for neonatal seizures (Herzlinger et al, 1977; Zelson et al, 1971). Exposure to barbiturates, alcohol, heroin, cocaine, or methadone commonly results in neurologic abnormalities that include tremors and irritability. More recently, withdrawal movements such as tremors have been identified with selective serotonin reuptake inhibitors (SSRIs) (Kuschel, 2007). Although noted during the immediate postnatal period, withdrawal symptoms may also occur as long as 4 to 6 weeks after birth (Kandall and Gartner, 1974; Zelson et al, 1971); EEG studies are useful to corroborate such movements with coincident electrographic seizures. Certain drugs such as short-acting barbiturates may be associated with seizures within the first several days of life (Bleyer and Marshall, 1972). Seizures may occur directly after substance withdrawal or may be associated with longer-standing uteroplacental insufficiency, promoted by chronic substance use and poor prenatal health maintenance by the mother. Careful review of placental/cord specimens may reveal chronic or acute pathologic lesions that contribute to antepartum or intrauterine asphyxia.

Inadvertent fetal injection with a local anesthetic agent during delivery may induce intoxication, which is a rare cause of seizures (Dodson, 1976; Hillman et al, 1979). Patients present during the first 6 to 8 hours of life with apnea, bradycardia, and hypotonia and are comatose, without brainstem reflexes. If the obstetric history indicates pudendal administration of an anesthetic to the mother, a careful examination of the child's scalp or body for puncture marks is indicated. Determination of plasma levels of the suspected anesthetic agent will establish the diagnosis. Treatment consists of ventilatory support and removal of the drug by therapeutic diuresis, acidification of the urine, or exchange transfusion. Antiepileptic medications are rarely indicated.

PROGRESSIVE NEONATAL EPILEPTIC SYNDROMES

Progressive epileptic syndromes rarely manifest during the 1st month of life (Mizrahi and Clancy, 2000). These children usually exhibit myoclonic or migratory seizures that are poorly controlled by antiepileptic medications, with brain malformations often demonstrable on brain imaging (Ekert et al, 1997; Ohtahara, 1978). These neonatal epileptic syndromes are termed *early myoclonic encephalopathy* or *early infantile epileptic encephalopathy* (Ohtahara syndrome), and the EEG commonly documents burst suppression or markedly disorganized background rhythms. Rarely, a neonate with idiopathic localization-related or partial seizures without neuroimaging abnormalities presents with intractable epilepsy (Natsume et al, 1996).

With neurocutaneous syndromes such as incontinentia pigmenti and tuberous sclerosis, symptomatic epilepsy during the neonatal period may be the presenting clinical manifestation of either of these genetic disorders. Incontinentia pigmenti is accompanied by a vesicular crusting rash, which initially mimics a herpetic infection. Seizures may or may not be present. The skin lesions evolve into lightly pigmented, raised sebaceous lesions in older infants and children. Tuberous sclerosis also rarely manifests with skin lesions in the newborn period. Hypopigmented lesions, initially noted under ultraviolet light, usually appear later during infancy. Two fetal presentations of tuberous sclerosis are that of the more common cardiac tumor, usually a rhabdomyoma, and rarely that of a congenital brain tumor, both noted on fetal sonography. Neonatal seizures also may be the presenting feature (Miller et al, 1998), with documentation of intracranial lesions on postnatal neuroimaging.

BENIGN FAMILIAL NEONATAL SEIZURES

The autosomal dominant form of neonatal seizures is a rare genetic epilepsy that should be considered in the context of a positive family history (Bjerre and Corelius, 1968; Pettit and Fenichel, 1980; Ryan et al, 1991). Exclusion of infectious, metabolic, toxic, or structural causes needs to be completed before this entity is considered in the diagnosis. The genetic defect was first described on chromosome 20q, specifically at the D20S19 and D20S20 loci, as well as a locus EBN2 on chromosome 8q24. By positional cloning, a potassium channel gene (*KCNQ2*) located on 20q13.3 was first isolated and found to be expressed in the brain (Bjerre and Corelius, 1968). A second potassium channel gene (*KCNQ3*) also has been described and may explain the variability in phenotypic expression of seizures and outcome (Leppert and Singh, 1999). Recently, mutations in ion channels also have been implicated in Jervell and Lange-Nielsen syndrome, whose symptoms include congenital deafness and cardiac arrhythmias (Jentsch et al, 2000). Infant outcomes range from excellent to guarded, depending on the persistence of seizures beyond the neonatal period. Response to antiepileptic medication is generally good, although some clinicians describe variable success. Further studies are needed to clarify the relationship between phenotypic and genotypic expressions of this disorder.

SEIZURES REFLECTING FETAL OR NEONATAL BRAIN DISORDERS: GUIDE TO DIFFERENTIAL DIAGNOSIS

The neurologist must place EEG-confirmed seizures in the context of historical, clinical, and laboratory evidence to determine both the pathogenesis and timing of a brain disorder. Seizures occurring in neonates who have experienced asphyxia support either acute intrapartum events or

antepartum disease processes, or both. Does the child with seizures also have clinical and laboratory signs of evolving cerebral edema? The presence of a bulging fontanel with neuroimaging evidence of increased intracranial pressure and cerebral edema (i.e., obliterated ventricular outline and abnormal diffusion-weighted MR images), hyponatremia, and increased urine osmolality (i.e., the syndrome of inappropriate secretion of antidiuretic hormone) more strongly suggest a more recent asphyxial disease process, in or around the intrapartum period, causing acute or subacute cerebral edema.

Alternatively, failure to document evolving cerebral edema during the first 3 days after asphyxia or documentation of encephalomalacia or cystic brain lesions on neuroimaging shortly after birth (even in the encephalopathic newborn) suggests a more chronic disease process with remote antepartum brain injury. Liquefaction necrosis requires 2 weeks or longer after a presumed asphyxial event to produce a cystic cavity (Friede, 1975) before becoming visible on neuroimaging.

Isolated seizures in an otherwise asymptomatic neonate also suggest a disease process that occurred during either the postnatal or the antepartum period. Neonates present with seizures as a result of postnatal illnesses from intracranial infection, cardiovascular lesions, drug toxicity, or inherited metabolic diseases. Children with antepartum injuries may express isolated seizures after in utero cerebrovascular injury secondary to thrombolytic and/or embolic disease of the mother, placenta, or fetus. Fetal injury alternatively may occur after ischemia-hypoperfusion events from circulatory disturbances such as maternal shock, chorioamnionitis, or placental fetal vasculopathy (Miller, 2000).

Only a fraction of neonates with cerebrovascular disease present with neonatal seizures (De Vries et al, 1997). Why some children remain asymptomatic until later during childhood is unknown. Neonatal expression of seizures may reflect superimposed stress during parturition, which lowers seizure threshold in susceptible brain regions that have been previously damaged.

After a careful review of the medical histories of the mother, fetus, and newborn, determination of serum glucose, electrolytes, ammonia, lactate, pyruvate, magnesium, calcium, and phosphorus levels may diagnose correctable metabolic conditions in newborns with seizures who will not require antiepileptic medications. CSF analyses including cell count, protein, glucose, lactate, pyruvate, amino acids, and culture studies are performed to assess for CNS infection, intracranial hemorrhage, and metabolic disease. Alternatively, metabolic acidosis on serial arterial blood gas determinations may suggest an inherited metabolic disease, particularly if intrapartum asphyxia was not judged to be severe. Absence of multiorgan dysfunction may alert the clinician to other potential causes of seizures besides intrapartum asphyxia. Signs of chronic in utero stress such as growth restriction, early hypertonicity after neonatal depression, joint contractures, or elevated nucleated red blood cell values all suggest longer-standing antepartum stress to the fetus. Genetic or syndromic conditions may contribute to the expression of neonatal encephalopathies independent of asphyxial injury (Felix et al, 2000). Careful review of placental and cord specimens also can be extremely useful to help time a brain insult. Neuroimaging, preferably using MR techniques, can locate, grade the severity of, and possibly time an insult (Leth et al, 1997) (i.e., using diffusion-weighted images). Ancillary studies may also include measurement of long-chain fatty acid and chromosomal/DNA analyses, as deemed necessary by family and clinical history. Finally, serum and urine organic acid and amino acid determinations may be needed to delineate a specific biochemical disorder for the child with a persistent metabolic acidosis. Lysosomal enzyme studies also are occasionally considered to diagnose specific enzymatic deficiencies in children with neonatal seizures.

CHALLENGES REGARDING PROGNOSTIC ASSESSMENTS

The mortality rate among infants who present with clinical neonatal seizures has declined from 40% to 15% (Volpe, 2001). Studies of EEG-confirmed seizures documented mortality rates of 50% in preterm and 40% in full-term infants during the 1980s (Scher and Painter, 1989; Scher et al, 1993), with the mortality rate dropping below 20% in the 1990s in the same obstetric center (Scher, 1997a). The incidence of adverse neurologic sequelae, however, remains high; approximately two thirds of survivors are so affected. Even if major neurodevelopmental sequelae such as motor deficits and mental retardation were avoided in survivors after neonatal seizures, subtle neurodevelopmental vulnerability may manifest in late teenage years as specific learning difficulties or poor social adjustment (Temple et al, 1995), underscoring more recent experimental findings of long-term deficits in animal populations (Holmes and Ben-Ari, 2001). The poor prognosis for premature infants with seizures is reflected in high rates of subsequent disability and mortality, suggesting that severity and timing of the pathologic process continue to be major determinants for outcome (Ronen et al, 2007).

Prediction of outcome should also consider the etiologic disorder for the seizures, such as severe asphyxia, significant craniocerebral trauma, and brain infections. More accurate imaging procedures (magnetic resonance imaging [MRI] in particular) have increased our awareness of destructive and congenital brain lesions with a higher risk for compromised outcome.

Interictal EEG pattern abnormalities are also extremely helpful in predicting neurologic outcome in the neonate with seizures (Bye et al, 1997; Monod et al, 1972; Sinclair et al, 1999; Tharp et al, 1981). Major background disturbances such as burst suppression are highly predictive of poor outcome, particularly when persistent abnormalities are still present on serial EEG studies into the 2nd week of life. Seizure patterns alone, however, are not accurate to predict outcome, unless quantified to high numbers, long durations, and multifocal distribution (McBride et al, 2000). In one study, normal findings on interictal EEGs were associated with an 86% chance of normal development at 4 years of age in 139 neonates with seizures (Rose and Lombroso, 1970); by contrast, neonates with markedly abnormal EEG background disturbances had only a 7% chance for normal outcome. Another study (Rowe et al, 1985) reported outcome in term and preterm infants with

seizures, concluding that the EEG background was more predictive of outcome than the presence of isolated sharp wave discharges. Even severe electroencephalographic abnormalities on single-channel spectral EEG recordings after asphyxia carry a higher risk for sequelae (Hellstrom-Westas, 1992).

Neonates with seizures have an increased risk for epilepsy during childhood (Watanabe et al, 1982). On the basis of clinical seizure criteria, 20% to 25% of neonates with seizures later develop epilepsy (Holden et al, 1982). Excluding febrile seizures, the prevalence of epilepsy by 6 to 7 years of age is estimated to be between 15% and 30%, based on EEG-confirmed seizures for an inborn hospital population; two thirds of this cohort were preterm neonates (Scher et al, 1993). These findings are in contrast with an incidence of 56% with epilepsy for an exclusively outborn neonatal population of primarily full-term newborns with seizures (Clancy and Legido, 1991). Epilepsy risk therefore reflects selection bias of specific study groups, as well as referral patterns in different hospital settings. For example, low birthweight, short gestational age, and intrauterine growth restriction are associated with an increased risk of epilepsy (Sun et al, 2008).

DIAGNOSTIC DILEMMAS REGARDING TREATMENT CHOICES

CORRECTIVE THERAPIES

Rapid infusion of glucose or other supplemental electrolytes should be initiated before antiepileptic medications are considered. Hypoglycemia can be readily corrected by intravenous administration of 5 to 10 mg/kg of a 10% to 15% dextrose solution, followed by an infusion of 8 to 10 mg/kg/minute. Persistent hypoglycemia may require more hypertonic glucose solutions. Rarely, prednisone, 2 mg/kg/day, may be needed to establish a glucose level within the normal range (Scher, 2001b).

Hypocalcemia-induced seizures should be treated with an intravenous infusion of 200 mg/kg of calcium gluconate. This dosage should be repeated every 5 to 6 hours over the first 24 hours. Serum magnesium concentrations also should be measured, because hypomagnesemia may accompany hypocalcemia; 0.2 mg/kg of magnesium sulfate should be given by intramuscular injection (Scher, 2001b).

Disorders of serum sodium are rare causes of neonatal seizures. Either fluid restriction or replacement with hypotonic solutions is generally the mode of therapy for correcting sodium dysmetabolism.

Pyridoxine dependency requires the injection of 50 to 500 mg of pyridoxine during a seizure with coincident EEG monitoring. A beneficial pyridoxine effect occurs either immediately or over the first several hours. A daily dose of 50 to 100 mg of pyridoxine should then be administered (Scher, 2001b).

ANTIEPILEPTIC MEDICATIONS

If the decision to treat neonates with AEDs is reached, important questions must be addressed with respect to who should be treated, when to begin treatment, which drug to use, and for how long. Some clinicians suggest that only neonates with clinical seizures should receive medications; brief electrographic seizures need not be treated. Others suggest more aggressive treatment of electrographic seizures, because uncontrolled seizures potentially have an adverse effect on immature brain development (Dwyer and Wasterlain, 1982; Wasterlain, 1997). Others warn that early administration of an AED, such as phenobarbital, even before signs of HIE appear, may have adverse effects on outcome in term infants (Ajayi et al, 1998).

Phenobarbital and phenytoin, nonetheless, remain the most widely used AEDs; use of benzodiazepines, primidone, and valproic acid has been anecdotally reported (Scher, 2001b). The half-life of phenobarbital ranges from 45 to 173 hours in the neonate (Lockman et al, 1979; Painter et al, 1978, 1981); the initial loading dose is recommended at 20 mg/kg, with a maintenance dose of 3 to 4 mg/kg/day. Therapeutic levels are generally suggested to be between 16 and 40 μg/mL; however, there is no consensus with respect to drug maintenance.

The preferred loading dose of phenytoin is 15 to 20 mg/kg (Painter et al, 1978, 1981). Serum levels of phenytoin are difficult to maintain because this drug is rapidly redistributed to body tissues. Blood levels cannot be well maintained using an oral preparation. A water-soluble form, fosphenytoin, may be administered at the same loading dose. This specific agent has less harmful effects on the vein where it is injected.

Benzodiazepines also may be used to control neonatal seizures. The drug most widely used is diazepam. One early study suggests a half-life of 54 hours in preterm infants to 18 hours in full-term infants (Smith and Masotti, 1971). Intravenous administration is recommended because the drug is absorbed slowly after an intramuscular injection. Diazepam is highly protein-bound; alteration of bilirubin binding is low. Recommended intravenous doses for acute management should begin at 0.5 mg/kg. Deposition into muscle precludes its use as a maintenance antiepileptic medication, because profound hypotonia and respiratory depression may result, particularly if barbiturates also have been administered.

Efficacy of Treatment

Conflicting studies report varying efficacy with phenobarbital or phenytoin. Most studies only apply a clinical end point to seizure cessation. One study (Painter et al, 1978) found that only 36% of neonates with clinical seizures responded to phenobarbital; another study noted cessation of clinical seizures with phenobarbital in only 32% of neonates (Lockman et al, 1979). With doses as high as 40 mg/kg (Gal et al, 1982), the rate of clinical seizure control was reported to be 85%. A more recent study reported that the earlier administration of high-dose phenobarbital in a group of asphyxiated infants was associated with a 27% reduction in clinical seizures and better outcomes than in a group of infants who did not receive high dosages (Hall et al, 1998). However, coincident EEG studies are now suggested to verify the resolution of electrographic seizures. A recent report suggests that 25% of neonates have persistent electrographic seizures after suppression of clinical seizure behaviors following drug administration (Scher, 1994). With use of the EEG to judge cessation of

seizures, neither phenobarbital nor phenytoin was effective in controlling seizure activity (Painter et al, 1999).

The use of free or drug-bound fractions of AEDs has been suggested to better assess both efficacy and potential toxicity of these drugs in pediatric populations (Painter et al, 1987). Drug binding in neonates with seizures has only recently been reported and can be altered in a sick neonate with organ dysfunction. Toxic side effects may result from elevated free fractions of a drug, which may adversely affect cardiovascular and respiratory functions. To guard against untoward effects, evaluation of treatment and efficacy must take into account both total and free AED fractions, in the context of the newborn's progression or resolution of systemic illness.

Novel Antiepileptic Drug Approaches

Mechanisms of seizure generation, propagation, and termination are different during early brain development as compared with more mature ages. These age-related mechanisms have partially been elucidated (Jensen, 1999; Sanchez and Jensen, 2001). Given that traditional antiepileptic medications have unacceptable efficacy to stop neonatal seizures for specific subsets of newborns, alternative medication options must be developed.

New antiepileptic alternatives to treat neonatal seizures are now being studied. One class of medications are the *N*-methyl-D-aspartate (NMDA) antagonists such as topiramate (Koh and Jensen, 2001). Experimental animal models of asphyxia-induced seizure activity in immature brains have indicated a certain degree of efficacy. Such models provide data regarding pharmacologi and physiological characteristics of neuronal responses after an asphyxial stress that cause excessive release of excitotoxic neurotransmitter (Jensen and Wang, 1996) such as glutamate. Specific cell membrane receptors termed metabotropic glutamate receptors (MGluRs) are sensitive to extracellular glutamate release and may play a role in epileptogenesis and seizure-induced brain damage (Aronica et al, 1997). One class of membrane receptor, for example, has been studied in rat pups after hypoxia-induced seizures, suggesting that MGluR downregulation can be associated with epileptogenesis in the absence of cell loss (Sanchez and Jensen, 2001). Subclasses of MGluRs will lead to investigations of novel drugs that block these membrane receptors as the mode of treatment for neonatal seizures (Lie et al, 2000).

Another therapeutic approach is suggested by experimental studies that demonstrate enhanced seizure susceptibility in the developing brain because γ-aminobutyric acid (GABA) exerts a depolarizing excitatory rather than repolarizing inhibitory action in immature subjects (Brooks-Kayal, 2005). This paradoxical action of GABA early in development may be due in part to age-related differences in chloride homeostasis (Lie et al, 2000). Chloride transport is a function of two membrane pumps with different time courses of expression. Early in development (i.e., in the rat, P3-P15 after birth), the Na^+-K^+-$2Cl^-$ cotransporter (NKCC1) imports large amounts of chloride into the neuron (along with sodium and potassium to maintain electroneutrality). This pump sets the chloride equilibrium potential positive to the resting potential so that when the $GABA_A$ receptor is activated, chloride flows out of the neuron, depolarizing it. Differences in cortical versus subcortical GABAergic signaling from this chloride transporter have been demonstrated, suggesting that electroclinical uncoupling of neonatal seizures occurs more likely in cortical regions where NKCC1 cotransporter is more active (Glykys et al, 2009). Over time, NKCC1 expression diminishes, and another chloride transporter, KCC2, is expressed. KCC2 has the opposite effect; it extrudes chloride out of the neuron, placing the equilibrium potential more negative than the resting potential so that $GABA_A$ receptor activation allows extracellular chloride to flow into the neuron, hyperpolarizing it and endowing GABA with inhibitory action.

Researchers have termed this the developmental "switch" in chloride homeostasis. This maturational aspect to the chloride ion may influence seizure susceptibility in the neonatal brain. The additional depolarization that is due to $GABA_A$ receptor activation augments excitation that may be initiated by the glutamate neurotransmission. As a result, there is a shift in the excitation-inhibition balance toward excessive excitation, and thus toward seizure activity. These conclusions have been suggested by Dzhala et al (2005), who described the developmental profile of NKCC1 in the human neonate. In the early postnatal period, NKCC1 rises to a peak and then declines to adult levels. This rearrangement of membrane receptors occurs over the first several months of life. In the same time period, KCC2 expression gradually rises to adult levels. Blocking NKCC1 function with a commonly used diuretic known as bumetanide prevents the accumulation of intercellular chloride and therefore counteracts the depolarizing action of $GABA_A$ receptor activation. Bumetanide reduces kainate-induced seizures in neonatal but not adult rats and bursts firing in hippocampus slices. As further evidence, in genetically engineered mice that lack NKCC1, bumetanide is not effective in ameliorating seizures, supporting its role as a specific inhibitor of NKCC1. Therefore, bumetanide is now considered a promising antiepileptic drug with a developmental target, namely the immature chloride cotransporter NKCC1. Some claim that this particular diuretic can be safely used in the neonate, although its long-term safety profile needs to be better studied. It has also been recently suggested that pharmacologic agents that can diminish bursting behavior in neonatal neurons can add an additional level to the control of seizures. Dzhala et al (2005) demonstrated that bumetanide rapidly suppresses synchronous bursts of network activity in P4-P8 hippocampus slices in the rat model. This supports the use of this agent as a potential antiepileptic medication in this age group. Clinical trials need to demonstrate that bumetanide or other similar diuretics can inhibit seizure activity, with or without conventional medications such as phenobarbital (Haglund and Hochman, 2005). It will be necessary to establish that these agents can reach the brain in appropriate concentrations and lack short- as well as long-term side effects.

There are still crucial issues regarding the theory that GABA-mediated excitation may play an important role in human neonatal seizures which may be amenable to treatment as discussed earlier. It is yet unknown why some GABA-ergic agents such as phenobarbital and

benzodiazepine fail to have adequate efficacy for human neonatal seizure control for a substantial subset of patients. Though seizures can be halted in a percentage of newborns, additional understanding of epileptogenesis in the immature brain must consider the timing and etiology-specific aspects of GABA-mediated mechanisms of seizures as they relate to asphyxia, infection, or trauma. A specific etiology may alter seizure threshold by epigenetic modification, changing the specific genetic variability within individuals in a time-sensitive manner. Based on up- or downregulation of genetic expression, individuals who suffer asphyxia, infection, or trauma may have variable vulnerability or resistance to GABA-mediated mechanisms for seizures. This generalization is further complicated by not only the timing of injury but also the specific brain region of damage, which may have occurred remotely either during the antepartum or during the intrapartum or neonatal period. Seizures from selectively damaged deep gray matter, neocortical layers, or white matter regions may respond differently to similar antiepileptic drug regimens. Therefore, one must consider whether neonatal seizures represent novel brain injury or are surrogates of injury resulting from etiologies either varied in brain location or during time periods beginning during fetal life (Scher, 2003). The neurologist must place events leading to seizures in the context of clinical, historical, and laboratory findings to determine both the pathogenesis and timing of an encephalopathic process in a neonate who is symptomatic with seizures. A new classification of neonatal seizures that integrates electrographic expression, brain region, etiology, and timing may then have more relevance to the choice of antiepileptic medication (Scher, 2006).

Discontinuation of Drug Use

The clinician's decision to maintain or discontinue AED use is also uncertain. Discontinuation of drugs before discharge from the NICU is generally recommended, because then clinical assessments of arousal, tone, and behavior will not be hampered by medication effect. However, newborns with congenital or destructive brain lesions on neuroimaging or those with persistently abnormal findings on neurologic examination at the time of discharge may require a slower taper off medication over several weeks or months. In most children with neonatal seizures, the seizures rarely reoccur during the first 2 years of life, and prophylactic AED administration need not be maintained past 3 months of age, even in the child at risk. This recommendation is supported by a recent study suggesting a low risk of seizure recurrence after early withdrawal of AED therapy in the neonatal period (Hellstrom-Westas et al, 1995). Also, older infants who present with specific epileptic syndromes, such as infantile spasms, will not respond to the conventional AEDs that were initially begun during the neonatal period. This honeymoon period without seizures commonly persists for many years in most children, before isolated or recurrent seizures appear.

The potential for damage to the developing CNS from AEDs also emphasizes the need to consider early discontinuation of these agents in the newborn period. Adverse effects on the morphology and metabolism of neuronal cells have been extensively reported from collective research performed over the past several decades (Mizrahi, 1999).

EFFECTS OF NEONATAL SEIZURES ON BRAIN DEVELOPMENT: CONSEQUENCES OF UNDERDIAGNOSIS

Embedded within the controversy regarding how to diagnose neonatal seizures (i.e., clinical vs. electroencephalographic) is the association of repetitive or prolonged seizures with brain damage both acutely and as a result of altered brain development. Linked to the clinician's concern for seizure duration is an appreciation of the diverse neuropathologic processes and etiologic disorders that cause neonatal seizures with resultant neurologic sequelae (Lien et al, 1995). CNS infections and severe asphyxia are two etiologic disorders that exemplify underlying pathophysiologic mechanisms responsible for brain damage in neonates independent of or with seizure expression.

During the acute phase of a neonatal brain disorder, seizures can cause or contribute to brain damage by drastically impairing the neurovascular unit. Such a unit is composed of pial and intraparenchymal cerebral arteries and arterioles, the extrinsic and intrinsic innervation of these vessels, and the perivascular astrocytes and neurons. Seizures can dramatically increase brain metabolism and cerebral blood flow during the ictal period, disrupt the blood-brain barrier, and cause an acute loss of cerebral pressure autoregulation, as well as a delayed impairment of cerebrovascular reactivity to various stimuli (Zimmerman et al, 2008). In addition to blood flow–related brain injury from seizure activity, seizures are associated with brain injury severity in a neonatal model of asphyxia. On postmortem examination, animals with seizures after asphyxia showed the greatest degree of neuropathologic injury compared to animals without seizures. Furthermore, animals with electrographic seizures with clinical signs had significantly greater histological damage compared to those with electrographic seizures alone, not apparent on MRI or spectroscopy. These results need to be duplicated in other animal studies as well as verified in human protocols involving seizures caused by multiple etiologies.

Adverse long-term effects of the seizure state on the developing brain have been reviewed (Holmes and Ben-Ari, 2001). Seizures can disrupt a cascade of biochemical and molecular pathways that normally are responsible for the plasticity or activity-dependent development of the maturing nervous system. Depending on the degree of brain immaturity, seizures may disrupt the processes of cell division, migration, and myelination; sequential expression of receptor formation; and stabilization of synapses—each of which contributes to the risk of neurologic sequelae, to varying degrees (Holmes, 2009; Holmes et al, 1998).

Experimental models of seizures in immature animals suggest comparatively less vulnerability to seizure-induced brain injury than in mature animals (Huang et al, 1999). In adult animals, seizures alter growth of hippocampal granule cells and of axonal and mossy fibers, resulting in long-term deficits in learning, memory, and behavior. A single prolonged seizure in an immature

animal, on the other hand, results in less cell loss or fiber sprouting and consequentially fewer deficits in learning memory and behavior. Resistance to brain damage from prolonged seizure activity, however, is age-specific, as evidenced by increased cell damage after only 2 weeks of age (Sankar et al, 2000). A 2001 study examined developmental changes in epileptiform activity in neocortical preparations in four different age groups and using four different pharmacologic models. The study confirmed that there are definite age-dependent differences in susceptibility to epileptiform activity in the neocortex. These developmental changes seem to relate to intrinsic network properties of the neocortex that are independent of ontogenetic differences in any specific neurotransmitter system (Wong and Yamada, 2001). Nonetheless, experimental neonatal status epilepticus in a rodent model resulted in classic hippocampal sclerosis and temporal lobe epilepsy (Dunleavy et al, 2009), suggesting there may be a threshold for recurrent seizures in an immature brain above which altered neuronal network connectivity leads to epilepsy at older ages.

Repetitive or prolonged neonatal seizures alternatively can increase the susceptibility of the developing brain to suffer subsequent seizure-induced injury during adolescence or early adulthood, by altering neuronal connectivity rather than increasing cell death (Holmes and Ben-Ari, 2001; Holmes et al, 1998; Koh et al, 1999). Neonatal animals subjected to status epilepticus have reduced seizure thresholds at later ages and demonstrate impairments of learning, memory, and activity levels after suffering seizures as adults. Proposed mechanisms of injury also include reduced neurogenesis in the hippocampus, for example, possibly because of ischemia-induced apoptosis, as well as necrotic pathways (McCabe et al, 2001). Other suggested mechanisms of injury include effects of nitric oxide synthase inhibition on cerebral circulation, which then contributes to ischemic injury (Takei et al, 1999). Neonatal seizures, therefore, may initiate a cascade of diverse changes in brain development that become maladaptive at older ages and increase the risk of subsequent damage after subsequent insults. Destructive mechanisms such as mossy fiber sprouting in the hippocampus or increased neuronal apoptosis may explain mutually exclusive pathways by which the immature brain suffers altered connectivity and reduced cell number, which is then "primed" for later seizure-induced cell loss at older ages.

The critical duration of seizures, whether cumulative or continuous, remains elusive with respect to resultant brain injury. Given that as many as one third of full-term infants experience electrographic seizures that satisfy a definition of status epilepticus (Scher et al, 1993), EEG documentation appears crucial to assign seizure duration. A study of 10-day-old rat pups indicated that prolonged seizures for 30 minutes after asphyxia resulted in exacerbation of brain injury specific to the hippocampus, while sparing the neocortex. Prolonged neonatal seizures do worsen damage incurred by an already compromised brain (Wirrell et al, 2001) in a region-specific manner. In a neonatal rodent model of brief recurrent seizures, Landrot et al (2001) demonstrated increased mossy fiber sprouting in the granule cells of the hippocampus, which correlated with impaired cognition and reduced EEG power spectra during adolescence. A companion study from the same laboratory demonstrated alterations in cognition and seizure susceptibility within 2 weeks of the last seizure before the adult pattern of mossy fiber distribution is achieved. Therefore, therapeutic strategies to alter the adverse outcomes of neonatal seizures must be initiated during or shortly after the seizures.

The overlapping effects of brain dysgenesis or injury from specific etiologic disorders versus seizure-induced brain damage make it difficult to differentiate preexisting brain lesions from the direct injurious effects of seizures themselves. The use of microdialysis probes in white and gray matter of piglet brains subjected to hypoxia indicates elevated lactate-pyruvate ratios after hypoxia but no direct association with seizure activity (Thoresen et al, 1998). These findings support the conclusion that seizures themselves may not always be injurious to brain.

The dearth of well-designed clinical investigations of outcome after neonatal seizures in humans unfortunately does not permit broad confirmation of these experimental findings. Better definitions of neonatal seizure severity, including electrographic expression and seizure duration, are required to help resolve this controversy. An investigation in human newborns with perinatal asphyxia suggests that seizure severity is independently associated with brain injury as measured by MR spectroscopy (Miller et al, 2002) and worse neurodevelopmental outcome (Glass et al, 2009a,b), but not all subjects had electrographic confirmation of seizures. Another study, however, used EEG confirmation of electrical status epilepticus and reported more severe neurodevelopmental disability and postnatal epilepsy (Pisani et al, 2007).

Aggressive use of antiepileptic medications without electroencephalographic confirmation contributes to the inaccurate estimate of seizure severity in neonates and possible medication-induced brain injury. Intractable seizures generally require the use of multiple antiepileptic medications, which may still not effectively control seizures (Painter et al, 1999). Drugs also may impede the clinician's ability to recognize persistent seizures, because of the uncoupling phenomenon in which the clinical expression is suppressed while the electrical expression of seizures continues. Clinical definitions of seizure occurrence and duration consequently underestimate seizure severity, which may be associated with increased risk for brain damage (Ekert et al, 1997). AED use also has secondary harmful effects on cardiac and respiratory functions, with resultant circulatory disturbances that will contribute to brain injury because of hypoperfusion (Lien et al, 1995). Finally, AED use may have teratogenic effects on brain development with exposure over long periods of time.

CHAPTER 64

Risk Assessment and Neurodevelopmental Outcomes

Mary Leppert and Marilee C. Allen

RISK OF NEURODEVELOPMENTAL DISABILITY

"Will my child survive?" "How will this illness influence my child's life?" These are the two questions most frequently asked by parents of infants in a neonatal intensive care unit (NICU). As difficult as it is to predict survival of a sick or very preterm infant, it is far more difficult to answer questions regarding quality of life for the infant who survives. How much recovery will there be? Will the child develop further complications? Most important, how will this early illness influence the child's neurologic, sensory, and cognitive development? For most conditions requiring neonatal intensive care, it is difficult to define the full extent (if any) of damage to or malformation of an infant's organ systems. Newborns have a remarkable potential for recovery, but how organs recover is poorly understood. Predicting the outcome for an individual NICU infant is therefore difficult.

Most commonly, *high risk* refers to the likelihood of neurodevelopmental disability, which is a group of interrelated, chronic, nonprogressive disorders of the central nervous system (CNS) caused by injury to or malformation of the developing brain. They form a spectrum ranging from cerebral palsy (motor impairment) and intellectual disability (cognitive impairment), to sensory impairment, to the more subtle disorders of CNS function (Table 64-1) (Accardo, 2008). These more subtle disorders of higher cortical function include language disorders, visual-perceptual problems, learning disability, minor neuromotor dysfunction, attention deficits, executive dysfunction, and behavioral problems. They have a lesser severity but a higher prevalence in the general population than is the case for the major disabilities (i.e., cerebral palsy and intellectual disability). *Intellectual disability* has supplanted the more stigmatic term *mental retardation*. Neurodevelopmental impairment (NDI) generally refers to cerebral palsy (CP), intellectual disability, severe hearing impairment, and severe visual impairment, and at times it may include severe learning disability, seizure disorder, or hydrocephalus.

Although preterm infants and sick full-term infants who required neonatal intensive care have an increased risk of neurodevelopmental disabilities compared with the general population, most do not develop major disability or NDI (Darlow et al, 2009). Although most children with disability manifest initial developmental delay, some have functional limitations without delay in milestone attainment. A preterm infant who was born at 27 weeks' gestation and had a right intraparenchymal hemorrhage had no delays when seen on follow-up at 14 months corrected for degree of prematurity. He walked independently, had a right pincer grasp, and said three meaningful words. On careful inspection, however, circumduction of his left foot was evident when he walked, and he had only a raking grasp with his left hand. Findings on examination—a tight left heel cord and some increased tone at his hips and on pronation and supination of his left arm—were consistent with a left spastic hemiplegia. Children with complex medical conditions may initially demonstrate developmental delay but not have long-term disability. An infant with chronic lung disease and mild hypotonia who is not rolling over by 6 months corrected for degree of prematurity has delayed development and is at risk for motor and language impairment. However, treatment of his lung disease may be associated with improved rate of attainment of developmental milestones, and he may have no or very mild impairment.

A large number of perinatal and demographic risk factors with differing capacities to predict neurodevelopmental disabilities have been identified and are summarized in Box 64-1. Multiple risk factors further increase risk of developmental disability (Behrman et al, 2007; Schmidt et al, 2003). Poverty increases the risks of prematurity and intrauterine growth restriction; low socioeconomic status, poor parental education, and maternal depression all have adverse effects on infant cognitive development and behavior (Behrman et al, 2007; Gray et al, 2004; Weisglas-Kuperus et al, 2009; Wood et al, 2005). A number of obstetric conditions (e.g., abruptio placentae, maternal antepartum hemorrhage) may be catastrophic, but prompt intervention can circumvent death and disability. Abnormalities on neonatal neurologic examination and neuroimaging studies are better predictors of outcome than preceding obstetric conditions, electronic fetal heart rate abnormalities, metabolic acidosis, or Apgar scores at birth (Graham et al, 2006, 2008; Handley-Derry et al, 1997; Lindstrom et al, 2008; Logitharajah et al, 2009; Nelson, 2002). As birthweight and gestational age decrease, rates of complications of prematurity and neurodevelopmental disability increase (Behrman et al, 2007). Rates of CP, cognitive impairment, and other neurodevelopmental disabilities increase with number and severity of neonatal complications, severity of neonatal encephalopathy, abnormalities on neonatal neurodevelopmental assessments, and neuroimaging abnormalities (Aarnoudse-Moens et al, 2009b; Allen and Capute, 1989; Amess et al, 1999; Behrman et al, 2007; Dixon et al, 2002; Handley-Derry et al, 1997; Krageloh-Mann and Cans, 2009; Marlow and Budge, 2005; Marret et al, 2007; Miller et al, 2005; Schmidt et al, 2003; Vohr et al, 2005b; Wyatt et al, 2007).

Neither risk nor statistical association implies causation, but studies of risk factors can provide important insights into etiology of neurodevelopmental disability (Allen, 2002; Behrman et al, 2007; Nelson, 2002; O'Shea, 2002).

TABLE 64-1 Prevalence of Neurodevelopmental Disabilities in the General Population

Disability	Prevalence per 1000 Children*
Cerebral palsy	1–4
Intellectual disability	7–40
Severe intellectual disability	4–5
Hearing impairment	1–3.1
Visual impairment	0.4–1.0
Specific learning disability	40–175
Speech and language disorders	20–74
Attention deficit hyperactivity disorders	14–74
Behavior disorders	3–15
Minor neuromotor dysfunction/ coordination disorder	50–150
Autism	2–7
Special education for disability	88
Cerebral palsy, intellectual disability, autism, *or* hearing *or* visual impairment	19

BOX 64-1 Categories of Perinatal Risk Factors

BACKGROUND CHARACTERISTICS

Socioeconomic status, social class, parental education, race, ethnic group

PRENATAL AND OBSTETRIC COMPLICATIONS

Maternal acute or chronic illness, maternal ingestion of drugs
Congenital infection, maternal urinary tract infections, chorioamnionitis
Multiple gestation, intrauterine death of a co-twin
Placental and cord problems (e.g., placental abruption, prolapsed cord)
Labor and delivery complications

PHYSICAL CHARACTERISTICS

Gender
Congenital anomalies, dysmorphic features, genetic syndromes
Prematurity, postmaturity
Intrauterine growth restriction/small for gestational age, microcephaly

CONDITION AT BIRTH

Apgar scores, cord pH, meconium staining, need for and response to resuscitation

NEONATAL COMPLICATIONS

Hypoxia, acidosis, hypotension/shock
Chronic lung disease/bronchopulmonary dysplasia, hypoxic respiratory failure, apnea
Sepsis, meningitis, necrotizing enterocolitis
Retinopathy of prematurity

MEASURES OF CENTRAL NERVOUS SYSTEM STRUCTURE AND FUNCTION

Clinical: stage of neonatal encephalopathy, neurodevelopmental examination, seizures
Neuroimaging: intraventricular hemorrhage, intraparenchymal hemorrhage, periventricular leukomalacia or evidence of white matter injury, encephalomalacia, ventricular dilation, cortical atrophy, hydrocephalus, injury to the deep gray nuclei and posterior limb of the internal capsule
EEG: burst-suppression pattern, low amplitude

An abnormal fetus with an unrecognized genetic disorder, prenatal insult, or malformation may grow poorly in utero, precipitate preterm delivery, fail to turn or descend properly, need stimulation to breathe at birth, and/or nipple-feed poorly. As many as 50% to 65% of children with CP were born at term, and many have evidence of intrauterine infection, coagulopathy, placental pathology, or death of a co-twin (Himmelmann et al, 2010; Nelson, 2002; Sellier et al, 2010). In a European collaborative study of 4002 children with CP who had birthweight (BW) at or above 2500 g, only 24% had received neonatal intensive care (Sellier et al, 2010). Strong evidence links cerebral palsy in preterm infants to ischemic and/or cytokine-mediated brain injury, with perhaps also a role for insufficient levels of developmentally regulated neuroprotective substances (e.g., thyroxine, hydrocortisone) (Mann et al, 2009; O'Shea, 2002; O'Shea et al, 2009).

The presence or absence of perinatal and neonatal risk factors can neither diagnose neurodevelopmental disability nor ensure normal development. Uncertainty regarding a child's outcome is difficult for both parents and professionals. Helping parents to recognize and cope with their fears allows development of a realistic plan for the future, including identifying family support systems, early intervention strategies, and community resources. The clinician should begin by describing the range of possible outcomes to parents. Mildly increased risk for disability should be acknowledged but put into perspective. Parents of infants with significant or multiple risk factors should be offered focused neurodevelopmental follow-up evaluation and support, especially during critical early years. A comprehensive, developmentally based, family-oriented follow-up clinic helps to ensure early diagnosis of neurodevelopmental disability, shape early intervention strategies to meet the infant's and family's evolving needs, and provide parents with continuity and ongoing support during a difficult period of uncertainty and adjustment.

NEURODEVELOPMENTAL OUTCOME

This section describes the outcome for several groups of high-risk infants cared for in the NICU. The reported incidences of disability differ from study to study because of variations in a number of factors: study criteria, ethnic and demographic composition of the study population, obstetric and neonatal care practices, follow-up rate, length of follow-up, and assessment methodologies. High follow-up rates are preferable but difficult to attain. Low follow-up rates raise concerns about bias—for example, one study found difficulty with follow-up to be associated with lower intelligence quotient (IQ), greater degree of disability, and single parents with less education (Callanan et al, 2001).

How the children are followed, and for how long, influences what neurodevelopmental disabilities are detected. Studies that evaluate infants up to 1 year focus on the major disabilities, particularly motor and sensory disabilities, but are inadequate for assessing mild CP, mild intellectual disability, or borderline intelligence. Mild to moderate sensory impairments may be missed if specific evaluations of

hearing and vision are not performed after initial screening in the NICU. Evaluating older children improves diagnostic accuracy and recognition of mild disabilities, but can lower follow-up rates. Follow-up assessments from 2 to 6 years can detect mild intellectual disabilities, minor neuromotor dysfunction, behavioral problems, attention deficits, and language delay. Questions about learning disability and other school-related problems require follow-up to school age. Longitudinal studies have found an increased incidence of school problems with longer periods of follow-up evaluation (Aylward, 2002; Msall and Tremont, 2002). The younger child with more subtle impairments often has some ability to compensate for learning difficulties or inefficiencies initially, but experiences difficulties when work becomes more complex, abstract thought and expression are required, and efficiency becomes important in completing homework and test-taking. Follow-up to adolescence and adulthood addresses questions about functional abilities, independence, and quality of life.

PRETERM INFANTS

Prematurity is a common, complex condition due to multiple gene-environmental interactions, including both maternal and fetal genomes, the intrauterine environment, and the mother's environment (Behrman et al, 2007). Prematurity is a major public health problem in the United States: it accounts for 64% to 75% of infant deaths, 42% to 47% of children with CP, 27% of children with significant cognitive impairments, and 23% to 37% of children with significant sensory impairments. A conservative estimate by the Institute of Medicine found the annual economic burden for preterm births in 2005 to be $26.2 billion ($51,600 per preterm infant born) over that of a full-term infant. The population of preterm infants is remarkably heterogeneous with respect to etiology, complications, and outcomes. Although it was initially defined by birthweight (BW <2500 g), and now by gestational age (GA <37 weeks), prematurity's defining characteristic is immature organ development for extrauterine life. Just as BW varies with GA, there is individual variation in degree of maturity for both BW and GA (Allen, 2005). Final common pathways to preterm delivery include spontaneous preterm labor, preterm rupture of membranes, and indicated preterm delivery for maternal or fetal health (Behrman et al, 2007). The multiple risk factors identified for each pathway overlap, yet the strongest predictor is a prior preterm birth. Inflammation and infection have been implicated as etiologies for preterm birth, complications of prematurity (e.g., chronic lung disease), and neurodevelopmental disability.

MOTOR IMPAIRMENT

Preterm infants exhibit a range of neuromotor abnormalities on exam, which often persist and may be accompanied by motor delay and/or motor impairment, as well as fine motor impairment, visual-spatial deficits, executive dysfunction, visual-perceptual impairment, and problems with motor planning and visual navigation (Bracewell and Marlow, 2002; Davis et al, 2007; Hadders-Algra, 2002; Johnson et al, 2009; Marlow et al, 2007; Mikkola et al, 2005; Pavlova et al, 2007; Samsom et al, 2002; Schmidhauser et al, 2006; Sigurdardottir et al, 2009; Venkateswaran and Shevell, 2008; Vohr et al, 2005a; Williams et al, 2010). Motor impairments in children born preterm range from severe to mild CP, to mild functional motor impairment, termed minor neuromotor dysfunction (MND) or developmental coordination disorder (DCD). For many preterm children with CP or MND/DCD, their motor impairment is far less disabling than their associated impairments (e.g., executive dysfunction, cognitive impairments, fine motor difficulties) and that lead to difficulties in the classroom and with their peers.

Most preterm infants do not develop CP (Tables 64-2 and 64-3). The risk for CP increases with decreasing GA and BW (see Tables 64-2 and 64-3). In large regional population studies, the prevalence of CP increased from 0.9 to 1.5 per 1000 live births of children born full term with normal BW, to 6.1 to 6.7 per 1000 live births at 32 to 36 weeks' gestation, 18.1 to 21.6 at 28 to 36 weeks' gestation, and 40.4 to 43.7 at 28 to 31 weeks' gestation; and from 6.7 to 10.5 per 1000 live births with BW 1500 to 2499 g, 39.5 to 50.6 for BW <1500 g, and 58.3 to 80 for BW <1000 g (see Table 64-2) (Dolk et al, 2006; Himmelmann et al, 2005, 2010; Platt et al, 2007; Sellier et al, 2010; Sigurdardottir et al, 2009; Surman et al, 2009). The preterm outcome studies in Table 64-3 reported the rate of CP in survivors (not per live births); this is an important distinction, because many infants born at 22 to 25 weeks' gestation die in the delivery room, in the NICU, and before follow-up studies assess their development (Bodeau-Livinec et al, 2008; Doyle, 2001; Groenendaal et al, 2010; Kutz et al, 2009; Marlow et al, 2005b; Wood et al, 2000). Two studies reporting rate of CP in survivors by each week of gestation found a progressive increase as GA decreased, from 0.7% at 34 weeks GA, to 4% at 32 weeks GA, to 19% at 26 weeks GA (Ancel et al, 2006; Marret et al, 2007). At the limit of viability, 12% to 23% of survivors born before 26 weeks' gestation had CP, and up to half had severe functional motor impairment (i.e., spastic quadriplegia or nonambulatory spastic diplegia) (Bodeau-Livinec et al, 2008; Hintz et al, 2005; Johnson et al, 2009; Marlow et al, 2005b; Stahlmann et al, 2009; Steinmacher et al, 2008; Voss et al, 2007; Wilson-Costello et al, 2005, 2007).

Spastic diplegia, with greater spasticity in the legs and no to minimal involvement of the arms, occurs in 44% to 68% of preterm children (Ancel et al, 2006; Behrman et al, 2007; Mikkola et al, 2005; Sigurdardottir et al, 2009; Wood et al, 2000). Some preterm outcome studies distinguish between disabling, moderate to severe motor impairment or nonambulatory CP and mild CP (Marlow et al, 2005b; Stahlmann et al, 2009). There is some disagreement as to the distinction between mild CP and MND. A child with tight heel cords and hyperreflexia who toe-walks initially but walks independently with heels down by age 2 may be classified as having either mild CP or MND. Some of these children require physical therapy and/or bracing with ankle-foot orthoses, but with age they improve and their gross motor dysfunction is much less obvious (their mild CP disappears).

Many preterm outcome studies have reported more mild gross and fine motor impairments and visual-perceptual and visual-spatial deficits in preterm infants, even those without CP or intellectual disability, than in full-term

TABLE 64-2 Prevalence of Cerebral Palsy (CP) by Gestational Age (GA) and Birthweight (BW) Categories

					<2500	16	1.6%

comparison children (Behrman et al, 2007; Bracewell and Marlow, 2002; Breslau et al, 2000; Davis et al, 2007; Goyen et al, 1998; Marlow et al, 2007; Mikkola et al, 2005; Pavlova et al, 2007; Schmidhauser et al, 2006; Williams et al, 2010). Asymmetric leg or hand function, balance problems, incoordination, poor postural stability, difficulty with motor planning (figuring out how to perform complex motor tasks), sensory-motor integration problems (e.g., difficulty tolerating certain textures of foods, touch or sounds) and fine motor dysfunction can interfere with development of self-help skills, ability to play on the playground, peer relationships, and self-esteem. These subtle impairments can lead to problems with dressing, cutting with scissors, handwriting, academic learning, and behavior. Prevalence varies with how the population is defined, age at evaluation, and assessment methods: 70% of 11- to 13-year-olds with BW below 1000 g had definite motor problems compared with 22% of controls, OR 9.5 (95% confidence intervals [CI] 3.7 to 24.3) (Burns et al, 2009); 9.5% of 8- to 9-year-olds with GA below 28 weeks had DCD compared with 2% of controls (p=0.001) (Davis et al, 2007); 20% to 30% of children born at 32 to 36 weeks' gestation had difficulty with fine motor coordination and visual-motor tasks (Huddy et al, 2001). In the EPICure longitudinal study, children born before 26 weeks GA in 1995 had much poorer performance on a variety of motor tasks than full-term controls, including sensorimotor difficulties, visuospatial problems, and overflow movements during motor tasks, as well as a higher prevalence of left-handedness (28% vs. 10%) (Marlow et al, 2007).

CP, Cerebral palsy (children with mild to severe CP/survivors assessed); *F/U Rate*, follow-up rate (number of children seen for assessment/number of survivors); *HI*, hearing impairment, generally severe (severe hearing loss, required hearing aids); *IQ*, intelligence quotient or equivalent (intellectual disability is IQ <70; borderline intelligence is IQ 70–84); *n*, number of children assessed per group; *NDI*, neurodevelopmental Impairment (generally CP, IQ <70, severe visual impairment and/or hearing impairment); *Normal*, as defined in each study (no mild, moderate, or severe neurodevelopmental disability); *VI*, visual impairment, generally severe (very poor visual acuity, blind or no light perception).
*Median (interquartile range).
†Data from the National Institute of Child Health and Development Neonatal Research Network.

The prevalence of mild to moderate motor impairment in children born preterm who did not have CP was estimated at 40.5/100 (95% CI 32.1, 48.9) from pooled data in a random effects metaanalysis of 15 published studies (Williams et al, 2010). Their estimate of the prevalence of moderate motor impairment from pooled data was 19.0/100 (95% CI 14.2, 23.8).

COGNITIVE IMPAIRMENT

Populations of preterm children demonstrate a normal range of intelligence, but with lower means than those of full-term controls, even after adjustment for socioeconomic status and neurologic injury or impairment (Aylward, 2002; Behrman et al, 2007; Bhutta et al, 2002; Charkaluk et al, 2010; Johnson, 2007; Johnson et al, 2009). The significance of a lower mean IQ is in the greater proportion of children with intellectual disability, borderline intelligence, and low average intelligence who have difficulties functioning at school and in society. A Norwegian study found that prevalence of intellectual disability was 1.4 times higher for children born at 32 to 36 weeks GA and increased to 6.9 times higher for children born before 32 weeks GA (Stromme and Hagberg, 2000). Two studies found that preterm children did much better on cognitive tests at school age compared with their performance on the Bayley Scale of Infant Development at age 2, especially in the children who had no neurologic impairment and mothers with a high educational level (Hack et al, 2005; Roberts et al, 2010).

Cognitive impairments are the most common disabilities in preterm children, and their prevalence increases with decreasing GA and BW categories (see Table 64-3) (Behrman et al, 2007; Bhutta et al, 2002; Johnson, 2007; Johnson et al, 2009; Kirkegaard et al, 2006; Stoinska and Gadzinowski, 2010; Weisglas-Kuperus et al, 2009). Most preterm outcome studies report that 8% to 11% of children born before 28 to 32 weeks' gestation and 14% to as high as 54% of children born before 26 to 28 weeks' gestation had cognitive scores more than 2 standard deviations (SD) below the test mean (i.e., IQ <70), in comparison with only 1% to 2% of full-term controls (Bode et al, 2009; Doyle and Anderson, 2005; Doyle et al, 2010; Hintz et al, 2005; Johnson et al, 2009; Larroque et al, 2008; Marlow et al, 2005b; Marret et al, 2007; Roberts et al, 2010; Sommer et al, 2007; Vohr et al, 2005b). In the EPICure study, 21% of 6-year-olds born before 26 weeks GA had IQ scores more than 2 SD below the test mean, 25% had IQ scores 1 to 2 SD below the mean, and only 54% had IQ scores in the normal range (i.e., above 1 SD below the mean), as compared with 0, 2%, and 98%, respectively, of full-term controls (Marlow et al, 2005b). The mean IQ of the full-term controls was 106 (SD 12): 41% of preterm children had IQ scores more than 2 SD below the mean of the full-term controls, and 71% had IQ scores more than 1 SD below their mean. In a Finnish preterm outcome study, full-term controls had a mean IQ of 110 (SD 12): Only 3.3% of children with BW below 1500 g had IQ scores more than 2 SD below test norms, but using data from their full-term control sample, this increased to 15.4% (Munck et al, 2010). The lower mean IQ in the preterm population is not due solely to neurologic impairment: a metaanalysis of 16 case-control studies of children 5 years or older found a persistently lower mean IQ score for preterm infants, and when children with neurologic impairment were excluded, the weighted mean difference decreased only from 10.9 (95% CI 9.2, 12.5) to 10.2 (95% CI 9.0, 11.5) (Bhutta et al, 2002).

Intelligence scores are a composite of scores on multiple cognitive processing subtests; many preterm children with normal IQ scores have problems with attention, memory, complex language processing, nonverbal reasoning, visual-perceptual abilities, and/or executive function that interfere with learning, behavior, and school performance (Aarnoudse-Moens et al, 2009a; Behrman et al, 2007; Bhutta et al, 2002; Caravale et al, 2005; Charkaluk et al, 2010; Grunau et al, 2002; Johnson, 2007; Litt et al, 2005; Marlow et al, 2007; Mulder et al, 2010). Difficulty in processing complex language makes it more difficult for a child to comprehend and follow school lessons or even directions. Early language disorders place children at higher risk for later language-based learning disability (reading and written language). Problems with visual perceptual abilities, visuospatial skills, and fine motor function contribute to difficulties with reading and writing. Processing speed, attention, working memory, flexibility generating ideas, organizing information, adaptability, and planning a sequence of actions in advance were much more difficult for 8-year-olds born before 28 weeks GA than for normal BW controls (Anderson and Doyle, 2003). A metaanalysis of 12 studies of executive function in preterm children born before 34 weeks' gestation and/or with BW <1500 g found that combined effect sizes were lower than those for full-term controls in measures of executive function: they had a decrement of 0.57 SD for verbal fluency, 0.36 SD for working memory, and 0.49 SD for cognitive flexibility (Aarnoudse-Moens et al, 2009b).

As many as 25% to 40% of children with BW below 1000 g have learning disabilities, especially in math or reading, and 50% to 70% require special education in school (Anderson and Doyle, 2003; Bhutta et al, 2002; Grunau et al, 2002; Litt et al, 2005; Saigal et al, 2000). A metaanalysis of 14 published papers on academic achievement of children born very preterm (before 34 weeks' gestation) and/or with BW at or below 1500 g found combined effect sizes that show that preterm children score 0.6 SD below full-term peers on mathematics tests, 0.48 SD below on reading tests, and 0.76 SD below on spelling tests (Aarnoudse-Moens et al, 2009b). Rates of learning disabilities, executive dysfunction, and school and behavior problems increase with decreasing GA and BW categories (Aarnoudse-Moens et al, 2009b; Anderson and Doyle, 2004; Behrman et al, 2007; Grunau et al, 2002; Johnson, 2007; Kirkegaard et al, 2006; Pinto-Martin et al, 2004; Saigal et al, 2000).

Behavioral problems are also more common in children born preterm than in full-term controls (Grunau et al, 2004; Johnson, 2007; Marlow et al, 2007; Stahlmann et al, 2009; Woodward et al, 2009). A metaanalysis of 16 case-control school-age outcome studies found higher prevalence of attention deficit hyperactivity disorder, externalizing symptoms (e.g., delinquency), and internalizing symptoms (e.g., anxiety, depression) in 67%, 69%, and 75% of studies, respectively (Bhutta et al, 2002). A more recent metaanalysis of nine studies on behavioral

problems of children born preterm found that attention problems were most pronounced in very preterm children and/or children with BW <1500 g (Aarnoudse-Moens et al, 2009b). Ratings by teachers and parents were 0.43 and 0.59 SD higher, respectively, than for controls. In contrast, the combined effect sizes for internalizing or externalizing behaviors were relatively small, <28.0 and <0.09, respectively. Children born preterm often have attention problems without hyperactivity and without disruptive behavior or conduct disorders (Johnson, 2007).

SENSORY IMPAIRMENTS

Retinopathy of prematurity continues to be a cause of severe visual impairment, especially in the most immature and smallest preterm infants (see Table 64-3). Myopia and strabismus are common in preterm infants and generally necessitate intervention. The incidence of hearing impairment in very preterm infants ranges from 1% to 11%, depending on the population and definitions used. Sensory input is crucial for learning, therefore sensory impairments are important to diagnose as early as possible. Yoshinaga-Itano et al (1998) found better cognitive and language scores in children who had their hearing impairment diagnosed and treated by 6 months than in children whose hearing impairment was identified later. Now, with universal hearing screening, all infants have their hearing screened in the neonatal period, but hearing should also be reevaluated whenever language delay is detected.

FUNCTION IN ADOLESCENCE AND ADULTHOOD

Most adolescents and adults born preterm demonstrate a normal range of intelligence, and most (56% to 82%) graduate from high school (Hack et al, 2002; Lefebvre et al, 2005; Saigal et al, 2006a). They require more special education support, however, and their competitive disadvantage persists. They continue to have lower mean cognitive scores than full-term controls: 87 versus 92 for 18-year-olds with BW below 1500 g (Hack et al, 2002); 94 versus 108, p <0.0001, for those with BW below 1000 g (Lefebvre et al, 2005), and 99 vs. 104, p <0.001. for adolescents with BW below 1000 g and who had no neurosensory impairment (Saigal et al, 2006b). In young adulthood, 11% with BW below 1500 g and 27% with BW below 1000 g continued to demonstrate neurosensory impairment; half of the young adults with BW below 1000 g who did not graduate from high school had neurosensory impairments (Hack et al, 2002; Saigal et al, 2006b). Young adult men born very preterm were significantly less likely to achieve high school or a postgraduate education than women. Compared with full-term control subjects, 20-year-olds with BW below 1500 g had lower math and reading academic achievement scores, fewer who graduated from high school (74% vs. 83%), and higher mean age at graduation (18.2 vs. 17.9 years) (Hack et al, 2002). A British educational study found lower test scores for the General Certificate of Secondary Education in graduates with BW below 1500 g than in control subjects born full-term (Pharoah et al, 2003).

Social-emotional and behavioral issues are more common in school-aged children born preterm: in a metaanalysis, 81% of studies reviewed found more behavior problems than controls, 67% found a higher prevalence of attention deficit disorder, 69% found a higher prevalence of externalizing symptoms (e.g., delinquency), and 75% found a higher prevalence of internalizing symptoms (e.g., anxiety, depression) (Bhutta et al, 2002). A study of children born before 29 weeks GA noted that they were more often the target of bullying (Nadeau et al, 2004). Teens and young adults born preterm (i.e., BW below 800 g, 1000 g and 1500 g, or GA below 35 weeks) report less confidence with their attractiveness, athletics, academic achievement, and romance than full-term controls, but similar self-esteem, social activities, and sense of their own quality of life (Cooke, 2004; Grunau et al, 2004; Saigal et al, 2006a). A study of young adults with BW below 1500 g found higher prevalence of anxiety/depression and withdrawal and fewer friends in women (but not in men) compared with full-term controls (Hack et al, 2004). However, compared with full-term controls, young adults with BW below 1500 g have the same or lower prevalence rates of delinquency, teen pregnancies, cigarette smoking, alcohol abuse, and illicit drug use, even when those with neurosensory impairments were excluded from analysis (Bjerager et al, 1995; Cooke, 2004; Gaddlin et al, 2009; Hack et al, 2002).

Although some outcome studies have found lower rates of educational attainment and employment in young adults with BW below 1500 g, a study of young adults born in the McMaster Health Region in Canada with BW below 1000 g found no significant differences in rates of high school graduation, enrollment in higher education, paid employment, living independently, marriage or cohabitation, or parenthood compared with full-term controls (Cooke, 2004; Hack et al, 2002; Saigal et al, 2006b). A 31-year follow-up study of offspring of mothers enrolled in an antenatal steroid trial found no differences between 126 adults born preterm and 66 full-term controls with respect to educational attainment, socioeconomic status, cognitive functioning, working memory, attention, psychiatric symptoms, or marital status (Dalziel et al, 2007). However, a very large population-based Norwegian study of adults born 1967–1976 and followed through 2004 found that rates of high school graduation, graduate education, and having children increased with increasing GA: the lowest rates were in those born at 22 to 27 weeks GA (Swamy et al, 2008). Reproductive rates were only 25% for women and 14% for men born at 22 to 27 weeks GA, compared with 68% for women and 50% for men born at term. Women born preterm were more likely to have preterm infants, and women born at 28 to 32 weeks GA were more likely to have a fetus or infant die.

SMALL-FOR-GESTATIONAL-AGE INFANTS

The term *small for gestational age* is an arbitrary classification that refers to an infant whose intrauterine growth is less than expected for gestational age at birth. It is, in fact, a heterogeneous category, with a wide range of causes, risk of perinatal complications, and outcomes. Small size at birth may be due to parental (especially maternal) small size; insult or injury to the fetus; fetal maldevelopment; congenital infection; maternal ingestion (e.g., cigarettes,

alcohol, narcotics); or deprivation of supply of oxygen or nutrients due to placental insufficiency or maternal illness. Magnitude of risk for death, perinatal complications, and neurodevelopmental disability varies with the cause of the intrauterine growth restriction (IUGR), the timing of the insult (if any), and the perinatal complications that the child encounters.

The small-for-gestational-age (SGA) infant whose mother is small is likely to be only mildly growth-restricted and have no increased risk of neurodevelopmental disability. With trisomy 18, poor fetal growth early in pregnancy is likely, with death within the first several months, or the affected child will develop multiple severe neurodevelopmental disabilities. The SGA infant with fetal alcohol syndrome has prenatal and postnatal growth deficiencies and an increased risk of congenital anomalies (e.g., characteristic facies, joint anomalies, ventricular septal defect) and CNS dysfunction (e.g., mild to moderate intellectual disability, tremors, fine motor incoordination, hyperactivity). Uteroplacental insufficiency often manifests later in pregnancy (after 27 or 28 weeks of gestation) and often causes asymmetric growth restriction with sparing of head growth. IUGR from uteroplacental insufficiency can be viewed as an adaptation to restricted supply of nutrients. Although it may be an effective human adaptation to adverse intrauterine circumstances, most IUGR infants survive, but they can have significant morbidity: perinatal complications (e.g., perinatal asphyxia, hypoglycemia), hypertension later in life (related to rapid postnatal weight gain), short stature, and school problems (Farfel et al, 2009; Hollo et al, 2002; Larroque et al, 2001; Low et al, 1992; Paz et al, 2001; Pryor et al, 1995; Rosenberg, 2008; Singhal et al, 2007; Strauss, 2000).

Studies that report developmental outcome of SGA infants generally exclude infants with congenital anomalies, genetic syndromes, or congenital infections. They follow primarily infants with placental insufficiency or unknown cause of IUGR, and they distinguish between the full-term and the preterm SGA infant. A population-based case-control study found a five- to sevenfold increased risk of developing CP in full-term singleton children born with severe IUGR compared with matched appropriate birthweight for gestational age (AGA) controls (Jacobsson et al, 2008). Prospective studies of children and adolescents born full term with IUGR find a slightly lower mean IQ score and higher incidences of academic failure (as high as 25% to 35%) and behavior problems in full-term SGA children than in full-term AGA children (Hollo et al, 2002; Larroque et al, 2001; Low et al, 1992; Paz et al, 2001; Pryor et al, 1995; Strauss, 2000). Despite having shorter stature, more academic problems, and lesser academic and professional achievements, adults born IUGR at term report being employed, married, and satisfaction with life at rates similar to those for AGA control subjects (Larroque et al, 2001; Strauss, 2000).

The preterm SGA infant has the disadvantages of both prematurity and IUGR; many are born preterm because of hostile intrauterine conditions causing signs of fetal distress. Their IUGR occurs earlier in the pregnancy and is more severe than the IUGR of full-term infants. Their IUGR status does not appear to increase their risk of CP over the risk of AGA preterm infants, but there is some evidence that they have a lower rate of normal neurodevelopmental outcome (Claas et al, 2010; Gray et al, 1998; Jacobsson et al, 2008). In a longitudinal study, young adults born with symmetric IUGR (i.e., head proportional with size at birth) had lower mean IQ scores than those in affected persons who had evidence of brain sparing, with asymmetric IUGR (Weisglas-Kuperus et al, 2009). Worsening uteroplacental insufficiency can accelerate fetal brain and lung maturation during the third trimester (Amiel-Tison et al, 2004a, 2004b; Scherjon et al, 2000). This adaptive response to increase survival if delivery is preterm has a cost in brain development, in terms of intelligence and behavior. Worsening intrauterine circumstances can overcome compensatory mechanisms. Infants born after detection by Doppler of abnormal blood flow patterns in the umbilical and fetal arteries tend to have reduced brain volumes and worse neurodevelopmental outcomes (Fouron et al, 2001, 2005; Maunu et al, 2007; Shand et al, 2009).

SICK FULL-TERM INFANTS

The full-term infant may require neonatal intensive care for a variety of reasons, including complications of IUGR, perinatal asphyxia, maternal substance abuse, congenital anomalies, or infection. It is most difficult to predict outcome in infants with poorly understood illness such as the newborn with sluggish but eventually good response in the delivery room, the newborn who appears septic but has negative culture results, the newborn who does not feed well initially, and others with undefined illness. Under most circumstances, these children will do well, but for some, initial illness may be a sign of a CNS disorder or systemic illness that contributes to abnormal outcome. Maternal drug use, infection, or congenital anomalies may underlie conditions that require neonatal intensive care, thereby adding to risk for disability.

HYPOXIC RESPIRATORY FAILURE

The most frequent cause of hypoxic respiratory failure requiring neonatal intensive care in full-term and late preterm infants (born after 33 weeks GA) is persistent pulmonary hypertension of the newborn, either as a primary disorder of neonatal adaptation or associated with meconium aspiration, pneumonia, sepsis, pulmonary hypoplasia, or respiratory distress syndrome. Follow-up of neonates who participated in trials of treatment with inhaled nitric oxide (iNO) or extracorporeal membrane oxygenation (ECMO) provides current data on neurodevelopmental outcomes in this population. Metaanalyses of randomized controlled trials (RCTs) found ECMO to be effective in reducing mortality and iNO to be effective in reducing need for ECMO, without adverse effects on neurodevelopmental outcomes (Finer and Barrington, 2006; Mugford, 2008). A large British RCT of ECMO versus conventional management found no differences in neurodevelopmental outcomes at 1, 4, and 7 years, but only half of assessed survivors (55% vs. 50%) had no disability (McNally et al, 2006). Neuromotor abnormalities were common (60%), but motor disability was moderate to severe in only 6% and mild in 10%. Most (76%) had normal cognitive scores, and 13% had cognitive scores below

2 SD below the mean. Many had difficulty with reading comprehension, visuospatial tasks, and verbal memory (39%, 26%, and 39% scored below the 10th percentile, respectively). A few had sensory impairments: 2% had significant visual impairment, 13% wore glasses, and 6% required hearing aids. The finding of a progressive hearing loss in children between 4 and 7 years highlights the need for serial audiologic evaluations in addition to neurodevelopmental follow-up evaluation in children who had hypoxic respiratory failure or persistent pulmonary hypertension as neonates.

RCT follow-up studies of iNO report that 7% to 13% developed CP, 22% to 30% had cognitive impairment, 2% had severe visual impairment, 7% to 19% had hearing impairment, 22% to 30% had intellectual disability, and 26% to 54% had some neurodevelopmental impairment (Konduri et al, 2007; Lipkin et al, 2002). A small study of 29 full-term infants with meconium aspiration syndrome (only 1 treated with iNO, 2 with ECMO) found that 7% developed CP by 3 years, 14% had intellectual disability, and 41% had mild deficits (i.e., hypotonia and/or mild speech delay) (Beligere and Rao, 2008).

NEONATAL ENCEPHALOPATHY

One recurring scenario in the NICU is that of the full-term infant who has either subtle or florid signs of neonatal encephalopathy (see Chapter 61). Neonatal encephalopathy is characterized by clinical findings (e.g., hyperexcitability, coma, seizures) that are used to categorize infants as to severity of encephalopathy (Sarnat and Sarnat, 1976). Not every neonate with encephalopathy has hypoxic-ischemic encephalopathy (HIE), and not every infant with obstetric or perinatal histories suggestive of hypoxia-ischemia has encephalopathy (Graham et al, 2006, 2008; Rafay et al, 2009). Although infants with low Apgar scores have increased risk of mortality and morbidity, these scores are very poor predictors of neurodevelopmental outcome unless they are persistently very low (Moster et al, 2001; Patel and Beeby, 2004). Increasing attention to the difficulties of defining encephalopathy has led to an appreciation of the complexities of determining causes, effects, and outcomes (Dixon et al, 2002; Nelson, 2002; Nelson and Lynch, 2004; Rafay et al, 2009; Shalak et al, 2003). In one study of neonates with cerebral infarctions, 52% had signs of fetal distress (e.g., abnormalities of fetal heart rate patterns), 56% required resuscitation at delivery, 56% developed encephalopathy, and 91% had seizures; on follow-up to 18 months, 48% developed CP, 41% had intellectual disability, 15% had visual impairments, and 50% had multiple impairments (Sreenan et al, 2000). Identifying the etiology of neonatal encephalopathy (e.g., HIE, stroke, meningitis) has important implications for immediate and long-term management. A number of recent randomized controlled trials of hypothermia to treat late preterm and full-term infants with perinatal HIE have demonstrated statistically significant decreases in mortality, neurodevelopmental disability, and combined outcome of death or neurodevelopmental disability (Azzopardi et al, 2009; Gluckman et al, 2005; Jacobs, 2007; Shankaran et al, 2008).

Severity of neonatal encephalopathy remains the best predictor of neurodevelopmental outcome, with or without therapeutic hypothermia (Dixon et al, 2002; Marlow et al, 2005a; Robertson et al, 1989; Ronen et al, 2007; van Kooij et al, 2010; Wyatt et al, 2007). The majority of infants with severe encephalopathy who survive develop major disabilities: 41% to 56% disabling CP (often spastic quadriplegia or mixed CP), 41% to 67% intellectual disability, 6% to 18% hearing impairment, 13% to 25% blindness (often cortical blindness), and 24% to 29% seizure disorder; 35% to 56% had multiple impairments, and at school age, only 21% had no academic special needs (Marlow et al, 2005a; Shankaran et al, 2008). Children with moderate encephalopathy fare somewhat better, but 6% to 21% have disabling CP, 21% to 30% have intellectual disability, 10% to 12% have sensory impairments, 15% to 21% have seizure disorder, and many of those without major disabilities have lower scores on tests of intelligence, visual-motor integration, vocabulary, reading, spelling, and arithmetic than such scores achieved by either healthy peers or children with mild encephalopathy (Handley-Derry et al, 1997; Marlow et al, 2005a; Shankaran et al, 2008). Of survivors treated with therapeutic hypothermia for HIE, 19% to 28% had disabling CP, 24% to 30% had intellectual disability, 7% to 10% had severe visual impairment, 4% to 8% had hearing impairment, 10% to 15% had a seizure disorder, and 19% to 21% had multiple impairments (Azzopardi et al, 2009; Gluckman et al, 2005; Shankaran et al, 2008).

The presence of seizures, abnormalities on neonatal neurodevelopmental examination, neuroimaging studies (especially magnetic resonance imaging [MRI]), and electroencephalography (EEG) can be helpful in predicting neurodevelopmental outcome for infants with neonatal encephalopathy. Of 62 full-term survivors who had had neonatal seizures, 17% developed CP, 14% had intellectual disability, 18% had seizure disorder, and 27% had learning disability (Ronen et al, 2007). Absence of seizures, higher amplitude on amplitude-integrated EEGs, and sleep-wake cycling on EEG by 36 hours are associated with better neurodevelopmental outcomes (Gluckman et al, 2005; Osredkar et al, 2005; Ronen et al, 2007; Wyatt et al, 2007). Severe motor and cognitive impairments are associated with injury to the deep gray nuclei, perirolandic cortex, and posterior limb of the internal capsule (Miller et al, 2005; Rutherford et al, 1998). Infants with a watershed pattern of injury to predominantly the white matter have more cognitive dysfunction than infants with encephalopathy who had normal neonatal MRIs (Miller et al, 2005). Clinical assessments of full-term infants with encephalopathy are also predictive of neurodevelopmental outcome: In addition to the Sarnat scoring system, the Amiel-Tison Neurological Assessment at Term and Prechtl's Assessment of General Movements are independent assessment tools that can improve prediction when used serially, or when combined with neuroimaging studies and/or EEGs (Amess et al, 1999; Cioni et al, 1997; Einspieler and Prechtl, 2005; Gosselin et al, 2005; Murray et al, 2010; Paro-Panjan et al, 2005). Assessments of neonatal brain structure and function using neuroimaging, EEG, and clinical assessments can be useful in determining timing, nature, and recovery from brain injury (Amiel-Tison, 2002; Chau et al, 2009; Liauw et al, 2009; Murray et al, 2010; Parikh et al, 2009).

CONGENITAL ANOMALIES

Congenital anomalies increase an infant's risk of CP and intellectual disability (Croen et al, 2001; Jelliffe-Pawlowski et al, 2003; Walden et al, 2007). Some studies of specific anomalies report neurodevelopmental outcomes, but more research is needed to define the scope of neurodevelopmental disabilities in these and other congenital anomalies requiring neonatal intensive care. A study of 17 infants with gastroschisis (11 preterm, 6 SGA) followed to a mean age of 20 months found their mean cognitive score was normal (101); 1 had a cognitive score below 70, and 2 had cognitive scores between 70 and 85 (South et al, 2008). Most (82%) continued to have bowel dysfunction.

A Dutch study of 33 children with congenital diaphragmatic hernia (not treated with ECMO) followed for 6 to 16 years found a normal mean IQ score for the group (100 ± 13.2), and 4 children had IQ scores more than 1 standard deviation below the mean (Peetsold et al, 2009). They had normal visual-motor integration abilities, but many had problems with sustained attention (39%), behavior (21%), and learning (30%).

Children with congenital heart disease have a higher prevalence of brain abnormalities on neuroimaging than controls, including evidence of white matter injury (32% vs. none in the controls) (Miller et al, 2007). Children with congenital heart disease may have cognitive, adaptive, and behavioral abnormalities related to brain malformations, brain maldevelopment due to differences in cardiovascular flow in utero, hypoxia/ischemia, and/or a prolonged circulatory arrest time or other problems during cardiac surgery (Goldberg, 2007; Ikle et al, 2003; Limperopoulos et al, 2000, 2002; Rudolph, 2010). In a study of infants with hypoplastic left hearts, neonatal assessment (before surgery) noted neurologic abnormalities in 56%, microcephaly in 36%, feeding abnormalities in 34%, and seizures in 7% (Limperopoulos et al, 2000). An evaluation several days before surgery (at a mean age of 7 months) revealed neuromotor abnormalities in 38%, microcephaly in 25%, gross motor delays in 26%, and fine motor delays in 23%. Postoperative findings were very similar to preoperative assessments: Only 12% developed neurologic abnormalities after surgery. The strongest predictors were preoperative abnormalities, cardiorespiratory status (neurologic abnormalities were present in 64% with preoperative O_2 saturations *below* 85% vs. 31% with preoperative O_2 saturations *above* 85%), and longer time on perioperative cardiopulmonary bypass.

Malformations of the nervous system are generally associated with increased risk of neurodevelopmental disability. In a study of 20 children with prenatally diagnosed isolated agenesis or hypoplastic corpus callosum who were followed for 3 to 16 years, 20% had severe disability, 25% had moderate disability, and 55% had normal neurodevelopmental outcome (including 73% with complete agenesis of the corpus callosum) (Chadie et al, 2008). A postnatal MRI showed additional major cerebral abnormalities in 3 of the 4 children with severe disability. Neuromotor dysfunction in children with meningomyelocele is determined by the level of the spinal cord lesion; 30% have intellectual disability due to malformations or effects of hydrocephalus, and many of those with normal intelligence have specific learning disabilities (Barf et al, 2003; Oakeshott and Hunt, 2003). Neurodevelopmental outcome for children with encephalocele is determined by degree and area of herniation of brain tissue and whether there are other associated brain malformations. Children with congenital hydrocephalus have a high incidence of mild neurocognitive impairment, but their prognosis is worse if they had significant prolonged increased intracranial pressure, infections, asphyxia, intracranial hemorrhage, or other brain anomalies (Mataro et al, 2001).

HEALTH AND GROWTH

Although NICU infants are much improved at the time of discharge, many have lingering medical problems that require close follow-up evaluation by their primary care providers (Behrman et al, 2007; Doyle et al, 2003; Huddy et al, 2008; Lipkin et al, 2002; McNally et al, 2006; Walden et al, 2007). They remain vulnerable to infections, further complications, difficulty feeding, and poor growth. Rehospitalization for illness (especially respiratory illness) or surgery (e.g., umbilical hernia repair, gastrostomy, Nissen fundoplication) is common. Adequate nutrition is essential for growth of the developing infant, especially for lung and brain growth. Good weight gain, linear growth, and head growth are reassuring that the child is doing well. Although most infants catch up in their growth within several years, some infants with extreme prematurity, IUGR, severe neonatal illness, or syndromes such as fetal alcohol syndrome always remain small for their age (Farfel et al, 2009; Hack et al, 2002; Pryor et al, 1995; Saigal et al, 2001; Strauss, 2000).

Infants who exhibit significant deviation below normal on growth curves should be evaluated for undetected or inadequately treated gastrointestinal, pulmonary, urologic, or cardiac conditions. Gastroesophageal reflux can lead to discomfort from esophagitis, irritability, extensor posturing, and poor growth. Some children with genetic syndromes or who were critically ill as newborns demonstrate decreased appetite, food refusal, and poor growth. Oromotor dysfunction, with poorly coordinated suck and swallow, must be considered in NICU newborns with poor growth, food refusal behaviors, or neurologic abnormalities. Infants with chronic lung disease or congestive heart failure may tire with feedings and require frequent interruptions because of exercise intolerance.

An oromotor evaluation by an occupational therapist or speech pathologist may include a radiographic swallow study to pinpoint the problem, to determine whether oral feeding is safe, and to assess how the infant handles liquids versus solid foods. The cause of the feeding problem determines treatment: positioning, thickening liquids, medications, and possibly surgery for infants with gastroesophageal reflux; calorically dense food for poor appetite and growth; behavior management program for food refusal behavior not due to organic causes; supplemental oxygen for children with intermittent hypoxia; and gastrostomy for children who chronically aspirate, have severe oromotor dysfunction, or demonstrate food refusal unresponsive to behavioral interventions. Children fed totally or primarily by gastrostomy require an oromotor stimulation program to maintain feeding skills and prevent oromotor hypersensitivity. When NICU infants are

discharged with gastrostomy, continuous feedings, special formulas, or dietary supplements, they require specific nutritional or gastrointestinal follow-up evaluation to address changing needs and parental concerns.

Chronic lung disease (i.e., bronchopulmonary dysplasia) is a complication of prematurity and respiratory failure in full-term newborns (Behrman et al, 2007; Doyle et al, 2003; McNally et al, 2006; Peetsold et al, 2009). These children are vulnerable to respiratory infections, and they frequently require bronchodilators, oxygen supplements, or diuretics. The experienced clinician uses clinical history, physical examination, evidence of growth, signs of exercise intolerance, and pulse oximetry (especially during feeding and sleep) in making decisions regarding tapering oxygen supplements and diuretics. Infants who are well oxygenated at rest may be relying on their reserves and have difficulties when nipple feeding or sleeping. Some infants with chronic lung disease have transient increases in oxygen requirements during periods of accelerated growth.

Developmental interventions for medically fragile infants should be home based whenever possible to reduce the risks of infection. Infants should be shielded from friends and family with infectious illnesses. Therapists who provide early intervention should be skilled in working with these infants, should recognize the signs of exercise intolerance or increasing distress, and should be trained in how to respond promptly in an emergency (e.g., cardiopulmonary resuscitation training). Infants on supplemental oxygen may need an increase in oxygen when handled.

Preterm infants and other high-risk infants need the protection from childhood illnesses that is conferred by immunization. Immunizations should be given according to the recommended schedule (Saari and the Committee on Infectious Diseases, 2003). Even in extremely preterm infants, full doses appropriate for chronologic age should be used. Infants who are still in the NICU or who are immunocompromised (or whose family includes an immunocompromised person) should not be given live viral vaccines. Pertussis protection should be deferred only for infants with signs of neurologic deterioration or uncontrolled seizure disorder, although it may be postponed pending diagnostic evaluation in a child with recent onset of seizures.

FOLLOW-UP EVALUATION OF THE HIGH-RISK INFANT

The American Academy of Pediatrics has established a policy for the screening and surveillance of developmental concerns in all children in the primary care setting (Council on Children with Disabilities et al, 2006). This policy is most germane to the high-risk NICU infant whose medical problems, increased risk of neurodevelopmental disability, and uncertainty regarding outcome necessitate long-term follow-up in a specialized, multidisciplinary setting.

IMPORTANCE OF DISCHARGE PLANNING

Good discharge planning aims to smooth the infant's transition from hospital to home and to provide the health care, developmental, and parental supports needed by the infant and family. A parent conference that reviews the infant's hospital course and plans for discharge provides an opportunity to discuss the infant's risk status, to assess the parents' understanding, to appreciate the infant's progress, and to begin to make plans for discharge home. In the review of the infant's various risk factors, an honest but sensitive discussion puts the infant's risk for neurodevelopmental disabilities into perspective, giving the range of possible outcomes. Parents should be reassured whenever possible, given the opportunity to hope, and provided with perspective on their infant's risks.

Discharge teaching includes well-baby care (for first-time parents); techniques of cardiopulmonary resuscitation (useful for all parents); use of any special equipment or medication; and recommendations regarding infant car seats, bedding, feeding, positioning, and handling. Plans for follow-up care after hospital discharge should address both the infant's and the family's special needs. All infants discharged from a NICU should have a designated primary care provider who can follow the infant closely and address the infant's special needs as they emerge. Preterm infants with retinopathy of prematurity, incompletely vascularized retinas, congenital infection, or cortical abnormalities require ophthalmologic follow-up evaluation. Infants who failed or did not receive audiologic screening require audiologic follow-up evaluation. Infants with specific medical conditions may require pediatric surgical, pulmonary, gastrointestinal, nutritional, cardiac, neurologic, orthopedic, or other subspecialty follow-up evaluations.

COMPREHENSIVE DEVELOPMENTAL FOLLOW-UP EVALUATION

Criteria for referral of high-risk NICU infants for comprehensive developmental follow-up vary widely, based on available resources, funding, geography, and family needs. Ideally, all NICU infants should be viewed as high risk and offered comprehensive developmental follow-up evaluations through school age. Incentives for families to return for follow-up evaluations encourage high follow-up rates, thereby providing NICUs with accurate outcome data for specific conditions. Close relationships between a NICU follow-up clinic and community health, educational, and social services promote coordination of intervention services based on the child's and family's needs. Limited resources and funding, organizational difficulties, and time constraints all interfere with ideal comprehensive, coordinated, family-focused follow-up and intervention efforts. Although often considered dispensable, developmental follow-up evaluations and early intervention should be viewed as an essential part of the continuum of care provided to high-risk infants and their families.

The goals of comprehensive, coordinated developmental follow-up are to help the family optimize the child's growth and development; to help integrate the child into the family, school, and community; and to intervene when possible to reduce future medical, social, and emotional costs. These goals are promoted by the recognition that each child is an individual with unique qualities, strengths, impairments, and abilities, and that each family differs in background, social supports, finances, and personal coping mechanisms.

Follow-up is a dynamic process that evolves as the child grows, develops, and increasingly interacts with his or her environment. Recognition of impairments, disabilities,

and handicaps relies on parental reports, an appreciation of individual variability in the normal pattern of development over time, and the examiner's assessment skills and ability to determine the significance of abnormalities or deviations from the normal pattern. Once recognized, problems should be discussed with parents, including a nonmedical definition of specific diagnoses (e.g., CP, learning disability) and identification of specific intervention strategies.

Assessing the development of the high-risk infant relies on the basic tools of medicine: the history and the physical examination. The focus of the developmental history is to obtain information about the infant's behavior (e.g., sleep, feeding, temperament, behavior problems) and developmental milestone acquisition. A history of milestone attainment is most effective when obtained at each follow-up visit (Accardo, 2008; Accardo and Capute, 2005; Allen and Alexander, 1997). The physical examination is expanded to a neurodevelopmental examination that includes an assessment of posture, muscle tone, reflexes, and functional abilities (Accardo, 2008; Amiel-Tison and Gosselin, 2001). Many follow-up clinics rely on neuropsychologists to evaluate the cognition of high-risk infants, either with sequential assessments or with one or two carefully timed assessments (e.g., at 12 or 24 months).

The developmental milestones should be viewed in terms of the major streams of development: gross motor, fine motor, adaptive, and language abilities (Accardo, 2008; Accardo and Capute, 2005). Gross and fine motor abilities are used to assess motor development and to screen for CP and minor neuromotor dysfunction. Children with CP generally have significant motor delay and persistent neuromotor abnormalities. Children with minor neuromotor dysfunction have milder or no delay and mild neuromotor abnormalities on examination. Delay in adaptive, or self-help, skills may be seen with intellectual disability, CP, minor neuromotor dysfunction, or environmental or behavioral causes. For example, not using a fork for eating may be because the child's mother did not introduce a fork (environmental) or because the child refuses to use a fork (behavioral). Delay in language abilities can signal intellectual disability, hearing impairment, language disorder, or autism spectrum and requires an audiologic evaluation as an initial assessment.

Assessing milestone acquisition in preterm infants raises the controversial question of whether to correct for the degree of prematurity. This issue is most important early in life and in extremely preterm infants. Consider the following example: An infant born at 27 weeks' gestation is now 6 months old and not yet rolling over, but she plays with her hands in midline and can support herself on her forearms in prone position. Her motor quotient (i.e., developmental age divided by chronologic age) is 50 (i.e., 50% of normal—therefore, delayed). If one corrects for degree of prematurity (using her term age equivalent/adjusted age/corrected age), her motor quotient is 100 (i.e., normal). Her developmental status at this age is determined by whether one corrects for degree of prematurity. As children age, the numeric difference in the adjusted and chronologic age developmental quotient becomes less significant, so correction for prematurity is no longer important by age 5 years.

When considering correction for degree of prematurity, the clinician should evaluate each stream of development separately because these may differ in responsiveness to environmental stimulation. Earlier exposure to the extrauterine environment may have greater effect on the development of language than on motor development. There is strong evidence that for motor abilities, one should fully correct for degree of prematurity (Allen and Alexander, 1990, 1992; Palisano, 1986). Language, a component of cognition, may be accelerated by early extrauterine experience. Traditionally, psychologists do correct for degree of prematurity in preterm infants when assessing cognition. They do not agree on full versus partial correction or on how long to correct: for 1 year, 2 years, or indefinitely (Allen, 2002; Aylward, 2002). There is some concern that correcting for degree of prematurity overestimates a child's cognitive abilities and may fail to identify those infants who would benefit from early intervention (Den Ouden et al, 1991; Thompson et al, 1993). Nevertheless, most agree to correct for degree of prematurity for at least 2 years. This issue is important early in infancy and with the most immature infants, but it influences outcomes until 8.5 years (Rickards et al, 1989). Preterm children with language or cognitive abilities consistently below those for their age corrected for degree of prematurity should be referred for multidisciplinary evaluation and early intervention.

Eligibility for surveillance or services for preterm infants differs in different geographic areas. Part C services (birth to 3 years) are required in every state of the United States, under federal law, but the terms of services differ. Some states offer periodic developmental surveillance for children born with any risk (established, biologic/medical, or environmental) of developmental delays, whereas other states do not. Furthermore, the criteria for service eligibility vary widely. Some states provide intervention services to children with delay based on chronologic age, other states wait until a child is delayed with respect to adjusted age, and still other states use a sliding scale correction of prematurity. The very definition of delay also varies by state: for some states a 25% delay in any expected stream of development qualifies a child for services, whereas in other areas children must demonstrate as much as 50% delay in one or more streams of development to qualify for intervention services (Shackelford, 2006).

REFERRAL FOR MULTIDISCIPLINARY EVALUATION AND EARLY INTERVENTION SERVICES

Infants with identified developmental delays should be referred for a multidisciplinary evaluation that assesses all aspects of development. Brain injury is more likely to be diffuse than focal, and more than one stream of development may be affected to varied degrees. Although the most obvious abnormality is identified first, this may not be the most disabling of the child's problems. A preterm infant who presents with delayed walking and tight heel cords may be diagnosed with mild spastic diplegia. This child has an excellent prognosis for walking, running, and good motor function. Problems associated with CP (e.g., learning disability, myopia, attention deficit) may have far more impact on the child's quality of life and adult functioning than will the presenting motor impairment.

Part H of Public Law (PL) 99-157 passed by the U.S. Congress in 1986, followed by the Individuals with Disabilities Education Act (IDEA, PL 101-476 and PL 102-119) in 1990, encouraged and then required states to provide a comprehensive, coordinated interagency system of early intervention services for infants and toddlers with developmental delays and with conditions that lead to developmental delays (e.g., Down syndrome, fetal alcohol syndrome). Some states also provide services for high-risk infants and their families. Infants may be referred by NICUs, NICU follow-up clinics, pediatricians, or families. Each child who is referred is entitled to a multidisciplinary assessment and a service coordinator to help coordinate the assessment and services. If the child is eligible for the program, the parents, service coordinator, and multidisciplinary team devise an individualized family service plan that identifies the child's and family's needs and what services will be used to address these needs. This program recognizes the importance of (1) viewing each child as a unique individual, (2) evaluating not only needs but also strengths, (3) including the family in the planning process, and (4) coordinating all intervention services. Early intervention strategies minimize secondary complications and provide much-needed parental support in coping with disability or uncertainty. The choice of interventions is determined by the individual child's developmental profile and health, the needs of the family, and available resources. Programs or services that enable the family to meet the child's needs better (e.g., drug counseling, transportation, parent support groups) also are identified.

Pediatricians and clinicians privileged with the care of children are encouraged to become familiar with the availability of early intervention services and how to access and collaborate with these services and their providers. The AAP stated that an environment should be created in which the physician, family, and other service providers work together in a caring, collegial and compassionate atmosphere that ensures that early intervention services are of high quality, accessible, continuous, comprehensive, and culturally competent (Duby, 2007).

Although a number of studies have demonstrated beneficial effects of early intervention programs, there is no proof that early intervention prevents neurodevelopmental disability (Achenbach et al, 1993; Bennett, 1991; Brooks-Gunn et al, 1994; Infant Health and Development Program, 1990; Palmer, 1988; Piper et al, 1986; Ramey et al, 1992; Rothberg et al, 1991). One difficulty lies with the use of the global term *early intervention*, which covers many different intervention strategies. Early intervention can be as nonspecific as providing social work support and parent classes on infant development or as specific as a physical therapy intervention aimed at facilitating coming to a sitting position from supine in a child with the prerequisite skills and postural reactions. Early intervention for a child with severe spastic quadriplegia would include recommendations for positioning and handling the child and providing adaptive equipment for sitting, traveling, eating, and communication. Designing good intervention trials that evaluate the efficacy of specific intervention strategies is complicated by the fact that each person is unique. This makes it difficult to define study sample criteria and outcomes and to match disabled children for randomization.

Nevertheless, each intervention strategy must be evaluated for efficacy in a well-defined population. Both hearing and visual impairments are responsive to early intervention services that can dramatically improve the child's functioning and quality of life, especially if begun early. Infants with severe hearing impairments may benefit from wearing hearing aids, learning to respond to and to use sign language, specific educational interventions using multiple sensory modalities and parental support. Studies have shown that a focused educational intervention for preterm infants has beneficial initial effects on cognition and behavior, although long-term benefits have not been proved (Achenbach et al, 1993; Brooks-Gunn et al, 1994; Infant Health and Development Program, 1990; Ramey et al, 1992). Few early intervention studies have evaluated whether there is an effect on function at school or at home. These functional abilities may be not only the most responsive to early intervention but also the most important outcome variables. Studies have been limited to short-term interventions. It stands to reason that the most benefit can be derived from long-term, continuous interventions.

SUMMARY

Although children who require neonatal intensive care have a higher incidence of neurodevelopmental disabilities and health sequelae, most survivors are healthy and function well. The likelihood, type, and severity of disability vary with the condition requiring neonatal intensive care, with various perinatal and demographic risk factors, and perhaps with availability of developmental supports for the child and social supports for the family. It is impossible to diagnose neurodevelopmental disabilities with certainty in the neonatal period. Absence of risk factors and neurologic abnormalities is reassuring. Multiple or severe risk factors can identify infants at high risk for disability.

The uncertainty regarding an infant's outcome and the dynamic nature of early infant and child development necessitate careful medical and developmental follow-up evaluation of high-risk NICU infants during infancy and childhood. Survival is not the only goal of neonatal intensive care. Because the NICU is but the first step in an infant's life, follow-up (or perhaps follow-through) is an important component of the continuum of care that should be offered to high-risk infants. The goals of follow-up are to assist the family to optimize the child's growth and development so that the child is as functional as possible and to help integrate the child into the family, school, and community.

Subtle cognitive, sensorimotor, and neurologic abnormalities can have a devastating impact on self-esteem, peer relationships, and school performance. Alerting parents, teachers, and friends about a child's difficulties and frustrations, and the impact of these on the child's self-esteem, allows them to provide a more supportive environment. By helping to maintain a child's self-esteem and to improve the child's ability to cope with the demands of school and playground, many secondary social and emotional problems can be prevented or ameliorated. Work to improve NICU outcomes includes developing both better neuroprotection strategies for the fetus and sick neonate and better methods of supporting developing infants and their families.

PART XIII

NUTRITION

CHAPTER 65

BREASTFEEDING

Lydia Furman and Richard J. Schanler

Exclusive breastfeeding through 6 months, with continued breastfeeding to 12 months and beyond, is recommended for all infants by the World Health Organization (WHO, www.who.int/topics/breastfeeding/en), the American Academy of Pediatrics (AAP, www.aap.org/breastfeeding), and other professional organizations. The success of adequate lactation depends on supportive attitudes of professional personnel in pediatrics and obstetrics, and on hospital routines and practices that are conducive to initiation and maintenance of breastfeeding, as well as awareness that many mothers will need instruction and assistance to establish breastfeeding. Much information must be shared with new parents in the short postpartum hospital stay, so both prenatal and postdischarge breastfeeding education and support are necessary. Caregivers should be trained to observe and document breastfeeding, and infants should have early follow-up at 3 to 5 days of age with a knowledgeable health care provider (AAP, 2005).

RATES OF BREASTFEEDING IN THE UNITED STATES

Although breastfeeding was the norm in the early part of this century, rates declined after World War II, likely because of the availability of commercial formulas. However, recognition of breastfeeding benefits grew during the 1970s, and rates more than doubled in the United States from 24.7% in 1971 to 59.7% in 1984 (Wright, 2001). The U.S. Centers for Disease Control and Prevention began monitoring annual breastfeeding rates through the National Immunization Survey (NIS), and these figures can be compared with the Department of Health and Human Services' Healthy People 2010 breastfeeding goals, which aimed for a 75% breastfeeding initiation rate in the postpartum period, and 50% and 25% of mothers to continue any breastfeeding at 6 and 12 months, respectively (Table 65-1) (U.S. DHHS and Office on Women's Health, 2000). New Healthy people 2020 goals seek to increase further the proportion of infants who are breastfeed, and aim for 82% initiation and 46% and 26% exclusive breastfeeding at 3 and 6 months, respectively (U.S DHHS, 2011). National rates of breastfeeding have increased since 1990 but do not yet meet Healthy People goals for initiation, duration, and exclusivity. One in four infants receives formula supplementation within 2 days of birth, and almost half (45.9%) receive formula before 6 months of age (Breastfeeding Data and Statistics, 2009). Although some states and population subgroups have met initiation and continuation goals, disparities related to race, ethnicity, age, and socioeconomic status have not been eliminated. Non-Hispanic African Americans and economically disadvantaged populations have the lowest breastfeeding rates for all measures at all infant ages, and women who are younger, unmarried, receive or are eligible for WIC, and who have a lower educational level are less likely to initiate or continue breastfeeding (Table 65-2) (Ryan and Zhou, 2006). Culturally specific feeding beliefs may also influence breastfeeding choice (Scrimshaw, 1984). Such an example from the Navajo culture is the belief that either negative emotions or, by contrast, positive maternal attributes, can be transmitted through breast milk (Wright et al, 2003). Racial and ethnic disparities in breastfeeding rates are an important arena for public health initiatives, and their elimination is a part of the Healthy People goals.

INTERVENTIONS TO SUPPORT BREASTFEEDING INITIATION AND CONTINUATION

In response to extensive formula marketing in the developing world with resulting high rates of infant morbidity and mortality, the World Health Assembly created The International Code of Marketing of Breastmilk Substitutes (1981) to promote ethical marketing of formula products (White, 2001). In 1992 UNICEF and WHO developed the Baby Friendly Hospital Initiative, an international program to promote breastfeeding supportive policies for birthing hospitals (Box 65-1). The BFHI ten steps in combination with an eleventh step, International Code adherence fulfilled by purchasing hospital formula rather than receiving it free, effectively increased breastfeeding rates worldwide (Merten et al, 2005). U.S. hospitals that adhere to evidence-based maternity practices significantly increase the likelihood of mothers initiating breastfeeding, exclusively breastfeeding, and breastfeeding beyond 6 weeks (DiGirolamo et al, 2008). Effective practices include BFHI recommendations such as initiating breastfeeding within 1 hour of birth, 24-hour rooming in, breastfeeding on demand, and avoidance of supplementation that is not medically necessary, as well as skin-to-skin (i.e., kangaroo) care and discontinuation of commercial gift bags with free formula samples (U.S. DHHS, CDC, 2008).

The combination of prenatal and postnatal assistance, breastfeeding support groups, educational interventions for fathers, and breastfeeding peer counselors (trained lay persons of a racial, economic, and ethnic background similar to the mother) are associated with increased breastfeeding duration and exclusivity (Britton et al, 2007; Chung et al,

TABLE 65-1 Healthy People Breastfeeding Goals and Rates of Breastfeeding in the United States*

Healthy People 2020 Objectives	2000	2001	2002	2003	2004	2005	2006
Breastfeeding Initiation and Duration							
82% initiation postpartum	70.9 ± 1.9	71.6 ± 1.0	71.4 ± 0.9	72.6 ± 0.9	73.1 ± 0.8	74.2 ± 1.2	74.0 ± 0.9

34% any breastfeeding at 12 months	15.7 ± 1.5	18.2 ± 0.9	19.0 ± 0.8	19.6 ± 0.8	21.4 ± 0.8	21.4 ± 1.1	22.7 ± 0.9
Exclusive Breastfeeding							
46% exclusive breastfeeding at 3 months	NA	NA	NA	29.6 ± 1.5	31.5 ± 0.9	31.5 ± 1.3	33.6 ± 1.0
26% exclusive breastfeeding at 6 months	NA	NA	NA	10.3 ± 1.0	12.1 ± 0.7	11.9 ± 0.9	14.1 ± 0.8

NA, Data were not collected and are not available.
Numbers represent percent of U.S. children who were breastfed, by birth year, National Immunization Survey, United States (percent ± half 95% confidence interval)
*Centers for Disease Control and Prevention: *Breastfeeding among U.S. children born 1999-2007*, CDC National Immunization Survey. Available at www.cdc.gov/breastfeeding/data/NIS_data/ and www.healthypeople.gov/2020/topicsobjectives2020/objectives list.aspx?topicid=26. Accessed May 17, 2011.

2008). Maternal employment is associated with decreased breastfeeding: initiation rates are significantly lower if the mother intends to return to work before 6 weeks postbirth, and breastfeeding continuation is lower among mothers working >20 hours per week (Meek, 2001; Wright, 2001). Workday strategies that include feeding the infant directly from the breast appear more effective than pumping only (Fein et al, 2008). Public policy changes may improve breastfeeding rates, because maternity leaves of <12 weeks are associated with increased risk of breastfeeding failure, whereas an increase in maternity leave time is associated with attainment of national goals for breastfeeding duration (Baker and Milligan, 2008; Guendelman et al, 2009).

THE EVIDENCE TO SUPPORT BREASTFEEDING

Each year approximately 10 million childhood deaths occur, largely due to diarrhea, malnutrition, malaria, acquired immunodeficiency syndrome, pneumonia, and measles, 90% in the 42 poorest countries in the world. Exclusive breastfeeding through 6 months of age has the potential to prevent 13% of these deaths and is the most effective international preventive health intervention for children under age 5 years (Jones et al, 2003). Human milk has widely acknowledged benefits across economic strata with respect to infant nutrition, gastrointestinal function, host defense, neurodevelopment, and psychological well-being for full-term and premature infants. The benefits of any breastfeeding as compared to no breastfeeding, as well as a "dose-dependent" effect of breastfeeding duration and exclusivity, are well documented. Maternal health benefits appear to increase with months of lactation and are also well described (Ip et al, 2007; Kramer et al, 2001). The resulting societal and economic benefits of full breastfeeding are significant.

NUTRITIONAL ASPECTS

The human milk model is used to design the composition of breast milk substitutes, because the goal for infant nutrition through the first year is to mimic the body composition of the breastfed infant. Human milk has a dynamic nutrient composition that changes through lactation, over the course of a day, and within a feeding, and differs between women. Components of human milk exert dual roles, active in both nutrition and immune function. A reference tabulation of the composition of human milk comparing early and more mature milk is given in Table 65-3 (Picciano, 2001). In the first few weeks after birth, the total nitrogen content of milk from mothers who deliver prematurely (preterm milk) is greater than milk obtained from women delivering at term (term milk) (Schanler, 1995). The total nitrogen content in both milks, however, declines similarly to approach what is called mature milk (Blanc, 1981).

The protein quality of human milk (whey 70% and casein 30%) differs from that of bovine milk (82% casein, 18% whey). Caseins are proteins with low solubility in gastric acid, whereas whey proteins remain in solution after acid precipitation. The whey protein fraction is more easily digested and promotes rapid gastric emptying. It also provides lower concentrations of phenylalanine, tyrosine, and methionine and higher concentrations of taurine than the casein fraction and serves as a model for enteral and parenteral amino acid mixtures. The major whey protein in human milk is α-lactalbumin, whereas that of bovine milk is β-lactoglobulin, the protein associated with cow's milk allergy. Lactoferrin, lysozyme, and secretory immunoglobulin A (sIgA) are specific immunoactive human whey proteins that resist proteolytic digestion and thus serve as a first line of defense by lining the gastrointestinal tract (Goldman et al, 1994). The lipid system in human milk, responsible for providing approximately 50% of the calories in the milk, is structured to facilitate fat digestion and absorption. The lipid system is composed of an organized milk fat globule, heat-labile bile salt-stimulated lipase, and a pattern of fatty acids (high in palmitic [C16:0], oleic [C16:1ω9], linoleic [C18:2ω6], and linolenic [C18:3ω3] acids) characteristically distributed on the triglyceride molecule (C16:0 at the 2-position of the molecule). The fat blends in formula are modified to contain greater medium and intermediate chain-length fatty acids, which are absorbed passively, in an attempt to mimic the superior fat absorption from human milk. The pattern of fatty acids in human milk also is unique in its composition of very long-chain polyunsaturated fatty acids. Arachidonic acid (C20:4ω6) and docosahexaenoic acid (C22:6ω3),

derivatives of linoleic and linolenic acids, respectively, are found in human but not bovine milk and have recently been added to formula. Arachidonic and docosahexaenoic acids are constituents of retinal and brain phospholipid membranes and have been associated with improved visual function and, potentially, neurodevelopmental outcome.

The carbohydrate composition of human milk is important as a nutritional source of lactose and for the presence of oligosaccharides. A softer stool consistency, more nonpathogenic fecal flora, and improved mineral absorption have each been attributed to small quantities of unabsorbed lactose. Oligosaccharides are carbohydrate polymers (also including glycoproteins) that, in addition to their role in nutrition, help protect the infant because their structure mimics specific bacterial antigen receptors and prevents bacterial attachment to the host mucosa. Fucosylated glycans specifically inhibit binding by Haemophilus influenzae, Campylobacter jejuni, and viral agents (Morrow et al, 2005). Oligosaccharides also are the prebiotics that stimulate the growth of nonpathogenic bifidus bacteria. The concentrations of calcium and phosphorus in human milk are significantly lower than in other milks because they are

BOX 65-1 Ten Steps to Successful Breastfeeding

Step 1—Have a written breastfeeding policy that is routinely communicated to all health care staff.
Step 2—Train all health care staff in skills necessary to implement this policy.
Step 3—Inform all pregnant women about the benefits and management of breastfeeding.
Step 4—Help mothers initiate breastfeeding within one hour of birth.
Step 5—Show mothers how to breastfeed and how to maintain lactation, even if they are separated from their infants.
Step 6—Give newborns no food or drink other than breast milk, unless *medically* indicated.
Step 7—Practice "rooming-in"—allow mothers and infants to remain together 24 hours a day.
Step 8—Encourage breastfeeding on demand.
Step 9—Give no pacifiers or artificial nipples to breastfeeding infants.
Step 10—Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.

present in more bioavailable forms: bound to digestible proteins and in complexed and ionized states (Neville and Waters, 1983). Thus, despite differences in mineral intake, bone mineral content of breastfed infants is similar to that of infants fed formula (Venkataraman et al, 1992). The concentrations of copper and zinc, despite their decline through lactation, appear adequate to meet the infant's nutritional needs, but the concentration of iron does not meet the growing infant's needs beyond 6 months, so a supplement in the form of iron-containing complementary feedings is indicated to prevent subsequent iron deficiency anemia (Casey et al, 1985; Dallman et al, 1980; Lönnerdal and Hernell, 1994).

Vitamin K deficiency may be a concern in the infant because bacterial flora are responsible for ensuring vitamin K adequacy. The intestinal flora of the breastfed infant make less vitamin K and its content in human milk is low; thus, a single dose of vitamin K should be given at birth (Greer and Suttie, 1988). The content of vitamin D in human milk is dependent on maternal vitamin D status. However, many women have insufficient vitamin D stores and their infants do not receive adequate sun exposure to permit skin production of vitamin D precursors. Vitamin D deficiency leading to rickets has been reported in breastfed infants, especially those with dark skin pigmentation, little exposure to sunlight, or associated with the appropriate use of sunscreen ointments (Kreiter et al, 2000). Infant supplementation with 400 IU of vitamin D daily is indicated (Wagner and Greer, 2008).

NUTRITIONAL IMPLICATIONS FOR THE PREMATURE INFANT

The nutritional adequacy of human milk for premature infants may be limited for several reasons. The energy and protein contents of breast milk aliquots brought to the neonatal nursery by the mother are highly variable (Polberger and Raiha, 1995). The most variable nutrient in human milk is fat, the content of which differs during lactation, throughout the day, from mother to mother, and within a single milk expression (Neville et al, 1984). Because human milk is not homogenized, the fat content separates from the body of milk during standing and may be lost if continuous tube feeding is used. In fact, much of the variation in energy content of milk as used in the nursery is a result of differences in and/or losses of fat in the unfortified milk (Greer et al, 1984; Schanler, 1988). Although concentrations of protein, sodium, and zinc decline through lactation, the nutrient needs of the premature infant remain higher than those of term infants until sometime after term postmenstrual age. Therefore, the physiologic decline in milk concentration of protein and micronutrients precedes any reduction in the infant's needs and results in an inadequate nutrient supply from human milk for the premature infant. With feeding of unfortified human milk, protein insufficiency is manifest by declines in growth rates and by lowered biochemical indicators of protein status (blood urea nitrogen and serum prealbumin) (Cooper et al, 1984; Kashyap et al, 1986; Tyson et al, 1983). The absolute inadequate intake of calcium and phosphorus results in a progressive decrease in serum phosphorus and increases in serum calcium and alkaline phosphatase activity compared with infants fed preterm formula (Pettifor et al, 1986; Rowe et al, 1979). Follow-up of premature infants fed unfortified human milk finds reduced linear growth at 18 months and relationships to adolescent height (Lucas et al, 1989).

Thus, premature infants weighing less than 1500 g at birth should receive human milk fortifier, a multinutrient supplement designed to meet their nutritional needs and prevent clinical deficiency diseases and growth failure. The fortifier adds not only protein, calcium, phosphorus, and calories but other micronutrients (Table 65-4**)**. Results from individual studies were confirmed by a systematic review that addressed multinutrient fortification of human milk and included a metaanalysis of controlled trials of human milk fortification compared with the feeding of unfortified human milk (Kuschel and Harding, 2005). The addition of multinutrient fortifiers to human milk resulted in short-term improvements in weight gain, increments in length and head circumference, and bone mineral content during hospital stay (Kashyap et al, 1990; Kuschel and Harding, 2005; Schanler et al, 1985).

Human milk fortifier usually is added once the premature infant is tolerating tube feeding of approximately 100 mL/kg/day and continued until the infant has achieved all oral feedings, a body weight of 1800 g, or is near discharge from the hospital. Subsequently, the infant may be fed unfortified breast milk, although monitoring of infant weight gain to achieve >20 g/day, linear growth of 0.5 cm/week, and of alkaline phosphatase levels, aiming for <450 IU/L, is suggested (Hall, 2001).

GASTROINTESTINAL FUNCTION

Many factors in human milk may stimulate gastrointestinal growth and motility and enhance maturity of the gastrointestinal tract. Bioactive factors such as lactoferrin may affect intestinal growth, glutamine affects intestinal

cellular metabolism, and nucleotides affect fecal flora. Gastric emptying is faster after infants are fed human milk than when they are fed commercial formula, and large gastric residual volumes are less frequent in preterm infants fed human milk (Schanler et al, 1999).

HOST DEFENSE

Specific factors such as sIgA, lactoferrin, lysozyme, oligosaccharides, growth factors, and cellular components augment the infant's active host defenses (Table 65-5) (Hamosh, 2001). The infant also receives specific passive immunity via the enteromammary immune system in which the mother produces sIgA antibody in response to foreign antigens, and specific antibodies are then elaborated at mucosal surfaces and in her breast milk (Kleinman and Walker, 1979).

In Brazil, infants who were completely weaned had 14.2 times the risk of death from diarrhea and 3.6 times the risk of respiratory infection compared with exclusively breastfed infants (Victora et al, 1987). Not only in developing countries, but also in the United States and other developed countries, there is a reduction in the incidence of gastrointestinal and respiratory diseases and otitis media that is directly attributed to breastfeeding (Dewey et al, 1995; Pisacane et al, 1992). As compared to infants who received no breast milk, a lower risk of otitis media is found among infants who received any breast milk (odds ratio [OR] = 0.77, 95% confidence interval = 0.64 to 0.91) and among those exclusively breastfed for >3 or >6 months (OR = 0.5,

95%CI = 0.36 to 0.70) (Ip et al, 2007). In an international study including developed and developing countries, comparing infants receiving no breast milk with those exclusively breastfed for 6 months, the median relative risk of diarrheal morbidity was 3.5 to 4.9 (Feachem and Koblinsky, 1984). Considering only infants in the developed world, the benefit of breastfeeding is maintained: the risk of non-specific gastrointestinal disease is lower in the 1st year of life among infants who receive exclusive or partial breastfeeding compared with those who received formula only (OR = 0.36, 95% CI = 0.32 to 0.41) for cohort studies) (Ip et al, 2007). Even after adjusting for relevant confounders such as daycare and smoke exposure and socioeconomic status, the risk of hospitalization due to lower respiratory infection (in developed countries) is significantly lower among infants exclusively breastfed for 4 months as compared to those receiving no breast milk (relative risk = 0.28, 95% CI = 0.14 to 0.54) (Ip et al, 2007). Lower respiratory tract illnesses in the first 4 months of life are less common and less severe among infants breastfed for 1 month or longer (Chantry et al, 2006) (Box 65-2).

Breastfeeding also confers a strong protective effect against Haemophilus influenzae type b infection (Arnold et al, 1993; Peterson et al, 1991). Urinary tract infections have been reported to be more frequent among formula-fed infants than among breastfed infants (Marild et al, 1990; Pisacane et al, 1992). Reduced adhesion to uroepithelial cells by pathogens as mediated by oligosaccharides, sIgA, or lactoferrin has been hypothesized as mechanisms for this protective effect (Coppa et al, 1990; Goldblum

BOX 65-2 Benefits of Breastfeeding for Mother and Child [22, 113, 116]

INFANTS AND CHILDREN*

Decreased frequency and severity of:
- Diarrheal illness
- Respiratory infections
- Necrotizing enterocolitis
- Otitis media

Decreased rate of:
- Urinary tract infection
- Bacterial sepsis

Lower risk of neonatal and infant death:
- Overall infant mortality (non-U.S.)
- Sudden infant death syndrome (SIDS) (U.S.)

Likely lower risk of chronic illness:
- Leukemia (ALL, AML)
- Diabetes (types 1 and 2)
- Obesity
- Atopic dermatitis and asthma
- Celiac disease and Crohn's disease

MATERNAL (WITH CUMULATIVE LACTATION OF 12 MONTHS OR GREATER)

Reduced risk of cancer:
- Breast cancer risk (OR = 0.72)
- Ovarian cancer risk (OR = 0.63)

Reduced risk of cardiovascular disease:
- Obesity (OR = 0.92)
- Hypertension (OR = 0.88)
- Hyperlipidemia (OR = 0.81)
- Cardiovascular disease (OR = 0.91)

Reduced risk of diabetes type 2 (among women without gestational diabetes; OR = 0.80)

ALL, Acute lymphoblastic leukemia; *AML,* acute myeloid leukemia; *OR,* odds ratio; *SIDS,* sudden infant death syndrome.
*See text for relative risks and odds ratios.

et al, 1989). Clinical studies throughout the world have also suggested a decrease in the rate of infection-related events in human milk–fed premature infants as compared with those fed formula (El-Mohandes et al, 1998; Hylander et al, 1998; Narayanan et al, 1980; Ronnestad et al, 2005; Schanler et al, 1999). Methodologic issues, including inability to truly randomize receipt of own mother's milk, varying definitions of human milk (mother's own vs. donor, frozen vs. fresh, mixed with formula), of volume of human milk intake (mL/kg/day vs. daily percent of enteral or all intake), and outcome (blood culture positive or infection at other sites) create difficulty interpreting results (de Silva et al, 2004; Schanler et al, 1999). However, lack of an exclusively human milk–fed cohort, for example, tends to strengthen not weaken positive studies, and the preponderance of available data appears to support a role for human milk in reducing episodes of late-onset sepsis. Fewer and less severe episodes of necrotizing enterocolitis are reported in premature infants who receive human milk, and this conclusion has stood up to metaanalysis (Furman et al, 2003; Ip et al, 2007; Lucas and Cole, 1990; Schanler et al, 1999; Schanler et al, 2002). Data from studies that quantified human milk intakes suggest that its protective effect (1) is optimized by exclusive human milk feeding, as in term infants, and (2) is likely dose-dependent with a threshold for protection (Furman et al, 2003; Schanler et al, 1999).

Finally, breastfeeding appears to be protective against sudden infant death syndrome (SIDS) (Ford et al, 1993; Ip et al, 2007). A metaanalysis of seven case-control studies found that infants with a history of being breastfed had a 36% reduction in risk for SIDS as compared with infants never breastfed (Ip et al, 2007). Without a known mechanism for this effect, it is possible that breastfeeding serves as a marker for other unmeasured maternal behaviors that reduce the risk of SIDS.

CHRONIC DISEASES OF CHILDHOOD

Data from epidemiologic studies suggest that certain chronic disorders have a lower incidence in children who were breastfed as infants (see Box 65-2). Because of the nature of these studies, causal relationships between breastfeeding and the health outcomes of interest are difficult to infer. Among these disorders are Crohn's disease, celiac disease, lymphoma, and leukemia (Akobeng et al, 2006; Koletzko et al, 1989; Kwan et al, 2004; Martin et al, 2005). A small protective effect of exclusive breastfeeding for >3 months against the development of type 1 diabetes has been reported, although this remains controversial (Caicedo et al, 2005; Ip et al, 2007; Norris and Scott, 1996). The cross-reaction of bovine milk β-lactoglobulin antibodies with pancreatic insulin–producing cell antibodies offers a possible mechanism (Karjalainen et al, 1992). There are also conflicting data regarding the protection afforded by breastfeeding against allergic disease (Friedman and Zeiger, 2005; Kramer, 1988). However, metaanalysis of prospective cohort studies supports the conclusion that exclusive breastfeeding for >3 months lowers the risk of atopic dermatitis (OR = 0.68, 95% CI = 0.52 to 0.88) and asthma (OR = 0.70, 95% CI = 0.60 to 0.81); risk is lowered further in the presence of a family history of atopy (atopic dermatitis [OR = 0.58 and asthma OR = 0.52]) (Arenz et al, 2004; Gdalevich et al, 2001a,b; Ip et al, 2007).

Several reports suggest a significant inverse relationship between breastfeeding duration and the development of overweight and obesity in adolescents and young adults (Gillman et al, 2001; von Kries et al, 1999). A significant reduction in the risk of overweight in later life was reported in two metaanalyses using good to moderate-quality studies that compared any breastfeeding to no breastfeeding (pooled adjusted ORs = 0.76 and 0.93) (Arenz et al, 2004; Owen et al, 2005). Most but not all studies also endorse a protective effect of breastfeeding against overweight/obesity in preschool and school-aged children. Although it is difficult to eliminate the possibility of residual confounding by unmeasured lifestyle factors, metaanalysis results in favor of this effect have been adjusted for the critical confounder of maternal body mass index, as well as many other confounders including birthweight for gestational age, race and ethnicity, and socioeconomic factors (Ip et al, 2007). It is speculated that breastfeeding promotes internal self-regulation of energy intake and less rapid early weight gain, is associated with lower rates of diabetes, and affects long-term programming of leptin metabolism (Dewey and Lönnerdal, 1986; Heinig et al, 1993; Singhal et al, 2002; Stettler et al, 2002).

NEUROBEHAVIORAL ASPECTS

Whether or not an improvement in cognitive ability is attributable to breastfeeding and human milk is difficult to determine. A small but significant increase in intelligence quotient has been associated with duration of breastfeeding among full-term and low-birthweight infants in some but not all studies and metaanalyses (Anderson et al, 1999; Horwood and Fergusson, 1998; Ip et al, 2007; Jain et al, 2002; Rogan and Gladen, 1993). Disagreement remains even (1) when results are adjusted for the key confounders of maternal intelligence, maternal education, and socioeconomic class, and (2) when only studies meeting strict clinical epidemiologic standards are included (Ip et al, 2007). Residual confounding due to unmeasured factors is difficult to exclude. Among premature infants, factors related to neonatal morbidity such as chronic lung disease and intraventricular hemorrhage must also be considered. Early work with premature infants suggested a benefit of human milk as compared to term formula on intelligence at age 8 years, but these results are difficult to extrapolate to the present because both formula and breast milk are now fortified (Lucas et al, 1992). More recently, significantly improved neurodevelopment among extremely low-birthweight infants as measured by the Bayley Scales of Infant Development II at 18 to 22 and 30 months of age has been correlated with the receipt of fortified human milk during hospitalization. The magnitude of the effect at 18 to 22 months was greatest in the highest quintile (>80%), which averaged 110 mL/kg/day of human milk, and at 30 months the effect persisted such that for every 10 mL/kg/day increase in human milk, the Mental Developmental Index increased by 0.59 points, the Psychomotor Developmental Index by 0.56 points, and the total behavior percentile score by 0.99 points (Vohr et al, 2006, 2007). Finally, maternal-infant bonding is enhanced during breastfeeding. The likely biologic basis for this universal observation is oxytocin, which causes the milk ejection reflex during nursing and serves as a central neurotransmitter that directly affects maternal nurturing behaviors, maternal-infant social interaction, gaze, vocalizations, and affectionate touch (Feldman et al, 2007).

MATERNAL BENEFITS

There are multiple positive effects of breastfeeding for the mother (see Box 65-2). Many clinicians believe that postpartum weight loss and uterine involution are more rapid while breastfeeding (Heinig and Dewey, 1997; Ip et al, 2007). Lactation has a beneficial effect on lipid and glucose metabolism and is associated with a reduction in type 2 diabetes and a lower risk of cardiovascular morbidities (Schwarz et al, 2009; Stuebe et al, 2005). Exclusive breastfeeding delays the resumption of normal ovarian cycles and the return of fertility in most mothers, likely because of an elevated prolactin level (McNeilly, 1993). The lactational amenorrhea method (LAM) is a highly effective global contraceptive program with efficacy rates of 98.5% to 100% (Labbok, 2001). The three criteria that ensure the lowest pregnancy rate are full breastfeeding (round-the-clock), no resumption of menses, and infant age <6 months (Labbok, 2001). Breastfeeding can therefore contribute to global child spacing, which additionally improves maternal health. Epidemiologic studies have documented a decreased incidence of premenopausal breast cancer and ovarian cancer in women who have breastfed (Collaborative Group on Hormonal Factors in Breast Cancer, 2002; Ip et al, 2007; Rosenblatt et al, 1993). Lactation also appears to protect against osteoporosis, because during lactation maternal bone density declines, yet it is normal in the postweaning period, suggesting mechanisms for catch-up mineralization (Kalkwarf et al, 1997; Specker et al, 1991).

SOCIETAL IMPACT OF BREASTFEEDING

The economic advantages of breastfeeding can be tangibly calculated. From a national economic perspective, it has been estimated that if 50% of infants enrolled in the WIC program were breastfed exclusively for just the first 3 months of life, a savings of approximately $4 million per month would be realized (Montgomery and Splett, 1997). These savings would accrue from a combined reduction in household expenditure on formula, as well as reductions in health care expenditures and reduced parental work absence due to the decreased rates of illness experienced by breastfed infants. It is estimated that health care costs significantly decrease with every additional month of breastfeeding and with each month delay in return to work after 3 months (Cattaneo et al, 2006). The U.S. Department of Agriculture Economic Research Service estimated that if levels of breastfeeding in the United States were elevated to the Healthy People 2010 (unrevised) goals, $3.6 billion would be saved (Weimer, 2001). Thus, extraordinary societal and economic incentives support attainment of full breastfeeding for each infant.

CONTRAINDICATIONS TO BREASTFEEDING

Few true contraindications to breastfeeding exist (Box 65-3). Mothers with fever or other minor illness should be permitted to breastfeed, because the infant has already been exposed to the infectious agent and will be able to benefit from the mother's developing immunity if breastfeeding can continue. Few maternal medications contraindicate breastfeeding, and alternative drug choices are available in most cases (U.S. National Library of Medicine, 2009). Mothers who have undergone breast reduction or breast implant surgery can breastfeed, but should work closely with a lactation consultant because milk supply may be negatively affected if ducts or nerves were severed during surgery.

ANATOMY AND PHYSIOLOGY OF LACTATION

Breast milk is produced by the mammary alveolar cells of the breast after childbirth. The mammary gland is a highly evolved skin gland, and its rudiments are first seen during the 6th week in utero. Mammogenesis, or breast development, begins during puberty with increased breast size due mainly to estrogen and lobuloalveolar development facilitated predominantly by progesterone. During pregnancy, with the support of these hormones

and others including prolactin and placental lactogen, breast glandular tissue further differentiates, and the alveolar epithelium proliferates and then becomes secretory. Research using ultrasound technology has changed understanding of breast anatomy (Figure 65-1) (Ramsay et al, 2005). It now appears that the milk ducts branch close to the nipple, that their number is lower and more variable than previously believed, that most glandular tissue is close to the nipple, and that the lactiferous sinuses, which were thought to store milk, do not exist. These findings have implications for hand expression of breast milk as well as for breast augmentation or reduction surgery.

The capability to secrete milk, or lactogenesis, begins by midpregnancy, although actual milk secretion does not occur at this time because of high circulating levels of progesterone (and probably estrogen). During pregnancy, secretory differentiation of the mammary epithelial cells into lactocytes that have the ability to produce milk components occurs: this is known as lactogenesis I. At the end of gestation, the alveoli are filled with proteins, including secretory IgA and leukocytes and desquamated cells. This initial glandular fluid is colostrum. Lactogenesis II or secretory activation of the lactocytes, also known as the milk coming in, occurs shortly after delivery, usually between days 2 and 8. This phase, defined by the copious onset of milk secretion, is triggered by birth and the drop in progesterone associated with removal of the placenta. The hormonal support of adequate circulating prolactin and cortisol are both required, and other hormones, including insulin and thyroid hormone, likely play a supporting role. During this time milk volume increases from about 50 to 100 mL per day to 500 mL per day, and transitional milk is produced, a descriptor for milk that is literally transitioning from colostrum to mature milk in composition (Neville et al, 2001).

The control of lactogenesis is completely hormonal. Evidence suggests that milk removal or infant suckling are not needed for the programmed changes of lactogenesis, although it is possible that milk removal improves the efficiency of early milk secretion (Pang and Hartman, 2007). Delayed lactogenesis II has been associated with placental retention (failure of progesterone to decline postpartum),

BOX 65-3 Contraindications to Breastfeeding

MATERNAL

Untreated active maternal miliary tuberculosis: Refrain from breastfeeding or infant contact until treated and no longer contagious—approximately 2 weeks

Active herpetic lesions on the breast: Refrain from breastfeeding until active lesions on breast and nipple have resolved. Vaginal herpes is not a contraindication

Active varicella (chickenpox) lesions on the breast: Express milk until lesions are crusted over, administer varicella immunoglobulin to infant

Active human immunodeficiency virus (HIV) infection: Active HIV is not an absolute contraindication in developing countries*

Active human T-lymphotrophic virus (HTLV, types 1 and 2) infection

Use of illicit drugs is an absolute contraindication: Drug-free methadone-maintained women can breastfeed

Chemotherapy: For duration of treatment; seek consultation for diagnostic studies utilizing radiation so as to determine duration of express and discard required

INFANT

Galactosemia: Lactose cannot be ingested and is the carbohydrate of breast milk

Other inborn errors of metabolism require consultation based on the specific metabolic defect

hypothyroidism, and theca lutein ovarian cysts, and for unknown reasons there are associations with cesarean delivery, premature delivery, and maternal insulin-dependent diabetes.

If the mother begins to feed her infant at the breast (or to express milk from the breast), then the next phase of lactation, called galactopoiesis or maintenance of milk secretion, starts at approximately day 9 postpartum and continues until weaning and involution of the breast. The control of galactopoiesis is both endocrine and autocrine. Prolactin and cortisol are necessary for milk production: prolactin binds to epithelial cell receptors and is responsible for activating the milk protein genes for alpha-lactalbumin and casein. Milk synthesis remains near 700 to 800 mL/day throughout lactation, but the actual volume of milk produced is dependent on milk removal. With decreased removal or incomplete emptying of the breast due to infrequent or inefficient infant sucking, milk synthesis is adjusted downward because of a locally produced whey protein called feedback inhibitor of lactation (FIL). FIL appears to act on alveolar cell receptors to decrease their sensitivity to prolactin and therefore to decrease milk production. The cellular mechanisms for milk synthesis and secretion are described elsewhere (Neville, 2001; Neville et al, 2001).

Milk that was accumulated in the alveoli cannot flow passively into the ducts. Actual milk ejection or galactokinesis is dependent on the hormone oxytocin, which is produced in the posterior pituitary. Oxytocin secretion is stimulated by infant suckling and other sensory inputs that mimic the infant, such as cry, sight, smell, and touch. Stretch receptors in the cannulicular ductal system are activated, and afferent nerve endings send a signal to the central nervous system. The alveolar lactocytes are wrapped with myoepithelial cells that lack innervation but have oxytocin receptors (Figure 65-2). In the presence of oxytocin, they squeeze milk into the ducts, leading to milk ejection. Prolactin originates in the anterior pituitary, and although secretion is also stimulated by sucking, its production is not inhibited by pain and stress like that of oxytocin, and the milk ejection reflex, or let down does not directly depend on it.

During weaning or extended periods of infrequent sucking at the breast, levels of prolactin drift downward. The tight junctions between alveolar lactocytes appear to open and allow for passage of electrolytes including sodium and chloride. Elevated breast milk sodium is associated with several clinical situations, including involution and remodeling of the mammary gland, which occurs with cessation of milk secretion.

THE MANAGEMENT OF BREASTFEEDING

The successful management of lactation begins before and during pregnancy (Freed et al, 1991; Lawrence, 1994). Formal prenatal breastfeeding education, in addition to the personalized information offered during prenatal visits, positively affects exclusive breastfeeding and breastfeeding at 6 months (Noel-Weiss et al, 2006). Ideally, breastfeeding education should precede pregnancy and be taught in secondary school and throughout the reproductive life cycle. Pediatricians have many opportunities to promote and normalize breastfeeding at the prenatal visit, if one is conducted, and during health maintenance visits at all ages. Prenatal obstetric visits provide significant opportunities for the obstetrician or nurse-midwife to promote and encourage breastfeeding. In support of this approach, maternal prenatal intention to breastfeed appears to be the best predictor of breastfeeding initiation and duration. A study of 10,548 women examined only intended duration of breastfeeding as an explanatory variable and correctly predicted 91.4% of breastfeeding initiation and 72.2% of infant feeding at 6 months (Donath and Amir, 2003).

HOSPITAL CARE

Hospital management of delivery room and postpartum routines has been shown to affect rates of breastfeeding (DiGirolamo et al, 2008). Optimal written hospital guidelines should seek to promote and support breastfeeding for each mother-infant dyad per recommendations of the American Academy of Pediatrics and the World Health Organization; maximize each mother's ability to meet her own breastfeeding goals; and maximize each infant's opportunity to receive full feeds of breast milk. Collaboration between all health professionals and staff interacting with the mother and infant is essential. The "ten steps" of the Baby Friendly Hospital Initiative serve as a useful and evidence-based guide to hospital policy (see Box 65-1). Each step may require changes in hospital routines that have endured over many years but are not conducive to breastfeeding. For example, mothers should be encouraged to put the infant to breastfeed within the 1st hour after birth. Newborns who are placed skin-to-skin on the mother's abdomen minutes after birth are able to initiate a crawl toward the breast and nipple, latch on, and begin sucking. The necessary medical routines of infant identification, drying, warmth, assessment, and administration of prophylactic eye drops and vitamin K can be performed without losing the opportunity for breastcrawl. Other Baby Friendly "steps" that promote breastfeeding include avoidance of supplements (formula or water) unless medically necessary, 24-hour infant rooming in, and avoidance

of pacifiers until breastfeeding is well established. If well-meaning health providers offer bottles or pacifiers, or hustle infants back to the nursery to facilitate morning report or other routines, mothers have fewer opportunities to read early infant hunger cues, to put the baby to breast, and to get the assistance that builds their confidence, and supplementation is likely to interfere with milk supply. Birthing hospitals that have been certified as Baby Friendly and thus adhere to the ten steps have sustained improvements in rates of breastfeeding initiation, even among high-risk maternal populations (Merewood et al, 2005). These benefits may extend to mother-infant dyads in adjoining neonatal intensive care units, although necessary modifications to the ten steps that accommodate the needs of premature infants have been proposed (Nyqvist, 2008).

INITIAL MANAGEMENT

Normal healthy infants are able to latch on to the breast in the first hour after birth (AAP, 2005). The goals for the infant during the postpartum stay include: (1) achievement of latch on to the breast within the first 6 hours of life, (2) feeding every 2 to 3 hours at the breast (8 to 10 times per 24 hours), (3) nursing at both breasts each feeding for up to 15 to 20 minutes per side, (4) ability to transfer milk (or colostrum) adequately at each feeding, and (5) that the mother will feel comfortable with the infant feeding at the breast. Maternal and infant risk factors for lactation difficulty (Box 65-4) should be identified within the first hours after birth so that interventions to promote maternal and infant health and the breastfeeding process can be promptly initiated, and this assessment process should be ongoing through the hospital stay.

LATCH-ON

Good latch is the cornerstone of successful breastfeeding because it permits adequate milk transfer to the infant and prevents excessive nipple pain for the mother. Brief videos are available that demonstrate how to assist a mother achieve latch. Nursing at the breast is fundamentally different from bottle-feeding in that the infant pumps the milk from behind the nipple while nursing rather than sucking on the nipple to elicit flow. There are several ways to hold an infant to breastfeed, but to achieve good latch, the mother and infant should be tummy-to-tummy, regardless of the holding position, with the infant facing the mother's body. The mother can hold her breast well behind the areola using a C hold with four fingers under the nipple and the thumb above. She then strokes the infant's mid upper lip with her nipple, and once rooting is elicited and the infant opens his mouth, she can promptly bring the infant in so he takes in the breast including the areola, not just the nipple. The mother's nipple is protected because it is well back in the infant's mouth, and the infant's jaw massages milk from behind the areola. The infant's nose and chin will contact the mother's skin and the mother should not have pain with infant sucking. Many women do acknowledge that breastfeeding is initially painful to just uncomfortable, including the uterine contractions elicited by oxytocin during let-down, but if breast or nipple pain persists, prompt breastfeeding assistance is needed.

BOX 65-4 Risk Factors for Lactation Failure or Difficulty

MATERNAL FACTORS

- Maternal chronic illness (e.g., cystic fibrosis, diabetes type 1 or 2)
- Anatomic
  - Prior breast surgery
  - Inverted nipples, nipple size mismatch with infant mouth
  - Tubular or variant breast shape (size per se is not a factor)
- Obesity
- History of prior breastfeeding difficulty
- Perinatal complications (e.g., hemorrhage, hypertension/preeclampsia, shock, infection)
- Cesarean delivery
- Multiples (twins, triplets, etc.)
- Maternal-infant separation
- Secondary—nipple trauma, nipple pain, engorgement

INFANT FACTORS

- Premature delivery <34 weeks
- Late preterm delivery (34 to 36 weeks' gestation)
- Term delivery at 37 weeks (some infants)
- Birthweight large or small for gestational age (LGA or SGA)
- No effective latch in the first 24 hours
- Anatomic or congenital anomaly
  - Trisomy
  - Major congenital malformation
  - Micrognathia, Pierre-Robin sequence
  - Cleft palate or lip
  - Macroglossia or ankyloglossia
- Neurologic abnormality with hypotonia or hypertonia
- Neonatal intensive care unit admission/perinatal complications (e.g., hypoxic-ischemic encephalopathy, pneumonia)
- Sleepy infant of any cause
- Maternal-infant separation
- Secondary—supplemented more than once in 24 hours, weight >7% below birthweight, excessive pacifier use

THE FIRST 2 WEEKS TO 2 MONTHS

Each hospital should establish breastfeeding support groups or work with organized community support groups so that families have a resource on leaving the hospital. All breastfed infants should be seen by a knowledgeable health care professional at 3 to 5 days of age to avoid potential problems of dehydration and severe jaundice (AAP, 2005).

The nursing history varies from infant to infant and over any 24-hour period, so although nursing every 1.5 to 3 hours is the average, some infants will "cluster feed," nursing more frequently for short periods. Without anticipatory guidance, new mothers may compare their infants to bottle-fed infants and misinterpret the normal frequency of breastfeeding to mean that they have insufficient milk. As infants get older, they nurse more efficiently, and the frequency and duration of feedings decrease. New parents may expect their baby to cry when he is hungry and need guidance that crying is a late sign of hunger and can result in an infant who is difficult to calm and latch. Earlier hunger signs include rooting, finger and fist sucking and lip smacking. Pacifiers may be a marker for breastfeeding difficulty, but because their use is associated with a possible reduction in SIDS risk, a pacifier can be introduced if desired once breastfeeding is well established after 2 to 3 weeks of age.

Once lactogenesis stage II is completed, an infant who did not lose excessive weight and who is nursing effectively should obtain enough milk to begin gaining weight, 15 to 30 grams per day, by day 4 or 5. At this rate, most breastfed infants will exceed their birthweight by 10 to 14 days, and gain 150 to 210 grams per week for the first 2 months. A breastfed infant who weighs less than birthweight at 2 weeks requires evaluation and intervention. Infants must receive vitamin K at birth and 400 IU of vitamin D daily (Wagner and Greer, 2008). Anticipatory guidance should include information about growth spurts, in which infants are restless and breastfeed more often than usual for 2 to 3 days. These typically occur at approximately ages 3 weeks, 6 weeks, 3 months, and every few months, and they may be exhausting for the mother. Because milk supply depends on infant demand, permitting the infant to breastfeed as needed is optimal. In addition, screening for maternal depression, which is associated with a decreased duration of breastfeeding, and for maternal concerns that can become barriers to continued breastfeeding, such as sore nipples, is critical (Dennis and McQueen, 2009).

Mothers who seek to combine breast and bottle or who face return to work can offer one bottle of expressed milk daily from the time breastfeeding is established at 2 to 3 weeks of age: many clinicians and mothers report that infants who are unaccustomed to a bottle will refuse one if not introduced before 1 month of age. Although exclusive breastfeeding through 6 months with addition of complementary feeds and continued breastfeeding until 1 to 2 years of age is clearly an evidence-based medical recommendation, mothers face many family and work constraints. Good information should be provided in a supportive nonjudgmental context about flexible ways to combine working outside the home with breastfeeding, especially because out-of-home employment is a risk factor for premature weaning. In addition to expressing and storing milk for bottle-feeding, mothers may want to identify reduced or flexible hours, take the infant to work, or breastfeed during breaks at a nearby childcare facility (Fein et al, 2008; Li et al, 2008).

BREASTFEEDING THE LATE PRETERM INFANT

Late preterm infants (34⁶⁄₇ to 36⁶⁄₇ weeks' gestation) are at high risk for complications of insufficient breast milk intake, including dehydration, hypernatremia, severe jaundice, and poor weight gain, and their mothers are at high risk for lactation failure due to immature and ineffective infant sucking (Raju, 2006; Watchko, 2006). Interventions to support breastfeeding in the late preterm infant include providing (1) positive personal support to the mother, (2) hands-on assistance with latch and infant positioning each feed, (3) encouragement of milk expression using a breast pump after each feed and every 2 to 3 hours (8 to 10 times per day) for 10 to 15 minutes, and (4) continuing rooming-in and skin-to-skin care as often as possible. Within hours of birth, the mother can be taught to hand-express colostrum to feed the baby, and within 24 hours of birth she can begin breast milk expression every 2 to 3 hours after breastfeeding using a hospital grade electric pump. Infant interventions include waking the infant to feed and providing supplementation with or after each feeding at least every 2 to 3 hours with expressed colostrum or breast milk (mixed with formula if there is not yet enough breast milk). The infant may appear sleepy and not awake spontaneously for feeds, so he or she should be waked on this schedule and supplemented after each breastfeed using a supplemental nursing system, bottle, cup, or syringe, to give a standardized quantity of milk. Some clinicians recommend 3 to 5 mL per kg per feed every 2 to 3 hours after day 1, whereas others recommend a schedule of 5 to 10 mL per feed on day 1, 10 to 20 mL per feed on day 2, 20 to 30 mL on day 3, and so forth, based on breastfeeding ability. This trio of nursing at the breast followed by supplementation (or simultaneous with nursing if a supplemental nursing system is used) and then maternal milk expression, comprises "triple feeds," a bridge to successful lactation for the at-risk maternal-infant dyad. In this manner the mother's milk supply is not at risk or diminished because of ineffective or infrequent sucking, and the physiologically immature infant is guaranteed sufficient intake. Whether intervention is required or breastfeeding appears to proceed smoothly, a breastfeeding management plan for discharge should be established before discharge.

MATERNAL BREASTFEEDING ISSUES

NIPPLE PAIN

Sore nipples and pain are the most common complaint of breastfeeding mothers in the immediate postpartum period. Early, mild discomfort is common, but severe nipple pain, the presence of cracks or bruises and skin lesions, or discomfort that continues throughout a feeding or that is not improving at the end of the 1st week should not be considered normal. The most common cause of nipple pain is difficulty with breastfeeding technique, specifically, poor position and/or improper latch, and prompt skilled help is the primary intervention. Limited milk transfer occurs when the infant is attached incorrectly, resulting in poor infant weight gain and impaired milk production. Potential causes of nipple pain include not releasing suction before taking the infant off the breast, overzealous breast cleansing, skin irritant preparations, unique skin sensitivity, skin trauma leading to impetigo, and Candida infection. Treatment for nipple pain depends on the underlying etiology. If severe trauma exists, it may be necessary either to express milk or use a nipple shield with guidance from a lactation consultant until healed.

ENGORGEMENT AND BLOCKED DUCTS

Physiologic breast fullness occurs due to vascular congestion during lactogenesis II. Pathologic engorgement, in which the infant cannot initially remove milk, is the firm, diffuse, and painful overfilling and edema of breasts usually due to rapid increase in milk volume, or to a skipped feeding. The best treatments for engorgement are a warm shower and gentle hand massage to soften the areola and permit the infant to attach, frequent effective breastfeedings (or milk expression with a pump if the infant is not able), and cold packs for 5 minutes after each feeding. Engorgement should not be confused with a plugged milk duct, which can result in a localized lump in one area of

the breast, usually due to infrequent or ineffective feedings or local pressure due to constrictive clothing. Treatment includes warm packs, gentle massage from the painful area toward the nipple, frequent effective feedings using different infant positions to facilitate emptying, and discontinuation of tight or underwire bras.

MASTITIS

As a single area of localized warmth, tenderness, edema, and erythema in one breast more than 10 days after delivery, mastitis may present with a sudden onset of breast pain, myalgia, and fever, or with flulike symptoms such as fatigue, nausea, vomiting, and headache. The infection commonly enters through a break in the skin, usually a cracked nipple. However, milk stasis and congestion from engorgement, or obstruction from plugged ducts, also can lead to mastitis. The treatment of mastitis includes antibiotics, and continuation of breastfeeding with frequent feeding (or pumping) to allow the drainage of the affected breast. Additional therapy includes the encouragement of fluid intake, bed rest, and pain control.

LOW MILK SUPPLY

Actual low milk supply most often results from infrequent and/or ineffective feedings at the breast, introduction of formula supplementation that decreases breastfeeding frequency, or early (before 3 weeks) introduction of bottles, each of which decrease milk supply because of inadequate milk removal. Primary treatment includes increased effectiveness and frequency of milk removal; galactagogues, such as metoclopramide, occasionally may be helpful if use is temporary and supervised. Maternal factors reducing milk supply during or after the postpartum period include primary or secondary hypoprolactinemia, absence of an intact adenohypophyseal axis, severe maternal illness including sepsis or hemorrhage, prior breast surgery, obesity (due to a decreased prolactin response to suckling), estrogen-containing contraceptives, and severe fatigue, stress, or pain (Rasmussen and Kjolhede, 2004). It is not clear whether maternal smoking actually reduces milk supply or is a behavioral risk factor for decreased duration of breastfeeding. Perceived low milk supply, in which the infant has a normal growth pattern but the mother believes she does not have sufficient milk, can result from growth spurts leading to increased infant demand, changes in the efficiency of the breast around 4 weeks leading to decreased apparent fullness before nursing, or increased efficiency of infant nursing beginning at 2 to 3 months leading to less frequent or shorter breastfeeding sessions. Infant weight check is diagnostic.

CONTRACEPTION

Data regarding the effect of hormonal contraception on milk supply is limited and contemporary studies are needed. There is clinical agreement that LAM (lactational amenorrhea method; see earlier discussion) and nonhormonal methods of contraception are preferable during breastfeeding. Data from WHO that are now more than 25 years old showed that estrogen-containing contraceptives significantly decrease milk supply, although they do not appear to affect infant growth (Tankeyoon et al, 1984). Limited evidence suggests no effect of progestin-only oral or injectable contraceptives on milk supply if initiated after milk supply is established; however, large prospective trials are needed (Perheentupa et al, 2003).

JAUNDICE AND BREASTFEEDING

The association between breastfeeding and jaundice is observed in two distinct entities: breastfeeding jaundice and breast-milk jaundice.

BREASTFEEDING JAUNDICE

Severe jaundice is the most frequent reason for readmission of late preterm and term infants, most of whom are breastfeeding. If there is any delay in lactogenesis II or if the infant has ineffective milk removal or infrequent sucking, less milk will be ingested and consequently less milk will be produced, leading to a cycle of decreased demand and decreased supply, with consequent starvation jaundice or breast-nonfeeding jaundice. The most common risk factor for inadequate milk removal is late preterm birth. Lack of milk leads to intestinal milk stasis. The neonatal intestine has highly active glucuronidases that cleave conjugated bilirubin to unconjugated bilirubin. The unconjugated bilirubin is readily reabsorbed and recirculated to the liver for conjugation. Milk, by providing calories and gastrocolic stimulation, alleviates the recirculation of bilirubin. Thus, the treatment focuses on improving maternal lactation and providing milk (expressed human milk, donor milk, or formula) to the infant.

Notably almost every reported case of kernicterus over the past two decades has been in breastfed infants, with late preterm infants overrepresented in the U.S. Pilot Kernicterus Registry (Bhutani and Johnson, 2006; Newman et al, 2003). Thus, primary prevention of "breast-nonfeeding jaundice" includes the measurement of total serum bilirubin at discharge to predict future therapy and establishment of optimal lactation. These factors need to be reassessed at the 3- to 5-day follow-up visit (AAP, 2005).

BREAST MILK JAUNDICE

In breastfed infants, total serum bilirubin concentrations remain elevated, and in a few infants this may last for as long as 12 weeks. In formula-fed infants, serum bilirubin declines, reaching values of less than 1.5 mg/dL by the 11th or 12th day after birth. It has been suggested that the elevation in serum bilirubin may be protective against oxidative injury because it has been shown to be an effective antioxidant in vitro. Because this is a normal response to breastfeeding, other than the jaundice the infants appear healthy. The infants have a normal physical exam and are growing normally. Mature human milk contains an unidentified factor that enhances the intestinal absorption of bilirubin in a susceptible host infant to produce jaundice. As the production of the factor diminishes over time and the liver matures, the serum bilirubin concentration

eventually returns to normal. Prolonged unconjugated hyperbilirubinemia in an outpatient infant may also be a result of galactosemia, hypothyroidism, urinary tract infection, pyloric stenosis, or low-grade hemolysis.

Breastfeeding should be continued and parents should be reassured. Persistent rise in serum bilirubin may necessitate a diagnostic challenge by interrupting breastfeeding for 24 to 48 hours. Following interruption of breastfeeding, the total serum bilirubin will decline markedly and not rise to prior levels with resumption of breastfeeding. If breastfeeding is interrupted, the mother should be encouraged and helped to maintain her milk supply. The mother may be reluctant to resume breastfeeding because of the association between breastfeeding and jaundice. A positive attitude on the part of the health care practitioners and assurance that this will not occur later may avoid termination of breastfeeding.

GROWTH OF THE BREASTFED INFANT

The rate and pattern of weight gain of breastfed infants differs from that of infants fed formula, and several studies have concluded that the breastfed infants should be considered the norm (Butte et al, 1984, 1990; Dewey et al, 1991, 1992). The World Health Organization recently published a new international growth reference based on the growth of healthy infants who were breastfed throughout the 1st year of life (de Onis et al, 2006). The new WHO Child Growth Standards (www.who.int/childgrowth) set the benchmark for growth and development of all children from birth to age 5, replacing old references, such as the U.S.-based National Center for Health Statistics (NCHS) growth charts, which were based on cross-sectional samples of children receiving both formula and breast milk and were specific to both time and place. The WHO Multicentre Growth Reference Study (MGRS) was undertaken between 1997 and 2003 and gathered primary longitudinal growth data from about 8500 children of differing ethnic, racial, and cultural backgrounds (Brazil, Ghana, India, Norway, Oman, and the United States). The participating children were selected based on the criteria for optimum environments for healthy development, including healthy feeding practices (specifically breastfeeding and good complementary feeding), good health care (including vaccinations and immunization), and mothers who did not smoke. The MGRS growth charts are based on the breastfed infant as the normative growth model and represent the current evidence-based standard for growth of the healthy child.

Clinicians occasionally are in doubt as to when to intervene if a breastfed infant is not gaining adequate weight (Powers, 2001). A newborn infant less than 2 weeks of age whose weight is more than 10% below birthweight must be evaluated, and an older infant who fails to regain birthweight by 2 weeks or is not gaining a minimum of 20 grams per day should be evaluated. The infant with growth faltering, when the weight-for-age (or weight-for-length) is more than 2 standard deviations below the mean or weight-for-age that crosses more than 2 percentile channels downward on the growth chart, should also be evaluated. Assessments of milk supply and intake, appropriateness of complementary foods, and the feeding environment all are part of evaluation of slow weight gain or faltering growth. Causes of growth problems not related to breastfeeding must be considered—for example, cystic fibrosis—as well as issues specific to breastfeeding, such as ankyloglossia.

COLLECTION AND STORAGE OF HUMAN MILK

Electric breast pumps enable optimal milk production for mothers separated, by either employment or hospitalization, from their infants. Mothers should maintain a milk pumping frequency of 6 to 8 times per day to achieve and maintain their milk production. Milk volume on day 4 may be predictive of supply at 6 weeks. Low milk production may be a problem in mothers of hospitalized newborns. Factors implicated in low supply include biologic immaturity of the mammary gland, maternal stress and/or illness, and difficulty maintaining a supply without a suckling infant. Hospital-based lactation programs and skin-to-skin care have been shown to increase duration of lactation (Bier et al, 1996; Meier and Engstrom, 2007).

There are many instances when mothers will be separated from their infants, and prior knowledge allows them to select methods to express and store their milk for future use. Return to work or school, illness, and hospitalization are some of the common reasons encountered by mothers who wish to learn about the methods for milk collection and storage. General techniques for ensuring cleanliness during milk expression begin with good hand washing with soap and water. Electric breast pumps generally are more effective than mechanical pumps or manual expression. Bicycle horn-type hand pumps may cause breast trauma and contamination of milk and should not be used. Many mothers find the double-collecting kits that enable simultaneous breast pumping from both breasts more efficient for milk expression. Collection kits should be rinsed, cleaned with hot soapy water, and dried in the air. Dishwasher cleaning is also adequate. Glass or hard plastic containers should be used for milk storage. Bacteriologic testing is not necessary for milk collected for feeding to a mother's own infant unless caregivers suspect that the technique for milk collection is not optimal. Milk to be fed within 5 days of collection can be refrigerated without significant bacterial proliferation.

Freezing is the preferred method of storing milk that will not be fed. Single milk expressions should be packaged separately for freezing and labeled with the date (and name of the infant if the infant is cared for in a child care center or hospital). Unlike heat treatment, freezing preserves many of the nutritional and immunologic benefits of human milk. When frozen appropriately, milk can be stored for as long as 3 to 6 months. Milk should be thawed rapidly, usually by holding the container under running tepid (not hot) water. Milk should never be thawed in a microwave oven. After milk is thawed, it should not be refrozen. Thawed milk should be used completely within 24 hours.

DONOR HUMAN MILK

Donor human milk has been increasingly offered and utilized in settings in which breast milk would benefit the infant, but the mother is unable to provide her milk, most

frequently in the NICU (Schanler et al, 2005). A Cochrane review concluded that feeding of preterm and low-birth-weight infants with donor milk as compared to preterm formula resulted in a lower risk of developing necrotizing enterocolitis but also led to lower rates of short-term growth (Quigley et al, 2007). A recent development in processing technology has enabled the use of an exclusively human milk diet composed of pasteurized donor human milk and human milk-based fortifier. When studied in extremely premature infants, the exclusively human milk–based diet was associated with lower rates of necrotizing enterocolitis than a diet containing any bovine milk–based products (Sullivan et al, 2009). This promising technology now allows the premature infant to receive a diet of exclusively human milk.

CONCLUSION

In summary, worldwide infant mortality rates are lower in breastfed infants compared with those fed formula, and evidence is compelling that breastfeeding significantly reduces the number and severity of infections in both term and preterm infants in developed and developing countries (Bahl et al, 2005; Chen and Rogan, 2004; Ip et al, 2007; Jones et al, 2003). Strong evidence demonstrates that breastfeeding also promotes maternal health. Breastfeeding also may be associated with long-term beneficial effects on infant health, growth, and development. Substantial improvements are needed in rates of breastfeeding, particularly among racial, ethnic, and socioeconomic subpopulations that suffer the highest infant morbidity and mortality rates. Health care practitioners are uniquely positioned to influence women in their decision to breastfeed. Practitioners should also be prepared to assist in the management of breastfeeding problems and in the logistics of breastfeeding. Discussion regarding the benefits of breastfeeding permits the mother to make an informed infant feeding choice, and for many women, physician support of breastfeeding is critical to their success in providing the best possible means of nourishing their infant.

CHAPTER 66

Enteral Nutrition for the High-Risk Neonate

Brenda B. Poindexter and Richard J. Schanler

Providing optimal enteral nutrition to high-risk premature neonates is a difficult clinical challenge. In order to achieve optimal growth, nutritional needs in the early neonatal period are greater than at any other time in life. The circumstance of premature delivery results in decreased nutrient deposition in the infant. Critical illness and immature gut motility and function often preclude intended delivery of nutrition. Despite the lack of evidence, fear of necrotizing enterocolitis if feedings are advanced too quickly may also limit provision of optimal enteral nutrition. Consequently, the premature infant requires specialized nutritional support to meet these great demands for growth.

Current recommendations for provision of enteral nutrition to premature infants are based on the goal of duplicating rates of intrauterine accretion of the fetus at the same postmenstrual age. However, this goal is rarely accomplished and the incidence of postnatal growth failure in very low-birthweight (VLBW) infants remains unacceptably high. Recent data from the NICHD Neonatal Research Network report that 91% of VLBW infants weigh less than the 10th percentile at 36 weeks' postmenstrual age (Fanaroff et al, 2007). Infants who experience one or more major morbidities such as bronchopulmonary dysplasia, severe intraventricular hemorrhage, necrotizing enterocolitis, or late-onset sepsis are at increased risk for growth failure. The association between suboptimal postnatal growth and poor neurodevelopmental outcomes at 18 to 22 months' corrected age is especially worrisome and emphasizes the importance of optimizing nutritional support for infants born prematurely.

Special considerations regarding nutrient needs of premature infants arise at birth. Because of limited body stores, increased energy expenditure, severity of illness, and/or immaturity and inability to tolerate enteral feedings, premature infants are given parenteral nutrition immediately from birth. Enteral feedings are often precluded because of the multiplicity of medical problems, but gastrointestinal priming with minimal quantities of milk is used to stimulate intestinal function. As the infant matures physiologically and the medical condition stabilizes, parenteral nutrition is slowly replaced with enteral nutrition. This chapter describes the basis of recommendations for enteral nutrient support for high-risk neonates. In addition, evidence regarding the initiation and advancement of enteral feedings in premature infants is discussed. Finally, special considerations for enteral nutrition after discharge from the neonatal intensive care unit are reviewed.

MACRONUTRIENT REQUIREMENTS IN THE ENTERALLY FED PREMATURE NEONATE

PROTEIN

When fetal life is interrupted by premature birth, significant protein deficits can occur and can be difficult if not impossible to recoup (Embleton et al, 2001). In several observational studies, early protein intake has been associated with postnatal growth in extremely premature infants. In fact, protein intake in the first 2 weeks of life in extremely low-birthweight infants is an independent prognostic determinant of growth (Berry et al, 1997). In addition, differences in weight gain velocity in these infants can be predicted by early protein intake (Berry et al, 1997; Olsen et al, 2002). Finally, there is increasing evidence that the amount of protein intake early in life correlates with improved neurodevelopmental outcomes. In order to optimize growth outcomes, particular focus must therefore be given to enteral protein intake.

The most commonly accepted goal of provision of enteral nutrition to premature infants is to achieve growth comparable to the fetus. At 26 weeks' gestation, the fetus accretes approximately 2.2 g/kg per day of protein; by term, this amount declines to approximately 0.9 g/kg per day. Protein losses are inversely related to gestational age, providing an explanation of higher protein requirements in extremely premature neonates. Accretion of protein is dependent on protein quantity and quality, energy intake, and underlying disease states (such as sepsis or surgical stress), as well as concomitant medications (such as systemic steroids, fentanyl, and insulin).

Using the factorial approach, Ziegler has estimated protein (and energy) requirements of VLBW infants to approximate the rate of fetal growth (Ziegler, 2007; Ziegler et al, 2002). In this model, protein requirements are estimated as the sum of needs for growth in addition to needs for replacement of protein losses. Based on this model, protein requirements for premature infants weighing 500 to 1200 grams are 4.0 g/kg per day; with increasing body weight, protein requirements determined by the factorial approach decrease. Enteral protein (and energy) requirements using the factorial approach are shown in Table 66-1. Protein and energy needs should be considered hand in hand, because protein synthesis requires energy. Extremely premature infants require a higher protein to energy ratio for optimal growth (also discussed in section on enteral energy requirements).

TABLE 66-1 Estimated Protein and Energy Requirements to Achieve Fetal Growth*

Weight (g)	Protein (g/kg/d)	Energy (kcal/kg/d)	Protein:Energy (g/100 kcal)
500–700	4.0	105	3.8
700–900	4.0	108	3.7
900–1200	4.0	119	3.4
1200–1500	3.9	125	3.1
1500–1800	3.6	128	2.8
1800–2200	3.4	131	2.6

*Based on factorial method (Ziegler EE, Thureen PJ, Carlson SJ: Aggressive nutrition of the very low birthweight infant, *Clin Perinatol* 29:225-244, 2002).

§From Agostoni C, Buonocore G, Carnielli VP, et al: Enteral nutrient supply for preterm infants: commentary from the European Society for Paediatric Gastroenterology, Hepatology, and Nutrition Committee on Nutrition, *J Pediatr Gastroenterol Nutr* 50:85-91, 2010.

Protein retention, or balance, generally is a function of protein intake if energy intake is adequate (Zlotkin et al, 1981). Enteral protein requirements are calculated to be higher than parenteral, because only approximately 85% of enteral protein is absorbed. In contrast to empiric methods, this approach does not take into consideration nutrient requirements for catch-up growth.

The Canadian Paediatric Society, the Life Sciences Research Office of the American Society for Nutritional Sciences, the American Academy of Pediatrics Committee on Nutrition, and the European Society for Paediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) Committee on Nutrition have all made recommendations regarding enteral protein intakes for VLBW infants; these recommendations are shown in Table 66-2. The recently updated commentary from the ESPGHAN Committee (Agostoni et al, 2010) has recommended the highest protein intake for infants up to 1000 g at 4.0 to 4.5 g/kg per day.

Further studies are required to more clearly define the upper limit of enteral protein intake in premature neonates to optimize growth and neurodevelopmental outcomes.

ENERGY

In utero, the fetus utilizes both glucose and amino acids as a source of energy. If energy intake is not adequate, protein utilization is not efficient, resulting in lower retention of nitrogen. As shown in Table 66-1, Ziegler and colleagues have estimated that energy requirements are lower in infants with lower body weight. Coupled with the inverse relationship between protein requirements and weight, the protein-to-energy ratio required to achieve fetal growth is highest in the most premature. The recommended energy intake for enterally fed premature infants ranges between 110 and 135 kcal/kg per day (Agostoni et al, 2010).

The optimal ratio of enteral protein to energy intake must be defined not only in terms of optimizing weight gain, but also by that which achieves optimal body composition. Consequently, attempting to duplicate the intrauterine environment may not be appropriate for extrauterine life, given differences in nutrient supply and metabolism. Changes in body composition in response to energy intake are an important consideration, because excessive energy intake can contribute to excessive fat deposition, and recent studies have suggested that rapid weight gain may be associated with adverse outcomes.

TABLE 66-3 Estimated Energy Requirements for Premature Infants

Factor	kcal/kg/d
Energy expenditure	
Resting metabolic rate	40–60
Activity	0–5
Thermoregulation	0–5
Synthesis/energy cost of growth	15
Energy stored	20–30
Energy excreted	15
Total energy requirement	90–120

The energy needs of the neonate are derived from a computation of the energy expenditure, energy storage, and energy losses. Energy expenditure consists of the energy needed to cover the resting metabolic rate, activity, thermoregulation, and the energy cost of growth. Energy storage consists of the energy (fat and lean mass) deposited for growth. Energy losses usually are due to incomplete absorption of nutrients and are greater in premature infants than in term infants or adults. The daily energy needs for the growing premature infant are summarized in Table 66-3. The largest component of the total estimated energy requirement is that needed for the resting metabolic rate. When nourished parenterally, the premature infant has less fecal energy loss, generally fewer episodes of cold stress, and somewhat lesser activity so that the actual energy needs for growth are lowered to approximately 80 to 100 kcal/kg/day. In circumstances of chronic disease, such as bronchopulmonary dysplasia, the resting energy expenditure rises significantly. Total energy needs in premature infants with bronchopulmonary dysplasia are

increased because of greater energy expenditure, activity, and fecal energy losses. It is not surprising to find that these infants may require 150 kcal/kg/day to achieve weight gain.

CARBOHYDRATES

The main carbohydrate in human milk is lactose, supplying nearly half of the total calories. Lactase (β-galactosidase) is an intestinal enzyme that hydrolyzes lactose to glucose and galactose in the small intestine. Despite lower levels of intestinal lactase activities in premature infants, premature infants are able to efficiently digest lactose. Nonetheless, many infant formulas designed for premature infants supply glucose polymers. Glucose polymers are digested by α-glucosidases; the activity level of these enzymes approximates adult levels much sooner than β-galactosidase, which theoretically makes glucose polymers easier for the premature infant to digest than lactose. Glucose polymers also have an advantage in that they increase caloric density without a rise in osmolality. Recommended carbohydrate intake for premature infants is 11.6 to 13.2 g/kg per day (Agostoni et al, 2010). This amount of intake will provide sufficient glucose to meet needs for total energy expenditure.

FAT

Fat provides a substantial source of energy for growing premature infants. Premature infants have low levels of pancreatic lipase, bile acids, and lingual lipase. Human milk, however, supplies a variety of lipases, including lipoprotein lipase, bile salt esterase, and nonactivated lipase. The composition of dietary fat affects absorption and digestion. The absorption of fatty acids increases with decreasing chain length and with the degree of unsaturation. Consequently, medium-chain triglycerides (6- to 12-carbon chain length) are hydrolyzed more readily than long-chain triglycerides. In contrast to formulas designed for term infants, premature infant formulas supply medium-chain triglycerides. Human milk supplies 8% to 12% of fat as medium-chain triglycerides. Recommended intake for lipid in enterally fed premature infants ranges between 4.8 and 6.6 g/kg per day. Of this amount, medium-chain triglycerides should be less than 40% of total intake (Agostoni et al, 2010).

COMPOSITION OF HUMAN MILK AND PREMATURE FORMULAS

Human milk is the preferred source of enteral nutrition for premature infants. However, as discussed later, in order to meet nutrient requirements and support optimal rates of growth and bone mineralization, fortification of human milk is recommended. The compositions of human milk/human milk fortifiers are shown in Table 66-4; the compositions of commercially available premature formulas are shown in Table 66-5.

PROTEIN

In the first few weeks after birth, the protein content of milk from mothers who deliver premature infants (preterm milk) is greater than that of milk obtained from women delivering term infants (term milk). The protein content of both preterm and term milk declines over time, such that beyond 2 weeks it levels off to that of what we call mature milk. The quality of protein—the proportion of whey and casein—in human milk is particularly suitable for the premature infant. Human milk contains 70% whey and 30% casein, whereas bovine milk contains 18% whey and 82% casein. A whey-or casein-dominant commercial formula, therefore, refers to these proportions of bovine milk. The whey fraction of milk consists of soluble proteins that are digested more easily. Human milk and then whey-dominated bovine milk, in that order, promote more rapid gastric emptying than occurs with casein-dominated milk.

The compositions of the whey fractions of human and bovine milks differ significantly. The major human whey protein is α-lactalbumin, a nutritional protein for the infant and a component of mammary gland lactose synthesis. Lactoferrin, lysozyme, and secretory immunoglobulin A are specific human whey proteins that are particularly resistant to hydrolysis, and, as such, line the gastrointestinal tract to play a primary role in host defense. These proteins, therefore, may be suitable for the premature infant who is exposed to multiple pathogens in the nursery environment. The three host defense proteins are present in only trace quantities in bovine milk.

The major amino acid for the fetus and in human milk is glutamine, which is not found in commercial formula because of problems with stability of the free amino acid. Glutamine, however, is an important amino acid for cell growth, specifically intestinal epithelial growth; has a role in immune function; and is a precursor in glutathione synthesis. When commercial formula was supplemented with glutamine under experimental conditions, although there was no difference in rates of sepsis, premature infants who received enteral glutamine supplementation had less feeding dysfunction than those who received unsupplemented formula (Vaughn et al, 2003). Further research efforts are under way to define how to supply this amino acid if human milk is not fed to premature infants.

The protein content of currently available premature formulas and human milk fortifiers when fed at 120 kcal/kg per day is shown in Table 66-6. Given the protein content of these current options, delivery of recommended amounts of enteral protein is a significant clinical challenge. Embleton and colleagues have reported that intake of both protein and energy in infants less than 30 weeks' gestation is consistently less than what is recommended (Embleton et al, 2001).

Although the protein content of human milk from mothers who deliver prematurely is higher than the protein content of human milk from mothers who deliver at term, the protein content of preterm human milk declines over time (from approximately 1.9 g/dL at 7 days of age to approximately 1.2 g/dL by 30 days). Consequently, human milk fortifiers are necessary to provide additional protein in an effort to meet the growth needs of the premature infant receiving human milk. Using standard human milk fortifier (4 packets per 100 mL of human milk), the protein content of preterm human milk at 1 month postnatal age can be increased to 2.14 g/dL (providing 3.3 g protein/kg per day if fed at 120 kcal/kg per day). However, to achieve

4.0 g/kg per day of protein with human milk, many units use additional powder fortifier, fortified donor milk, 30 kcal/oz preterm formula, or the addition of a protein supplement. Recently, a pasteurized donor human milk–based human milk fortifier (Prolact-Plus, Prolacta Bioscience) was evaluated in extremely premature infants. Compared to infants receiving a mother's milk–based diet that also included bovine milk–based products, an exclusively human milk–based diet was associated with lower rates of necrotizing enterocolitis (Sullivan et al, 2010).

The Life Sciences Research Office of the American Society for Nutritional Sciences published guidelines for nutrient requirements of preterm infant formulas in 2002 (Klein, 2002). In order to meet the recommended intake of enteral protein, premature formula or human milk would need to supply 3.2 to 4.1 g protein per 100 kcal. When 24 calorie/oz preterm formula is fed at 120 kcal/kg per day, only one currently available formula supplies 4 g/kg per day of protein (Similac Special Care High Protein; Abbott Nutrition). The use of a higher-protein premature formula (3.6 g protein/100 kcal) was studied by Cooke and Embleton (Cooke et al, 2006). Compared with use of standard preterm formula (3.0 g/100 kcal), use of the higher-protein formula resulted in increased protein accretion

and improved weight gain without evidence of toxicity. Many strategies are employed at various neonatal intensive care units to increase protein intake, most requiring the addition of a protein supplement to enteral nutrition. It is important to point out that increasing caloric density with only carbohydrate and fat (such as adding polycose and/or medium chain triglyceride oil) results in a protein content that is significantly less than the amount required by extremely premature infants. Calorically dense feedings (greater than 24 kcal/oz) should be considered for infants who cannot meet their needs for growth using standard preterm formula (or standard fortified breast milk). In these situations, proportional growth should be considered more than absolute weight gain.

FAT

The lipid system in human milk is structured in a way that facilitates fat digestion and absorption. In human milk, fat exists as organized fat globules containing an outer protein coat and an inner lipid core. The type of fatty acids (high palmitic 16:0, oleic 18:1, linoleic 18:2ω-6, and linoleic 18:3ω-3), their distribution on the triglyceride molecule (16:0 at the 2 position of the molecule), and the presence of bile salt–stimulated lipase are important components of the lipid system in human milk. Because the lipase is heat-labile, the superior fat absorption from human milk is reported only when unprocessed milk is fed.

The most variable nutrient component in human milk is fat, the major energy source, making up nearly 50% of the calories. The fat content of human milk varies among women, changes during the day, rises slightly during lactation, and increases dramatically within a single milk expression. The variability in total fat content is unrelated to maternal dietary fat intake. Because it is not homogenized, the fat separates out of human milk on standing. The separated fat may adhere to collection containers, feeding tubes, and syringes. If significant fat is lost, energy intake may be compromised in the premature infant.

Manufacturers of infant formulas modify their fat blends to mimic the fat absorption from human milk. This accounts for differences in the constituent fatty acids between human milk and cow's milk–based formulas. Generally, commercial formulations have a greater quantity of medium-chain fatty acids (MCFAs) to compensate for the absence of lipase and the unique structure of triglycerides in human milk. In human milk, saturated fatty acids, particularly palmitic acid, are esterified in the 2 position of the triglyceride molecule. The end product of digestion of the triglyceride is a 2-monoglyceride and minimal free fatty acid. The 2-monoglyceride is absorbed better than the free fatty acid. This enhanced absorption is important because free palmitic acid has a great tendency

to bind with minerals to form soaps. In that event, both fat and mineral absorption would be limited. Thus, the overall structure of human milk is designed to provide optimal fat and mineral absorption.

Essential Fatty Acids

The essential fatty acids, linoleic and linolenic acids, are present in ample quantities in human milk and commercial formula. Without an adequate intake of these fatty acids, essential fatty acid deficiency (thrombocytopenia, dermatitis, increased infections, and delayed growth) can develop in as little as 1 week. Only 0.5 g/kg/day (~4% of total energy intake) of essential fatty acids will prevent the deficiency. α-Linolenic acid is an important precursor for synthesis of both eicosapentaenoic acid and docosahexaenoic acid (DHA). The very long-chain polyunsaturated fatty acids arachidonic acid (20:4ω-6) and DHA (22:6ω-3) are found in human but not bovine milk and are components of phospholipids found in brain, retina, and red blood cell membranes (Uauy and Hoffman, 1991). Arachidonic and docosahexaenoic acids functionally have been associated with body growth, vision, and cognition (Carlson et al, 1996a, 1996b). In addition, the fatty acids are integral parts of prostaglandin metabolism. When their diet was supplemented with polyunsaturated fatty acids, formula-fed premature infants had red blood cell concentrations of DHA paralleling those of similar infants fed human milk. Follow-up studies of such supplemented infants suggest improvements in visual acuity compared with unsupplemented infants, but of similar magnitude to that in infants fed human milk (Heird and Lapillonne, 2005). Improvement in cognitive measures during the 1st year of life have also been shown. Both arachidonic acid (AA) and DHA are now added to premature formula. Recommended intakes for DHA and AA are 11 to 27 mg/100 kcal and 16 to 39 mg/100 kcal, respectively (Agostoni et al, 2010).

Medium-Chain Fatty Acids

The proportion of MCFAS, here defined as carbon length 6:0 to 12:0, is less than 12% of total fatty acids in human milk but approaches 50% in preterm formulas. MCFAs are not essential fatty acids. Previous reports suggested that MCFAs were absorbed passively and to a greater extent than long-chain fatty acids (LCFA) and affected growth and mineral absorption positively. However, when added exogenously to milk, MCFAs have been reported to adhere to feeding tubes, thereby diminishing fat delivery to the infant. No compelling data exist to suggest that a high proportion of MCFAs is needed for preterm formulas. Indeed, formulas containing a very high proportion of MCFAs (>80%) may produce essential fatty acid deficiency if fed for a prolonged period of time.

The variability in the fat content of human milk may be used to advantage in the premature infant. Most milk transfer during a feeding occurs in 10 to 15 minutes, but continued milk expression yields a milk with a progressively higher fat content—the hindmilk—than the earlier foremilk. The fat content of hindmilk may be 1.5- to 3-fold greater than that of foremilk. The use of hindmilk in selected cases may provide the premature infant with additional energy. Fractionation of each milk expression into two portions, foremilk and hindmilk, is practical if the mother's milk production is greater than that needed by the infant. No differences between fractions were observed for the concentration of nitrogen, calcium, phosphorus, sodium, or potassium. Copper and zinc concentrations declined by approximately 5% from foremilk to hindmilk.

The differences between foremilk and hindmilk also should be considered in terms of the distribution of calories. Fat and protein compose 42% and 12%, respectively, of calories in foremilk and 55% and 9% of calories in hindmilk. Theoretically, the long-term feeding of hindmilk could exert a negative effect on protein status. A greater proportion of protein calories (10% to 12%) is recommended for premature infants.

CARNITINE

Carnitine is synthesized from lysine and methionine and serves as an important effector of fatty acid oxidation in the mitochondria. The provision of carnitine in the diet results in improved fatty acid oxidation. Human milk contains abundant carnitine, and all infant formulas are supplemented with carnitine.

INITIATION AND ADVANCEMENT OF ENTERAL FEEDS

In early postnatal life, extremely premature infants are dependent on the parenteral route if nutrient requirements are to be met. The strategy employed to transition to full enteral feeds is the source of much debate, and there is considerable variation in practice among different neonatal intensive care units. The primary questions that clinicians must consider include when to initiate enteral feeds, how to advance feedings (continuously or more slowly at first), and how rapidly to advance the enteral feeding volume. These questions have been difficult to study in a rigorous manner but have been addressed in a series of Cochrane systematic reviews by Kennedy and Tyson (Kennedy et al, 2000; Tyson and Kennedy, 2000). The primary question is to determine the optimal feeding regimen that does not increase the incidence of necrotizing enterocolitis.

GASTROINTESTINAL PRIMING

The lack of enteral nutrients poses several problems for the development of the intestinal tract. In several animal species, the absence of enteral nutrients is associated with diminished intestinal growth, atrophy of intestinal mucosa, delayed maturation of intestinal enzymes, and increases in permeability and bacterial translocation. A lack of enteral nutrients also affects intestinal motility, perfusion, and hormonal responses. The hormonal response to feeding premature infants has been evaluated by measuring the plasma concentrations of a variety of gastrointestinal hormones in response to milk feeding during the 1st week after birth (Lucas et al, 1986). Significant hormonal surges were noted after milk feeding, but no response was observed in the absence of feeding. In further investigations, it was

observed that hormonal surges of gastrin, gastric inhibitory polypeptide, and enteroglucagon occurred after the feeding of small quantities of milk (24 mL), but motilin surges were not observed until the cumulative milk intake was 700 mL.

The foregoing observations prompted prospective randomized clinical studies of the effects of small volumes of milk given as early minimal enteral feeding, or trophic feeding, in premature infants. When studied in the 1st or 2nd week after birth, infants who received "early" milk feedings had a better feeding tolerance when feedings were advanced, required a shorter duration of parenteral nutrition, and had a lower incidence of conjugated hyperbilirubinemia compared with similar infants given only parenteral nutrition during the same interval (Slagle and Gross, 1988). The lower alkaline phosphatase activity, primarily of bone origin, was observed for 14 weeks, well beyond the initial intervention in the 1st week. Significant stimulation of gastrointestinal hormones, such as gastrin and gastric inhibitory polypeptide, also was reported after the early feeding of small quantities of milk (Meetze et al, 1992). Intestinal motility patterns matured more rapidly in premature infants receiving early enteral feeding (Berseth, 1992). Subsequent investigations demonstrated that trophic feeding was associated with greater absorption of calcium and phosphorus, greater lactase activity, and reduced intestinal permeability. The metaanalysis of several studies of gastrointestinal priming indicated that its use was associated with a shorter time to regain birthweight, fewer days when feeding was withheld, and a shorter duration of hospitalization, but no increase in the incidence of necrotizing enterocolitis. The infants also had the usual pathologic conditions of patent ductus arteriosus, intraventricular hemorrhage, or systemic hypotension.

MINERAL, VITAMIN, AND TRACE ELEMENT SUPPLEMENTATION

The recommended oral intake for vitamins is shown in Table 66-7; recommended intake for minerals and trace elements is shown in Table 66-8.

CALCIUM AND PHOSPHORUS

Calcium and phosphorus are primary components of the skeleton, accounting for 99% and 85%, respectively, of bone mass. The goal for premature infant nutrition is to achieve a bone mineralization pattern similar to that in the fetus, to avoid osteopenia and fractures. Preterm human milk contains approximately 250 mg/L and 140 mg/L, respectively, of calcium and phosphorus. In contrast, the calcium and phosphorus contents of enteral products designed for premature infants in the United States are significantly greater. In human milk, calcium and phosphorus exist in ionized and complexed forms that are easily absorbed. Thus, in the design of commercial formulas, greater quantities of these minerals are added to compensate for their poorer bioavailability. However, distinct from the term infant, the premature infant requires significantly greater quantities of calcium and phosphorus than can be provided in human milk.

*From American Academy of Pediatrics: *Pediatric nutrition handbook*, Elk Grove Village, Ill, 2009, American Academy of Pediatrics.
†From Agostoni C, Buonocore G, Carnielli VP, et al: Enteral nutrient supply for preterm infants: commentary from the European Society for Paediatric Gastroenterology, Hepatology, and Nutrition Committee on Nutrition, *J Pediatr Gastroenterol Nutr* 50:85-91, 2010.

For the human milk–fed premature infant, calcium and phosphorus are deficient throughout lactation, and levels are far below those necessary to achieve respective intrauterine accretion rates. Deficient intakes of calcium and phosphorus are associated with biochemical markers such as low serum and urine phosphorus concentrations, elevated serum alkaline phosphatase activity, and elevated serum and urine calcium concentrations. Usually, serum phosphorus concentrations are the best indicators of calcium and phosphorus status in human milk–fed premature infants. Prolonged deficiency of these minerals tends to stimulate bone resorption to normalize serum calcium concentrations. This bone activity often is correlated with elevated serum alkaline phosphatase activity. It has been reported that a majority of premature infants who had an elevated serum alkaline phosphatase activity were those fed human milk. Moreover, follow-up evaluations of the same infants at 9 and 18 months noted that linear growth was significantly lower in the group that had the higher serum activity of alkaline phosphatase in the neonatal period. A high alkaline phosphatase value in the neonatal period is a negative predictor of height in 9- to 12-year-old adolescents (Fewtrell et al, 2000).

The supplementation of human milk with both calcium and phosphorus not only improves the net retention of both minerals but also improves bone mineral content. Current management of human milk–fed premature infants emphasizes the need for supplements of both calcium and phosphorus. A linear relationship exists between calcium (or phosphorus) intake and net retention in enterally fed premature infants. Premature infants receiving unfortified human milk never achieve intrauterine accretion rates for calcium and phosphorus. Intakes of approximately 200 and 100 mg/kg/day, respectively, of calcium and phosphorus can be achieved with the use of specialized human milk fortifiers and preterm formulas, thus making it possible to meet intrauterine estimates. However, term infant formulas and specialized (not "preterm") formulas provide inadequate quantities of calcium and phosphorus to meet the needs of growing premature infants. Several factors affect the absorption of calcium and phosphorus, including postnatal age and intake of calcium, phosphorus, lactose, fat, and vitamin D. Vitamin D, however, is responsible for only a small component of calcium absorption in premature infants.

The time to supply sufficient calcium and phosphorus stores for premature infants is during the initial hospitalization, before their discharge and the beginning of exclusive breastfeeding. However, because of the need for prolonged parenteral nutrition and the inability to provide "catch-up" quantities of calcium and phosphorus in milk, some infants may benefit from additional calcium and phosphorus after hospital discharge.

MAGNESIUM

Approximately 60% of body magnesium is in bone. Preterm human milk contains approximately 30 mg/L of magnesium. The absorption of magnesium is significantly greater from unfortified human milk than from formula. Net magnesium retention in human milk–fed premature infants meets intrauterine estimates.

TRACE ELEMENTS

Zinc

Several factors affect the zinc needs of the enterally fed premature infant. Fetal accretion of zinc is approximately 0.85 mg/kg/day. Growth is a major determinant of zinc needs. The major excretory route is via the gastrointestinal tract. Infants with large gastrointestinal fluid losses may become zinc deficient. Premature infants receiving pooled pasteurized human milk (zinc intake of approximately 0.7 mg/kg/day) are in negative zinc balance for 60 days postnatally and never meet the intrauterine accretion rate. In contrast, intakes of 1.8 to 2 mg/kg/day are associated with a net retention of zinc that surpasses intrauterine accretion rates. The classic signs of zinc deficiency include an erythematous skin rash involving perioral, perineal, and facial areas, as well as the extremities. Although there are limitations to the assay, plasma zinc values lower than 50 μg/dL are highly suggestive of deficiency. A very low activity of serum alkaline phosphatase, a zinc-dependent enzyme, also is suggestive of deficiency. Reports of symptomatic zinc deficiency in unsupplemented human milk–fed premature infants serve as a reminder of the decline in milk zinc concentration as lactation advances.

Copper

No universally accepted methods exist to assess copper status clinically. Balance study data provide only an estimate of copper retention at one point in time. Premature infants receiving pooled pasteurized human milk (copper intakes of approximately 85 μg/kg/day) are in negative copper balance for 30 days postnatally and never meet the intrauterine accretion rate. Human milk fortifier supplies additional copper. Symptoms of copper deficiency include osteopenia, neutropenia, and hypochromic anemia. Because copper is excreted in bile, cases of severe cholestasis warrant limiting copper intakes.

Iron

The iron needs of the premature infant are determined by birthweight, initial hemoglobin, rate of growth, and magnitude of iron loss and/or volume of transfused blood. Postnatal iron metabolism occurs in three phases. In the first phase, there is decreased erythropoiesis. The hemoglobin concentration declines to a nadir, physiologic anemia of prematurity, which is at approximately 2 to 3 months of postnatal age. In the second phase, the hemoglobin rises as active red cell production is occurring. In this phase, iron is needed. The third phase is an exhaustion of iron stores, or late anemia of prematurity, observed if iron supplementation is inadequate.

The concentration of iron in human milk declines through lactation. Premature infants fed human milk are in negative iron balance, which, in the absence of transfusion, can be corrected with iron supplements. Iron absorption also appears to be facilitated by a modest degree of anemia. Thus, the usual recommendations for premature infants suggest delaying iron supplementation until 2 to 3 months of postnatal age, when hemoglobin concentrations are at a nadir.

Generally, ferrous sulfate (elemental iron, 2 mg/kg/day) drops are used in human milk–fed premature infants beginning soon after the achievement of complete enteral feedings. Formula-fed premature infants should receive iron-fortified formula from the onset of milk feeding.

Sodium and Potassium

Premature infants generally need more sodium per unit of body weight than is needed by term infants. This increased need is due to immature renal sodium conservation mechanisms. Sodium wasting is inversely related to gestational age. A comparison of sodium intakes of 2.9 and 1.6 mEq (mmol)/kg/day in premature infants suggested that the former intake provided more appropriate serum sodium concentrations. Hyponatremia also may occur in premature infants primarily fed human milk because the sodium content of preterm milk continues to decline through lactation. The need for these electrolytes may increase during or after diuretic usage.

Vitamins

The fat-soluble vitamins A, D, E, and K are stored in the body, and large doses may result in toxicity. Water-soluble vitamins—thiamine, riboflavin, niacin, vitamin B_6, folate, vitamin B_{12}, pantothenic acid, biotin, and vitamin C—are not stored in the body, and excess intakes are excreted in the urine or bile (vitamin B_{12}). The intake of water-soluble vitamins, therefore, should be at frequent intervals to avoid deficiency states. Vitamin A and riboflavin concentrations decline in human milk under conditions of light exposure and after passage through feeding tubes. As a consequence of exposure to air, ascorbic acid concentrations are lower in pooled human milk. Supplementary vitamins are provided in human milk fortifiers and in preterm formulas. Once feedings in the premature infant change to unfortified human milk or standard formula, a multivitamin supplement should be added.

The American Academy of Pediatrics Committee on Nutrition recently issued new guidelines doubling the amount of recommended vitamin D to 400 IU per day for infants (American Academy of Pediatrics, 2009). The recommendation applies to infants receiving human milk and those who are consuming less than 1 quart of infant formula per day. The change in the recommendation is based in part on the risk of rickets in exclusively breastfed infants who are not supplemented with 400 IU of vitamin D per day.

POSTDISCHARGE NUTRITION FOR THE PREMATURE INFANT

Growing evidence suggests that the quality of early nutrition support has long-term implications for infant health and development. The goal of in-hospital nutritional support is to meet intrauterine rates of nutrient accretion. Accordingly, the premature infant should receive fortified human milk or preterm formula during the hospitalization period. Hospital discharge, however, frequently occurs before the completion of the intrauterine growth phase (up to approximately 36 weeks). Moreover, during hospitalization, despite what we may consider to be optimal nutrient support, growth deficits emerge, such that at discharge the infant is well below the 10th percentile on corresponding growth charts. Thus, concerns about nutrition support extend into the postdischarge period. Unfortunately, unlike in the term infant, whose needs are modeled after the healthy breastfed infant, and the premature infant, whose needs are determined by the intrauterine growth model, there are no references to determine the nutritional needs of the premature infant at discharge.

The 1st year of life represents a crucial time of brain growth. Observational studies have found that failure to catch up in weight by 8 months of age was associated with lower scores on the Bayley Scales of Infant Development, poor head circumference growth, and higher rates of neurosensory impairment (Hack et al, 1982).

The composition of postdischarge formulas designed for the premature infant are shown in Table 66-9. These formulas supply more energy (22 calories/oz), protein (2.8 g/100 kcal), calcium, phosphorus, and zinc. Compared to term formula, these formulas provide 49% more protein, 10% more calories, 48% more calcium, 62% more phosphorus, and 75% more zinc. Ongoing fortification of human milk should also be considered for premature infant and can be accomplished in a variety of ways, including the addition of a postdischarge formula to human milk in order to increase energy, protein, calcium, and phosphorus intake.

Carver and colleagues performed a clinical trial in which infants with birthweight less than 1800 grams were randomized to receive term formula or a nutrient-enriched formula until 12 months corrected age. These workers found that infants who received the nutrient-enriched formula had improved proportional growth, because they weighed more at 6 and 12 months corrected age, had greater body length at 6 months corrected age, and were found to have better head circumference growth at term and at 1, 2, 6, and 12 months corrected age. The nutrient-enriched formula was of particular benefit to infants with birthweight less than 1250 grams (Carver et al, 2001). Bishop and colleagues found increased bone mineral content up to 9 months corrected age in infants who received nutrient-enriched formula compared to term formula (Bishop et al, 1993).

Nutrition should be discussed during the discharge planning process with the families of former premature infants. In addition, these plans should be discussed with the primary medical caregiver to ensure a smooth transition to the outpatient setting. Premature infants who are formula-fed should be fed nutrient-enriched postdischarge formula for the 1st year of life. The duration of use will vary depending on the severity of postnatal growth failure, bone health, and proportional growth after NICU discharge. Likewise, growth of premature infants who are discharged on human milk should be closely monitored to ensure optimal proportional growth.

CHAPTER 67

Parenteral Nutrition

Brenda B. Poindexter and Scott C. Denne

Effective nutritional support of premature and critically ill infants is largely dependent on parenteral nutrition, especially in early postnatal life. In practice, the supply of nutrients to preterm neonates—especially extremely low-birthweight (ELBW) infants—is rarely adequate, and these infants accumulate major deficits in early postnatal life (Berry et al, 1997; Embleton et al, 2001; Olsen et al, 2002). A high proportion of ELBW infants exhibit poor growth in the neonatal intensive care unit (NICU), with those at the lowest gestational age and birthweight at greatest risk (Clark et al, 2003; Fanaroff et al, 2007). However, growing evidence indicates that early use of parenteral nutrition may minimize protein losses and improve growth outcomes (Poindexter, 2005; Stephens et al, 2009; Thureen et al, 2003; Wilson et al, 1997). For example, Wilson et al (1997), in a randomized clinical trial in 125 sick very low-birthweight (VLBW) infants, demonstrated that early aggressive parenteral nutrition combined with early enteral feeding reduced growth failure without an increased incidence of adverse clinical consequences or metabolic derangements. More recent observational studies have produced similar results (Poindexter, 2005; Valentine et al, 2009). In addition to improved growth outcomes, Stephens et al (2009) found an association between increased protein and energy intake in the 1st week of life and higher Bayley Mental Development Index scores at 18 months corrected age. Parenteral nutrition solutions, although still imperfect, have improved markedly from the early days of use, and complications are less common. At present, improved growth outcomes in preterm infants appear to require a more sustained effort at providing parenteral nutritional support, especially in early postnatal life. This means initiating parenteral nutrition within the first 24 hours, continuing until enteral nutrition supplies at least 75% of the total protein and energy requirements, and reinstituting parenteral nutrition quickly whenever enteral feeding is suspended.

COMPONENTS OF PARENTERAL NUTRITION

PROTEIN

The initial goal of parenteral nutrition is to minimize losses and preserve existing body stores; this is particularly important for protein. Protein losses are significant in all neonates in the absence of amino acid intake, and these losses are the highest in the most immature neonates. For example, 26-week-gestation infants lose 1.5 g/kg/day of body protein; protein losses in term infants are approximately half that rate (0.7 g/kg/day) (Denne et al, 1996). These high rates of loss in extremely premature infants result in substantial protein deficits. If extremely premature infants are provided with no amino acid supply, they lose over 1.5% of their body protein per day when they should be accumulating protein at a rate of 2% per day. After only 3 days of no protein intake, a 10% protein deficit results.

Fortunately, there is good evidence that early amino acid intake can compensate for high rates of protein loss and thus preserve body protein, even at low caloric intakes (Kashyap and Heird, 1994; Rivera et al, 1993; Saini et al, 1989; Van Lingen et al, 1992). Amino acid intakes of 1.1 to 2.3 g/kg/day at caloric intakes of 30 to 50 kcal/kg/day change the protein balance from significantly negative to neutral or positive in sick VLBW infants (Rivera et al, 1993; Saini et al, 1989; Van Lingen et al, 1992). More recently, Thureen et al (1998) conducted a randomized trial of 1 g/kg/day versus 3 g/kg/day amino acid intake immediately after birth in extremely premature infants. Despite a modest caloric intake in both groups (approximately 50 kcal/kg/day), protein accretion was significantly greater in the higher amino acid intake group. In all these studies evaluating the effect of early amino acid intake in premature infants, no differences in ammonia concentrations or acid-base status were observed between infants who received amino acids and those who did not (Paisley et al, 2000; Rivera et al, 1993; Saini et al, 1989; Van Lingen et al, 1992). In addition, these studies demonstrated no relationship between amino acid intake and blood urea nitrogen (BUN), although two recent studies reported modestly elevated BUN levels in infants receiving higher amino acid intakes at 7 days of age (Blanco et al, 2008; Clark et al, 2007). The fact that BUN concentrations do not usually correlate with amino acid intake in early postnatal life suggests these levels are related primarily to fluid status and that increased BUN levels should not be used as an indication of protein excess. These data indicate that providing parenteral amino acids at a rate of 2 to 3 g/kg/day as soon as possible after birth (within hours) can preserve limited body protein stores in sick premature and ELBW infants, even at low caloric intakes.

It is important to point out that even though parenteral amino acid administration is beneficial at low caloric intakes, increasing caloric intake is likely to improve protein accretion. Older studies in premature infants have suggested that increasing caloric intake from 50 to 80 kcal/kg/day can significantly improve protein balance (Pineault et al, 1988; Zlotkin et al, 1981). Based on currently available data, 70 to 80 kcal/kg/day may be sufficient to maximize protein accretion. However, additional energy beyond this amount probably is necessary to produce appropriate fat accretion (see "Energy" section).

The ultimate goal of parenteral amino acid administration is to achieve the rate of fetal protein accretion. Based on a variety of studies measuring protein losses and balance, 3.5 to 4.0 g/kg/day of amino acids is a reasonable

estimate of parenteral protein requirements in ELBW infants (Ziegler, 2007) (Table 67-1). Recent evidence suggests that up to 4.0 g/kg/day of amino acids is well tolerated by ELBW infants (Porcelli and Sisk, 2002). For premature infants with birthweights of over 1000 g, estimated parenteral protein requirements are 3.0 to 3.5 g/kg/day. Estimates for term infants are 2.5 to 3 g/kg/day. Parenteral protein intake recommendations for premature infants are shown in Table 67-1.

The composition of currently available amino acid solutions is shown in Table 67-2. These amino acid solutions were designed to mimic plasma amino acid concentrations in healthy 30-day-old breastfed term infants (TrophAmine) or fetal or neonatal cord blood amino acid concentrations (Primene). No convincing information exists to support the superiority of one neonatal amino acid solution over another.

Although the current neonatal amino acid solutions represent a substantial advance over previous casein

‡Mixture of L-tyrosine and *N*-acetyltyrosine.

hydrolysates and early crystalline amino acid mixtures, specific deficiencies remain. Glutamine, an amino acid abundantly supplied by breast milk and potentially conditionally essential in premature infants, is not included in any available amino acid solution because of issues of stability. However, the NICHD Neonatal Research Network conducted a multicenter, randomized clinical trial of parenteral glutamine supplementation and found that parenteral glutamine supplementation did not decrease mortality or the incidence of late-onset sepsis in ELBW infants (Poindexter et al, 2004). In addition, glutamine had no effect on tolerance of enteral feeds, necrotizing enterocolitis, or growth. Tyrosine has very limited solubility, so little is included in current amino acid solutions. TrophAmine contains a soluble derivative of tyrosine (*N*-acetyltyrosine), but this derivative appears to have poor bioavailability. A variety of studies in premature infants suggest that the tyrosine supply may not be optimal in current amino acid solutions (Brunton et al, 2000). Cysteine is not included in most amino acid solutions because it is not stable for long periods. However, a cysteine hydrochloride supplement that can be added to the parenteral nutrition solution just before delivery is commercially available. There is evidence to support that when cysteine hydrochloride supplements are added to parenteral nutrition, nitrogen retention is improved in premature infants (Soghier and Brion, 2006). The addition of cysteine hydrochloride also improves the solubility of calcium and phosphorus in parenteral nutrition solutions and also may improve the status of the important antioxidant glutathione. For these reasons, the addition of cysteine hydrochloride (40 mg/g of amino acid, up to a maximum of 120 mg/kg) is recommended. Cysteine hydrochloride can result in metabolic acidosis, but this possibility can be appropriately countered by the use of acetate in the parenteral nutrition solution as a buffer (Peters et al, 1997).

ENERGY

The initial goal of parenteral nutrition in early postnatal life is to provide sufficient energy intake to at least match rates of energy expenditure in order to preserve body energy stores. Measures of energy expenditure in premature infants have ranged between 30 and 70 kcal/kg/day; energy expenditure increases with energy intake and with advancing postnatal age (Bauer et al, 2003a, 2003b; Torine et al, 2007; Weintraub et al, 2009). Energy expenditure also appears to be greater at lower birthweights (Weintraub et al, 2009). An intake of approximately 70 kcal/kg/day is a reasonable clinical goal to achieve neutral or slightly positive energy balance, although because of glucose and lipid intolerance, this intake may not be able to be achieved for a number of days after birth. Nevertheless, maximizing energy intake within the limits of glucose and lipid tolerance can minimize accumulating energy deficits. It is also important to note that common clinical conditions such as sepsis and chronic lung disease can significantly increase energy expenditure, which can further exaggerate energy deficits (Bauer et al, 2003c; Torine et al, 2007).

To support normal rates of growth, a positive energy balance of 20 to 25 kcal/kg/day must be achieved (Denne, 2001). This requires 90 to 100 kcal/kg/day for preterm infants with birthweights of less than 1000 g and 100 to 110 kcal/kg/day for ELBW infants (see Table 67-1). A parenteral intake of 80 to 90 kcal/kg/day is most often sufficient for term infants. Most of the parenteral calories are best supplied by a balanced caloric intake of lipid and glucose. Parenteral energy requirements are less than those required for enteral nutrition because no energy is lost in the stools. Recommendations for parenteral energy intake are shown in Table 67-1.

GLUCOSE

Glucose is typically the first parenteral nutrient provided to the preterm infant, and glucose administration is begun minutes after birth in order to maintain glucose homeostasis and preserve endogenous carbohydrate stores. Although the precise definitions of hypoglycemia and hyperglycemia remain a topic of debate, maintaining glucose concentrations of above 40 mg/dL and below 150 to 200 mg/dL is a reasonable clinical goal (Cornblath et al, 2000). Hypoglycemia is easily avoided in preterm infants by maintaining a constant intravenous glucose delivery, but hyperglycemia is more often problematic, especially in ELBW infants shortly after birth. Hyperglycemia is very common in this population in early postnatal life, with more than three fourths of ELBW infants having glucose concentrations exceeding 150 mg/dL, and a third of infants with frequent glucose concentrations over 180 mg/dL (Beardsall et al, 2008; Blanco et al, 2006).

Glucose infusion rate of 4 to 7 mg/kg/minute (70 to 110 mL/kg/day of 10% dextrose in water [$D_{10}W$]) is an appropriate starting point for most infants. This rate of glucose infusion approximates or slightly exceeds the rate of endogenous glucose release from the liver in term and premature infants with birthweights above 1000 g; therefore, this rate of glucose infusion serves to preserve the limited carbohydrate stores in these infants. For ELBW infants, a rate of 8 to 10 mg/kg/minute is required to match endogenous glucose production (Hertz et al, 1993). Unfortunately, many infants will not tolerate this rate of glucose infusion for several days without hyperglycemia. Because ELBW infants can have fluid requirements in excess of 100 mL/kg/day, beginning with 5% dextrose may be necessary to maintain glucose infusion rates in the range of 4 to 7 mg/kg in order to achieve glucose homeostasis.

A gradual increase in glucose intake over 2 to 7 days, up to 13 to 17 g/kg/day, is usually tolerated when the glucose is combined with amino acid intake. An infusion rate of 18 g/kg/day is a reasonable maximum for intravenous glucose delivery, because higher rates probably exceed the glucose oxidative capacity (Chessex et al, 1995; Jones et al, 1993). Exceeding glucose oxidative capacity will drive extensive lipogenesis, an energy-expensive process. Supplying appropriate amounts of glucose rarely requires glucose solution concentrations in excess of 12.5%, unless infants are fluid-restricted. Recommendations for glucose intake during parenteral nutrition are provided in Table 67-1.

Some ELBW infants have difficulty tolerating even moderate rates of glucose delivery. This problem usually can be overcome by a temporary reduction in the glucose infusion rate. The use of insulin in this situation remains a controversial practice. Collins et al (1991), in a

small randomized controlled trial, demonstrated increased weight gain in infants who received insulin infusions. No differences in head circumference or length were observed between these infants and controls, suggesting that insulin may have produced increases in fat mass but not in lean tissue. Poindexter et al (1998) evaluated the effect of insulin on protein metabolism using a euglycemic hyperinsulinemic clamp. Insulin infusion resulted in no improvement in protein balance and unexpectedly produced significant lactic acidosis. An international, randomized clinical trial was recently conducted to determine whether early insulin therapy would reduce hyperglycemia and improve outcomes in VLBW infants (Beardsall et al, 2008). The study demonstrated no improvements in mortality, sepsis, growth, intracranial disease, necrotizing enterocolitis, or chronic lung disease and was terminated early because of futility concerns. The authors concluded that there is little clinical benefit of routine early insulin administration; although insulin may decrease the incidence of hyperglycemia, early insulin may also increase the number of episodes of hypoglycemia. Nevertheless, there are rare ELBW infants who remain hyperglycemic despite very low glucose infusion rates; these infants may require exogenous insulin beginning at 0.05 unit/kg/hour for a short period of time to produce normoglycemia.

Meeting the goal of 13 to 17 g/kg/day of intravenous glucose will result in a caloric intake of 45 to 60 kcal/kg/day, which is insufficient by itself to meet total energy needs. Intravenous lipids are necessary to supply the rest of the nonprotein calories. A balanced glucose and lipid approach to supplying nonprotein calories has a number of advantages: it better approximates the carbohydrate-to-fat ratio in enteral feedings, it may improve overall protein accretion, and it minimizes overall energy expenditure (Nose et al, 1987; Van Aerde et al, 1989).

LIPIDS

Intravenous lipids are made up of triglycerides, phospholipids from egg yolk to emulsify, and glycerol, which is added to achieve isotonicity. Intravenous lipid solutions commercially available in the United States are derived from soybean oil (Intralipid) or a combination of soybean oil and safflower oil (Liposyn II); these solutions contain long-chain triglycerides. Differences in lipid source result in a slightly different fatty acid profile; the compositions of intravenous lipid solutions are shown in Table 67-3. All available intravenous lipid products have a fatty acid profile substantially different from that of human milk. At present, there is not convincing information that any of the solutions produce clinically different outcomes.

Intravenous lipid solutions contain lipid particles similar in size to endogenously produced chylomicrons. These particles are hydrolyzed by lipoprotein lipase into free fatty acids. Lipoprotein lipase activity and triglyceride clearance are reduced in preterm infants of less than 28 weeks' gestation (Brans et al, 1986). Although heparin can release lipoprotein lipase from the endothelium into the circulation, at present no evidence exists that this increases lipid utilization in preterm infants (Spear et al, 1988). In the absence of any information demonstrating clinical benefit of heparin administration, the routine addition of heparin in lipid infusions is not recommended.

TABLE 67-3 Composition of Parenteral Lipid Emulsions

	Intralipid 20%	Liposyn-II 20%	Omegaven*

DHA, Docosahexaenoic acid; *EPA*, eicosapentaenoic acid.
*Omegaven is not approved for use in the United States and is only available under experimental or compassionate use protocol. Omegaven is only available as a 10% solution (10 g lipid per 100 mL).

Linoleic and linolenic acids cannot be endogenously synthesized and therefore are essential fatty acids for humans. Biochemical evidence of essential fatty acid deficiency may be noted in preterm infants within 72 hours of birth (Foote et al, 1991). Essential fatty acid deficiency can be avoided if 0.5 to 1.0 g/kg/day of intravenous lipid is provided. Additional intravenous lipid beyond these amounts is necessary if the energy requirements of preterm infants are to be met in early postnatal life.

The early administration of intravenous lipids to preterm infants has been the subject of discussion and debate; this debate has centered primarily on the acute metabolic effects of early intravenous lipids and the potential long-term consequences. Gilbertson et al (1991) evaluated the short-term metabolic effects of early intravenous lipids in a randomized controlled trial. This study examined 29 infants requiring mechanical ventilation with an average gestational age of 28 weeks and an average birthweight of 1.1 kg. One group received intravenous lipid at 1.0 g/kg/day beginning on day 1; this was gradually increased to 3.0 g/kg/day by day 4. The control group received intravenous lipid only after day 8. There were no differences in PO_2, PCO_2, hyperglycemia, bilirubin concentrations, thrombocytopenia, or free fatty acid concentrations between the two groups. In addition, triglyceride concentrations were similar in both groups. Another trial using a slightly different study design produced similar results (Murdock et al, 1995). Current evidence strongly suggests that intravenous lipids can be administered to sick preterm infants in early postnatal life without causing acute metabolic derangements.

Concern about the long-term safety of early intravenous administration of lipids, particularly the possibility of an increase in mortality and bronchopulmonary dysplasia, was raised by some early observational studies. A recent metaanalysis of randomized controlled studies found no

increase in chronic lung disease resulting from early lipid administration to premature infants (Simmer and Rao, 2005). In view of these data and of the essential fatty acid and caloric needs of sick premature infants, early intravenous lipid administration (on day 1 of life) is a recommended clinical practice.

The rate of intravenous lipid infusion is important, and plasma lipid clearance is improved when intravenous lipid is given as a continuous infusion over 24 hours (Putet, 2000). Lipid infusion rates in excess of 0.25 g/kg/hour are associated with decreases in PO_2 (Brans et al, 1986). Lipid infusion rates well under this value can easily be achieved in clinical practice if lipids are provided over 24 hours in an amount not exceeding 3 to 4 g/kg/day. This level of lipid intake is usually sufficient to supply the caloric needs of preterm infants (in combination with glucose) and is usually tolerated by premature infants. Triglyceride concentrations are most often used as an indication of lipid tolerance, and maintaining triglyceride concentrations below 150 to 200 mg/dL seems desirable. Recommendations for parenteral lipid intake are provided in Table 67-1.

Numerous studies have documented superiority of 20% over 10% lipid emulsions (Putet, 2000). Lipid clearance is improved with the 20% solutions because these solutions have half the amount of phospholipid emulsifier relative to the same amount of triglycerides. Phospholipids can combine with cholesterol to form lipoprotein X, which ultimately interferes with the clearance of infused triglycerides. Consequently, the use of 10% lipid emulsions should be avoided. A 30% lipid solution has recently become available and may confer even more advantages, although there currently are no comparative data.

Concern has been expressed about the use of intravenous lipids in infants with hyperbilirubinemia, because free fatty acids may displace bilirubin from albumin-binding sites, potentially increasing the risk of kernicterus. A recent study that measured free bilirubin in relation to intravenous lipid intake in premature infants less that 33 weeks' gestation demonstrated an increase in free bilirubin with higher intravenous lipid intakes in infants less than 29 weeks' gestation, but not for those at higher gestational ages (Amin et al, 2009). Although the clinical significance of this finding is uncertain, it may be reasonable to consider reducing intravenous lipids in extremely premature infants with significant hyperbilirubinemia.

Intravenous lipid emulsions may undergo lipid peroxidation, with the formation of organic free radicals, potentially initiating tissue injury. Light, especially phototherapy, may play some role in increasing lipid peroxidation in intravenous lipid emulsions (Neuzil et al, 1995). However, multivitamin preparations included in the intravenous solutions are major contributors to generation of peroxides, and lipid emulsions may have only a minor additive effect (Lavoie et al, 1997). Some small studies have suggested that light protection may reduce chronic lung disease, but these results have not been consistent (Bassiouny et al, 2009; Chessex et al, 2007; Sherlock and Chessex, 2009). On the basis of these findings, some clinicians protect intravenous lipid solutions from light, although the importance or clinical efficacy of this practice remains in doubt. Only a large randomized clinical trial is likely to resolve this issue (Sherlock and Chessex, 2009).

Carnitine facilitates transport of long-chain fatty acids through the myocardial membrane and thereby plays an important role in their oxidation. Premature infants receiving parenteral nutrition have low carnitine levels, but the clinical significance of this finding remains uncertain. Metaanalysis of the studies evaluating carnitine supplementation in parenteral nutrition showed no evidence of effect on ketogenesis, lipid utilization, or weight gain (Cairns and Stalker, 2000). At present, insufficient information is available to support a recommendation for the routine supplementation of parenterally fed neonates with carnitine.

ELECTROLYTES, MINERALS, TRACE ELEMENTS, AND VITAMINS

Sodium needs are low in the first few days of life because of the expected free water diuresis. For ELBW infants, addition of sodium to the parenteral nutrition solution may not be necessary until about day 3 of life. It is, however, necessary to frequently measure sodium concentrations and water balance. After the initial diuresis, 2 to 4 mEq/kg/day is usually sufficient to maintain serum sodium in the normal range, but ELBW infants sometimes require higher sodium intakes to compensate for larger renal sodium losses. Chloride requirements follow the same time course as for sodium requirements and also are 2 to 4 mEq/kg/day. Once electrolytes are added to the parenteral nutrition solution, chloride intake should not be less than 1 mEq/kg/day, and all chloride should not be omitted when sodium bicarbonate or acetate is given to correct metabolic acidosis. Potassium requirements again are low in the first few days of life, and potassium should probably be omitted from parenteral solutions in ELBW infants until renal function is clearly established. Potassium intakes of 2 to 3 mEq/kg/day are usually adequate to maintain normal serum potassium concentrations.

Parenteral nutrition solutions usually require the addition of anions, as either acetate or chloride. In general, excess anions should be provided as acetate in order to prevent hyperchloremic metabolic acidosis. A randomized controlled trial demonstrated that acetate in parenteral nutrition solutions effectively ameliorates acidosis (Phelps and Cochran, 1989).

Supplying calcium and phosphorus in parenteral nutrition remains a significant clinical challenge because of limited solubility. It is currently not possible to supply enough calcium and phosphorus to support adequate bone mineralization in preterm infants using the solutions available in the United States. In other countries, organophosphate preparations are available (e.g., glycerophosphate), and calcium and phosphorus can be supplied in parenteral nutrition solutions in amounts that approximate enteral intakes. Precipitation of calcium and phosphorus remains an issue in the United States, however, and the solubility of calcium and phosphorus in parenteral nutrition solutions depends on temperature, type and concentration of amino acid, glucose concentration, pH, type of calcium salt, sequence of addition of calcium and phosphorus to the solution, the calcium-to-phosphorus ratio, and the presence of lipid. Adding cysteine to parenteral nutrition solutions lowers the pH, which improves calcium and phosphorus solubility. Intakes of 60 to 80 mg/kg/day

of elemental calcium (1.5 to 2.0 mmol/kg/day) and 48 to 60 mg/kg/day of phosphorus (1.5 to 2.0 mmol/kg/day) have been recommended for premature infants receiving parenteral nutrition (Atkinson and Tsang, 2005). A calcium-to-phosphorus ratio of 1.7:1 by weight (1.3:1 by molar ratio) may be optimal for bone mineralization, but it appears that neonates can tolerate and adjust to molar ratios over the range of 0.8 to 1.5 (Atkinson and Tsang, 2005). In general, calcium and phosphorus should be added to parenteral nutrition solutions in early postnatal life. Magnesium also is a necessary nutrient and should be supplied at 3 to 7.2 mg/kg/day. Calcium, phosphorus, and magnesium serum concentrations should be frequently monitored.

Recommendations for trace elements in term and preterm infants are primarily derived from the American Society for Clinical Nutrition (ASCN) guidelines from 1988 (Greene et al, 1988). There is reasonable consensus that zinc should be included early in parenteral nutrition solutions (250 μg/kg/day for term infants, 400 μg/kg/day for preterm infants). Other trace elements probably are not needed until after the first 2 weeks of life.

The recommended intakes of trace elements for term and preterm infants are shown in Table 67-4. Zinc and copper are available in the sulfate form and can be added separately to parenteral solutions. Several pediatric trace metal solutions are available that contain zinc, copper, magnesium, and chromium in various proportions; these solutions are usually provided at 0.2 mL/kg/day. When trace metal solutions are used, additional zinc usually is needed to provide the recommended intake for preterm infants. Supplementation with selenium is suggested after 2 weeks of age, because preterm infants can become selenium deficient after 2 weeks of exclusive parenteral nutrition. In infants with cholestasis, copper and manganese should be discontinued, and chromium and selenium should be used with caution and in smaller amounts in infants with renal dysfunction. At present, parenteral iron is recommended only when preterm infants are nourished exclusively by parenteral solutions for the first 2 months of life.

The recommended intakes of vitamins for term and preterm infants on parenteral nutrition are shown in Table 67-5. Currently only one pediatric multivitamin preparation is available, and it is delivered with a standard dosage of 2 mL/kg/day (maximum 5 mL/day) in preterm infants and 5 mL/day in term infants. These dosages provide higher amounts of most of the B vitamins and lower amounts of vitamin A relative to the recommendations.

TABLE 67-4 Recommended Parenteral Intake of Trace Elements for Term and Preterm Infants

Trace Element	Term (μg/kg/day)	Preterm (μg/kg/day)
Chromium*	0.20	0.2
Copper†	20	20
Iron‡	—	—
Fluoride§	—	—
Iodide	1	1
Manganese†	1	1
Molybdenum	0.25	0.25
Selenium*	2	2
Zinc‖	250	400

Data from the American Society for Clinical Nutrition, Subcommittee on Pediatric Parenteral Nutrient Requirements, from the Committee on Clinical Practice Issues: *Am J Clin Nutr* 48:1324-1343, 1988.
ASCN, American Society for Clinical Nutrition; *TPN*, total parenteral nutrition.
*Renal dysfunction can cause toxicity.
†Impaired biliary excretion can cause toxicity.
‡Recommendation is made with caution because of very limited experience with intravenous iron in infants and lack of a safe, acceptable intravenous preparation (estimated daily intravenous requirement is 100 μg/kg for term infants and 200 μg/kg for preterm infants).
§Because of a lack of information on the compatibility of fluoride with TPN and on the contamination level of fluoride in TPN solutions, firm recommendations cannot be made; with long-term TPN (longer than 3 months), a dosage of 500 μg/day may be important in preterm infants, who already have a higher incidence of subsequent dental caries.
‖ The only trace element recommended on day 1 of parenteral nutrition. If the infant requires TPN for longer than 3 months, the dosage must be reduced to 100 μg/kg/day.

COMPLICATIONS OF PARENTERAL NUTRITION

Although a wide variety of complications associated with parenteral nutrition were reported in the early days of use, most of these are now rare with current parenteral solutions. Many of the complications (electrolyte and glucose imbalance) can be prevented or corrected by manipulating the constituents of the infusate. The primary complications of parenteral nutrition as currently used are cholestasis and those related to the infusion catheter.

Cholestatic jaundice as a result of hepatic dysfunction is a well-recognized complication of parenteral nutrition. The initial histologic lesion is cholestasis, both intracellular and intracanalicular, followed by portal inflammation and progression to bile duct proliferation after several weeks of parenteral nutrition. Cholestasis most often resolves after discontinuation of parenteral nutrition and initiation of enteral feedings. Some rare instances of irreversible liver failure have been documented, but this seems to occur only after several months of use.

The etiology of parenteral nutrition–associated liver disease (PNALD) cholestasis is unknown and most likely multifactorial. The patients at greatest risk are critically ill premature infants who are susceptible to multiple insults, such as hypoxia, hemodynamic instability, and sepsis. The most frequently identified risk factors in parenteral nutrition–associated cholestasis are duration of parenteral nutrition, degree of immaturity, and delayed enteral feeding (Steinbach et al, 2008). There is also evidence that being small for gestational age is also an independent risk factor for PNALD (Robinson and Ehrenkranz, 2008). The incidence of cholestasis in premature infants less than 30 weeks' gestation has recently been estimated at 11% (Steinbach et al, 2008).

There is expanding evidence that even small-volume enteral feedings can reduce the incidence of cholestasis. Early studies of parenteral nutrition suggested a possible relationship between the quantity of amino acids and hepatic dysfunction. More recent studies, using historical controls, suggest that the newer amino acid solutions may result in less cholestasis (Heird et al, 1987). The specific role of the quantity and composition of parenteral amino acids in the cause of cholestatic jaundice in premature infants remains unclear. Some investigators have

TABLE 67-5 Recommended Parenteral Intake of Vitamins for Term and Preterm Infants

Vitamin	Term (daily dose)		Preterm (dose/kg/day)*	
	Recommended	MVI-Pediatric (1 vial: 5 mL)	Recommended	MVI-Pediatric (40% of vial: 2 mL/kg/day)

*Maximum not to exceed dosage for term infant. *Note*: American Society for Clinical Nutrition (ASCN) recommendations (1988) currently are not achievable because no ideal intravenous vitamin preparation is available for preterm infants; 40% of a vial (2 mL/kg/day) of MVI-Pediatric (Armor, USA; Rorer, Canada) is the closest intake that can be achieved.
†This does not include the 0.5 to 1 mg of vitamin K to be given at birth, as recommended by the American Academy of Pediatrics.

hypothesized that fish-oil lipid emulsions prevent steatosis, potentially through improved triglyceride clearance and antiinflammatory properties (Alwayn et al, 2005).

There have been several reports in infants of improvement in PNALD with the fish oil–based product Omegaven (Diamond et al, 2009; Gura et al, 2008; Puder et al, 2009). Puder et al (2009) performed an open label trial of Omegaven in 42 infants with short bowel syndrome with PNALD, and compared them with a similar cohort of short bowel syndrome infants who received only soy-based intravenous lipids. The group receiving Omegaven had lower rates of mortality and liver transplantation, and a higher rate of cholestasis reversal. However, this therapy is currently only available in the United States through research or compassionate use protocols. Data from randomized clinical trials are needed before recommending change in clinical practice to include Omegaven for the treatment of PNALD.

Some infants with cholestasis will require continued parenteral nutrition. In these infants, the use of small-volume enteral feeding in combination with parenteral nutrition may stabilize or improve hepatic function. The use of phenobarbital and ursodeoxycholic acid has been shown to be beneficial in some studies of older children and adults. However, a recent study in preterm infants demonstrated that tauroursodeoxycholic acid did not prevent the development of parenteral nutrition-associated cholestasis and was ineffective in reducing cholestasis once it occurred (Heubi et al, 2002). At present, the routine use of ursodeoxycholic acid or phenobarbital in parenteral nutrition-associated cholestasis cannot be recommended.

Catheter-related complications remain an important problem with parenteral nutrition; the major complication is infection. Two of the most common bacterial pathogens are *Staphylococcus epidermidis* and *Staphylococcus aureus*. Fungal infections also occur, *Candida albicans* and *Malassezia furfur* being the most common agents. The incidence of sepsis during parenteral nutrition is higher at the lower gestational ages and also increases with the duration of parenteral nutrition. Parenteral nutrition–associated sepsis is likely to be a product of many factors, not the least of which is that the most immature and critically ill patients are most likely to receive parenteral nutrition for prolonged periods. In infants who have developed cholestasis while receiving parenteral nutrition, the rate of sepsis may be increased. The infusate itself also may play a role in the development of sepsis; an association has been reported between the use of intravenous lipid and coagulase-negative staphylococcal bacteremia and *M. furfur* fungemia (Freeman et al, 1990; Redline et al, 1985). At present, avoiding parenteral nutrition–associated infections is best accomplished by meticulous attention to sterile technique in catheter care and early initiation and advancement of enteral nutrition. Prophylactic low-dose vancomycin may diminish the incidence of parenteral nutrition-associated sepsis, but in view of concerns about toxicities and the potential for antibiotic resistance, this approach cannot be recommended (Craft et al, 2002).

Complications specifically related to the catheter also have been reported. Broviac catheters are difficult to place and are associated with thrombosis in neonates (Sadiq et al, 1987). In most NICUs, Broviac catheters have largely been replaced by small-bore Silastic catheters placed percutaneously. However, all central catheters, including the small-bore variety, have produced life-threatening complications. Pericardial tamponade and significant pleural

effusions are known complications of the use of central catheters in neonates (Aiken et al, 1992; Giacoia 1991). Although these are uncommon events, clinical awareness and early recognition of these complications can prevent mortality.

USE OF PARENTERAL NUTRITION IN THE NEONATAL INTENSIVE CARE UNIT: A PRACTICAL APPROACH

The preceding portion of this chapter has presented the scientific basis for recommendations regarding provision of parenteral nutrition to neonates. The following paragraphs present a practical approach to the administration of parenteral nutrition, with a particular emphasis on ELBW infants.

Every clinician caring for ELBW infants must recognize the urgent need to initiate intravenous amino acids shortly after birth. As mentioned previously, the ELBW infant loses 1.5% of total body protein each day that amino acids are withheld. Consequently, the goal of early parenteral nutrition should be to limit catabolism and preserve endogenous protein stores. Numerous studies have clearly demonstrated both the safety and efficacy of early amino acids in accomplishing this goal, even at low caloric intakes.

We recommend starting 3.0 g/kg/day of amino acids on the 1st day of life. This can be accomplished simply by adding one of the crystalline amino acid solutions designed for use in neonates (Aminosyn-PF, Primene, Premasol, or TrophAmine) to glucose to use as the initial maintenance fluid in ELBW infants. We recommend developing a neonatal amino acid stock solution, made in advance in the pharmacy. The solution contains amino acids in a 7.5% dextrose that, when delivered at 60 mL/kg/day, provides 3 g/kg/day of amino acids. Additional fluids with or without electrolytes and/or a higher concentration of dextrose are "Y'd in," with adjustments as needed for the individual infant's fluid, dextrose, and electrolyte requirements, eliminating the need to discard the bag of parenteral nutrition fluid for such changes in status. It is important to note that this stock solution should not be increased beyond 60 mL/kg/day; any alterations to total fluids must be made with ancillary fluids This mixture of glucose and amino acids can be given via a peripheral intravenous line, umbilical venous line, or percutaneous central venous catheter. Increased use of percutaneously placed central venous catheters has certainly facilitated early and widespread use of parenteral nutrition in premature infants. In our nursery, strong consideration is given to percutaneous central venous line placement in ELBW infants early in their postnatal course.

To meet growth requirements, 3.5 to 4.0 g/kg/day of amino acids is required. It is important to point out that such amounts are merely estimates, and protein requirements to sustain optimal growth in ELBW infants might be even higher. Once administration of amino acids is initiated, intake can be advanced to meet requirements for growth over a relatively short period. We typically advance amino acid intake 3.5 g/kg/day by the 2nd day of life. Given the available data, we also recommend the addition of cysteine to the amino acid solution (40 mg/g of amino acids, to a maximum of 120 mg). However, we delay adding cysteine until other electrolytes are included in the parenteral nutrition solution so that acetate can be added to buffer the cysteine acid load.

TABLE 67-6 Caloric Value of Parenteral Nutrition Solutions

Composition*	kcal/kg/day	% of Nonprotein Calories
Example 1: Total Fluids at 110 mL/kg/day		
10% dextrose	37	55
3 g/kg/day lipid	30	45
3.5 g/kg/day amino acids	14	—
Total	81	—
Example 2: Total Fluids at 80 mL/kg/day		
12.5% dextrose	34	53
3 g/kg/day lipid	30	47
3.5 g/kg/day amino acids	14	—
Total	78	—
Example 3: Total Fluids at 140 mL/kg/day		
12.5% dextrose	60	67
3 g/kg/day lipid	30	33
3.5 g/kg/day amino acids	14	—
Total	104	—

*Dextrose: 3.4 kcal/g; protein: 4 kcal/g; lipid (20% emulsion): 10 kcal/g.

Glucose should be supplied in a quantity sufficient to maintain normal plasma glucose concentrations. As discussed previously, glucose production and utilization rates are highest in the most premature infants; their glucose needs are in the range of 6 to 8 mg/kg/minute, whereas the term infant's needs are approximately 3 to 4 mg/kg/minute. Giving 10% dextrose at 100 mL/kg/day provides a glucose infusion rate of 7 mg/kg/minute. Starting infants with birthweights less than 1000 g on 5% dextrose is likely to be prudent if their total fluid requirements are greater than 120 to 150 mL/kg/day.

Lipids should be started within the first 24 hours of life, usually at 1.0 g/kg/day. We typically start lipids at 1.0 g/kg/day and advance by 0.5 to 1.0 g/kg/day to a usual maximum of 3 g/kg/day while monitoring and maintaining serum triglycerides at less than 200 mg/dL. Given the numerous advantages over 10% solutions, 20% lipid emulsions should always be used. To facilitate clearance and to avoid impairment of oxygenation, lipids should be infused over a 24-hour period. There is currently no evidence to support the use of cyclic infusion in the acute setting of the NICU.

Caloric goals during parenteral nutrition are lower than with enteral feeds. To achieve optimal protein retention, approximately 70 to 80 kcal/kg/day is a reasonable goal. To optimize growth, somewhat higher caloric intakes may be necessary. The nonprotein balance between carbohydrate and lipid should be approximately 60:40. These goals can usually be achieved using glucose solutions with concentrations no greater than 12.5% (Table 67-6).

There is a paucity of data related to monitoring laboratory tests during provision of parenteral nutrition. Suggested monitoring for infants receiving parenteral

TABLE 67-7 Suggested Monitoring During Parenteral Nutrition

Parameter	Frequency
Weight	Daily
Length and OFC	Weekly
Serum glucose	1×/shift during week 1, then daily
Serum Na, K, Cl, BUN, Ca, P, Mg, hematocrit	2–3×/week during week 1, then weekly
Alkaline phosphatase, ALT (SGPT), GGT, fractionated bilirubin	Weekly

ALT, Alanine aminotransferase; *BUN*, blood urea nitrogen; *GGT*, gamma-glutamyl transferase; *OFC*, occipitofrontal circumference; *SGPT*, serum glutamate-pyruvate aminotransferase.

nutrition is shown in Table 67-7. All of these laboratory tests may not be appropriate in ELBW infants because of constraints related to blood sampling.

The use of parenteral nutrition should be accompanied by the early initiation of enteral feeds (within the first 1 to 3 days of life). Parenteral nutrition should be continued until enteral feedings are well established and providing approximately 100 to 110 kcal/kg/day, although availability of intravenous access may necessitate earlier termination of parenteral nutrition in some circumstances. As enteral feeds are advanced, the protein and lipid contents of the parenteral nutrition can be gradually decreased. In addition, careful and prompt attention to reinstitution of parenteral nutrition during episodes of intolerance of enteral feeds cannot be overemphasized. Infants with intolerance of enteral feeds in whom nothing-by-mouth (NPO) status is frequently necessary present an additional challenge. In such infants, it may be prudent to determine full-volume parenteral nutrition needs as for NPO status and to then run the parenteral nutrition solution at a lower rate if enteral feeds are administered. With this approach, if a change to NPO status becomes necessary after administration of the parenteral nutrition fluid has begun, the volume can be safely increased without compromising caloric and protein intake.

PART XIV

Gastrointestinal System

CHAPTER 68

Developmental Anatomy and Physiology of the Gastrointestinal Tract

Reed A. Dimmitt and Eric Sibley

STRUCTURAL AND FUNCTIONAL DEVELOPMENT

Understanding the development of the human gastrointestinal tract, from both an anatomic and cellular basis, has a long history, dating back more than a century. This knowledge encompasses prenatal in utero and postnatal processes. Changes in both morphogenesis and cellular differentiation drive structural formation of the gastrointestinal tract in the developing embryo. Digestive function continues to develop following birth. Advances in molecular biology have revealed that specific aspects of gastrointestinal tract development involve genetically controlled interaction between trophic compounds and cellular receptors, as described later for the different organs of the gastrointestinal tract.

From a global perspective, the gastrointestinal tract results from embryonic invagination and folding during week 4 of gestation. Eventually, the buccopharyngeal and cloacal membranes rupture, permitting a direct communication between the fetal gastrointestinal tract and the in utero environment. A series of folding, lengthening, and luminal dilation events result in the formation of the foregut (esophagus, stomach, duodenum, liver, and pancreas); the midgut (jejunum, ileum, ascending colon, and transverse colon); and hindgut (descending colon, sigmoid colon, and rectum). With additional elongation and growth during the first trimester, the developing gut migrates into the umbilical cord. It returns to the fetal abdominal cavity and rotates counterclockwise around the axis of the superior mesenteric artery around 20 weeks' gestation (Figure 68-1). Thus, by the second trimester, basic morphogenesis of the fetal gastrointestinal tract is complete. Additional in utero and postnatal functional maturation is still necessary. For example, gastrointestinal motility is markedly disorganized at 24 weeks' gestation. Although dysmotility is a normal developmental "milestone" in the fetal environment, uncoordinated peristalsis in the extremely low-birthweight infant is associated with significant postnatal problems.

Knowledge of the cellular and molecular processes of early morphogenesis is rapidly expanding and involves crosstalk between maternal and fetal factors during development. We first discuss the embryology of the gastrointestinal tract in advance of discussing functional development including digestion.

FOREGUT

ESOPHAGUS

The normal morphogenesis of foregut can be subdivided into five successive developmental stages (Kluth et al, 2003). In the first stage, occurring at days 22–23, the primitive foregut differentiates into ventral and dorsal structures, termed the lung field and esophageal area, respectively. The esophageal area has one cell layer consisting of 10 somites. In the second stage, the lung bud develops from the caudal lung field proximal to the liver. Next, in the third stage, longitudinal ridges appear inside the lumen of the developing foregut, which results in a distinct and separate dorsal esophageal area. The fourth stage involves proliferation of the longitudinal ridges, resulting in a tracheoesophageal septum. Subsequently, apoptosis in the central section of the septum begins the initial separation of the dorsal and ventral compartments. In the fifth stage, there is the formation of definitive respiratory and esophageal structures between weeks 6 and 7 of gestation.

Researchers utilizing *Drosophila* and murine models have identified a myriad of key signaling pathways in foregut development. For example, the hedgehog signaling pathway appears to be essential for maintaining stem cell niches as well as directing developmental axes (Figure 68-2) (Lees et al, 2005). Hedgehog binds to a cell membrane receptor Patched (Ptc) resulting in downstream signaling and transcription factor mediated cell differentiation. Defects in this pathway are associated with congenital anomalies of the foregut.

STOMACH

By week 6 of gestation, the fetal stomach is well defined. The muscular layers (the inner circular and outer longitudinal) become visible by 9 weeks. By week 12 of gestation, the gastric mucosa has differentiated into the various types of epithelium: the zymogen, endocrine, mucous, and parietal cells. By 16 weeks, all of these cells are secreting their respective cellular products.

Several trophic factors have been shown to be involved in gastric epithelial differentiation. Crosstalk between transforming growth factor-β1 and basement membrane

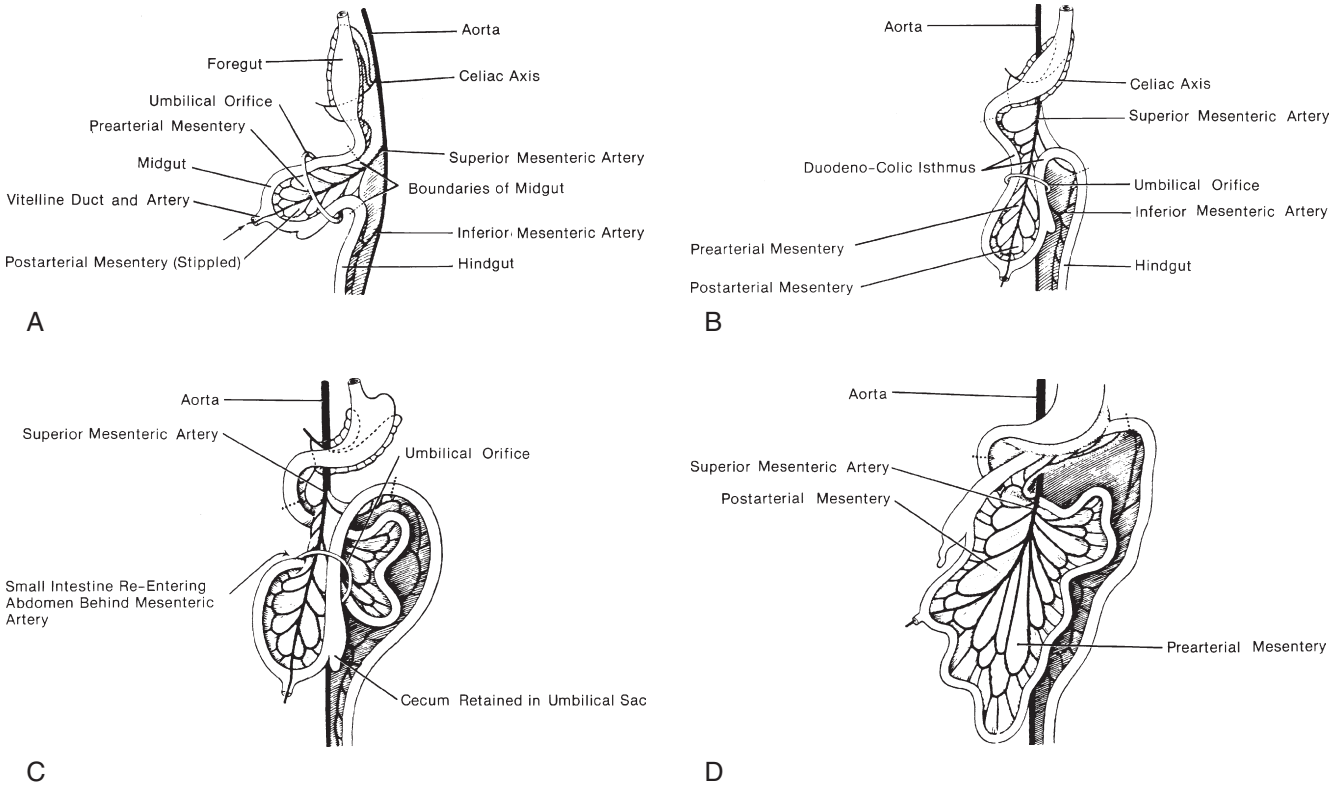

FIGURE 68-1 Diagrams showing normal rotation of alimentary tract. A, Fifth week of intrauterine life *(lateral view)*. The foregut, midgut, and hindgut are shown with their individual blood supply supported by the common dorsal mesentery in the sagittal plane. The midgut loop has been extruded into the umbilical cord. **B,** Eighth week of intrauterine life *(anteroposterior view)*. The first stage of rotation is being completed. Note the narrow duodenocolic isthmus from which the midgut loop depends and the right-sided position of the small intestine and left-sided position of the colon. Maintenance of this position within the abdomen after birth is termed *nonrotation*. **C,** About the 10th week of intrauterine life, during the second stage of rotation *(anteroposterior view)*. The bowel in the temporary umbilical hernia is in the process of reduction; the most proximal part of the prearterial segment entering the abdomen to the right of the superior mesenteric artery is held forward close to the cecum and ascending colon, permitting the bowel to pass under it. As the coils of small intestine collect within the abdomen, the hindgut is displaced to the left and upward. **D,** Eleventh week of intrauterine life at the end of the second stage of rotation. From its original sagittal position, the midgut has rotated 270 degrees in a counterclockwise direction about the origin of the superior mesenteric artery. The essentials of the permanent disposition of the viscera have been attained. *(**A** to **D**, From Gardner CE Jr, Hart D: Anomalies of intestinal rotation as a cause of intestinal obstruction*, Arch Surg *29:942-946, 1934. Copyright 1934, American Medical Association.)*

proteins called laminins are important mediators of gastric epithelial polarity (Basque et al, 2002). Fibroblast growth factors 10 and 2, proteins in the hedgehog pathway, are strong determinants of gastric epithelial differentiation, in particular with parietal cell differentiation (Spencer-Dene et al, 2006).

LIVER AND PANCREAS

The liver and pancreas develop from two different anatomical domains of the definitive endodermal epithelium of the embryonic foregut. Fate-mapping experiments demonstrate that the liver arises from precursor cells in the developing ventral foregut as well as from a small group of endodermal cells tracking down the ventral midline. During foregut closure, the medial and lateral domains come together. The pancreas is also induced in lateral endoderm domains, adjacent and caudal to the lateral liver domains, and in cells near the dorsal midline of the foregut (Zaret and Grompe, 2008).

After the initial differentiation, several transcription factors shape the developing liver precursor cells into hepatocytes and bile duct cells. In an even more complex process, the pancreatic cells are induced to become specific endocrine, acinar, or ductal cells (Figure 68-3).

From an organogenesis aspect, rotation and fusion of the dorsal and ventral pancreatic buds occur by 7 weeks' gestation. By 14 weeks, immunoreactive insulin can be detected and pancreatic zymogen granules are present in the acinar cells. By 16 weeks, amylase is present. Trypsin, lipase, and amylase are secreted into the duodenum by 31 weeks (Zoppi et al, 1972). As mentioned earlier, the liver is derived as an outbudding from the foregut. The cranial portion of the bud differentiates into hepatic parenchyma, and the caudal portion into the gallbladder. Specific hepatic lobules and bile canaliculi can be detected by 6 weeks. Bile acids are present in the liver by 12 weeks and are actively secreted into the small intestine by 22 weeks' gestation.

MIDGUT AND HINDGUT

Although portions of the small intestine are derived from the foregut and midgut and portions of the colon are derived from the midgut and hindgut, we discuss these portions of the gastrointestinal tract from an end-organ perspective.

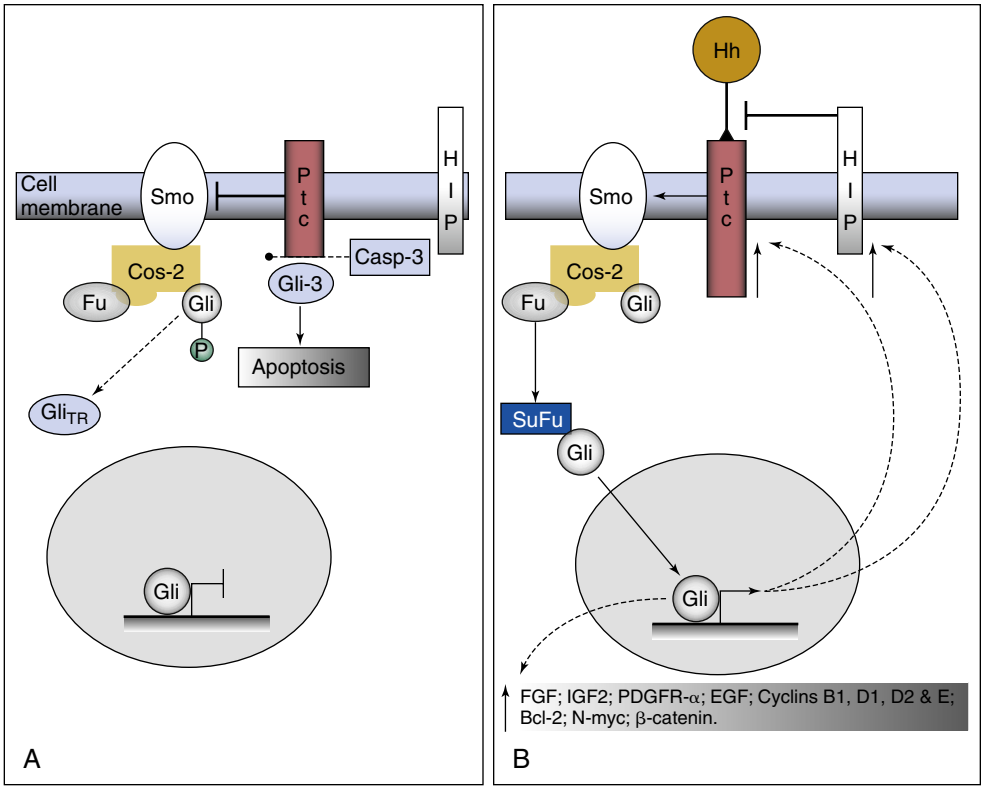

FIGURE 68-2 Hedgehog (Hh) signaling in mammalian cells. In the absence of Hh **(A)**, the receptor Patched *(Ptc)* exerts an inhibitory effect on Smoothened *(Smo)*, a transmembrane protein with homology to G-protein-coupled receptors. In the presence of Hh ligand-binding **(B)**, the inhibitory action of Ptc on Smo is released. The full Gli product is now stabilized and transferred to the nucleus. Once in the nucleus, the full Gli product binds to and upregulates transcriptional targets, including Ptc and another Hh-binding protein, *HIP*. In this manner, excess Hh is sequestered and the pathway regulated.

SMALL INTESTINE

The ultimate digestive function of the small intestine requires intestinal epithelium to secrete digestive enzymes and to provide sufficient surface area to absorb nutrients. Therefore, it is important to understand the development of the cellular differentiation as well as overall intestinal length.

As previously mentioned, the hedgehog signaling pathway is also important in endodermal and mesodermal differentiation in small intestinal development. In addition, the genes encoding for the transcription factors *Sox9*, *Sox17*, and *SRY* have been shown to be essential in endoderm differentiation, whereas the *Hox* family of transcription factors are involved in mesodermal differentiation (de Santa Barbara et al, 2003).

After differentiation, the intestinal villous and crypt development is under the control of several growth factors that are secreted in autocrine, paracrine, endocrine, and exocrine pathways (Ménard, 2004). Glucagon-like peptide 1 and 2 are secreted by intestinal neurons and L cells, respectively, and are associated with increased intestinal length (Sigalet et al, 2004). Clinical trials in adults are underway administering glucagon-like peptide 2 in patients with short bowel syndrome and may eventually show promise in pediatric patients with intestinal failure.

The small intestine is well developed after its extracorporeal migration into the umbilical cord. Rapid epithelial proliferation occludes the small-intestinal lumen early in development, but the lumen becomes patent at 12 weeks' gestation. There is a gradual development of digestive function that is not fully complete until 34 weeks' gestation, thus posing additional problems regarding administering enteral nutrition to premature infants.

COLON

The hindgut is formed by an early dilatation of the fetal cecum at 4 weeks' gestation. By 12 weeks, this primitive structure takes on the gross anatomic features of the colon. At this same time, the midgut rotation is completed, resulting in the cecum being located in the right lower abdominal space. The hallmark of colonic function is coordinated motility, especially in the development of the rectum. The rectum forms by 8 weeks, and formation of complete muscle layers and neural migration of neural crest cells are accomplished by 24 weeks. By 22 weeks, the premature colon maintains some aspects of the small intestine, including villi and disaccharidase function. With developmental maturation, the colonic crypt structures dominate the mucosal surface, and the intestinal characteristics diminish (Raul et al, 1986).

From a cellular developmental aspect, several trophic factors have been linked to colonic differentiation. Elf-3, a member of the Ets transcription factor family, controls intestinal epithelial differentiation during development by regulating the expression of growth factor receptors in

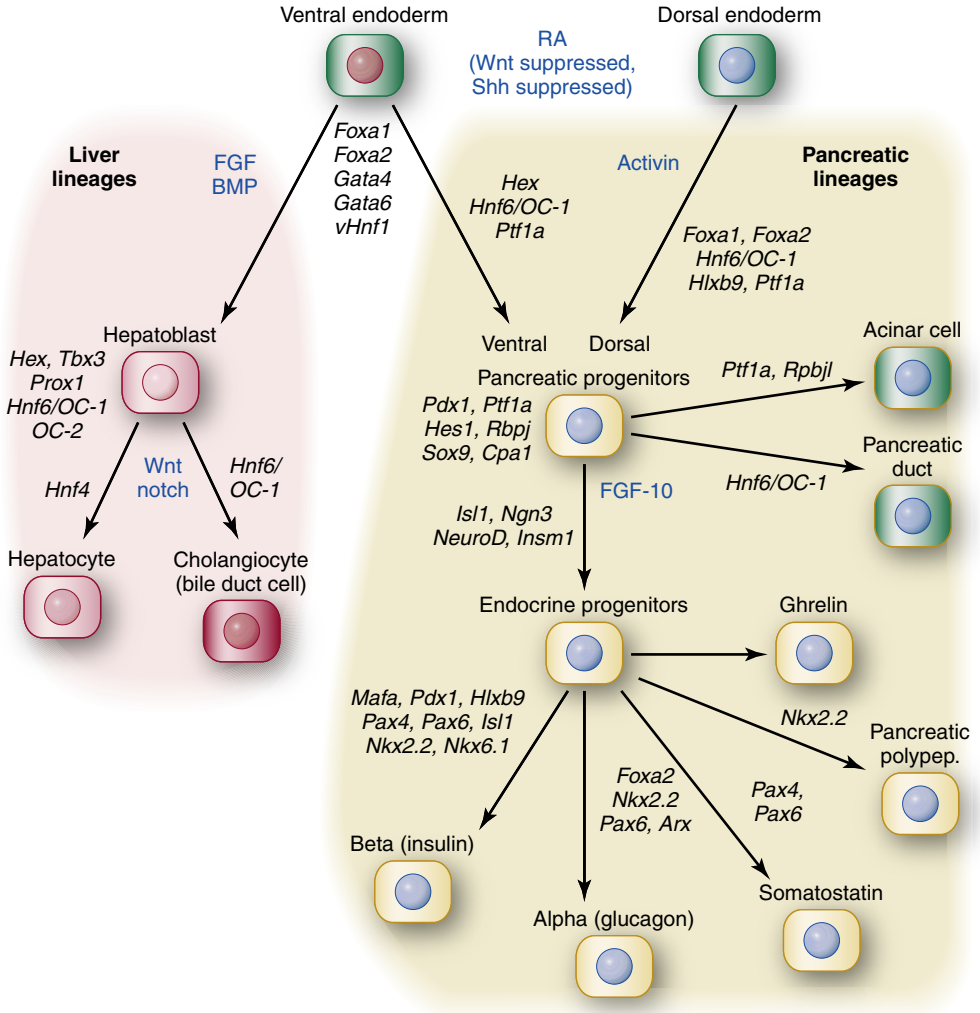

FIGURE 68-3 Regulatory factors controlling cell type lineages within the liver and pancreas. Transcription factor genes involved in differentiation are noted in italics. *(From Zaret KS, Grompe M: Generation and regeneration of cells of the liver and pancreas,* Science *322:1490-1494, 2008.)*

epithelial cells (Jedlicka and Gutierrez-Hartmann, 2008). Recently identified molecules termed micro-RNAs have been shown to regulate cell differentiation and maintenance of the pluripotent stem cells (Monzo et al, 2008).

The developing enteric nervous system is derived in a large part from the vagal neural crest cells with additional contribution from migration of the precursor cells from the sacral region. Molecules that have been shown to control the migration of ganglion cells include the RET/GFRa1/GDNF and endothelin receptor-B/endothelin-3 signaling pathways, transcription factors such as Phox2b, Sox10, Pax3, Mash1, Hox11L1 and Sip1, the hedgehog signaling system, neurotrophins, and bone morphogenetic proteins (Burns and Thapar, 2006). Defects in these molecules may be related to congenital colonic disease, including Hirschsprung's disease.

MUCOSAL IMMUNE SYSTEM DEVELOPMENT

The gastrointestinal tract is the largest immune organ in the body and thus warrants review of its development. As with other aspects of gastrointestinal tract development, the mucosal immune system undergoes both fetal and postnatal changes. The dramatic changes following exposure to food and bacterially derived molecules after birth have been shown to be a major determinant in ongoing mucosal immune modification.

Mucosal immunity is composed of innate and adaptive arms. The innate immune system includes a chemical/noncellular component (e.g., gastric acid, intestinal mucous layer, epithelial barrier function, and defensins), as well as a cellular compartment (e.g., neutrophils, macrophages, and antigen-presenting cells). The adaptive immune system is made up of T cell lymphocytes and B cell–mediated humoral immunity.

Although primarily considered to be involved in digestion, gastric acid, bile salts, and pancreatic secretions function to inhibit potential pathogenic bacterial growth. Clinical investigators have demonstrated that delaying feedings in premature infants results in decreased gastric acid secretion, possibly the mechanism whereby trophic feedings prevent necrotizing enterocolitis (NEC) (Berseth et al, 2005; Hyman et al, 1983). In addition, administering histamine H_2 blockers to premature infants is associated with increased sepsis (Beck-Sague et al, 1994) and NEC (Guillet et al, 2006).

Mucins, glycoproteins, immunoglobulins, glycolipids, trefoil factors, and albumin are all constituents of the luminal mucus layer. Previously, it was believed that mucus functions in a nonspecific manner to prevent bacterial adhesion and expel potential pathogens. It is now clear that certain components of the mucus layer are involved in mucosal healing. Specifically, the trefoil factor family has proangiogenic and antiapoptotic qualities, as well as modulating cell-to-cell contacts and potentiating epidermal growth factor (Hoffmann, 2005).

The epithelial barrier function is accomplished by intracellular proteins that anchor the cells to each other, preventing large molecules from penetrating. Recently, it has been shown that these proteins are not just "spot welds" but are dynamic in nature and respond to physiologic and pathologic stimuli (Graham et al, 2009). In addition, dendritic cells, a type of antigen-presenting cells, can sample the microbiota of the intestinal lumen by sending "periscopes" through the tight junctions, suggesting an epithelial-immune cell interaction.

Defensins are antimicrobial proteins secreted by specialized intestinal epithelium called Paneth cells. It appears that defensins are uniformly expressed in the gastrointestinal tract at 14 weeks' gestation but are restricted to the small intestine by 17 weeks. The number of Paneth cells and expression of defensins in 24-week infants is significantly lower than in term infants and may be associated with increased sepsis and NEC in premature infants (Mallow et al, 1996).

The cellular components of innate immunity include macrophages and granulocytes. Macrophages are present in the fetal intestine as early as week 11 of gestation. A recent study has demonstrated that chemerin is a potent recruiter of intestinal macrophages with peak level production at 20–24 weeks (Maheshwari et al, 2009).

Previously, the cells of the innate immune system were believed to act in a nonspecific manner in response to pathogenic stimuli. It is now clear that specific bacterial components signal through membrane-associated receptors termed toll-like receptors (TLRs). For example, lipopolysaccharide from gram-negative bacteria is the ligand for TLR-4, which results in a downstream inflammatory response. TLRs are expressed by both immune cells and gastrointestinal epithelial cells. TLR4 is expressed on fetal enterocytes as early as 18 weeks' gestation (Fusunyan et al, 2001) and may be induced following birth with the acquisition of the intestinal microbiota.

The adaptive immune system of host defense is composed of T cells and humoral immunity. Lymphocytes have been shown to proliferate in response to mitogenic stimuli at 12 weeks' gestation. Peyer's patches are lymphoid tissue that process lumen antigens. M cells are differentiated intestinal epithelia that function to process antigens to lymphocytes and other cells in Peyer's patches and can be observed at 17 weeks' gestation. Peyer's patches are essential for the production of plasma cells that secrete mucosal associated immunoglobulins.

Once naive T cells interact with antigen, they develop into specific phenotypes based on their cytokine production. Currently, T cell subsets include T-helper cell 1 (Th1), Th2, Th17 (producing IL-17), and regulator T cells (Weaver et al, 2006). In the sterile in utero environment, T cells are predominantly Th2, promoting a symbiosis between fetus and mother. On presentation with antigen, there is a switch to the more mature cells. The gestational age at which this T cell commitment can occur is unknown and is a fertile area for future research.

GASTROINTESTINAL MICROBIOTA

The newborn infant is born with a sterile gut that acquires its microbiota in the postnatal period. On the basis of some classic culture-based studies performed in the 1970s and 1980s, the term infant microbiota was determined. The composition of the infant microbiota is less complex and features a higher proportion of facultative bacteria than in the adult. The facultative bacteria are the first to colonize secondary to the oxygen content of the intestine, which prevents the growth of obligate anaerobic bacteria. Thus, after the acquisition and expansion of facultative *Escherichia coli* and *Enterococcus* spp., the intestinal oxygen is consumed, thereby allowing for subsequent colonization by anaerobic *Bifidobacterium*, *Bacteroides*, and *Clostridium* spp. (Adlerberth, 2008).

DIGESTIVE PHYSIOLOGY

The human gastrointestinal tract functions to digest and absorb nutrients consumed in food. Nutrient digestion consists of breaking down carbohydrates, proteins, and fats to smaller component molecules (monosaccharides, oligopeptides and amino acids, and free fatty acids and monoglycerides) that can be transported into absorptive intestinal epithelial cells and then into the portal circulation. Human digestive function matures throughout embryogenesis as the gastrointestinal organs develop and acquire different digestive capacities.

CARBOHYDRATE DIGESTION

Carbohydrates supply approximately 40% of ingested calories in term infants. Dietary carbohydrates consist of sugars and starches. Lactose is the predominant sugar in human breast milk and most milk-based infant formulas. Before absorption of its constituent glucose and galactose monosaccharides, the lactose disaccharide must be hydrolyzed by the enzymatic action of the intestinal lactase enzyme. Lactase is a membrane-bound protein present on the apical surface of enterocytes, the intestinal absorptive cells. During early fetal life, lactase gene is expressed in the colon and small intestine. By term, however, a spatial gradient of lactase gene expression is established, with peak expression in the proximal intestine (Raul et al, 1986). Lactase activity increases during fetal maturation, with the greatest increase, about fourfold, occurring during the third trimester (Weaver et al, 1986). In the absence of sufficient lactase hydrolysis, undigested lactose can result in an osmotic diarrhea. Although preterm infants have relatively low levels of lactase activity, they are often able to sustain normal growth with little diarrhea when fed breast milk or lactose-containing formula (MacLean and Fink, 1980). Some formulas also contain complex carbohydrates in the form of glucose polymers. Glucose polymers require amylase for hydrolysis. The process of complex

carbohydrate digestion is initiated in the lumen of the gastrointestinal tract by the action of alpha-amylases secreted by the salivary gland and the pancreas. Because pancreatic amylase levels are low in neonates, salivary amylase supports a significant amount of glucose polymer digestion along with the mucosal glucoamylase enzyme (Hodge et al, 1983). Glucoamylase is a membrane-bound hydrolase synthesized by the enterocyte that removes single glucose residues from alpha (1–4) chains of glucose polymers. Glucoamylase activity is detectable as early as 13 weeks' gestation and increases two- to threefold in the near-term newborn (Ménard, 1994).

The monosaccharide products of luminal and membrane-bound hydrolysis of carbohydrates are transported across both the apical and basolateral enterocyte membranes and into the portal circulation. Active glucose and galactose transport into enterocytes is carried out predominantly by the apical sodium-glucose cotransport protein, SGLT1. Glucose and galactose are transported out of the enterocyte by the basolateral GLUT2 transport protein. Congenital defects of the SGLT1 protein result in rare cases of glucose-galactose malabsorption characterized by severe, watery, acidic diarrhea in the newborn period (Martín et al, 1996). Treatment consists of a glucose- and galactose-free diet, initially given as a fructose-based formula.

PROTEIN DIGESTION

Proteins contribute less than 10% of ingested calories in infants. Many of the amino acids used for protein synthesis are produced within the body. Essential amino acids, however, must be provided through dietary protein. Similar to digestion of complex carbohydrates, protein digestion involves both luminal and mucosal enzymatic hydrolysis. Proteins are initially digested within the intestinal lumen by proteases secreted by the stomach (pepsin) and pancreas (trypsin, chymotrypsin, carboxypeptidase, elastase). The final products of luminal digestion are amino acids and oligopeptides composed of 2- to 6-amino-acid residues. Digestion of oligopeptides greater than two residues is performed by mucosal membrane-bound brush-border peptidases. Bi- and tripeptides can be transported through the enterocyte membrane via the proton-coupled PEPT1 transporter and may be further hydrolyzed by cytosolic peptidases that exist within the cell or transported out of the cell and into the portal system as peptides (Liang et al, 1995). Amino acids are transported into enterocytes by a great variety of amino acid transporters. The activities of most of the brush-border and cytosolic peptidases are well developed in the preterm infant. There is evidence, however, that some milk proteins may be absorbed intact into the circulation (Kuitunen et al, 1994).

FAT DIGESTION

Fat provides 40 to 50% of the caloric intake of the newborn. Similar to carbohydrate and protein digestion, fat processing is initiated in the lumen before mucosal absorption. By means of enzymatic action, lingual, gastric, and pancreatic lipases function to hydrolyze fat to its constituent free fatty acids and monoglycerides. Pancreatic lipases are in relatively low concentration at birth. Lingual lipases and gastric lipases, however, are present by 26 weeks' gestation and thus contribute significantly to neonatal fat digestion (Hamosh et al, 1981). In addition, a bile salt–dependent lipase present in human milk is capable of hydrolyzing fats (Freed et al, 1987). Bile salts secreted by the liver and gallbladder are necessary for efficient absorption of fats and function to emulsify fat in the intestinal lumen. Bile flow to the intestine increases rapidly after birth and initiation of feeding. After luminal hydrolysis of fat, mixed micelles of fatty acids and monoglycerides diffuse directly across the cell membrane of mucosal intestinal cells.

CHAPTER 69

Structural Anomalies of the Gastrointestinal Tract

Clara Song, Jeffrey S. Upperman, and Victoria Niklas

DISORDERS OF THE MOUTH AND NECK

MOUTH

Small nodules are present on the hard palate and mandibular and maxillary ridges in 80% of newborns. Nodules on the hard palate are called *Epstein's pearls*, whereas those on the mandibular and maxillary alveolar ridges are called *Bohn's nodules*. Both types of nodules are generally 1–3 mm in size and are thought to be remnants of salivary gland tissue. Most nodules usually disappear spontaneously within the first 3 months of life.

Cysts filled with mucus within the floor of the mouth are called *ranulas*. Clinically, ranulas are classified into two types, simple ranulas or superficial ranulas or plunging or cervical ranulas. Simple ranulas are usually pea-sized, disappear spontaneously, and are generally of no consequence. Plunging ranulas generally involve the submandibular and submental space of the neck, and although some of these cysts resolve, a large or persistent ranula may lead to feeding difficulties, thereby requiring surgical excision or marsupialization (Patel et al, 2009; Zhi et al, 2008).

Malignant tumors of the mouth are rare in the newborn. An *epignathus* is any tumor that arises from the upper jaw or palate and projects from the mouth. These tumors may be polyps, dermoids, adenomas, or teratomas, or rarely a granulosa cell tumor called *epulis* (Kumar and Sharma, 2008). In addition to a careful physical examination, these tumors should be evaluated with computed tomography (CT) or magnetic resonance imaging (MRI) so as to fully define the extent of the tumor and to determine whether it impinges on the nasopharynx, airway, or esophagus. Tumors that impinge on the nasopharynx, airway, or esophagus or those with in infants with clinical signs and symptoms such as respiratory distress or feeding difficulties will need definitive treatment by surgical removal.

Tumors of the salivary gland (with the parotid gland being most commonly affected) may arise anywhere in the gland. Although they are typically confined to the intracapsular portion of the gland, sentinel lesions on the surface of the gland may be present (Bradley et al, 2007; Mehta and Willging, 2006; Myer and Cotton, 1986). These tumors should be evaluated by Doppler ultrasound and then further evaluated with CT or MRI (Lowe et al, 2001). Histologic diagnosis may be confirmed by open biopsy or excision. Hemangioma-endothelioma and mixed tumors are the most common noninflammatory tumors. Hemangiomas often give a bluish hue to overlying skin and may transiently increase in size with crying because of blood-filling by the cavernous tissue component of the tumor. Juxtaparotid lymphangiomas are rare, but they tend to be multiloculated and composed of cystic spaces of varying sizes that may increase in size because of an upper respiratory tract infection. Local resection is generally the treatment of choice (Har-El et al, 1985; Thompson, 2002).

Infection of the parotid gland (suppurative parotitis) or salivary gland (sialadenitis) should be considered in cases in which these glands rapidly enlarge and display signs of inflammation during the 1st month of life. Primary sialadenitis, however, is extremely rare, and most cases of sialadenitis in the submaxillary gland result as extensions from the parotid gland. The diagnosis may be confirmed by applying gentle pressure on the gland and expressing pus from the Stensen duct. *Staphylococcus aureus* or *Escherichia coli* is commonly isolated, but broad-spectrum antimicrobial coverage should be started until the organism has been identified and sensitivities have been established, because sepsis and extension to include the salivary glands are not uncommon.

TONGUE

Congenital disorders of the tongue include agenesis, true hypertrophy, enlargement due to lymphangiomas, aberrant thyroid tissue and abnormalities of fixation. Abnormalities of the tongue may also be associated with breathing or feeding difficulties. Aglossia congenita, or congenital absence of the tongue, is extremely rare, but affected infants retain taste sensation and can learn to speak. Ankyloglossia inferior ("tongue-tie") is also common in newborns (Hall and Renfrew, 2005). The short frenulum, however, does not usually interfere with sucking and swallowing, and the frenulum usually lengthens with age.

Ankyloglossia superior, attachment of the tongue to the roof of the mouth, is a rare anomaly that must be recognized at birth because respiratory obstruction may occur (Bolling et al, 2007). Other lesions, such as micrognathia, macroglossia, and cleft palate, are frequently associated with this anomaly.

Neonates with true macroglossia, or enlargement of the tongue, often have continuous protrusion of the tongue and associated difficulties with feeding as well as noisy respirations and possible respiratory failure. These infants often have Down or Beckwith-Wiedemann syndrome. Lymphangioma and idiopathic muscular hypertrophy are additional common causes of macroglossia. A tongue with lymphangioma appears as a raised, firm mass with a warty-looking surface. The treatment for lymphangioma is surgical removal, if possible, or reduction of the tumor bulk with reshaping of the tongue. Infants with idiopathic muscular hypertrophy should be treated conservatively, because the relative size of the tongue often decreases as the mandible grows during infancy.

Thyroid tissue may be present as a solid or cystic mass in the posterior midline of the tongue or under it. If

FIGURE 69-1 *(See also Color Plate 28.)* **Cystic hygroma of the face and neck.** Prenatal diagnosis of this large lesion led to the delivery of this infant using ex utero intrapartum treatment. *(From* Archives of Pediatrics & Adolescent Medicine, *155:1271-1272, 2001, Copyright 2001, American Medical Association. All rights reserved.)*

enlargement of the tongue is due to ectopic thyroid tissue, no other thyroid tissue may exist. Normal migration of the thyroid gland did not occur during development. Therefore, before resection of any midline lingual tumor, a thyroid scan should be performed to rule out a lingual thyroid gland.

NASOPHARYNX

Nasopharyngeal tumors are rare and may include polyps, dermoids, or teratomas. Often these tumors are on a stalk and project into the mouth. Those not projecting externally may be palpated as movable, sausage-shaped masses in the pharynx. These tumors should be excised urgently because they often cause respiratory distress from upper airway obstruction. Intubation under direct laryngoscopy may be warranted.

NECK

Cystic hygroma is the most common lateral neck mass in the newborn (Figure 69-1). Cystic hygromas are derived from lymphatic tissue and are present as multilobular, multicystic masses that may rapidly enlarge and cause severe respiratory compromise. Dynamic MRI or CT imaging is useful in identifying the extent and intrathoracic course of these masses. Excision is the treatment of choice, although sclerotherapy has been used for very large or recurrent tumors (Samuel et al, 2000). Infants diagnosed prenatally with giant lymphangiomas (or other giant tumors of the neck) benefit from controlled cesarean section delivery using an ex-utero intrapartum treatment (EXIT) procedure. In these cases, intubation through a tracheotomy after partial dissection of the mass away from the trachea is life-saving (Mychaliska et al, 1997).

Branchial cleft anomalies may manifest as skin tags, pits, sinuses, fistulas, or cysts in the preauricular and lateral cervical regions. Most lesions are remnants of the second branchial cleft and pouch, and 10% to 15% occur bilaterally (Bill and Vadheim, 1955). Sinuses and fistulas may be discovered during the newborn period, but cysts often require time to fill and usually are not recognized until later in childhood. Ultrasound or CT scan of the neck may be useful to define anatomic relationships, and surgical removal is the treatment of choice.

The so-called sternomastoid tumor, also called the "pseudotumor" of infancy, can be seen and palpated as a smooth oval mass within the body of the sternocleidomastoid muscle. The cause is unknown, but the incidence is seven times higher after breech delivery (Ling and Low, 1972) and among infants who have had specific fetal positioning in utero (Rosegger and Steinwendner, 1992). Histopathology suggests that it results from endomysial fibrosis characterized by deposition of collagen and fibroblasts around individual muscle fibers that subsequently undergo atrophy. Torticollis may develop in up to 20% of cases, and in those cases, hip dysplasia may be present (Porter et al, 1995). Even if torticollis is not present, the head may still be rotated to the side opposite to that of the tumor. If cranial and facial asymmetry result in severe hemihypoplasia, cosmetic surgical correction may be indicated if the hemihypoplasia does not resolve within 6 to 12 months (Wirth et al, 1992).

Midline neck masses in newborns include cystic hygromas, hemangiomas, dermoid cysts, teratomas, enlarged thyroid tumors or goiters, and ectopic thyroid or thymic tissue. Goiters visible at birth may be associated with maternal hypothyroidism, hyperthyroidism, or euthyroidism. The second most common location for ectopic thyroid tissue, after the base of the tongue, is the anterior midline of the neck, just at or below the hyoid bone (Meyerowitz and Buchholz, 1969). Although this tissue may be easily mistaken for a thyroglossal duct cyst, such cysts rarely are present in the newborn. Therefore, before removal of ectopic thyroid tissue, a thyroid scan should be performed to determine if the ectopic thyroid is the infant's only functioning thyroid tissue. Thymic tissue arises high in the cervical region of the embryo as two lateral buds. The buds migrate caudad and join in the anterior mediastinum. Abnormal migration results in ectopic location or cyst formation (or both); the aberrant tissue or cyst may manifest as a lateral or midline neck mass and require surgical removal (Thompson and Love, 1972).

DISORDERS OF THE ESOPHAGUS

ESOPHAGEAL ATRESIA WITH TRACHEOESOPHAGEAL FISTULA

Definition

Esophageal atresia (EA) and tracheoesophageal fistula (TEF) may occur as separate congenital defects, but more frequently they are seen together as a compound defect. Esophageal atresia with a distal tracheoesophageal fistula is by far the most common form, accounting for 85% of cases (Figure 69-2) (Raffensperger, 1990).

Epidemiology

The incidence of EA with TEF ranges from 1 in 3000 to 1 in 4000 live births (Raffensperger, 1990). Most series show a slight male predominance and an increased incidence

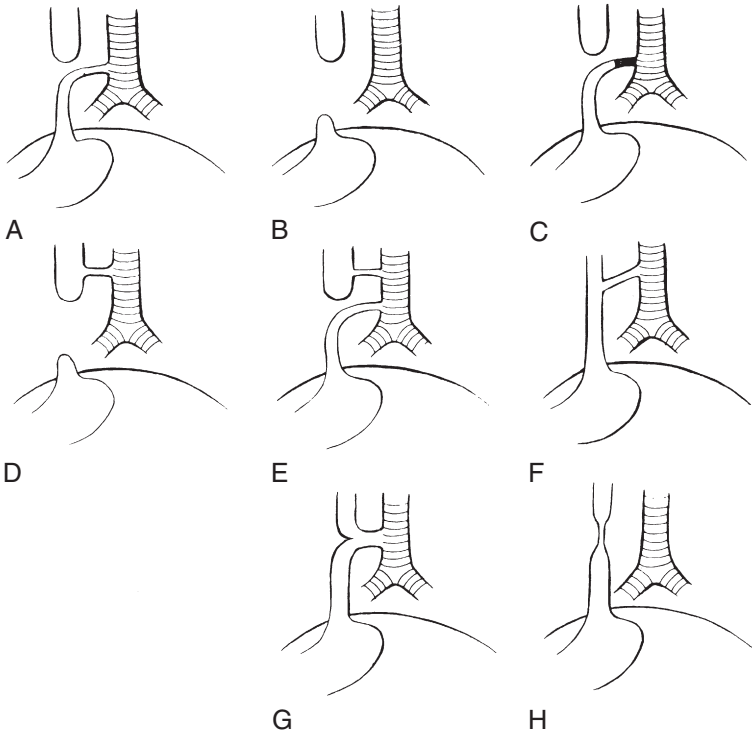

FIGURE 69-2 Types of tracheoesophageal fistulas. A is overwhelmingly the most common, accounting for 85% of esophageal malformations. **B** is next most common and can be distinguished from **A** by the absence of air in the intestinal tract on radiographs. All of the other types have been noted sporadically. *(From Avery ME, et al:* The lung and its disorders in the newborn infant, *ed 4, Philadelphia, 1981, WB Saunders.)*

in premature infants (Reckham, 1981). The role of genetic factors is unclear, although this anomaly has been described in siblings as well as in identical twins (Hausmann et al, 1957; Woolley et al, 1961). In addition, two kindreds with autosomal dominant transmission have been reported (Pletcher et al, 1991).

Etiology

The anomaly occurs before the 8th week of gestation, although the exact mechanism is unknown. It is thought to result from abnormal division or compression at the time the foregut divides into a ventral and a dorsal tube, giving rise to the trachea and esophagus. When this process of division is abnormal or when there is compression of these primitive tubes by an extrinsic structure such as an anomalous blood vessel, EA or TEF, or both, may result.

Diagnosis

Polyhydramnios is present in approximately one third of pregnancies with EA because the fetus is unable to swallow amniotic fluid. Within hours after birth, infants with EA accumulate large amounts of oral secretions, which may precipitate coughing or choking, with consequent respiratory distress. Infants vomit when they are fed, and in cases with a distal tracheoesophageal connection, abdominal distention may ensue as the intestine fills with air. The presence of a flat or gasless abdomen should suggest an isolated EA without a distal TEF (see Figure 69-2). Some patients with a gasless abdomen, however, may have a TEF that is partially obliterated but that will still require surgical ligation (Goh et al, 1991). The most dramatic presentation of TEF occurs when the fistula is proximal to the EA. Affected infants develop life-threatening respiratory failure from aspiration almost immediately after birth. Infants with the so-called H-type TEF (see Figure 69-2) usually do not develop symptoms in the newborn period. Instead, these infants frequently present with a history (over months to years) of mild respiratory distress related to feeding or recurrent pneumonia.

If a diagnosis of EA is suspected, a soft 5 or 8 French feeding tube can be passed into the esophagus until it meets resistance. On occasion, the tube will coil in a blind pouch, creating the false impression that the esophagus is patent. In such cases a plain x-ray film confirms coiling of the feeding tube, frequently in an air-filled upper esophageal pouch (Figure 69-3). The presence of gas in the abdomen suggests that a distal TEF is present.

Treatment

Preoperative care of the infant with EA includes the insertion of a sump suction catheter into the proximal esophageal pouch for the continuous evacuation of secretions. The preoperative pulmonary complications associated with EA/TEF occur because of aspiration of oral contents or reflux of gastric contents into the airway. Placing a tube with continuous suction into the proximal esophageal pouch can minimize the aspiration of saliva. The infant also should be maintained in an upright position to decrease reflux of gastric secretions through the fistula and into lungs. In addition, minimizing positive-pressure ventilation can minimize gastric distention and reflux of

FIGURE 69-3 Anteroposterior view of the chest of a female infant with esophageal atresia and tracheoesophageal fistula. A large upper pouch is outlined by air and by a curled nasogastric tube. Air is seen within the abdomen, indicating a tracheoesophageal fistula.

FIGURE 69-4 Perineum of male newborn with an imperforate anus.

gastric contents. Treatment with systemic antacids can also reduce reflux of acidic gastric contents into lung or distal esophageal pouch. Hydration is maintained by intravenous fluids, and surgical repair is undertaken as soon as the infant's general condition permits.

If progressive gastric distention occurs, a decompressive gastrostomy can be performed. An associated duodenal atresia should also be considered in severe cases of gastric distention necessitating emergent placement of a gastrostomy tube (Holder, 1993). If the fistula is large, there may be significant loss of tidal volume if the infant requires positive pressure ventilation. This volume loss can usually be controlled by connecting the gastrostomy to a chest tube system under water seal (Fann et al, 1988). In extreme cases in which the infant may not tolerate a thoracotomy and definitive procedure, a Fogarty catheter can be passed with a bronchoscope to occlude the fistula (Filston et al, 1982).

Preoperative evaluation in infants with EA/TEF should include an evaluation for other major anomalies, as they occur in 50% to 70% of these patients (Harmon and Coran, 1999; Holder, 1993; Rejjal, 1999). The VACTERL association consists of *vertebral anomalies*, *anal agenesis* (imperforate anus) (Figure 69-4), *cardiac defects* (most commonly patent ductus arteriosus, atrial septal defect, and ventricular septal defect), *tracheo esophageal fistula*, *renal anomalies*, and *limb anomalies* (most often radial anomalies) and is present in 25% to 30% of children with EA/TEF (Corsello et al, 1993; Harmon and Coran, 1999; Manning et al, 1986; Quan and Smith, 1973). Infants with EA/TEF within the VACTERL association tend to have higher proximal pouches, more complications, and a higher mortality than those in infants with isolated EA/TEF (Greenwood and Rosenthal, 1976; Holder, 1993; Touloukian and Keller, 1988; Weber et al, 1980). In particular, the presence of cardiac defects has a significant impact on mortality rates in EA/TEF (Spitz, 1993). Gastrointestinal anomalies occur in 15% of patients, with anal atresia being the most common, although duodenal atresia may also occur (Harmon and Coran, 1999; Holder, 1993).

Operative strategy in EA/TEF is based on the anatomy and whether other anomalies are present. In general, the infant who lacks other anomalies and has a reasonably stable pulmonary status should undergo primary repair of the atresia and ligation of the fistula soon after birth. To accomplish this, an extrapleural or transpleural approach is used, the fistula is divided, and an anastomosis between the proximal and distal esophageal segments is achieved using an end-to-end anastomosis. In infants with extreme pulmonary compromise or significant associated anomalies, an initial gastrostomy for decompression with later repair of the EA/TEF may be indicated. Infants with the lowest probability of survival are likely to benefit from a staged approach (Alexander et al, 1993; Spitz et al, 1987).

Postoperative care consists of respiratory support, antibiotics, and intravenous nutritional support. Enteral feedings via a gastrostomy or a transpyloric tube may be started on the 3rd or 4th postoperative day. These feedings initially are given by continuous infusion because the stomach is often small. Bolus feedings are usually introduced once full enteral feeds are established, with oral feedings 7 to 10 days postoperatively after confirmation by a radiographic contrast study that there are no esophageal anastomotic leaks. Some investigators have questioned whether contrast studies are necessary for infants who remain free of clinical symptoms related to postoperative complications (Yancher et al, 2001).

Complications after repair of EA/TEF include esophageal anastomotic leak, esophageal stricture, gastroesophageal reflux, recurrent fistula, and tracheal obstruction. The incidence of anastomotic leak is 10% to 15% (Harmon and Coran, 1999). The diagnosis may be made by noting the presence of saliva in the chest tube, but it is confirmed by a contrast swallow study. Management is expectant because most of these leaks close spontaneously. A minor esophageal stricture is almost universal after repair of an EA/TEF. Significant strictures occur in 5% to 10% of infants (Harmon and Coran, 1999). The diagnosis is confirmed by barium swallow examination. Treatment of esophageal strictures is with serial esophageal dilatation, either with Jackson dilators or by balloon dilatation (Benjamin et al, 1993; Shah and Berman, 1993). Esophageal strictures are

also one of the most common late complications of EA repair and manifest with abnormal esophageal motility and dysphagia. Esophageal strictures at the anastomotic site should be suspected if feeding difficulty develops, particularly after the 3rd week. Repeated balloon dilation may be necessary to relieve the stricture, although residual esophageal dysmotility may persist for a lifetime. Gastroesophageal reflux occurs in 40% to 70% of these children because of an abnormal angle and incompetence of the lower esophageal sphincter in addition to abnormal motility in the body of the esophagus across the anastomosis (Holder, 1993; Jolley et al, 1980; Pieretii et al, 1974; Whitington et al, 1977). Medical therapy with antacids and intestinal motility agents may be successful initially, but many patients require antireflux surgery. Clinically significant tracheal obstruction may occur in as many as 25% of children with EA/TEF as a consequence of tracheomalacia (Corbally et al, 1993; Harmon and Coran, 1999). The onset of respiratory symptoms with or immediately after feeding usually occurs in the months after repair of EA/TEF but may be in the immediate postoperative period (Holder, 1993). The diagnosis of tracheal obstruction due to tracheomalacia is made by bronchoscopy (Holder, 1993). In the child without significant distress, most symptoms subside over the first year or two of life (Holder, 1993). The surgical treatment of severe tracheomalacia is aortopexy, or suspension of the aorta (and therefore the anterior trachea) to the posterior surface of the sternum (Corbally et al, 1993; Holder, 1993). The incidence of recurrent fistula is probably less than 10% (Harmon and Coran, 1999). Recurrence of TEF usually occurs in the immediate postoperative period, but the diagnosis may not be made for months or years. The manifestations of a recurrent fistula are similar to aspiration with gastroesophageal reflux: coughing with feeds and recurrent pulmonary infections. Small fistulas may close spontaneously, but if a fistula persists for longer than 4 weeks, surgical closure is indicated (Harmon and Coran, 1999). Most surgeons prefer to wait 3 to 6 months after the initial EA/TEF repair, if possible, allowing inflammation and edema to decrease (Holder, 1993).

Prognosis

The overall survival rate in term infants without respiratory complications preoperatively approaches 95% (Holder and Ashcraft, 1970). Among premature infants or those with moderate to severe respiratory disease, survival is 85%. Infants with multiple anomalies or those with severe respiratory disease have a 75% survival rate. Infants with a birthweight less than 1500 g and a major cardiac anomaly have a significantly lower survival rate of 50% (Spitz et al, 1987).

TRACHEOESOPHAGEAL FISTULA WITHOUT ESOPHAGEAL ATRESIA

Only 5% of TEFs occur in the absence of EA. Symptoms include coughing and cyanosis with feeding and recurrent episodes of pneumonia. If the diagnosis of TEF is suspected, oral feedings should be withheld, and a specialized contrast esophagram using a catheter gradually withdrawn through the esophagus should be performed in an attempt to demonstrate the fistula. If this is unsuccessful, simultaneous endoscopic examinations of the trachea and esophagus may be done with instillation of small amounts of methylene blue into the trachea while simultaneously evaluating for its appearance in the esophagus. Most of these fistulas are located superior to the second thoracic vertebra and can be repaired through a right cervical neck incision.

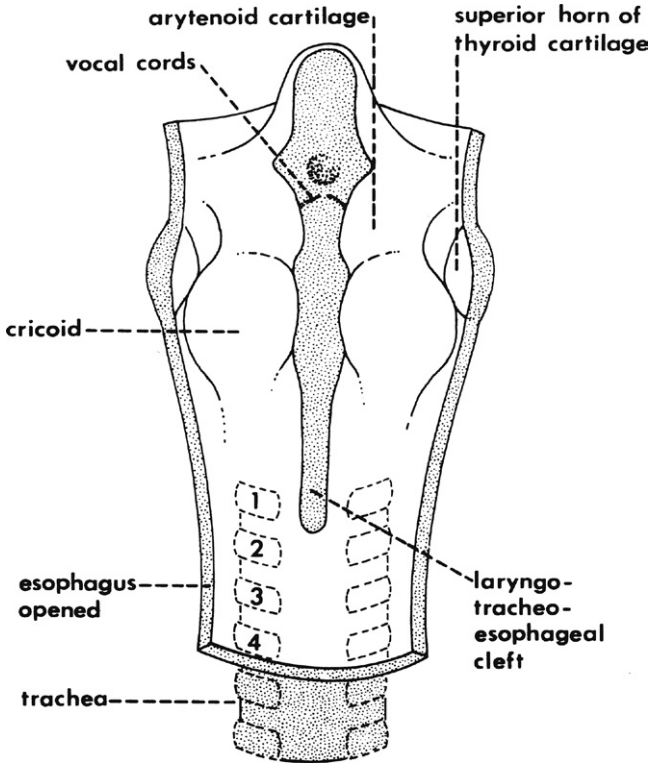

FIGURE 69-5 Illustration of the anatomy of a laryngotracheoesophageal cleft. *(From Burroughs N, Leape LL: Laryngotracheoesophageal cleft: report of a case successfully treated and review of the literature*, Pediatrics *53:517, 1974. Reproduced by permission of* Pediatrics.*)*

LARYNGOTRACHEOESOPHAGEAL CLEFT

Laryngotracheoesophageal cleft is a communication of the larynx and trachea with the esophagus. The defect varies in length, with the shortest being the length of the arytenoid cartilages and the longest extending the entire length of the trachea (Figure 69-5). These clefts form between the 5th and 7th weeks of gestation when there is a failure of the rostral advance and fusion of lateral ridges of the laryngotracheal groove. One fifth of the clefts are associated with EA and TEF. Clinical presentation occurs early in the newborn period and is similar to that for EA/TEF, except that stridor also may be present. A carefully done esophageal dye study should establish the diagnosis. Tracheal spillover, however, may be misinterpreted to be due to the presence of a high H-type fistula or the presence of incoordination of the swallowing mechanism. Patients with clefts should undergo bronchoscopic evaluation with immediate surgical repair. A temporary tracheostomy is often placed because breakdown of the closure is common.

CONGENITAL ESOPHAGEAL STENOSIS

Congenital esophageal stenosis is a very rare anomaly caused by inborn malformation of the esophageal wall musculature (Nihoul-Fekete et al, 1987). It may take the form of a membranous web or diaphragm or a fibromuscular thickening or may be secondary to tracheobronchial remnants in the wall of the esophagus. The last-named is the most common form and typically occurs in the distal esophagus. This condition may also be associated with EA (Ibrahim et al, 2007). Many infants are asymptomatic until solid foods are introduced into the diet. In the neonatal period, the condition may manifest with severe regurgitation and respiratory distress. The diagnosis may be difficult to establish, although a contrast esophagram will usually reveal the narrowing. Fibromuscular hypertrophy and occasionally webs can be treated with repeated dilatations; surgical resection is the treatment of choice for all other lesions. An antireflux procedure is added for distal lesions but should be avoided before definitive surgery in the presence of stricture, gastroesophageal reflux or dysmotility (Ibrahim et al, 2007).

ESOPHAGEAL DUPLICATION CYSTS

Esophageal duplications are very rare and represent 10% to 15% of all gastrointestinal duplications. The overall incidence of esophageal duplications is approximately 1 in 8200, with a majority occurring in males (Arbona et al, 1984). The incidence of cystic duplications is even less common. The duplications occur when ventral budding of the lung primordium from the embryonic foregut at 3 to 4 weeks' gestation does not occur normally (Phillapart and Farmer, 1998). This results in the formation of vacuoles and in the obliteration of the esophageal lumen during early development. If vacuoles coalesce during recanalization, duplications are formed. The cysts are usually small and may be located anywhere in the posterior mediastinum or neck. Other associated congenital anomalies include EA, TEF, intestinal duplications, and spinal/vertebral anomalies (Eichmann et al, 2001). Cysts often manifest asymptomatically during childhood, or with digestive or respiratory signs and symptoms even in the neonatal period (Stewart et al, 1993). These signs and symptoms can include stridor, respiratory distress, difficulty swallowing, failure to thrive, or cough due to displacement of mediastinal structures (Eichmann et al, 2001). Associated vertebral anomalies suggest the presence of a neurenteric cyst, which may have a connection to the spinal canal. Diagnosis is confirmed by CT, and treatment involves surgical excision.

RUPTURE OF THE ESOPHAGUS

Esophageal perforation most commonly occurs in premature infants after placement of a nasogastric tube or occur secondary to esophageal intubation with an endotracheal tube (Krasna et al, 1987), although spontaneous rupture of the esophagus has been described. The inability to advance a nasogastric tube, hematemesis, and hydropneumothorax may be presenting manifestations. An esophagram can confirm the diagnosis, and urgent cessation of feeding and surgical repair are indicated; often a later contrast swallow study is indicated.

DISORDERS OF THE STOMACH

GASTRIC DUPLICATION

Gastric duplications are spherical or hollow tubular structures that are contiguous with the stomach wall and are lined by a mucosal layer from gastric, small bowel, or colonic epithelium but contain a smooth muscle coat contiguous with the muscle of the stomach. Most duplications do not communicate with the gastric lumen and are located along the greater curvature of the stomach. Embryologically they arise during the 4th week of gestation, when the embryonic notochordal plates and endoderm normally separate. A band between them may cause a traction diverticulum, leading to cyst formation. In addition, communication between the duplication and the pancreatic duct may lead to pancreatitis (Kaneko et al, 1999). Associated anomalies occur in 50% of these patients, the most common being esophageal duplication and vertebral abnormalities. Patients usually present at less than a year of age with vomiting, poor feeding, and failure to gain weight. Infants may also present with an abdominal mass or gastric outlet obstruction that may be confused with pyloric hypertrophy. The mucosal lining of cysts is often gastric, which can lead to melena or hematemesis from chronic "gastritis" (Holcomb et al, 1989). Treatment is complete surgical excision of the duplication and any accompanying cysts.

CONGENITAL GASTRIC OUTLET OBSTRUCTION

This rare condition may be caused by either a membrane or atresia, located in either the antrum or pylorus. An incomplete web or diaphragm may also be present, causing partial obstruction. Maternal polyhydramnios occurs in half of the cases. The defect may be due to vascular compromise early in gestation, similar to that causing intestinal and colonic atresias. Associated anomalies are frequent, including epidermolysis bullosa (Okoye et al, 2000). The presence of a gasless abdomen on plain film and the failure of contrast material to leave the stomach on an upper gastrointestinal series are suggestive of the diagnosis and warrant urgent operative intervention. Treatment involves excision of the defect with pyloroplasty, but some patients may require a gastroduodenostomy.

PYLORIC STENOSIS

Definition and Epidemiology

Idiopathic hypertrophy of the pyloric muscle in early infancy results in partial gastric outlet obstruction. The incidence is 1 in 1000 to 3 in 1000 live births, and males are affected four times more often than females. First-born infants account for half of the cases. Whites are at greater risk than African American infants. Premature infants are affected with the same frequency as for term infants (Laron and Horne, 1957).

Etiology

The exact cause of pyloric stenosis is unknown. Hereditary factors may play a role because there is a 7% incidence of pyloric stenosis among the siblings of affected patients. Pyloric stenosis has been documented in the literature to have an association with prostaglandin infusion, erythromycin administration, esophageal atresia, cystic fibrosis, Gilbert syndrome, epidermolysis bullosa, and Jacobsen syndrome (Callahan et al, 1999; Czernik and Raine, 1982; Dereure et al, 2001; Honein et al, 1999; Kakishi, 2002; Murthi and Nour, 2004; Schinzel et al, 1977; Trioche et al, 1999).

Diagnosis

Nonbilious emesis is the primary presenting symptom. It may occur from birth to 12 weeks, but most often the onset is between the 3rd and 5th week of postnatal life. In premature infants, the onset follows the same pattern postnatally, regardless of the postconceptional age. At first, vomiting may occur infrequently. With time, the frequency, volume, and projectile nature of emesis become characteristic. Weight loss, dehydration, and a hypokalemic, hypochloremic metabolic alkalosis may occur as a consequence of the vomiting. Gastric peristaltic waves may be seen passing obliquely from the left upper quadrant across the midline when the infant is fed. In most instances of pyloric stenosis, a definite tumor, or "olive," can be palpated in the epigastric area or just to the right of the midline in the right upper quadrant. Jaundice may occasionally occur, but indirect hyperbilirubinemia recedes 5 to 10 days after pyloromyotomy. Ultrasound examination is confirmatory, having replaced the upper gastrointestinal series as the diagnostic modality of choice (Figure 69-6) (Hallam et al, 1995). Infants with other primary surgical conditions may not present with signs and symptoms typical of pyloric stenosis. Emesis or increased residuals in these patients are often falsely attributed to postsurgical ileus, and electrolyte abnormalities are often precluded by postoperative fluid and electrolyte management (Murthi et al, 2004).

Differential diagnosis of pyloric stenosis includes infantile pylorospasm, which is distinguished from pyloric stenosis by ultrasonographic evaluation (Cohen et al, 1998). The cause of pylorospasm is unknown. In infants with both pylorospasm and infantile pyloric stenosis, some data suggest that a lack of nitric oxide synthase in pyloric tissue may be involved (Vanderwinden et al, 1992). Conservative medical management consisting of treatment with antacids, histamine H_2 receptor blockers, and metoclopramide may relieve the spasm. Pylorospasm usually is transient and resolves within 1 to 2 weeks.

Treatment

The stomach should be decompressed with a tube placed and connected to low intermittent suction; dehydration and accompanying metabolic alkalosis should be corrected with intravenous fluids before surgery. Pyloromyotomy involves splitting the hypertrophied pyloric muscle, and may be performed through a periumbilical incision or laparoscopically (Shankar et al, 2000). Feedings may be resumed 6 to 12 hours after surgery and advanced toward a regular schedule.

FIGURE 69-6 Ultrasonographic study of the right upper quadrant in a 1-month-old infant with a 1-week history of vomiting. The length (from + to +) of the pylorus is 18.4 mm (normal up to 16 mm), and wall thickness (H) is 4.5 mm (normal is up to 4.0 mm). The *arrows* outline the muscular wall and point to the lumen *(L)*. *A* is the antral lumen. *(Courtesy of Dr. Ronald M. Cohen, Children's Hospital, Oakland, Calif.)*

Prognosis

Surgery is curative. Complications may include incomplete pyloromyotomy and perforation.

GASTRIC PERFORATION

Spontaneous perforation of the stomach in the newborn occurs most often during the first few days of life (Figure 69-7) (St. Vil et al, 1992). Perinatal stress leading to localized ischemia appears to be the causative mechanism in most cases, although in some, no cause can be identified. Potential causes include rapid overdistention of the stomach, trauma from passage of a nasogastric tube, and spontaneous rupture of weak points in the gastric wall along the greater curvature where muscle is deficient. Rates of mortality are notably higher in preterm infants and infants born with lower birthweight (Lin et al, 2008).

Signs and symptoms typically occur by the 2nd to 5th day and include refusal to feed, vomiting, respiratory distress, decreased activity and abdominal distention. Plain x-ray films of the abdomen show the presence of free air. Immediate decompression, fluid resuscitation, and broad-spectrum antibiotic administration should be followed by immediate surgical exploration and repair . Early recognition and treatment result in a higher survival rate.

DISORDERS OF THE INTESTINE

MECHANICAL OBSTRUCTION

Complete or partial obstruction of the small bowel or colon is not unusual in the newborn. A variety of lesions, intrinsic or extrinsic, may be responsible (Table 69-1).

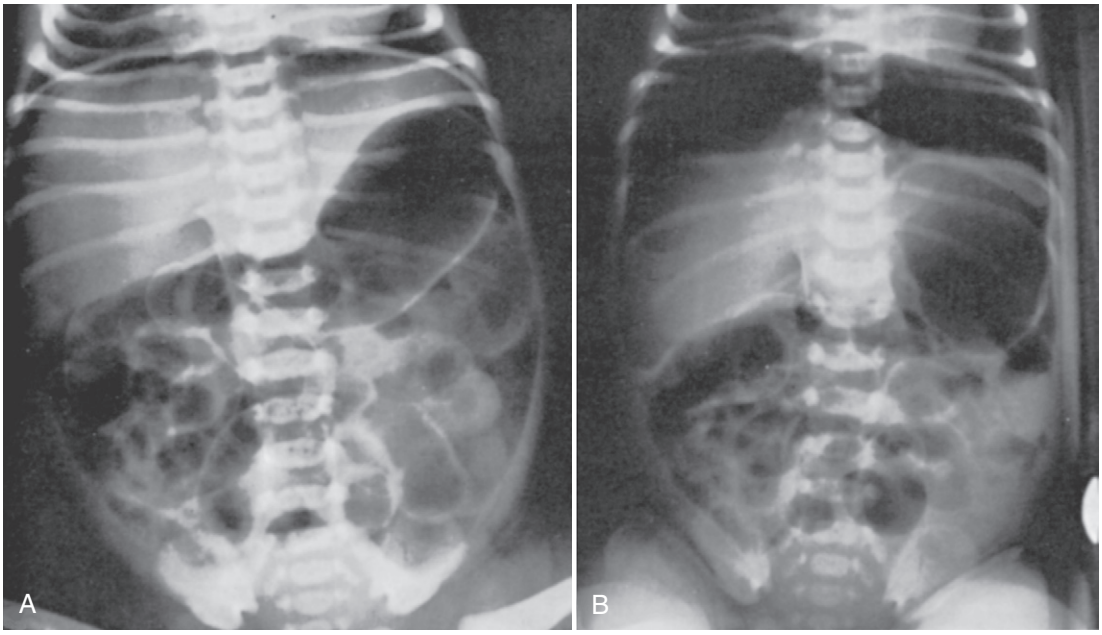

FIGURE 69-7 **A,** Anteroposterior view of abdomen of an infant in erect position at 72 hours of life shows air underneath the diaphragms as well as air within the stomach and small intestine. **B,** Ten hours later, the radiograph reveals progressive accumulation of free peritoneal air under the diaphragm.

TABLE 69-1 Causes of Intestinal Obstruction in the Newborn

Congenital	Acquired	Functional
Atresia	Necrotizing enterocolitis	Hirschsprung's disease
Stenosis	Intussusception	Meconium plug syndrome
Meconium ileus	Peritoneal adhesions	Ileus
Anorectal malformations		Peritonitis
Enteric duplications		
Volvulus		
Peritoneal bands		
Annular pancreas		
Cysts and tumors		
Incarcerated hernias		

Success or failure in terms of morbidity and mortality depends not so much on pinpointing the exact location of the lesion as on correctly diagnosing obstruction as the cause of clinical symptoms and then instituting prompt operative intervention.

Bilious emesis with abdominal distention and the failure to pass meconium are highly suggestive of the presence of intestinal obstruction. If the obstruction is high or complete, symptoms start soon after birth. Bilious emesis suggests that the lesion is located distal to the ampulla of Vater, whereas sporadic vomiting may be seen in patients with partial obstruction caused by malrotation, intestinal duplication, or annular pancreas. Abdominal distention may be present soon after birth, reaching a peak at 24 to 48 hours with visible peristaltic waves. Failure to pass meconium within 24 hours after birth suggests the presence of a lower intestinal or colonic obstruction. Infants with high obstruction, or even those with obstruction as low as the ileum, may still pass meconium, so this finding by itself does not exclude obstruction. Prenatal diagnosis of gastrointestinal obstruction by fetal ultrasound imaging has been successful (Langer et al, 1989) and has become more common.

The initial radiographic studies should be plain x-ray films obtained with the infant in supine and left lateral positions. Normally, air fills the stomach immediately after birth, the small bowel within 12 hours, and the colon within 24 hours. When obstruction exists, the air pattern stops abruptly at that point, leaving the remainder of the bowel airless. Obstruction at the pylorus produces one large bubble outlining the dilated stomach, whereas duodenal obstructions produce a "double-bubble" appearance (Figure 69-8). Distal obstructions show a series of dilated, air- and fluid-filled loops of intestine. Obstruction resulting from meconium ileus is an exception in that air-fluid levels are not usually seen. In an incomplete obstruction, gas may be seen distal to dilated loops of bowel.

If the diagnosis is in doubt or a meconium plug is suspected, a contrast enema can be done. The finding of a microcolon is consistent with smalle-intestinal atresia or meconium plug with ileus. An upper gastrointestinal series is done only if the plain film and enema are nondiagnostic.

ATRESIAS

Definition and Etiology

Atresia, complete obstruction of the lumen of bowel, should be distinguished from *stenosis*, which is a narrowing of the lumen. Atresias account for one third of all intestinal obstructions in the newborn, occurring in 1 of every 1500 live births. Sites of occurrence, in order of frequency, are jejunoileal, duodenal, and colonic. Failure of the gut to recanalize during the 8th to 10th weeks of gestation seems to be the most likely cause for duodenal atresia. In the jejunum, ileum, and colon, intrauterine vascular compromise may be responsible for bowel atresias (Louw,

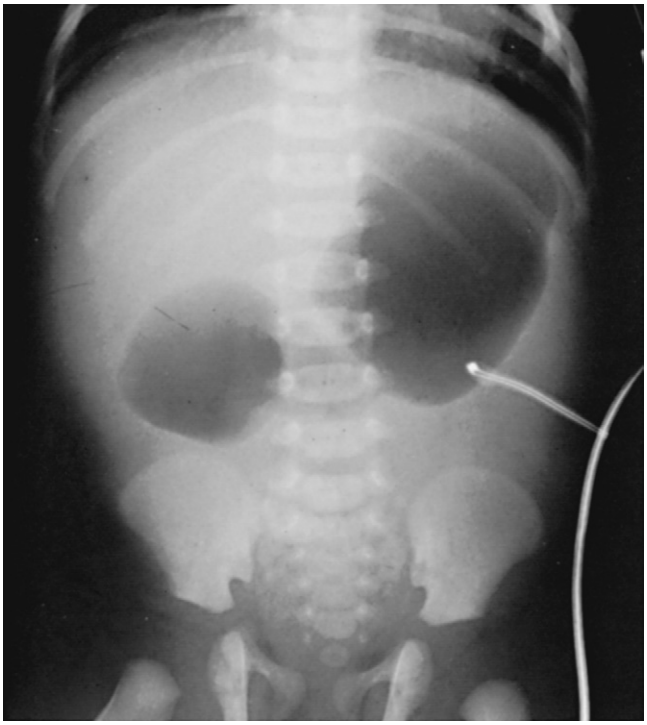

FIGURE 69-8 Abdominal film from a 12-hour-old infant with vomiting. A "double-bubble" sign is present. At laparotomy, duodenal atresia was found. *(Courtesy of Dr. Ronald M. Cohen, Children's Hospital, Oakland, Calif.)*

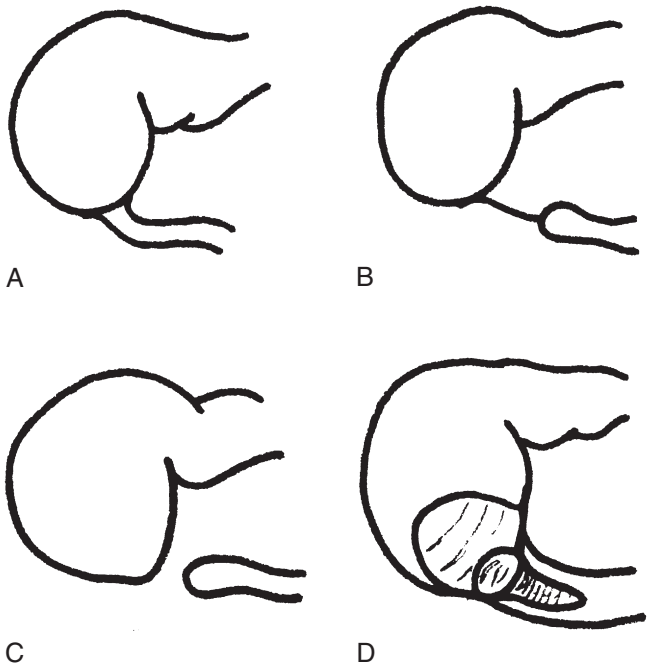

FIGURE 69-9 Forms of intrinsic duodenal obstruction. A, Duodenal atresia with continuity of the bowel wall. **B,** Duodenal atresia with a fibrous cord joining segments. **C,** Complete atresia with two separate segments. **D,** Windsock deformity.

1966). Other potential causes in utero include incarceration of the physiologic umbilical hernia, localized volvulus, intussusception, focal peritonitis, and peritoneal band formation. Mortality is low, regardless of location of atresia, but increases if there are associated congenital anomalies and in low-birthweight infants (less than 2 kg) (Piper et al, 2008).

Duodenal Atresia

Thirty percent of all atresias occur in the duodenum, and most are distal to the ampulla of Vater. Incidence of duodenal atresia ranges from 1 in 5000 to 1 in 10,000 live births, with males slightly more affected than females (Choudhry et al, 2009; Kimura and Loening-Baucke, 2000). Many infants with duodenal atresia have a history of polyhydramnios and are born before term (Dalla Vecchia et al, 1998). Other associated anomalies include Down syndrome, cardiovascular malformations, malrotation, EA, TEF, small-bowel lesions, anorectal lesions, renal anomalies, and VACTERL association (Choudhry et al, 2009; Dalla Vecchia et al, 1998). Congenital duodenal obstruction can be due to an atretic lesion or duodenal web, duodenal stenosis, and annular pancreas, which can also be found incidentally and may not be the actual cause of obstruction. Anatomically, duodenal atresia may occur in several forms (Figure 69-9). Prenatal diagnosis by fetal ultrasound is becoming increasingly frequent (Stoll et al, 1996).

Bilious emesis on the first day of life and a history of polyhydramnios are common presenting features. Abdominal distention is usually absent. Dehydration with metabolic alkalosis rapidly ensues. The diagnosis may be made on plain abdominal radiographs with the appearance of the "double-bubble" sign (see Figure 69-8). Overall survival rate is high, with reported mortality rates of 5% or less. Mortality rate increases if congenital anomalies, especially cardiac lesions, are present (Choudhry et al, 2009; Escobar et al, 2004). Long-term follow-up is important because late complications, such as gastroesophageal reflux disease, delayed gastric emptying, peptic ulcer disorders, megaduodenum, and intestinal obstructions due to adhesions, may occur into adulthood (Escobar et al, 2004).

Medical therapy consists of the passage of a nasogastric tube and correction of dehydration and electrolyte abnormalities. Prompt surgical intervention is necessary, although with a clear diagnosis, surgery may be delayed in very low-birthweight infants. Because of the high incidence of multiple atresias (15%), inspection of the entire bowel is carried out before bypassing the obstruction with a duodenoduodenostomy (Weber et al, 1986). An excessively distended proximal duodenum may need to be tapered as well, in an effort to reduce the duodenal dysmotility that often delays the start of normal feeds. The outcome for these infants generally is good but depends on their associated anomalies.

Jejunoileal Atresia

Fifty percent of intestinal atresias occur in the jejunum or ileum. Incidence of jejunoileal atresia is reported between 1 in 330 and 1 in 1500 live births (Sai Prasad and Bajpai, 2000). Premature birth is not uncommon (Stollman et al, 2009). Associated extraintestinal anomalies are infrequent but can include cardiac, renal, skeletal, and central nervous

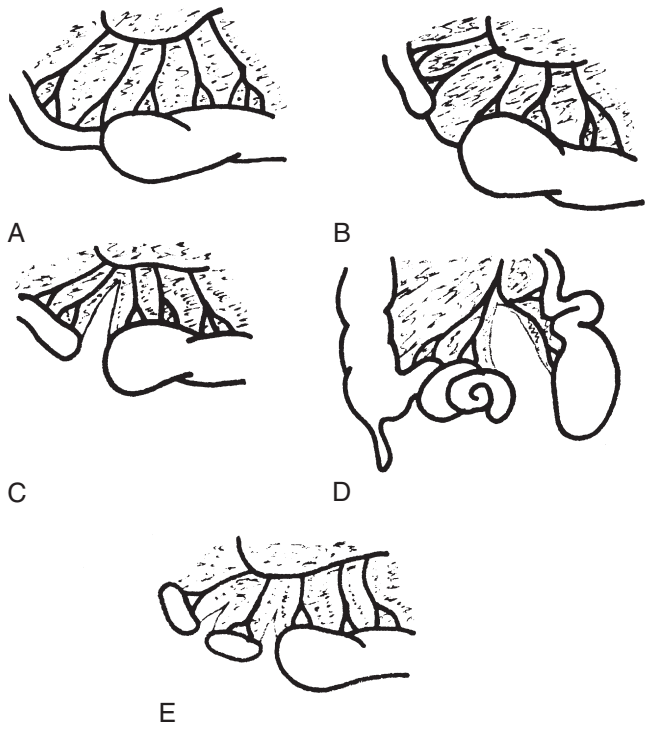

FIGURE 69-10 Classification of intestinal atresias. A, Mucosal atresia with intact bowel wall and mesentery. **B,** Blind ends joined by a fibrous cord. **C,** Blind ends separated by a mesenteric defect. **D,** Blind ends with the "apple peel" atresia. **E,** Multiple atresias.

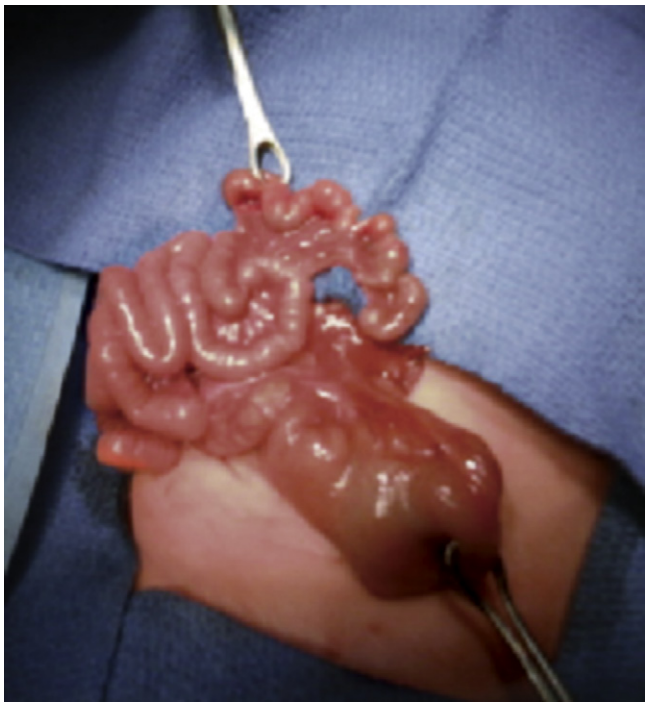

FIGURE 69-11 Multiple intestinal atresias are visualized at laparotomy. Dilated loops of the bowel are seen proximal to the obstruction.

system abnormalities (occurring in 7% of cases) (Dalla Vecchia et al, 1998). Anomalies of the gastrointestinal tract can occur in up to 24% of infants and can include gastroschisis, omphalocele, malrotation, Meckel's diverticulum, biliary atresia, situs inversus abdominalis, ectopic pancreas, and abnormal gallbladder. Numerous studies have also reported an association with cystic fibrosis (CF) (Stollman et al, 2009). Jejunoileal atresias are thought to result from a late intrauterine mesenteric vascular accident. Jejunoileal atresias are equally distributed between the jejunum and ileum and are multiple in 10% to 20% of cases (Grosfeld et al, 1979). A useful classification is shown in Figure 69-10 (Grosfeld et al, 1979). Intestinal length may be significantly decreased in type IIIb atresias ("apple peel" or "Christmas tree" deformity) and in type IV multiple atresias ("string of sausages" appearance). Prenatal ultrasound diagnosis is possible but is less accurate than in duodenal atresia (Figure 69-11).

Signs and symptoms of small bowel atresia include maternal polyhydramnios, bilious vomiting, abdominal distention (which may not become obvious until the 2nd or 3rd day of life), failure to pass meconium, and jaundice. Passage of meconium does not exclude atresia, because 20% to 40% of newborns with the condition will pass some meconium. Plain abdominal radiographs show varying amounts of dilated, thumb-sized loops of bowel ("rule of thumb"), air-fluid levels, and absence of rectal gas (Figure 69-12). Peritoneal calcification signifies the presence of meconium peritonitis, the result of a prenatal intestinal perforation. Contrast enema (usually using water-soluble contrast material) is the diagnostic test of choice. Contrast material may not reach the obstruction, but the appearance of a microcolon in the normal anatomic position is strong evidence that other lesions, such as malrotation, colonic atresia, and aganglionosis, are unlikely. Meconium ileus, or a functional obstruction by inspissated meconium, should be excluded by careful evaluation of clinical and diagnostic tests, because in most such cases, this condition can be managed nonoperatively.

The type of surgical procedure used to repair intestinal atresias will depend on the lesion, but most often it involves resection of the atretic segment(s) with primary end-to-end anastomosis or an intercurrent enterostomy with a take-down at a later date. Significant luminal discrepancies between the proximal and distal ends are addressed by amputation of large blind pouches, tapering enteroplasty, and/or end-to-oblique anastomosis at the time of the primary surgery or more commonly on take-down of the enterostomy. A certain degree of functional obstruction may still be encountered postoperatively, especially in proximal atresias. Prognosis is excellent, except with types IIIb and IV atresias, in which significant mesenteric defects may result in short bowel syndrome. Postoperative complications include sepsis, anastomotic leak, wound infection, necrotizing enterocolitis, bowel obstruction, and vitamin B_{12} deficiency. Mortality is low, but is higher in cases that result in short bowel syndrome (Stollman et al, 2009).

Colonic Atresia

Fewer than 10% of cases of intestinal atresia occur in the colon, and stenosis is even less common. Associated anomalies may occur in one third of the infants, and up to 20% of cases may be accompanied by other intestinal atresias. Clinical signs and symptoms of colonic atresia

FIGURE 69-12 Anteroposterior view of abdomen of male newborn with intestinal atresia. Multiple dilated bowel loops are present. Microcolon is evident from the contrast enema.

FIGURE 69-13 Anteroposterior view of abdomen of newborn with colonic atresia. Distal microcolon is evident by contrast enema.

include abdominal distention and vomiting beginning on the 2nd or 3rd day of life and failure to pass meconium. On plain radiographs, dilated loops of bowel are present, often with a distal cutoff (Figure 69-13). Pneumoperitoneum from intestinal perforation is found in 10% of cases. A contrast enema is essential for diagnosis, showing a distal microcolon, although the atretic segment may be visualized directly (Figure 69-14). The preferred surgical approach involves resection of the atretic segment and primary anastomosis (Davenport et al, 1990). This approach has replaced various staging procedures in stable patients without peritonitis. Outcome generally is very good.

FIGURE 69-14 Colonic atresia is visualized at laparotomy. Proximal dilated bowel is evident.

MECONIUM ILEUS

Definition and Etiology

Meconium ileus refers to an intraluminal intestinal obstruction produced by thick inspissated meconium. Ninety percent of patients with meconium ileus have CF, and 10% to 15% of these infants have a history of meconium ileus. More than 70% of cases of CF are associated with a deletion of three nucleotides in the cystic fibrosis transmembrane conductance regulator gene *(CFTR)* on the long (q) arm of human chromosome 7, although other mutations have been described; not all variants are associated with meconium ileus (Mornet et al, 1988; Rommens et al, 1989). In utero, some CF fetuses produce exceptionally viscid secretions from the mucous glands of the small intestine. The meconium formed is dry and contains higher-than-usual concentrations of protein, including albumin (Schwachmann and Antonowicz, 1981). The abnormal meconium adheres firmly to the mucosal surface of the distal small bowel, creating an intraluminal obstruction. Histologically, the goblet cells and mucous glands are prominent and distended with an eosinophilic material that merges with intraluminal meconium for a cast of the crypts and villi. Proximal to the obstruction, there may be intestinal muscular hypertrophy.

Diagnosis

Meconium ileus often manifests with signs of obstruction, but without perforation within the first 48 hours in an otherwise healthy-appearing infant. Obstruction

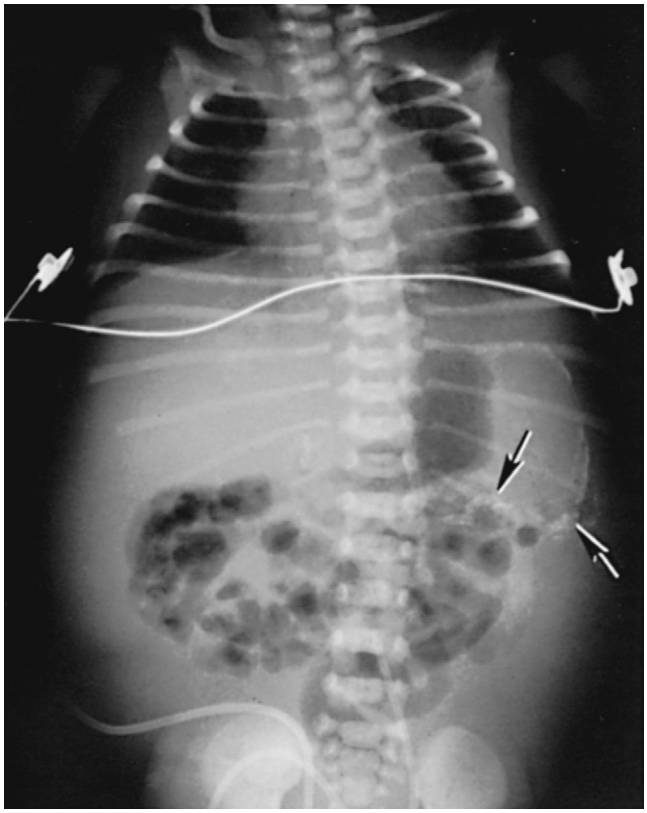

FIGURE 69-15 Radiographic appearance of ascites and abdominal calcifications (*arrows*) secondary to meconium peritonitis in a newborn infant. No gas is present in the rectum. The infant had ileal atresia, and a subsequent sweat chloride test was positive for cystic fibrosis. *(Courtesy of Dr. Ronald M. Cohen, Children's Hospital, Oakland, Calif.)*

usually occurs in the middle and distal ileum. Abdominal distention generally develops between 12 and 24 hours of life with no passage of meconium, although vomiting is uncommon. Physical examinations may reveal firm palpable masses throughout the abdomen that are freely movable in any direction (i.e., doughy abdomen). Meconium ileus complicated by volvulus, atresias, perforation and meconium peritonitis, or pseudocyst formation is found in 30% to 50% of the cases (Rescorla and Grosfeld, 1993). Newborns with the latter complications present earlier and appear more ill—often with severe vomiting, signs of neonatal sepsis, and more marked abdominal distention causing respiratory distress—than those with simple meconium ileus.

Radiographic examination shows dilated loops of bowel. Fluid levels are inconspicuous because of the viscous nature of meconium, which produces a coarse granular appearance ("ground-glass" appearance or "soap bubble" sign), typically in the right lower quadrant. The abdominal film may show, in addition to distended gas-filled loops, intraabdominal calcification indicative of intrauterine perforation and meconium peritonitis (Figure 69-15). The presence of air-fluid levels suggests the presence of jejunal or ileal atresia. The presence of a single grossly distended loop of bowel suggests the presence of postnatal volvulus. Perforations after birth result in free intraperitoneal air. Newborns suspected of having meconium ileus or any other distal bowel obstruction should undergo a contrast enema study. In meconium ileus, this study typically shows a microcolon and obstruction by multiple filling defects in the terminal ileum.

All newborns with meconium ileus should be evaluated for CF. Boat and co-workers (1989) have reviewed the clinical, physiologic, and genetic aspects of CF. The identification and cloning of the primary CF gene and the ability to identify mutations causing CF have advanced the clinician's ability to provide accurate diagnosis as well as counseling (Kerem et al, 1989b; Lemna et al, 1990; Rommens et al, 1989).

Treatment

In simple meconium ileus, approximately 60% of infants have their obstruction successfully relieved by the diagnostic contrast enema, ideally using a water-soluble contrast agent (Kao and Franken, 1995). Before the hyperosmolar enema is given, other complications such as perforation, volvulus, or atresia must be excluded. The hypertonic enema draws water into the intestinal tract, dislodging and breaking up meconium. Because of rapid fluid shifts, great care must be taken to maintain fluid and electrolyte balance. Failure of the contrast to dislodge the inspissated meconium after two attempts is an indication for surgical intervention. If the enema is successful, acetylcysteine, 5 mL every 6 hours, may be given via a nasogastric tube to help complete the clean-out.

Surgical intervention in simple meconium ileus usually consists of enterotomy with acetylcysteine irrigation and immediate closure. Other procedures such as resection of the ileum, with or without construction of various defunctioning ileostomies, are rarely indicated (Rescorla and Grosfeld, 1993). Complicated meconium ileus always requires surgical intervention, and the choice of operative procedure depends on the pathologic findings.

Prognosis

Operative mortality is minimal for simple meconium ileus. Perforation and electrolyte imbalance are the main complications of hyperosmolar enemas (Kao and Franken, 1995). Long-term outcome is influenced by the severity of pulmonary involvement.

Meconium plug syndrome is a similar entity not related to CF. Affected infants present similarly clinically, yet on contrast enema the obstruction is colonic and uniformly relieved during the study. Because of the diagnostic similarity and the fact that some children with CF may present with this pattern, testing for CF is indicated in all newborns with meconium obstruction (Rosenstein, 1978).

ANORECTAL MALFORMATIONS

Definition and Epidemiology

Anorectal anomalies occur in 1 of every 5000 births and are slightly more common in males (deVries and Cox, 1985). Associated anomalies occur in more than half of affected infants and are more frequent in "high" forms (see Etiology). Most frequent are vertebral, genitourinary, and gastrointestinal malformations (Kiely and Pena, 1998).

In infants with trisomy 21, 95% of those with anorectal malformations have imperforate anus without fistulas, as opposed to only 5% of all patients with anorectal anomalies (Levitt and Pena, 2007).

Etiology

The proctoderm comprises the anus and a canal that extends cephalad a short distance to meet the blind end of the hindgut, which has simultaneously moved caudad. Around weeks 7 to 8 of gestation, these should make contact, separated only by an anal membrane. At the same time, the lower urinary tract develops alongside the lower intestinal tract, separated by the urorectal membrane. Anal malformations arise locally from maldevelopment within the proctoderm. Atresias, stenoses, and fistulas arise from imperfect resolution of the anorectal membrane with or without concomitant failure of the urorectal membrane to separate completely the rectal and genitourinary components.

Anorectal malformations have traditionally been classified on the basis of the level of the rectal pouch (above the levator sling, or "high"; below it, or "low"; or at the level, "intermediate") and the presence or absence of an associated fistula (Levitt and Pena, 2007; Pena, 1997). A fistula is present in 95% of the cases, either externally as an anocutaneous fistula or internally as a rectourethral or rectovesical fistula.

Diagnosis and Treatment

Diagnosis is based on careful perineal examination, with imaging studies reserved for cases of diagnostic uncertainty and for evaluation of associated anomalies. The two key considerations in the assessment are the need for a colostomy and the presence of significant associated anomalies. The level of the defect may be clinically identifiable. Infants with low defects may have cutaneous fistulas, meconium present at the perineum, a bulging anal membrane, and well-formed buttocks. Females will often pass meconium through a perineal, vestibular, or vaginal fistula, or the anomaly may manifest as a cloaca (i.e., one-hole perineum). Male infants with low defects may have a bucket-handle malformation (a midline bridge of skin) or cutaneous fistulas that may track along the midline raphe toward the penis, discharging a tiny epithelial pearl or a meconium drop (see Figure 69-4) (Levitt and Pena, 2007). Finding meconium in the urine or air in the bladder may identify the presence of an internal fistula.

Plain abdominal radiographs may show progressive distal bowel obstruction. The traditional "invertogram" used to identify the distance between the rectal pouch and the skin has been replaced by a cross-table prone film obtained with the pelvis elevated, although this study should not be done in the first 24 hours of life, because the radiographic appearance may suggest a falsely increased gap (Kiely and Pena, 1998). Perineal ultrasound examination may prove to be more accurate than plain films. Abdominal ultrasonography, cardiac echography, and skeletal films may be required to rule out associated anomalies. The management of low defects includes several procedures aimed at restoring the anorectal canal, by cut-back of a cutaneous fistula, anal transposition, or limited posterior sagittal anorectoplasty (Kiely and Pena, 1998). High and so-called intermediate defects require an immediate colostomy, followed by elective repair. Before the final repair, a distal colostogram allows precise localization of the fistula. Although there are multiple approaches to the definitive correction of anorectal malformations, the aim of all is to close any fistula and then tunnel the rectal pouch through the anatomic sphincter muscle to the anoderm. The posterior sagittal anorectoplasty popularized by Pena has become the most frequently performed procedure worldwide (Kiely and Pena, 1998).

Prognosis

Although the surgical mortality rate is low and primarily dependent on associated anomalies, functional long-term results are variable. Children born with low defects often will be chronically constipated; incontinence may occur in 30% to 35% of patients with high defects (Ditesheim and Templeton, 1987). Furthermore, quality of life correlates closely with whether continence can be established (Ditesheim and Templeton, 1987). Nevertheless, a majority of these children can be rendered functionally continent through a bowel management program, anorectal biofeedback, and antegrade enemas via a cecostomy in selected patients (Paidas, 1997).

ENTERIC DUPLICATIONS

Duplications of the gastrointestinal tract are relatively rare. Developmentally, the most favored hypothesis is the split notochord, resulting from adherence between ectoderm and endoderm in the neural plate (Pang et al, 1992).

Duplications may occur anywhere from the mouth to the rectum, although a majority are found in the small bowel. Associated anomalies, especially of the intestinal tract, are common. Duplications are generally located on the mesenteric side of the lumen, are lined by intestinal mucosa, and share a common wall and mesenteric blood supply with the adjacent intestine. Most duplications are spherical, presenting as cysts occasionally communicating with the main enteric lumen. Tubular duplications may involve long segments of bowel but are rare.

Many duplications manifest in the neonatal period, usually with obstructive signs in the presence of a palpable mass (Stringer and Spitz, 1995). Esophageal duplications may cause respiratory distress, whereas ectopic gastric tissue may cause rectal bleeding from peptic ulceration. Plain films of the abdomen may show displacement of adjacent viscera by a mass. Upper and/or lower gastrointestinal contrast studies may demonstrate a filling defect or, rarely, a communication between the cyst and normal bowel. Ultrasound diagnosis is possible both prenatally and postnatally, based on a characteristic appearance of the wall of the mass. CT or MRI is the modality of choice for imaging thoracic duplications.

The treatment of choice is surgical excision with primary anastomosis, although partial excision with destruction of residual enteric lining may be necessary for long tubular duplications (Stringer and Spitz, 1995).

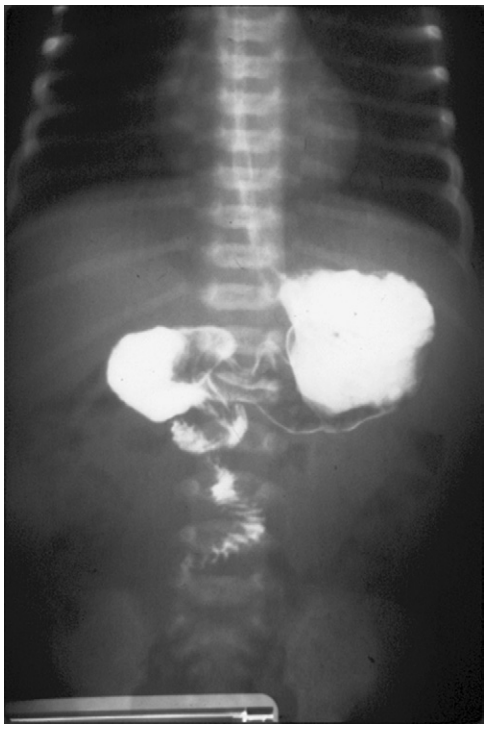

FIGURE 69-16 Anteroposterior view of abdomen of male infant with midgut volvulus. The contrast shows the duodenojejunal junction to be to the right of the spine, indicative of underlying malrotation. The proximal jejunum is obstructed in the "coil spring" appearance of acute midgut volvulus.

MALROTATION AND MIDGUT VOLVULUS

Presentation

Anomalies of intestinal rotation occur in 1 in 6000 live births. Malrotation of the gut occurs between 8 and 10 weeks of gestation, when the elongating intestine returns to the abdominal cavity. If the mesenteric attachments do not develop properly, the midgut lies free, attached to the posterior abdominal wall at only two points: the duodenum and the proximal colon. It may therefore twist in either direction, but when volvulus occurs, it is usually in the clockwise direction. Midgut volvulus may occur any time postnatally, but 80% of cases are found in the neonatal period (Seashore and Touloukian, 1994). Although rare, cases of fetal volvulus with and without malrotation have been reported. Signs develop with or immediately after delivery and include a tense and distended abdomen, bloody stools, and dark discoloration of the abdominal wall (Cullen's sign). Other signs may include maternal polyhydramnios, presence of an abdominal mass, ascites, bilious emesis and/or gastric aspirate, peritoneal calcifications signifying meconium peritonitis after intrauterine intestinal perforation, or even systemic shock. Fetal volvulus has been associated with hydrops fetalis, preterm delivery, fetal demise, and spontaneous abortion (Morikawa, 1999). Morbidity and mortality with fetal volvulus are high, largely because of late diagnosis. Infants with malrotation and midgut volvulus may have other associated congenital anomalies, such as intestinal atresias, gastroschisis, omphalocele, congenital diaphragmatic hernia, and annular pancreas, as well as chromosomal abnormalities, namely trisomies (Molvarec et al, 2007).

The newborn with midgut volvulus presents with high intestinal obstructive symptoms, often in the 1st week of life. Sudden bilious vomiting with abdominal distention in a previously well newborn is particularly suggestive. Mesenteric vascular compromise of the midgut leads to rapidly progressive intestinal ischemia and necrosis, peritonitis, sepsis, and shock. Laboratory investigations usually reveal biochemical signs of visceral ischemia, coagulopathy, and sepsis.

Plain abdominal films may show a high intestinal obstruction, although the closed-loop obstruction produced may fail to show air-fluid levels, because the compromised bowel often is filled with fluid alone (Figure 69-16). Findings on plain radiographs may therefore be variable and cannot be used to rule out a midgut volvulus. A "gasless abdomen" finding is particularly worrisome. A "double-bubble sign" on radiograph suggesting duodenal atresia has been described in the literature to be malrotation with volvulus (Gilberson-Dahdal et al, 2009). If surgical treatment is delayed in these cases, an ultrasound examination should be performed to evaluate for volvulus. The stable infant with suspected volvulus should undergo an urgent upper gastrointestinal contrast study to document the position of the duodenojejunal flexure and to identify any proximal obstruction. Ultrasound examination may reveal the "whirlpool sign" in an acute volvulus or may document the correct or reversed position of the superior mesentery artery and vein (Pracros et al, 1992). The infant with peritonitis and suspected midgut volvulus should be promptly resuscitated and taken for immediate laparotomy.

Treatment

At laparotomy, the volvulus is reduced by counterclockwise rotation, and intestinal viability is carefully assessed. Frank necrotic bowel is removed, followed by either primary anastomosis or stoma creation. A Ladd's procedure is also carried out, including lysis of peritoneal bands, appendectomy, and replacement of the bowel in a malrotated position with the cecum on the left lower quadrant. An appendectomy is carried out because a subsequent diagnosis of appendicitis may be difficult (the appendix will not be located in the lower right quadrant). Recurrent volvulus after this procedure is very unusual (Yu et al, 2009).

The infant with necrosis of the entire midgut presents a particularly challenging problem. A second-look laparotomy in 12 to 36 hours is often undertaken to assess intestinal viability. Options in the case of minimal intestinal recovery include intestinal failure protocols and bowel-lengthening procedures, intestinal transplantation, and compassionate care alone.

INTUSSUSCEPTION

Intussusception is the telescoping of one loop of bowel into another loop of bowel. Although intussusception is a relatively common cause of intestinal obstruction in infants 6 to 18 months of age, it is very rare in neonates. Prenatal intussusception is responsible for some cases of intestinal atresia (Wang et al, 1998). In premature infants,

intussusception may manifest without a specific leading point and with a picture mimicking that of necrotizing enterocolitis (Mooney et al, 1996). In the full-term newborn, a colonic leading point is often encountered (Wang et al, 1998). Should a diagnosis of intussusception be entertained, ultrasound examination and/or contrast enema are indicated. Hydrostatic reduction is not usually successful in neonates, and therefore a laparotomy with operative reduction or resection is necessary.

CHAPTER 70

Innate and Mucosal Immunity in the Developing Gastrointestinal Tract: Relationship to Early and Later Disease

Camilia R. Martin and W. Allan Walker

The fully developed gastrointestinal (GI) tract reaches a total length of approximately 22 to 30 feet (Hounnou et al, 2002) and has a mucosal surface area of 300 to 400 m^2 (DeWitt and Kudsk, 1999), which is equivalent to the size of a singles tennis court. Coexistent within the intestinal tract is a diverse microbial community with an abundance of organisms that exceeds the number of cells in the entire human body by 10-fold (Bjorksten, 2004). During development of the GI tract, the interaction between this microbiome and the intestinal mucosal epithelium is an essential component in the education of the host's immune and inflammatory responses against foreign antigens.

The anatomic and functional development of the GI tract begins during early embryogenesis and continues well into childhood. In addition to the essential digestive and absorptive capacities provided by the gastrointestinal system, the intestinal tract will also become the largest defense barrier and immune organ in the body. Its complex anatomic structures and dynamic functions protect the host from an onslaught of dietary and environmental antigens, which begins immediately after birth. These multiple layers of intestinal defenses are elegantly coordinated and tightly regulated. The immune and inflammatory responses initiated by the intestinal mucosa must constantly balance between eliciting a tolerant response to environmental antigens that facilitate further intestinal development with a more aggressive inflammatory attack against potential pathogens that risk the health of the host.

Abnormal development and regulation in the balance between immune tolerance and inflammatory responsiveness result in an inappropriate host response to antigenic challenges. This increases the vulnerability of the host to diseases of chronic, unregulated inflammation and dysregulated immunity.

DEVELOPMENT OF THE INTESTINAL TRACT

The development of the intestinal tract spans the periods of early embryogenesis (i.e., fetal development) to the introduction of solid foods (i.e., late infancy to early childhood). This period of ontogeny can be separated into five developmental phases (Table 70-1) (Wagner et al, 2008). Embryonic organogenesis and primitive gut formation is established in phase I. In phase II, the GI tract becomes a tubular structure, anatomic development (elongation and formation of villus structures) continues, and the functional role of the intestinal epithelium is initiated. Phase III is characterized by rapid linear growth, continued anatomic development of the villus architecture, and ongoing cellular differentiation with maturation of specific cellular physiologic functions. Phase IV begins immediately after birth when postnatal structural and immune development are mediated by the interaction between the host and exogenous, environmental exposures. This developmental phase is mostly directed by the establishment of the intestinal microbiome and the response to dietary factors present in human milk and/or formula. Weaning from human milk or formula and the introduction of solid foods signal is the beginning of phase V. During this period, structural development of the intestines and maturation of mucosal immunity are refined.

FETAL DEVELOPMENT

The first three phases of intestinal development occur in utero. By the end of the first trimester many of the epithelial cellular elements, including specialized cells, have made their appearance (Table 70-2). During this same period of embryogenesis, development of the anatomic structures necessary for optimal function of the GI tract is established, including formation of tight junctions and crypt villi. Also in the first trimester and into the early part of the second trimester, additional specialized cells establish their presence; the products of these specialized cells begin to be metabolized and secreted (e.g., mucin, defensins, lysozymes), and cell surface receptors can be identified (e.g., Toll-like receptor [TLR]-2, TLR-4) (Buisine et al, 1998; Fusunyan et al, 2001; Louis and Lin, 2009; Mallow et al, 1996; Neu and Li, 2003; Rumbo and Schiffrin, 2005).

ROLE OF AMNIOTIC FLUID IN EARLY GASTROINTESTINAL DEVELOPMENT

The development, maturation, and maintenance of the intestinal tract's complex functions require interaction with environmental exposures. This process will repeat itself with each changing environment and antigenic exposure; these periods include intrauterine life (fetus), postnatal introduction to the environment and to human milk or formula as the sole dietary source (early infancy), transition to solid foods (late infancy), and expansion of the dietary repertoire and thus the diversity of antigenic exposure (early childhood).

Therefore, one of the first influential factors in the development of intestinal structure and function is exposure to amniotic fluid. The amniotic fluid cavity is identified early

TABLE 70-1 Phases of Gut Development

Phase	Time Period	Development
Phase I	0–5 weeks' gestation	Embryonic phase of organogenesis
		Primitive gut forms
Phase II	Early to mid-gestation	Entrance and exit sites of gastrointestinal tract form
		Selective growth and apoptosis with formation of rudimentary primitive gut tube
		Formation of mouth and anus
		Swallowing begins
Phase III	Late gestation	Characterized by active differentiation
		Crypts increase in cell number causing cells to migrate up villi
		Starts several weeks before birth
		Characterized by more rapid growth than fetal body as a whole
		Rate of growth continues through the first feedings
		Growth accompanied by selective apoptosis; occurs not only at the tips of villi but in crypts as well
Phase IV	Birth–6 months	Begins after birth with exposure to enteral nutrition
		Human milk feedings bring about more rapid mucosal differentiation and development than artificial feedings
		Mucosal growth continues during infancy: fission and deepening of crypts, increasing villus width and number, and the appearance of submucosal folds
		GI tract is confronted with largest antigenic load to body in form of dietary proteins, commensal organisms, and pathogens: greater antigenic load with artificial feedings
		Mucosal immune system of gut develops extraordinary ability to distinguish between foreign pathogens and safe nutrient proteins and commensal organisms: process facilitated by human milk, leads to effective oral tolerance; success of such local interactions between local innate and specific immunity becomes the prerequisite for lifelong health
Phase V	>6 months	Occurs during weaning phase in late infancy/early childhood during transition from milk feedings to complementary, solid foods
		Second phase of mucosal expansion associated with epithelial hyperplasia that renders the gut similar in function to that of older children and adults

Modified from Wagner CL, Taylor SN, Johnson D: Host factors in amniotic fluid and breast milk that contribute to gut maturation, *Clin Rev Allerg Immunol* 34:191-204, 2008.

in embryogenesis, and amniotic fluid rapidly accumulates during early gestation (Underwood and Sherman, 2006). Initially, amniotic fluid is predominantly composed of water and solute from maternal plasma that is delivered to the fetus via the placenta and diffuses from the nonkeratinized fetal tissues into the amniotic space. As gestation lengthens, there are other contributors to the contents of amniotic fluid, including the placenta, amniotic membranes, and the fetus. It is not until the second half of pregnancy that the fetus actively and significantly contributes to the volume and composition of the amniotic fluid, mainly through swallowing and urination (Underwood et al, 2005).

Amniotic fluid is a complex, dynamic fluid whose composition varies over the gestational period. Proteomic analysis of amniotic fluid at 16 to 18 weeks' gestation identified more than 500 proteins, although many more are likely to exist (Cho et al, 2007). Amniotic fluid is enriched with hormones, trophic or growth factors, nutrients and other plasma proteins, modulators of coagulation, modulators of immunity and inflammation, and mediators of cell growth and differentiation, which together facilitate the development of many organ systems, especially the gastrointestinal system (Box 70-1) (Cho et al, 2007; Underwood et al, 2005; Underwood and Sherman, 2006; Wagner et al, 2008). However, additional studies are needed to further characterize the changes in the relative concentrations of trophic factors and cytokines in amniotic fluid across gestational ages and its specific effects on intestinal development.

In week 16, the fetus begins to swallow amniotic fluid, ingesting approximately 450 to 1000 mL per day during the third trimester and in late gestation (Louis and Lin, 2009; Montgomery et al, 1999; Neu and Li, 2003; Rumbo and Schiffrin, 2005). Thus, early in the second trimester until parturition, the intestinal tract of the fetus is continuously bathed in amniotic fluid, and the presence of this flow as well as the exposure to its complex components is essential for its proper growth and differentiation. When the flow of amniotic fluid to the GI tract is disrupted, intestinal development is hampered, with reduced intestinal growth and decreased digestive and absorptive capabilities (Mulvihill et al, 1985, 1986; Sangild et al, 2002; Trahair and Sangild, 2000; Wagner et al, 2008). Many of the proteins found in amniotic fluid also have a direct role in facilitating intestinal development and likely work optimally in concert with each other rather than alone (Wagner et al, 2008). More specifically, the trophic factors epidermal growth factor (EGF), transforming growth factor (TGF)-β, TGF-β_1, insulin-like growth factor (IGF)-1, granulocyte colony-stimulating factor (G-CSF), and erythropoietin (EPO) have been shown to be important for stimulating intestinal growth, cellular differentiation, and maturation of cellular absorptive and secretive functions (Underwood and Sherman, 2006).

TABLE 70-2 Fetal Development of the Intestinal Tract

Developmental Feature	Gestational Age, Weeks
Specialized Cells	
Intraepithelial lymphocytes	8
Intestinal absorptive epithelium	9

*Some investigators note the presence of mucin as early as 6–7 weeks' gestation (Buisine MP, Devisme L, Savidge TC, et al: Mucin gene expression in human embryonic and fetal intestine, *Gut* 43:519-524, 1998).

INNATE AND MUCOSAL IMMUNITY OF THE INTESTINAL TRACT

Soon after delivery, phase 4 of gastrointestinal development begins. During this phase, the infant is rapidly presented with environmental and dietary stimuli (e.g., microorganisms, food antigens, and xenobiotics) that directly influence ongoing intestinal development and maturation of physiologic functions and mucosal immunity. The successful interaction between these antigenic exposures and the host's cellular responses is essential for the development of the innate and adaptive mucosal immunity of the GI tract and ultimately long-term protection of the host. An inappropriate intestinal response to environmental challenges may lead to altered immune and inflammatory regulation with local (GI) and systemic consequences.

However, before understanding the potential influences of environmental exposures on intestinal development and mucosal immunity, the specific structures that exist to coordinate this interaction must be reviewed. The intestinal components that make up the layers of defense and mediate appropriate oral tolerance or aggressive responsiveness can be found within the single-layer epithelial cell wall and within the structures that comprise the gut-associated lymphoid tissue (GALT).

INTESTINAL BARRIER FUNCTION: THE EPITHELIAL CELL LAYER AND TIGHT JUNCTIONS

The intestinal epithelium is a single layer of cells composed of multiple cell types, including enterocytes; enteroendocrine cells; intraepithelial lymphocytes; goblet cells; Paneth cells; and microfold or M cells (Figure 70-1)

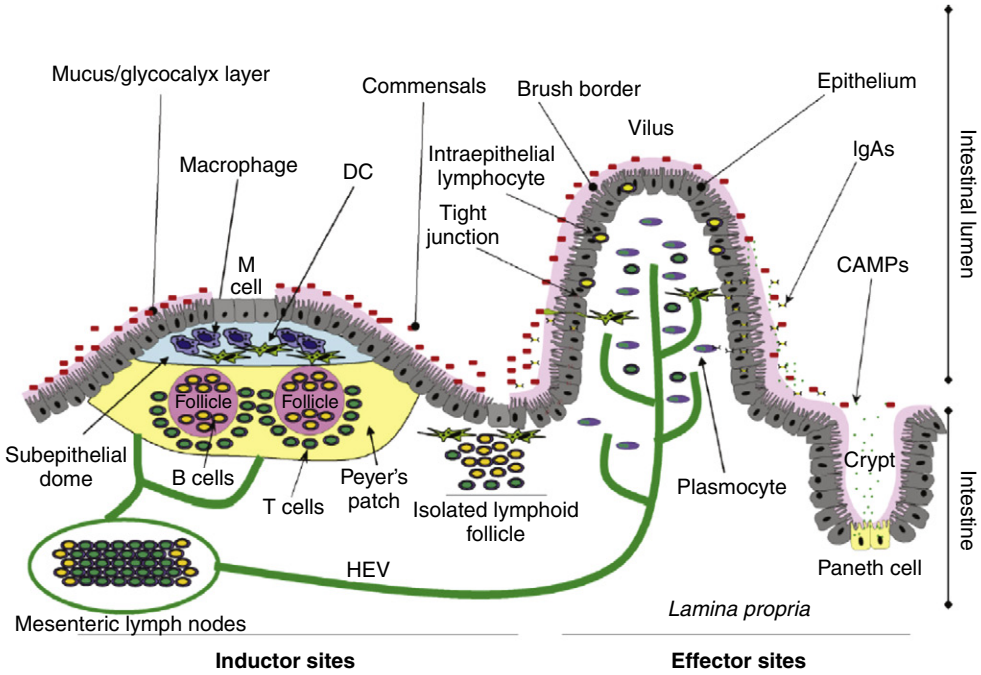

FIGURE 70-1 Structural components of the intestinal epithelial barrier and immune system. Epithelial cell layer: enterocytes, enteroendocrine cells, intraepithelial lymphocytes, goblet cells, Paneth cells, and microfold or M cells. Gut-associated lymphoid tissue (GALT): *inductor sites*: mesenteric lymph nodes, Peyer's patches, isolated lymphoid follicles; *effector sites*: epithelium (intraepithelial lymphocyte) and lamina propria IgA-producing plasma cells, primed T cells, monocytes, and mast cells. *(From Magalhaes JG, Tattoli I, Girardin SE: The intestinal epithelial barrier: how to distinguish between the microbial flora and pathogens*, Semin Immunol *19:106-115, 2007.)*

(Lievin-Le Moal and Servin, 2006; Magalhaes et al, 2007; Yu and Yang, 2009). Each of these cells has individualized specialized functions (discussed in further detail below); together their cell-to-cell interactions and adherence form the basis of the intestinal cell barrier and the first-line defense against the potential penetration of pathogenic bacteria and antigens into the underlying mucosa.

The intestinal barrier is maintained by regulation and maintenance of two pathways: the transcellular pathway and the paracellular pathway (Groschwitz and Hogan, 2009). Three junctional complexes regulate the paracellular pathway: tight junctions (TJs), adherens junctions (AJs), and desmosomes. These junctional complexes serve as trafficking police by not allowing passage of macromolecules but allowing for essential transfer of fluids, electrolytes, and small peptides. Forty different proteins have been found to be important components of TJs, including ZO-1, -2, and -3 linker proteins, occludins, and claudins. AJs consist of cadherin-catenin complexes (Lievin-Le Moal and Servin, 2006). This dynamic and complex network of proteins interacts with each other but is also influenced by external factors. For example, permeability may be altered by pathologic insults or by other factors such as zonulin, a protein that appears to increase permeability across tight junctions and has been implicated in the pathogenesis of celiac disease and type-1 diabetes (Fasano and Shea-Donohue, 2005; Vaarala et al, 2008). In addition, tumor necrosis factor (TNF)-α, interferon (IFN)-γ, and nitric oxide have all been shown to cause barrier dysfunction, whereas TLR2-activated protein kinase C isoforms influence arrangement of ZO-1 junction proteins, increasing barrier integrity. Optimization of tight junctions is also mediated by the short-chain fatty acid butyrate and the amino acid glutamine (Fasano and Shea-Donohue, 2005; Neu and Mackey, 2003)

SPECIALIZED EPITHELIAL IMMUNE CELLS

Goblet cells originate from crypt stem cells and migrate along the crypt-villus axis as they mature (Lievin-Le Moal and Servin, 2006). Goblet cells secrete mucins, which are high-molecular-weight glycoproteins that form a protective layer against offending antigens. Mucin is a complex matrix of water, electrolytes, mucins, glycoproteins, immunoglobulins (sIgA), glycolipids, and albumin (Neu and Mackey, 2003). Mucin binds to bacteria and prevents direct epithelial binding by microorganisms; facilitates bacterial removal by the luminal stream; and binds to trophic and other factors (e.g., epidermal growth factor, intestinal trefoil factor) that are critical for intestinal development, maintenance of intestinal health, and intestinal repair (Louis and Lin, 2009). More than 20 mucin genes have been identified, with MUC2 being the predominant mucin produced by intestinal goblet cells. There is a continuous production of mucins to maintain a constant mucin layer; however, mucin production can also be upregulated with exposure to specific bioactive factors such as hormones, inflammatory mediators, and factors derived from microbial residents of the GI tract (e.g., lipopolysaccharides, flagellin A, lipoteichoic acids) (Dharmani et al, 2009). In addition to mucins, intestinal goblet cells also produce intestinal trefoil factor (TFF), specifically TFF3, and resistin-like molecule-β (RELM-β) (Dharmani et al, 2009). Potential roles of TFF include stabilization

of the mucin layer and reparation of mucosal injury. In addition to regulation of barrier function, RELM-β also appears to be involved in positive feedback to the goblet cell to increase mucin production.

Paneth cells are located in the crypt bases and, unlike goblet cells, do not migrate up the crypt-villus axis (i.e., they remain in the crypt base). Paneth cells produce antimicrobial peptides (AMPs) in response to lipopolysaccharide (LPS) and other enteric pathogen exposures. Their position in the crypt bases near stem cells allows them to protect these nondifferentiated cells from microbes and preserves the regenerative ability of the intestinal epithelium (Keshav, 2006). Of note, additional observations suggest that other intestinal epithelial cells besides Paneth cells can produce AMPs (Lievin-Le Moal and Servin, 2006). AMPs are currently categorized into two main families: defensins (α and β) and cathelicidins. They appear to exert their antimicrobial effects by incorporating into the cell membrane and creating pores allowing for the influx of anions and killing of the offending organism (Louis and Lin, 2009). α-Defensins, also known as cryptidins, are activated by matrix metalloprotease-7 (MMP-7) to microbicidal peptides (Schenk and Mueller, 2008). Other bactericidal compounds found in Paneth cells include lysozyme and phospholipase A2 type IIA (Keshav, 2006).

Microfold or M cells reside within the epithelial cell layer overlying organized foci of lymphoid tissue. Similar to goblet cells, M cells originate from the crypt, differentiate, and migrate along the crypt-villus axis. However, unlike their neighboring cells, M cells lack microvilli on their luminal surfaces. Rather, the luminal surface has microfolds, giving rise to its name. Additionally, on the basolateral surface, there are multiple invaginations that house immune cells such as lymphocytes and macrophages. Via phagocytosis, M cells sample and engulf luminal antigens and microorganisms and present them to the underlying effector immune cells (Hathaway and Kraehenbuhl, 2000; Miller et al, 2007).

GUT-ASSOCIATED LYMPHOID TISSUE

GALT has two main components: the inductor sites and the effector sites (see Figure 70-1) (Magalhaes et al, 2007). The inductor sites represent the structures where immune responses are initiated, namely antigen uptake and processing (Magalhaes et al, 2007; Neurath et al, 2002). It is within these structures that antigen-presenting cells (APCs) activate CD4 T cells, CD8 T cells, and B cells. The inductor sites consist of mesenteric lymph nodes, Peyer's patches, isolated lymphoid follicles (ILFs), and cryptopatches, which are clusters of immature lymphocytes that give rise to ILFs.

Effector cells are the immune cells, which, once activated, modulate downstream immune and inflammatory signaling. Effector sites are the locations where these effector cells reside; these include the epithelium and the lamina propria. The primary effector cell within the epithelium is the intraepithelial lymphocyte. These are scattered T lymphocytes that are situated along the basolateral side of the single epithelial cell layer and are capable of producing cytokines. The lamina propria is home to numerous effector cells, including IgA-producing plasma cells, primed T cells, monocytes, and mast cells (Magalhaes et al, 2007).

Monocytes give rise to macrophages and dendritic cells. *Macrophages* are preferentially positioned in the subepithelial region but may also reside in the intraepithelial region. Macrophages rapidly phagocytose invading bacteria and subsequently eradicate the organism by generation of superoxide and inducible nitric oxide (Schenk and Mueller, 2008). In addition, macrophages serve to scavenge dying cells and foreign debris and remodel tissue after inflammatory damage (Schenk and Mueller, 2008). Intestinal macrophages are able to perform these duties without cell activation or cytokine production because they lack pathogen recognition receptors, Fc receptors for IgA and IgG, and complement receptors (Schenk and Mueller, 2008). *Dendritic cells* are APCs that reside in Peyer's patches as well as scattered throughout the GI tract. The scattered dendritic cells insert their dendritic extensions between the epithelial cells across the tight junctions to sample luminal antigens (Schenk and Mueller, 2008).

Mast cells bind IgE via Fc epsilon receptors and release histamine and serotonin. These mediators upregulate mucin production, increase intestinal permeability, contract smooth muscle cells, and are a chemoattractant for granulocytes (Neu and Mackey, 2003).

COORDINATED LAYERS OF DEFENSE: PUTTING IT ALL TOGETHER

NONSPECIFIC PHYSICAL AND CHEMICAL BARRIERS

On entering the intestinal lumen, a foreign antigen (e.g., bacterial pathogen, food antigen, or xenobiotic) encounters many tightly coordinated layers of mucosal defenses. The first layer of defense is a series of physical and chemical barriers designed to provide constant surveillance and prevent epithelial adherence and translocation of the potential pathogens or passage of these antigens between the paracellular spaces. Within this first line of defense are the acidic environment of the stomach, the numerous digestive enzymes that exist along the entire GI route, and bile salts (Martin and Walker, 2006). These factors serve to digest dietary nutrients, but a side benefit of this digestive process is the destruction of ingested pathogens and other potentially immunogenic proteins into small, nonimmunogenic molecules of less than approximately 10 amino acids in length (Mayer, 2003). Additional mechanisms of the initial mucosal defense include production of mucus by goblet cells to inhibit microbial adherence, presence of polymeric secretory IgA within this mucus layer to bind luminal antigens, peristalsis to facilitate removal of antigen-antibody complexes (Walker, 2002; Winkler et al, 2007), secretion of antimicrobial peptides by Paneth cells (Keshav, 2006), and maintenance of tight junctions to prevent paracellular passage (Groschwitz and Hogan, 2009).

ANTIGEN SAMPLING AND PRESENTATION

Bacterial, dietary, and/or xenobiotic antigens that are present in the intestinal lumen are internalized and processed by several pathways: the M cell pathway; the intraepithelial dendritic cell pathway; and the enterocyte pathway

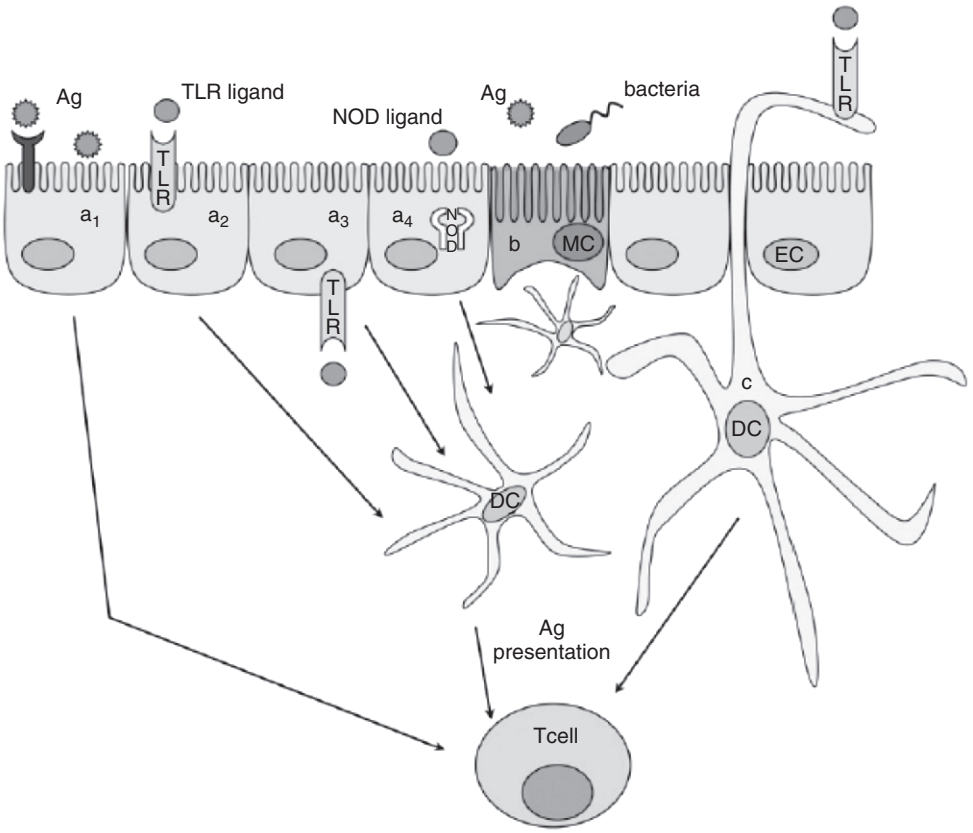

FIGURE 70-2 Antigen (Ag) sampling. *a*, enterocyte pathway; a_1, pinocytosis, receptor-mediated endocytosis; a_2, apical Toll-like receptor (TLR) recognition; a_3, basolateral TLR recognition; a_4, nucleotide-binding oligomerization domain (NOD) receptor recognition; *b*, M cell pathway; *c*, intraepithelial dendritic cell pathway. *(From Winkler P, Ghadimi D, Schrezenmeir J, Kraehenbuhl JP: Molecular and cellular basis of microflora-host interactions*, J Nutr *137:756S-772S, 2007.)*

by nonspecific pinocytosis, receptor-mediated endocytosis, toll-like receptor (TLR) recognition, or nucleotide-binding oligomerization domain (NOD) receptor recognition (Figure 70-2) (Winkler et al, 2007).

M Cell and Dendritic Cell Pathway

As previously described, M cells reside within the single-cell epithelial layer and are uniquely positioned over organized sections of lymphoid tissue and Peyer's patches. M cells sample antigens, actively transport them into the submucosa, and present them to effector cells, such as dendritic cells and lymphocytes. This process leads to T cell differentiation and B cell activation. Similarly, dendritic cells that have interdigitated their dendritic extensions across the paracellular junctions sample luminal antigens and migrate to lymphoid structures to participate in T and B cell activation.

Receptor-Mediated Endocytosis and Processing: Toll-like and NOD Receptors

Pattern recognition receptors (PRRs), such as TLRs, formylated peptide receptors, and NOD receptors, recognize and bind to highly conserved specific pathogen regions or molecular motifs, commonly referred to as pathogen-associated molecular patterns (PAMPs) or microb associated molecular patterns (MAMPs). The conservation of these molecular motifs among microorganisms of the same class allows the mucosal cell to recognize most microorganisms by using a select group of PRRs. General classes of PAMPs include nucleic acids (e.g., dsRNA in viral organisms), polypeptides (e.g., flagellin), and macromolecules (e.g., lipopolysaccharide in the bacterial cell wall of gram-negative organisms and peptidoglycan in the bacterial cell wall of gram-positive organisms) (Louis and Lin, 2009).

TLRs are transmembrane proteins that are expressed on the luminal or basolateral surfaces of host defense cells. The extracellular component of leucine-rich repeat recognition domain binds to the specific PAMP, while the intracellular interleukin-1 receptor-like domain activates cytoplasmic proteins responsible for downstream signaling (Louis and Lin, 2009; Macdonald and Monteleone, 2005). To date, 11 TLRs have been identified. Each TLR recognizes and binds with specific PAMPs, some unique to that particular TLR and some overlapping with other TLRs. TLR4 is preferentially expressed by enterocytes within crypts, whereas TLR2, TLR3, and TLR5 are preferentially expressed on the villus enterocytes (Fusunyan et al, 2001; Winkler et al, 2007). Of note, TLR5 is unique in that it is situated at the basolateral surface below the tight junctions. NODs are distinct from TLRs in that they reside within the cell's cytoplasm. Of special interest to the intestinal tract, NOD1 and NOD2 (also known as caspase recruitment domain 4 [CARD4] and CARD15) are

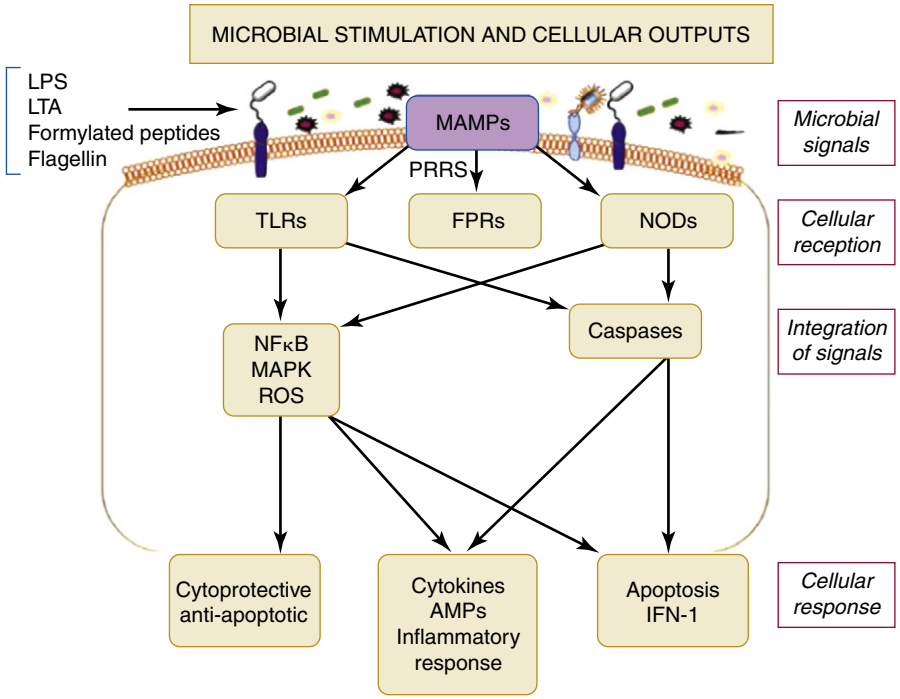

FIGURE 70-3 PRR-PAMP (MAMP) complex activation and downstream signaling. Microbial components such as lipopolysaccharide *(LPS)*, lipoteichoic acid *(LTA)*, formylated peptides, and flagellin serve as microbial-associated molecular patterns *(MAMPs)* and signal pattern-recognition receptors *(PRRs)* including toll-like receptors *(TLRs)*, formylated peptide receptors *(FPRs)*, or nucleotide-binding oligomerization domain-like receptors *(NODs)*. Integration of these signals evokes cellular outputs based on the initial perception of the triggering organism. Output can be a protective response to commensal microbiota or an inflammatory response to pathogenic organism(s), or it can trigger apoptosis. *(From Sharma R, Tepas JJ 3rd: Microecology, intestinal epithelial barrier and necrotizing enterocolitis,* Pediatr Surg Int *26:11-21, 2010.)*

expressed within intestinal antigen-presenting cells and epithelial cells (Winkler et al, 2007).

The PAMP–PRR complex results in the activation of several, well-described cytoplasmic signaling pathways. These pathways include activation of nuclear factor kappa B (NF-κB), mitogen-activated protein kinase (MAPK), and interferon regulatory factor (IRF) (Louis and Lin, 2009; Neish, 2009). Modulation of these pathways involves a regulated series of phosphorylation and ubiquitination. With ubiquitination, NF-κB, MAPK, and IRF are free to translocate into the cell's nucleus and upregulate the production of downstream molecules that combine to initiate an inflammatory response to effectively rid the body of the invading pathogen. This diverse group of molecules includes cytokines, antimicrobial peptides, chemotactic messengers, adhesion molecules, and other acute-phase reactants (Louis and Lin, 2009; Sharma and Tepas, 2010). Concomitant with activation of these proinflammatory pathways is the stimulation of apoptotic pathways (via caspases) to assist in the removal of infected or injured cells (Figure 70-3) (Louis and Lin, 2009; Sharma and Tepas, 2010).

Th1/Th2 Polarization

Downstream signaling mediated by PRR-PAMP complexes activates APC differentiation, which in turn modulates the differentiation of T-helper (Th) cells. The specific class of APC mediates the type of differentiation that the T-helper cells will undergo. For example, the $CD8^+$ dendritic cell regulates the maturation of the Th cell to a Th1 cell, whereas the $CD8^-$ dendritic cell activates Th2 cells. Th1 cells increase cytokine production of IFN-γ and lymphotoxin, activate macrophages, and are associated with delayed-type hypersensitivity. Th2 cells increase the production of interleukin (IL)-4, IL-5, IL-9, and IL-13. Th-2 cells mediate allergic responses and facilitate antibody production, mast-cell degranulation, and eosinophil activation (Neurath et al, 2002) (Figure 70-4).

EXOGENOUS EXPOSURES AND THEIR IMPACT ON INNATE INTESTINAL IMMUNE DEFENSES

BACTERIAL COLONIZATION

Ultimately the intestinal microbiota will consist of 10^{13} to 10^{14} microorganisms representing 800–1000 species of bacteria that encode millions of genes. The abundance of microorganisms increases distally along the intestinal tract (Martin and Walker, 2008). Interestingly, colonization profiles are unique to the location within the intestinal tract, and this is true not just across the major divisions (e.g., ileum vs. colon), but also across the microstructures within the gut (e.g., microbiota within the lumen, vs. within the mucus layer, vs. within the crypts, vs. colonization and adherence on the intestinal epithelial cells) (Lievin-Le Moal and Servin, 2006).

Establishment of the microbial ecosystem begins soon after delivery, when the newborn gut leaves a predominantly sterile environment and is rapidly exposed to environmental bacteria. If the infant was born by vaginal

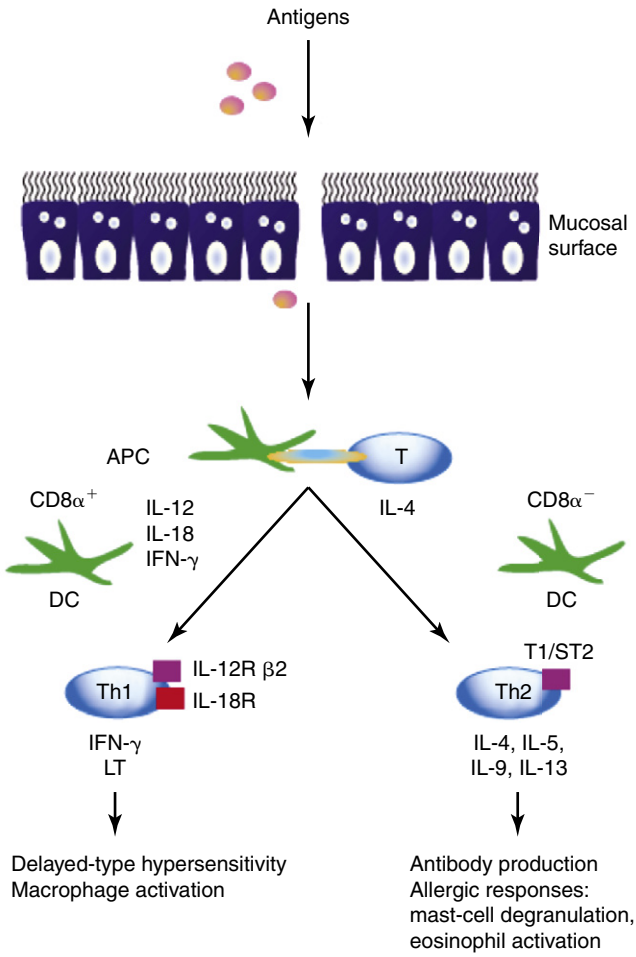

FIGURE 70-4 Th1/Th2 polarization. *(From Neurath MF, Finotto S, Glimcher LH: The role of Th1/Th2 polarization in mucosal immunity*, Nat Med *8:567-573, 2002.)*

delivery, this first exposure is dominated by the microorganisms that make up the mother's vaginal and fecal microflora. Subsequent to this exposure, microorganisms are introduced into the intestinal tract with the commencement of enteral feedings.

To effectively colonize the intestinal epithelium, bacteria adhere in a lectin-like manner to carbohydrate receptors or glycoconjugates. Glycoconjugate expression is controlled by glycosyltransferase enzymes, which are developmentally regulated, and ongoing maturation of this process is stimulated by colonizing bacteria (Forchielli and Walker, 2005; Walker, 2002).

During the 1st week of life, the bacterial colonization profile of a healthy, full-term infant is unstable and constitutes a simple array of organisms. This is quickly followed by a persistent, more stable colonization density in the range of 10^9–10^{10} per gram of stool (Favier et al, 2002; Palmer et al, 2007). Once the intestinal flora pattern is established, there is relative stability in this microbial population, with very few shifts in colonization profiles over time. However, shifts do occur, mainly in response to major changes in dietary intake such as introduction of solid foods (Palmer et al, 2007; Stark and Lee, 1982b) or with medication use (antibiotics). Within a short period of time after the initiation of a microbial shift, stability is reestablished (Palmer et al, 2007). By the end of the 1st year of life, colonization patterns begin to mirror those seen in adults (Palmer et al, 2007; Stark and Lee, 1982b).

The timing of microbial colonization and the specific composition of the established microbiome vary with mode of delivery, diet, and other environmental exposures (hospital environment, antibiotic use).

Mode of Delivery

Infants born by vaginal delivery possess a microbiome pattern that is similar to the mother's vaginal and fecal microflora (Mandar and Mikelsaar, 1996; Palmer et al, 2007). In contrast, infants delivered by cesarean section demonstrate delayed colonization and lack of microbial diversity (Fanaro et al, 2003; Palmer et al, 2007). Once colonization does occur, patterns tend to reflect the indigenous microbial population that resides in the infant's environment, with low levels of strict anaerobes (Bennet and Nord, 1987; Neut et al, 1987; Penders et al, 2006) such as *Bifidobacterium* and *Bacteroides*, and a higher proportion of *Clostridium difficile* (Penders et al, 2006).

Diet

Infants fed human milk tend to demonstrate *Bifidobacterium*, a commensal organism with multiple immune benefits, as the predominant organism within their intestinal microbiota. Other organisms that may be present in lesser quantities include staphylococci, streptococci, and lactobacilli (Balmer and Wharton, 1989; Harmsen et al, 2000). Other obligate anaerobes are rare (Balmer and Wharton, 1989; Fanaro et al, 2003; Hopkins et al, 2005; Penders et al, 2006). In contrast, the intestinal flora of formula-fed infants is more likely to have a greater number of pathogenic species such as enterococci, coliforms, and clostridia (Balmer and Wharton, 1989; Benno et al, 1984; Fanaro et al, 2003; Harmsen et al, 2000; Hopkins et al, 2005; Penders et al, 2005, 2006; Yoshioka et al, 1983). The unique contributions of breast milk, such as the presence of oligosaccharides and immunomodulators, likely explain, in part, the disparate colonization patterns observed between breastfed and formula-fed infants (Agostoni et al, 2004).

Environment

The environment in which the infant resides exerts a strong influence over the final composition of the intestinal microbiota. Important for the preterm or ill term newborn, hospitalized infants tend to have a predominance of pathogenic organisms, such as coliforms, *Bacteroides*, and *Clostridium* organisms (Fanaro et al, 2003; Penders et al, 2006), a pattern reflective of their high-risk residence. In addition, infants who reside in the same environment share similar microbiotas. This is best demonstrated in sibling studies and in studies of infants hospitalized in the same institution or ward. These observations all support the profound impact the physical environment exerts on establishment of the intestinal microbiota (Fanaro et al, 2003; Lundequist et al, 1985; Palmer et al, 2007).

BOX 70-2 Nutritional and Bioactive Compounds Found in Human Milk

PROTEINS
α-Casein
β-Casein
κ-Casein
α-Lactalbumin

LIPIDS
LCPUFAs (AA, DHA, EPA)
Conjugated linoleic acid
Cholesterol
Milk fat globule membrane

CARBOHYDRATES
Lactose
Oligosaccharides
Mucins

ENZYMES
α-Amylase
α_1-Antitrypsin
Bile salt–stimulated lipase
Lacto- and myeloperoxidase
Haptocorrin
Folate-binding protein
Glycoconjugates

IMMUNE FACTORS
Immunoglobulins (sIgA, IgA, IgG, IgM)
Lactoferrin
Lysozyme
Lactoadherin
Nucleotides
Toll-like receptors
Cytokines, interleukins
Macrophages
Lymphocytes
Neutrophils
Commensal microorganisms

GROWTH FACTORS
Insulin-like growth factors (IGF-1, IGF-2)
Epidermal growth factor (EGF)
IGF-binding protein
TGF-α
TGF-β
Nerve growth factor
Human growth factor
G-CSF
VEGF
Erythropoietin

LCPUFA, long-chain polyunsaturated fatty acid; *AA,* arachidonic acid; *DHA,* docosahexaenoic acid; *EPA,* eicosapentaenoic acid; *GCSF,* granulocyte colony-stimulating factor; *TGF,* transforming growth factor; *VEGF,* vascular endothelial growth factor.
*The proportion of these bioactive compounds will vary over time from colostrum to more mature milk.

Antibiotic Use

Antibiotics influence both the density and composition of microorganisms within the intestinal tract (Palmer et al, 2007). As would be expected, antibiotics tend to ameliorate commensal, low-resistance organisms while leaving behind more pathogenic organisms. As an effect potentially detrimental to the host, organisms such as *Bifidobacterium* and *Bacteroides* are significantly reduced (Bennet and Nord, 1987; Penders et al, 2006). And, perhaps even more concerning, after the course of antibiotics has been completed, there is slow restoration of the *Bifidobacterium* population, and the *Bacteroides* population is unlikely to be reestablished (Bennet and Nord, 1987). Additionally, delayed colonization with *Lactobacillus* spp., increased *Klebsiella* spp., and rapid colonization with staphylococci have been observed with antibiotic use (Magne et al, 2005).

The Intestinal Microbiota and Gut Immunity and Inflammation

Although the gut serves as the largest defense barrier and actively protects itself from invasion by pathogenic organisms, establishment of a stable and diverse intestinal microflora and the ensuing "microbial-epithelial crosstalk" between colonizing, commensal bacteria and the intestinal epithelium is essential for optimal development of mucosal immunity and regulation of intestinal inflammation. This interaction is essential for proper development of host immunity (Artis, 2008; Macpherson and Harris, 2004; Vanderhoof and Young, 2002). A diverse array of organisms within the intestinal microbiota allowing for a healthy microbial-epithelial interaction enables many downstream benefits to intestinal development and mucosal immunity. These benefits include: maintaining mucosal barrier integrity by reducing mucosal permeability, increasing mucus production, strengthening intestinal tight junctions, increasing the production of small proline-rich protein-2a (sprp2a), and inhibiting bacterial translocation (Deplancke and Gaskins, 2001; Kennedy et al, 2002; Lievin-Le Moal and Servin, 2006; Mack et al, 1999; Madsen et al, 2001; Orrhage and Nord, 1999; Panigrahi et al, 1994; Schenk and Mueller, 2008; Stratiki et al, 2007); regulating bacterial adherence and colonization of pathogenic organisms by producing antimicrobial peptides such as defensins, reducing intraluminal pH, and competing for cell surface binding sites; collectively, this protective role is also known as "colonization resistance" (Bernet et al, 1994; Collins and Gibson, 1999; Ouellette, 2004; Vollaard and Clasener, 1994); enhancing intestinal immune defenses by increasing production of IgA, short-chain fatty acids, and blood leukocyte phagocytosis (Fukushima et al, 1998; Schiffrin et al, 1995; Sudo et al, 1997; Viljanen et al, 2005; Weng et al, 2007); and regulating intestinal inflammation by mediating Th-cell differentiation, increasing antiinflammatory cytokine production, and decreasing the production of proinflammatory cytokines (Caplan and Jilling, 2000; Fujii et al, 2006; Klinman et al, 1996; Marin et al, 1998; Millar et al, 2003; Murch, 2001; Takeda et al, 2006). In the last scenario, one mechanism by which commensal bacteria reduce the production of proinflammatory mediators is by inhibiting the activation of NF-κB. This is in contrast to the proinflammatory upregulation of NF-κB by pathogenic organisms and associated antigens (LPS) (Claud and Walker, 2001; Magalhaes et al, 2007; Walker, 2002).

DIET: HUMAN MILK AND INFANT FORMULA

Similar to amniotic fluid, breast milk is rich with bioactive components that are essential in providing the immature newborn a complement of innate immune functions during the early postnatal transitional period while the immature newborn develops its own innate immune defenses (Newburg and Walker, 2007). The factors in breast milk have been shown to promote postnatal structural development of the intestinal tract; yield a favorable, beneficial bacterial colonization pattern; deliver bactericidal proteins; and provide other immune defenses (Box 70-2)

(Donovan, 2006). In addition, human milk adapts to meet the needs of the infant and to appropriately provide the essential nutrients to optimize the infant's developmental stage. For example, growth and immune factors tend to be higher in preterm milk than in term milk (Donovan, 2006; Walker, 2010).

Factors present in breast milk have been shown in piglet and rodent models to contribute to the ongoing structural development of the intestinal tract. When provided breast milk (especially colostrum) versus formula or in the absence of any enteral substrate, animals receiving breast milk demonstrate an increase in mucosal mass and villus height (Sangild, 2006). Morphologic studies of human infants to examine the potential benefits of breast milk are more difficult to perform for obvious reasons. However, studies evaluating diet and intestinal barrier function have been performed in human infants and can be used as an indirect measure for morphologic development and integrity. Indeed, infants fed predominantly formula versus breast milk demonstrated increased intestinal permeability, suggesting compromise in intestinal barrier function (Taylor et al, 2009).

As described, infants fed breast milk exhibit a greater representation of commensal organisms, such as *Bifidobacterium* and *Lactobacillus*, conferring multiple benefits to the developing intestinal tract and accompanying mucosal immunity. Many bioactive compounds in breast milk contribute to the beneficial microbial-epithelial interaction, such as the presence of oligosaccharides and other natural prebiotics. Interestingly, the microbiome that exists within breast milk itself may also be important in providing immunologic immunity to the infant. Commensal bacterial isolates, such as certain *Staphylococcal* species, streptococci, and *Lactobacillus*, have been found in breast milk, and these organisms have been shown to be bactericidal against *Staphylococcus aureus*, an important pathogen in neonates. Also observed in this study was the *production* of nicin, a known bactericidal agent, by the breast milk isolate *L. lactis* (Heikkila and Saris, 2003). Other bactericidal agents that have been found in breast milk include defensins and cathelicidin, which also demonstrate antimicrobial activity against neonatal pathogens such as *Staphylococcus aureus*, group A *Streptococcus*, and *Escherichia coli* (Murakami et al, 2005). In addition to antimicrobial peptides, breast milk contains a host of other immunomodulators (including nutritional) that ultimately benefit the infant.

Over time, the composition of formula has been iteratively modified; however, formula continues to fall short of being able to provide the multitude of factors that are present in breast milk, and thus, infants fed formula fail to share the same health benefits seen in breastfed infants. Infants fed predominantly breast milk have a reduced incidence of infections (e.g., diarrhea, upper respiratory illness, otitis media, urinary tract infections, bacteremia) (Hengstermann et al, 2010; Quigley et al, 2009), atopic illnesses (e.g., eczema, asthma) (Bener et al, 2007), and autoimmune diseases (e.g., celiac disease, type 1 diabetes mellitus) (Auricchio et al, 1983; Sadauskaite-Kuehne et al, 2004). Specifically for the preterm infant, infants fed breast milk are less likely to develop necrotizing enterocolitis (NEC) compared to infants fed formula (Schanler et al, 1999).

TABLE 70-3 NICU Exposures and Potential Consequences on Intestinal Barrier Defense and Bacterial Colonization in Premature Infants

	Exposure	Potential Consequences
Nonspecific barrier defense	Prematurity	↓ immunoglobulin levels
		↓ production of digestive enzymes
		↓ production of mucus
		Dysfunctional peristalsis
	Delayed feeding	Villous atrophy
		↓ production of digestive enzymes
		↓ production of mucus
		↓ peristalsis
	Medications	
	Histamine H_2 receptor blockers	↓ gastric acidity
	Vasopressors and Indocin	↑ risk for intestinal ischemia and enterocyte injury
	Sedatives and paralytic agents	↓ peristalsis
Bacterial colonization	Prematurity	Accentuated inflammatory response
		Abnormal glycosylation pattern
	Delayed feedings	Delay in bacterial colonization
	Broad-spectrum antibiotics	Prolonged sterilization of gut
		Delayed colonization of beneficial, commensal bacteria
		Preferred bacterial colonization of pathogenic bacteria
	Formula feeding and hospitalization	Preferred bacterial colonization of pathogenic bacteria

From Martin CR, Walker WA: Intestinal immune defences and the inflammatory response in necrotising enterocolitis, *Semin Fetal Neonatal Med* 11:369-377, 2006.

IMPACT OF ALTERED MUCOSAL IMMUNITY ON EARLY AND LATER DISEASE

PREMATURITY AND NECROTIZING ENTEROCOLITIS

Inadequate Physical and Chemical Barriers

Developmental immaturity of the immune system, hospital environmental exposures, and medical interventions combine to hamper postnatal development of innate and mucosal immunity in the preterm infant (Table 70-3) (Martin and Walker, 2006). These factors pose potential threats to the preterm infant, particularly to conditions mediated by altered mucosal immunity and intestinal bacterial colonization.

The first line of defense of nonspecific physical and chemical barriers is disrupted because of inadequate production of gastric acidity, digestive enzymes, mucus, immunoglobulins, and decreased peristalsis. In addition, common medication exposures (antibiotics, histamine H_2 receptor blockers, vasoconstrictors, sedatives, and paralytics)

decrease these inherent defenses by decreasing expression of antibacterial peptides (Louis and Lin, 2009; Schumann et al, 2005), altering natural acidity, and decreasing peristalsis. As a result, there is a reduced ability to eliminate pathogenic organisms, allowing for increased epithelial adherence and bacterial translocation. Inadequate development of mucosal immunity is further exacerbated by induced mucosal and villus atrophy that likely develops as a consequence of prolonged absence of enteral feedings (Niinikoski et al, 2004).

Abnormal Colonization of the Preterm Gut

Although it was once thought that the in utero environment was sterile, bacteria have been identified in early meconium samples in preterm infants, suggesting a potential prenatal influence on early intestinal bacterial colonization (Mshvildadze et al, 2008). Once a more broad microbial community has been established, the fecal organisms commonly observed in preterm infants include enterococci, members of Enterobacteriaceae, *E. coli*, staphylococci, streptococci, *Clostridium*, and *Bacteroides* (Millar et al, 2003; Penders et al, 2006; Schwiertz et al, 2003; Stark and Lee, 1982a). This bacterial profile is distinctly different from those seen in breastfed term infants, yet, similar to patterns exhibited by formula-fed full-term infants. However, in contrast to formula-fed term infants, the colonization by these pathogenic bacteria persists longer (Sakata et al, 1985) and there was slow development of colonization by the commensal bacterium *Bifidobacterium* (Stark and Lee, 1982b).

The differences in bacterial colonization patterns between healthy, full-term infants and preterm infants can be partially explained by the inadequate physical and chemical barriers described earlier, which allow for greater penetration and adherence by pathogenic organisms; immaturity of epithelial glycoconjugate expression (an important modulator of bacterial adherence) (Claud et al, 2004; Walker, 2002); and the unique environmental exposures experienced by the preterm infant. Almost universally, preterm, low-birthweight infants experience delayed enteral feedings, are exposed to early and prolonged broad-spectrum antibiotics, and are introduced to residential hospital flora. Each of these factors contributes to delayed intestinal colonization by commensal, nonpathogenic bacteria, a predominance of pathogenic bacteria, and a lack of microbial diversity (Agarwal et al, 2003; Butel et al, 2007; Fanaro et al, 2003; Magne et al, 2005).

As reviewed, in the mature enterocyte, commensal bacteria inhibit the activation of NF-κB, which is in contrast to pathogenic bacteria that activate NF-κB (Claud and Walker, 2001; Walker, 2002). Of particular importance to the premature neonate is the developmentally reduced expression of inhibitor kappa B (IκB), an inhibitory protein to NF-κB, which, when bound, inhibits NF-κB translocation into the cell nucleus and transcription of proinflammatory mediators. As a result, the immature enterocyte is in an activated, proinflammatory state, and this excessive inflammatory response is seen with both commensal and pathogenic bacteria (Claud et al, 2004).

Necrotizing Enterocolitis

NEC is a devastating gastrointestinal disease predominantly observed in preterm infants. The pathogenesis is incompletely understood and is likely multifactorial. As discussed, the preterm infant possesses and experiences multiple perturbations to postnatal intestinal and immune development, all of which likely work in concert with one another to increase the vulnerability of the preterm infant to NEC. Just a few examples that illustrate this are: the increased prevalence in formula-fed infants (lack of exposure to the bioactive compounds found in breast milk); the disparate intestinal bacterial colonization profiles observed in infants who developed NEC versus control infants (Wang et al, 2009) (lack of benefits offered by commensal bacteria and increased risk of increased inflammation and bacterial translocation by pathogenic bacteria); the reduction of NEC with the use of probiotics; and the increased incidence of NEC after exposure to prolonged antibiotics (delayed bacterial colonization with preference for pathogenic microorganisms) and to H_2 blockers (decrease gastric acidity, thus dampening one component of the first line of defense against pathogenic antigens provided by the intestinal tract) (Cotten et al, 2009; Guillet et al, 2006).

In the absence of TLR4, as demonstrated by the TLR4 knockout mouse, the development of NEC is prevented (Leaphart et al, 2007). This supports the general hypothesis that the expression and modulation (i.e., suppression or activation) of TLR4 are important in the pathogenesis of NEC. Downregulation of TLR4 suppresses downstream proinflammatory signaling as observed with postnatal intestinal bacterial colonization by commensal organisms, whereas TLR4 activation results in increased proinflammatory signaling. In addition, TLR4 activation may mediate other downstream pathways, reducing the epithelial cells' capacity for regeneration and proliferation (Sodhi et al, 2010). Activation of TLR4 is mediated by LPS and possibly other stressors such as hypoxia, conditions often utilized to induce NEC in animal models, and shared risk factors in preterm infants at risk for NEC. Thus, the balance between TLR4 suppression and activation is likely to be critical in determining the postnatal susceptibility to NEC in the preterm infant (Abreu, 2010).

ATOPIC DISEASES

The incidence of allergic diseases has dramatically increased over the past several decades in developed countries. The potential mechanism for this phenomenon has been termed the *hygiene hypothesis* (Bach, 2002; von Mutius, 2007). The interaction with microbes and subsequent colonization by these organisms are essential in the development of mucosal immunity. With colonization of a diverse microbial population, the newborn shifts from a predominant Th2 cellular response (conditioned during fetal development to prevent maternal rejection of the fetus) (Morein et al, 2007), to a Th1 cellular response. However, in developed countries with improved hygiene and sanitation, the diversity of microbes in the intestinal ecosystem is lacking, and Th2 cellular responses continue to dominate (Tlaskalova-Hogenova et al, 2002). Supporting the vital contribution that the intestinal ecosystem plays in development of allergic responses are the observations

of different colonization patterns observed in atopic subjects versus healthy controls (Bjorksten, 2004; Vaarala et al, 2008) and the reduction of atopic diseases with probiotic supplementation (Bjorksten, 2005). Other defects in mucosal immunity observed that allergic individuals have increased intestinal permeability and a deficiency of IgA.

DISEASES OF AUTOIMMUNITY: INFLAMMATORY BOWEL DISEASE, CELIAC DISEASE, AND TYPE 1 DIABETES

Alterations in several areas of innate mucosal immunity play a significant role in the pathogenesis of Crohn's disease, celiac disease, and type 1 diabetes mellitus. Individuals with Crohn's disease have impaired intestinal barrier function; differential expression in toll-like receptors (TL3, TL4); and Th1-dominated cellular responses. Differential expression in TLRs and Th1-dominated cellular responses likely contribute to the inappropriate, excessive inflammatory response to antigenic stimuli (toward *both* commensal and pathogenic bacteria), which is one of the hallmarks of this disease (Cario and Podolsky, 2000; Sartor, 2008). IL-12 and STAT4 activation are important for Th1 T-cell differentiation. Increased IL-12 production noted in Crohn's patients and in animal models, in addition to the observation of successful suppression of intestinal inflammation with IL-12 agonists, provides supporting evidence for the importance of Th1-mediated chronic intestinal inflammation (Macdonald and Monteleone, 2005; Neurath et al, 2002). An imbalance in Th1/Th2 cellular responses in Crohn's patients is further suggestive with the finding that a genetic mutation in the nucleotide-binding oligomerization domain 2 (NOD2) gene, a protein that in its native form inhibits TLR2 activation, is more common in patients with Crohn's disease compared to controls (O'Neill, 2004).

The role of impaired intestinal barrier function has been well established in Crohn's disease (Schulzke et al, 2009). The presence of a "leaky gut" also has been established to be important in the pathogenesis of other autoimmune diseases such as celiac disease and type 1 diabetes mellitus. Furthermore, barrier dysfunction and increased intestinal permeability likely precede the clinical presentation of these autoimmune diseases.

The process by which a breach in intestinal barrier function leads to celiac disease has become the model of intestinally mediated autoimmune diseases. Gliadin (the protein in wheat, barley, and rye) activates myeloid differentiation primary-response gene 88 (MyD88), which, in turn, upregulates the release of zonulin. Zonulin upregulation opens the tight junctions, allowing for intraepithelial passage of gliadin into the intestinal submucosa to interact with effector immune cells and increase the production of proinflammatory cytokines, ultimately leading to intestinal inflammation and cell damage (Fasano and Shea-Donohue, 2005). Removal of gluten from the diet halts this process, allowing for restoration of intestinal barrier function and intestinal recovery.

The interplay among altered intestinal bacterial colonization, impaired barrier function, and a dysregulated proinflammatory response has been implicated in the pathogenesis of type 1 diabetes mellitus (Vaarala et al, 2008). However, currently much of the evidence for aberrant intestinal microbiota comes from animal models where the microbial composition and the microbial-epithelial interaction are manipulated by antibiotic administration in non-obese diabetic mice. Similar to subjects with Crohn's disease, compared with controls, individuals with type 1 diabetes mellitus have impaired intestinal barrier function as demonstrated by permeability studies using mannitol and lactulose. Altered barrier function has also been shown in animal models in those that eventually develop diabetes. Diabetic animals have decreased expression of claudin, an important protein in tight junction complexes, before the onset of disease. Finally, examination of intestinal biopsies from children with type 1 diabetes mellitus demonstrated an increased presence and expression of inflammatory cells and biomarkers (e.g., HLA class II molecules, intercellular adhesion molecule [ICAM]-1, IL-4, IL-1α) within the villus architecture.

OBESITY

Altered bacterial colonization patterns are evident in obesity. In animal models of genetic obesity, obese mice have distinctly different microbial colonization patterns compared to their lean littermates with bacteria counts higher in Firmicutes and lower in Bacteroidetes. These microbial shifts are also seen in diet-induced animal models of obesity by placing the mice on a prolonged Western diet (Reinhardt et al, 2009). In humans, childhood obesity is increased in formula versus breastfed infants. And, as discussed earlier, different microbial colonization patterns exist between these two groups, suggesting that their ecosystem may play a role in the propensity for obesity. In a longitudinal study of childhood obesity, infants who later developed obesity, compared to infants who maintained a normal weight in childhood, had a fecal microbial pattern that contained lower concentrations of *Bifidobacterium* and higher concentrations of *S. aureus*. Obesity has been associated with low-grade chronic inflammation; thus, the reduction of the commensal organism *Bifidobacterium* and the increased presence of the pathogenic organism *S. aureus* may, in part, contribute to the pathogenesis of chronic inflammation (Kalliomaki et al, 2008).

In addition, the intestinal ecosystem is an important modulator of the host's metabolic activities, some of which are important to the pathogenesis of obesity. Metagenomic studies of the microbiota in obese patients demonstrate an increased presence of genes that are involved in energy harvest. Other metabolic pathways mediated by the microbiota include increased hepatic lipogenesis; decreased fatty acid oxidation in skeletal muscle; and LPS-mediated chronic inflammation in adipose tissue (Reinhardt et al, 2009).

CONCLUSION

The GI tract serves many complex nutritional and immune functions critical for survival. The morphologic development of the intestinal tract to serve these specialized functions begins in early embryogenesis and continues throughout childhood. Exposure to amniotic fluid followed by postnatal exposures to human milk, formula, and

environmental microorganisms is essential for the continued anatomic differentiation of the intestinal tract and development of mucosal immunity. Ultimately, multiple layers of immunologic defenses and a balance between oral tolerance and inflammatory responsiveness are established and maintained throughout the life of the host. Perturbations to this balance or to any component of the multiple layers of mucosal defenses increase the vulnerability of the host to atopic diseases, autoimmune disorders, or conditions mediated by chronic, unregulated inflammation.

CHAPTER 71

Abdominal Wall Problems

Dan Poenaru

DISORDERS OF THE UMBILICAL REGION

The umbilical region is the site of intricate, complex activity during embryonic life. Early in gestation, a widely open communication exists between the yolk sac and primitive gut. Later, the entire midgut passes through this communication to form a large physiologic umbilical hernia that persists in utero for several weeks. Thereafter, the gut returns to its position in the abdominal cavity. By the third trimester, the aperture around the vessels, omphalomesenteric (vitelline) duct, and urachus begins to narrow. After birth, the umbilical arteries contract, blood flow ceases, their intimal and medial layers undergo aseptic necrosis, and the stump separates. Alterations in this orderly but complex sequence of events result in serious congenital anomalies.

UMBILICAL CORD LESIONS

NONCOILED UMBILICAL BLOOD VESSELS

The three vessels within the cord are coiled to form a helical structure. The number of twists can vary greatly (ranging from 0 to 40) and, rarely, reaches 380 per cord (Donlon and Furdon, 2002). Left-twisted vessels outnumber right-twisted vessels 7 to 1. Absence of any twists occurs in about 4% of pregnancies (Strong et al, 1993). The helical structure is identifiable by ultrasound examination by the end of the first trimester. Although how the vessels come to have this geometric arrangement has not been established, such a configuration—like that of a telephone cord—is more able to resist external compression, stretch, or torsion, and the cord remains flexible (Strong et al, 1993). The absence of coils is associated with increased abnormalities that include single umbilical artery, trisomy 21, and coarctation of the aorta. Approximately 10% of infants without coils are stillborn, and the incidence of preterm birth is greater than expected.

SINGLE UMBILICAL ARTERY

Normally the umbilical cord is composed of two arteries and a vein. A single umbilical artery occurs in 1% of single births and in 7% of twin births. The presence of a single umbilical artery is higher among aborted fetuses and thus is thought to be a marker for increased fetal risk (Deshpande et al, 2009; Mu et al, 2008). Among newborns with single umbilical artery, there is a higher incidence of poor fetal growth and a slightly increased risk for renal anomalies. Therefore, the presence of a single umbilical artery warrants careful intrauterine monitoring, although postpartum imaging may not be warranted (Deshpande et al, 2009).

UMBILICAL GRANULOMA AND POLYP

If the separation of the umbilical stump is delayed beyond 5 to 8 days after birth, granulation tissue may be produced, delaying epithelialization (Figure 71-1). Judicious desiccation with silver nitrate is the treatment of choice if the granuloma does not resolve.

Granulomas must be differentiated from umbilical polyps, which typically contain gastric or intestinal mucosa (Figure 71-2). Treatment is surgical excision, without need of exploring the peritoneal cavity (Pacilli et al, 2007).

DELAY IN SEPARATION OF THE CORD

If the umbilical cord fails to separate after more than 14 days, investigation for a possible defect in neutrophil function and chemotaxis should be undertaken.

ABDOMINAL WALL DEFECTS

UMBILICAL HERNIA

The umbilical ring is formed when the mesoderm of the muscle and fascia around the umbilical vessels and urachus contracts. Umbilical hernias are caused by failure of closure of the umbilical ring; unlike the case of omphaloceles, skin and subcutaneous tissue cover the defect. These lesions are found in 30% of African American infants and in 4% of white infants; there is a high familial incidence. The condition is more common in low-birthweight babies and in infants with trisomy 21.

The actual fascial defect varies in size, ranging from 1 to 4 cm in diameter. The sac may contain a loop of bowel that is easily pushed back into the abdomen, or preperitoneal fat. Approximately 80% of these hernias close spontaneously by 3 to 4 years, and the risk of incarceration is exceedingly low. Spontaneous closure is less likely in hernias with fascial defects greater than 1.5 cm. Surgical correction is therefore only indicated in large-defect hernias, in children over 4 to 6 years of age, or if symptoms occur (Poenaru, 2001).

OMPHALOCELE

Definition and Epidemiology

Omphalocele refers to a congenital defect in the formation of the umbilical portion of the abdominal wall that is larger than 4 cm in diameter (Table 71-1; Figure 71-3). The defect occurs in 1 in 6000 to 1 in 10,000 live births. Although many omphaloceles are isolated defects, some are part of a constellation of malformations (such as the Beckwith-Wiedemann syndrome or trisomy 18), and a few cases are associated with maternal ingestion of valproic acid

FIGURE 71-1 Umbilical granuloma, characterized by fleshy appearance but without any central depression or lumen.

FIGURE 71-2 Umbilical polyp. The lesion is skin-covered.

TABLE 71-1 Characteristics of Gastroschisis and Omphalocele

Defect	Gastroschisis	Omphalocele
Covering sac	Absent	Present, but may be torn
Fascial defect	Small	Small or large
Cord attachment	Onto the abdominal wall	Onto the sac
Herniated bowel	Edematous	Normal
Prematurity (%)	50–60	10–20
Associated anomalies (%)	10–15	45–55
Gastrointestinal	18	37
Cardiac	2	20
Trisomy syndromes	—	30
Necrotizing enterocolitis (%)	18	Only if sac is ruptured
Malabsorption	Common	Only if sac is ruptured

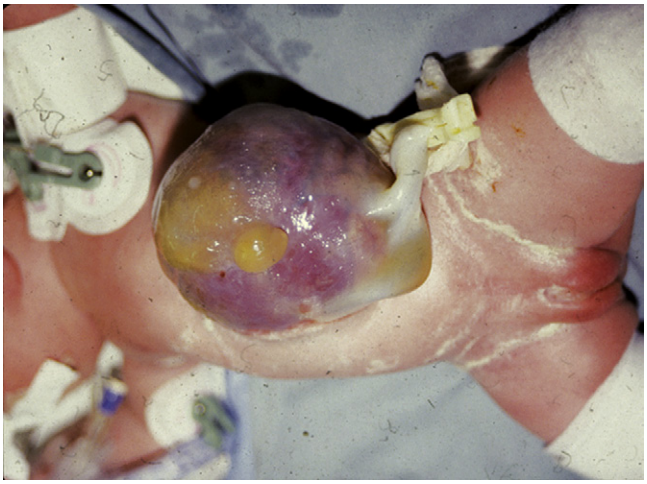

FIGURE 71-3 *(See also Color Plate 29.)* **Female newborn with omphalocele.** The fascial defect is large, situated at the base of the umbilical cord, covered by a glistening membrane and containing both liver and bowel.

for seizure control (Boussemart et al, 1995). Omphalocele is also present in infants who have the OEIS complex, a constellation of anomalies that includes omphalocele, bladder exstrophy, imperforate anus, and spinal defects (Tiblad et al, 2008). Associated malformations are present in 75% of the patients, compared to only 15% in the case of gastroschisis (Stoll et al, 2008). By the very nature of the developmental defect (see later discussion), all infants with omphalocele have malrotation.

Etiology

Early in fetal life, the small intestine lies outside of the abdominal cavity. By the 10th week, the midgut returns to the abdomen, and the somatic layers of the cephalic, caudal, and lateral folds join to close the defect in the abdominal wall. For unknown reasons, this closure may not occur. Several types of omphalocele are recognized, based on the specific fold that fails to close. *Epigastric omphalocele* occurs when there is abnormal closure of the cephalic fold. Because these somites also form the lower thoracic wall, failure of closure results in the Cantrell pentalogy, which includes cleft sternum, diaphragmatic defects, pericardial defects, cardiac anomalies, and omphalocele. *Classic omphalocele* occurs when there is an interruption in lateral fold development, resulting in an abdominal wall defect that lies between the epigastric and hypogastric regions. In addition to loops of bowel, liver also may herniate through the abdominal wall defect. The umbilicus arises from an anterior position on the omphalocele, and the muscular abdominal wall is normal. Failure in closure of the caudal fold results in a *hypogastric omphalocele*. Associated defects include bladder exstrophy and imperforate anus.

Diagnosis

Alpha-fetoprotein (AFP) is synthesized in the fetal liver and is excreted by the fetal kidneys. It also crosses the placenta and appears in the maternal circulation by 12 weeks' gestation. Maternal plasma levels of AFP are elevated when fetuses have neural tube defects, abdominal wall defects, or

atresia of the duodenum or esophagus. Maternal serum AFP is used as a screening test, although there is a 40% rate of false-positive results. Analysis of amniotic AFP and acetylcholinesterase-pseudocholinesterase levels can be sensitive in detecting abdominal wall defects, especially gastroschisis (Saleh et al, 1993; Saller et al, 1994). Human chorionic gonadotropin levels have shown promise in small series in detecting abdominal wall defects (Schmidt et al, 1993).

Ultrasound evaluation is not useful during the first trimester, when the midgut is normally herniated. Beyond 14 weeks, however, this modality has a 96% sensitivity (Patel et al, 2009). The combined use of maternal serum AFP and ultrasound examination at 19 weeks has been shown in a series of 8000 patients to have excellent sensitivity in identifying abdominal wall defects (Luck, 1992). Once an abdominal wall defect has been identified, ultrasound examination often can distinguish omphalocele from gastroschisis. Because the association of cardiac anomalies and chromosomal disorders is high, fetal echocardiography and amniocentesis should also be performed. Vaginal delivery does not adversely affect outcome; therefore, the need for cesarean section should be based on obstetric indications alone (Segel et al, 2001). If not discovered prenatally, the diagnosis is obvious at birth. If the sac ruptures, the bowel loops may become edematous and matted together, mimicking gastroschisis.

FIGURE 71-4 Newborn with gastroschisis managed in a sterile bag (bowel bag) up to the nipple line. The bag protects the baby from heat and water loss while allowing good visualization of the herniated bowel.

Treatment

The presence of exteriorized bowel results in heat loss and extravasation of fluid and provides a major portal of entry for bacteria. When the omphalocele is first seen, the sac should be kept moist by wrapping it with gauze sponges that have been soaked in warmed normal saline. A plastic covering is then wrapped around the defect to limit water and heat loss (Figure 71-4). Care should be taken to prevent angulation of the sac when the child is prone, to prevent kinking of mesenteric vessels. Alternatively, the infant can be positioned on the side, with the exteriorized bowel in an anterior position. A nasogastric tube is passed to decrease the accumulation of air in the bowel. The infant should be given 1.5 times the maintenance intravenous fluid volume and broad-spectrum antibiotics. Thereafter, any inspection and manipulation of the abdominal contents should be done with sterile gloves.

Operative repair should be undertaken as soon as possible, ideally within 2 to 4 hours of birth. Small defects can be closed with a single-stage repair. For larger defects, primary repair may cause respiratory failure and abdominal compartment syndrome because the abdominal cavity is too small to accommodate the bowel. Complications of compartment syndrome include renal failure, hypotension from compression of the vena cava, hepatic ischemia, and intestinal ischemia. In affected infants, a staged repair is performed using a prosthetic device called a *silo* to cover the defect (Figure 71-5). Final closure can then be achieved after gradual reduction of the bowel into the abdominal cavity over 7 to 10 days (Dunn and Fonkalsrud, 1997). Selected "giant omphaloceles" can also be initially managed non-operatively with silver sulfadiazine, followed by abdominal wall closure later in infancy (Lee et al, 2006)

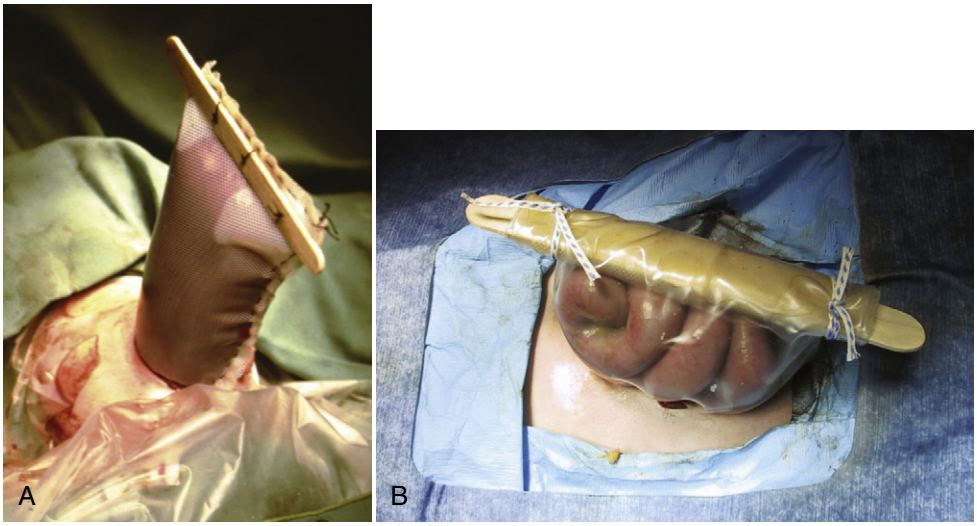

FIGURE 71-5 Use of a Silastic silo in the management of gastroschisis. A, Sutured silo immediately after construction. **B,** Ready-made silo after several reduction turns.

FIGURE 71-6 Hernia of the umbilical cord. This is in fact a small omphalocele, containing only bowel loops in a small sac within the umbilical cord.

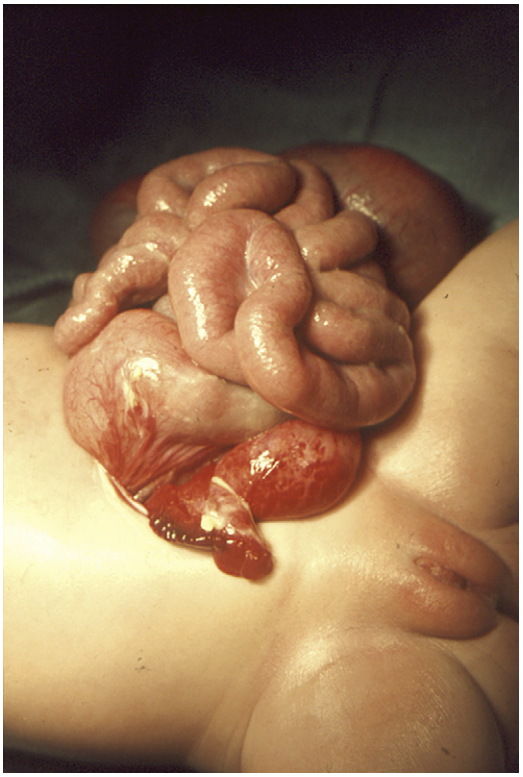

FIGURE 71-7 *(See also Color Plate 30.)* **Female newborn with gastroschisis.** The fascial defect is relatively small and situated to the right of the umbilical cord and contains exposed bowel (as well as an ovary in this instance).

Postoperatively, protracted ileus may occur, necessitating prolonged parenteral nutrition. Attention must also be directed to the diagnosis and management of associated anomalies.

Prognosis

The mortality rate with associated heart disease is 80%. In the absence of heart disease, 70% to 90% of infants with omphalocele survive (Forrester and Merz, 1999; Kitchanan et al, 2000).

CORD HERNIA

A small omphalocele is called a *cord hernia*. By definition, the defect in the abdominal wall is less than 4 cm in diameter, and the exteriorized sac contains only loops of bowel (Figures 71-6). This defect arises between the 8th and 10th weeks as a result of failure of closure of the umbilical ring. Cord hernias can be missed at birth, and the intestine can be injured by careless proximal application of the cord clamp. Otherwise, these defects are easily managed by primary closure at birth and have an excellent outcome.

GASTROSCHISIS

Definition and Epidemiology

Gastroschisis is the herniation of abdominal contents through an abdominal wall defect, usually occurring on the right side of a normally positioned umbilical cord (Figure 71-7). This lesion was traditionally less frequent than omphalocele, but its incidence is increasing worldwide (Srivastava et al, 2009; Vu et al, 2008). The defect appears most common among young mothers and those of low gravidity (Fillingham and Rankin, 2008). Associated anomalies are found in only 15% of patients, the vast majority being intestinal atresias (Stoll et al, 2008). Infants with gastroschisis tend to have intrauterine growth restriction (Santiago-Munoz et al, 2007) .

Etiology

Although the cause of these lesions is not known, many investigators speculate that they may be of vascular origin. Intrauterine interruption of the omphalomesenteric artery has been proposed, an explanation that accounts for many of the clinically observed differences between this lesion and omphalocele (Hoyme et al, 1981).

Diagnosis and Treatment

As described for omphalocele, gastroschisis can be correctly diagnosed prenatally (Figure 71-8). Because the peritoneal sac is absent, the fetal bowel is continuously bathed in amniotic fluid, which results in a significant intestinal "peel," causing poor intestinal motility. As with omphalocele, the need for cesarean section should be restricted to obstetric indications only, despite some evidence that prelabor cesarean section results in better outcome because of the ensuing absence of the fibrous peel (Serra et al, 2008).

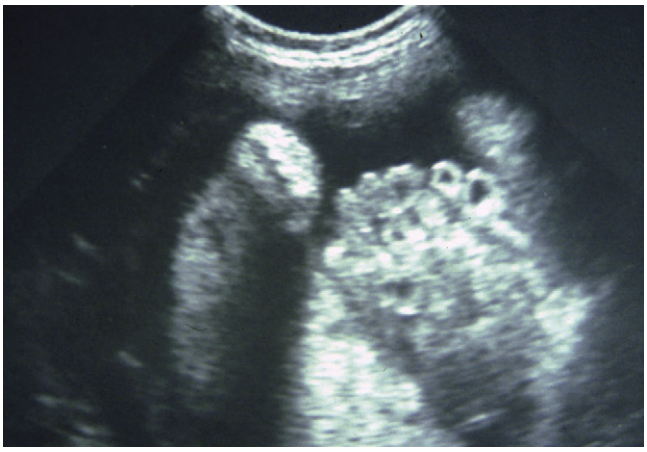

FIGURE 71-8 Ultrasound image of fetus with gastroschisis. The intestinal loops are seen free in the amniotic sac.

FIGURE 71-9 *(See also Color Plate 31.)* **Newborn with prune-belly syndrome.** The laxity of the abdominal wall musculature is obvious.

The diagnosis is readily made at birth. The entire gastrointestinal tract usually is eviscerated, but unlike with omphalocele, the liver is not exteriorized. The intestinal loops usually are covered by a thick fibrous "peel," which makes them firm, often with a cauliflower-like appearance. Intestinal atresias may be apparent as well. Rare complications include intrapartum mesenteric disruption, prenatal volvulus, and closure of the abdominal wall defect around the exteriorized gut (i.e., closing gastroschisis) (Houben et al, 2009). All of these events can cause catastrophic intestinal loss.

As described for omphalocele, the bowel contents should be kept moist and relatively sterile at birth. A nasogastric tube is passed for decompression, and 1.5 times the maintenance intravenous fluid volume is given. Broad-spectrum antibiotics also should be started. Because the abdominal wall defect often is small, vascular compromise occurs more readily, and great care should be taken to position the infant and the exteriorized bowel to prevent kinking of mesenteric vessels. Unlike with omphalocele, primary closure is possible in 90% of patients, but larger defects may require staged repair. A spring-loaded Silastic silo device that can be placed at the bedside allows early closure of the defect and avoids the need for emergency surgery (Jensen et al, 2009; Pastor et al, 2008). Alternatively, simple cases of gastroschisis can be managed with a sutureless bedside technique not requiring general anesthesia (Sandler et al, 2004). All techniques of intestinal protection and abdominal wall closure appear, however, to be equally effective, and only failure to obtain primary closure is associated with significant delays in resuming intestinal function (Weinsheimer et al, 2008). Postoperatively, prolonged ileus often occurs because of intestinal dysmorphology, which often includes the myenteric plexus. Despite this ileus, minimal enteral feeding in the early postoperative period can decrease time to discharge and overall mortality (Walter-Nicolet et al, 2009). Affected infants are at increased risk for necrotizing enterocolitis (Oldham et al, 1988). Intestinal atresias usually are not repaired at the initial procedure because of the fibrous peel and therefore require repair at 3 to 4 weeks of age (Snyder et al, 2001). One third of babies with gastroschisis will experience growth delay in infancy, and prolonged intestinal dysmotility is common (Phillips et al, 2008; South et al, 2008).

Prognosis

Mortality rates have decreased to 5% to 10% (Fillingham and Rankin, 2008; Kitchanan et al, 2000). Postoperative recovery may be longer in infants undergoing repair of gastroschisis than in those with omphalocele. Enteral feedings may not be established until 2 months after operation, and some infants will require home parenteral nutrition (Molik et al, 2001). In spite of these initial feeding difficulties, most gastroschisis survivors maintain normal growth during infancy and childhood (Davies and Stringer, 1997).

PRUNE-BELLY SYNDROME

Prune-belly syndrome refers to a triad of anomalies consisting of a deficiency of abdominal musculature, cryptorchidism, and urinary tract abnormalities—in fact, it has also been called the "triad syndrome." The most common urinary tract anomalies seen are megaloureter, cystic renal dysplasia, urethral obstruction, and megacystis (Woods and Brandon, 2007). Malrotation occurs in 30% of cases, and cardiac anomalies in 20%. The syndrome rarely occurs in females, and its exact cause is unknown. Theories include failure in the development of the abdominal wall between the 6th and 8th weeks of gestation and primary urethral obstruction with early bladder distention (Woods and Brandon, 2007). At birth, the defect is obvious on inspection. The abdomen is shapeless, and the skin hangs in wrinkled folds (Figure 71-9). There may be an open patent urachus, which by itself signals a poor prognosis. Of immediate concern is evaluation for and relief of urinary tract obstruction. Approximately 20% of patients with prune-belly syndrome die in the neonatal period from renal dysplasia or pulmonary hypoplasia, but of those who survive, 30% develop renal failure during childhood (Burbige et al, 1987). Surgical management of the genitourinary tract remains controversial, with advocates of both watchful waiting and major reconstruction. The latter should be performed only where specialized surgical and anesthesia expertise are available, because the surgery is challenging and postoperative complications are frequent.

FIGURE 71-10 Infant with large right-sided inguinal hernia. The right inguinal canal is visibly distended by the herniated bowel.

The undescended testes are corrected in childhood for monitoring and psychological reasons.

INGUINAL HERNIA

The gonads are formed during weeks 5 to 12 of gestation. The testes descend through the internal ring at 28 weeks. In the general population, inguinal hernias occur in 1% of all live births. The incidence of inguinal hernia in low-birthweight infants varies between 3% for birthweights of 1500 to 2000 g to 42% for birthweights of 500 to 1000 g (Peevy et al, 1986). With preterm delivery and the accompanying increase in intraabdominal pressure, testicular descent and inguinal canal closure are impaired, thus explaining the increased incidence of inguinal hernia (Figure 71-10).

Additional risk factors for inguinal hernias are cystic fibrosis, congenital dislocation of the hip, presence of a ventriculoperitoneal shunt, and abdominal wall defects. Incarceration and strangulation are common in infant hernias. The combined incidence of these complications is as high as 30% (Rowe and Clatworthy, 1970), although it appears to be lower in preterm infants. Therefore, repeated examinations may be necessary, particularly if the infant's clinical status becomes unstable or if a tense, fluctuant scrotal mass or vomiting develops. Most of these incarcerated hernias may be reduced nonoperatively by placing the infant in the Trendelenburg position with sedation and application of an ice pack to the inguinal-scrotal area. Successful reduction should be followed by surgical repair in 24 to 48 hours (allowing for resolution of local edema). Failure of reduction necessitates immediate surgical repair.

FIGURE 71-11 *(See also Color Plate 32.)* **Bilateral infantile hydroceles.** The scrotum is distended by fluid, whereas the inguinal canals are normal.

Nonincarcerated hernias in infants require repair as soon as convenient, preferably within 1 to 2 weeks of diagnosis (Zamakhshary et al, 2008). Premature babies are traditionally operated on just before their discharge from the neonatal intensive care unit, or very soon afterward—although earlier repair may be technically easier for large hernias (Ein et al, 2006). Postoperative apnea occurs in about 5% of preterm infants, particularly those with a history of apneas (Murphy et al, 2008). Postoperative overnight admission for apnea monitoring is therefore indicated for higher-risk outpatients until 48 weeks of postconceptional age. The lowest incidence of apneas occurs with surgery performed using spinal block without sedation (Somri et al, 1998). Other specific postoperative complications include persistent scrotal swelling, recurrence, testicular atrophy, and injury to the vas deferens. Recurrence is highest in premature babies (Vogels et al, 2009). Contralateral exploration is probably not indicated in most cases, because the actual risk of a metachronous hernia has been generally estimated at below 10% (Ein et al, 2006; Zamakhshary et al, 2009).

HYDROCELE

A *hydrocele* is a collection of fluid in the scrotum without an obvious inguinal hernia. The typical hydrocele is noted at or shortly after birth as a unilateral or bilateral swelling in the scrotum, which may fluctuate in size.

The scrotum is enlarged, may be very tense with fluid, and usually is nontender, often with a bluish appearance; the inguinal canal is normal (Figure 71-11). Differentiation between hydrocele and hernia is critical and may be difficult in the infant. Transillumination is useful, but findings must be interpreted cautiously, because fluid or gas-filled bowel may transilluminate in small infants. An irreducible yet nontender groin or scrotal mass probably is a hydrocele.

The recommended management of a hydrocele is observation during the first 1 or 2 years of life, unless a hernia cannot be excluded. Hydroceles that persist or appear beyond that age are unlikely to resolve spontaneously, and affected infants should therefore undergo elective surgical repair.

URACHAL LESIONS

The urachus is the remnant of the allantois that extends from the bladder portion of the cloaca to the umbilicus. The urachus may remain completely patent throughout its length or fail to obliterate (Figures 71-12 and 71-13). All varieties of this defect are rare, and treatment is customized to each patient (Galati et al, 2008).

COMPLETELY PATENT URACHUS

A completely patent urachus manifests with the passage of urine from the umbilicus. Radiopaque contrast material injected into the orifice outlines the urachal tract and fills the bladder. Treatment consists of surgical excision of the umbilicus along with the entire urachus down to the bladder. Results are typically good.

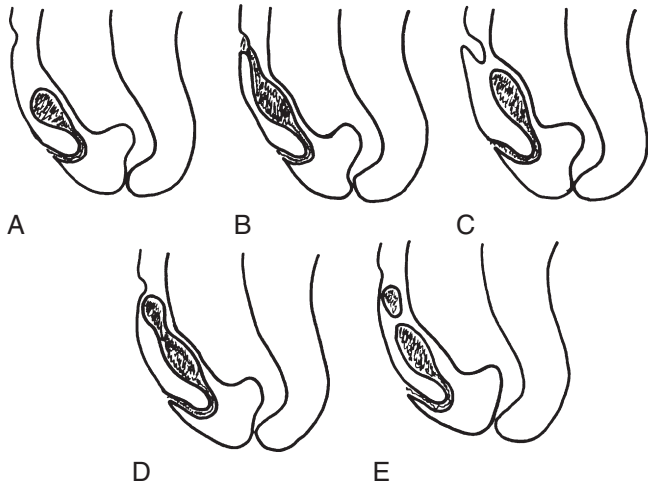

FIGURE 71-12 Urachal anomalies. A, Normal anatomy. **B,** Completely patent urachus. **C,** Blind external tract: urachal sinus. **D,** Blind internal tract: bladder diverticulum. **E,** Urachal cyst.

BLIND EXTERNAL URACHUS

When only the distal end of the urachus fails to obliterate, a draining sinus results. Drainage of urine begins sometime after the cord separates. Surgical excision of the sinus tract is required if it persists beyond 6 months of life (Galati et al, 2008).

BLIND INTERNAL URACHUS

Failure of obliteration of the proximal end of the urachus results in a bladder diverticulum. It produces no symptoms and may be coincidentally discovered on cystogram. Nothing needs to be done surgically.

URACHAL CYST

Incomplete obliteration of the midportion of the urachus leads to the development of a urachal cyst. Cysts may present at birth or may grow slowly and become obvious at any time during infancy or childhood, often through infection. Ultrasound examination is diagnostic. Treatment involves surgical resection, which may be preceded by incision and drainage of the superimposed abscess.

MALFORMATIONS OF THE OMPHALOMESENTERIC DUCT

In the developing embryo, the omphalomesenteric (vitelline) duct connects the yolk sac to the primitive midgut through the umbilical cord. In the normal course of ontogeny, the duct becomes obliterated and disappears. Under certain circumstances however, all or portions of the duct may persist (Figures 71-14 and 71-15). This may cause symptoms through drainage, infection, and intestinal obstruction. As with urachal remnants, presentation and management vary with each type (Snyder, 2007).

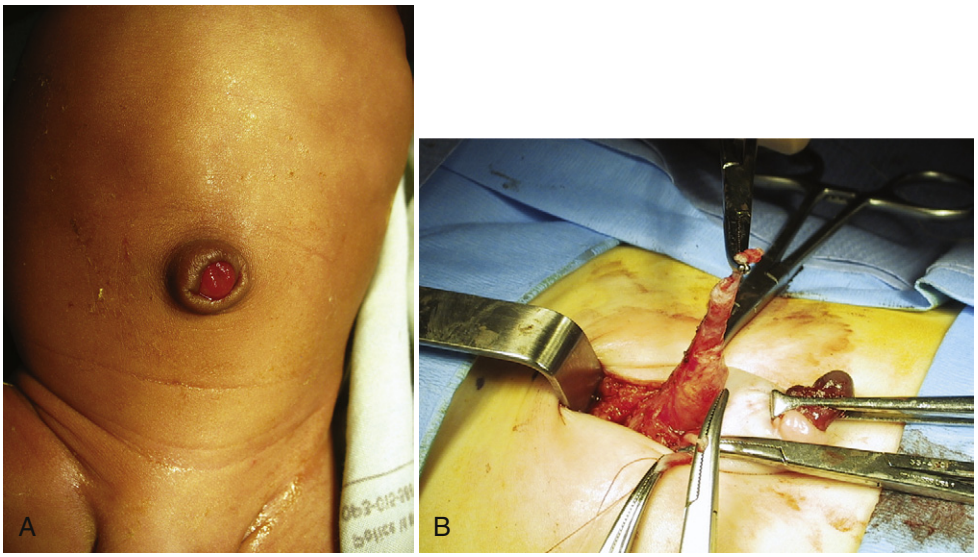

FIGURE 71-13 Patent urachus. A, Appearance of defect. **B**, Operative photograph of the urachal remnant with wide attachment to the bladder.

PATENT OMPHALOMESENTERIC DUCT

Patent omphalomesenteric duct is an enteroumbilical fistula, manifesting with the passage of meconium or fecal matter through the umbilicus. The condition may begin at birth or occur within 1 to 2 weeks. The most significant danger with this lesion is evagination (prolapse) of the small bowel through the umbilical orifice, with a significant increase in mortality. Once this lesion is diagnosed, it should be corrected by surgical excision of the umbilicus and the duct.

OMPHALOMESENTERIC SINUS

Failure of distal closure of the omphalomesenteric duct leads to the formation of a sinus. Persistent watery discharge from the umbilical cord is the initial presentation. Examination of the umbilicus reveals a red nodule projecting from the base. Gentle massage results in the extrusion of mucus, which differentiates this lesion from an umbilical granuloma. Injection of radiopaque contrast material outlines the sinus tract. Treatment consists of surgical excision.

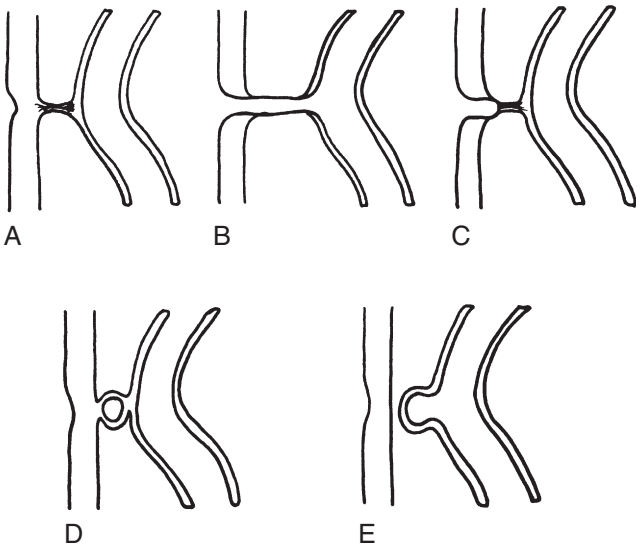

FIGURE 71-14 Omphalomesenteric (vitelline) duct anomalies. A, Normal anatomy. **B,** Patent omphalomesenteric duct. **C,** Blind external tract: umbilical sinus. **D,** Omphalomesenteric duct cyst. **E,** Blind internal tract: Meckel's diverticulum.

OMPHALOMESENTERIC DUCT CYST

When the middle portion of the omphalomesenteric duct persists and eventually fills with secretions, a cyst forms. This lesion may be detected as an enlarging umbilical mass. Treatment consists of surgical excision.

MECKEL'S DIVERTICULUM

When the proximal, or intestinal, end of the omphalomesenteric duct fails to become obliterated completely, an outpouching of the ileum persists. The diverticulum may vary in size, shape, and point of attachment, although the junction usually lies at some point in the distal ileum (Figure 71-16). It must arise from the antimesenteric side of the bowel, a feature that distinguishes Meckel's diverticulum from enteric duplications. Its distal end usually lies free in the peritoneal cavity, but in some cases it is attached to the umbilicus by a fibrous cord and in a small minority remains patent to the umbilicus (omphalomesenteric fistula). Twenty percent of these diverticula contain ectopic pancreatic or gastric tissue.

Incidence

Meckel's diverticula can be discovered in 1.5% to 2% of all persons. Only a small proportion of these diverticula ever become symptomatic, and when they do, this usually happens beyond the age of 4 months. Only exceptionally do they cause illness in the neonatal period. Affected males outnumber females in a ratio of 3:1 to 5:1.

Meckel's diverticulum manifests clinically with bowel obstruction, intestinal bleeding, inflammation, or perforation (Menezes et al, 2008). A pancreatic or gastric mass may act as a leading point to produce intussusception. Gastric mucosa may cause peptic ulceration and bleeding; the latter is almost always the presenting sign if Meckel's diverticulum becomes symptomatic. The fibrous cord, if present, may produce intestinal obstruction. Rarely, inflammation of the diverticulum may lead to peritonitis.

Diagnosis

Hemorrhage from the bowel is the definitive sign of a Meckel's diverticulum. Older children and adults may present with signs and symptoms of diverticulitis, but this

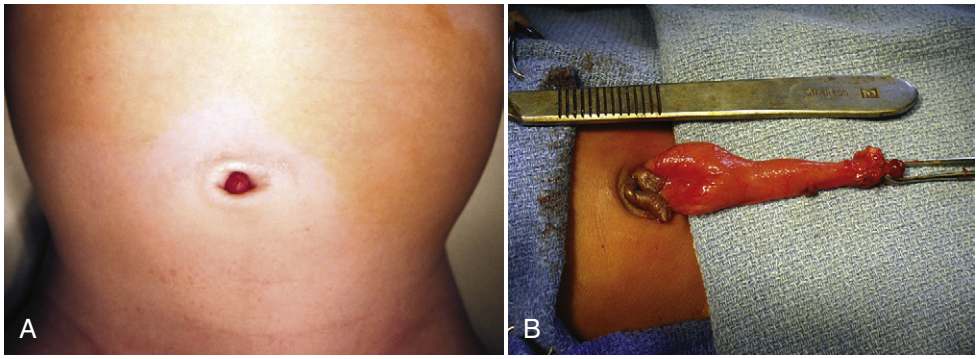

FIGURE 71-15 Omphalomesenteric duct remnant. A, Appearance of the umbilicus. **B**, Operative picture of wide patent remnant attached to anti-mesenteric side of the ileum.

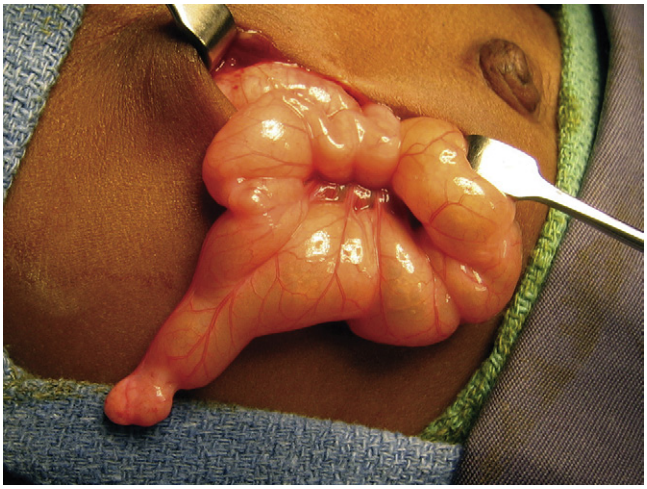

FIGURE 71-16 Meckel's diverticulum. Note the solid tip of the diverticulum, which probably is filled by ectopic gastric or pancreatic tissue.

condition has never been described in young infants. Hemorrhage is often sudden and catastrophic, causing a precipitous fall in the hematocrit and a shock-like state within a few hours. The first few stools passed may be composed almost entirely of unchanged blood; later, they become burgundy-colored and then tarry. In other instances, bleeding is constant and occult. About 25% of persons with Meckel's diverticulum present with intussusception.

Meckel's diverticulum must be differentiated from other disorders that produce gross bleeding from the bowel: peptic ulcer, enteric duplication, intestinal polyp, intussusception, and intestinal hemangioma. Anal fissure, proctitis, and ulcerative colitis ordinarily do not lead to gross hemorrhage, blood loss being confined to the passage of bloody mucus or of stools containing a surface accumulation of blood. The most useful point in the differential diagnosis is that hematemesis usually coexists with rectal bleeding when peptic ulcer is present, whereas hematemesis rarely occurs with Meckel's diverticulum. Enteric duplications are often palpable.

The diagnostic test of choice for Meckel's diverticulum is a technetium-99m pertechnetate scan ("Meckel scan"), which detects the ectopic gastric mucosa. This test is most useful in patients presenting with rectal bleeding—the false-negative rate is high in patients with other symptoms (Menezes et al, 2008). Pentagastrin or cimetidine is useful in enhancing the image of gastric mucosa on subsequent technetium scans.

Treatment

Resuscitation and blood replacement therapy is the initial treatment regardless of the cause of bleeding. If bleeding ceases, careful observation for recurrence of bleeding is often all that is indicated, because peptic ulcer rarely recurs. A second episode of bleeding, however, strongly suggests that other diagnostic procedures may be needed, including endoscopy, laparoscopy, and laparotomy. Surgical treatment is generally reserved for symptomatic diverticula and those thought to contain ectopic tissue (Snyder, 2007). Diverticulectomy is increasingly performed by laparoscopy.

CHAPTER 72

The Developing Intestinal Microbiome: Implications for the Neonate

Josef Neu, Christopher M. Young, and Volker Mai

The recent development of non–culture-based-techniques to evaluate the microbial genome is providing new insights into the relationship that exists between microbes and their mammalian hosts, especially the microbes that reside in the gastrointestinal (GI) tract (Gill et al, 2006). Using this technology has shown that the gene pool contributed by the gut microbiota vastly exceeds that of the human genome. It has been suggested that of the cells in the average human, only 10% are mammalian and the rest are microbial (Gill et al, 2006; Xu and Gordon, 2003). These organisms mostly reside within their host in a symbiotic and/or commensal manner. During the course of evolution, the host has developed defensive responses against microbes that are considered foreign, but at the same time has developed a mechanism that provides not only tolerance but a welcoming environment that benefits both microbes and the host (Bäckhed et al, 2005; Hooper, 2004; Hooper and Gordon, 2001; Hooper et al, 2002). This chapter provides an overview of the current knowledge of the intestinal microbiome and how it relates to neonatal and subsequent health via its interaction with the developing GI tract. Included is a brief description of new and developing technologies that are rapidly advancing this field. This chapter also provides brief overviews of several clinical aspects of microbe/host interaction, including basic interactions between the microbiome and the intestinal immune system; intrauterine and fetal life as it relates to premature labor; maternal and perinatal influences on postnatal health in the premature and term infant; and disease entities such as necrotizing enterocolitis (NEC) and sepsis.

THE MICROBIOME

BEYOND CULTURE

In 1683, Antonie van Leeuwenhoek wrote about his observations of the microorganisms associated with his own teeth. These were the first recorded observations of bacteria living in a human host (Gest, 2004). In the field of digestive physiology, it has long been known that microbes are abundant in the intestine, but they were initially considered to have no beneficial effect for the host. This concept is changing. New technologies are rapidly deepening our knowledge and appreciation of our microbial companions. These non–culture-based methods have shown that the majority of microbes in the intestine cannot be cultivated and isolated in culture with current methods. New information is emerging about the extensive role microbes play in human physiology, health, and disease. It is estimated that there are thousands of bacterial species within our bodies, most of them in our intestines. Recent studies have shown that the communities of microbes in the intestine have a profound effect on digestive physiology, development, and health of the host (Dethlefsen et al, 2007; Gill et al, 2006; Hooper, 2004; Stappenbeck et al, 2002). This finding has led to the concept of a microbiome, which includes the microbiota and their complete genetic elements. The microbial metagenome is defined as the totality of microbes, their genetic elements (genomes), and their environmental interactions in a defined environment. A defined environment could, for example, be the gut of a human being or a soil sample.

Efforts to sequence the human intestinal microbiome are revealing a high degree of complexity, and additional technologies are emerging that will help to describe not only the composition of the human intestinal microbiota, but also the molecular, immunologic, and metabolic interactions that these organisms have with their host, along with their functional implications. The success of newly developed technologies has laid the groundwork for studies related to the Human Microbiome Project (Turnbaugh et al, 2007) that intend to further characterize the human microbiome as well as develop a better understanding of its role in health and disease.

NEW TECHNOLOGIES FOR ANALYSIS OF THE HUMAN MICROBIOME

Until the beginning of the last decade, culture-based techniques were the mainstay of evaluating intestinal microbes and still form the basis for diagnostic clinical microbiology. However, a majority of bacterial cells seen microscopically in feces cannot currently be cultured in the laboratory (Ben-Amor et al, 2005). The recently developed high-throughput molecular techniques analyze microbial DNA and RNA and can be divided into 16S rRNA–based and metagenomic approaches. The 16S rRNA gene is used as a stable phylogenetic marker to define which microbes are present in a sample and in what proportion (Pace, 1997). More complex metagenomic studies, in which community DNA is subjected to shotgun sequencing, can give additional insight into the metabolic potential of the microbiome (Rondon et al, 2000). A comprehensive review of these techniques is beyond the scope of this chapter, but we offer a brief summary of some of the more commonly used techniques in Table 72-1.

Both methods include the extraction of community DNA or RNA from feces or other samples of interest. The 16S rRNA is a part of the ribosomal RNA. It is commonly used for phylogenetic studies, because some regions of the gene encoding it are highly conserved and can act as primer binding sites, whereas other regions containing phylogenetic information are highly variable. As a result, various 16S rRNA–based methods have been incorporated into diagnostic clinical microbiology as a rapid, accurate alternative to phenotypic culture-based methods of bacterial identification.

TABLE 72-1 Summary of Selected 16S rRNA–Based Techniques Used for Identifying Intestinal Microbiota

Technique	Primary Function	Advantage(s)	Disadvantage(s)
DGGE/TGGE/ ARISA	Qualitative determination of dominant microbes and of overall microbiota diversity	Diversity analyses	Does not provide direct identification of microbes
Fluorescence in situ hybridization (FISH)	Quantitative analysis of total fecal bacteria and of targeted groups of bacteria	Analysis of targeted bacteria using specific probes Not based on PCR, thus free of PCR bias	Requires a priori knowledge of target bacterial 16S rRNA sequences for design of probes Only a few probes can be used for one analysis
16S rRNA pyroseqencing	Comprehensive analysis of 16S rRNA content in community DNA for detection of known as well as unknown bacteria	Provides a comprehensive overall analysis of microbes Currently one of the best techniques for identification of microbes that cannot be analyzed by culture-based methods	Currently very costly, but high-throughput, automated technology is increasing the efficiency and utility

Following DNA extraction from fecal samples, amplification of the targeted 16S rRNA genes can be achieved with universal polymerase chain reaction (PCR) primers capable of amplifying rRNA genes from most bacteria with similar efficiency. Alternatively, specific primers designed to amplify rRNA genes from a particular bacterial group of interest can be used to test for their presence by conventional PCR assay or to enumerate them using a quantitative PCR approach. PCR amplicons can also be sequenced using novel high-throughput pyrosequencing technology. Based on the degree of nucleotide similarity (usually between 95% and 99%), sequences can be separated into operational taxonomic units that form the basis for comparisons of microbiota composition and diversity between samples.

Profiling approaches include denaturing gradient gel electrophoresis (DGGE), temperature gradient gel electrophoresis (TGGE), and automated ribosomal interspacer analysis (ARISA) (Fisher and Triplett, 1999; Muyzer, 1999). These techniques allow for an efficient qualitative initial profiling of microbiota composition that can be applied to large studies. In DGGE, DNA isolated from fecal samples and variable region(s) of the 16S rRNA are amplified with universal or group specific primers, one of which contains a GC clamp to facilitate stronger adherence of the two DNA strands (PCR) (Muyzer, 1999). The products are then separated on a denaturing gradient gel that achieves separation of same-sized DNA fragments present in the mixed pool of DNA fragments based on the differences in melting characteristics that are due mainly to varying GC content. The resulting separated bands can be cut and eluted from the gel, followed by sequencing to identify the bacterial group or species that contributed to the template DNA. These fingerprinting methods, although efficient for initial screening, are limited in that only the most abundant members of the community can be observed.

Currently any in-depth analysis of microbial community composition, such as that present in the intestine, takes advantage of high-throughput sequencing for both 16S rRNA and metagenomic approaches, mainly through 454 illumina sequencing (Tringe and Hugenholtz, 2008). This technique allows for the simultaneous identification of the bacterial lineages that are present in a complex community DNA sample at a depth that exceeds conventional Sanger sequencing by many fold. An in-depth description goes beyond the scope of this chapter but can be obtained at http://www.454.com. Briefly, a PCR amplification step occurs in microreactors (emulsions) surrounding microbeads. The amplified DNA can then be sequenced based on the light-emitting pyrosequencing technique. Sequences from multiple samples can be barcoded and pooled, reducing the sequencing cost per sample. Sequences can then be classified according to taxonomy (16S) and function (metagenomics). Sequencing is especially useful when determining which specific species, genes, or pathways differ between communities.

Another molecular technique that does not require PCR or sequencing, fluorescence in situ hybridization (FISH), uses group- or species-specific labeled probes designed with data previously derived from sequencing (Zoetendal et al, 2004) to quantify microbiota composition. The probes are tagged with a 5′ fluorescent dye that permits both detection and quantification of the specific bacterial populations. Other microbiota analysis approaches include short sequence tags (Fisher and Triplett, 1999) and microarrays (He et al, 2007). The latter approach was recently used by Palmer et al (2007) to track development of the human intestinal microbiota in infancy.

All of these techniques have advantages and disadvantages including various biases. Cutting costs of the more in-depth sequencing techniques and data analysis using advanced bioinformatics tools remains a huge challenge.

THE "OMES"

The foregoing discussion underlines the fact that the human organism is composed of and controlled by not only its mammalian genetic complement (human genome) but also the microbial genetic component (microbiome). These synergize with the environmental factors, such as nutrition, to make up the epigenome, proteome, transcriptome, and metabolome. Alterations in the intestinal microbiome have been linked to numerous pathologic processes and conditions such as obesity, autoimmune diseases, allergy, asthma, eczema, and even the induction of premature labor, some of which are described in this chapter. The role of intestinal microbes, especially during early development in these highly interrelated components, is in its early phases of understanding but is clearly related to human health and disease and is fertile for future investigation (Turnbaugh and Gordon, 2008).

BOX 72-1 Functions of Microbiota

- **I.** Metabolic/nutritional
  - **a.** Vitamin production
  - **b.** Short-chain fatty acids (SCFAs)
  - **c.** Conversion of phytoestrogens/bile acids, etc.
- **II.** Intestinal development
  - **a.** Epithelial proliferation, restitution (regeneration?)
  - **b.** Crypt development
  - **c.** Angiogenesis
- **III.** Exclusion of pathogens
- **IV.** Innate immune regulation
  - **a.** Modulation of cytotoxic response
  - **b.** Enhanced recognition and destruction of pathogens
- **V.** Adaptive immune regulation
  - **a.** Development of tolerance

ACTIVITIES OF THE INTESTINAL MICROBIOME

Using the aforementioned techniques, the investigation of the biomes and how they interact within the intestine is becoming progressively more feasible. The human metaorganism contains a prokaryotic component in the intestine that comprises nearly 10^{14} (Muyzer, 1999) cells that weigh over 1 kg in the adult. There is a marked aboral gradient in the number and types of microbes in different regions of the intestine, with 10^{11} (Ben-Amor et al, 2005) in the ascending colon, $10^{7\text{-}8}$ (Dethlefsen et al, 2007; Gest, 2004) in the distal ileum, and 10^{3} (Bäckhed et al, 2005; Xu and Gordon, 2003) in the jejunum. A better understanding of many of the activities of the microbiota in the GI tract (Box 72-1) is emerging. Here we describe functional aspects of the microbiome and interactions with the intestinal epithelium by anatomic site: the small intestine primarily as the site of immunoreactivity and the large intestine functioning as a bioreactor (Neish, 2009).

INFLAMMATION AND IMMUNITY

The intestinal microbes represent a key regulatory element for the appropriate development of the adaptive immune system and also for the innate inflammatory response. For the innate component, the intestinal epithelium partially relies on various receptors, such as the Toll-like receptors (TLRs), to act as an interface between the luminal microbiota and signal transduction pathways. As various studies have shown, TLRs are cell-surface receptors that recognize specific microbial ligands from both pathogens and commensals, enabling the innate immune system to recognize nonself and activating both innate and adaptive immune responses (Takeda et al, 2003). Nucleotide-binding oligomerization domains (NODs) have a similar function with recognition of foreign molecules within the cellular compartment. These studies suggest that the epithelium and resident immune cells do not simply tolerate commensal microorganisms but are dependent on them for the appropriate induction of immune responses. Commensal bacteria contain a variety of molecules such as lipopolysaccharide (LPS), lipoteichoic acid, and short nucleotide multimers that, on lysis of bacteria, can interact in the normal intestine with a population of surface TLRs. The resultant ongoing signaling enhances the ability of the epithelial surface to withstand injury while also priming the surface for enhanced repair responses (Madara, 2004; Strober, 2004). Therefore, either the disruption of TLR signaling or the removal of TLR ligands compromises the ability of the intestinal surface to protect and repair itself in the face of inflammatory or infectious insult (Rakoff-Nahoum et al, 2004).

THE BIOREACTOR FUNCTION

Complex carbohydrates are poorly digested by the human digestive system and require the intestinal microbiota for breakdown via fermentation. In the distal intestine, primarily the proximal colon, the intestinal microbiome is highly metabolically active; these activities might best be studied using metabolomic methodologies. The fermentation end products include short-chain fatty acids (SCFAs) such as acetate, propionate, and butyrate. The SCFAs influence various aspects of intestinal physiology beyond being a main caloric source, especially for the epithelial colonocytes (they supply an estimated 5–15% of human energy requirements). The various SCFAs possess differentiating and growth-promoting activities that are thought to be related to their effects on histone deacetylase activity; they may also have epigenetic effects. SCFAs have immunomodulatory effects and major effects on the interepithelial tight junctions. Examples of processes that can be mediated via the gut microbiota's metabolic functions include how differences in the microbial population affect obesity, non–insulin-dependent diabetes, and atherosclerosis (Ley et al, 2006). In the distal intestine, primarily the colon, undigested complex carbohydrates in the weaned individual are primarily vegetable fibers, whereas in the infant, it is primarily undigested human milk oligosaccharide and in some cases, primarily very preterm infants, nonabsorbed lactose. Thus, even if there is a deficiency of lactase activity in the small intestine of very premature neonates, a healthy distal intestinal flora is able to "salvage" some of the undigested lactose into absorbable and usable two- to four-carbon energy sources (Figure 72-1) (Kien, 1996).

DEVELOPMENT OF THE INTESTINAL MICROBIOME

THE FETAL MICROBIOME AND PRETERM BIRTH

Preterm birth is a leading cause of infant death and also major lifelong health problems, which include cerebral palsy and neurodevelopmental delays, vision loss, and GI problems related to short-gut syndrome. There appear to be several predisposing factors for preterm birth, but one component that clearly plays a role is the so-called fetal inflammatory response syndrome (FIRS).

Emerging evidence suggests that microbes may play a role in premature labor through interactions with fetal intestine that result in an inflammatory immune response (Figure 72-2). This hypothesis is supported by (1) the association between microbial colonization of the amniotic fluid, FIRS, and premature labor (Andrews et al, 1995; Bobitt and Ledger, 1997; Goldenberg et al,

2008; Romero et al, 1988, 1998, 2007), (2) the observation that the fetus swallows large quantities of amniotic fluid during the late second and third trimesters of pregnancy (Brace and Wolf, 1989; Gilbert and Brace, 1993), and (3) the induction of systemic inflammation to be derived from the GI tract (Carrico et al, 1986), especially that of the fetus in utero (Nanthakumar et al, 2000). Recent studies using non–culture-based techniques reveal a significant prevalence of microbes in amniotic fluid that cannot be readily cultured using standard laboratory techniques (DiGiulio et al, 2008; Han et al, 2009). These observations are in contrast to results from earlier culture-based studies that did not detect microbial presence in amniotic fluid and can be rationalized by the conclusion that in the amniotic fluid of many women who deliver prematurely, there are bacteria present that have not previously been cultured by standard techniques. Furthermore, it has been suggested that a greater degree of prematurity is associated with the 16S rRNA bacterial load in the amniotic fluid, even in the absence of ruptured membranes (DiGiulio et al, 2008).

Although the inflammatory mediators that are related to premature delivery could originate from the placenta, the fetal GI tract is a more likely origin of the inflammatory response and to our knowledge has not been previously implicated in FIRS. Evidence for a fetal origin stems from several studies, including the original findings of elevated proinflammatory cytokines obtained by cordocentesis (Gomez et al, 1998; Pacora et al, 2002; Romero et al, 2007), suggesting a fetal origin. The fact that the white blood cells found in amniotic fluid are predominantly of fetal origin is also germane (Sampson et al, 1997). More recent studies underscore the important role of the fetus in initiation of the cascade of responses causing premature labor.

This concept of the fetal intestinal origin of FIRS stems from the observation that the fetus is known to swallow large quantities of amniotic fluid (Brace and Wolf, 1989; Gilbert and Brace, 1993). This amniotic fluid subsequently reaches the fetal distal small intestine, an organ that was initially found in rodents to be significantly more sensitive to inflammatory stimuli than more mature intestines (Chan et al, 2002). In humans, the fetal intestine has also been found to respond to stimuli such as LPS even more robustly than more mature intestine (Nanthakumar et al, 2000). The fact that the intestine has been called the "motor that drives systemic inflammation and multiple organ failure" (Carrico et al, 1986) is highly relevant to our hypothesis because this "motor" could be driving the fetal inflammatory response that leads to premature labor. This fetal inflammatory response not only is critical in terms of premature labor, but has also been linked to other morbidities affecting multiple organ systems in the neonate (Dammann et al, 2001, 2002; Gotsch et al, 2007; Nelson et al, 1998; Yoon et al, 2003, 2000).

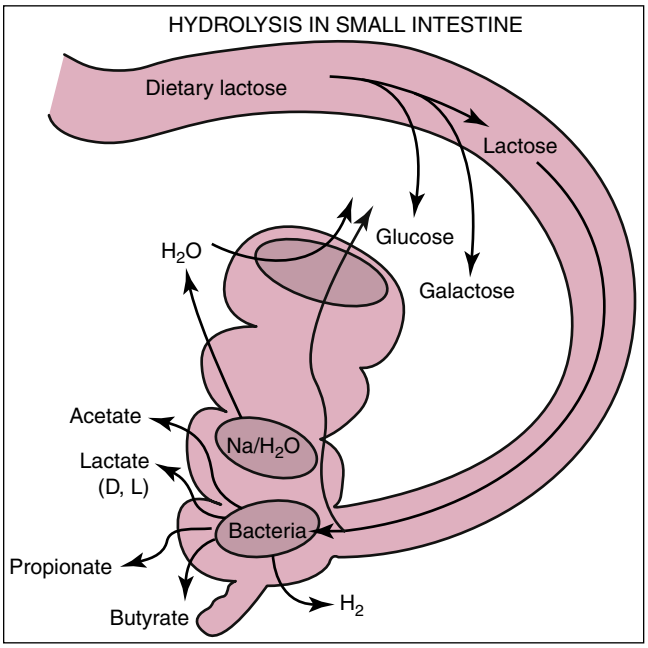

FIGURE 72-1 Fate of unhydrolyzed lactose in the intestine. Dietary lactose that is not hydrolyzed and absorbed in the small intestine passes to the distal intestine, where it is broken down into the short-chain fatty acids acetate, propionate, and butyrate, which can act as substrates for energy production and play other important roles such as controlling proliferation and differentiation and maintaining integrity of intercellular junctions.

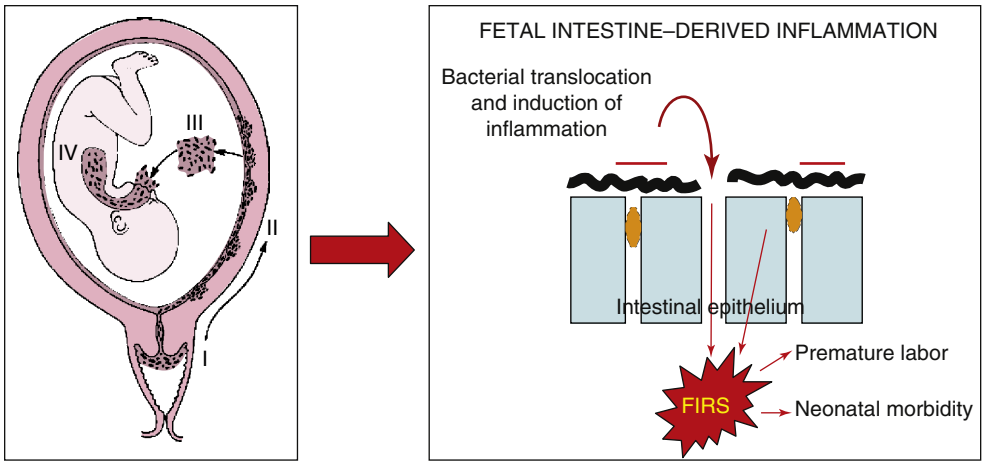

FIGURE 72-2 Proposed fate of microbes in amniotic fluid. Microbes in amniotic fluid are swallowed by the fetus, and these in turn can be translocated through the intestinal epithelium and incite inflammation that may affect distal organs as well as potentially incite uterine contraction and premature delivery.

THE PREMATURE INFANT MICROBIOME

The microbial population of the developing GI tract of the premature infant affects maturation and optimal function of the intestinal innate and adaptive immune system. Because a major role has been ascribed to systemic (usually intestine derived) inflammation on several neonatal diseases including NEC, chronic lung disease, intraventricular hemorrhage, periventricular leukomalacia, and hematopoietic abnormalities, factors that may modulate these responses originating in the intestine are of interest.

Over the past few years, a body of literature has emerged supporting that overproduction of interleukin-8 (IL-8) is a critical, and arguably the most important, component of the systemic inflammatory response in neonates. The role of IL-8 in chorioamnionitis, intracerebral hemorrhage, and lung disease is compelling (De Dooy et al, 2001; Kohse et al, 2002; Shalak et al, 2002; Tauscher et al, 2003; Yoon et al, 2003). High concentrations of IL-8 are frequently noted in the plasma and affected tissues of patients who exhibit these problems. This leukocyte chemoattractant chemokine, which can be produced in large quantities by the intestine, has thus been causally linked to some of these problems, implying that modulation of intestinal production of IL-8 may be a key to prevention. It is notable that infant intestine appears to be much more sensitive to stimuli, such as LPS and flagellin that induce IL-8, than is adult intestine (Claud et al, 2004; Nanthakumar et al, 2000). The relationship of this and other inflammatory mediators and the intestinal microbiota as they relate to neonatal inflammatory conditions remains to be elucidated.

NUTRITION AND THE DEVELOPING INTESTINAL MICROBIOME

A more specific understanding of the neonatal intestinal microecology as it relates to inflammatory mechanisms may lead to measures that can prevent diseases. In the premature infant, the reliance on parenteral nutrition while providing few or no enteral nutrients may be highly significant in the promotion of intestinal inflammation, because the presence of enteral nutrients can prevent gut-derived inflammation (Kudsk, 2002). Whether this is partially due to stimulation of commensal bacterial growth is speculative. Several in vitro studies have shown that probiotics (live, heat-killed, and DNA from probiotic bacteria) can downregulate intestinal IL-8 production (Bai et al, 2004; Jijon et al, 2004; Li et al, 2009; Lopez et al, 2008; Ma et al, 2004; Rachmilewicz et al, 2004; Zhang et al, 2005) induced by proinflammatory stimuli such as LPS.

Human milk contains a wide array of biologically active components. The growth of pathogenic bacteria and viruses is known to be inhibited by proteins such as lactoferrin, secretory IgA, and peptides formed from human milk during digestion (Lonnerdal, 2004). Human milk is an important factor in the initiation, development, and composition of the neonatal gut microbiota. It has been found to be a significant source of lactic acid bacteria that appear to be of endogenous origin and not contaminants from the breast skin (Martin and Walker, 2006; Perez et al, 2007). The lactobacillus isolated from milk of healthy mothers is phylogenetically related to strains commonly used in commercial probiotic products and shares characteristics such as survival in GI tract conditions, production of antimicrobial compounds, adherence to intestinal cells, production of biogenic amines, and patterns of antibiotic resistance. Among the numerous substances present in human milk, some of the oligosaccharides have a prebiotic effect, stimulating the development of bifidobacteria in the colon (Coppa et al, 2004). Breastfed infants, unlike those who are formula fed, have an intestinal ecosystem characterized by a strong prevalence of bifidobacteria and lactobacilli (Bourlioux et al, 2003; Saavedra, 2001). Human milk can be considered a synbiotic (Coppa et al, 2004), because it contains live beneficial bacteria (probiotics) as well as nutrients that can enhance their growth (prebiotics).

PROBIOTICS

Probiotics are dietary supplements of live microorganisms thought to be healthy for the host organism. According to the currently adopted definition by FAO/WHO, probiotics are "live microorganisms which, when administered in adequate amounts, confer a health benefit on the host" (FAO/WHO, 2001). There is an increasing body of evidence supporting the health benefits of probiotics for premature infants. The decrease in NEC incidence and overall mortality reported from a small number of these studies has catalyzed the routine use of these agents. However, sufficient evidence of both short- and long-term safety and health effects beyond infancy is lacking.

CONCERNS ABOUT ADMINISTRATION OF LIVE MICROBES (PROBIOTICS)

Despite the large body of evidence supporting the health benefits of probiotics, several concerns have been raised about the possibility of unwanted side effects. This concern is especially valid in sick patients or very young individuals where microbiota manipulation may result in adverse effects (Besselink et al, 2008; Boyle et al, 2006; Honeycutt et al, 2007; Neu, 2007; Singhi, 2007; Taylor et al, 2007). Another key issue concerns the safety aspects of bacteria added to particular products marketed for improvement of general health or treatment of (post) infectious symptoms. In some cases, virulence potential has been detected in probiotic bacterial strains. There is also concern that horizontal gene transfer can result in acquisition of virulence genes or antimicrobial resistance in probiotic bacteria (Wassenaar et al, 2008). Antimicrobial resistance in these probiotic bacteria can potentially aid the spread of undesired resistance in intestinal bacterial populations.

One of the known mechanisms of probiotics is the capability of modulating an overaggressive inflammatory response (Claud et al, 2004; Neish, 2002; Zhang et al, 2005), but under certain circumstances probiotics may actually incite an inflammatory response of their own, especially in highly susceptible individuals (Boyle et al, 2006; Liong, 2008). There is some concern that probiotic bacteria may translocate to the locally draining tissues and circulatory system, causing bacteremia, especially in immunocompromised individuals. Contrary to some of the initial studies that demonstrated positive benefits of probiotics in patients with atopic dermatitis, considerable

controversy is rising, as studies are beginning to show that there may be detrimental effects at later stages of life (Boyle et al, 2008). For example, in one study supplementation with *Lactobacillus rhamnosus* GG during pregnancy and early infancy neither reduced the incidence of atopic dermatitis nor altered its severity in affected children, but was associated with an increased rate of recurrent episodes of wheezing bronchitis (Kopp and Ghosh, 1995).

Despite justified enthusiasm for the beneficial use of probiotics in premature infants for the prevention of NEC based on randomized controlled trials (Bin-Nun et al, 2005; Lin et al, 2005), data from one of the most recent multicenter trials suggests that the group with the smallest infants with birthweights (<750 g) may actually be at *increased* risk for sepsis (12 infants in the probiotic group and 1 infant in the control group developed sepsis) when given prophylactic probiotics (Lin et al, 2008).

There is concern that probiotics may establish inappropriate residence in the gut that prevents normal colonization of other microflora in the GI tract, resulting in subsequent alteration of normal immune system development (Neu, 2007). There is also concern that manipulation before establishment of a normal core microbiome in newborns may incur risks such as consequences of imbalanced fermentation profiles (Neu, 2007).

These concerns prompt consideration of alternative agents such as prebiotics, which are usually indigestible oligosaccharides that prompt growth of resident (and, it is hoped, beneficial) microorganisms. "Postbiotics," products of microbial fermentation, such as the SCFAs acetate, propionate, and butyrate, may also provide beneficial effects (Roy et al, 2006). Accumulating evidence suggests that other small molecules derived from lysed microorganisms (usually molecules acting on Toll-like and other signal transduction receptors in the intestinal epithelium, dendritic cells, and other immunoreactive intestinal cells) may confer the same benefits as probiotics without incurring the risks associated with a live organism.

CONCLUSION

The ongoing revolution in microbial genomics and metabolomics as applied to the developing intestinal microbiota provides exciting avenues for studying basic scientific processes and applications to the prevention and treatment of diseases. We are just beginning to scrape the surface of the potential application of this emerging science as it pertains to the newborn infant. The relationship of the developing microbiome to intestinal development, nutrition, inflammation, the immune system, and how it relates to numerous diseases in the infant as well as subsequent health in the adolescent and adult is rapidly emerging. It is likely that our understanding of the developing microbiome will offer revolutionary means to prevent disease and promote future health.

CHAPTER 73

Necrotizing Enterocolitis and Short Bowel Syndrome

Michael Caplan

NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis (NEC) is an acute inflammatory necrosis of the bowel that primarily afflicts preterm infants. Although there is significant geographic variation, the incidence ranges between 7% and 10% for infants born weighing less than 1500 g. Of the infants in whom NEC develops, the mortality rate ranges from 25% to 30%, and up to 50% receive a surgical procedure. NEC survivors have a significant risk for gastrointestinal complications such as intestinal stricture or short bowel syndrome (SBS), and the risk for abnormal neurodevelopmental outcome is significantly increased, particularly in patients with NEC requiring surgery. Although still under investigation, it appears that probiotic supplementation in high-risk premature infants may significantly reduce the risk of disease in this fragile population.

EPIDEMIOLOGY AND PATHOGENESIS

The incidence of NEC varies geographically and temporally; it ranged between 2% and 22% in an NICHD observational study of very low-birthweight (VLBW) infants (Uauy et al, 1991) and was reported to be 28% in Hong Kong (Siu et al, 1998), 14% in Argentina (Halac et al, 1990), and 7% in a cohort of <2000-g preterm infants from Austria (Eibl et al, 1988). Although NEC is infrequent in full-term infants (5% to 10% of reported cases), in this population it is often associated with other conditions such as congenital heart disease, birth asphyxia, polycythemia, exchange transfusion, or intrauterine growth restriction (Bolisetty and Lui, 2001). In preterm infants, the incidence of NEC varies inversely with gestational age and birthweight, and studies suggest a higher incidence in boys and African-American infants (Ryder et al, 1980).

The age at onset of NEC is inversely related to gestational age, with a mean age of 3 to 4 days for term infants and 3 to 4 weeks for infants born at less than 28 weeks' gestation. Most patients with NEC have been previously fed via the enteral route. Although NEC does occur in unfed premature infants, spontaneous intestinal perforation (SIP), a distinct pathologic entity, commonly presents in extremely low-birthweight (ELBW) infants during the first couple of weeks after birth and before the initiation of feeding (Gordon, 2009; Swanson et al, 2009). Patients with SIP present earlier and seem to have a better prognosis than those who develop the clinical and pathologic hallmarks of NEC (Table 73-1).

NEC cases typically present sporadically and without warning in neonatal intensive care units, but occasionally are associated with epidemics related to a specific pathogen. A wide variety of organisms have been associated with these outbreaks, including *Klebsiella pneumoniae*, *Escherichia coli*, clostridia, coagulase-negative staphylococci, and rotavirus. It is currently hypothesized that NEC is not directly caused by infectious agents, but the presence of abnormal microbial flora with additional risk factors of bowel ischemia, immaturity of host mucosal defense, and enteral feedings is thought to contribute to the initiation and pathogenesis of disease, presumably due to the activation of the inflammatory response (Frost et al, 2008).

Bowel Ischemia

Early observations suggested that profound intestinal ischemia led to intestinal necrosis similar to NEC in situations associated with birth asphyxia and shock associated with other conditions. Similar to the "diving reflex" observed in aquatic mammals, it was hypothesized that in periods of stress, blood flow was diverted away from the splanchnic circulation, resulting in bowel injury (Touloukian et al, 1972). Neonatal animals have been shown to have abnormal regulation of the intestinal circulation that may predispose them to NEC. The basal intestinal vascular resistance is elevated in the fetus and soon after birth decreases significantly, allowing for the rapid increase in intestinal blood flow that is necessary for robust intestinal and somatic growth (Nowicki and Miller, 1988). It has been shown that this change in the resting vascular resistance is dependent on the balance between dilator (nitric oxide) and constrictor (endothelin) mediators and the myogenic response, and altered levels of these vasoactive mediators are observed in human patients with NEC (Nowicki et al, 2005, 2007). In response to circulatory stress, neonates respond with compromised intestinal flow and/or vascular resistance. In response to hypotension, newborn animals (3-day-old but not 30-day-old swine) appear to have defective pressure-flow autoregulation, resulting in compromised intestinal oxygen delivery and tissue oxygenation (Nowicki and Minnich, 1999). There are multiple chemical mediators (nitric oxide, endothelin, substance P, norepinephrine, and angiotensin) that affect intestinal vasomotor tone, and in the stressed newborn, abnormal regulation of these may result in compromised circulatory autoregulation, leading to perpetuation of intestinal ischemia and tissue necrosis.

Clinical factors associated with altered intestinal blood flow might influence the risk for NEC. Umbilical arterial catheters might pose a threat to the intestinal vasculature, although there is no clear data that demonstrate a higher risk for NEC in patients with these devices (Davey et al, 1994). The presence of the patent ductus arteriosus (PDA) and a left-to-right shunt results in compromised blood flow to the intestine during diastole. In a randomized, controlled trial in infants whose birthweights were less than 1000 g, prophylactic closure of the ductus arteriosus by surgical ligation reduced the rate of NEC from 30% in the control group, compared with 8% in the early-closure group

TABLE 73-1 Clinical Differences between Necrotizing Enterocolitis (NEC) and Spontaneous Intestinal Perforation (SIP)

	NEC	SIP
Incidence <1500 g	7–10%	2–3%
Age at onset	2–6 weeks	0–14 days
Pneumatosis	Yes	No
Enteral feedings	Yes	No
Histologic evidence of villus necrosis	Yes	No
Mortality	10–30% above baseline	5–10% above baseline

(Cassady et al, 1989). Other studies suggest that treatment of the PDA with indocin, rather than the PDA itself, increases the risk for disease due to the effects of indocin on the intestinal circulation (Fowlie, 2000). Maternal cocaine use can cause fetal intestinal vasoconstriction and, in some animal studies and preterm human observational trials, is associated with an increased risk for NEC (Kilic et al, 2000). Finally, recent studies have suggested an association between packed red blood cell transfusions and an increased risk for NEC, and in these patients it is surmised that the rapid correction of significant anemia may influence intestinal vascular autoregulation (Mally et al, 2006).

Host Defense Factors

As reviewed in Chapter 70, host defense in the preterm gastrointestinal tract is markedly impaired. In order to prevent pathogens from invading the mucosal lining and causing invasive infection, intestinal host defense is exceedingly complex and includes (1) physical barriers such as skin, mucous membranes, intestinal epithelia and microvilli, epithelial cell tight junctions, and mucin; (2) immune cells such as polymorphonuclear leukocytes, macrophages, eosinophils, and lymphocytes; and (3) multiple biochemical factors. Intestinal permeability is impaired in the neonate, and especially the preterm neonate, and allows immunoglobulins, proteins, and carbohydrates to traverse into the systemic circulation (Piena-Spoel et al, 2001). Intestinal mucus, a complex gel consisting of water, electrolytes, mucins, glycoprotein, immunoglobulins, and glycolipids, protects against bacterial and toxin invasion and is abnormal in developing animals and perhaps premature infants (Clark et al, 2006). Additionally, key bacteriostatic proteins are secreted from epithelium that bind to or inactivate the function of invading organisms. Human defensins and intestinal trefoil factor are proteins that are developmentally regulated and might play a role in the development of NEC (Salzman et al, 2007; Shi et al, 2007).

Immunologic factors that contribute to host defense are compromised in developing animals. For example, intestinal intraepithelial lymphocytes (IELs) are decreased in neonates (B and T cells) and do not approach adult levels until 3 to 4 weeks of life (Kuo et al, 2001). Newborns have markedly reduced secretory immunoglobulin A (IgA) in salivary samples, reflecting the decreased activity presumed in intestine (Eibl et al, 1988). Breast milk feeding provides significant supplementation; formula-fed neonates have impaired intestinal humoral immunity, and this deficiency may predispose to the increased incidence of infectious diseases and NEC noted in this population. Of interest, oligosaccharides have recently been added to neonatal formula to approximate human milk, and this supplementation appears to increase secretory IgA as well as alter the microbial flora to resemble that observed in a breastfed infant; it could also influence the development of intestinal infection and inflammation (Scholtens et al, 2008).

Multiple biochemical factors contribute to the maintenance of gut health and integrity, and many are suppressed in the preterm newborn patient or animal. Critical factors that appear to influence mucosal homeostasis include lactoferrin (Yen et al, 2009), glutamine (Neu, 2001), growth factors such as epidermal growth factor (EGF) (Halpern et al, 2006a), heparin-binding (HB)-EGF (Feng et al, 2006), transforming growth factor (TGF) (Claud et al, 2003), insulin-like growth factor (IGF) (Ozen et al, 2005), erythropoietin (EPO) (Ledbetter and Juul, 2000), gastric acid, polyunsaturated fatty acids (Carlson et al, 1998; Lu et al, 2007), nucleotides, and many others. These factors contribute to gut maturation and regulation of the inflammatory cascade, a complex system that is altered in the neonate and are discussed in detail in a subsequent section.

Because NEC occurs less frequently among infants fed breast milk, and because breastfeeding appears to protect infants from a number of diseases, numerous investigators have attempted to delineate the factors in breast milk that contribute to neonatal host defense. As detailed in Chapter 65, breast milk contains immunoglobulins, leukocytes, and numerous antibacterial agents that are not present in artificial cow's milk–based formula. In a variety of animal studies and human trials, supplementation with substances present in human milk has reduced the risk for NEC, including IgA/IgG, leukocytes, lactoferrin, polyunsaturated fatty acids, platelet-activating factor (PAF)-acetylhydrolase, EGF, HB-EGF, and EPO (see references just given).

Enteral Feeding

Most infants who develop NEC have begun enteral feeding. The mechanism whereby feeding promotes the initiation of disease is not clear, although reports have suggested potential mechanisms such as osmolar stress (Willis et al, 1977), by-product synthesis of toxic short-chain fatty acids (Nafday et al, 2005), intestinal distention following rapidly advancing feeding volumes leading to abnormal vascular regulation, activation of gut hormones and mediators, and altered bile acid metabolism (Halpern et al, 2006b). Early studies suggested that delaying the initiation of feeding reduced the incidence of NEC; however, more recent reports have not confirmed these observations, and multiple trials to evaluate the safety and benefit of early hypocaloric feedings suggest that these are well tolerated and provide beneficial effects (Tyson and Kennedy, 2000). Nonetheless, these studies have not been appropriately powered to identify an increased rate of NEC, and in one trial the prolonged use of small enteral feeding volumes for the first 10 feeding days reduced the incidence of NEC compared to infants whose feeding volumes were increased daily by 20 mL/kg/day increments (Berseth

et al, 2003). Precise recommendations regarding feeding volumes, time of feeding initiation and advancement, fortification strategies, and feeding strategies during times of additional risk factors such as PDA, indocin treatment, and the presence of an umbilical arterial catheter will require additional information.

BACTERIAL COLONIZATION AND THE PRO-INFLAMMATORY RESPONSE

As compared to full-term, nursing infants, who have a rich diversity and large quantities of bacteria colonizing their distal intestinal tracts, preterm infants have significantly fewer bacterial species and numbers, and less diversity (Gewolb et al, 1999; Palmer et al, 2007). Of interest, a recent study demonstrated that patients with NEC had even less microbial diversity than gestational age–matched controls, suggesting that the total bacterial milieu might influence the development of intestinal injury in this population (Wang et al, 2009). Although commensal organisms that promote intestinal health and protect against inflammatory responses are prominent in full-term neonatal flora, as in older children and adults, in preterm infants these organisms, including *Bifidobacteria* spp. and *Lactobacillus* spp., are distinctly uncommon (Gewolb et al, 1999). These features of the bacterial flora unique to the VLBW infant are thought to initiate pro-inflammatory signaling in the context of formula feeding, intestinal ischemic stress, and deficient host mucosal immune responses.

It is now well recognized that bacteria and other pathogens initiate a complex signaling cascade via the binding to and activation of specific pattern recognition receptors, called human Toll-like receptors (TLRs), that are present on most cells and tissues (Akira and Hemmi, 2003; Gribar et al, 2008). In the case of gram-negative enteric bacteria such as *Escherichia coli*, cell wall lipopolysaccharide (LPS) activates the specific TLR4 on inflammatory and immune cells, and a series of signal transduction events ultimately result in the nuclear translocation of nuclear factor kappa B (NF-κB) and transcription of proinflammatory genes such as interleukin (IL)-1, IL-8, tumor necrosis factor, inducible nitric oxide synthase (iNOS), and phospholipase A_2. These mediators have been shown to be elevated in preterm infants with NEC, and they ultimately result in a robust inflammatory response (Caplan et al, 1990b; Edelson et al, 1999; Harris et al, 1994). Although proinflammatory activation appropriately protects against bacterial invasion at the mucosal environment in normal circumstances, in the setting where antiinflammatory signaling is inadequate, overzealous responses can lead to intestinal inflammation and necrosis.

It is theorized that the premature infant is more prone to proinflammatory signaling without balanced antiinflammatory responses following bacterial-TLR activation, and that these differences contribute to the pathogenesis of NEC. When counterregulatory responses are insufficient, pathologic changes to gut mucosa occur and may include accentuated apoptosis of epithelial cells (Jilling et al, 2004), perturbation of tight junctional proteins and complexes (Clark et al, 2006), increased mucosal permeability (Langer et al, 1993), bacterial translocation (Deitch et al, 1991), alterations of vascular tone and microcirculation (Reber et al, 2002), and additional neutrophil infiltration and accumulation leading to intestinal necrosis. Specific alterations in neonatal anti-inflammatory responses have been identified, and include (1) propensity to synthesize IL-8 in response to bacterial stress (Claud et al, 2004); (2) deficiency in PAF-acetylhydrolase activity, the degrading enzyme for PAF, a potent phospholipid mediator shown to initiate mucosal injury (Caplan et al, 1990a); and (3) increased activity of intestinal NF-κB due to inhibition of inhibitory protein IκB (De Plaen et al, 2007). Recent studies have shown that although epithelial cells normally do not express TLR4 on the mucosal surface, in stressed neonatal animals and in preterm infants with NEC, TLR4 expression is upregulated on the apical surface of epithelial cells (Jilling et al, 2006; Leaphart et al, 2007). This finding may further explain the robust and unusual proinflammatory response observed in neonates with necrotizing enterocolitis. Finally, because epidemiologic studies suggest an increased risk of disease depending on gender, race, and twin siblings of affected patients (Holman et al, 1997), single-nucleotide polymorphisms have been evaluated in this context, and polymorphisms of several inflammatory genes have been identified that might lead toward a predilection of NEC (Young et al, 2009).

CLINICAL PRESENTATION

The clinical signs and symptoms of NEC are variable and can include abdominal distention, vomiting or increased gastric residuals, bilious drainage from enteral feeding tubes, or hematochezia, and in some cases tenderness and discoloration (Figure 73-1). Frequently present are nonspecific systemic signs that may include temperature instability, apnea, lethargy, poor perfusion, or hypotension. Similar to patients with septic shock who demonstrate a robust inflammatory response, NEC patients can have abnormal white blood cell counts, thrombocytopenia, capillary leak, intravascular volume depletion, metabolic acidosis, acute tubular necrosis, respiratory failure, hypotensive shock, and death.

FIGURE 73-1 Clinical presentation of a preterm infant with necrotizing enterocolitis. This infant was born at 28 weeks' gestation and had been receiving enteral feedings for 1 week when he developed acute abdominal distention, hematochezia, and vomiting. Note the discoloration of the skin overlying the abdomen. Also, this infant required endotracheal intubation because of respiratory compromise that occurred as a result of the upward pressure of the abdominal contents on the diaphragm. *(Courtesy Dr. Lalo Cabrera-Meza, Baylor College of Medicine, Houston, Texas.)*

TABLE 73-2 Modified Bell's Staging Criteria for Necrotizing Enterocolitis

Stage	Systemic Signs	Intestinal Signs	Radiologic Signs	Treatment
I: Suspected				
A	Temperature instability, apnea, bradycardia	Elevated pregavage residuals, mild abdominal distention, occult blood in stool	Normal or mild ileus	NPO, antibiotics × 3 days
B	Same as for IA	Same as for IA, plus gross blood in stool	Same as for IA	Same as for IA
II: Definite				
A: Mildly ill	Same as for IA	Same as for I, plus absent bowel sounds, abdominal tenderness	Ileus, intestinal pneumatosis	NPO, antibiotics × 7–10 days
B: Moderately ill	Same as for I, plus mild metabolic acidosis, mild thrombocytopenia	Same as for I, plus absent bowel sounds, definite abdominal tenderness, abdominal cellulitis, right lower quadrant mass	Same as for IIA, plus portal vein gas, with or without ascites	NPO, antibiotics × 14 days
III: Advanced				
A: Severely ill bowel intact	Same as for IIB, plus hypotension, bradycardia, respiratory acidosis, metabolic acidosis, disseminated intravascular coagulation, neutropenia	Same as for I and II, plus signs of generalized peritonitis, marked tenderness, and distention of abdomen	Same as for IIB, plus definite ascites	NPO, antibiotics × 14 days, fluid resuscitation, inotropic support, ventilator therapy, paracentesis
B: Severely ill, bowel perforated	Same as for IIIA	Same as for IIIA	Same as for IIB, plus pneumoperitoneum	Same as for IIA, plus surgery

NPO, Nulla per os (nothing by mouth).

The diagnostic radiographic hallmark of NEC is the presence of pneumatosis intestinalis, and this finding has been clearly established as a critical diagnostic criterion in the staging system suggested by Bell et al and modified by Walsh and Kliegman (Bell et al, 1978; Walsh and Kliegman, 1986) (Table 73-2). Pneumatosis represents gas accumulation in the bowel wall that includes hydrogen gas that is produced from bacterial metabolism of carbohydrate substrate (Figure 73-2). Portal venous gas is also diagnostic of NEC even in the absence of pneumatosis intestinalis, and early studies suggested that this presentation carried a worse prognosis (Figure 73-3) (Molik et al, 2001). If NEC progresses to bowel perforation, pneumoperitoneum may be identified. Most typically, free air is visualized on a cross-table lateral or right lateral decubitus film (Figure 73-4). Occasionally, free air can be visualized as a central periumbilical collection on an anteroposterior film—the "football sign" (see Figure 73-4, *B*). Recent studies have demonstrated that ultrasonographic findings of pneumatosis and portal venous air are easily appreciated by the trained observer, and that abdominal ultrasound imaging may allow for earlier and more precise diagnosis, and in cases of medical NEC that improve, quicker advancement toward enteral feeding (Bohnhorst et al, 2003; Dordelmann et al, 2008).

TREATMENT

Medical Management

The medical management of NEC is focused on providing aggressive supportive care, because no specific interventions have been shown to limit the progression of disease. Initial treatments include the discontinuation of enteral feedings, decompression of intestinal contents with nasogastric drainage, and broad-spectrum antibiotic therapy. Antibiotic regimens should cover typical nursery enteric flora and may include ampicillin/aminoglycoside, ampicillin-cephalosporin, or, in settings with frequent staphylococcal colonization, vancomycin-aminoglycoside. Although only 20% to 30% of NEC cases identify positive blood cultures (Kliegman and Fanaroff, 1984), treatment usually continues for 7 to 10 days even with sterile blood cultures; however, the utility of this approach has not been carefully studied. Because NEC is an inflammatory process that results in substantial third-space fluid loss, liberal use of volume support may be needed during the first 48 to 72 hours of treatment, even without overt intravascular volume depletion. In addition to the aggressive use of fluids and volume expanders such as albumin, pressor agents such as dopamine may be required to maintain the infant's blood pressure and peripheral perfusion. Because many infants with NEC develop apnea or respiratory compromise owing to abdominal distention and upward compression on the diaphragm, intubation and ventilatory support may be required. Frequent monitoring of blood gases, complete blood counts, electrolytes, and serum glucose is essential in these critically ill patients, who develop metabolic acidosis, hyperkalemia, thrombocytopenia, neutropenia, hyper- or hypoglycemia, and anemia with disseminated intravascular coagulation.

Surgical Management

Despite optimal neonatal intensive care, between 10% and 30% of patients with NEC will succumb to this disease (Badowicz and Latawiec-Mazurkiewicz, 2000; Lin and

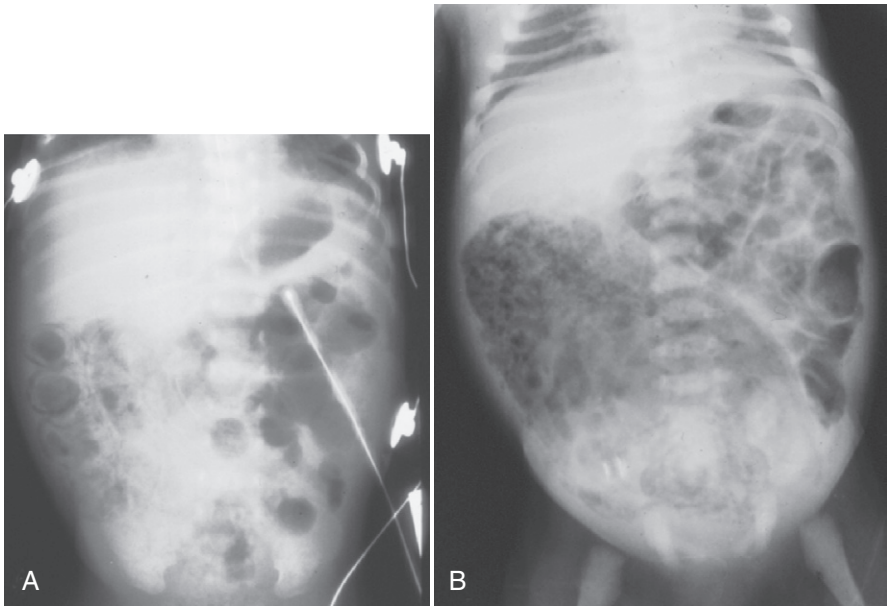

FIGURE 73-2 **A,** Typical abdominal radiographic appearance of intestinal pneumatosis seen in necrotizing enterocolitis: dark concentric rings around the bowel loops in the right upper quadrant. **B,** This radiograph displays the *bubbly gas* pattern occasionally seen in necrotizing enterocolitis. *(Courtesy Dr. Lalo Cabrera-Meza, Baylor College of Medicine, Houston, Texas.)*

FIGURE 73-3 This radiograph displays the presence of portal gas, which is seen as linear dark streaks within the hepatic density. *(Courtesy Dr. Lalo Cabrera-Meza, Baylor College of Medicine, Houston, Texas.)*

Stoll, 2006). One third of the patients present with a milder form of disease that resolves with medical therapy alone, and approximately 50% of cases require surgical intervention. The most common indication for surgery is the presence of pneumoperitoneum. Other indications may be the presence of clinical deterioration despite aggressive medical therapy, the presence of a fixed dilated loop of bowel on serial radiographs, and evidence of peritonitis and gangrenous bowel obtained by paracentesis, but none of these are absolute. The goals of surgery are to resect necrotic bowel, to decompress the intestine and free intraperitoneal air, and to preserve as much bowel length as possible.

Because surgical intervention does not appear to alter the progression of ongoing inflammation and disease, the timing, benefit, and approach for surgery in NEC cases remains controversial. Although most physicians agree that a procedure is indicated in a case of NEC with perforation, the utility and effectiveness of these interventions have not been well studied. Yet, it is thought that decompression with a percutaneous drain might be as effective as an exploratory laparotomy. A peritoneal drain allows for decompression of intraabdominal gas that might impede respiratory function and, in these situations, appears to provide time for natural healing to occur. In several studies, including an observational prospective trial (Blakely et al, 2006), a randomized trial (Moss et al, 2006), and an international randomized trial (Rees et al, 2008), there were no differences in effect between peritoneal drain and laparotomy on mortality or short-term gastrointestinal function in cases of NEC with perforation, or NEC with worsening clinical signs and symptoms. Of note, in these studies, many patients with a percutaneous drain never required additional surgical exploration, suggesting that definitive intervention was not required and in fact might not alter the outcome of the disease.

LONG-TERM COMPLICATIONS

Although more than 70% of patients with NEC survive, long-term gastrointestinal complications include intestinal strictures and SBS. Strictures result from fibrotic healing of inflamed intestine and occur in 10% to 35% of patients with medical and surgical disease (Horwitz et al, 1995). Patients with strictures typically develop recurrent abdominal distention 2 to 3 weeks after recovery from NEC, but

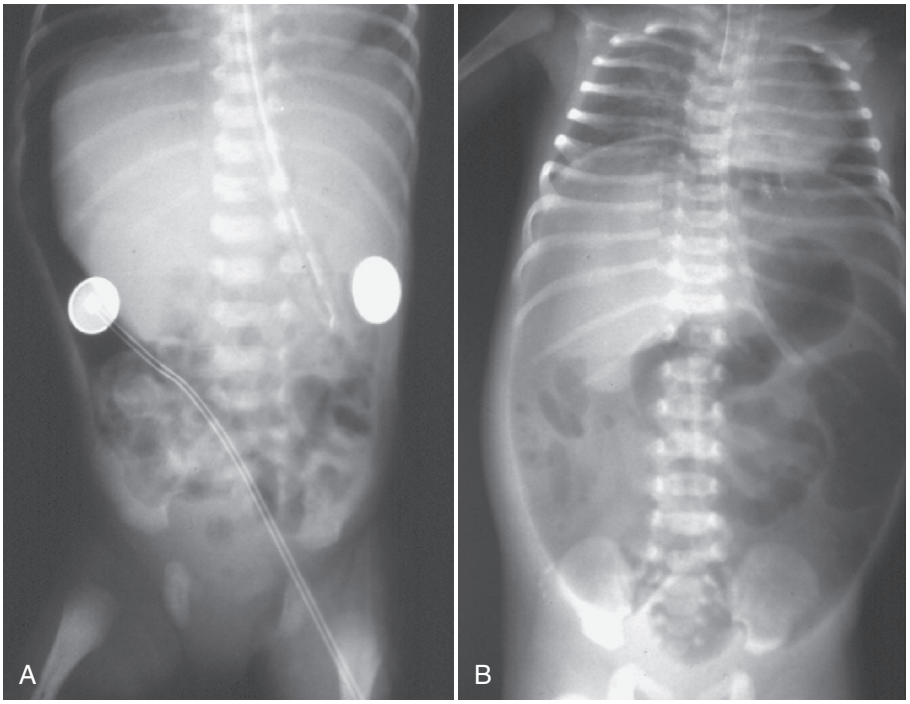

FIGURE 73-4 **A,** This radiograph demonstrates intestinal perforation as displayed by the presence of a gas lucency that lies between the hepatic density and the outer abdominal wall. **B,** This radiograph is from another infant whose bowel is perforated. In **B,** air lies anterior to the loops of intestine as well as along the right abdominal wall, where it is displacing loops of bowel medially. *(Courtesy Dr. Lalo Cabrera-Meza, Baylor College of Medicine, Houston, Texas.)*

these can be diagnosed months or years after the initial presentation (Figure 73-5). Many cases can be managed medically, but if the narrowing is severe, surgical resection is often required.

SBS occurs when inadequate bowel remains following NEC with or without surgery to allow normal growth on enteral nutrition. Although there is controversy regarding the amount of bowel length needed to support adequate growth, it is estimated that infants require a minimum of 25 to 40 cm of viable small intestine (Galea et al, 1992). As outlined in a subsequent section, medical and surgical management must address issues related to malabsorption, bacterial overgrowth, and alterations in intestinal transit.

Neurodevelopmental impairment (NDI) is observed with increased frequency following the diagnosis of NEC in premature infants. In a series of observational trials, the risk of cerebral palsy and/or mental retardation in afflicted patients is as high as 57% compared with gestational age– and birthweight-matched controls with much lower rates, and patients with surgical NEC have a 1.8 relative risk of NDI compared with age-matched controls (Hintz et al, 2005). The etiology of this serious long-term complication is thought to be related to white matter injury following systemic inflammatory activation and/or nutritional deficiencies associated with prolonged lack of enteral nutrition. Further studies are needed to define the pathogenesis and to establish preventive approaches, but caution should be used in counseling parents of these high-risk patients.

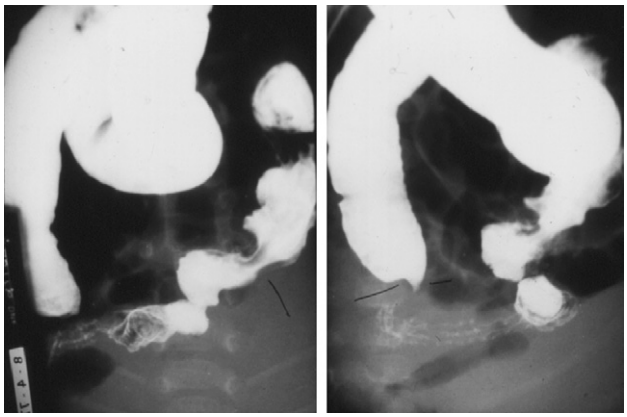

FIGURE 73-5 This barium study was obtained in an infant who had recovered from necrotizing enterocolitis and was experiencing intermittent episodes of abdominal distention when enteral feedings were given. Note that multiple areas of stricture are present. *(Courtesy Dr. Lalo Cabrera-Meza, Baylor College of Medicine, Houston, Texas.)*

PREVENTIVE STRATEGIES

Because the onset of NEC is typically acute and disease progresses rapidly, no therapeutic intervention introduced after confirmation of the diagnosis has been efficacious. Nonetheless, many approaches have been attempted to prevent NEC in animal and human studies, but there are no currently accepted strategies that are deemed standard-of-care, besides judicious human milk feeding. Nonetheless, although human milk feeding for preterm infants in neonatal intensive care units throughout the United States has increased dramatically over the past decade, there has not been a reduction in the overall incidence of NEC, and therefore new preventive strategies are desperately needed. Lower rates of NEC have been shown in animal models following breast milk feeding (Dvorak et al, 2004), IgA supplementation (Barlow et al, 1974), antibiotic prophylaxis, steroids (Israel et al, 1990), probiotics (Caplan et al, 1999; Siggers et al, 2008), polyunsaturated

fatty acids (Lu et al, 2007), PAF antagonists (Caplan et al, 1997a), PAF-acetylhydrolase (Caplan et al, 1997b), EGF (Dvorak et al, 2008), trefoil factor (Shi et al, 2007), leukocyte depletion (Sun et al, 1996), bile acid transport inhibitors (Halpern et al, 2006b), and oxygen radical scavengers (Cueva and Hsueh, 1988). In human studies, prevention trials with IgA/IgG (Eibl et al, 1988), steroids (Halac et al, 1990), polyunsaturated fatty acids (Carlson et al, 1998), arginine (Amin et al, 2002), donor human milk (Lucas and Cole, 1990), and antibiotics (Siu et al, 1998) have been conducted with limited success, but because of various problems, including poor study design, risks of intervention, lack of reproducibility, and weak statistical power, these approaches have yet to become routine strategies in the neonatal intensive care unit for preterm infants. A recent study suggests that lactoferrin, an iron transport protein that has additional antiinflammatory and antimicrobial activity, not only reduces the risk of late-onset sepsis in preterm infants, but also might lower the incidence of NEC.

Probiotic supplementation is a promising approach for the prevention of NEC in VLBW infants (Caplan, 2009). Studies suggest that probiotic colonization in VLBW infants is abnormal, and multiple biologic mechanisms have been identified that could explain their effects on proinflammatory signaling and disease (Walker, 2008). There have now been several international trials that demonstrate the efficacy of probiotic prophylaxis for the prevention of NEC (Bin-Nun et al, 2005; Dani et al, 2002; Hoyos, 1999; Lin et al, 2005, 2008; Samanta et al, 2009; Walker, 2008), and although the specific probiotic species and dosing varies between studies, the cumulative results identified a reduction in NEC from 142 of 2143 controls (6.6%) to 53 of 2093 treated patients (2.5%, $p < 0.01$). Despite these exciting results, additional studies are warranted before clear standard-of-care can be recommended, because of some potential concerns. First, probiotic preparations have not been carefully regulated, and because some studies have shown inaccuracies in the reported organism species and content, appropriate quality control measures are warranted. Second, various probiotic species have differing effects, and the optimal probiotic combination and optimal dosing strategy are not clearly elucidated. Third, recent studies have shown potential harm with probiotic prophylaxis, with increased mortality in critically ill adult patients with pancreatitis (Besselink et al, 2008), and increased asthma in childhood (Kalliomaki et al, 2007). Finally, although probiotic sepsis has not been observed in the NEC prevention trials, careful culturing strategies are not routinely used, and studies have now identified probiotic sepsis in neonatal patients in other clinical situations, so appropriate vigilance is essential.

SHORT BOWEL SYNDROME

The normal small intestine length in the term infant is 200 to 300 cm. The most common causes of short gut in the newborn is bowel resection after NEC, midgut volvulus, or congenital anomalies such as jejunal or ileal atresia and gastroschisis. Thus, newborns most typically have a short gut characterized by losses of ileum and the ileocecal valve (ICV). Estimates suggest that 25 cm of bowel with an intact ICV and 42 cm without an ICV is the minimum for successful survival and adaptation in full-term neonates (Galea et al, 1992). Nonetheless, the diagnosis of SBS is made using functional criteria rather than on actual gut length, and typically is based on the prolonged need for parenteral nutrition for more than 6 weeks (Ching et al, 2007).

SBS is more common in VLBW infants observed in the neonatal intensive care unit setting, and most of these are due to NEC (96%). Information from a recent cohort identified that 0.7% of these patients had SBS, and it was more common in ELBW infants, boys, and patients that were small for gestational age (Cole et al, 2008). Follow-up of these patients demonstrated, not surprisingly, an increased risk for death and at, 18 to 22 months of life, an increased need for tube feedings, rehospitalization, and growth delay.

TREATMENT

Multidisciplinary care is essential for patients with SBS and requires parenteral and enteral nutritional support, management of ongoing medical issues including cholestasis, in some cases surgical intervention with intestinal lengthening procedures, and occasionally intestinal or intestinal/hepatic transplantation (Goulet et al, 2009; Gupte et al, 2006).

Because bile salts, fat-soluble vitamins, and trace minerals are absorbed in the distal ileum, infants with SBS are prone to steatorrhea and specific vitamin and mineral deficiencies. Cholestyramine, an ion-exchange resin that binds bile salts, often is used to reduce steatorrhea. Fat malabsorption is common, and replacements should be provided with careful monitoring. Recent reports suggest that patients with SBS and severe cholestasis on complete intravenous nutrition are deficient in omega-3 fatty acids, and that intravenous fish oil supplementation can markedly improve the clinical status of these patients, particularly in regard to liver failure (Gura et al, 2008). Deficiencies of vitamins A, D, E, K, and B_{12} as well as zinc and magnesium all have been described in infants with short gut. Therefore, levels of all of these substrates should be monitored and supplemented appropriately.

Bacterial overgrowth can occur as a result of reflux of colonic contents into the distal ileum in the absence of an ileocecal valve, in abnormal peristalsis, or in the presence of fistulas (Cole and Ziegler, 2007). Bacterial overgrowth can impair fat and vitamin B_{12} absorption and depress mucosal function, resulting in malabsorption and profound diarrhea. Symptomatic improvement with antibiotic regimens such as metronidazole or vancomycin may occur, and recently clinicians have utilized probiotics for this clinical situation (De Groote et al, 2005).

Tolerance of enteral feedings with adequate growth is not easily achieved in many cases. In a recent report, remaining bowel length and plasma bilirubin level correlated with ultimate success in transitioning from intravenous to enteral feeding (Nucci et al, 2008). To enhance mucosal growth and improve bowel function, the use of additives such as glutamine and IGF-1 has been attempted, with equivocal results (Chu et al, 2004). One recent report showed benefit with EGF in five patients with SBS,

particularly on nutrient absorption, but without beneficial effects on weight gain or liver function tests (Sigalet et al, 2005).

Although most infants can be managed medically until intestinal adaptation occurs, approximately 10–15% are dependent on total parenteral nutrition. Several surgical options are available for this group of patients (Hosie et al, 2006; Javid et al, 2005; Misiakos et al, 2007). Techniques include reversal of a small segment of bowel to slow transit, tapering or plicating dilated loops of intestine to improve motility, and intestinal lengthening procedures such as Bianchi's isoperistaltic doubling and Kimura's isolated segments technique. Experience with these procedures remains limited, and their associated complication and failure rates are high; still, they constitute a less invasive option than intestinal transplantation, which can be considered for selected patients. A review by one center reported a 3-year survival rate of 60% for intestinal transplantation used in SBS patients following the diagnosis of NEC (Vennarecci et al, 2001). Because of the lack of adequate donors and the guarded long-term prognosis for these complex patients, individual decision making is difficult and requires the coordinated efforts of multiple health care professionals in selected centers.

CHAPTER 74

Disorders of the Liver

Frederick J. Suchy and Nanda Kerkar

Liver disease in the newborn has long been a challenge, and can present with a clinical spectrum ranging from asymptomatic abnormalities on liver biochemical tests to fulminant hepatic failure. Cholestasis is usually present, because of the immaturity of hepatic excretory function (Balistreri, 2002). Indeed, there are more distinct and unique causes of cholestatic jaundice in the neonate than at any other time of life (Suchy, 2004). The ability to make a specific diagnosis is complicated by similar clinical and biochemical features of neonatal liver disease caused by congenital malformations, inborn errors of metabolism, genetic cholestatic syndromes, and perinatal infections. Early diagnosis may allow treatment of some metabolic or infectious disorders and surgical management of biliary anomalies.

APPROACH TO THE NEWBORN WITH LIVER DISEASE

Jaundice persisting beyond 2 weeks is considered to be prolonged jaundice. Cholestasis is present if more than 20% of an elevated total bilirubin is conjugated. The common causes of neonatal cholestasis are listed in Boxes 74-1 and 74-2 and in Table 74-1. The amount of blood that can be drawn from a small infant is limited, and hence it is important to prioritize laboratory tests based on the clinical scenario, including whether the infant is sick with/without liver failure, is premature in the neonatal intensive care unit, or is a relatively well term infant.

In an infant with liver failure, effort should be focused on excluding life-threatening, treatable causes of liver dysfunction such as sepsis, neonatal hemochromatosis, metabolic/endocrine problems, and bleeding from vitamin K deficiency. History of consanguineous marriages and neonatal deaths should be solicited. Bacterial infections with both gram-positive and gram-negative organisms and viral infection with herpes simplex or an enterovirus should be excluded, especially if there is concern about sepsis. Neonatal hemochromatosis is a rare but important cause of liver failure in infancy that is diagnosed by demonstrating iron deposition in extrahepatic areas, particularly salivary gland (buccal biopsy) and heart/pancreas (magnetic resonance imaging [MRI]). If the cholestatic infant is also hypoglycemic and/or hypotensive, endocrine problems such as hypopituitarism or metabolic problems such as galactosemia should be considered, and excluded by pituitary function tests and galactose-1-phosphate uridyl transferase enzyme analysis. Nonketotic hypoglycemia is usually indicative of fatty acid oxidation defects, and acyl carnitine profile is a good screening test. Tyrosinemia and inborn errors of bile acid metabolism can lead to liver failure, and testing urine for organic acids and abnormal bile acid metabolites can be diagnostic. Sometimes liver failure can be part of a systemic disease, that is, mitochondrial disease—lactic acidosis is characteristic, and the pH and lactate/pyruvate ratio should be tested in such infants.

BOX 74-1 Infections Associated With Neonatal Liver Disease

BACTERIAL AND PARASITIC

Bacterial sepsis
Syphilis
Listeriosis
Tuberculosis
Urinary tract infection
Toxoplasmosis
Malaria

VIRAL

Cytomegalovirus
Herpes (simplex, zoster, human herpes virus 6)
Rubella
Reovirus
Adenovirus
Enteroviruses
Parvovirus B6
Syncytial giant cell hepatitis with paramyxoviral-like inclusions
Hepatitis B
Hepatitis E

BOX 74-2 Biliary Tract Disorders of the Newborn

Biliary atresia
Choledochal cysts
Spontaneous perforation of the common bile duct
Mucous plug syndrome
Neonatal sclerosing cholangitis
Paucity of intrahepatic bile ducts (nonsyndromic)
Alagille syndrome
Caroli's disease/syndrome
Cystic fibrosis
Idiopathic bile duct stricture (possibly congenital)
Cholelithiasis
Acute cholecystitis
Chronic cholecystitis
Acalculous cholecystitis
Acute hydrops of the gallbladder

Infants with liver failure often are listed for liver transplantation, but it is important to rapidly establish that there are no contraindications for transplantation, such as sepsis, systemic disease, or hemophagocytic lymphohistiocytosis. The last should be suspected if there is fever in association with liver failure, characteristically with pancytopenia, hypofibrinogenemia, and hypertriglyceridemia. The bone marrow histology is useful in ruling out storage disorders such as Niemann-Pick disease and Gaucher's disease.

If the infant is a stable premature infant, the duration of total parenteral nutrition, the lack or amount of enteral feeding, episodes of sepsis, medications causing cholestasis

TABLE 74-1 Inborn Errors of Metabolism With a Neonatal Hepatic Phenotype

Disorder	Defect	Clinical Features
Galactosemia*	Galactose-1-phosphate uridyl transferase	Jaundice, hepatomegaly, vomiting, hypoglycemia, *Escherichia coli* sepsis
Tyrosinemia*	Fumarylacetoacetate hydrolase	Jaundice, hepatosplenomegaly, failure to thrive, ascites, coagulopathy, and rickets
Fructosemia	Fructose-1,6-biphosphate aldolase	Vomiting, hypoglycemia, and hypophosphatemia, hepatomegaly jaundice on exposure to fructose
Niemann-Pick disease type C	Defective lipid trafficking/storage	Cholestasis, hepatomegaly, fetal ascites, neurodegeneration
Gaucher disease type 2	Acid β-glucosidase	Cholestasis, hepatomegaly, neurodegeneration
α_1-Antitrypsin deficiency	α_1-Antitrypsin	Cholestasis
Bile acid synthetic defects	Multiple enzymatic defects	Cholestasis, liver failure, fat-soluble vitamin deficiencies
Mitochondrial respiratory chain defects	Complexes I, III or IV, or mtDNA depletion/mutation	Liver failure, lactic acidosis, multisystem disease
Citrin deficiency	Mitochondrial aspartate-glutamate transporter	Cholestasis, coagulopathy, failure to thrive, hypoglycemia, fatty liver, hyperaminoacidemia
Disorders of fatty acid oxidation*	Multiple enzymatic and transport defects	Nonketotic hypoglycemia, cholestasis, coagulopathy, multisystem disease
Glycogen storage diseases	Multiple enzymatic defects	Hepatomegaly, hypoglycemia, hyperuricemia in type 1, hyperlipidemia, lactic acidosis
Wolman disease	Lysosomal acid lipase	Cholestasis, hepatomegaly, vomiting, diarrhea, adrenal calcifications
Zellweger's syndrome	Peroxisomal biogenesis	Cholestasis, hepatomegaly, severe neurologic dysfunction, hypotonia, craniofacial abnormalities

*Detected by newborn screening in some states.

including trimethoprim-sulfamethoxazole, cephalosporin, anticonvulsants, and episodes of significant hypoxia or hypotension should be carefully assessed. Inspissated bile syndrome is the transient conjugated hyperbilirubinemia that occurs during the recovery phase of hemolysis, when it appears that the bilirubin is conjugated more rapidly that it can be excreted (Hickey and Power, 1956). In the term infant, presence of dark urine and acholic stools should raise the index of suspicion for an obstructive cause of jaundice—biliary atresia, choledochal cyst, or biliary stricture. Older infants may have pruritus; failure to thrive; bleeding from vitamin K deficiency; problems related to fat malabsorption such as steatorrhea and vitamin A, D, E, and K deficiency; and complications related to portal hypertension such as ascites, gastrointestinal bleeding, and hypersplenism. During the physical examination, syndromic features should be looked for—Alagille syndrome and Down syndrome are associated with cholestasis. Laboratory investigations include complete blood count, international normalized ratio, liver function tests with fractionated bilirubin, α_1-antitrypsin phenotype, thyroxine, thyroid-stimulating hormone, cortisol, iron, ferritin, immunoreactive trypsin, galactose-1-phosphate uridyl transferase, cholesterol, triglycerides, TORCH, hepatitis B virus, parvovirus, human immunodeficiency virus, serum and urinary organic acids, amino acids, and bile acid metabolites (Suchy, 2004). In the sick infant, blood glucose, lactate, ammonia, pH, paracentesis, and blood and urine culture are also necessary. A chest x-ray and abdominal ultrasonography should be requested. If there is history of meconium ileus, screening tests for cystic fibrosis should be performed. If cholestasis is associated with a low serum γ-glutamyl transpeptidase, then progressive familial intrahepatic cholestasis or a bile acid synthetic defect are high in the differential diagnosis. Liver biopsy is essential in persistent cholestatic jaundice, unless the infant's condition precludes the procedure. Bone marrow biopsy and skin fibroblast culture may be necessary in storage disorders. Hepatobiliary scintigraphy, endoscopic retrograde cholangiopancreatography, and MRI may also be helpful in select cases. Exploratory laparotomy and intraoperative cholangiogram is the gold standard for diagnosis of biliary atresia.

INFECTIONS OF THE LIVER IN THE NEWBORN

Idiopathic neonatal hepatitis should be considered an obsolete and misleading term that was once used to denote the process of intrahepatic cholestasis and giant cell transformation of hepatocytes (Balistreri, 2002; Balistreri and Bezerra, 2006). It is now recognized that multinucleated giant cells are a prototypical response of the immature liver to a wide range of injuries, including biliary obstruction, infection, and metabolic diseases. A disorder should now be designated as neonatal hepatitis only if an infectious disorder has been documented or considered likely on the basis of other clinical features associated with congenital infection (Balistreri, 2002; Balistreri and Bezerra, 2006). Box 74-1 lists the infectious disorders that can be associated with neonatal hepatitis and includes the complex of toxoplasmosis, rubella, cytomegalovirus, herpes, and others designated by the acronym *TORCH*. Specific culture, serologic studies and approaches in molecular microbiology such as the polymerase chain reaction are used to establish a specific diagnosis.

BACTERIAL INFECTIONS

Cholestatic jaundice has long been associated with severe bacterial infections in the neonate (Balistreri, 2002). Both gram-positive and gram-negative organisms have been implicated. Cholestasis results from the effects of circulating endotoxin from bacteria that significantly alters the expression of transporters that contribute to bile formation. The release of cytokines in response to the infection also impairs hepatobiliary function. Septicemia is often present, but cholestasis can also be observed with urinary tract infections in the absence of a positive blood culture (Garcia and Nager, 2002). Liver dysfunction rapidly improves with appropriate antibiotic therapy.

CONGENITAL SYPHILIS

Despite routine maternal screening, congenital syphilis remains a significant perinatal infection that should be considered in the differential diagnosis of any neonate with hepatitis (Walker and Walker, 2007). Florid cases with typical findings in bone, skin, central nervous system, and liver may be obvious to the clinician, but milder cases may present with hepatitis, skin rash, and failure to thrive with or without a purulent nasal discharge. Hepatosplenomegaly is usually present (Chakraborty and Luck, 2008). Laboratory studies reveal modest elevation of serum aminotransferases and conjugated hyperbilirubinemia. Liver biopsy usually shows a diffuse mononuclear cell infiltration and a dissecting lobular fibrosis. Spirochetes may be identified using silver stains. A definitive diagnosis can be made by finding spirochetes in exudates from skin or mucosal lesions on dark field microscopy or a direct fluorescent antibody test. The well-known nontreponemal antibody tests (VDRL, rapid plasma reagin [RPR], and automated RPR test [ART]) should be positive. The fluorescent treponemal antibody absorption and *Treponema pallidum* particle agglutination tests should provide a presumptive diagnosis. Treatment with penicillin is highly effective. Liver dysfunction may take several months to resolve (Long et al, 1984).

CYTOMEGALOVIRUS

Congenital cytomegalovirus (CMV) infection affects 1% to 2% of newborns, but only about 10% of infected infants are symptomatic at birth with intrauterine growth retardation, microcephaly, intracerebral calcifications, jaundice, retinitis, and hepatosplenomegaly. Fetal ascites and hydrops may occur (Kenneson and Cannon, 2007). Conjugated hyperbilirubinemia and elevated aminotransferase values are typical (Fischler et al, 1999). Liver biopsy may show giant cell transformation, portal inflammatory infiltrates, extramedullary hematopoiesis, bile ductular proliferation, and portal or interstitial fibrosis. Large intranuclear inclusions are typically found in bile duct epithelium and to a lesser extent in hepatocytes.

Perinatal infection with CMV may also occur in infants as early as 3 weeks of age from exposure to maternal secretions, from ingestion of breast milk, or from blood products (Capretti et al, 2009; Kenneson and Cannon, 2007). Although most babies are asymptomatic, a sepsis-like condition can occur with hepatosplenomegaly, elevated serum aminotransferases, pneumonitis, leukopenia, and thrombocytopenia. Very low-birthweight infants are particularly prone to develop symptomatic illness (Capretti et al, 2009).

CMV may be isolated from multiple sites including the nasopharynx, urine, peripheral blood leukocytes, and liver tissue (Maine et al, 2001; Mendelson et al, 2006). Detection of the viral genome in urine or serum by PCR may be used to diagnose congenital and perinatal CMV infection (Soetens et al, 2008).

Ganciclovir has been used to treat some congenitally and perinatally infected infants, but its efficacy and safety in this age group remain unsettled. Infants with severe systemic disease including hepatitis may benefit (Ozkan et al, 2007). Although some treated infants have had improvement or maintenance of normal hearing when tested later, the effect on liver disease remains to be demonstrated (Fischler et al, 2002). Cirrhosis and noncirrhotic portal hypertension occur rarely (Ghishan et al, 1984).

HERPES SIMPLEX

Herpes simplex may cause hepatitis as part of a disseminated infection in the newborn. Although in utero infection can occur, most herpes infections are transmitted at birth and are associated with primary infection in the mother rather than reactivation of a previous infection (30% to 50% vs. approximately 5% or less). Neonates with disseminated disease may not manifest skin lesions initially, so herpes simplex infection should be considered in any newborn who appears septic, particularly with severe hepatic dysfunction (Caviness et al, 2008). Involvement of the central nervous system often occurs and may present with seizures. Although liver tests may be mildly abnormal, infants often present with jaundice, hepatosplenomegaly, markedly elevated aminotransferases, and coagulopathy (Verma et al, 2006).

Diagnosis relies on positive cultures from secretions, blood, urine, cerebrospinal fluid, and scrapings from vesicles. Direct fluorescent antibody staining of vesicle contents may facilitate a more rapid diagnosis. Polymerase chain reaction analysis may be used to detect herpes simplex virus DNA in CSF and blood. Liver histopathology shows extensive bland necrosis, often with hemorrhage and minimal inflammation. Intranuclear acidophilic inclusions are found in hepatocytes.

Parenteral treatment with acyclovir may be life-saving, but many infants with disseminated disease and encephalitis have significant neurologic sequelae (Kimberlin et al, 2001a). Approximately one fourth of infants will still die despite antiviral therapy (Kimberlin, 2001; Kimberlin et al, 2001b). Liver transplantation has been successful in a few neonates with fulminant hepatic failure without severe encephalitis (Lee et al, 2002; Twagira et al, 2004).

HEPATITIS VIRUSES (A, B, C, D, AND E)

The classic hepatitis viruses (A, B C, D and E) are rarely a cause of significant liver disease in the neonate, but there are several issues of importance to be considered in the newborn.

Acute hepatitis A during pregnancy is associated with a high risk of maternal complications and preterm labor (Elinav et al, 2006). Hepatitis A infection may be acquired in the neonate via the fecal-oral route or by blood transfusion from a blood donor incubating the infection. These infants are virtually always asymptomatic, but present a hazard for transmission to adults, particularly to caretakers in the nursery (Chodick et al, 2006).

Materno-fetal transmission of hepatitis E virus (HEV) occurs, but the virus is particularly dangerous for the mother, resulting in a mortality rate of 25% to 45% if the acute infection occurs during the third trimester of pregnancy (Khuroo and Kamili, 2009). Vertically transmitted HEV infection can cause clinical hepatitis or even fulminant hepatic failure in neonates. The hepatitis and viremia resolve in surviving infants.

Newborns have a 95% chance of acquiring hepatitis B if the mother is chronically infected with hepatitis B or suffers acute hepatitis B in the third trimester or early in the postpartum period (Shah et al, 2009). In utero transmission is rare and is not preventable with postnatal immunoprophylaxis. Most cases of vertical transmission occur during delivery and can be prevented by prompt postnatal administration of hepatitis B immunoglobulin and hepatitis B vaccine. Infants acquiring hepatitis B are usually asymptomatic and immunotolerant in that they have normal or near-normal liver tests and very high levels of hepatitis B DNA in blood (Chang, 2007). Fulminant hepatitis B has been reported rarely in infants born to mothers with precore mutations in hepatitis B DNA.

Transmission of hepatitis C occurs only in about 5% of infants born to infected mothers (Indolfi and Resti, 2009). The risk of transmission correlates with the degree of maternal viremia. Mothers infected with the human immunodeficiency virus often manifest high levels of hepatitis C RNA, and are more likely to transmit infection to their newborns (Marine-Barjoan et al, 2007). Infants infected with hepatitis C are generally asymptomatic and have normal liver tests. In infants born to infected mothers, passively acquired maternal serum antibody to hepatitis C virus may persist for up to 18 months. If there is reason to exclude infection with hepatitis C at an earlier time, measurement of hepatitis C RNA in serum is feasible. Hepatitis C infection is not a contraindication to breastfeeding if the mother's nipples are not damaged.

ENTEROVIRAL INFECTIONS

Disseminated enteroviral infections with fulminant hepatic failure occurs predominantly in newborns (Abzug, 2004). Risk factors for severe enteroviral disease include prematurity, absence of neutralizing antibody from the mother to the infecting serotype, and maternal illness before and around the time of delivery. Infants appear septic with fever, irritability, lethargy, anorexia, and rash. The polymerase chain reaction is more sensitive and rapid than viral culture for detecting enteroviruses in cerebrospinal fluid, blood, urine, and throat specimens. Intravenous immunoglobulin has been used as a therapeutic agent for neonates with life-threatening infections, but clinical efficacy has not been established. Pleconaril, an investigational agent that inhibits viral attachment to host cell receptors and uncoating of viral nucleic acid, has shown some success in treating neonates with severe hepatitis and/or myocarditis in uncontrolled reports (Bauer et al, 2002). It was not effective in a double-blind placebo-controlled trial in infants with enterovirus meningitis (Abzug et al, 2003).

DISORDERS OF THE BILE DUCTS

There are many disorders that primarily and secondarily involve bile ducts in the newborn (see Box 74-2) (Birnbaum and Suchy, 1998). The intra- and extrahepatic bile ducts may be affected by abnormal morphogenesis and are particularly susceptible to injury from infection, inborn errors of metabolism, or even the immune system.

BILIARY ATRESIA

Biliary atresia (BA) is the most common cause of end-stage liver disease in infants and is the leading indication for liver transplantation in pediatrics. The incidence is estimated to be between 1 in 8000 and 1 in 12,000 live births and has a female predominance. BA appears to be secondary to an inflammatory process of unknown etiology resulting in fibrous obliteration of the biliary tract. There is no excretion of bile from the liver into duodenum leading to cholestasis, fibrosis and ultimately cirrhosis. Anatomically, BA has been classified into three types based on the extent and site of fibrosis in the biliary tree, based on data produced by the Japanese Society of Pediatric surgeons (Kasai et al, 1976):

Type 1: Atresia of the common bile duct with patent proximal ducts
Type 2: Atresia involving the hepatic duct but with patent proximal ducts
Type 3: Atresia involving the right and left hepatic ducts at the porta hepatis

Type 3 is the most common (88%) and has the worst prognosis. The term *extrahepatic biliary hypoplasia* refers to the cholangiographic demonstration of a patent but narrow biliary tree. The term *intrahepatic biliary atresia* is a misnomer and should be replaced by *paucity of intrahepatic bile ducts* or *intrahepatic bile duct hypoplasia* (Mowat, 1994).

Two forms of biliary atresia have been described based on clinical features: the more common perinatal or acquired form (80%) and the rarer fetal or embryonic form (20%) (Suchy et al, 2007), which is associated with congenital abnormalities. In 51 of 251 (20%) patients with BA, (a) single or dual anomalies involving cardiac, gastrointestinal, or urinary systems were found in 30 (59%); (b) combinations of anomalies within the laterality sequence (polysplenia, cardiovascular defects, asplenia, abdominal situs inversus, intestinal malformation, and anomalies of the portal vein and hepatic artery) were present in 15 (29%); and (c) intestinal malrotation occurred in 6 (12%), some with preduodenal portal vein. The term *BASM* (biliary atresia splenic malformation syndrome) has been proposed to describe a subgroup of infants with BA who also had a macroscopic splenic anomaly (Davenport et al, 2006). Of 548 infants with BA studied in a single institution, 56 (10.2%) had BASM and 37 were females. Splenic abnormalities included polysplenia (n = 43, 77%), double spleen (n = 7, 12%), and asplenia (n = 6, 11%). Situs inversus abdominis

was noted in 21 cases (37%). The portal vein was abnormal in 35 (61%) of the infants, and the inferior vena cava was absent in 22 (39%). Structural cardiac anomalies were noted in 25 (45%) infants. Maternal diabetes mellitus was noted in 12.5% of pregnancies, and this may be of significance because a relationship between maternal diabetes and experimental situs inversus (Maeyama et al, 2001) as well as human L/R asymmetry malformations has been reported (Martinez-Frias, 2001). The prognosis of infants with BASM was appreciably worse (Davenport et al, 2006).

Pathogenesis

The cause of biliary atresia is unknown. The disease is not inherited, and there have been several reports of dizygotic and monozygotic twins discordant for biliary atresia (Bezerra, 2005). There is no evidence that biliary atresia results from a failure in morphogenesis or recanalization of the bile duct during embryonic development. An ischemic or toxic origin of extrahepatic bile duct injury is unlikely. Congenital infections with cytomegalovirus, rubella virus, reovirus 3, human herpesvirus 6, and papillomavirus occasionally have been implicated in some infants (Sokol and Mack, 2001). Initial reports of the involvement of group C rotavirus in biliary atresia have not been confirmed (Bobo et al, 1997). Clinical features support the view that in most cases, injury to the biliary tract occurs after birth (Sokol and Mack, 2001).

Human leukocyte antigen B12 (HLA-B12) has been found more frequently among biliary atresia patients without associated anomalies. The HLA haplotypes -A9, -B5, -A28, and -B35 occur more frequently (Silveira et al, 1993). Microarray gene chip analysis of cRNA from livers of infants with biliary atresia has revealed a coordinated activation of genes involved in lymphocyte differentiation and inflammation (Bezerra et al, 2002). The overexpression of osteopontin and interferon (IFN)-γ suggests a potential role of Th1-like cytokines in disease pathogenesis. Oligoclonal expansions of CD4 and CD8 T cells in liver and extrahepatic bile duct remnant tissues also have been found, indicating the presence of activated T cells reacting to specific antigenic stimulation in biliary atresia (Mack et al, 2007). Even after restoration of bile flow by portoenterostomy, circulating markers of inflammation persist, with clear progressive elevation in both Th1 effectors (interleukin [IL]-2 and IFN) and some Th2 effectors (IL-4), as well as the macrophage marker (TNFα). Increased expression of soluble cell adhesion molecules, sICAM-1 and sVCAM-1, likely reflects ongoing recruitment of circulating inflammatory/immunocompetent cells into target tissues (Nararyanaswamy et al, 2007). It remains unknown whether this immune response is induced by a viral infection or reflects a genetically programmed response to an infectious or environmental exposure. Maternal microchimerism has been demonstrated in BA, and it has been suggested that maternal cells could elicit an immune response similar to graft-versus-host disease (Kobayashi et al, 2007; Mieli-Vergani and Vergani, 2009).

Extrahepatic anomalies occur in 10% to 25% of patients and include cardiovascular defects, polysplenia, malrotation, situs inversus, and bowel atresias (Tanano, 1999). Loss of function mutations in the *CFC1* gene have been found in some patients who have heterotaxia, including an infant with biliary atresia and polysplenia (Bamford et al, 2000). This gene encodes for CRYPTIC, a protein that is involved in establishing the left-right axis during morphogenesis. However, mutations in the *INV* gene, which is also involved in determining laterality, were not found in limited studies of infants with biliary atresia and heterotaxia (Schon et al, 2002). In a microarray analysis of liver tissue from infants with the embryonic form of biliary atresia, often associated with extrahepatic malformations, a unique pattern of overexpression of genes involved in chromatin structure/histone deacetylation and of imprinted genes was found, implying a failure to downregulate embryonic gene programs that influence development of the liver and other organs (Zhang et al, 2004). There have been reports of identifying Jagged1 missense mutation in 10% of patients with BA (Kohsaka et al, 2002) and higher frequency of α_1-antitrypsin heterozygosity in children with BA (Campbell et al, 2007), both of which were associated with worse prognosis, but larger studies are needed to confirm these findings (Mieli-Vergani and Vergani, 2009).

Clinical Features

Infants with BA are typically born at term, with normal birthweight, and present in the first few weeks of life with history of jaundice lasting for more than 2 weeks, pale stools, and dark urine (Sokol et al, 2003). Occasionally, infants may present with bleeding secondary to vitamin K deficiency. In the fetal/embryonal type, infants are usually jaundiced with acholic stools from birth, whereas in the more common perinatal type, stools are pigmented at birth and then become acholic with progressive jaundice in the first few weeks of life (Suchy, 2004). On physical examination, there may be hepatomegaly or hepatosplenomegaly and ascites.

Laboratory studies initially reveal evidence of cholestasis, with a serum bilirubin level of 6 to 12 mg/dL, at least 50% of which is conjugated (Sokol et al, 2003). Serum aminotransferase and alkaline phosphatase levels are moderately elevated. Serum γ-glutamyl transpeptidase and 5′ nucleotidase levels may be markedly elevated.

Diagnosis

The gold standard for making a diagnosis of BA is exploratory laparotomy with intraoperative cholangiogram, because sometimes even the histology on liver biopsy can be ambiguous. BA is the most common surgically correctable liver disorder in infancy (Sokol et al, 2003). Outcome after Kasai portoenterostomy is dependent on the timing of the procedure, with best results achieved earlier in the course of the disease. However, establishing a diagnosis early remains a challenge, because there are no convenient means of screening newborns. The American Academy of Pediatrics currently recommends that infants who are jaundiced at 3 weeks of age should have a measurement of total and conjugated bilirubin (Sokol et al, 2007). A conjugated bilirubin that is more than 20% of an elevated serum bilirubin is diagnostic of cholestasis and potentially serious liver disease. Asking about the color of stools and examining the color of a fresh specimen of stool is helpful

in distinguishing between cholestasis (acholic, pale) and unconjugated hyperbilirubinemia (pigmented, green/yellow). In some countries, especially in Asia, a stool card is used to allow identification of acholic stools by parents to facilitate early diagnosis of BA (Hsiao et al, 2008).

Ultrasonography plays an important role in distinguishing BA from other causes of neonatal cholestasis. Using the gallbladder shape and wall structure sonography could identify BA with a sensitivity of 90% and specificity of 92.4% in 346 infants with conjugated hyperbilirubinemia (Farrant et al, 2000). Some find the triangular cord sign, which represents a cone-shaped fibrotic mass cranial to the bifurcation of the portal vein, very useful in the diagnosis of BA (Choi et al, 1996), but others are unable to detect it sonographically (Shneider et al, 2006a). Absence of the common bile duct can sometimes be defined on imaging, as can situs inversus and some of the other malformations associated with the fetal type and the BASM subgroup in BA. On T2-weighted MRI, moderately high signal intensity along the portal tract that extends from the porta hepatis correlated with periductal edema and inflammatory cell infiltration (Schneider et al, 2006). Although BA can be diagnosed on the basis of lack of visualization of either common bile duct or the common hepatic duct, findings on MRI should always be interpreted in conjunction with the clinical information.

Hepatobiliary scintigraphy is a noninvasive way for ruling out extrahepatic biliary atresia. Technetium-99m iminodiacetic acid derivatives are excreted from the blood by hepatocytes and excreted into the bowel through the biliary system. Infants characteristically need to be primed with phenobarbitone for 3 to 5 days before the test, because it increases bilirubin conjugation and has a choleretic effect. If there is excretion of labeled tracer in the intestine, then BA is ruled out. Conversely, if there is no excretion of tracer, then the diagnosis is not necessarily BA, but is also seen in severe neonatal hepatitis and interlobular bile duct paucity (Gilmour et al, 1997). The scintigraphy test is of value in infants in the intensive care unit who are of low birthweight or on oxygen where excretion of tracer in the gut rules out BA and allows the liver biopsy to be postponed/avoided. In the older infant above 6 to 7 weeks, the test may not be as useful, because it causes delay by a week, given the need for phenobarbitone priming and the fact that a definitive diagnosis is not possible without a liver biopsy with or without an intraoperative cholangiogram. Some have used scintigraphy in combination with serum γ-glutamyl transpeptidase levels (Arora et al, 2001; Stipsanelli et al, 2007), and others have primed with ursodeoxycholic acid in an effort to improve sensitivity of the test (Poddar et al, 2004). Duodenal fluid may be obtained to assess the bilirubin content, and if fluid is bile stained, then BA is ruled out. Endoscopic retrograde cholangiopancreatography permits visualization of the biliary tree in young infants, but is technically challenging in the newborn (Guelrud et al, 1991).

Liver biopsy is an essential tool in the evaluation of an infant with conjugated hyperbilirubinemia and should be performed preferably before 8 weeks of age. The histologic features of BA (Figure 74-1) include cholestasis, periportal ductular proliferation, and the presence of bile plugs in cholangioles and interlobular bile ducts (Ishak and Sharp, 2002). These findings are highly suggestive of biliary obstruction, but bile ductular proliferation can also be seen in α_1-antitrypsin deficiency. Giant-cell transformation is seen in 15% of cases. Fibrosis is progressive with eventual development of biliary cirrhosis (Lefkowitch et al, 1998).

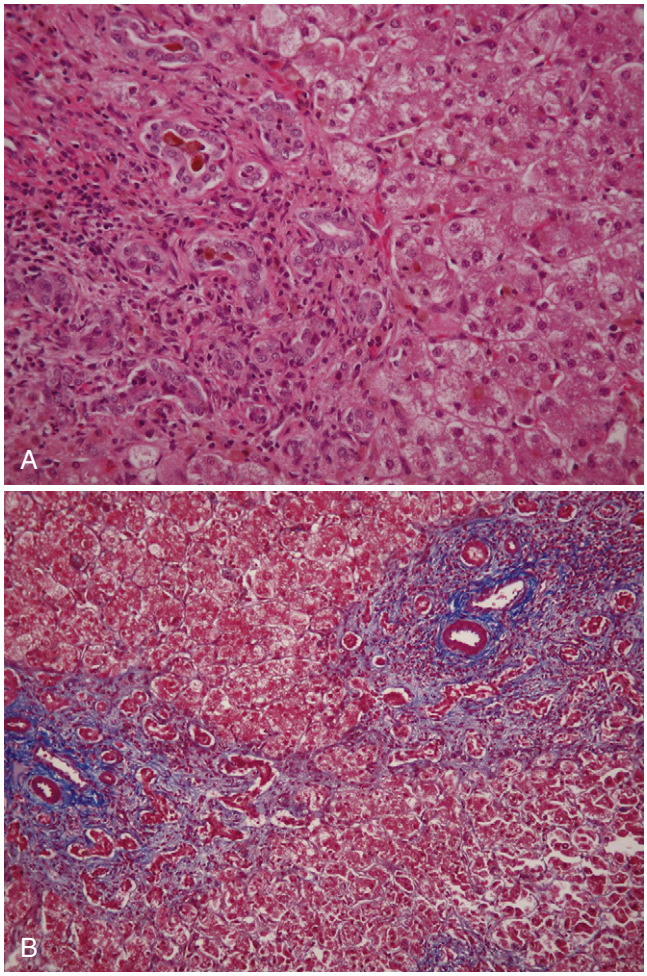

FIGURE 74-1 Liver biopsy from an infant with biliary atresia. **A,** Portal tracts are expanded by bile ductular proliferation and fibrosis. Bile ductules contain bile plugs. **B,** *(See also Color Plate 33.)* Trichrome stain demonstrates portal tract fibrosis.

Management

Based on results of laboratory tests, imaging, and liver histology, when clinical suspicion for BA is high, exploratory laparotomy is planned. If the diagnosis of BA is confirmed on intraoperative cholangiography, the Kasai hepatoportoenterostomy (HPE) procedure is performed. In the Kasai portoenterostomy, an anastomosis between the porta hepatis and a retrocolic Roux-en-Y loop of jejunum is fashioned (Ishak and Sharp, 2002). If successful, bile flow is restored from the intrahepatic ducts to the bowel. The outcome after surgery correlates to timing of surgery. Some series have reported that bile flow can be reestablished in 80% of the infants if surgery is performed early, that is, before 60 days, but the biliary drainage can decrease considerably when surgery is performed later, between 90 and 120 days of life (Balistreri et al, 1996; Mieli-Vergani

et al, 1989). A simple rule of thumb for estimating outcome after Kasai portoenterostomy is that two thirds of infants will have successful drainage, but despite this, two thirds of those with bile drainage will require liver transplantation at some stage in their lives. When there is no biliary drainage established for up to 8 weeks after the procedure, infants require liver transplantation. Results are best if the surgeon is experienced and the operation performed in a specialist center. Some have used the size of the bile duct remnant at the hilum to predict outcome, those with diameter above 150 μm having increased chance of good bile flow (Chandra and Altman, 1978). Parameters associated with poor outcome include white race, the severity of the intrahepatic biliary cholangiopathy, the presence of cirrhosis on initial liver biopsy, and absence of ducts at the hilum (Balistreri et al, 1996). Growth failure after HPE was associated with transplantation or death by 24 months of age (DeRusso et al, 2007). There was markedly improved survival in children with total bilirubin level <2 mg/dL at 3 months after HPE (Shneider et al, 2006b).

Attempts have been made over the years to use corticosteroids after HPE to reduce the inflammatory cascade in an attempt to reduce future fibrosis, with varying results (Davenport et al, 2007; Dillon et al, 2001; Kobayashi et al, 2005). Postoperatively, infants are typically maintained on a formula containing high levels of medium-chain triglycerides, supplemented with fat-soluble vitamins, and ursodeoxycholic acid to stimulate bile flow (Sokol, 1994).

The life expectancy without surgery in BA is at most 2 years. In the United States, BA remains the most frequent indication for liver transplantation in pediatrics. Indications for liver transplantation in BA include failed Kasai hepatoportoenterostomy; increasing cholestasis, pruritis, and/or failure to thrive; recurrent cholangitis with bile lakes in the liver on imaging studies; complications related to portal hypertension, including gastrointestinal bleeding not controlled with medical management and decompensated liver disease with ascites; worsening synthetic function (prolonged international normalized ratio and low albumin); and encephalopathy (Shneider and Mazariegos, 2007).

CHOLEDOCHAL CYSTS

Choledochal cysts are congenital anomalies of the biliary tract with dilatations of the extrahepatic and sometimes intrahepatic biliary system (Miyano and Yamataka, 1997). After BA, choledochal cyst is the most common surgical cause of obstructive jaundice in the newborn period. The frequency of choledochal cysts is about 1 in 15,000 live births in Western countries, and as high as 1 in 1000 live births in Japan (Suchy et al, 2001). There is a marked female predominance (4:1), regardless of racial origin. The etiology of choledochal cyst is not known. An anomalous pancreaticobiliary ductal anatomy (with a long common channel before it enters the duodenum) is reported in 70% to 90% of patients with choledochal cyst (Mackenzie et al, 2001; McWhorter, 1924). This may allow reflux of pancreatic enzymes into the common bile duct, resulting in inflammation, weakness, and dilatation. Other etiologic mechanisms include congenital weakness of the common bile duct and obstruction of the distal common bile duct leading to dilatation (Balistreri et al, 1996). Predominant extrahepatic biliary dilatation has been found in several patients with autosomal recessive polycystic kidney disease (Goilav et al, 2006).

Depending on the extent and shape of the biliary dilatation, choledochal cysts have been classified into several types (Todani et al, 1977). Type Ia is a cystic dilatation of the common bile duct, Ib a focal segmental dilatation of the distal common bile duct, and Ic a fusiform dilatation of both the common hepatic duct and common bile duct. In type II, the cyst forms a diverticulum from the extrahepatic bile duct. Type III, also known as choledochocele, is a dilatation of the distal common bile duct lying mainly within the duodenal wall. Type IV is essentially type I anatomy with either intrahepatic bile duct cyst (IVa) or choledochocele (IVb). Some authors refer to Caroli's disease with multiple cystic dilatations of the intrahepatic biliary tree as type V choledochal cyst. Type Ia is seen most frequently.

Cholestasis is a common presenting feature, and one fifth of those diagnosed with choledochal cyst are jaundiced in the 1st year of life (Altman, 1992). The classic triad of symptoms—intermittent obstructive jaundice, abdominal pain, and a cystic abdominal mass—rarely present in infancy. Care must be taken during examination that the choledochal cyst is not ruptured during palpation.

Ultrasonography is most frequently done to diagnose a choledochal cyst and has even been used to detect a choledochal cyst in the fetus (Bancroft et al, 1994; Kim et al, 1995). Magnetic resonance cholangiography is being used increasingly to evaluate the extent of the cyst and defects within the biliary tree and to detect an anomalous junction of the pancreaticobiliary duct (Kim et al, 2000).

Complications include recurrent cholangitis, biliary cirrhosis, rupture with bile peritonitis, pancreatitis, portal vein thrombosis, hepatic abscess, gallstones, and later cholangiocarcinoma of the cyst wall.

An operative cholangiogram is done to define the extent of intrahepatic and extrahepatic disease. Complete excision of the cyst mucosa is considered essential for successful management of choledochal cysts, as cholangiocarcinoma has been reported in up to one fourth of patients with residual cystic tissue (Todani et al, 1977). Biliary tract continuity is maintained through a choledochojejunostomy with Roux-en-Y anastomosis (McWhorter, 1924). For symptomatic patients, especially when BA is high in the differential, it is advisable to perform surgery before 2 months of age to prevent progressive liver damage and fibrosis (Davenport et al, 2003).

NEONATAL SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis may present in the neonatal period and, in contrast to older children, is not associated with inflammatory bowel disease or autoimmune markers (Amedee-Manesme et al, 1987). Cholestatic jaundice and acholic stools occur within the first weeks of life (Batres et al, 2005). Cholangiography demonstrates a patent biliary system, but with rarefaction of segmental branches, stenosis, and focal dilatation of the intrahepatic bile ducts (Debray et al, 1994). The extrahepatic bile ducts may be involved in most patients. Jaundice may subside

spontaneously, but progression to biliary cirrhosis may still occur later in childhood.

The neonatal ichthyosis–sclerosing cholangitis syndrome is a rare autosomal recessive syndrome characterized by scalp hypotrichosis, scarring alopecia, ichthyosis, and sclerosing cholangitis. Mutations in the gene coding for the tight junction protein claudin-1 have been found in these patients (Hadj-Rabia et al, 2004).

SPONTANEOUS PERFORATION OF COMMON BILE DUCT

Spontaneous perforation of common bile duct is a rare cholestatic disorder of infancy (Chardot et al, 1996). The perforation usually occurs at the junction of the cystic and common ducts. The cause is unknown, but congenital or acquired weakness at the site, obstruction at the distal end of the common bile duct from stenosis, or inspissated bile have been proposed (Sahnoun et al, 2007).

Infants present with poor weight gain, jaundice, acholic stools, dark urine, and ascites. Progressive abdominal distention usually occurs due to ascites with bile staining of umbilical and inguinal hernias.

Mild to moderate conjugated hyperbilirubinemia with minimal elevation of serum aminotransferase levels is typical. Abdominal paracentesis reveals clear bile-stained ascitic fluid, which usually is sterile. Ultrasonography confirms ascites, which is sometimes loculated in the right upper quadrant. There is no biliary dilatation. Hepatobiliary scintigraphy is diagnostic, showing free accumulation of isotope within the peritoneal cavity (Ford et al, 1988).

Operative cholangiography is required to demonstrate the site of the perforation. At laparotomy, drainage of bilious ascites and repair of the perforation usually provide effective treatment (Davenport et al, 1991). Cholecystojejunostomy may be required in some infants with stenosis of the common bile duct.

PAUCITY OF INTERLOBULAR BILE DUCTS

Paucity of interlobular bile ducts on a liver biopsy has been defined as the ratio of the number of interlobular bile ducts to the number of portal tracts of less than 0.4 (Kahn, 1991). It may be an isolated and unexplained finding in idiopathic neonatal cholestasis or a feature of a heterogeneous group of disorders that include congenital infections with rubella and cytomegalovirus and genetic disorders such as α_1-antitrypsin deficiency and inborn errors of bile acid metabolism (Kahn et al, 1986).

ALLAGILLE SYNDROME

Alagille syndrome, or syndromic paucity of interlobular bile ducts, is the most common form of familial intrahepatic cholestasis (Alagille et al, 1987). This disorder is characterized by chronic cholestasis, a decreased number of interlobular bile ducts, and a variety of other congenital malformations.

An autosomal dominant mode of transmission with incomplete penetrance and variable expressivity has been established. Mutations in the *jagged1 (JAG1)* gene on the short arm of chromosome 20 have been identified in approximately 94% of affected patients (Colliton et al, 2001). *JAG1* encodes a ligand in the Notch signaling pathway that is involved in cell fate determination during development. Mutations in the gene encoding for the NOTCH2 receptor have recently been found in patients with Alagille syndrome who were negative for JAG1 mutations (McDaniell et al, 2006).

Chronic cholestasis of varying severity affects 95% of patients (Emerick et al, 1999). Onset in the neonate is common with jaundice and clay-colored stools. Intense pruritus and xanthomata develop later. The liver and spleen are often enlarged. Dysmorphic facies may be difficult to recognize in the newborn, but become more characteristic with age (Emerick et al, 1999, Kamath et al, 2002). The forehead is typically broad; the eyes are deeply set and widely spaced. The mandible is somewhat small and pointed, imparting a triangular appearance to the face. Other extrahepatic anomalies occur variably and commonly include congenital heart disease, particularly peripheral pulmonic stenosis; butterfly vertebrae; posterior embryotoxon of the eye; and impaired growth. Abnormalities of the kidney, the systemic vasculature, and pancreas are other manifestations (Emerick et al, 1999).

There is variable elevation of the serum conjugated bilirubin concentration. Serum alkaline phosphatase, bile acids, γ-glutamyl transpeptidase, and 5′-nucleotidase levels may be extremely high. Serum aminotransferase levels are mildly to moderately increased. Serum cholesterol levels may be 200 mg/dL or higher. Serum triglyceride concentrations of 500 to 1000 mg/dL are commonly found.

The nonspecific histologic features during the first months of life may include ballooning of hepatocytes, cholestasis, portal inflammation, and giant-cell transformation (Kahn, 1991). The number of interlobular bile ducts may not be decreased on initial liver biopsy, but bile duct injury may be present, consisting of lymphocytic infiltration, pyknosis of biliary epithelium, and periductal fibrosis. Serial liver biopsies may show progressive loss and paucity of bile ducts by the age of 6 months. The extrahepatic bile ducts are patent but usually narrowed or hypoplastic.

The mechanisms involved in the pathogenesis of bile duct paucity and cholestasis have not been defined. It is also unknown how the hepatobiliary disease relates to the multiplicity of congenital anomalies found in other organ systems. Notch signaling has an important role in the differentiation of biliary epithelial cells and is essential for their tubular formation during development. A lack of branching and elongation of bile ducts during postnatal liver growth likely contributes to peripheral bile duct paucity and cholestasis (Libbrecht et al, 2005).

Varying degrees of cholestasis, sometimes worsened by intercurrent viral infections, typically occur. Pruritus, cutaneous xanthomata, and neuromuscular symptoms related to vitamin E deficiency may cause significant morbidity. Provision of an adequate caloric intake, prevention or correction of fat-soluble vitamin deficiencies, and symptomatic measures to relieve pruritus are important. The long-term prognosis depends on the severity of the liver disease and associated malformations (Lykavieris et al, 2001). Neonatal cholestatic jaundice has been associated with poorer survival with native liver (Lykavieris et al,

2001). Survival and candidacy for liver transplantation may be limited by the severity of associated cardiovascular anomalies.

CYSTIC DILATATION OF THE INTRAHEPATIC BILE DUCTS

Cystic dilatation of the intrahepatic bile ducts is an inherited disorder characterized by saccular dilatation of several segments of the intrahepatic bile ducts (Desmet, 1998). There are two variants: Caroli's disease, characterized by ectasias of the intrahepatic bile ducts without other abnormalities and Caroli's syndrome, in which congenital ductal dilatation is associated with features of congenital hepatic fibrosis and the renal lesion of autosomal recessive polycystic renal disease (ARPKD) (Bergmann et al, 2004). Caroli's syndrome is more common, but both varieties are inherited in an autosomal recessive fashion.

Patients may present in the newborn period with cholestasis from ascending cholangitis and calculus formation within the abnormal bile ducts (Guay-Woodford and Desmond, 2003; Keane et al, 1997). Caroli's disease has been detected in utero with fetal ultrasound findings of a cystic liver mass and echogenic kidneys (Sgro et al, 2004). Fever, abdominal distention, jaundice, and an enlarged, tender liver are typical. Markedly enlarged kidneys from ARPKD can be palpated.

Elevated serum alkaline phosphatase activity, direct-reacting bilirubin levels, and leukocytosis may be observed during episodes of acute infection. Ultrasonography shows the dilated intrahepatic ducts with intraductal lithiasis and sludge and cystic renal disease, but definitive diagnosis and extent of disease must be determined by percutaneous transhepatic or magnetic resonance cholangiography (Brancatelli et al, 2005). Most patients with Caroli's syndrome have mutations in the *PKHD1* (polycystic kidney and hepatic disease 1) gene (Bergmann et al, 2005).

Cholangitis and sepsis are treated with broad-spectrum antibiotics. Ursodeoxycholic acid therapy may help to inhibit formation of biliary sludge and promote bile flow. Intraductal calculi may require surgery (Arnold and Harrison, 2005).

PARENTERAL NUTRITION ASSOCIATED CHOLESTASIS

Parenteral nutrition–associated cholestasis (PNAC) is frequently seen in newborn infants. Premature infants and those with short bowel syndrome are particularly susceptible (Robinson and Ehrenkranz, 2008). Additional risk factors include an immaturity of liver function, repeated bouts of infection, exposure to endotoxin from bacterial overgrowth of the intestine, lack of enteral feeding, and possibly toxicity from some of the components of the parenteral nutrition solution (Forchielli and Walker, 2003).

The pathophysiology of PNAC has not been completely defined and is likely to be multifactorial. Enteral feedings are trophic for biliary secretion through the release of gastrointestinal hormones such as cholecystokinin, glucagon, gastrin, and enteroglucagon. Biliary stasis leading to gallbladder sludge and stones reflects decreased gallbladder contraction from the lack of enterally stimulated cholecystokinin release. Endotoxin resulting from bacterial overgrowth of the small intestine and from sepsis is a potent inhibitor of transporters for bile acids and other organic anions that are essential for bile formation. Lipid emulsions used in parenteral nutrition have recently been implicated in contributing to cholestasis (Shin et al, 2008). Stigmasterol, a soy lipid-derived phytosterol, has been found to potently antagonize the expression of several critical bile acid transport proteins, including the bile salt export pump and the organic solute transporter (Carter et al, 2007).

Cholestasis typically develops with prolonged use of parenteral nutrition. The clinical features are similar to other cholestatic disorders of the newborn and include elevated serum concentrations of bilirubin, bile acids, and aminotransferases. Alternative causes of cholestasis must be excluded, including biliary tract disorders, perinatal infections, and inborn errors of metabolism.

Hepatocellular and canalicular cholestasis, steatosis, and periportal fibrosis are seen on liver biopsy. Bile ductular proliferation and giant-cell transformation of hepatocytes can also be observed. Evolution to biliary cirrhosis can occur with continued use of parenteral nutrition.

Without a precise knowledge of the factors that cause PNAC, the prevention and treatment of the condition remain problematic. Enteral feedings are extremely important not only for stimulating bile flow, but also for promoting intestinal adaptation in infants with short gut syndrome. Even nutritionally insignificant amounts of enteral feedings may be beneficial. Ursodeoxycholic acid given in doses of 10 to 20 mg/kg of body weight may be helpful in stimulating bile flow and diminishing cytotoxicity from more hydrophobic bile salts (Arslanoglu et al, 2008; Chen et al, 2004a). There is increasing interest in replacing soy-based lipid emulsions with fish oil–based lipid emulsions (Cheung et al, 2009; Gura et al, 2008). Prevention or even reversal of PNAC has been observed in a limited number of infants (de Meijer et al, 2009). Liver transplantation or combined liver-intestinal transplantation may be the only option in patients with end-stage liver disease and extreme short bowel syndrome.

CYSTIC FIBROSIS

Infants with cystic fibrosis may present with cholestasis during the first weeks of life (Colombo, 2007; Lamireau et al, 2004). Meconium ileus may be associated and provide a clue to the underlying diagnosis (Lamireau et al, 2004). Variants in mannose binding lectin and ABCB4 genes may be genetic modifiers influencing the risk for liver disease in CF (Tomaiuolo et al, 2009). Conjugated hyperbilirubinemia and modest elevation of aminotransferases may be observed in the newborn. Serum cholesterol may be low. Liver biopsy shows cholestasis and bile ductular proliferation consistent with an obstructive process (Brigman and Feranchak, 2006). The findings may mimic biliary atresia, and the typical mucus plugs observed later in bile ducts may not be present in the newborn with cystic fibrosis. Meconium ileus may be another diagnostic clue. Operative cholangiography may sometimes be required to exclude biliary atresia. However, neonatal screening tests and eventual sweat chloride analysis should be diagnostic.

Treatment with ursodeoxycholic acid (20 to 40 mg/kg/day) usually leads to improvement in liver biochemical tests, but it is uncertain whether the course of the liver disease is altered (Cheng et al, 2000). The jaundice often resolves even without treatment and does not predict severe liver disease later in life (Shapira et al, 1999).

PROGRESSIVE FAMILIAL INTRAHEPATIC CHOLESTASIS (PFIC)

It has long been recognized that progressive, intrahepatic cholestasis may have a genetic basis, and have its onset in the newborn period. Mutations in several genes encoding transport proteins that contribute to bile formation have been defined in recent years (Alissa et al, 2008).

PFIC1

Patients with PFIC1 (also called Byler disease) present in the newborn or by the age of 1 year with severe cholestasis that progresses to cirrhosis at a variable rate (van Mil et al, 2001). Hepatosplenomegaly, diarrhea, malabsorption, and failure to thrive are common in the first months of life. Fat-soluble vitamin deficiencies occur, resulting in rickets and coagulopathy. Intractable pruritus, a dominant feature of the disease, is generally not observed until approximately 3 months of age,

Serum γ-glutamyl transpeptidase activity and cholesterol concentration are paradoxically normal. The serum bile acid concentration is elevated. Serum aminotransferases are moderately elevated.

A bland hepatocellular, canalicular cholestasis is typical on liver biopsy early in the course of the disease. Cirrhosis eventually occurs. Electron microscopy shows distended bile canaliculi containing unusually coarse and granular bile.

Patients with PFIC1 have mutations in the gene encoding ATP8B1, a P-type ATPase, that is an aminophospholipid flippase localized to the liver canalicular, cholangiocyte, and intestinal apical membranes (Bull et al, 1998). It remains unsettled as to how mutations in the ATP8B1 gene lead to progressive cholestasis. The ordering of aminophospholipids in lipid bilayers in part mediated by ATP8B1 may play a role in regulating important lipid-dependent signaling pathways and the activity of membrane receptors and transport proteins, including those involved in regulating bile acid homeostasis (Chen et al, 2004b). Moreover, the loss of canalicular phospholipid membrane asymmetry may also render the canalicular membrane susceptible to the damaging effects of hydrophobic bile salts. The FIC1 gene is also highly expressed in other organs, including the lungs, small intestine, pancreas, and kidneys, which may account for the extrahepatic manifestations of the disease such as lung disease and diarrhea.

Biliary diversion or ileal bypass may be successful in decreasing pruritus and slowing the progression of liver injury by depleting the liver and intestines of hydrophobic bile acids (Arnell et al, 2008). Liver transplantation may be required in patients with cirrhosis or pruritus refractory to other therapies. Patients may still manifest growth failure, malabsorption, and pancreatitis after an otherwise successful liver transplant because of the extrahepatic expression of ATP8B1.

PFIC2

PFIC2 is caused by mutations in *ABCB11*, which codes for the bile salt export pump (BSEP), the predominant transporter for bile acids on the liver canalicular membrane (Jansen et al, 1999, Suchy and Ananthanarayanan, 2006). Bile secretory failure occurs leading to retention of bile salts and other biliary constituents in the hepatocyte and progressive liver damage (Strautnieks et al, 1998, 2008).

Severe cholestasis begins in the newborn. Jaundice, failure to thrive related to fat malabsorption, and poor intake occur. Fat-soluble vitamin deficiencies are common. Hepatosplenomegaly is usually present. Severe pruritus develops in the first months of life. Progression to cirrhosis is rapid without therapy. Hepatocellular carcinoma and cholangiocarcinoma may occur, even in the 1st year of life (Knisely and Portmann, 2006).

Similar to patients with PFIC-1, serum γ-glutamyl transpeptidase is low, and serum cholesterol levels are normal or near normal. In contrast to patients with PFIC-1, serum aminotransferase levels are usually elevated to over five times normal values.

The histopathology of PFIC2 shows a marked, nonspecific giant-cell hepatitis and lobular cholestasis, similar to many liver diseases of the neonate. Electron microscopy demonstrates dilated bile canaliculi that contain finely granular or filamentous bile. The lack of BSEP immunohistochemical staining on the canalicular membrane is useful diagnostically (Jansen et al, 1999).

Intractable pruritus and progressive liver disease have also been treated with biliary diversion or ileal exclusion. A risk for liver cancer may still exist despite clinical improvement. Liver transplantation is required in many patients.

PFIC3

This disorder is due to mutations in the *MDR3* gene, which encodes a transporter required for biliary phosphatidylcholine secretion (Jacquemin et al, 1999). The age of onset of PFIC3 with jaundice, hepatomegaly, growth failure and acholic stools is extremely broad, but onset has been observed in the 1st month of life (mean age approximately 3.5 years). Pruritus is usually mild. Liver disease tends to evolve slowly to biliary cirrhosis.

In contrast to the other forms of PFIC, the serum concentration of γ-glutamyl transpeptidase is elevated in PFIC3, often over 10 times the normal value (Jacquemin et al, 2001). Other liver tests are variable. Serum cholesterol concentration is usually normal. The cardinal feature of PFIC3 is markedly reduced concentrations of biliary phospholipids (Oude Elferink and Paulusma, 2007).

The histopathology of PFIC3 shows bile ductular proliferation and mixed inflammatory infiltrates. Periductal sclerosis affecting the interlobular bile ducts eventually occurs. Extensive portal fibrosis evolves into biliary cirrhosis in older children.

Oral administration of ursodeoxycholic acid appears to be of value in some patients, particularly those with mild MDR3 mutations and residual biliary phospholipid secretion (Jacquemin et al, 1997). The rationale underlying this therapy is that enrichment of bile with this hydrophilic bile acid reduces cytotoxic injury to hepatocytes and bile ducts

and stimulates bile flow. Other patients progress to biliary cirrhosis and ultimately require liver transplantation.

METABOLIC LIVER DISEASE

The liver is involved primarily or secondarily in many inborn errors of metabolism that often present in the first weeks of life, as the infant adjusts to the extrauterine environment. Establishing a specific diagnosis is critically important for genetic counseling and to allow specific therapy in some cases or liver transplantation if the disease is restricted to the liver. Presymptomatic diagnosis and early treatment made possible by newborn screening has changed the natural history of several disorders such as galactosemia and tyrosinemia.

In inborn errors of metabolism such as hereditary tyrosinemia, the absence of a critical enzyme may cause an accumulation of toxic metabolites that damage the liver and other organs. In other disorders, progressive liver injury may occur because of failure to produce essential compounds necessary for normal hepatic function. For example, an inborn error of bile acid metabolism leads to progressive cholestasis because of a lack of bile acid synthesis and impairment of bile flow. Severe liver injury may also result from sequestration of an abnormally synthesized product within the liver, as observed in α_1-antitrypsin deficiency or lysosomal storage disorder.

Clinical features of metabolic liver disease may be nonspecific and can overlap with other hepatic disorders, including viral hepatitis or drug-induced liver injury, or mimic septicemia. Jaundice, vomiting, hepatosplenomegaly, failure to thrive, developmental delay, hypotonia, seizures, and progressive neuromuscular dysfunction may occur (see Table 74-1). Initial laboratory studies are often nonspecific and may include jaundice, hypoglycemia, hyperammonemia, increased aminotransferase levels, acidosis, and hypoprothrombinemia.

HEREDITARY TYROSINEMIA TYPE I

Hereditary tyrosinemia type I is an autosomal-recessive disorder of the tyrosine degradation pathway caused by deficiency of fumarylacetoacetate hydrolase (Mitchell et al, 2007). Highly reactive, electrophilic metabolites of tyrosine, succinyl acetate, succinyl acetone, fumaryl acetoacetate, and maleyl acetoacetate, accumulate and bind to sulfhydryl groups, leading to tissue injury. Many secondary enzymatic and biochemical defects occur in tyrosinemia as a result of the accumulation of these precursor compounds. Succinyl acetoacetate is one example that can inhibit the enzyme porphobilinogen synthase, leading to the accumulation of 5-aminolevulinic acid and symptoms of acute, intermittent porphyria (Grompe, 2001). A transient, benign form of hypertyrosinemia is a self-limiting condition primarily of premature infants, probably caused by an immaturity of tyrosine degradation pathway.

The acute form of the disease presents in the first weeks of life with jaundice, hepatosplenomegaly, failure to thrive, anorexia, ascites, coagulopathy, and rickets. The disorder may begin in utero as evidenced by the presence of cirrhosis and ascites at the time of birth.

Laboratory studies usually show compromise of hepatic synthetic function with hypoalbuminemia and a decrease in vitamin K–dependent coagulation factors (Grompe, 2001). Serum aminotransferase values are mildly to moderately increased. Total and direct bilirubin concentrations are variably increased. Hypoglycemia is common. Hemolytic anemia may occur. Fanconi's syndrome resulting from renal tubular dysfunction may lead to hyperphosphaturia, glucosuria, proteinuria, and aminoaciduria. Serum tyrosine and methionine concentrations are markedly elevated (Russo et al, 2001). Serum α-fetoprotein concentrations are often markedly elevated even in cord blood, supporting the prenatal onset of liver disease.

Phenolic acid by-products of tyrosine metabolism, succinyl acetone and succinyl acetoacetate, are excreted in urine and are diagnostic of this disorder.

Histologic examination of the liver reveals fatty infiltration, iron deposition, varying degrees of hepatocyte necrosis, and pseudoacinar formation. Significant fibrosis may be present early in life with gradual evolution to multinodular cirrhosis. Regenerative nodules mimicking neoplasms may be present in some patients. Hepatocellular carcinoma (HCC) may develop later.

The acute form of type 1 tyrosinemia is usually fatal in the 1st year of life without therapy (Ashorn et al, 2006). Dietary restriction of phenylalanine, methionine, and tyrosine does not prevent progression of the liver disease or development of hepatocellular carcinoma. Medical therapy with 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) is effective in reversing the metabolic abnormalities in hereditary tyrosinemia type 1 (Santra and Baumann, 2008). NTBC treatment reduces flux through the tyrosine degradation pathway, preventing formation of toxic metabolites. With NTBC treatment, serum α-fetoprotein levels decrease and liver synthetic function normalizes. NTBC usually provides protection against HCC if it is started in infancy, but cases of HCC have occurred even when NTBC was started at 5 months of age. AFP is a marker for both the development of liver cancer and the inadequate control of metabolic derangement of tyrosinemia type I itself. Liver transplantation will be required in such cases (Lam et al, 2002).

In asymptomatic newborns identified by newborn screening in Quebec and treated with NTBC within 1 month, none have developed hepatic dysfunction or liver nodules over a follow-up period of up to 9 years (Mitchell et al, 2007). However, the long-term risk for developing hepatocellular carcinoma even in patients who were treated early remains unknown.

α_1-ANTITRYPSIN DEFICIENCY

Antitrypsin is the principal serum protease. α_1-Antitrypsin deficiency can be associated with cholestatic jaundice in the neonate. Patients with homozygous deficiency of this protein (the PiZZ phenotype) have low serum α_1-antitrypsin activity, usually in the range of 10% to 15% of normal values (Kohnlein and Welte, 2008). The incidence of the most common deficiency phenotype, PiZZ, is 1 in 2000 to 1 in 4000 live births.

Measurement of α_1-antitrypsin concentration alone is unreliable for diagnosis because the protein is an

acute-phase reactant and may be elevated in the presence of inflammation (Perlmutter et al, 2004). Heterozygotes with the SZ and MZ phenotypes have a less severe reduction in serum α_1-antitrypsin concentration and do not develop liver disease. However, α_1-antitrypsin heterozygosity may be a modifier for other liver diseases.

Cholestatic jaundice occurs in approximately 10% to 15% of infants with the PiZZ phenotype (Teckman and Lindblad, 2006). Hepatomegaly and acholic stools may occur. Patients rarely may present with signs of advanced liver disease such as ascites or gastrointestinal bleeding. Although asymptomatic, another 40% to 50% of homozygous infants have abnormal liver biochemical tests in the first months of life.

Giant-cell hepatitis is a typical histologic finding in the neonate. Bile ductular proliferation may be observed initially; later, paucity of bile ducts may be found. Periodic-acid-Schiff–positive, diastase-resistant inclusions within hepatocytes, especially in the periportal region, represent the abnormal α_1-antitrypsin accumulation but are not prominent before 4 months of age (Teckman, 2007). Fibrosis is variable, but cirrhosis has been reported rarely in the neonatal period.

It is unknown why only 10 to 15% of neonates with the homozygous deficiency manifest liver disease. The PiZZ defect is caused by substitution of a lysine for a glutamate at position 342, leading to misfolding of the protein and its retention in the endoplasmic reticulum (Perlmutter, 2006; Perlmutter et al, 2007). Mutant α_1-antitrypsin molecules polymerize in the ER by a loop-sheet insertion mechanism, and are toxic to hepatocytes (Kohnlein and Welte, 2008).

The outcome of neonatal liver disease related to α_1-antitrypsin deficiency is variable (Perlmutter, 2002, 2004). Patients may present with or develop cirrhosis within the first months of life. However, in most infants, the jaundice clears by 4 months of age, but variable liver test abnormalities may persist. There is no specific treatment for α_1-antitrypsin deficiency. Liver transplantation is curative for patients with end-stage liver disease; the recipient assumes the Pi type of the donor organ.

INBORN ERRORS OF BILE ACID METABOLISM

Bile acids are required to drive bile secretion, and thus any impairment in bile acid biosynthesis or transport can result in cholestasis. At least 14 enzymatic steps are required in the liver to convert cholesterol into the primary bile acids cholic and chenodeoxycholic acid. Inherited defects in nine of these enzymes have now been described that often result in neonatal liver disease (Bove et al, 2000, 2004).

Primary defects in bile acid biosynthesis generally present with intrahepatic cholestasis (Heubi et al, 2007). A severe giant cell hepatitis is often found on liver biopsy. The serum γ-glutamyl transpeptidase concentration is paradoxically normal. The enzymatic block in bile acid synthesis results in a failure to produce normal primary bile acids required for generating bile flow and in accumulation in the liver of bile acid precursors that are intrinsically cholestatic and hepatotoxic. In marked contrast to other cholestatic disorders, inborn errors of bile acid biosynthesis are not associated with pruritus (Setchell and Heubi, 2006). Measurement of serum bile acids by standard methods can be a useful initial screening test for these disorders in that primary bile acids are very low to absent, even in the face of severe cholestasis. These defects are detected by analysis of urine in reference laboratories by liquid secondary ionization mass spectrometry. Gas chromatography–mass spectrometry of urine, serum, and bile as well as enzymatic and molecular assays for some of the defects are used to establish a specific diagnosis.

Prompt diagnosis of an inborn error of bile acid metabolism is important because several of these disorders can be treated with oral bile acid replacement (Heubi et al, 2007). Treatment with the primary bile acid, cholic acid, has been particularly successful in patients with 3β-hydroxy-C_{27}-steroid oxidoreductase deficiency and Δ4-3-oxosteroid-5-β-reductase deficiency. Cholic acid provides the missing end product required to generate bile flow and downregulates the production of toxic bile acid precursors. Therapy is lifelong. Ursodeoxycholic acid, which is commonly used in other forms of cholestasis even in newborns, is ineffective because it does not inhibit the bile acid synthetic pathway and production of toxic intermediates.

GALACTOSEMIA

Galactosemia is caused by a genetic defect in the metabolism of monosaccharide galactose, which is a constituent of lactose, the main carbohydrate of milk (Bosch et al, 2006). Galactose is normally metabolized to glucose via three separate enzymatic reactions involving galactokinase, galactose-1-phosphate uridyl transferase, and uridine diphosphate galactose-4-epimerase. The most common severe defect involves a deficiency of galactose-1-phosphate uridyl transferase. The enzymatic defect results in the accumulation of toxic metabolites, galactose-1-phosphate and galactitol (Leslie et al, 2003). Inheritance is in an autosomal-recessive fashion.

The clinical presentation of galactosemia occurs in the newborn period after ingestion of galactose. Early manifestations include jaundice, lethargy, vomiting, acidosis, cataracts, failure to thrive, and bleeding. Indirect hyperbilirubinemia is commonly seen and can be accompanied by coagulopathy (Leslie et al, 2003). Gram-negative sepsis is also a common presenting feature. Untreated disease is likely to result in liver failure and severe neurologic injury.

Even though many states now screen for galactosemia, clinicians should not wait for these results to begin therapy in infants with suggestive symptoms. Urine reducing substances are detected in infants fed galactose-containing formulas, although urine glucose dipsticks are negative. Measurement of galactose-1-phosphate uridyl transferase activity should ultimately be performed using red blood cells in all cases. Mutation analysis is also feasible.

Treatment consists of strict elimination of galactose from the diet (Bosch, 2006). This should be initiated as soon as the diagnosis is suspected in order to prevent liver failure. This will normally reverse the hepatic dysfunction associated with galactosemia. Dietary therapy is not entirely successful in the long term, in that patients may still manifest some degree of growth impairment, developmental retardation, motor dysfunction, and hypogonadism (Hughes et al, 2009; Panis et al, 2007).

GLYCOGEN STORAGE DISEASE

The glycogen storage diseases result from inherited, enzymatic defects in glycogen metabolism. Clinical phenotypes result from the inability to utilize glycogen stores, accumulation of glycogen within the liver and/or other tissues, and the toxic effects of certain abnormal types of glycogen.

Type I glycogen storage disease may present in the neonate with hypoglycemia and lactic acidosis (Melis et al, 2005). Hepatomegaly, hyperuricemia, and hyperlipidemia typically occur. Two forms of type I disease exist: deficiencies in glucose-6-phosphatase (type Ia) and glucose-6-phosphate translocase (type Ib). Fasting hypoglycemia can be life threatening in both variants. Significant hypoglycemia may also be seen in glycogen storage disease types III (debranching deficiency), VI (liver phosphorylase deficiency), and IX (hepatic phosphorylase kinase deficiency) (Janecke et al, 2004).

Hepatomegaly can also be seen in types III, IV (branching deficiency), and VI, where normal glycogen breakdown is impaired.

Diagnosis of the specific type of glycogen storage disease is critical for proper treatment and for prediction of prognosis and potential complications. Specific enzymatic assays and DNA diagnostic tests are available in specialty laboratories for each of the disorders, using liver, muscle, leukocytes, and fibroblasts.

Treatment in many of these disorders, particularly glycogen storage disease type I, is directed at maintaining normal blood sugar levels. Frequent feeding of high-carbohydrate-containing foods and nocturnal administration of slow-release glucose polymers, such as uncooked cornstarch, are utilized (Correia et al, 2008; Heller et al, 2008). This prevents the development of hypoglycemia and also limits incorporation of excess dietary glucose into glycogen.

PRIMARY MITOCHONDRIAL DISORDERS

Neonatal liver failure may occur in association with deficiency of complexes I, III or IV (cytochrome c oxidase) of the respiratory chain (Lee and Sokol, 2007). Activities of mitochondrial respiratory chain enzymes can be measured in affected tissues. Point mutations in mitochondrial or nuclear DNA have been detected in some patients with neonatal liver failure. Because of heteroplasmy, mitochondrial DNA (mtDNA) mutations are not uniform in all tissues, so patients may present exclusively with liver disease or with variable involvement of other organ systems.

Lethargy, hypotonia, vomiting, seizures, and poor feeding may be present from birth. Evidence of liver synthetic failure may occur with hypoglycemia, hypoproteinemia, hyperbilirubinemia, hyperammonemia, and coagulopathy (Lee and Sokol, 2007). Prenatal onset with fetal hydrops and congenital ascites has been reported. A key diagnostic feature in these patients is the presence of lactic acidosis and an elevated molar ratio of plasma lactate to pyruvate (normal <20:1) (Lee and Sokol, 2007).

Microvesicular and macrovesicular steatosis with abnormally increased mitochondrial density and swelling is typical on liver biopsy or postmortem specimens. Cholestasis, bile ductular proliferation, and fibrosis or even cirrhosis may be present.

The prognosis for patients with acute liver failure secondary to a mitochondrial disorder is extremely poor. There is no proven medical therapy. Liver transplantation has been successful in patients whose disease is restricted to the liver. MRI and magnetic resonance spectroscopy are critical in patients with acute liver failure as part of the pretransplant evaluation of the central nervous system (Lee and Sokol, 2007). Neurologic deterioration may still occur later even after an initially normal study.

Citrin deficiency is an autosomal recessive disorder that presents in the neonate with cholestasis, coagulopathy, failure to thrive, hypoglycemia, fatty liver, and hyperaminoacidemia (Hutchin et al, 2009; Tamamori et al, 2002). The majority of patients have been of Asian descent. Citrin is a mitochondrial aspartate-glutamate transporter, SLC25A13, which acts as part of the malate-aspartate shuttle in the liver and is thus important for aerobic glycolysis and gluconeogenesis. The varied clinical features may be confusing and mimic many neonatal cholestatic disorders (Sokol and Treem, 1999). Histopathology shows hepatocellular steatosis and cholestasis (Song et al, 2009). Increased serum citrulline and arginine together with galactosuria are nonspecific biochemical markers. The diagnosis can be confirmed by mutation analysis. Liver disease is rarely progressive. Clinical and biochemical abnormalities inexplicably resolve, usually without special treatment, by the age of 1 year in most patients (Tamamori et al, 2002).

CHOLESTASIS AND CONGENITAL HYPOPITUITARISM

Hypopituitarism should be considered in infants presenting with cholestasis and hypoglycemia (Binder et al, 2007). The combined or isolated hormonal deficiencies that may be associated with cholestasis include decreased production of growth hormone, cortisol, and thyroid hormone. Many of these infants have structural abnormalities of the brain on MRI, including hypoplasia of the optic nerves and optic chiasm, agenesis of septum pellucidum, and abnormalities of the corpus callosum and hypothalamopituitary axis (Webb and Dattani, 2010). These are key features of septo-optic dysplasia. There may be a wide spectrum of abnormalities present on imaging that may be limited to hypoplasia or aplasia of the anterior pituitary. Intrahepatic cholestasis may be seen in this disorder. Pituitary hormones may have a trophic effect on bile secretion, but the cholestatic liver disease cannot be solely explained on the basis of hormonal deficiencies. Liver biopsies may show giant-cell transformation of hepatocytes, but paucity of the intralobular bile ducts has also been observed (Binder et al, 2007). Hormone replacement usually leads to resolution of the cholestasis. Septo-optic dysplasia has been associated in some cases with mutations in two genes encoding the transcription factors, *HESX1* and *SOX2*.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

Hemophagocytic lymphohistiocytosis (HLH) is a disorder characterized by systemic inflammation caused by the uncontrolled proliferation of activated lymphocytes and histiocytes with massive release of inflammatory cytokines

(Filipovich et al, 2008). In the newborn, the acquired and genetic forms of the disorder are triggered by infections including enterovirus, herpes viruses, and CMV (Suzuki et al, 2009; Tanoshima et al, 2009). The process can begin in utero with nonimmune hydrops fetalis. The liver is invariably involved, even to the point of hepatic failure. Prolonged fever, hepatosplenomegaly, rashes, neurologic dysfunction, lymphadenopathy, and jaundice typically occur. Pancytopenia, elevated serum aminotransferases, bilirubin, elevated triglycerides and ferritin, and low fibrinogen are markers of the disorder. Hemophagocytosis by activated, morphologically normal macrophages is a cardinal feature that may be difficult to demonstrate in the bone marrow or on a liver biopsy early in the course of the disease (Janka, 2007).

Impaired function of natural killer cells and cytotoxic T cells reflect underlying immune dysfunction in genetic and acquired cases (Filipovich, 2008). The genetic disorders associated with HLH discovered so far all disrupt the pathway for granule-mediated cytotoxicity of target cells and eventual activation-induced apoptosis of activated T cells. Defects affect intracellular membrane trafficking mediated by Syntaxin 11, granule exocytosis mediated by MUNC 13-4, or pore-forming cytolysis by perforin (Horne et al, 2008). Mutation analysis may provide a specific diagnosis.

The prognosis for untreated HLH, particularly the familial cases, is extremely poor (Janka, 2007). However, the basis of initial therapy of HLH consists of combinations of proapoptotic chemotherapy and immunosuppressive drugs including corticosteroids targeting the hyperactivated T cells and histiocytes. For patients with a genetic cause, hematopoietic stem cell therapy offers the only possibility for definitive therapy (Cesaro et al, 2008).

NEONATAL HEMOCHROMATOSIS

Neonatal hemochromatosis is a form of neonatal liver failure caused by maternal-fetal alloimmune injury to hepatocytes (Whitington, 2007). Although there is in utero onset of hepatic and extrahepatic hemosiderosis, this entity is not related to hereditary hemochromatosis and is not caused by a primary defect in fetal iron metabolism. As is the case with other alloimmune disorders, the rate of occurrence of severe disease in subsequent newborns after the index case is 60% to 80%. A recent study has shown that occurrence of severe neonatal hemochromatosis in at-risk pregnancies can be significantly reduced by treatment with high-dose intravenous immunoglobulin during gestation (Whitington and Kelly, 2008).

Cholestatic jaundice with coagulopathy and/or ascites at birth is typical. Hypoalbuminemia, hypoglycemia, hyperammonemia, and high iron saturation and serum ferritin levels support the diagnosis. Extrahepatic siderosis can be found on biopsy of a minor salivary gland or MRI of the pancreas and/or heart. Liver histology reveals nonspecific findings of well-established fibrosis or cirrhosis, significant hepatocellular loss, and reactive bile ductular proliferation.

Infants with neonatal hemochromatosis have an expected mortality of more than 90% unless prompt medical treatment and/or liver transplantation is undertaken (Rodrigues et al, 2005). Early recognition of neonatal hemochromatosis is a requisite for survival. Medical therapy consists of a combination of antioxidants (vitamin E in the form of tocopheryl polyethylene glycol succinate, selenium, and *N*-acetylcysteine), membrane stabilizers (prostaglandin E_1), and iron chelators (deferoxamine) (Grabhorn et al, 2006). The efficacy of this therapy alone is uncertain, but at least it appears to stabilize infants as a bridge to liver transplantation. In a recent study the addition of intravenous immunoglobulin markedly improved survival without liver transplantation (Rand et al, 2009). Liver transplantation has been successful, but mortality in these acutely ill babies may still exceed 50%. Recurrence of the disease after successful medical therapy or after liver transplantation has not been reported (Heffron et al, 2007).

LYSOSOMAL STORAGE DISEASES

There are more than 50 different lysosomal storage diseases that are caused by enzymatic defects leading to the accumulation of specific substrates that determine their clinical features and outcome (Ballabio and Gieselmann, 2009; Staretz-Chacham et al, 2009). Affected neonates often appear normal at birth, but some babies may demonstrate subtle features and may be mildly symptomatic in the newborn period. Although a detailed discussion of these diseases is beyond the scope of this chapter, it is important to consider that many lysosomal storage diseases may present in the newborn period with involvement of the liver.

Hepatosplenomegaly is a regular presenting feature. A lysosomal storage disease should be considered, particularly if perinatal viral infections, sepsis, and biliary obstruction are excluded. Extrahepatic features such as hypotonia and seizures may be present. Coarse facial features may also be recognized. Several disorders have been associated with nonimmune fetal hydrops and congenital ascites including type 2 Gaucher's disease, sialidosis type II, galactosialidosis, infantile sialic acid storage disease, Salla disease, mucopolysaccharidosis types IV and VII, GM1 gangliosidosis, I-cell disease, Niemann-Pick types A and C, Wolman's disease, and Farber's disease. Neonatal cholestasis has been described in Niemann-Pick type C, I-cell disease, and Gaucher's disease (Garver et al, 2007).

Early diagnosis is critical for genetic counseling, providing a prognosis, and maximizing the potential benefit from emerging enzyme-replacement, cell-based, and pharmacologic therapies (Platt and Lachmann, 2009; Wynn et al, 2009). Owing to the overlap of clinical features in many of these diseases, it is difficult to establish a diagnosis based solely on clinical presentation and findings on a liver biopsy. A specific diagnosis often relies on laboratory assays for detection of the stored product including urinary excretion, enzymatic assays on leukocytes or cultured fibroblasts, and DNA mutational analysis.

CONGENITAL DISORDERS OF GLYCOSYLATION

Congenital disorders of glycosylation (CDG) are inborn errors of metabolism caused by defective N-glycosylation of proteins (Collins and Ferriero, 2005). Because glycoproteins are critically important in metabolism, cell recognition and adhesion, membrane trafficking, host defense,

and antigenicity, it is not surprising that CDG can affect multiple organ systems including the liver, with protean clinical manifestations even in the newborn.

At least 12 of the 30 known subtypes involve the liver (Iancu et al, 2007). Hepatomegaly and elevated serum aminotransferases are common. Other common clinical features include dysmorphic facies, mental retardation, failure to thrive, seizures, hypotonia, diarrhea, protein-losing enteropathy, recurrent infection, and coagulopathy. The histopathology is not well defined in most subtypes, but steatosis, fibrosis, and even cirrhosis have been described. A process similar to congenital hepatic fibrosis occurs in CDG-1b.

CDG should be considered in any infant with cryptogenic liver disease. Isoelectric focusing to detect the abnormally glycosylated transferrin is the commonly used diagnostic test, but some forms cannot be detected using this method. Mass spectroscopy and mutation analysis may be of value in some cases (Biffi et al, 2007). There is no specific treatment for most of these disorders.

DISORDERS OF FATTY ACID OXIDATION

Acute liver injury can occur in infants from inherited defects in fatty acid oxidation, resulting from energy deprivation and the accumulation of toxic metabolites of fatty acid oxidation (Rinaldo and Matern, 2000). The liver is central to fatty acid metabolism and requires fatty acid transport into hepatocytes and mitochondria and a series of enzymatic steps that generate energy from oxidation of fatty acids. Hepatopathy has been described in two thirds of the more than 20 defects in fatty acid oxidation. At least six disorders cause relatively severe liver disease, including a long-chain fatty acid transport defect, carnitine palmitoyltransferase deficiency, long-chain hydroxyacyl-CoA-dehydrogenase deficiency, α and β trifunctional protein defects, and short-chain hydroxyacyl-CoA-dehydrogenase deficiency (Rinaldo et al, 2002).

The typical case of severe liver disease often follows the catabolic stress of fasting or intercurrent illness. Nonketotic hypoglycemia is a hallmark feature of these disorders. Serum aminotransferase levels are often markedly elevated with variable degrees of cholestasis and coagulopathy. Myopathy (skeletal and/or cardiac) may be an accompanying feature.

Prompt recognition of defects in fatty acid metabolism is critical for proper treatment. Diagnostic assays that examine intermediate metabolites of fatty acid oxidation need to be performed during illness, because many of the metabolites will rapidly clear with treatment. Nonspecific screening assays and more specific enzymatic and DNA diagnostic tests are used in the evaluation (Gregersen et al, 2001). Initial studies should include assays of plasma carnitine, acylcarnitines, free fatty acids, urine organic acids, and acylglycines. Microvesicular steatosis is a common although not universal feature in fatty acid oxidation defects.

Treatment focuses on stopping ongoing fatty acid oxidation and fat catabolism through the intravenous infusion of 12 to 15 mg/kg/min of glucose. Subsequent avoidance of fasting is crucial, but the benefits of carnitine administration and specific dietary fat restrictions or supplementation are uncertain (Spiekerkoetter et al, 2009a, 2009b). In cases of liver failure or recurrent bouts of severe hepatic injury, liver transplantation should be considered if there is no evidence of severe systemic or neurologic disease (Alonso, 2005).

GALLSTONES AND CHOLECYSTITIS

Gallstones are rarely detected on a fetal ultrasound (Munjuluri et al, 2005). Most of these infants are asymptomatic postnatally and may have spontaneous disappearance of gallstones over the first few months of life.

Gallstones and calculous cholecystitis occur particularly in premature infants, who have undergone a period of prolonged fasting on parenteral nutrition without frequent gallbladder stimulation (Wilcox et al, 1997). Additional risk factors for development of gallstones in these infants include frequent blood transfusions, episodes of sepsis, abdominal surgery, and use of diuretics and narcotic analgesics. The composition of gallstones in such cases has not been well studied, but limited data suggest they are mixed cholesterol–calcium bilirubinate stones. Asymptomatic gallstones may disappear spontaneously, but may be associated with biliary obstruction and cholecystitis requiring surgical intervention.

Brown pigment gallstones have been associated with biliary obstruction in infants, and are composed of varying proportions of calcium bilirubinate, calcium phosphate, calcium palmitate, cholesterol, and organic material (Treem et al, 1989). In several cases, there was high β-glucuronidase activity in bile, possibly related to bacterial infections of the biliary tract.

LIVER TUMORS

Infantile hemangiomas and hemangioendotheliomas are benign vascular tumors of the liver and account for almost one fifth of liver tumors in childhood (Lopez-Terrada and Finegold, 2007). The presence of visible cutaneous strawberry hemangiomas may suggest the presence of a vascular tumor in the liver. Measuring thyroid function can be very useful as the hemangiomatous tissue produces high levels of type 3 iodothyronine deiodinase, causing hypothyroidism (Huang et al, 2000). A serious complication is high-output cardiac failure and the Kasabach-Meritt syndrome with consumptive coagulopathy, anemia, and thrombocytopenia (Beller and Ruhrmann, 1959). Medical treatment is with steroids. Diuretics, digoxin, hepatic artery ligation, and surgical resection are used if there is heart failure. Liver transplantation is an option when medical treatment fails or there is concern for angiosarcoma.

Malignant liver tumors account for 1.1% of all childhood tumors in the United States (Lopez-Terrada and Finegold, 2007). Hepatoblastoma is the commonest and has a strong association with prematurity; the majority are diagnosed by 1 year of age. Elevated levels of serum α-fetoprotein are associated with 80% to 90% of hepatoblastomas. Treatment is complete resection with or without chemotherapy. Liver transplantation is indicated when tumor resection is not feasible, provided there is no extrahepatic metastasis at the time of transplant.

PART XV

Hematologic System and Disorders of Bilirubin Metabolism

CHAPTER 75

Developmental Biology of the Hematologic System

Annie Nguyen-Vermillion and Sandra E. Juul

EMBRYONIC HEMATOPOIESIS

Hematopoiesis is the overall process by which self-renewing multipotential stem cells give rise to the multiple lineages of differentiated blood cells (Figure 75-1). This complex process is guided by the coordinated expression of growth factors, some of which act on primitive progenitor cells that can give rise to multiple cell lineages, and others of which support lineage-committed multipotential hematopoietic stem cells (HSCs). Hematopoiesis begins early in embryonic life, with the first hematopoietic cells appearing in the mouse yolk sac at embryonic day 7.5 (Palis and Yoder, 2001; Yoshimoto and Yoder, 2009). By day 10 of mouse gestation, HSCs are present in the aorto-gonado-mesonephron (AGM); activity then shifts to the liver, and finally to the bone marrow (Charbord et al, 1996). Each cell line undergoes developmental changes that are unique and specific. The details of these systems and the resulting clinical impact of these changes are reviewed individually in the following chapters.

STEM CELL BIOLOGY

Pluripotential stem cells sustain marrow function throughout a person's lifetime. A unique characteristic of these cells is that their direct offspring include at least one identical daughter cell, thus perpetuating the population. In contrast, progenitor cells are more differentiated and give rise only to cells more differentiated than themselves. The fate of any particular developing cell is determined by its microenvironment.

The developmental changes in the number, function, and location of HSCs are of great interest to transplantation biologists and gene therapists. The cycling potential and proliferative capacity of HSCs vary with the anatomic source of the cells, and with the age at which the cells are harvested. The sensitivity of these cells to recombinant cytokines also changes with age. Thus, improving the understanding of the ontogeny of these cells will be helpful in optimizing their clinical use.

Embryonic and fetal HSCs are capable of repopulating an adult organism (Fleischmann et al, 1984). In contrast, transplanted adult stem cells have a lower capacity for self-renewal, often resulting in late graft failure. This may be because the adult stem cells continue to express the adult differentiation program despite the fetal environment, indicating an irreversible change in gene expression (Fleischmann et al, 1984). Other explanations for the decrease in proliferative potential may have to do with the accrual of DNA damage over time and loss of telomere repeats with each stem cell division, limiting the replicative potential of stem cells (Notaro et al, 1997; Vaziri et al, 1994; Warren and Rossi, 2009). The increase in cell replication required after engraftment may impose replicative stress on the HSC, decreasing telomere length and resulting in a pronounced aging effect (Wynn et al, 1998).

There is ongoing research focused on optimizing stem cell harvesting techniques. Cell surface markers, which are dependent on cell maturity and gestational age, are often used to identify and separate HSCs using monoclonal antibodies and FACS analysis. For example, CD34, a cell-surface sialomucin, is an antigen commonly used to select hematopoietic stem cells and early erythropoietic progenitor cells. Combining CD34 positivity with the absence of lineage-specific markers (lin–) allows one to select a cell population highly enriched for the cells desired for transplantation. Research is also focused on optimizing stem cell harvest sites. Both bone marrow and cord blood are rich in stem cells and have long been used as progenitor cell pools. The collection of stem cells from peripheral blood by stimulated apheresis, with ex vivo expansion of select populations, is now also a viable option (Brugger et al, 2000; Pettengell et al, 1994a, 1994b).

Umbilical cord blood (UCB) is a source of HSCs that can be harvested and used for transplantation in patients with bone marrow failure, malignancies, and immunodeficiencies (Warwick and Armitage, 2004). UCB can be harvested directly from the umbilical cord after birth. Although small volumes are collected, the cells have a high proliferation index, so fewer cells can be used when compared to bone marrow transplantation (Schoemans et al, 2006). Because of the presumed immaturity of the cord blood cells, human leukocyte antigen (HLA) matching is less stringent for UCB (Rubinstein et al, 1998), allowing for more efficient donor unit identification compared with using a bone marrow registry (Barker et al, 2002; Beatty et al, 2000). This feature of UCB also allows for improved matching ability for patients in minority ethnic populations, because bone marrow registry matches are frequently in short supply. Promising strategies to increase cells available for transplantation include combining multiple units

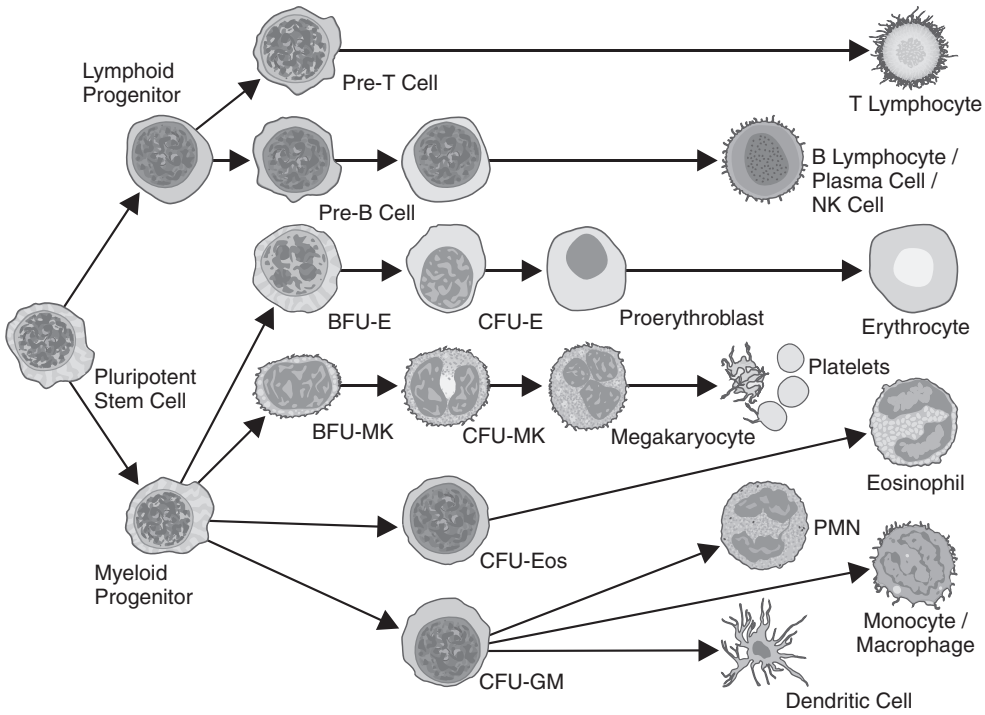

FIGURE 75-1 Overview of hematopoiesis. Hematopoietic lineages are outlined in this simplified overview of hematopoiesis. *BFU*, Burst-forming unit; *CFU*, colony-forming unit; *E*, erythroid; *GM*, granulocyte-macrophage; *MK*, megakaryocyte; *NK*, nonkiller; *PMN*, polymorphonuclear. *(Courtesy Alexander R. Vermillion.)*

of UCB (Barker et al, 2005) and ex vivo expansion of UCB units (Papassavas et al, 2008).

The first successful use of UCB for HSC transplantation purposes was in 1989 between HLA-identical siblings for severe aplastic anemia from Fanconi's anemia (Gluckman et al, 1989). Since then, thousands of UCB transplantations have been done to treat malignancies such as acute lymphoblastic leukemia, acute myeloid leukemia, and chronic myeloid leukemia; bone marrow disorders such as Fanconi's anemia; immunodeficiencies such as severe combined immune deficiency; metabolic disorders; and hemoglobinopathies (Prasad and Kurtzberg, 2009).

UCB can be stored in public or private commercial banks. Donation of harvested cells to public cord blood banks allows for storage in a central repository available to all individuals in need of transplantation. Private banking makes the stored UCB available at a cost for future use by individuals or family. However, there is a low likelihood of any one individual needing an autologous cord blood transplant (Johnson, 1997).

The optimal timing of umbilical cord clamping is controversial. Delaying cord clamping by 30 seconds to 1 minute provides increased blood volume to the neonate, but less is then available for UCB collection, whereas early cord clamping enables significantly more blood to be collected from the placenta after birth but less for the infant. A 2004 Cochrane review suggests that delayed clamping is associated with less intraventricular hemorrhage and fewer transfusions (Rabe et al, 2004). Recent studies have shown only a modest decrease in need for blood transfusions after delayed cord clamping, despite the improvement in red blood cell volume and hematocrit (Strauss et al, 2008).

DEVELOPMENTAL ASPECTS OF ERYTHROPOIESIS

Erythropoiesis is the process of perpetual production of red blood cells (*erythro*, "red"; *poiesis*, "growth"). Serial adaptations occur throughout development so as to meet the changing oxygen demands of the embryo, fetus, and neonate. The type of cells produced, the locations in which they are produced, and even the microenvironments within these locations change as development proceeds (Figure 75-2). The molecular mechanisms involved in instituting, regulating, and maintaining these adaptations are complex.

PRIMITIVE AND DEFINITIVE ERYTHROPOIESIS

During development, two types of red blood cells are formed: primitive and definitive erythrocytes. The liver is the primary organ of hematopoiesis during fetal life, but before the liver is formed, primitive red cells are formed in the yolk sac (Yoshimoto and Yoder, 2009). Hemogenic endothelium, a subset of early endothelium, gives rise to HSCs (Chen et al, 2009; Eilken et al, 2009; Lancrin et al, 2009). Large primitive red cells are produced in blood islands of the yolk sac days after implantation of the embryo. These cells enter the newly formed vasculature of the embryo, where they continue to divide and differentiate for several days. This process is only minimally responsive to the growth factor erythropoietin (EPO) (Lin et al, 1996; Wu et al, 1995b). Primitive erythroblasts are large (>20 μm), CD34-negative, and contain predominantly embryonic hemoglobin. Hemoglobin synthesis continues until cell replication ceases (Boussios and Bertles, 1988).

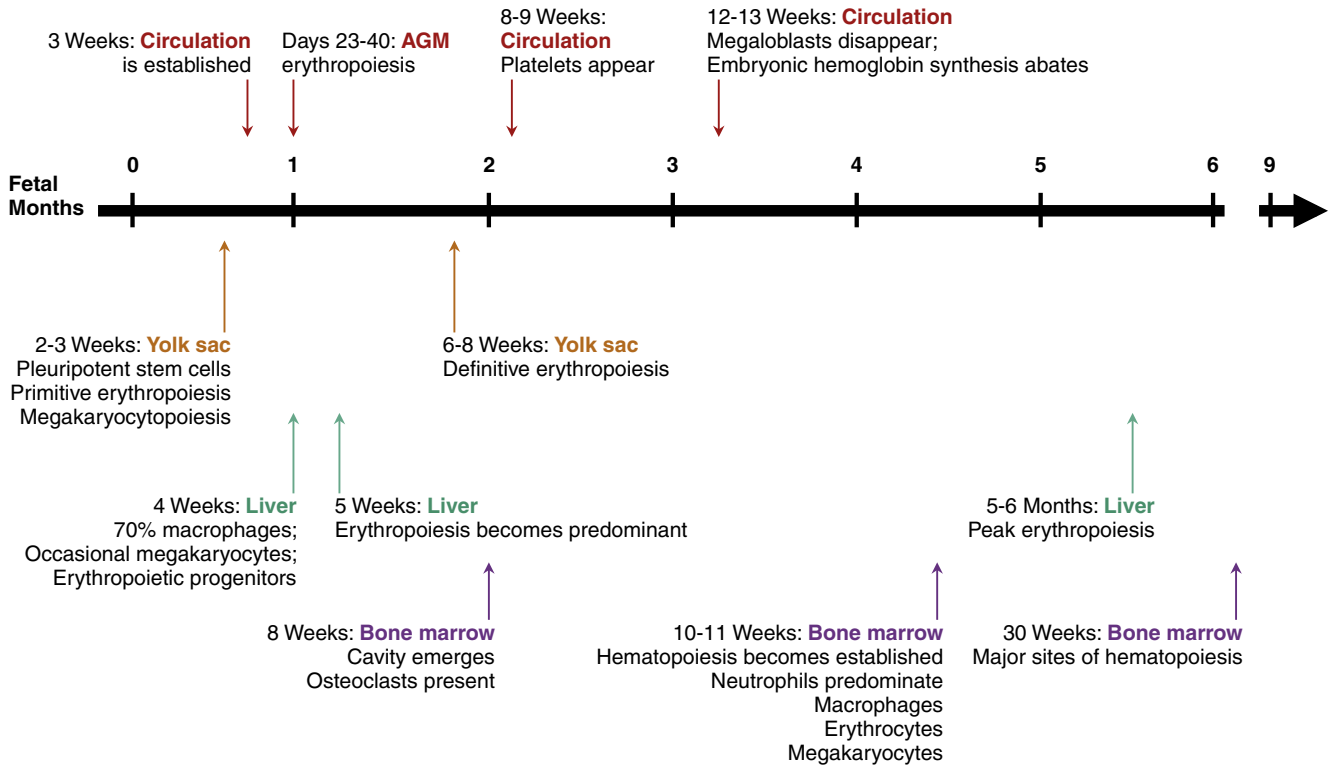

FIGURE 75-2 Changing sites of hematopoiesis during human gestation. Fetal gestation is shown in months along the central horizontal arrow. The timing of significant events during hematopoiesis is shown, beginning with primitive erythropoiesis and megakaryocytopoiesis in the yolk sac and ending with definitive hematopoiesis in the bone marrow during late gestation. *AGM*, Aorto-gonado-mesonephron.

In mice, a transition to definitive erythropoiesis occurs at embryonic day 13.5 (full gestation is 21 days). Definitive erythropoiesis is characterized by smaller (<20 μm) $CD34^+$ erythroblasts, which produce fetal and adult hemoglobins, extruding their nuclei when mature. Unlike primitive erythropoiesis, this process is dependent on Janus kinase (JAK) signal transduction and EPO stimulation (Neubauer et al, 1998; Tavassoli, 1991; Wu et al, 1995b). Primitive erythroblasts normally undergo apoptosis, becoming extinct during fetal life, whereas definitive erythroblasts are able to self-renew (Dieterlen-Lievre, 1997).

SWITCH OF THE PRIMARY SITE OF ERYTHROPOIESIS

Humans have four main sites of embryonic and fetal erythropoiesis: yolk sac, aorta (ventral aspect), liver, and bone marrow. In rodents, the spleen is also an important site of hematopoiesis, but there is no evidence for this in healthy humans (Calhoun et al, 1996; Wolf et al, 1983). Studies using an in vitro embryonic stem cell differentiation system have shown that endothelial cells, primitive hematopoietic cells, and definitive blood-cell colonies arise from a common *Flk-1* expressing progenitor (Lancrin et al, 2009). Between embryonic days 8 and 11.5, *Runx 1*, a transcription factor, is required for the formation of HSCs and their progenitors (Chen et al, 2009). Primitive progenitor cells first develop in the yolk sac, followed by the rise of definitive progenitors, also in the yolk sac (Palis, 2008; Palis et al, 2001). Another source of the early definitive progenitors is along the ventral aspect of the embryonic aorta (Palis, 2008; Tavian et al, 1996; Tavian and Peault, 2005). Once circulation is established, progenitors from all lineages are detected in the blood, then in the fetal liver, and finally in the marrow (Palis et al, 1999; Tavian et al, 2001).

Yolk Sac

The yolk sac is an extraembryonic structure that can be subdivided into the primary and secondary yolk sac. The primary yolk sac is transient and has no known hematopoietic function. In humans, it forms by proliferation and differentiation of primitive endodermal cells 7 to 8 days after conception. These endodermal cells give rise to mesodermal precursors (intermediate cells). The primary yolk sac then collapses into small vesicles, and the secondary yolk sac is formed from its remnants at 12 to 15 days postconception. By 16 to 19 days postconception, primitive erythropoiesis is found in the human yolk sac (Kelemen et al, 1979; Kennedy et al, 1997; Tavassoli, 1991). The secondary yolk sac is an active site of protein synthesis, nutrient transport, and hematopoiesis (Enders and King, 1993). Primitive hematopoietic cells, adherent to surrounding endothelial cells, are first observed at day 16 in the mesodermal layer. These hematopoietic-endothelial cell masses have been described as blood islands (Zon, 1995). As maturation proceeds, these blood islands migrate toward each other, merging to form a network of capillaries. Small clusters of undifferentiated cells, the hemangioblasts, and clusters of primitive erythroblasts are observed in the small vessels present at this developmental stage (Enders and King, 1993). As differentiation proceeds, endothelial

and hematopoietic cell lineages emerge. These cell lines share common molecular markers and responsiveness to a cohort of growth factors, and, depending on the microenvironment, they can be derived from a common stem cell in culture (Choi, 1998; Choi et al, 1998; Eichmann et al, 1997; Lancrin et al, 2009; Lux et al, 2008; Palis and Yoder, 2001; Robertson et al, 1999).

After the 6th week postconception, definitive erythroblasts are found in the yolk sac. A decline in yolk sac hematopoiesis is observed after the 8th week of gestation (Enders and King, 1993). There are in vivo differences in the hematopoietic potential of yolk sac cells, compared to those in the liver. Yolk sac–derived hematopoietic cells have more restricted potential in vivo, because only red cells and macrophages are present in the yolk sac (Enzan, 1986), while progenitor cells in the liver develop into the full spectrum of hematopoietic lineages (Palis et al, 1999). However, when yolk sac–derived stem cells are cultured in vitro or are transplanted, they are multipotent, illustrating the importance of the microenvironment in the development of committed cell lineages (Tavassoli, 1991).

Aorto-Gonado-Mesonephron (AGM)

Another site of early erythropoietic activity in the developing human embryo is the ventral aspect of the aorta, in the periumbilical region (Huyhn et al, 1995; Tavian and Peault, 2005). At around the 23rd postconceptional day in humans, the multipotent hematopoietic progenitor cells in this region are more numerous than in the yolk sac or the liver (Huyhn et al, 1995). By day 40 of gestation, hematopoiesis in this site is concluded.

Liver

A short time after the onset of blood circulation (4 to 5 weeks' gestation), erythropoiesis begins in the liver (Kelemen et al, 1979). As in the yolk sac, primitive erythroblasts predominate in early erythropoiesis. However, over the next 4 weeks, definitive erythrocytes become the predominant red cell form. During this time, the liver mass increases 40-fold, with hematopoietic cells comprising 60% of the liver by weeks 11 to 12 (Thomas and Yoffey, 1964). Meanwhile, other hematopoietic cell lineages are also produced in the liver. Early in this process (5 weeks), macrophages predominate, with approximately 1 granulocyte to every 9 macrophages (Slayton et al, 1998). In contrast to the yolk sac, during the period of peak hepatic hematopoiesis (weeks 6 to 18), production of all hematopoietic cell lines (erythrocytes, macrophages, megakaryocytes, granulocytes, and lymphocytes) occurs. Between 18 and 21 weeks' gestation, hematopoiesis in the liver diminishes, but the liver continues as an erythropoietic organ until term.

Bone Marrow

As hepatic hematopoiesis diminishes, the bone marrow becomes the primary site of erythropoiesis and remains so throughout postnatal life. The process of erythropoiesis in marrow begins at about 8 weeks, again, with primitive erythrocytosis (Kelemen et al, 1979). Over the next several gestational weeks, a switch to definitive erythropoiesis occurs, and by 14 weeks, only definitive erythroblasts are present. As with the liver, production of all hematopoietic cells occurs in bone marrow. Erythropoietic cells constitute a maximum of 35% of total bone marrow cells at week 12 of gestation, falling to between 20% and 30% thereafter (Charbord et al, 1996; Thomas and Yoffey, 1962).

FACTORS INFLUENCING THE SITES OF ERYTHROPOIESIS

The microenvironment at each site of hematopoiesis influences the type and timing of hematopoietic development. The microenvironment includes hematopoietic growth factors and cytokines, as well as the extracellular matrix in which the cells proliferate.

Growth factors are thought to act mainly as permissive and/or selective signals, allowing already committed cell types to proliferate and differentiate. Growth factors important for definitive erythropoiesis include EPO, stem cell factor (SCF) (*c*-kit), interleukin-3 (IL-3), thrombopoietin (TPO), and possibly insulin, and insulin-like growth factor 1 (IGF-1), both of which act as nonessential survival factors for $CD34^+$ cells (Muta and Krantz, 1993; Muta et al, 1994; Ratajczak et al, 1998). These growth factors work in concert to promote definitive erythropoiesis. However, EPO is the primary growth factor: in the absence of EPO signaling, as in the case for both EPO and EPO receptor null mutations, definitive erythropoiesis does not occur. Null mutations of either EPO or its receptor are lethal at 13.5 days' gestation in the mouse, because of severe anemia (Wu et al, 1995a, 1995b).

EXTRAMEDULLARY HEMATOPOIESIS

After the bone marrow has been established as the primary site of erythropoiesis, extramedullary hematopoiesis occasionally occurs as a pathologic process. This can occur with severe bone marrow failure of any etiology, but common causes include congenital rubella, cytomegalovirus, and parvovirus B19 infection. Extramedullary hematopoiesis has been documented in many tissues, including the liver, spleen, adrenal glands, pancreas, thyroid gland, endocardium, testes, uterus, skin, and brain. When the skin is involved, this results in the classic "blueberry muffin" rash seen in newborns with congenital rubella or CMV infection.

ONTOGENY OF ERYTHROCYTES

The earliest precursor cells specific to the erythroid lineage are the burst-forming unit-erythroid (BFU-E). BFU-E have low numbers of EPO receptors (Sawada et al, 1988, 1990) and respond to EPO, as well as GM-CSF and IL-3. As these cells mature into colony-forming unit-erythroid (CFU-E) and proerythroblasts, they become highly dependent on EPO, which is reflected by the high density of EPO receptors on the cell membrane (up to 1000 per cell) (Broudy et al, 1991). Mature erythroblasts have fewer EPO receptors and therefore are less sensitive to EPO stimulation, and reticulocytes and erythrocytes have no EPO receptors and are unresponsive to EPO. These

mature cells are unique, in that they do not have a nucleus, DNA, RNA, ribosomes, or mitochondria. The principal functions of mature erythrocyte metabolism are to maintain adequate adenosine triphosphate (ATP) stores, to produce reducing substances to act as antioxidants, and to produce 2,3-diphosphoglycerate (2,3-DPG), which modifies the oxygen affinity of hemoglobin.

Important developmental changes occur in hematocrit, reticulocyte count, red cell morphology, membrane content, deformability, life span, and metabolism. Over the course of gestation, there is a rise in expected hematocrit, from 36% ± 3% at 18 to 20 weeks' gestation (fetal samples) to 55% ± 6% (Jopling et al, 2009) expected at term birth. In order to maintain this increase in hematocrit and blood volume (up to 7 mL/day during the last trimester) associated with fetal growth, the production of approximately 50×10^9 erythrocytes per day is required, based on animal experiments (Bell and Wintour, 1985). During this same period of fetal development, erythrocyte size (the mean cell volume) decreases from 134 ± 9 fL to 119 ± 9 fL (Forestier et al, 1991; Zaizov and Matoth, 1976). A recent study examined erythrocyte indices over a wide range of gestational ages to develop new reference ranges (Christensen et al, 2009). Christensen et al (2009) showed erythrocytes to be very large in neonates at the limits of extrauterine viability, with a steady decrease in size as gestational age increases. At term, the mean cell volume remains larger than that of normal healthy adults. Mean cell volume continues to drop postnatally, reaching a nadir at 4 to 6 months of life. It then increases to reach adult values (88 ± 8 fL) by approximately 1 year of life.

Reticulocytes are near-mature erythrocytes released from the bone marrow into the circulation. Although the nucleus has been extruded, they retain cytoplasmic organelles such as ribosomes, mitochondria, and Golgi bodies for approximately 24 hours. These newly released cells can be differentiated from mature red blood cells by staining with new methylene blue or brilliant cresyl blue, which stain the nucleic acid within the cells. Evaluation of a patient's reticulocyte count can be used to assess the level of erythrocyte production, because high values indicate active erythropoiesis, whereas depressed numbers indicate low levels of erythropoiesis. At birth, reticulocyte counts in preterm infants tend to be higher than in term infants (400,000 to 550,000 vs. 200,000 to 400,000) (Christensen, 2000). Absolute reticulocyte counts, reticulocyte percentage of total red cells, and corrected reticulocyte counts can be obtained. In general, when evaluating neonates, the corrected reticulocyte count is the most helpful, because this reflects the reticulocyte response relative to the hematocrit. This corrected value is calculated as: patient's reticulocyte percentage (%) × patient's hematocrit (%) ÷ desired or optimal hematocrit (45%). Some laboratories also report a reticulocyte production index (RPI), which corrects, in addition, for reticulocyte maturation or shift. This can be helpful in differentiating hypoproliferative anemia (RPI <2) from a hyperproliferative or hemolytic anemia (RPI >3).

Red cell morphology is quite heterogeneous in preterm and term infants as compared with adults. Irregularly shaped cells such as poikilocytes, acanthocytes, schizocytes, and burr cells are common in the blood smears of neonates. This reflects developmental changes in cell membrane deformability and flexibility. The neonatal red blood cell membrane has decreased deformability, which contributes to its decreased life span of approximately 70 days as compared to 120 days for the adult red blood cell. Membrane characteristics become more adultlike by 4 to 6 weeks of age.

DEVELOPMENTAL CHANGES IN THE REGULATION OF ERYTHROPOIESIS

The principal growth factor that regulates erythropoiesis is EPO. This 30.4-kDa glycoprotein contains 165 amino acids and is extensively glycosylated, with 40% carbohydrate content. EPO maintains red cell production during fetal, neonatal, and adult life by inhibiting apoptosis of erythroid progenitors and by stimulating their proliferation and differentiation into normoblasts (Jelkmann, 1992; Moritz et al, 1997; Palis and Segel, 1998). Because very little EPO crosses the placenta, the EPO concentrations measured in the fetus reflect fetal synthesis (Eichhorn et al, 1993; Widness et al, 1991). EPO production begins early in fetal life, and it has been identified in extraembryonic coelomic fluid and amniotic fluid (Campbell et al, 1992). The primary site of EPO production during fetal life is the liver, with transition to the kidney postnatally (Fahnenstich and Dame, 1996; Koury and Koury, 1993; Koury et al, 1993). This transition is mediated in part by expression of GATA-4 (Dame et al, 2004). Production of EPO is stimulated by hypoxia via hypoxia-inducible factor (HIF) 1 and 2 pathways (Dioum et al, 2009; Fisher et al, 2009; Lam et al, 2009; Semenza, 2009; Webb et al, 2009). HIF is a DNA-binding complex composed of two subunits: HIF-1b, which is not oxygen responsive and is constitutively expressed, and either HIF-1a or HIF-2a, both of which are highly oxygen sensitive. The HIF complex is, in turn, regulated by prolyl hydroxylase domain enzymes 1 to 3 (Weidemann and Johnson, 2009). Elevated EPO concentrations (up to 8000 μ/mL) have been reported in pathologic states such as fetal hypoxia, anemia, and placental insufficiency and in infants of diabetic mothers (Buescher et al, 1998; Stangenberg et al, 1993).

During fetal development, circulating EPO concentrations range from 4 μ/mL at 16 weeks' gestation to 40 μ/mL at term (Clapp et al, 1995; Fahnenstich et al, 1996; Forestier et al, 1991). An unhealthy intrauterine environment can result in increased EPO production, reflecting fetal hypoxemia (Halmesmäki et al, 1990; Ruth et al, 1990; Teramo et al, 1987). After birth in healthy term infants, serum EPO concentrations decrease at birth to reach a nadir between the 4th and 6th weeks after birth (Brown et al, 1983; Ruth et al, 1990). By 10 to 12 weeks of age they reach adult concentrations (approximately 15 μ/mL) (Kling et al, 1996). These changes in EPO concentrations are consistent with the changes in hemoglobin and hematocrit seen following term birth (physiologic anemia). In preterm infants, the anemia is more severe and persists longer, leading to the anemia of prematurity described earlier. EPO concentrations in these infants are inappropriately low, forming the rationale for recombinant human EPO therapy.

ONTOGENY OF HEMOGLOBIN CHAINS

Organization and Structure of the Hemoglobins

Hemoglobin is a tetrameric molecule comprised of two pairs of polypeptide subunits. As development proceeds, various hemoglobins are constructed by combining two α-like globins (ζ or α) with two β-like globins (ε, γ, δ, or β) to form a hemoglobin tetramer. These tetramers include the embryonic hemoglobins, Hb Gower 1 ($\zeta_2\varepsilon_2$), Hb Gower 2 ($\alpha_2\varepsilon_2$), and Hb Portland 1 ($\zeta_2\gamma_2$), fetal hemoglobin (Hb F) ($\alpha_2\gamma_2$), and the adult hemoglobins Hb A ($\alpha_2\beta_2$) and Hb A_2 ($\alpha_2\delta_2$). Their expression and proportion depend on gestational age but can, in part, be modified by external mechanisms. The basic function of the various hemoglobins is similar, but their oxygen affinity differs. As the hemoglobins switch from embryonic to fetal to adult forms, oxygen affinity decreases. Thus, the switch from embryonic to fetal to adult hemoglobin synthesis is a major mechanism by which the developing fetus adapts from the hypoxic intrauterine to the oxygen-rich extrauterine environment (Bard, 2000).

Changes in Hemoglobin Synthesis With Development

The genes within the α- as well as the β-globin families are expressed according to a strict ontogenetic schedule, and the quantitative expression of the genes from each of these families is strictly balanced and coordinated (Bard, 2000). Hemoglobin synthesis begins around 14 days postconception, with synthesis of ζ- and ε-globin chains. These are replaced by the synthesis of α- and γ-globin chains by the 5th to 7th week of gestation (Hb Gower 2, Hb Portland 1, and Hb F become predominant) (Gale et al, 1979). By 12 weeks' gestation, Hb F ($\alpha_2\gamma_2$) accounts for almost all of the hemoglobin produced (Cividalli et al, 1974). After the 20th week of gestation, no ε-globin chains are produced, but the production of the ζ-globin chains can persist through the last trimester in pathologic conditions such as homozygous α-thalassemia. Expression of the γ-globin gene peaks during mid-gestation and declines rapidly during the last month of fetal gestation. β-Globin synthesis, required for Hb A, starts at the 6th week of gestation, increasing as γ-globin synthesis declines, a transition that continues to the 6th month of life (Bard, 1975; Kazazian and Woodhead, 1973). Thus, Hb A synthesis quantitatively increases first after the 30th week of gestation. At the end of the last trimester, a rapid switch from the synthesis of fetal hemoglobin to adult hemoglobin occurs, falling from 85% at 34 weeks' gestation, to 60% to 80% at birth (Peri et al, 1998). The synthesis of δ-globin chains, required for HbA_2 ($\alpha_2\delta_2$), begins at the 34th to the 35th week of gestation. After birth, a rapid increase in HbA and HbA_2 occurs.

RED BLOOD CELL TRANSFUSION

Transfusion of red blood cells (RBCs) increases blood volume and red blood cell content, thereby increasing oxygen-carrying capacity. We have had the capacity to store blood for future transfusions since the early 1900s (Rous and Turner, 1916a, 1916b). In the early years, cells were kept viable in a citrate and glucose solution, but current solutions make it possible to store cells for more prolonged periods (up to 42 days): citrate-phosphate-dextrose (CPD), citrate-phosphate-dextrose-adenine (CPDA), and various additive solutions (AS), which may contain additional dextrose, mannitol, and adenine (Hess, 2009). The hematocrit of "packed RBCs" ranges from 50% to 80%. During storage, the RBCs undergo metabolic and structural changes. 2,3-DPG, antioxidant, and ATP content decrease, glycolysis decreases, osmotic fragility increases, and deformability decreases (Högman et al, 1985; Lockwood et al, 2003). ATP-dependent membrane pumps are dysfunctional, so extracellular potassium increases at 1 mEq/day, which can be dangerous when transfusing large volumes (Hall et al, 1993; Hess, 2009). Oxidative damage occurs in lipids and proteins during storage and irradiation (Dumaswala et al, 2000; Sharifi et al, 2000). Proinflammatory compounds accumulate during storage of blood, particularly if it is not leukoreduced. After an RBC transfusion, the mean potential life span of the RBC is 85 days with a mean half-life of 43 ± 11 days (Strauss et al, 2004).

Risks of RBC transfusion may be due to the storage process, the transfusion itself, and the association with oxidative damage. Because of the storage process and increasing age of the stored blood, RBC transfusion exposes the recipient to high levels of potassium, glucose, hydrogen, and lactic acid; the clinical significance depends on the age of the blood and the volume transfused (Sümpelmann et al, 2001). Although rare, transfusion-transmitted bacterial infections can occur as a result of bacterial contamination of stored blood (Niu et al, 2006; Wagner, 2004). Other risks of RBC transfusion include viral infections, transfusion-related acute lung injury (TRALI), and graft-versus-host reaction. Multiple RBC transfusions may also put the patient at risk for iron overload and oxidative injury (Sullivan, 1988). There are 200 mg of iron in a 420-mL unit of whole blood, which is then processed into 250-mL units of packed RBCs (Porter, 2001), so a unit of blood with a hematocrit of 60% contains 0.7 mg/mL of iron, which becomes available as the cells turn over. There is increased unbound iron in stored blood, which may increase reactive oxygen species (Hirano et al, 2001). In retrospective and observational studies, increased numbers of RBC transfusions have been associated with retinopathy of prematurity (Dani et al, 2001; Hesse et al, 1997), bronchopulmonary dysplasia, necrotizing enterocolitis, and diuretic use (Valieva et al, 2009).

Optimal hematocrit values and indications for transfusions in infants in the neonatal intensive care unit (NICU) remain controversial. In the past, infants were transfused for hematocrits less than 40%. Because of the risk of transfusions and lack of evidence for benefit, more restrictive transfusion guidelines have been proposed. Most studies comparing restrictive to liberal transfusion practices in premature infants have not demonstrated any benefit to maintaining higher hemoglobin levels (Bell et al, 2005; Brooks et al, 1999; Kirpalani et al, 2006). However, restrictive guidelines were associated with increased periventricular leukomalacia and severe intracranial hemorrhage in one trial of restrictive versus liberal transfusion

guidelines for premature infants (Bell et al, 2005). Unfortunately, because brain injury was not a primary outcome variable for the study, no baseline cranial ultrasounds were done before study entry, so it is not clear whether the increased morbidity was transfusion related (Bell et al, 2005). Currently, there is no ideal marker to identify the need for transfusions in neonates, although the following have been studied: clinical indicators (Bifano et al, 1992; Wardle and Weindling, 2001), lactic acid concentration (Frey and Losa, 2001; Izraeli et al, 1993; Möller et al, 1996; Takahashi et al, 2009; Wardle and Weindling, 2001), and echocardiographic findings (Alkalay et al, 2003; Böhler et al, 1994; Nelle et al, 1997). Delayed cord clamping has also been studied as a means to increase the baseline hematocrit value in newborns with modest clinical benefits (Rabe et al, 2004; Strauss et al, 2008). The collection of UCB for autologous blood transfusions in premature infants and neonates with known surgical diseases has been proposed but is not generally practiced (Ballin et al, 1995; Imura et al, 2001; Jansen et al, 2006; Khodabux and Brand, 2009; Khodabux et al, 2008). Current practices focus on minimizing phlebotomy losses, minimizing exposures to multiple donors with the use of divided aliquots from single donors (Mangel et al, 2001), using EPO to increase endogenous red blood cell production, and tolerating lower hematocrit values in clinically stable patients (Bishara and Ohls, 2009).

BILIRUBIN METABOLISM

The primary source of bilirubin in the fetus and newborn is from the breakdown of heme derived from hemoglobin in circulating erythrocytes. Heme is a porphyrin ring surrounding a ferric (Fe^{3+}) ion. The rate-limiting step in the breakdown of this molecule is the formation of biliverdin, a process controlled by heme oxygenase (Beri and Chandra, 1993; Rodgers and Stevenson, 1990). The iron molecule is recycled, and biliverdin is then reduced to bilirubin IXα by biliverdin reductase. In utero, unconjugated bilirubin is processed by the mother after placental transfer. Thus under normal circumstances, the fetal liver plays only a minor role in bilirubin excretion. Unconjugated bilirubin is lipophilic and is tightly bound to albumin in the circulation. The conjugation of bilirubin results in a relatively polar, water-soluble molecule, bilirubin diglucuronide, which can be excreted. This process occurs in the liver and is dependent on ligandin, a transfer protein, and uridine diphosphoglucuronyl transferase. The conjugating ability of the fetus and newborn is impaired relative to older cohorts because of reduced transferase activity and low levels of uridine diphosphoglucuronic acid (Dennery et al, 2001).

DEVELOPMENTAL ASPECTS OF MEGAKARYOCYTOPOIESIS

Platelets are small (average volume of 7.5 fL) anucleated fragments of megakaryocytes, which circulate as smooth disks when unactivated. The normal circulating life span of a platelet is 10 days. Platelets provide the first line of defense in hemostasis. When a breach of the vascular endothelial lining occurs, platelets are activated and adhere to the exposed subendothelium. These activated platelets generate various mediators, including the potent vasoconstrictor thromboxane A2, and ADP, both of which further contribute to hemostatic plug formation.

SITES OF MEGAKARYOCYTE PRODUCTION

Megakaryocytopoiesis is the process by which megakaryocytes and ultimately platelets develop. As with erythropoiesis, the sites of megakaryocytopoiesis change during embryonic and fetal development. In mouse development, megakaryocytes have been identified in the early yolk sac (McGrath and Palis, 2005). These cells, when cultured in the presence of SCF, IL-3, IL-6, EPO, TPO, and G-CSF, can produce not only erythroid bursts but also megakaryocyte colonies. The megakaryocyte progenitors share a common progenitor with primitive hematopoietic cells (McGrath and Palis, 2005). In humans, electron micrographic studies have shown megakaryocytes present in the liver and circulatory system as early as 8 weeks postconception (Hesseldahl and Falck Larsen, 1971).

MEGAKARYOCYTE PRECURSORS

Megakaryocytopoiesis begins with the pluripotent hematopoietic stem cells, which give rise to myeloid progenitor cells (CFU-S), then burst-forming unit-megakaryocyte (BFU-MK) cells, followed by colony-forming unit-megakaryocyte (CFU-MK) cells (see Figure 75-1). Further maturation brings these small mononuclear cells, which are largely indistinguishable from monocytes, to large polyploid cells that are easily recognized based on their phenotype. The process of megakaryocyte differentiation has been separated into four stages. Stage I cells, or megakaryoblasts, are the smallest and most immature. As cells mature through stages II (promegakaryocytes), III (granular megakaryocytes), and IV (mature megakaryocytes), the nucleus becomes multilobed, the cytoplasm becomes increasingly eosinophilic by Wright-Giemsa staining, and cellular size increases from 6 to 24 μm up to as great as 50 μm. The presence of granules increases steadily until in the mature cells they become organized into "platelet fields." Unlike other cell lines, as the nucleus of a megakaryocyte matures, it undergoes endomitosis or endoreduplication, a process by which cell ploidy is increased in the absence of cell division. Megakaryocytes from adults typically have a modal ploidy of 16N, whereas comparable samples from preterm or term infants have a significantly lower ploidy of <8N (Slayton et al, 2005). Megakaryocytes from newborns are also typically smaller than in adults, although they manifest features of mature megakaryocytes. Adult-sized megakaryocytes appear by 2 years of age. Typically, smaller cells with lower ploidy produce less platelets than do larger cells with higher ploidy. Despite this, the platelet count in fetuses and newborns is near the normal adult range (Wiedmeier et al, 2009).

CONTROL OF MEGAKARYOCYTOPOIESIS

Multiple cytokines participate in the process of megakaryocytopoiesis; however, TPO is the principal one. SCF, IL-3, and IL-6 increase ploidy and size of megakaryocytes.

IL-11 also stimulates the proliferation of megakaryocyte progenitors and induces megakaryocyte maturation, while still other growth factors such as EPO, Kit ligand, GM-CSF, IL-1, basic fibroblast growth factor, platelet-derived growth factor, and interferon-γ have a less clearly defined role. Some cytokines inhibit thrombopoiesis, including TGF-β and platelet factor-4 (Gewirtz et al, 1995). The magnitude of the influence of these growth factors changes with development.

THROMBOPOIETIN

The presence of a growth factor to regulate platelet formation was first hypothesized in the 1950s, but it was not actually realized until 1994, when the protein was isolated by five independent laboratories (Kaushansky, 2006; Kaushansky et al, 1995). TPO is composed of 332 amino acids and contains two domains. The amino-terminal is the active domain (153 amino acids) and bears marked homology to EPO. TPO is produced primarily by the liver and kidney, although other tissues express small amounts. TPO acts as a potent stimulator of all stages of megakaryocyte growth and development by binding to its specific cell surface receptor, *c-mpl*. In TPO and *c-mpl* knockout models, platelet production is 10% to 15% of controls, confirming that TPO is the primary regulator of platelet production, but also indicating that alternative pathways exist for megakaryocytopoiesis. Regulation of TPO is unusual: TPO is bound to the surface of platelets by its receptor and destroyed, thereby reducing megakaryocyte exposure to the hormone (Kaushansky, 1998). Serum TPO concentrations tend to be lower in preterm infants than in older infants and children, and the TPO response to thrombocytopenia is less robust as gestational age decreases. This is counterbalanced by an increased sensitivity of megakaryocyte precursors to TPO (Sola et al, 1999, 2000).

DEVELOPMENTAL CHANGES IN PLATELET COUNT

Fetal platelet counts increase with gestation. At 15 weeks' gestation, average platelet counts are 187,000/μL, increasing to 274,000/μL at term. Overall, however, preterm infants have somewhat lower platelet counts than those of adults with a broader range of normal (100,000 to 450,000/μL) (Wiedmeier et al, 2009).

PLATELET TRANSFUSIONS

Clinical practice regarding platelets and platelet transfusion is quite variable because no evidence-based guidelines are available. In a 2005 Web-based survey of neonatologists in the United States and Canada, wide variations in practice were noted in both countries, with platelet transfusions frequently administered to nonbleeding neonates with platelet counts greater than 50,000/μL. This practice was particularly common during indomethacin treatment, before or after procedures or operations, or after diagnosing intraventricular hemorrhages (Josephson et al, 2009). This is of concern because several studies have shown a correlation between the number of platelet transfusions received by hospitalized neonates and mortality rate (Baer et al, 2007; Garcia et al, 2001). For example, in a study of 1600 thrombocytopenic NICU patients, those who received platelet transfusions had higher mortality rates: 2% with no transfusions, 11% with 1 or 2 transfusions, 35% with >10 transfusions, and 50% with ≥20 platelet transfusions (Baer et al, 2007). Clearly, this was partially due to the underlying illness that required the infant to be transfused. However, because transfusion practices vary so widely, investigators were able to ascribe some of the increased mortality risk to harmful effects of multiple platelet transfusions (Baer et al, 2007). In an attempt to create a reasonable yet safe approach to platelet transfusions, two guidelines were prospectively compared: one based on platelet count and the other on platelet mass (platelet count times mean platelet volume). Although the number of platelet transfusions per patient remained the same, fewer patients were transfused when platelet mass was used as a transfusion trigger (Gerday et al, 2009). In a thorough review by Roberts et al (2008), it was recommended that prophylactic transfusions of platelets be avoided after the 1st week of life unless the platelet count falls below 30,000/μL. During the 1st week of life, for preterm infants, in the absence of better data, these workers recommend a transfusion trigger threshold of 50,000/μL. For patients with platelet counts greater than 50,000/μL, transfusions should be reserved for those with active serious bleeding. Another controversy concerns what kind preparation of platelets to transfuse in volume-sensitive neonates: single-donor, multiple-donor, single-unit, or volume-reduced multiple-unit preparations. In general, 10 to 20 mL/kg of single-donor platelets should raise the platelet count by more than 100,000/μL. In the absence of consumption, platelets should remain in circulation approximately 1 week. Volume-reduced or pooled platelets should be avoided when possible, because such processing results in platelet activation and decreased function, with no evidence of benefit.

DEVELOPMENTAL ASPECTS OF GRANULOCYTOPOIESIS

Early hematopoiesis is characterized almost exclusively by erythropoiesis, although a small number of macrophages are produced in the yolk sac. After circulation begins in the 4th to 5th week of gestation, macrophages appear in the liver, brain, and lungs. During the 5th week, hematopoiesis begins in the liver, and the first hematopoietic cells to appear are macrophages (Kelemen and Janossa, 1980). Whether Kupffer cells originate in the yolk sac and migrate to the liver or rise de novo in the liver is unknown. The marrow space begins to develop around the 8th week after conception, and, as is true in the liver, the first hematopoietic cells to appear in the bones are phagocytes (Kelemen and Janossa, 1980; Slayton et al, 1998b). These phagocytic osteoclasts seem to core out the marrow space. When hematopoiesis is established in the marrow at 10 to 11 weeks postconception, primarily neutrophils are produced, in contrast to the liver, where primarily macrophages are present (Slayton et al, 1998a, 1998b).

The thymus appears around 8 weeks postconception. T-cell progenitors are thought to migrate from the fetal liver to the thymus at 8 to 9 weeks postconception (Haynes

et al, 1989), and by the 10th week, lymphoid cells constitute 95% of this organ, with granulocyte precursors and macrophages making up the remainder. B cell precursors first appear in the omentum and the fetal liver at 8 weeks postconception. B cell production in the omentum occurs transiently from 8 to 12 weeks (Solvason and Kearney, 1992), while production continues in the fetal liver. Regulatory T cells are found in the thymus and secondary lymphatic organs in the early second trimester and are proposed to be involved in self-reactivity and immune tolerance (Cupedo et al, 2005; Izcue and Powrie, 2005).

The spleen is an important secondary lymphatic organ in humans. The spleen does not have intrinsic granulocytopoiesis and erythropoiesis activities or produce hematopoietic growth factors (Calhoun et al, 1996), and lymphocytes appear to migrate there through fetal blood. Lymphocytes begin to appear in the spleen around 11 weeks postconception. By the 22nd week, 70% of the cells are lymphocytes (Kelemen et al, 1979).

OVERVIEW OF HEMATOPOIETIC CYTOKINES

Hematopoietic growth factors can be classified into two groups: those responsible for the regulation of myeloid and erythroid growth and differentiation, called colony-stimulating factors (CSFs), and those concerned with immunity, called lymphokines. Once sequenced, lymphokines are assigned interleukin (IL) numbers. There is a great deal of functional overlap between hematopoietic growth factors (redundancy), and each growth factor has a multiplicity of biological actions (pleiotropy). Thus, more than one cytokine controls cells in any cell lineage, and most factors affect cells in more than one lineage (Kaushansky, 2006).

EPO, GM-CSF, and G-CSF belong to a family of hematopoietic cytokines that share a predicted tertiary structure and function by binding to specific cell surface receptors. Specific ligand binding results in allosteric changes in the receptor molecules, which, depending on the type of receptor, results either in protein kinase activation, as with macrophage-colony stimulating factor (M-CSF) (Nicola et al, 1997), or in a cascade of intracellular signaling via the JAK-2 kinase mechanism, as is characterized by EPO (Watowich et al, 1996).

Many of the hematopoietic cytokines were discovered by virtue of their growth-promoting effects on hematopoietic cell lines, or their specific immune functions. It was initially assumed that their effects were specific to the hematopoietic system. This view has been challenged, because functional receptors are expressed by other cell types, with clear nonhematopoietic functions as reviewed by Schneider et al (2005) and Juul (2004). For example, both glia and neurons produce many of the cytokines once thought restricted to the hematopoietic system and, furthermore, they express receptors for these peptides, suggesting the capability of both paracrine and autocrine interaction (Konishi et al, 1993; Masuda et al, 1993). EPO and G-CSF are both available in recombinant form and are FDA-approved for clinical use.

CHAPTER 76

Hemostatic Disorders of the Newborn

Guy Young

OVERVIEW OF HEMOSTASIS

Hemostasis refers to the process in which bleeding is staunched at the site of damaged and disrupted endothelium (Roberts et al, 2006). The process is the result of a dynamic interplay among the subendothelium, the endothelium, and circulating cells and proteins. When blood vessel injury occurs, an immediate response of plasma and cellular components must occur in order to minimize bleeding and begin tissue repair; however, this process must be confined to the area of injury so that pathologic thrombosis does not occur. The hemostatic (coagulation) process is often described in three phases—the vascular phase, the platelet phase, and the plasma phase, all of which occur essentially simultaneously. The vascular phase is mediated by the release of local vasoactive agents and results in vasoconstriction at the site of injury, resulting in a reduction in blood flow. Although an intact endothelial cell lining promotes the fluidity of blood by secreting substances such as prostaglandin I_2 (which inhibits platelet aggregation) once blood vessel injury occurs, the underlying subendothelium is exposed, and procoagulant proteins such as tissue factor, collagen, and von Willebrand factor (VWF) come into contact with blood. Circulating VWF comes into contact with collagen in the subendothelium, leading to unfolding of this large multimeric protein, which exposes the platelet receptor, glycoprotein Ib. Platelets then bind to VWF forming a layer bound to the subendothelium in a process termed *platelet adhesion*. Once platelets are bound to the subendothelium, they are activated, resulting in a shape change and release of vasoactive and hemostatic substances, including thromboxane A_2, serotonin, and adenosine diphosphate (ADP), leading to additional vasoconstriction and platelet aggregation thus forming the platelet plug.

The plasma phase of coagulation occurs initially as a result of the exposure of tissue factor in the subendothelium. Tissue factor (TF) binds to and activates factor VII to form the TF:FVIIa complex (also called the extrinsic tenase), which then binds to and activates factor X (FX) to FXa. The TF:FVIIa:FXa converts a small amount of prothrombin to thrombin. This relatively small amount of thrombin then results in a number of reactions aimed at generating a large amount of thrombin, known as the thrombin burst, which is required for normal clot formation. These reactions include platelet activation, resulting in the expression of platelet factor V on the surface of the platelet, as well as activation of (FV) to FVa. In addition, thrombin leads to the activation of factor VIII (FVIII) by its release from VWF and activates FXI. The TF:FVIIa complex mentioned earlier also activates factor IX (FIX) to FIXa, which then binds to the surface of activated platelets at the site of bleeding. Activated FVIII then binds to FIXa, forming the potent intrinsic tenase complex and resulting in the conversion of large amounts of FX to FXa, which then associates with FVa on the activated platelet surface, resulting in the thrombin burst.

The rapid generation of a large amount of thrombin then results in reactions that lead to the formation of a stable fibrin clot. First, thrombin cleaves fibrinogen to form the insoluble fibrin strands that make up the structural element of the fibrin clot. The thrombin burst also leads to two important steps that are important in rendering the clot more resistant to fibrinolysis. Thrombin activates factor XIII which leads to crosslinking of the fibrin monomers into stable fibrin polymers. Second, thrombin activates thrombin-activatable fibrinolysis inhibitor (TAFI), further changing the structure of fibrin and enhancing its resistance to tissue plasminogen activator (tPA)-mediated fibrinolysis, ultimately resulting in a stable clot. This fibrin clot is what results in the cessation of bleeding and acts as the scaffold for tissue repair, which eventually leads to complete restoration of the endothelial lining.

As part of the repair process, the fibrin clot undergoes fibrinolysis, resulting in a blood vessel segment indistinguishable from that which was in place before the injury. The fibrinolytic process is a simpler process with fewer proteins and is initiated by the release of tPA near the site of injury. This leads to the conversion of plasminogen to plasmin, which via interactions with lysine and arginine residues on fibrin is able to cleave fibrin into fragments that then dissolve into the blood.

Both the hemostatic and fibrinolytic processes are regulated by inhibitors whose function is to contain these processes to the site of injury and to quench the reactions, thus preventing them from becoming systemic and pathologic. The hemostatic system has two major inhibitors: (1) antithrombin and (2) the protein C–protein S complex. Antithrombin is released at the margins of endothelial injury and binds in a 1:1 complex with thrombin, resulting in inactivation of any thrombin that is not bound by the forming clot. Any excess free thrombin at the margins of the forming clot binds to thrombomodulin, a receptor on the surface of intact endothelial cells, resulting in a complex that then activates protein C to activated protein C, which in conjunction with protein S inactivates activated FV and FVIII. This negative feedback then leads to a reduction in further thrombin generation, resulting in the quenching of the formation of fibrin. The fibrinolytic system also has inhibitors—principally—plasminogen activator inhibitor-1 (PAI-1), which as its name implies inhibits tPA, and α_2-antiplasmin, which inhibits plasmin.

This intricate system is designed to allow for hemostasis to take place only at the site of injury and for fibrinolysis to follow the formation of the fibrin clot as part of the tissue repair process. Disorders resulting in excessive bleeding can occur secondary to a malfunction of any of the foregoing processes and may be the result of either congenital or acquired conditions. For example, conditions resulting in either a reduced number or a dysfunction of platelets or a reduced amount of or abnormally formed VWF will result in what are termed *disorders of primary hemostasis*, which

collectively manifest with similar symptoms. In addition, deficiencies of clotting factors can be the result of acquired or congenital defects, and such deficiencies can lead to a wide variety and severity of bleeding symptoms. Note, disorders resulting in excess fibrinolysis can be due to either an overabundance of fibrinolytic proteins such as tPA or a deficiency of inhibitors to fibrinolysis such as PAI-1.

Defects in the inhibitory proteins of the hemostatic system can result in a predisposition to thrombosis. These conditions include deficiencies of antithrombin or proteins C and S, molecular defects in prothrombin and factor V, elevations in homocysteine leading to endothelial damage, and reduced fibrinolytic capacity secondary to elevations in lipoprotein(a). This chapter discusses the pathophysiology, clinical presentation, diagnosis, prognosis, and treatment of defects in the coagulation system resulting in disorders of excessive bleeding or thrombosis.

DEVELOPMENTAL HEMOSTASIS

There are major differences between the neonatal hemostatic system and that of adults (or even older children) (Andrew, 1995, 1997). Although the general structure and function of the subendothelium and endothelium is felt to be the same in neonates as in older children, this is a difficult area to study. The number of platelets throughout late fetal life and the neonatal period is the same. However, there appears to be a deficit in platelet function in platelet aggregation studies, and the platelet function analyzer (PFA-100) and bleeding times in neonates are shorter than in older children and adults, probably because of their higher hematocrit and VWF levels. It is not clear whether neonatal platelets function differently from those of older children and adults (Israels, 2009). With the exception of fibrinogen, circulating levels of most coagulation proteins are different from those of adults (Andrew, 1995). Although levels of FVIII and VWF are normal to elevated in the immediate newborn period, levels of the other procoagulant clotting factors are lower. In addition, levels of the natural inhibitors to coagulation (antithrombin, protein C, and protein S) are also lower, resulting in a hemostatic system that is balanced (similar to the adult system). However, that balance is more precarious, because relatively small changes in one protein or another result in a more significant relative change of this balance. Thus, neonates are at increased risk for bleeding as well as thrombosis. Last, the fibrinolytic capacity of neonates is less than that of adults because there is a relative (physiologic) plasminogen deficiency in neonates. This in part probably accounts for the increased incidence of thrombosis in neonates.

INTRODUCTION TO BLEEDING DISORDERS

Excessive bleeding may occur in the immediate newborn period (uncommonly even in utero) or anytime thereafter. Bleeding symptoms may result from derangements in the hemostatic system or secondary to anatomic defects, surgery, or trauma. Furthermore, bleeding symptoms may be confined to specific anatomic sites or may occur in multiple sites. Finally, bleeding symptoms may be present in multiple family members or may occur in the absence of a family history. All of this information is important for clinicians to arrive at a correct diagnosis rapidly and with minimal yet correctly sequenced laboratory testing. Thus, a detailed patient and family history is a vital part of the approach to each patient with a potential bleeding disorder.

Obtaining a detailed patient and family history is crucial regardless of previous laboratory testing. The history includes a detailed discussion of specific bleeding symptoms or abnormalities. Information regarding bleeding symptoms should include location, frequency and pattern, and duration in terms of both appearance of symptoms and time required for cessation. The location may suggest the part of the hemostatic system affected—patients with disorders of primary hemostasis (platelets and VWF) often experience mucocutaneous bleeding, including easy bruising and mucous membrane bleeding, whereas patients with disorders of secondary hemostasis (coagulation factor deficiencies) may experience deep tissue bleeding including the joints, muscles, and central nervous system. Additional important information to be collected includes the current medications the patient is receiving, because these may affect the hemostatic system; the presence or absence of a family history of bleeding; and a history of hemostatic challenges, including surgery, trauma, and perinatal bleeding. The goal at the end of the history is to establish the likelihood of a bleeding disorder, because this judgment determines the required laboratory investigation.

The laboratory evaluation includes performance of initial screening tests. The most common screening tests used include the complete blood count (CBC), prothrombin time (PT), activated partial thromboplastin time (aPTT), and a screening test of platelet function such as the platelet function analyzer (PFA). Of note, the PFA may not be sufficiently sensitive or specific to be useful, and its inclusion as a screening test is controversial. Assaying for specific factors and more detailed examination of platelet function can be performed if indicated by the results of the screening tests. It is important to note that these screening tests are not sensitive to all abnormalities associated with a bleeding disorder, including von Willebrand's disease (VWD), FXIII, PAI-1, and α_2-antiplasmin deficiencies; therefore, a patient history suggestive of a bleeding disorder always warrants further testing regardless of the results of these screening tests. Abnormalities of screening tests do not necessarily represent the presence of a pathologic process, because these tests are sensitive to handling, may vary in reliability based on laboratory, and may be influenced by medications including herbal therapies, as well as other issues. Specific examples of artifactually abnormal results include an elevated PT and/or PTT secondary to poor specimen handling or an abnormal PFA secondary to the ingestion of medications or supplements known to affect platelet function. Finally, as previously mentioned, the normal ranges for the prothrombin time and activated partial thromboplastin time are different from those of adults, and the normal ranges provided by most laboratories are based on adult normative values. It is important to refer to the normal ranges for the specific neonatal age when determining whether either of these assays or specific factor assays are abnormal. See Figure 76-1 for an algorithmic approach to the bleeding patient.

HEMORRHAGIC DISORDERS

THROMBOCYTOPENIA

Etiology/Pathophysiology

Thrombocytopenia is a common occurrence in the neonatal intensive care unit, and there are many conditions that can result in neonatal thrombocytopenia (Bussel and Sola-Visner, 2009; Sola-Visner et al, 2009). The conditions that lead to thrombocytopenia can be separated in two ways. One approach is to distinguish these based on whether thrombocytopenia is likely caused by a hematologic disorder, so-called primary thrombocytopenia, or whether the thrombocytopenia is due to nonhematologic conditions, medications, or procedures such as extracorporeal membrane oxygenation (ECMO), which is referred to as secondary thrombocytopenia. Another approach is to separate the disorders according to those that are congenital (Table 76-1) versus those that are acquired (Table 76-2). One can arrive at a reasonable differential diagnosis using either approach. In general, otherwise-well neonates presenting with thrombocytopenia (either noted incidentally or in association with bleeding symptoms) will be found to have primary thrombocytopenia, whereas ill neonates (often premature) have multiple conditions or medications that are associated with or can lead to thrombocytopenia such that it is difficult to discern one specific underlying cause. It is important to make this distinction in order to pursue a reasonable evaluation that will have a high probability of determining a diagnosis without requiring numerous unnecessary laboratory assays. For the otherwise-well neonate, a detailed approach (see later discussion) will likely lead to a diagnosis from which one can determine the prognosis and treatment, if necessary. If secondary thrombocytopenia is suspected, the prudent approach would be to treat the underlying disorders with the expectation of normalization of the platelet count once the patient improves. Such an approach will also avoid many unnecessary blood tests. If the thrombocytopenia persists after improvement

TABLE 76-1 Congenital Causes of Thrombocytopenia

of the neonate's condition, then a thorough evaluation for primary disorders can be undertaken.

Primary thrombocytopenia can be due to congenital or acquired disorders. Some congenital conditions will be obvious immediately (thrombocytopenia–absent radius [TAR] syndrome), whereas others (congenital amegakaryocytic thrombocytopenia [CAMT]) will require specialized testing (Geddis, 2009). Although congenital thrombocytopenias are rare, several acquired conditions are not uncommon with the most important of these being the immune thrombocytopenias (Bussel and Sola-Visner, 2009). There are two forms of this condition. The first form occurs when the mother has autoimmune thrombocytopenia, either pre existing or developing during pregnancy, resulting in transplacental transfer of her autoantibodies which react with the newborn's platelets resulting in what can be termed passive transfer immune thrombocytopenic purpura (ITP). The second form, termed neonatal alloimmune thrombocytopenia (NAIT), results from the passive transfer of maternal alloantibodies directed against paternally derived platelet antigens that are present on the neonate's platelets. In the first form, the mother most often has thrombocytopenia herself whereas in the second form, the mother's platelet count is normal. Other hematologic disorders resulting in acquired thrombocytopenia include disseminated intravascular coagulation (DIC), which itself has many causes, and certain vascular malformations (kaposiform hemangioendotheliomas and tufted angiomas), which result in platelet consumption (Hall, 2001). In addition, deep vein thrombosis (DVT) in the neonatal period often results in thrombocytopenia. These conditions may be considered secondary causes in some respects; however, because they have a defined hematologic cause, they are grouped with the primary disorders.

There are numerous causes of acquired thrombocytopenia (see Table 76-2) (Sola-Visner et al, 2009). The most common are sepsis (bacterial or viral), congenital viral infections (i.e., TORCH [*t*oxoplasmosis, *o*ther infections, *r*ubella, *c*ytomegalovirus, *h*erpes simplex]), necrotizing enterocolitis, chronic lung disease, and certain medications. Often, an ill neonate with thrombocytopenia will have multiple possible causes of thrombocytopenia, and it is difficult to point to one specific problem as the main culprit. In such situations, successful treatment of the underlying condition should result in resolution of the thrombocytopenia, and a detailed evaluation is rarely fruitful and generally unnecessary. One exception to the foregoing is identifying a specific medication that clearly causes thrombocytopenia, in which case elimination or substitution of this medication by another may result in improvement in the platelet count.

Clinical Presentation

Newborns with thrombocytopenia may present with signs of bleeding (most often mucocutaneous), or the discovery of low platelets may be an incidental finding on a CBC performed for other reasons (i.e., presumed sepsis). When newborns have bleeding attributed solely to thrombocytopenia, the platelet count is usually substantially reduced ($<30 \times 10^9$/L). Patients presenting with bleeding may be recognized immediately after birth by bruising on the face or head related to the trauma associated with delivery or may have a cephalhematoma. Bruising and petechiae also may be seen on other parts of the body. Occasionally, internal hemorrhage may have occurred pre- or perinatally, and in such circumstances, clinical signs will relate to the site of bleeding. Intracranial hemorrhage can manifest with a bulging fontanel or with signs of neurologic compromise such as seizures, apnea, or respiratory distress. It should be noted that for patients with NAIT, the incidence of intracranial hemorrhage (ICH) is 25%, although often this occurs in utero. Other deep tissue bleeding occurs only rarely and may present with bloody stools, abdominal distention or gross hematuria. It is incumbent on the physician to request appropriate diagnostic imaging studies if internal hemorrhage is suspected, particularly in a thrombocytopenic neonate. When bleeding occurs outside the immediate newborn period, the symptoms are generally similar to those described earlier, with the exception of the presence of birth trauma. Again, mucocutaneous bleeding is the most common manifestation of bleeding due to thrombocytopenia, although internal hemorrhage should be considered if there are suggestive clinical signs.

Thrombocytopenia may also present as an incidental finding or rarely as a result of a known family history of a thrombocytopenic disorder. When thrombocytopenia presents incidentally, the platelet count tends to be higher (usually $>50 \times 10^9$/L). When this occurs, a thorough evaluation of the patient's history up to this point is warranted to see if a secondary cause can be identified. For example,

one should consider why the CBC was performed in the first place. For example, was there a concern for sepsis or other infection? Most often, a secondary cause can be identified, and thus further evaluation is not necessary. In such cases, the thrombocytopenia will presumably resolve once the secondary cause is resolved.

Rarely, when a newborn is found to have thrombocytopenia, incidentally or otherwise, careful assessment of the family history will reveal the presence of a parent or other family member with thrombocytopenia. In such instances, identifying the condition in the family member should result in directed laboratory assessment to identify the same condition in the patient. It should be noted that in many instances a family history of thrombocytopenia will be present, but the family member will not know the cause of his/her condition. In this situation, it would be appropriate to perform an evaluation in the family member, thus sparing the newborn from venipuncture.

Diagnosis

As previously discussed, whether or not to embark on a detailed diagnostic evaluation of neonatal thrombocytopenia depends in part on whether the cause is believed to be primary or secondary. Primary thrombocytopenia always warrants an evaluation aimed at arriving at the correct diagnosis. If secondary thrombocytopenia is present, then a detailed evaluation may not be warranted, and identifying and treating the underlying cause should suffice to restore the platelet count to normal.

Before launching a laboratory investigation, it is paramount to obtain not only a detailed history of the newborn, but, as is often the case with neonates, a history of the mother's overall health as well as her pregnancy. In addition, obtaining the family history may yield important clues, particularly the presence of thrombocytopenia in previous children, especially if that thrombocytopenia occurred in the newborn period. Among the most important pieces of information to obtain would be the mother's platelet count: Thrombocytopenia in the mother is often due to ITP (which can be acquired during pregnancy), which will often lead to neonatal thrombocytopenia. In addition, pregnancy complications such as pregnancy-induced hypertension, preeclampsia/eclampsia, and the HELLP syndrome may result in neonatal thrombocytopenia. The presence of neonatal thrombocytopenia in a previous pregnancy strongly suggests the possibility of NAIT, especially if the thrombocytopenia in the previous newborn resolved during infancy. The presence of chronic thrombocytopenia in family members, particularly first-degree relatives, suggests the presence of a congenital thrombocytopenia—in particular, the myosin heavy chain-9 (MYH-9) related disorders (Althaus and Greinacher, 2009) (see Table 76-1), because these are inherited in an autosomal dominant fashion. In addition to maternal and other family history, the history of the neonatal course is crucial. Perinatal hypoxia, for example, often results in temporary thrombocytopenia, as does the presence of sepsis or other infections. Furthermore, identifying the presence of any of the many causes of acquired thrombocytopenia is important (see Table 76-2).

A thorough physical examination is another crucial aspect not only in determining the cause of the thrombocytopenia but also to assess the potential for bleeding complications. The presence of physical stigmata associated with thrombocytopenic disorders can at times reveal the diagnosis without much additional testing, as in the TAR syndrome wherein a plain film of the forearm is diagnostic. The presence of findings suggestive of TORCH infections (small for gestational age, hepatosplenomegaly) or chromosomal disorders (trisomy 13, 18, and 21) may also be revealing and lead to the performance of specific laboratory tests (see later discussion). The presence of a vascular malformation suggests that thrombocytopenia may be due to consumption of platelets by the mass. Occasionally, thrombocytopenia may be the only laboratory manifestation of a secondary cause; for example, this finding in association with hepatosplenomegaly suggests the possibility of a storage disease. The laboratory assessment for conditions that are known to cause thrombocytopenia in the neonate should be tailored to the findings on history and physical examination (Table 76-3 summarizes laboratory assessment for specific conditions). In most cases, thrombocytopenia is due to secondary causes, is mild to moderate, and does not cause bleeding, and thus, a laboratory investigation may not be necessary. If the thrombocytopenia may be due to the presence of easily assayed secondary causes or if it is due to a primary cause, laboratory assessment is warranted and may include any of the following: laboratory testing for NAIT (see later discussion), TORCH evaluation, chromosomal analysis (e.g., karyotype, fluorescence in situ hybridization), evaluation for metabolic disorders, or evaluation for genetic thrombocytopenias (MYH-9 disorders, congenital amegakaryocytic thrombocytopenia). Testing for NAIT is crucial not so much for the newborn in question but for subsequent pregnancies, because invariably the condition will be repeated, and often with worse thrombocytopenia and perhaps a worse outcome (Bussel and Sola-Visner, 2009). This testing does not require blood from the newborn, but rather, blood from both parents, and testing should be done in a reputable laboratory

TABLE 76-3 Laboratory and Imaging Evaluation of Thrombocytopenia

Maternal Platelet Count Normal	Maternal Thrombocytopenia	Congenital Anomalies Present

equipped to perform this analysis. If the laboratory test result is abnormal, a specific diagnosis can be made, and then any necessary treatment plans can be undertaken.

Treatment

The management of thrombocytopenia in neonates is dependent more on the diagnosis and presence of bleeding than on the platelet count. For example, for the same platelet count, patients with NAIT generally have worse bleeding and worse outcomes than patients with passive transfer ITP. Because patients with NAIT have a much higher rate of ICH, treatment of such patients should be much more aggressive. Similarly, neonates with thrombocytopenia due to DIC will likely bleed at higher platelet counts than patients with congenital thrombocytopenias. The management approaches can be divided into *therapeutic*, defined as treatment given for the management of bleeding, and *prophylactic*, wherein treatment is only given for a low platelet count, in the absence of bleeding. Treatment decisions would be simplified if bleeding could be expected to occur at a specific platelet count threshold; however, unfortunately, there are no data to suggest a specific platelet count below which prophylactic treatment should be instituted for any of the causes of thrombocytopenia. Thus, it is incumbent on the treating physician to weigh the risks and benefits of therapy before instituting any specific treatment.

With this in mind, the following are the major potential therapeutic options for managing thrombocytopenia (assuming treatment is under way for the underlying disorder of secondary thrombocytopenias):

- Observation
- Platelet transfusion
- Intravenous immunoglobulin (IVIG)
- Corticosteroids

In addition, adjuvant treatments to manage bleeding include antifibrinolytic agents, topical agents, and direct pressure.

The management of immune thrombocytopenia (passive transfer ITP and NAIT) may include IVIG, corticosteroids, and platelet transfusions (Bussel and Sola-Visner, 2009). For patients in whom treatment is warranted, IVIG has been shown to be effective at raising the platelet count in both conditions, although this increase in platelet count takes 24–48 hours, making this approach reasonable only for patients in whom treatment is given either for mild bleeding symptoms (mucocutaneous bleeding) or prophylactically. Although data are lacking regarding specific platelet count thresholds, most neonatologists and hematologists would recommend treating patients with passive transfer ITP who have platelet counts $<10 \times 10^9$/L and withholding treatment for platelet counts $>30 \times 10^9$/L. For platelet counts in between, either observation or treatment is reasonable. Conversely, because of the high risk of ICH in patients with NAIT, it is suggested that all such patients with platelet counts less than 50×10^9/L receive treatment with IVIG and additionally, receive a platelet transfusion if ICH has occurred or if it occurred in previously affected siblings. If the antibody specificity is known (from a previously affected newborn), then it is important to make an effort to obtain antigen-negative platelets, but only if this will not result in a delay in platelet administration. Random-donor (i.e., antigen-untested) platelets will often result in a rise in the platelet count, although this rise may be more short-lived than for antigen-negative platelets. One strategy is to administer antigen-untested platelets and simultaneously collect platelets from the mother (by definition she is antigen-negative), if feasible, for subsequent use. It is not common to confirm the diagnosis of NAIT in first-borns; however, if the clinical suspicion is high, aggressive treatment is warranted. Although NAIT will resolve over a period of days to weeks, it is recommended that the platelet count be followed closely and transfusions administered for platelet counts of $<50 \times 10^9$/L, at least in the 1st week of life, as this is the highest-risk period for ICH in the postnatal period. If therapy with IVIG is effective, the platelet count may rise and remain elevated for several weeks, obviating the need for further platelet transfusions.

Newborns with congenital thrombocytopenia can present with a wide range of platelet counts, and in these disorders, the risk for bleeding *does* relate to the degree of thrombocytopenia. Fortunately, most patients with these disorders do not have severe thrombocytopenia (platelet count $<10 \times 10^9$/L); thus, the risk for bleeding is low, and observation is the recommended approach. For bleeding that occurs in these conditions, the only treatment that can raise the platelet count is a platelet transfusion; thus, it is important to weigh the risks and benefits of therapy.

For newborns with secondary thrombocytopenia, the emphasis of treatment should be on managing the underlying condition. Normalization of the platelet count is expected once the underlying condition resolves. If bleeding occurs, platelet transfusions should raise the platelet count in most instances and will be effective at controlling the bleeding so long as the bleeding was not due to other causes such as abnormal coagulation factor levels. The decision to give platelet transfusions depends on multiple factors including the platelet count, presence of other risk factors for bleeding, the underlying medical condition, recent invasive procedures, and the need for ongoing platelet-inhibiting medications. Last, the effectiveness of nonspecific methods for managing bleeding should not be underestimated. The use of direct pressure or topical agents is an effective way to arrest bleeding if the source of bleeding is easily accessible. Both topical thrombin (bovine or human) and fibrin sealant can be applied directly to sites of bleeding and are generally safe and often effective. Antifibrinolytic agents (ε-aminocaproic acid and tranexamic acid) are also quite safe and can be effective, particularly for mucous membrane bleeding. These agents inhibit plasmin-mediated thrombolysis and presumably exert their effect by stabilizing the less-than-ideal clots that are formed in patients with bleeding disorders in general, including platelet function defects. Thus, one can think of these agents as effective at preventing rebleeding, a common problem in bleeding disorders. These agents can be given intravenously or orally and can be used either therapeutically after bleeding has occurred or prophylactically as part of perioperative management. Regarding adverse effects, topical thrombin use can rarely result in the development of antibodies against FV which can result in severe bleeding (it is believed, though not clinically proved, that the use of the human protein will

result in a lower risk for antibody development than the bovine version). Antifibrinolytics can increase the risk for thrombosis; however, in general the benefits for managing bleeding far outweigh this relatively small risk. Otherwise, these agents do not appear to have side effects in neonates.

Outcomes

The outcome of neonates with thrombocytopenia depends almost exclusively on the occurrence of serious bleeding. For neonates with NAIT who have suffered an ICH, there may be permanent sequelae, whereas for those without serious bleeding, the prognosis is excellent because the thrombocytopenia will fully resolve. The same can be said for patients with passive transfer ITP. For neonates with secondary thrombocytopenia, the outcome largely depends on the condition that led to the thrombocytopenia in the first place. Once the underlying condition resolves, the thrombocytopenia resolves.

For patients with congenital thrombocytopenia, there are variable outcomes related to the specific disorders. For example, patients with CAMT often go on to develop aplastic anemia and rarely, leukemia—usually when they are several years old. In fact, these patients may not even be diagnosed in the newborn period unless they develop bleeding or a CBC is performed. Ultimately, the prognosis of these patients depends on their response to treatment of the aplastic anemia or leukemia. For the other congenital thrombocytopenias, the outcome is more favorable and, similar to CAMT, some may not be diagnosed in the newborn period. Patients with TAR syndrome will, of course, be diagnosed immediately because of their obvious deformity. They have a very favorable hematologic outcome: The platelet count tends to improve over time, with many patients achieving platelet counts $>100 \times 10^9$/L. For the various *MYH9* gene mutations, the hematologic outcome is excellent; many of these patients do not bleed despite their thrombocytopenia, because their larger than normal platelets exert increased functionality compared to normal-sized platelets. Some patients with these disorders will develop renal failure, deafness, and/or cataracts; however, this will occur many years after the newborn period and often not until the second or third decade of life.

PLATELET FUNCTION DISORDERS

Etiology/Pathophysiology

As discussed earlier, platelets play a major role in hemostasis both by supporting the cellular structure for the primary platelet plug and by providing a phospholipid surface on which the plasma elements involved in coagulation can bind. Thus, a decrease in the platelet count and/or poor platelet function can result in bleeding symptoms. Abnormalities in platelet function can occur in any of the multitude of components (functional, structural, and regulatory proteins) required for normal platelet function. For example, defects in glycoprotein Ib or IIb/IIIa result in Bernard-Soulier disease or Glanzmann's thrombasthenia (the most severe platelet function defect), respectively (Nurden and Nurden, 2008). The most common platelet function defect, the δ-storage pool defect, results in reduced secretion of ADP. However, the degree of bleeding associated with this condition rarely leads to manifestation in the neonatal period.

The differential diagnosis of platelet function defects can be divided into congenital and acquired defects and can be thought of in terms of the structural components of the platelets. As mentioned, congenital disorders of platelet receptors such as glycoprotein Ib and IIb/IIIa result in Bernard-Soulier disease and Glanzmann's thrombasthenia, respectively. There are genetic defects resulting in δ-storage pool defect (including the common ADP secretion defect and the less common absence of dense bodies associated with Hermansky-Pudlak syndrome) and α-granules (gray platelet syndrome). Although there are likely many more genetic defects as yet unidentified in the various steps involved in normal platelet function, a platelet function defect can often be determined from laboratory testing. However, further delineating the defect is difficult, because the types of assays required to uncover the specific defect are not available in commercial laboratories.

Acquired platelet defects are most commonly due to medications, chronic medical conditions (uremia being the prime example), or medical interventions such as ECMO. The list of medications resulting in platelet dysfunction is vast, and it is suggested that in the evaluation of a patient with a bleeding disorder who is receiving medication, a reference manual be consulted to assess the possibility that this medication leads to platelet dysfunction. The most common medications resulting in platelet dysfunction include aspirin and other nonsteroidal antiinflammatory drugs (indomethacin), prostacyclin, certain anticonvulsants (valproic acid in particular), and some antibiotics.

Among the medical disorders associated with platelet dysfunction, the most common and best described is uremia. Although the exact mechanism by which the platelets are affected is not clear, a prevailing theory is that the accumulation of certain substances associated with uremia disrupts the platelet phospholipid surface. Last, other than prescribed medications, certain medical procedures are associated with platelet dysfunction, with the most common being the use of extracorporeal circuits (ECMO and cardiopulmonary bypass). There are probably a number of mechanisms involved in this process; however, clearly the passage of platelets through an artificial surface affects the ability of platelets to adhere and aggregate. A detailed review of platelet function defects is beyond the scope of this chapter; there are a number of excellent review articles that address the topic of platelet function defects.

Clinical Presentation

Patients with platelet function disorders present with bleeding signs similar to thrombocytopenia. In essence, this includes mucocutaneous bleeding (nose, mouth, gastrointestinal tract, genitourinary tract) and bruising. The extent, location, and nature of the bruises are generally related to birth trauma and invasive procedures. Rarely, some patients may present as a result of a family history of bleeding without having bleeding themselves. Last, patients may present as the result of an abnormal screening test (bleeding time, PFA) ordered by a surgeon before

undergoing a medical procedure. In such situations, it is critical to take a detailed medical history, because it is possible that such patients do not have a bleeding disorder.

Diagnosis

The diagnosis of platelet function disorders in neonates is problematic, because the tests either are difficult to perform (the bleeding time) or require a large amount of blood (platelet aggregation studies) (Israels, 2009). Although the PFA has been used in the neonatal population, there are few studies establishing normal ranges, and the test should not be performed in patients with thrombocytopenia and anemia, a common finding in the neonatal intensive care unit. Importantly, the first step in evaluating a patient for a platelet function disorder is ensuring that the platelet count is normal, because the assays of platelet function will be abnormal if the platelet count is low, thereby rendering the results useless. In addition, some assays such as the PFA will also be abnormal if there is significant anemia. A CBC is thus the first laboratory test that should be performed, and it should be done before embarking on platelet-specific assays.

There are two tests that can screen for platelet function disorders; however, both have significant limitations. The original screening test is the bleeding time, a test that is notoriously difficult to perform, particularly in neonates, and as a result has fallen out of favor and is no longer recommended. The PFA is a widely used laboratory assay available in most coagulation laboratories and is a useful screening assay to evaluate for disorders of primary hemostasis. Normal ranges for the PFA have been established in neonates (Israels et al, 2009). Patients with severe platelet function defects such as Bernard-Soulier and Glanzmann's thrombasthenia always have significantly abnormal results. The PFA is often abnormal in the milder disorders such as the common ADP secretion defects; however, its sensitivity for these disorders is not sufficient to allow such defects to be ruled out if the results are normal. The PFA is also abnormal in patients on aspirin (both cartridges) and clopidogrel and ticlopidine (the collagen/ADP cartridge). The effects of other medications known to affect platelet function (e.g., valproic acid) are not clear. Thus, the PFA is a useful screen for the platelet function defects. However, it cannot rule out milder defects. Thus, if a bleeding disorder is suspected based on history, further testing is required even if the PFA result is normal.

The major specific assay of platelet function is platelet aggregometry. This assay uses a set concentration of platelet-rich plasma and assesses platelet aggregation via light transmission after addition of a variety of platelet agonists (ADP, epinephrine, ristocetin, arachidonic acid, collagen, and thrombin-related activation peptide). Neonates have reduced aggregation compared to older children and adults; however, the clinical utility of testing in newborns is questionable and as stated in the PFA-100 assay, the clotting time for newborns is actually shorter than those for older children and adults, suggesting better platelet function. Thus it remains unclear whether neonatal platelets are hyper- or hyporesponsive. The major limitation of platelet aggregometry in neonates is the large amount of blood required (20–30 mL depending on the platelet count and how many agonists will be tested). Furthermore, as with the PFA, many medications and supplements affect platelet aggregation studies, and thus, if possible, the assay should be done when patients are no longer receiving these medications or supplements. A more detailed discussion of platelet aggregation can be found in the reviews of platelet function disorders. Some platelet function defects lead to easily identifiable ultrastructural changes in the platelets that can be visualized by electron microscopy. In particular, patients with a deficiency or absence of dense bodies (δ-storage pool deficiency) or α-granules (gray platelet syndrome) can be demonstrated by electron microscopy. Last, flow cytometry can quantify the levels of platelet surface receptors and can confirm the diagnosis of Bernard-Soulier and Glanzmann's thrombasthenia if the diagnosis is in doubt after platelet aggregation studies.

Treatment

The management of congenital platelet function defects relies on several medications and platelet transfusions in dire situations when the medications or local measures are ineffective. In acquired conditions, reversal of the condition that led to the platelet dysfunction will reverse the platelet defect, but this is not always possible. In such situations, the approach to management of bleeding is similar to that for congenital disorders—for example, platelet transfusions or the medications described later. Several medications have nonspecific mechanisms whereby they can enhance hemostasis when platelet function is abnormal. These include desmopressin, antifibrinolytic agents, and recombinant activated FVII (rFVIIa). Desmopressin has been demonstrated to improve platelet function in many congenital disorders, in uremia, and during cardiopulmonary bypass. The mechanism whereby it exerts its effect is not clear, although it is known that this agent increases circulating levels of VWF and FVIII. This medication can be given intravenously or subcutaneously. Desmopressin is generally a very safe agent, although it can lead to vasodilatation, resulting in reductions in blood pressure sufficient to lead to clinical signs, and because it is an analogue of antidiuretic hormone, it can lead to water retention and hyponatremia, which can result in seizures. Neonates are at particularly high risk for this complication; thus, if desmopressin is employed, monitoring of serum sodium levels is essential. As discussed previously for thrombocytopenia, antifibrinolytic agents are excellent adjunctive therapies.

Recombinant FVIIa was developed for the management of bleeding in patients with hemophilia and inhibitors; however, it has been shown to also be effective for managing severe bleeding in patients with severe platelet function defects. It is licensed in Europe for the management of bleeding in patients with Glanzmann's thrombasthenia who are refractory to platelet transfusions. Although there are some reports touting the effectiveness of this agent in platelet function defects, other reports are less complimentary. The drawbacks of this agent are the expense and the risk for thrombosis. Thus, it is suggested that rFVIIa be used only for patients with severe bleeding in whom standard therapeutic measures have failed. The use of this

agent in neonates has been reported, and it appears that neonates are at increased risk for thrombosis from this agent compared with older children when it is employed for unlicensed uses (Young et al, 2009).

For severe bleeding that has not responded to the measures just described, a platelet transfusion should be given in order to provide normally functioning platelets. Although most platelet function defects are mild enough that this will never be required, for the more severe disorders such as Bernard-Soulier and Glanzmann's thrombasthenia, a platelet transfusion may be life-saving. The risks associated with a platelet transfusion are no different from those for other patients, with one important exception: Patients with Bernard-Soulier and Glanzmann's thrombasthenia are at risk for alloimmunization, resulting in the formation of antibodies to GPIb and IIb/IIIa, respectively. Once these antibodies develop, future platelet transfusions are likely to be ineffective. Thus, it is *imperative to withhold platelet transfusions for these patients except in life-threatening hemorrhage*, *because it may be possible to use this therapy only once in a patient's lifetime*. Last, as described earlier, the benefits of local measures cannot be overstated in the management of bleeding.

Prognosis and Outcomes

Most platelet function disorders are mild and easily managed with the aforementioned approaches. For most patients, these disorders rarely lead to serious bleeding complications. Among the more serious conditions, Glanzmann's thrombasthenia is the most severe and is the one most likely to result in neonatal bleeding, although most patients will not present during this time unless they undergo a hemostatic challenge. After discharge from the neonatal intensive care unit or newborn nursery, patients with platelet function disorders largely lead normal lives with easily manageable and rarely serious bleeding. Patients with Glanzmann's thrombasthenia have the worst outcomes, but even these patients manage to lead relatively normal lives, although they are more likely to require treatment and have interruptions in their daily lives due to bleeding symptoms.

VON WILLEBRAND'S DISEASE

Etiology/Pathophysiology

As discussed previously, VWF is the primary plasma protein required for platelet adhesion, and it also plays an important role in platelet aggregation. The absence (or reduced amount) of VWF or abnormal VWF function leads to defects in platelet adhesion and aggregation resulting in increased bleeding. In addition, VWF is the carrier protein for FVIII, and patients with VWF may have reduced levels of circulating FVIII, further affecting the quality of hemostasis. The effectiveness of VWF as an adhesive protein relies on multimerization of the protein, resulting in very large molecules (among the largest made in the body) that comprise what are known as high-molecular-weight multimers.

Similar to platelet disorders, VWD can be either congenital or acquired, although the congenital form is by far the most common (Nichols et al, 2008). Many mutations have been identified in the various structural components, which can lead either to reduced production or secretion of normally structured VWF or to the production of a dysfunctional protein. As a result of the variety of mutations, VWD has been subcategorized into two basic types: a quantitative defect that can be partial (type 1) or complete (type 3), and qualitative defects (type 2). Table 76-4 describes this classification and diagnosis of VWD in detail. Type 1 is due to reduced amounts of plasma VWF that can result from either decreased production/secretion of VWF or increased clearance of circulating VWF (Vicenza type). Type 3 is due to a complete absence of protein in the plasma and is likely due to severe mutations in the VWF gene. There are four recognized type 2 defects. Type 2A is due to defects in multimerization and results in an absence of large and medium-sized multimers, required for normal platelet adhesion. Type 2B is due to a gain-of-function mutation (similar to platelet type VWD) in VWF leading to increased binding of the high-molecular-weight multimers to circulating platelets, effectively removing these from the available pool in the plasma. Type 2M is due to a mutation resulting in the loss of the ability of

VWF to bind to platelets. Type 2N is due to a defect in the binding of VWF to FVIII resulting in a reduction in circulating FVIII. In general, patients presenting with this subtype are compound heterozygotes for a type 1 defect and the type 2N mutation. These patients are often difficult to distinguish from those with mild hemophilia without the performance of an assay specific to the condition (see Diagnosis section, later).

Acquired von Willebrand's syndrome (AVWS) is a rare condition that has been reported in a variety of unrelated medical conditions. In children, it has been associated with Wilms' tumor, congenital heart disease, and systemic lupus erythematosus. The pathophysiology of the acquired von Willebrand's syndrome is heterogeneous and depends on the associated condition. Some of the described mechanisms are antibody formation, decreased production, proteolysis, and adsorption of VWF onto malignant cells.

Clinical Presentation

The clinical presentation of VWD rarely occurs in the newborn period and is essentially identical to that of platelet function disorders described earlier, with the following exceptions. First, VWD is more common and better described than platelet function defects such that some patients will present based on a known family history in the mother or father. Second, there are relatively few medications that affect production or function of VWF, although valproic acid has been implicated as one of the medications that can lead to AVWS. Third, the disorders that lead to AVWS are different from those that lead to platelet dysfunction.

Diagnosis

The diagnosis of VWD relies on testing for the presence and the two functions of VWF (see Table 76-4). The initial assays for VWD include measurement of the amount of VWF (the VWF antigen assay), the platelet binding function (ristocetin cofactor assay), and the FVIII binding function (FVIII activity). Based on these results, additional testing can be ordered in consultation with a pediatric hematologist.

Treatment

The principles of managing VWD are similar to those for managing platelet dysfunction, with the major exception that replacement therapy rather than platelet transfusion is accomplished with VWF-containing concentrates derived from human plasma. Mild to moderate bleeding associated with type 1 VWD is best managed with desmopressin and, if necessary, antifibrinolytic agents. As noted previously, desmopressin may lead to hypotension and hyponatremia, particularly in neonates. In the case of VWD, the mechanism of action of desmopressin has been well described and is the result of secretion of stored VWF from the Weibel-Palade bodies in endothelial cells. More than 90% of patients with type 1 disease will respond with often dramatic increases in VWF. It should be noted that repeated administration of desmopressin will lead to tachyphylaxis, presumably from exhaustion of the storage pool of VWF. Thus it is best to administer desmopressin no more than once daily and no more than 2 days in a row, although exceptions can be made. Desmopressin in general should not be used for patients with type 2 disease and is ineffective in type 3 disease. There are some reports of the benefits of desmopressin in all type 2 subtypes, although it should be used with caution in patients with type 2B because it could lead to significant thrombocytopenia as a result of in vivo platelet aggregation (Peyvandi et al, 2008).

For patients with types 2 and 3 disease who develop significant bleeding, replacement therapy with a VWF-containing concentrate should be given. There are currently four products available in the United States (Humate P, Alphanate, Wilate and Koate DVI), with similar products available in other countries. All of these concentrates contain VWF and FVIII in varying ratios and with variable amounts of the different-sized multimers. Although there are theoretical advantages to having a higher (or lower) ratio of VWF to FVIII, the fact is that all of these products have been demonstrated to be effective for the management of bleeding and for the prevention of bleeding in patients requiring invasive procedures. The choice of which product to use is at the discretion of the treating physician in consultation with the hematologist. Often, hospital formularies carry only one of the products, simplifying the choice for inpatient use. All the products are safe, although it should be pointed out that they are all derived from human plasma (all undergo viral inactivation methods and there is no known transmission of infectious agents with any of the products). As with all human plasma products, there is a possibility of allergic reactions, but these have been infrequently reported.

Antifibrinolytic agents and topical agents are useful adjunctive therapies and can be used as described earlier. The benefits and risks of these agents are the same as previously described. Management of bleeding in AVWS is the same as for congenital VWD. However, because this is an acquired condition, treatment of the underlying disorder leading to AVWS should be undertaken in order to resolve the VWF defect.

Prognosis and Outcomes

Patients with most forms of VWD largely lead live normal lives with easily manageable and rarely serious bleeding. Only patients with type 3 VWD, the rarest subtype, suffer from recurrent and serious bleeding leading to complications such as chronic joint disease.

HEMOPHILIA A AND B (FACTOR VIII AND IX FACTOR DEFICIENCY)

Etiology/Pathophysiology

The physiology of hemostasis described earlier demonstrates the critical roles that FVIII and FIX play in ensuring proper thrombin generation and ultimately fibrin clot formation. The absence of either FVIII or FIX results in reduced thrombin generation on the surface of the activated platelets at the site of bleeding. This results in a clot with poor structural integrity, which can be seen on

electron microscopy with the formation of large, coarse fibrin strands, rather than the thinner strands that form a much tighter network. In addition, reduced thrombin generation results in decreased generation of activated FXIII, which is required for crosslinking the fibrin monomers and decreased generation of TAFI, both of which result in a clot that is less resistant to thrombolysis. Thus, deficiencies of FVIII or FIX result in less well formed clots that are more susceptible to fibrinolysis. This results in the bleeding manifestations seen in patients with hemophilia.

Deficiencies of FVIII and FIX most commonly occur as a result of genetic mutations on the X chromosome where both genes reside. These deficiencies therefore occur much more commonly in males as a result of the hemizygosity state. Heterozygous females may have mild hemophilia as a result of nonrandom X-chromosome inactivation with resultant FVIII or FIX levels in the range of mild hemophilia described later. In the past, these women were called symptomatic carriers; however, they are now more appropriately classified as having mild hemophilia. There are a variety of mutations that can result in hemophilia. The type of mutation (deletion, inversion, missense, nonsense) and the part of the protein that is affected will determine the severity of the disease. Although hemophilia is an X-linked disorder, in approximately 25% of cases, no family history is identified. In such cases, either there were no affected males (or symptomatic females) in the pedigree, or a new mutation arose in either the patient or more often the mother or the maternal grandfather's germ cells, as has been demonstrated for one particular mutation in FVIII known as the intron 22 inversion.

Acquired hemophilia is a very rare condition and can present during pregnancy. Because the antibodies are most often of the IgG subtype, it is possible for these antibodies to be transplacentally transferred, resulting in the same condition in the fetus and newborn. The symptoms of acquired hemophilia are similar to those of congenital hemophilia; however, there seems to be a higher predilection for mucocutaneous bleeding. Otherwise, there is no specific bleeding pattern, although it is rare for there not to be significant cutaneous bleeding.

Clinical Presentation

The clinical presentation of congenital hemophilia is highly variable and depends on the severity of the disease and on whether or not a family history is present (Kulkarni et al, 2006). For patients with a known family history (particularly if the mother is an obligate carrier, e.g., the daughter of a hemophiliac), the diagnosis can be made shortly after birth by assaying FVIII or FIX from umbilical cord blood. Prenatal testing can be performed; however, it is not generally recommended, because it should not alter the course of the pregnancy or the planned mode of delivery (the mode of delivery of a known hemophiliac remains somewhat controversial). For patients in whom there is no family history or for whom testing was not done after birth, symptoms can develop at any time and more or less correlate with the severity of disease.

Severe hemophilia (defined as a factor level below 1%) can manifest in the newborn period with any of the following: intra- or extracranial bleeding, prolonged bleeding from venipuncture or heelstick puncture, prolonged bleeding after circumcision, excessive bruising, muscle hematomas after intramuscular injections such as vaccinations, or bleeding after surgery. For patients in whom none of these symptoms develop, the presentation will occur later in life and thus not under the purview of a neonatologist.

Diagnosis

The laboratory diagnosis of hemophilia is fairly straightforward. A clinical suspicion for a bleeding disorder should trigger the ordering of a PT and PTT, and the PTT is nearly always abnormal. There are rare instances where the PTT may not be abnormal. After the identification of a prolonged PTT, factor levels will elucidate the type (FVIII or FIX) and the severity of hemophilia. There are several caveats to the measurement of factor levels. First, proper specimen procurement and handling is critical; otherwise, results may be falsely low. Second, testing of cord blood specimens may result in levels that may be somewhat above what they would be on repeat testing; thus, although cord blood factor levels are useful in determining the presence of hemophilia, it is recommended that additional testing be done at a later date in order to ascertain more accurately the severity of hemophilia. Third, the normal range for FVIII in the newborn is at or slightly higher than adult normal values. However, FIX levels are significantly lower in newborns than in adults (consult a table for the exact levels at different ages in the 1st month of life). Of note, preterm neonates have even lower FIX levels. Fourth, the factor assays at very low levels (1–2%) are less reliable, and thus repeated testing is recommended in order to differentiate patients with severe and moderate hemophilia. Fifth, there are rare occasions when a patient may have a normal factor level on the one-stage clotting assay (the one most commonly used in the United States), whereas an abnormal result will be obtained on the two-stage chromogenic assay. Last, inflammation may increase FVIII levels for patients with mild hemophilia, and thus it is best to measure levels while patients are in their usual state of health.

Treatment

The mainstay of hemophilia treatment is factor replacement therapy. A number of factor concentrates are commercially available for both FVIII and FIX deficiency. The choice of which specific product to use is complicated by issues such as the availability and cost of each agent as well as real and perceived benefits of plasma-derived versus recombinant products and among different generations of recombinant FVIII products, of which there are currently four agents and five products (one agent is marketed and sold under two names by two pharmaceutical companies). Ultimately, the choice of factor concentrate should be made in consultation with a pediatric hematologist.

Many neonates will not require treatment during the newborn period because they will not manifest bleeding symptoms (or the diagnosis will not have been made). For those in whom bleeding has occurred, factor replacement therapy is indicated, and the specific dosing regimen should be determined in consultation with a pediatric hematologist. For those with a known prenatal or early

postnatal diagnosis in whom circumcision (or any other surgical procedure) is to be performed, treatment with factor replacement is mandatory in order to prevent bleeding and improve the outcome of the procedure. On rare occasions, neonates will present with severe bleeding symptoms such as ICH. In such cases, factor replacement therapy should be initiated as soon as possible, and therapy should be continued for at least several days if not several weeks. The duration and intensity of therapy depends on the location and severity of bleeding. Again, dosing regimens can be determined in consultation with a pediatric hematologist.

Adjuvant therapies for hemophilia exist that are similar to those for platelet defects and VWD. For patients with mild FVIII deficiency, desmopressin can increase factor levels to hemostatic levels and can be useful for the management of minor bleeding. The use of antifibrinolytic agents for mucous membrane bleeding is also effective and can be used as an adjunct to desmopressin or factor replacement.

The most important complication of factor therapy in hemophilia is the development of neutralizing antibodies termed inhibitors. Inhibitors render standard factor replacement therapy ineffective, resulting in bleeds that are more difficult to control, which leads to increased morbidity and mortality (Young, 2006). The incidence of inhibitors in previously untreated FVIII-deficient patients is between 20% and 35%, whereas for FIX-deficient patients it is approximately 5%. The prevalence of inhibitors is approximately 10% in FVIII deficiency and 3% to 5% in FIX deficiency. Inhibitors will rarely manifest in the newborn period, because in general it takes 10 to 20 doses of factor before an inhibitor develops, and most neonates will not receive this many doses of factor except for those with major bleeding symptoms. For those in whom multiple doses have been administered, the possibility for the development of an inhibitor should be considered if bleeding occurs despite factor replacement therapy.

The management of bleeding episodes in patients with inhibitors can be a significant challenge, and much of the morbidity from hemophilia in the United States occurs in patients with high-titer inhibitors. Presently, there are only two agents available for the management of bleeding in inhibitor patients, activated prothrombin complex concentrate (APCC) (FEIBA, Baxter, Westlake Village, CA) and recombinant activated factor VII (rFVIIa; Novoseven, Novo Nordisk, Bagsvaerd, Denmark). Activated prothrombin complex concentrate is a plasma-derived mixture of clotting factors, some of which are activated. The mechanism of action is felt to be due to the presence and action of activated FX and prothrombin, although this product also contains activated FIX and FVII as well as a small amount of nonactivated FVIII. Recombinant activated FVII is (as its name implies) a recombinant form of activated FVII and contains no other human proteins. The mechanism of action of rFVIIa involves the generation of thrombin on the surface of activated platelets through tissue-factor-dependent and -independent mechanisms. Both products have been demonstrated to be safe and effective, with variable response rates generally between 70% and 90%, depending on the study. Both products have a long track record of safety (more than 30 years for APCC and 10 years for rFVIIa), with few reported thrombotic events in patients with hemophilia and inhibitors. In addition, from an infectious disease standpoint, the APCC has an excellent safety record with no documented transmission of viral infections, whereas rFVIIa has, as expected, no known transmission of any infections. Because APCC contains small amounts of FVIII, it could in theory lead to an increase in the inhibitor titer (anamnesis); thus, it is recommended to avoid APCC if possible in the newborn period. Again, management of bleeding is critical, so this is not a contraindication to using APCC during this time, and if a bleeding episode does not respond to rFVIIa, then APCC should be used without hesitation. Dosing for these agents should be done in consultation with a pediatric hematologist. For patients receiving inhibitors in whom invasive procedures are required, rFVIIa can be used perioperatively to prevent bleeding (APCC can be used as well if rFVIIa is not effective). In the extraordinarily rare circumstance of acquired hemophilia antibodies passively transferred to a newborn, the management of bleeding is similar to that of congenital hemophilia with inhibitors.

Prognosis and Outcomes

Currently, patients with severe hemophilia in whom inhibitors do not develop and who are on prophylaxis have an excellent prognosis and often lead normal lives free of debilitating hemophilic arthropathy. This has been documented well by the Swedish cohort for almost the past 40 years. For patients with inhibitors, the prognosis is more guarded. For those in whom ITT is effective, their outcome can be as good as for those who never developed an inhibitor, provided they did not develop joint damage before tolerization. It is likely, however, that many of these patients will have had a number of bleeding episodes in joints, muscles, or, rarely, in the brain, and that some of these patients will have permanent deficits. For inhibitor patients in whom ITT was not successful, significant joint morbidity is very common, often leading to permanent disability and relatively poor quality of life. Nevertheless, with the reduced reluctance to perform surgery in inhibitor patients combined with the increased use of prophylaxis, it is possible to intervene and ameliorate the effects of joint damage and allow patients to lead more productive lives.

RARE FACTOR DEFICIENCIES

Etiology/Pathophysiology

As with deficiencies of FVIII and FIX, deficiencies in other important hemostatic clotting factors result in reduced thrombin generation or, particular to FXIII, reduced fibrin cross-linking resulting in poor clot formation and reduced resistance to fibrinolysis. Deficiencies of fibrinogen and FII, FV, FVII, FX, FXI, and FXIII all result in variable bleeding diatheses (Peyvandi et al, 2008). In general, the severity of the bleeding is related to the factor levels (although this is less clear for FXI deficiency).

Rare factor deficiencies can be the result of genetic defects or acquired conditions. The genes for all of the

TABLE 76-5 Classification of Vitamin K Deficiency Bleeding (VKBD)

Feature	Early	Classical	Late
Age	<24 hours of age	1–7 days	2 weeks and older
Risk factors	Maternal medications (vitamin K antagonists, anticonvulsants, antituberculin drugs)	Lack of prophylactic vitamin K treatment, poor feeding (particularly if breastfed)	Exclusive breastfeeding, poor feeding, gastrointestinal disorders, liver disease, pancreatic disease, antibiotic therapy
Sites of bleeding	Cephalhematoma, umbilical stump, intracranial	Gastroinestinal, umbilicus, mucocutaneous, circumcision, intracranial	Intracranial, mucocutaneous, gastrointestinal
Frequency	Less than 5% in at-risk population	With prophylactic vitamin K—extremely rare, Without prophylactic vitamin K (0.01% to 1%)	Variable depending on age and conditions listed above
Treatment	Prothrombin complex concentrates, vitamin K (may not be effective)	Parenteral vitamin K (intravenous preferred) Prothrombin complex concentrates for active bleeding	Vitamin K, prothrombin complex concentrates for active bleeding, recombinant factor VIIa (for mild cases in which only the PT is prolonged)
Prevention	Avoidance of above medications during pregnancy	Vitamin K prophylaxis at birth	Adequate vitamin K replacement (in many cases will need to be parenteral)

PT, Prothrombin time.

foregoing factors are located on somatic chromosomes and thus affect males and females equally. The specific defect will dictate the resultant factor activity level and thus the phenotypic severity. In neonates, acquired rare factor deficiencies are more common and can result from a variety of conditions, including vitamin K deficiency, liver disease, and Kasabach-Merritt syndrome.

Vitamin K is required for the gamma-carboxylation of FII, FVII, FIX, and FX, and the absence of gamma-carboxylation renders these proteins nonfunctional. Vitamin K deficiency still occurs in newborns, particularly in those born at home where vitamin K administration is less likely to occur or in those children whose parents refuse vitamin K administration for their child. Vitamin K deficiency bleeding (VKDB) is classified as early, classical or late (Table 76-5) (Shearer, 2009). Early onset occurs in the first 24 hours of life and is due to the cross-placental transfer of compounds that interfere with vitamin K metabolism or function including some anticonvulsants, antibiotics, antituberculin agents and vitamin K antagonists e.g., warfarin. Classical VKDB occurs in the 1st week of life and is due to a physiologic deficiency in vitamin K at birth combined with a lack of vitamin K in breast milk or due to inadequate feeding. Vitamin K prophylaxis has its biggest impact on preventing this type of VKDB. Late-onset VKDB can occur at any age, although it is classically described as occurring between 2 weeks and 6 months of age. Almost all infants with the disorder are exclusively breastfed because it is believed to be caused by inadequate vitamin K content in breast milk. In late-onset vitamin K deficiency, additional risk factors for vitamin K deficiency must be present that intuitively have in common reduced vitamin K intake and absorption. Some examples of conditions that lead to late-onset vitamin K deficiency are liver or pancreatic disease, both leading to an inability to absorb fat-soluble vitamins; gastrointestinal disorders that affect intestinal flora, because a secondary source of vitamin K is production by intestinal microorganisms; prolonged antibiotic use, again due to an alteration of intestinal flora; and ingestion (accidental or otherwise) of vitamin K antagonists, which, although perhaps not technically vitamin K deficiency, can be overcome with vitamin K.

Before the widespread use of vitamin K prophylaxis, the incidence of classical VKDB was reported to be as high as 1.5%; however, the condition now is considered rare. A recent comprehensive survey from Great Britain and Ireland demonstrated a rate of 0.14 per 100,000 live births in a population with a high rate of prophylactic vitamin K administration. The incidence for early- and late-onset VKDB is not known. However, early-onset VKDB occurs in only a small proportion (probably <5%) of at-risk births. The variety of conditions that lead to late-onset VKDB make defining the incidence challenging.

Regarding the other rare factor deficiencies, all are known to occur in association with specific medical conditions. Specifically, hypofibrinogenemia can result from liver disease, the Kasabach-Merrit syndrome (hemangioma with consumptive coagulopathy), and DIC. Factors II, VII, and X are vitamin K dependent (as is FIX, which was covered in the preceding section) and synthesized in the liver, and thus they become deficient in liver failure and vitamin K deficiency as described earlier. In addition, FII deficiency can rarely occur as part of the antiphospholipid syndrome, which, although uncommon in newborns, can result from transplacental transfer of maternal antibodies. Deficiency of FV has been reported after exposure to topical thrombin (commonly used in cardiac surgery) as a result of autoantibody formation. DIC is a serious disorder resulting from a variety of medical conditions which leads to consumption of clotting factors and thus can result in bleeding. In DIC, multiple factors are often deficient.

Finally, there are two inherited multifactor deficiency disorders. One results in deficiencies of FV and FVIII and is the result of a mutation in a protein (endoplasmic reticulum Golgi intermediate compartment [ERGIC]-53) required for assembly and secretion of these two similarly

TABLE 76-6 Bleeding Sites/Symptoms and Factor Replacement Choices for Rare Factor Deficiencies

Factor Deficiency	Bleeding Sites	Other Symptoms	Factor Replacement	Causes for Acquired Deficiency
Fibrinogen	No typical sites	Splenic rupture Miscarriage Thrombosis	Fibrinogen concentrate (RiaStap) Cryoprecipitate	Liver disease Asparaginase therapy DIC
FII (prothrombin)	No typical sites	None	PCC	Vitamin K deficiency Liver disease Vitamin K antagonists Antiphospholipid syndrome
FV	No typical sites	None	FFP Platelet transfusion	Exposure to topical bovine thrombin
FVII	Intracranial	Thrombosis	rFVIIa	Vitamin K deficiency Liver disease Vitamin K antagonists
FX	Intracranial	None	PCC	Vitamin K deficiency Liver disease Vitamin K antagonists Amyloidosis
FXI	Postoperative or trauma-related	None	FFP (FXI concentrates are available in some countries)	Autoantibodies (rare)
FXIII	Intracranial Umbilical stump	Poor wound healing Miscarriage	Cryoprecipitate pdFXIII concentrate is available in the US as part of a clinical trial	Cardiopulmonary bypass Inflammatory bowel disease

FFP, Fresh frozen plasma
RiaStap (fibrinogen concentrate) is licensed only for congenital afibrinogenemia.
Recombinant FVIIa is licensed for the treatment of congenital FVII deficiency.
Prothrombin complex concentrates (PCC) are not licensed for the treatment of rare factor deficiencies and contain variable amounts of FII, FVII, and FX (the amounts are in the prescribing information). Dosing is based on FIX units.

structured proteins. A second disorder results in deficiency of all of the vitamin K–dependent proteins and is due to a number of mutations in enzymes in the vitamin K pathway. Both conditions are very rare and have mostly been reported in consanguineous families. Both can lead to significant bleeding symptoms.

Clinical Presentation

The clinical presentation of the congenital rare factor deficiencies is similar to that for hemophilia and can be discovered as a result of a known family history, although this is far less common for these deficiencies because their mode of inheritance is autosomal recessive. More likely, they present with excessive bleeding, which ranges from mild mucocutaneous bleeding to catastrophic ICH. Unique features for each factor deficiency can be found in Table 76-6. Several conditions leading to rare factor deficiencies can present in the newborn period. As mentioned, DIC can be the result of a variety of clinical conditions, most commonly sepsis, and often the coagulation problems (bleeding or thrombosis) present after the onset and even the diagnosis of the underlying condition. Patients with the Kasabach-Merritt syndrome will usually (although not always) have an easily visible mass, which can occur anywhere. Occasionally, the lesion leading to Kasabach-Merritt syndrome is deep-seated and not obvious on physical examination, in which case it may be diagnosed by diagnostic imaging. Patients with coagulopathy associated with liver failure should (although again this is not universal) have clear signs of liver dysfunction.

Diagnosis

Once suspected, the diagnosis of rare factor deficiencies is relatively straightforward. In many patients, the presentation may be obvious, such as those with signs of liver failure, a lesion suspicious for Kasabach-Merritt syndrome, conditions associated with DIC, or a history of a lack of vitamin K administration. Regarding the laboratory diagnosis, all of the described deficiencies with the exception of FXIII deficiency result in a prolonged PT, PTT, or both. Depending on the results of these screening tests, specific factor assays can be performed, leading to the correct diagnosis. For example, deficiencies of FII, FVII, FIX, and FX suggest either vitamin K deficiency or liver disease, whereas significant hypofibrinogenemia is associated with DIC or Kasabach-Merritt syndrome (other factor deficiencies are associated with these conditions, but a low fibrinogen is a hallmark of these conditions). FXIII deficiency can be diagnosed via a qualitative assay (clot solubility assay) or a quantitative assay. The clot solubility assay is abnormal only if the FXIII level is less than about 5%; thus, it is not sensitive for milder deficiencies, although it is not clear that mild FXIII deficiency results in a bleeding diathesis.

Treatment

In neonates with rare factor deficiencies, there is nearly always an acquired cause; therefore, treatment of that condition should result in resolution or improvement of the factor deficiencies. For vitamin K deficiency, treatment with vitamin K will result in complete resolution of the factor deficiencies. Importantly, however, if patients have

active bleeding, it should be noted that the correction of the deficiencies will take as long as 24 hours, thus necessitating immediate factor replacement therapy to control the bleeding. Products referred to as prothrombin complex concentrates contain all the vitamin K–dependent factors and should be administered immediately if vitamin K–deficient bleeding is occurring. Consultation with a hematologist is recommended to assist in selection of the correct product and dose.

For patients with DIC or liver disease, correction of those conditions will result in correction of the factor deficiencies. For patients with active bleeding, fresh frozen plasma and cryoprecipitate are the treatment of choice to correct the factor deficiencies of DIC, whereas for liver failure, the prothrombin complex concentrates and cryoprecipitate (if the fibrinogen is low) are the treatment of choice. In patients with Kasabach-Merritt syndrome, treatment of the lesion will result in correction of the factor deficiencies, and because hypofibrinogenemia and thrombocytopenia are likely the main causes for bleeding, treatment with cryoprecipitate and platelet transfusions may be effective. It should be emphasized that the foregoing therapies are recommended only if bleeding is occurring and not simply for abnormal laboratory test results.

For the rare patient with congenital factor deficiencies, the hallmark of therapy is replacement of the deficient factor either after bleeding occurs or prophylactically as described for FVIII and FIX earlier. Table 76-6 lists the available therapies for factor replacement. For the most part, patients with these factor deficiencies are treated only when they bleed; however, there are some notable exceptions. Because severe deficiencies of FX and FXIII frequently result in catastrophic ICH, such patients should receive lifelong prophylaxis. For FX deficiency, this is accomplished by twice-weekly infusions of prothrombin complex concentrate (PCC), whereas for FXIII, this is accomplished via monthly infusions of cryoprecipitate or plasma-derived FXIII concentrate (Corifact, CSL Behring, King of Prussia, Penn.). Severe FVII deficiency can also result in ICH, although less so than for FX and FXIII deficiencies, and prophylactic therapy with rFVIIa should be considered.

Prognosis and Outcomes

The congenital rare factor disorders are highly variable conditions both within each specific deficiency and among the deficiencies. Furthermore, not only are the acquired conditions leading to rare factor deficiencies variable, but some may spontaneously remit (FV antibodies secondary to topical thrombin), whereas others have significant morbidity and mortality (liver failure). Thus, it is difficult to discuss prognosis and outcome in general for these disorders. Suffice it to say that mild or moderate congenital rare factor deficiencies do not generally lead to major health problems, and the bleeding associated with these conditions can be easily managed. For severe congenital deficiencies, particularly those associated with serious bleeding complications, prophylactic therapy is an effective approach, and for such patients, outcomes are excellent so long as they have not yet suffered permanent sequelae as the result of a bleed. For patients with acquired rare factor deficiencies, outcomes are excellent for those who recover from their underlying condition that led to the coagulopathy—again, so long as they have not suffered a catastrophic bleed. For those whose underlying condition cannot be readily treated, their prognosis is generally poor and more often related to consequences of the underlying condition rather than bleeding, although occasionally the bleeding in and of itself leads to severe sequelae.

THROMBOTIC DISORDERS

PHYSIOLOGY OF THROMBOSIS

The pathophysiology of thrombosis in neonates fits well within the concepts of Virchow's triad, which includes hypercoagulability, disturbances in blood flow, and endothelial damage or disruption (Bagot and Arya, 2008). When this paradigm is applied to neonates, patients with thrombosis will have at least one, if not two or three, of these abnormalities ongoing. With respect to hypercoagulability, neonates physiologically are all deficient in proteins important in inhibiting coagulation (proteins C and S and antithrombin), with premature neonates being even more deficient than full-term ones. Although neonates are also deficient in procoagulant proteins, the combination of the physiologic deficiency along with other disturbances pointed out by Virchow will tilt the precarious hemostatic balance in favor of thrombosis. In addition, neonates who develop thrombotic complications may have inherited abnormalities that predispose to thrombosis (so-called inherited thrombophilia). The most striking example is that of the neonate with severe (usually homozygous) protein C deficiency who presents with purpura fulminans immediately after delivery with thrombotic complications occurring in utero (Thornburg and Pipe, 2006). Another example is that of the newborn with homocystinuria resulting in very high homocysteine levels, which is associated with arterial and venous thrombosis. The second aspect of Virchow's triad is disturbances in blood flow, such as the stasis or hemodynamic compromise that is associated with hypotension. There are a variety of situations in neonates where this may occur. Perhaps the most obvious example would be in the neonate presenting with shock (for any reason) in whom sluggish blood flow may result in the formation of thrombi. Other examples are congenital heart disease with anomalous blood flow; polycythemia in, for example, infants of diabetic mothers; and cyanotic heart lesions. Last, endothelial damage or disruption is another important aspect of the pathophysiology of thrombosis, and by the far the most common reason for this is vascular catheterization, which could be temporary, that is, diagnostic cardiac catheterization, or of much longer duration, such as the use of central venous catheters. In fact, the vast majority of neonates with thrombosis have catheter-related thrombosis. Taking all of the foregoing into consideration, it should not be surprising that neonates have the highest rate of thrombosis of all the pediatric age groups.

TABLE 76-7 Risk Factors for Deep Vein Thrombosis

Inherited	Acquired
Protein C deficiency	Intravascular catheters
Protein S deficiency	Congenital heart disease
Antithrombin deficiency	Infection
Factor V Leiden	Immobilization
Prothrombin mutation	Artificial heart valves
Hyperhomocysteinemia	Dehydration
Lipoprotein(a) elevation	Surgery
	Trauma
	Malignancy
	Antiphospholipid antibody syndrome

FIGURE 76-2 Femoral deep vein thrombosis. Note the swollen leg with venous congestion pattern on the skin.

VENOUS THROMBOSIS

Epidemiology

As stated earlier, neonates have the highest rate of thrombosis (including DVT) of all the pediatric age groups. A variety of studies have reported an incidence rate for neonatal thrombosis of between 13% and 65% (Veldman et al, 2008). A 1995 study determined that 2.4 of 1000 newborns admitted to the neonatal intensive care unit develop a thrombotic event; however, that number is surely higher today, given the increased use of central venous catheters and improved survival of critically ill neonates (Veldman et al, 2008). There are numerous risk factors associated with DVT in newborns (Table 76-7). The most common cause for thrombosis is the presence of central venous catheters, although the precise incidence is unknown. Some studies have shown rates as high as approximately 60% (Veldman et al, 2008; Hermansen and Hermansen, 2005). As can be expected, these events occur in the region of the catheter tip or insertion point. All types of venous catheters, from umbilical venous catheters to centrally inserted tunneled catheters to peripherally inserted central catheters, can lead to thrombosis (Hermansen and Hermansen, 2005).

Other important causes of venous thrombosis in newborns include congenital heart disease, sepsis (particularly with DIC), dehydration, perinatal asphyxia; although rare, genetic disorders should also always be considered. Patients with congenital heart disease, although at risk for developing catheter-related thrombosis, are also at risk for a variety of non-catheter-related thrombotic events. In such cases, thrombotic events occur either in the heart with atrial or, more rarely, ventricular thrombi or in surgically created shunts such as Blalock-Taussig shunts. Pulmonary emboli may also occur as a result of thrombi presenting in the pulmonary artery. In patients with sepsis, most thrombotic events are associated with catheters; however, when accompanied by hemodynamic instability or DIC, venous thrombosis can occur in any of the deep veins. Perinatal asphyxia with or without therapeutic hypothermia and dehydration can result in cerebralsinus thrombosis, although patients may have clots elsewhere. Patients with perinatal asphyxia can also develop non–catheter-related DVT as a result of prolonged reduced blood flow. Last, newborns apart from older children have a predilection for developing renal vein thrombosis for reasons which are not clear. It typically occurs in patients with inferior vena cava thrombosis secondary to catheters as a result of extension but idiopathic cases are not unusual. In some registries, renal vein thrombosis accounted for as much as 58% of all neonatal thrombosis although in other thrombosis registries, it occurred in just 2% of affected patients (Chalmers, 2006). This is likely due to differences in definitions. Regardless, renal vein thrombosis is an important manifestation of venous thrombosis in the neonatal population (Lau et al, 2007).

Clinical Presentation

As stated, DVT is most often associated with the presence of central venous catheters, and when considering the clinical presentation, the mere presence of a catheter should trigger an assessment by history and examination, including catheter location. The typical signs of venous thrombosis are related to decreased venous drainage of the area distal to the thrombus. Thus, thrombosis affecting the limbs will initially result in swelling and pain (difficult to assess in neonates) of the affected extremity (Figure 76-2). Occlusion of the central veins is often asymptomatic and discovered as an incidental finding on an imaging study, or it can result in dramatic physical signs such as in superior vena cava syndrome. Occasionally, the presentation may be more subtle, such as ascites (secondary to portal vein thrombosis) or organomegaly (typically associated with renal or splenic vein thrombosis). The same physiologic principle applies, however, which is decreased venous drainage of an affected organ or location. In superior vena cava syndrome, the onset of symptoms is fairly acute, with an often dramatic swelling of the head and neck associated with significant headache and discomfort. Thrombosis affecting particular organs will often result in nonspecific signs and symptoms such as ascites (portal vein), splenomegaly with or without hypersplenism (splenic vein), hematuria (renal vein), abdominal pain (mesenteric vein), or hepatomegaly and hyperbilirubinemia (hepatic vein). Another manifestation of venous thrombosis is cerebral sinus thrombosis. It most often presents in neonates suffering from dehydration or those with head and neck infections. Occasionally, no cause is identified. The symptoms again are related

to decreased venous drainage, with the brain being the affected organ. Clinical manifestations are often nonspecific and include signs of raised intracranial pressure such as a bulging fontanel, irritability, and rarely neurologic disturbances such as seizures or focal neurologic signs, particularly if venous infarcts have occurred. Early diagnosis of the thrombosis as well as its underlying cause is important in order for treatment to be effective at preventing permanent neurologic sequelae.

Last, pulmonary embolism is an important and often undiagnosed event in children and particularly difficult to diagnose in sick neonates, who often already have reduced pulmonary capacity. In otherwise well neonates, the symptoms are usually subtle because of the inherent ability of patients of this age to compensate for hypoxemia, and the symptoms when they do occur are nonspecific and include tachypnea, cough, chest pain, and rarely respiratory distress. Hypoxemia is not always present. Pulmonary embolism should be in the differential diagnosis for newborns with a known thrombus and unusual or unexpected pulmonary symptoms when alternative diagnoses have been eliminated.

Unique to newborns, thrombocytopenia not infrequently occurs as a manifestation of thrombosis. For reasons that are unclear, although thrombocytopenia in and of itself is not a manifestation of DVT in older children, newborns with thrombosis may have thrombocytopenia solely as a clinical manifestation of the clot itself, and this in fact may be the presentation of thrombosis. Thus, in a newborn with unexplained thrombocytopenia, thrombosis must be considered in the differential diagnosis.

Diagnosis

There are two important points of discussion when it comes to the diagnosis of DVT in newborns: the identification of the location and extent of the thrombus, and the underlying conditions and risk factors that may have caused the thrombus to occur in the first place.

Once a thrombus is suspected, the appropriate diagnostic imaging study should be performed to confirm the clinical suspicion (Veldman et al, 2008). The most common imaging approach for venous thrombosis is Doppler ultrasonography. This method assesses the veins by direct visualization for thrombosis, detection of flow via the Doppler effect, and compressibility. Other imaging modalities include computed tomography (CT), CT venography, magnetic resonance imaging (MRI) or MR venography, and echocardiography. It is important to note that none of the listed approaches has been formally studied in newborns, and it is difficult to determine which methods would be most suitable for any given situation. The "gold standard" for diagnosing venous thrombosis is venography. However, despite its high sensitivity and specificity, it is not frequently used because of the need to place a peripheral intravenous line, the availability and relative ease of Doppler ultrasonography, and the reluctance of many radiologists to perform the test. Venography is nonetheless the most reliable diagnostic method. In clinical practice, the general approach is to order the simplest and least invasive imaging study first (Doppler ultrasonography), followed by the more logistically complicated and/or expensive studies (MRI, CT, venography) if the first approach is not adequate.

Although Doppler ultrasonography is sensitive for the lower extremities, it has very poor sensitivity (approximately 30% in a study of young children) for veins proximal to the distal subclavian vein because of the presence of the clavicle overlying the subclavian vein, the inability to compress the veins, and the depth of the veins in the chest (Male et al, 2003). Of note, venography is not sensitive for thrombosis in the internal jugular veins, because the injected dye will not flow in a retrograde fashion. Thus both ultrasonography and venography (or an alternative) are required for a complete assessment of the upper venous system. Cerebral sinus thrombosis is most effectively diagnosed via MRI/MRV of the brain, and although a CT scan may reveal the abnormality, a normal study does not exclude the diagnosis. Pulmonary embolism when suspected is best diagnosed via CT venography.

The second aspect of the diagnostic evaluation in neonates with thrombosis is the identification of specific risk factors and underlying conditions that led to the DVT (Kenet and Nowak-Gottl, 2006; Veldman et al, 2008). This has important implications regarding management of the patient, including the decision to anticoagulate and, if so, with which agent, at what intensity, and for what duration, as well as decisions regarding vascular access, such as removing a central venous catheter. In addition, the diagnosis of a thrombotic event may lead to an explanation of clinical findings such as thrombocytopenia or cardiac dysfunction that will have implications for the management of these disorders. Nearly all newborns with DVT have multiple risk factors leading to the development of the thrombotic event.

The risk factors associated with pediatric thrombosis can be separated into two main groups: inherited and acquired (see Table 76-7). For each individual patient, it is important to document all of the potential risk factors that may have been associated with the induction of the thrombotic event. If acquired risk factors are identified that can be eliminated or ameliorated, this may be helpful in the management of the thrombosis (see Treatment section, later). For example, a dehydrated infant with cerebral sinus thrombosis would obviously benefit from rehydration. The decision to treat or remove other risk factors is less straightforward. For example, although it may be beneficial from the standpoint of the clot to remove a catheter that led to a thrombosis, when evaluating the patient's situation as a whole, it may be prudent to leave the catheter in place and treat with anticoagulation. Removing a central venous catheter from one location where a clot developed only to place a new catheter in a new location where another clot could develop may not be the best approach. If, on the other hand, the patient can be managed without a central venous catheter, it then would be appropriate to remove this catheter.

Genetic risk factors obviously cannot be modified, and whether or not testing for these risk factors should be done is controversial (Kenet and Nowak-Gottl, 2006). On the one hand, identification of a genetic risk factor may provide insight into why a thrombotic event occurred. On the other hand, in a neonate with multiple risk factors (especially those with a central venous catheter) what, if any, role the genetic risk factor played cannot be ascertained.

TABLE 76-8 Laboratory Evaluation for Thrombophilia

Inherited Causes	Acquired Causes
Protein C activity	Antiphospholipid antibodies (anticardiolopin antibodies, anti-β2 glycoprotein I antibodies, lupus anticoagulant)
Protein C antigen	
Protein S activity	
Protein S activity, free	
Protein S activity, total	
Antithrombin activity	
Antithrombin antigen	
Factor V Leiden (DNA assay)	
Prothrombin mutation (DNA assay)	
Homocysteine level	
Lipoprotein(a) level	

A second argument in favor of testing is that on occasion, identifying a genetic abnormality may lead to changes in the treatment approach. For example, an elevated homocysteine level may lead to identification of an inherited disorder of metabolism, which would lead to therapy aimed at lowering the homocysteine level or, if that were not possible, anticoagulation therapy, which would be continued perhaps indefinitely. An additional argument against testing is that in approximately 10% of whites (less so in nonwhites), a genetic defect will be identified, and yet the attribution of the genetic defect (e.g., factor V Leiden) to the causation of the thrombosis in a neonate with multiple acquired risk factors is not clear. Furthermore, even if a genetic defect is identified, how (if at all) it should change the management approach is not clear because of a lack of evidence-based studies in children in general and in neonates in particular. Thus, it is important to consider the pros and cons of performing a thrombophilia laboratory evaluation before embarking on such an evaluation, and in particular, the physician ordering such tests should have a clear idea of how the results would affect ongoing management. Under some rare circumstances, testing is warranted. These circumstances would include those in which a neonate with purpura fulminans may have severe protein C deficiency (or rarely severe protein S deficiency) and a newborn has an idiopathic DVT, which, as mentioned is a very rare event. It is suggested that a pediatric hematologist with expertise in coagulation disorders in neonates be consulted before testing in order to be sure that testing is necessary in the first place, and second, that the appropriate tests are in fact ordered.

Table 76-8 provides a general overview of the tests.

The extent of the laboratory investigation for thrombophilia is controversial. In general, the following first-line tests should be included: genetic analysis for factor V Leiden and the prothrombin G20210A mutation; assays for proteins C and S and antithrombin; measurement of homocysteine and lipoprotein(a) level; and evaluation for antiphospholipid antibodies, including lupus anticoagulant, anti-cardiolipin, and anti-β2 glycoprotein I antibodies. Additional conditions and the tests to assess them that are not usually part of the first line of tests include elevated FVIII (FVIII activity), dysfibrinogenemia (thrombin time, reptilase time, functional fibrinogen), and disorders of fibrinolysis (euglobulin clot lysis time). Finally, it should be noted that children (particularly infants) have different normal ranges for many of the mentioned tests compared to adults, yet most laboratories will only report a reference range for adults; thus at first glance it appears that all neonates are deficient in antithrombin, protein C, and protein S (Andrew, 1995, 1997). Furthermore, some tests performed during the acute phase may be abnormal simply as a result of consumption of proteins. Thus, pediatric laboratory results should be interpreted with these caveats.

The most common genetic condition associated with thrombosis is the factor V Leiden mutation. It occurs in approximately 5% of whites or those of mixed race with white ancestry. The diagnosis is based on identifying the mutation in a simple DNA-based assay. This mutation does not alter the procoagulant function of factor V but results in resistance to deactivation such that the molecule remains in the active state. Therefore, it is referred to as a "gain-of-function" mutation. The relative risk of venous thrombosis in heterozygotes is approximately 8, whereas the relative risk in the homozygous state is approximately 80.

The second most common mutation associated with thrombosis is the prothrombin G20210 mutation (generally referred to as the prothrombin mutation). It also occurs solely in whites and affects about 2% to 3% of individuals in this group. The diagnosis is based on identifying the mutation in a simple DNA-based assay. The relative risk of DVT in adults is approximately 2 to 3. Unlike factor V Leiden, the prothrombin mutation has been associated with arterial thrombosis in adults and children, with a predilection for venous and arterial thrombosis in the central nervous system.

The next section describes three related disorders that are referred to as the classical thrombophilic defects. As described in the first section, the coagulation system is composed of procoagulants as well as natural inhibitors. These natural inhibitors are proteins C and S and antithrombin (previously referred to as antithrombin III). Protein C is activated by thrombin via a cell surface receptor known as thrombomodulin and, along with its cofactor, protein S, deactivates factors VIII and V (the main catalysts required for thrombin generation). Deficiencies of proteins C or S result in an inability to deactivate the coagulation system, thus resulting in hypercoagulability (Knoebl, 2008; ten Kate and van der Meer, 2008). Heterozygous protein C deficiency occurs in about 1 in 300 individuals, and heterozygous protein S deficiency occurs in about 1 in 5000 individuals (Petaja and Manco-Johnson, 2003; ten Kate and van der Meer, 2008). In general, these conditions are associated with venous thrombosis, and the first thrombotic event occurs between the 2nd and 4th decade of life. The relative risk for a first venous thrombosis in children is around 8 for protein C deficiency and 6 for protein S deficiency (Young et al, 2008). Conversely, homozygous individuals will present in the immediate newborn period with purpura fulminans and often have central nervous system thrombosis, including thrombosis in the retinal vessels resulting in retinal detachment and resultant loss of vision (Petaja and Manco-Johnson, 2003). Although newborns presenting with purpura fulminans will usually have other conditions such as sepsis and DIC, any neonate presenting with purpura fulminans should be evaluated for deficiencies of protein C and S as rapidly as possible, because treatment could be life-saving and will

prevent complications such as brain injury, vision loss, and skin necrosis. Homozygous protein C deficiency occurs in about 1 in 500,000 individuals, whereas homozygous protein S deficiency occurs in about 1 in 1 million individuals (Petaja and Manco-Johnson, 2003). The diagnosis is based on laboratory assays that can assess the presence and activity of these proteins. The presence of the proteins is measured by immunologically based assays called protein C and S antigen. The function of the proteins can be assayed by tests referred to as either protein C (or S) activity or function. Ultimately, it is the protein function that is the most important to measure; thus, if only one test is ordered it should be the functional assay. It is critical to understand that neonates are physiologically deficient in both proteins C and S, and their levels in the first few days of life are normally about 25% of adult norms. Few laboratories have normative values for neonates; thus, in interpreting the results, the normal ranges provided by the laboratory should be ignored. If the laboratory does not provide normative values for neonates, then one should refer to published reference values from previous studies. For the rare infant with purpura fulminans, assessing proteins C and S is critical, because the homozygous state can be identified by demonstrating unmeasurable levels of the proteins.

Congenital antithrombin deficiency occurs less commonly than deficiencies of proteins C and S, with an incidence of about 1 in 500 to 1 in 5000 (Patnaik and Moll, 2008). The relative risk for a first venous thrombosis in children is approximately 9 (Young et al, 2008). Antithrombin downregulates the thrombotic process by directly binding to and inactivating thrombin, and a deficiency of antithrombin results in hypercoagulability due to the excess thrombin. Although antithrombin deficiency most often is associated with venous thrombosis, it can also result in arterial thrombosis. Homozygous antithrombin deficiency has never been identified and is known to be lethal in animal knockout models; thus it is felt to be incompatible with life. Heterozygous deficiency usually manifests in later childhood or young adulthood and not in the neonatal period. The diagnosis is based on measuring antithrombin levels as described earlier for proteins C and S; as stated previously, measuring the function of antithrombin is the most important laboratory assay, and as with proteins C and S, antithrombin levels are physiologically low in newborns. Unlike protein C or S deficiency, acquired isolated antithrombin deficiency is not uncommon and most often occurs in patients with protein-losing syndromes such as protein-losing enteropathy, nephrosis, or chronic chylothorax. In addition, patients on extracorporeal circulation often have consumption of antithrombin. In patients with such disorders, antithrombin levels should be monitored.

Homocysteine is a naturally occurring amino acid that in high levels leads to damage to the endothelium, resulting in arterial and venous thrombosis (Cattaneo, 1999). A number of genetic and acquired conditions can result in hyperhomocysteinemia. There are a number of inborn errors of metabolism that result in elevated homocysteine levels and occasionally extremely elevated levels as in homocystinuria, a mutation in cystathione β-synthase. Other inborn errors of metabolism in the same metabolic pathway can result in mild to moderate elevations in homocysteine (for details, see Chapter 22). Importantly, a thrombotic event including stroke may be the presenting feature for these inborn errors of metabolism, and measurement of homocysteine can thus lead to the diagnosis.

Lipoprotein(a) is one of the many lipoproteins such as cholesterol present naturally in the plasma. Its function is unknown, but its structure, which is similar to that of plasminogen, results in competition with binding sites on tissue plasminogen activator, thereby inhibiting fibrinolysis. This is felt to be the mechanism by which elevated lipoprotein(a) results in thrombosis. There have been a number of epidemiologic studies of lipoprotein(a) in children, although not specifically neonates, and the results demonstrate an association with both venous thrombosis and stroke (Young et al, 2008).

An important acquired risk factor for thrombosis in neonates is passive transfer of maternal antiphospholipid antibodies (Boffa and Lachassinne, 2007). This may occur from a mother known to have this condition or from an asymptomatic mother. There are reports of venous thrombosis occurring in newborns in association with the presence of antiphospholipid antibodies, which are presumed to have been transferred from the mother. De novo antiphospholipid antibodies have also been reported; however, the incidence of this condition is unknown.

Treatment

It should be noted that there is a near-complete lack of evidence-based medicine when it comes to treatment-related decisions in the management of neonatal thrombosis. This must be tempered with the knowledge that despite the lack of information, patients must still be treated. There are published treatment guidelines for the management of pediatric (including neonatal) thrombosis, but these are based largely on the opinions of a small group of experts, and most recommendations are based on the lowest level of evidence (i.e., case reports, case series, and small cohort studies) (Monagle et al, 2008). The following discussion should be interpreted in light of this caution, and the most important recommendation is to solicit the consultation of a pediatric hematologist with a specific interest in pediatric thrombosis.

There are two principles that need to be taken into consideration in managing DVT in neonates. First is the need to prevent an embolic event. This is of particular importance in neonates because a venous thrombus will likely embolize to the central nervous system because of the patent foramen ovale. Second, treatment of the thrombus itself is important in order to prevent the postthrombotic syndrome (PTS). PTS is caused by venous insufficiency secondary to valvular damage caused by the thrombus and results in an inability to drain the affected area. This results in swelling and pain in the area distal to the damaged vein. PTS is largely confined to the extremities and mostly to the lower extremities, but similar events can occur elsewhere. For example, ascites resulting from a portal vein thrombosis is essentially due to the same physiologic problem. Prevention of PTS is the most important reason to treat DVT. Although embolic events could be catastrophic, they are uncommon. PTS has been demonstrated in 10% to 60% of children with DVT (the widely varying outcomes result from the lack of a single definition

or scoring system for PTS). Although PTS will rarely manifest in the neonatal period, early treatment of DVT in the neonatal unit is an important factor in prevention.

After the diagnosis of DVT is made, treatment should begin immediately, because delays could result in treatment failure. Unless there is a contraindication to anticoagulation, therapy should not be withheld. Once a thrombus is identified, an assessment for acquired risk factors should be performed in order to determine whether any of these factors can be eliminated, such as removing a central line that is no longer needed, or treating dehydration, infections, or an elevated homocysteine level. Regardless of whether such risk factors can be removed or ameliorated, that treatment step is not a substitute for anticoagulation.

With respect to medical therapy, anticoagulation is always necessary. If there is a temporary contraindication to anticoagulation (planned invasive procedure in the next 1 to 2 days), then therapy can be withheld until the contraindication no longer exists. Currently, the anticoagulants that can be used in newborns are limited to unfractionated heparin (hereafter referred to as heparin), low-molecular-weight heparin (LMWH), and warfarin. All three have significant limitations that have been reviewed elsewhere (Young, 2004), and a detailed discussion is beyond the scope of this chapter. Suffice it to say that heparin has a rapid onset of action (after a bolus) and has a short half-life such that it is given via continuous infusion, whereas LMWH (mostly enoxaparin) has somewhat longer onset of action (several hours) and a longer half-life such that it is dosed twice daily and is administered via subcutaneous injection. Intravenous LMWH should not be administered outside the context of a clinical trial. Warfarin is the only orally available anticoagulant; however, its numerous drug and food interactions as well as the fact that it cannot be compounded into a liquid reduce its utility in neonates. Furthermore, achieving a therapeutic international normalized ratio (INR) in infants occurs only about 50% of the time, such that the safety of this agent in neonates from both the bleeding perspective (increased INRs) or thrombotic standpoint (decreased INRs) is questionable. It is best to avoid warfarin in the newborn period unless there is a clear reason why it would be a better option than LWMH (artificial heart valves, for example). Although there are published therapeutic ranges for both heparin (PTT level) and LMWH (anti-Xa level), the evidence that these specific intensities are related to a clinical outcome is not available. There is also no available evidence regarding the duration of therapy, although the general recommendation is 3 to 6 months based on extrapolation from adult data. Again, it is recommended that decisions regarding choice of anticoagulant and intensity and duration of therapy be discussed in consultation with a pediatric hematologist with specific expertise in pediatric thrombosis. Furthermore, because many newborns with DVT are discharged before reaching these time points, such consultation would help facilitate outpatient follow-up. Of note, other than rare situations, thrombolysis is not recommended for the management of DVT in newborns because of the increased risk for ICH, particularly in preterm neonates. In selected and severe situations such as superior vena cava syndrome and pulmonary embolism, thrombolysis could be considered, but such therapy should only be performed under the direct supervision of a hematologist (or other physician) with expertise on its use and only after a discussion with the parents regarding the risks and benefits of this approach.

With rare exceptions, the results of the thrombophilia evaluation (if it is performed) will not affect the approach to management. First, therapy will need to be initiated before results are generally available, and second, the presence of most of the thrombophilias discussed earlier will not influence the choice, intensity, or duration of anticoagulation. Although two recent studies suggested that there is an increased risk for thrombosis recurrence with deficiencies of proteins C and S and antithrombin and with the prothrombin mutation, it is not clear how this evidence should be translated to treatment (Young et al, 2008). In some circumstances, the results of the thrombophilia evaluation will affect therapy. The most obvious example is that of homozygous protein C or protein S deficiency, in which replacement therapy is mandatory (Thornburg and Pipe, 2006). Historically, replacement therapy was accomplished via frequent infusions of fresh frozen plasma; however, the availability of a protein C concentrate (Ceprotin, Baxter, Westlake Village, Calif.) currently makes protein C replacement significantly simpler. Unfortunately, protein S replacement still relies on frequent plasma infusions. For patients with homozygous protein C deficiency, replacement therapy is required lifelong with infusions administered three times per week. For those with homozygous protein S deficiency, there is no standard approach because there are so few cases reported, and prophylactic replacement with fresh frozen plasma, although feasible, is logistically difficult. Once the initial purpura fulminans is treated, ongoing therapy with anticoagulation can be considered. Replacement therapy is not indicated for heterozygotes. In addition to the foregoing, patients with low antithrombin levels may have heparin (and LMWH) resistance because these medications require antithrombin to exert their effects. Antithrombin replacement can be achieved via both a plasma-derived (Thrombate III, Talecris, Research Triangle Park, NC) and more recently a recombinant product (Atryn, GTC Biotherapeutics, Framingham, Mass.). Although a low antithrombin level in the newborn period may not be diagnostic of a genetic deficiency, the low levels nevertheless could result in heparin resistance such that replacement therapy may be indicated. Last, identification of elevated homocysteine levels, whether moderate or severe, will result in therapy aimed at lowering the levels via vitamin B therapy. In summary, treatment of DVT relies on removing or ameliorating acquired risk factors, anticoagulation, and management of a thrombophilic defect in the rare instances when these are found and can be treated.

Outcomes

There is little to no reported research on the outcome of neonates with DVT. Although there is little doubt that PTS occurs, its incidence and severity as a result of neonatal DVT are unknown. Even less is known regarding the outcomes of pulmonary embolism, cerebral sinus thrombosis, portal or renal vein thrombosis, and superior vena cava syndrome. Outcome after neonatal venous thromboembolism is one of the many needed areas for future pediatric thrombosis research.

STROKE

Epidemiology

The term *stroke* is quite ill defined in pediatrics, necessitating a few comments. For the purposes of this chapter, stroke is defined as ischemic brain injury resulting from occlusion of the arterial blood supply to or within the brain. In some publications (Kirton and de Veber, 2009), cerebral sinus thrombosis has been included in the stroke definition; however, although brain infarction can occur in this condition, cerebral sinus thrombosis is more appropriately included with DVT because it shares all the same features as other DVT and is treated similarly. In addition to strokes resulting from vascular occlusion, there are a number of metabolic disorders that can result in a clinical scenario similar to stroke and that result from a lack of required nutrients, toxic effects or other mechanisms; however, because these conditions are metabolic in nature, they are covered in other chapters.

The neonatal period is one of the most common times for a pediatric patient to present with stroke. It is estimated that from 18 to 43 per 100,000 neonates will have acute ischemic stroke (Bernard and Goldenberg, 2008; Kirton and de Veber, 2009). A number of risk factors have been identified that are associated with stroke in the newborn period. These include placental disorders (especially those associated with placental thrombosis), perinatal asphyxia, congenital heart disease, anomalous vasculature, vascular malformations, and perinatal infections including TORCH infections (Bernard and Goldenberg, 2008). Other risk factors include some thrombophilias such as homozygous protein C deficiency, elevated lipoprotein(a), and hyperhomocysteinemia (Bernard and Goldenberg, 2008). Despite detailed investigations, in many instances no clear cause for stroke is identified. There is a notion that many of these events occur as a result of a perinatal embolic event in which tissue such as amniotic fluid or placental thrombi enter the neonatal venous system, resulting in a paradoxic embolus. Unfortunately, it is currently not possible to prove this by any diagnostic test.

Clinical Presentation

The clinical presentation of neonatal stroke ranges from the dramatic (seizures) to the subtle (poor feeding) to an asymptomatic incidental imaging finding. Approximately half of patients with acute ischemic stroke present with seizures within hours up to a day or two after delivery. Other presenting manifestations include nonspecific respiratory abnormalities such as apnea or grunting and occasionally feeding difficulties. Focal neurologic signs are rare, although occasionally seizures will be focal, at least initially, before becoming generalized. On occasion, central nervous system imaging is obtained for reasons unrelated to the foregoing symptoms, and an infarct is found incidentally with no symptoms. Not infrequently, patients may present months later with what is presumed to be neonatal stroke when they have focal neurologic signs or even seizures without a precipitating event, and imaging demonstrates an old infarct. Such infants will obviously not present in the newborn period.

Diagnosis

The diagnosis of acute ischemic stroke requires imaging of the brain with either CT or MRI. Although CT imaging may be easier to obtain, MRI is more sensitive, and its higher resolution as well as the ability to obtain a variety of image types (T1, T2, and diffusion weighting) allows for better characterization of the lesion. Occasionally, a stroke may be suspected based on head ultrasound; however, in such cases obtaining an MRI is recommended. After identification of the lesion by diagnostic imaging, a full and detailed evaluation for the determination of risk factors is warranted (as discussed with DVT). It is critical to identify, if possible, the risk factors that led to the stroke, because this will dictate the treatment and assist in formulating a prognosis. For example, the presence of a stroke may unmask a previously undiagnosed heart lesion, a vascular malformation, or a severe thrombophilia. In many instances, no risk factors will be found, making decisions regarding treatment and discussion of prognosis vis-à-vis a second stroke difficult. For situations in which risk factors are identified, management of such conditions is an important step toward preventing a second event.

One approach to an evaluation for risk factors is first to obtain a detailed history from the parents regarding the pregnancy and family history of thrombotic events. Second is to rule out important causes for stroke such as congenital heart disease and vascular malformations. This evaluation would include an echocardiogram and possibly a cerebral angiogram or cardiac catheterization. If a venous catheter is present either in the umbilical vein or elsewhere, evaluation for DVT is required, because the stroke may have resulted from a paradoxical venous embolus. The likelihood of a venous thrombus in the absence of a catheter is so remote that such an evaluation is unnecessary unless a venous catheter is present or there is a suspicion for a venous thrombosis based on clinical grounds.

From the standpoint of a laboratory evaluation, obtaining a thrombophilia evaluation as described previously remains controversial, especially if other risk factors are identified. In the absence of any identifiable risk factors, a thrombophilia evaluation would be a reasonable course of action. The question is which assays to perform and, importantly, when to perform them, either in the neonatal period or at the age of 6 months or beyond. The advantage of obtaining an evaluation in the newborn period is the possibility of identifying an abnormality that requires treatment such as severe protein C or S deficiency or hyperhomocysteinemia. The disadvantage is that because levels of proteins C and S and antithrombin are physiologically low in the newborn period, it will be necessary to repeat these tests after 6 months of age in order to be sure that normal adult levels have been achieved. Thus, the most prudent approach if one elects to perform a thrombophilia evaluation is to at least obtain protein C and S activity levels, an antithrombin level, and a homocysteine level initially, and to perform the rest of the evaluation when repeating the protein C and S and antithrombin levels at 6 months of age. In addition to the genetic defects described earlier, it is important to evaluate for the antiphospholipid syndrome, because it is possible for the antibodies to be transplacentally transferred from an asymptomatic mother.

Abnormal results in the newborn should prompt an evaluation of the mother.

Other laboratory tests that could be considered are an erythrocyte sedimentation rate, C-reactive protein, and TORCH screen if indicated. Last, if at all possible, pathologic examination of the placenta may reveal the presence of thrombi, which could indicate that the stroke was the result of embolization from placental thrombi.

Treatment

The management of acute ischemic stroke depends largely on the etiology if it can be identified. Obviously, a heart lesion resulting in embolization of thrombi requires rapid correction, as do vascular lesions resulting in ischemia. Severe thrombophilia such as hyperhomocysteinemia or protein C and S deficiency requires specific therapies as previously described. In the more typical situation, however, either no risk factors or more subtle nonspecific risk factors such as infection are present. In such situations, management is much less straightforward. There are no clinical trials that have evaluated anticoagulation or antiplatelet therapy in a prospective or controlled fashion. Although treatment guidelines have been published, these are based on very low-level evidence, as is the case for DVT (Monagle et al, 2008). Although anticoagulation therapy is clearly required for management of DVT and often for acute ischemic stroke in older children, the appropriateness of such therapy for neonates is questionable. If the stroke was felt to be the result of a perinatal embolic event, then the likelihood of a second stroke is essentially zero because, clearly, the risk factor (the birth process and fetal circulation) will never recur. Thus, secondary prevention with anticoagulation or antiplatelet therapy is not required. For those neonates with clear ongoing risk factors such as congenital heart disease or thrombophilia, anticoagulation/antiplatelet therapy should be considered. Unfortunately, data do not exist to support decisions such as which agent to use, at what intensity, and for what duration. For lesions that are clearly arterial, antiplatelet therapy with aspirin is the most appropriate approach, whereas for venous emboli, anticoagulation is more appropriate. Combining these two therapies is another approach although the risk for bleeding certainly rises in this situation. Antiplatelet therapy with aspirin appears to be safe; non–weight-based dosing at 40 mg will result in a significant antiplatelet effect. Anticoagulation therapy as for DVT can be used (see DVT section for details). It is suggested that consultation with a pediatric hematologist and/or neurologist with specific expertise in childhood stroke be sought to assist with therapeutic decisions and for ongoing follow-up after discharge.

Outcomes

Neonates who suffer an overt symptomatic stroke have quite variable and rather unpredictable outcomes. Even those in whom a large area of infarction occurs may have an excellent neurologic outcome, demonstrating the known plasticity of the newborn brain. On average, about 50% to 75% of patients with acute ischemic stroke will have neurologic sequelae, most commonly hemiplegia and epilepsy (Kirton and de Veber, 2009). Other defects such as vision loss, language deficits, and general cognitive impairment may also be noted. It is important to note that the outcomes do not necessarily correlate with the severity of the lesion, making it hard to predict the outcome in any individual patient. It is suggested that the prognosis be discussed in general and broad terms and that parents be made aware that although neurologic sequelae are common, they are not universal, and that their child should have careful monitoring of development such that specific interventions (physical, occupational and speech therapy, for example) begin as early as possible.

Fortunately, recurrence is rare in neonatal stroke, except for patients with the specific disorders discussed earlier, and in such cases preventive therapy with antiplatelet or anticoagulant medications presumably reduces the risk of recurrence, although there are no data to support this.

ARTERIAL THROMBOSIS (NOT RELATED TO THE CENTRAL NERVOUS SYSTEM)

Epidemiology

Peripheral and central arterial thrombosis is not common, although the incidence is not known. It occurs almost exclusively in association with either arterial catheterization or an inadvertent arterial injury during venous catheterization (Aslam et al, 2008). Arterial thrombosis can occur in any vessel that is catheterized; however, because the most common sites for catheterization are the femoral arteries and aorta (umbilical catheters), these would be the most common sites affected. Patients at highest risk are those with congenital heart disease who may undergo multiple catheterizations of the femoral artery, and premature patients in whom umbilical artery catheters are commonly used. On rare occasion, patients my develop thrombosis of the arteries feeding a visceral organ, with renal artery thrombosis being the most common. Even in this setting, it may have resulted from the presence of an umbilical artery catheter.

Clinical Presentation

Patients with femoral or subclavian/brachial artery thrombosis present with signs of decreased perfusion and ischemia distal to the occlusion. This may include color changes such as pallor or cyanosis, decreased pulses, and eventually tissue necrosis. The signs and symptoms are generally quite obvious (Figure 76-3) and may develop suddenly or may occur incrementally, that is, first loss of pulses followed by color changes followed by necrosis. The presentation of thrombosis in the aorta is usually an incidental finding determined by diagnostic imaging of the abdomen or chest for other reasons. When symptoms are present, they may be subtle, such as differential blood pressures between the upper and lower extremities. Rarely, there may be signs of decreased perfusion distal to the occlusion with symptoms similar to the foregoing. Renal artery thrombosis manifests with hypertension due to disruption of the renin-angiotensin-aldosterone system. Thrombosis of arteries to other organs is extremely rare and will manifests with organ dysfunction.

FIGURE 76-3 *(See also Color Plate 34.)* Arterial thrombosis with skin necrosis.

FIGURE 76-4 Aortic thrombus diagnosed by magnetic resonance imaging.

Diagnosis

The diagnosis is based on demonstrating arterial occlusion by diagnostic imaging. The most commonly used imaging modality is Doppler ultrasonography, which is sensitive for peripheral arteries as well as the femoral and subclavian arteries and the abdominal aorta. The proximal portion of the thoracic aorta can be visualized by echocardiography. Large visceral arteries can also be assessed by ultrasonography. When ultrasonography is not diagnostic, CT/CT angiography or MRI/MR angiography can often demonstrate the thrombus (Figure 76-4). Occasionally, treatment involves catheter-directed thrombolysis (see later discussion), and in such instances, an angiogram is performed before the procedure, which can further define the occlusive lesion.

As in the previous sections, an assessment of the risk factors that led to the thrombosis is crucial only in this instance, the cause is usually obvious because, again, catheterization is nearly always the cause of arterial thrombosis

FIGURE 76-5 Arterial thrombosis of digital artery before treatment with tPA. See Figure 76-6.

in neonates. With this in mind, it is difficult to justify a thrombophilia evaluation in this group of patients, with the exception being the rare patient in whom no cause for the thrombosis can be identified.

Treatment

The first and most important aspect of therapy is to remove the arterial catheter if it is still in place. This is in contradistinction to the recommendation for venous catheters and DVT. Second, determining the degree of obstruction and ischemia is crucial, because this will dictate the aggressiveness of the therapeutic approach. For patients in whom perfusion is relatively maintained, simply removing the catheter may be sufficient. For those with more significant perfusion deficits, such as absent pulses and signs of diminished perfusion (pallor, prolonged capillary refill), anticoagulation therapy with unfractionated heparin is recommended. For those with a complete occlusion or with significant ischemia or signs of necrosis, thrombolysis should be attempted so long as there are no contraindications (Raffini, 2009). This can be achieved via systemic infusion or local infusion. The advantages of a systemic infusion are that it does not require an interventional radiologist or other specialist, can be initiated almost immediately, and is often very effective (Figures 76-5 and 76-6). If local thrombolysis is feasible, then this has the advantage of using lower doses and directing the thrombolysis at the thrombus. This results in improved safety due to the lower doses used as well as the potential for more rapid resolution. For systemic thrombolysis with alteplase (tPA)—the only currently available agent studied in neonates—the recommended dose is 0.1 to 0.5 mg/kg/hour with no bolus. Systemic tPA should be administered only under the supervision of a physician (often a hematologist) experienced with the use of this agent, because it carries with it a significant risk for bleeding. This risk is significantly increased in premature infants. In general, tPA is contraindicated in patients who have had recent (approximately 7 days) surgery or other invasive procedures. Some guidelines recommend administering low-dose heparin (10 units/kg/hour) in conjunction with tPA,

FIGURE 76-6 Arterial thrombosis of digital artery after treatment with tPA.

although the utility of this approach is not clear. Full-dose anticoagulation should not be given in conjunction with tPA.

Once the thrombus resolves and blood flow is restored, anticoagulation is recommended for at least several weeks until the endothelium of the vessel heals. Again, there are no studies supporting such an approach, but it is reasonable from a physiologic point of view. How long to treat depends on the extent and severity of the thrombus, and this decision should be made in conjunction with a pediatric hematologist familiar with neonatal thrombosis. The management of asymptomatic thrombi is unclear. On the one hand, blood flow is probably not normal in that segment, suggesting that the thrombus may worsen; however, because these are incidental findings, it is possible that the thrombus may resolve without any treatment. What is clear, though, is that aggressive therapy is not warranted. Clearly, more research in the management of neonatal arterial (and venous) thrombosis is needed.

Outcomes

The outcome for peripheral arterial thrombosis is fairly straightforward. If tissue perfusion is restored before permanent injury, then the outcome is excellent in general; however, leg length discrepancy can occur if there is a significant enough residual decrease in blood flow to the affected leg. Poor outcomes can range from loss of skin requiring plastic surgery to amputation of digits and even limbs. The long-term outcome of asymptomatic aortic thrombi is unknown. The outcome of visceral artery thrombosis is dependent on survival of the organ. Unilateral renal atrophy due to renal artery thrombosis can result in severe hypertension, which can be difficult to manage.

CHAPTER 77

Erythrocyte Disorders in Infancy

Dana C. Matthews and Bertil Glader

NORMAL ERYTHROCYTE PHYSIOLOGY IN THE FETUS AND NEWBORN

FETAL ERYTHROPOIESIS

Fetal erythropoiesis occurs sequentially during embryonic development in three different sites: yolk sac, liver, and bone marrow (Brugnara and Platt, 2009). The growth factors and cytokines that regulate embryonic hematopoiesis are the subject of active study (Orkin and Zon, 2008), and animal work suggests that they are different from those that regulate proliferation and differentiation of stem cells in later life (Zon, 1995). Yolk sac formation of red blood cells (RBCs) is maximal between 2 and 10 weeks' gestation. Myeloid, or bone marrow, production of RBCs begins around week 18, and by the 30th week of fetal life, bone marrow is the major erythropoietic organ. At birth, almost all RBCs are produced in the bone marrow, although a low level of hepatic erythropoiesis persists through the first few days of life. Sites of fetal erythropoiesis occasionally are reactivated in older patients with hematologic disorders such as myelofibrosis, aplastic anemia, and severe hemolytic anemia.

RBC production in extrauterine life is controlled in part by erythropoietin, a humoral erythropoietic-stimulating factor (ESF) produced by the kidney. The role of erythropoietin in the developing fetus has not been completely defined, but ESF is not thought to influence yolk sac erythropoiesis. It may have a role in hepatic erythropoiesis and may partially regulate RBC production by the bone marrow (Finne and Halvorsen, 1972). ESF is detected in fetal blood and amniotic fluid during the last trimester of pregnancy. The concentration of this hormone increases directly with the period of gestation, and thus, erythropoietin levels in term newborns are significantly higher than in premature infants. This difference may reflect some degree of fetal hypoxia during late intrauterine life. Increased ESF titers also are seen in placental dysfunction, fetal anemia, and maternal hypoxia (Finne, 1966). Fetal RBC formation is not influenced by maternal erythropoietin, because transfusion-induced maternal polycythemia (decreased maternal ESF levels) has no effect on fetal erythropoiesis (Jacobson et al, 1959). Maternal nutritional status also is not a significant factor in the regulation of fetal erythropoiesis, because iron, folate, and vitamin B_{12} are trapped by the fetus irrespective of maternal stores. Most studies have demonstrated that women with severe iron deficiency bear children with normal total body hemoglobin content (Lanzkowsky, 1961). However, a recent study of the correlation between severe maternal iron deficiency anemia and lower cord blood hemoglobin and ferritin levels in cord blood recently reported (Kumar et al, 2008) suggests that placental iron transport mechanisms may not always be adequate in severe maternal iron deficiency.

Hemoglobin, hematocrit, and RBC count increase throughout fetal life (Table 77-1). Extremely large RBCs (mean corpuscular volume [MCV] of 180 fL) with an increased hemoglobin content (mean corpuscular hemoglobin [MCH] of 60 pg/cell) are produced early in fetal life. The size and hemoglobin content of these cells decrease throughout gestation, but the mean corpuscular hemoglobin concentration (MCHC) does not change significantly. Even at birth, the MCV and MCH are greater than those in older children and adults. Many nucleated RBCs and reticulocytes are present early in gestation, and the percentage of these cells also decreases as the fetus ages.

Hemoglobin production increases markedly during the last trimester of pregnancy. The actual hemoglobin concentration increases, but, more important, body weight, blood volume, and total body hemoglobin triple during this period. Fetal iron accumulation parallels the increase in total body hemoglobin content. The neonatal iron endowment at birth, therefore, is directly related to total body hemoglobin content and length of gestation. Term infants have more iron than premature infants.

RBC PHYSIOLOGY AT BIRTH

In utero, the Po_2 in blood delivered to the tissues is only one third to one fourth the value in adults. This relative hypoxia may be responsible for the increased content of erythropoietin and signs of active erythropoiesis (nucleated RBCs, increased reticulocytes) seen in newborns at birth. When lungs become the source of oxygen, hemoglobin-oxygen saturation increases to 95% and erythropoiesis decreases. Within 72 hours, erythropoietin is undetectable, nucleated RBCs disappear, and by 7 days, reticulocytes decrease to less than 1%.

The concentration of hemoglobin during the first few hours of life increases to values greater than those in cord blood. This is both a relative increase caused by a reduction in plasma volume (Gairdner et al, 1958) and an absolute increase caused by placental blood transfusion (Usher et al, 1963). The umbilical vein remains patent long after umbilical arteries have constricted, and thus transfusion of placental blood occurs when newborns are placed at a level below the placenta. The placenta contains approximately 100 mL of fetal blood (30% of the infant's blood volume). Approximately 25% of placental blood enters the newborn within 15 seconds of birth, and by 1 minute, 50% is transfused. The time of cord clamping is thus a direct determinant of neonatal blood volume. The blood volume in term infants (mean of 85 mL/kg) varies considerably (50 to 100 mL/kg) because of different degrees of placental transfusion (Usher et al, 1963). These differences are readily apparent when the effects of early versus delayed cord clamping are compared at 72 hours of age: 82.3 mL/kg (early clamping) versus 92.6 mL/kg (delayed clamping).

TABLE 77-1 Mean Red Blood Cell (RBC) Values During Gestation

Age (wk)	Hb (g/dL)	Hematocrit (%)	RBC (10^6/mm^3)	Mean Corpuscular Volume (fL)	Mean Corpuscular Hb (pg)	Mean Corpuscular Hb Concentration (g/dL)	Nucleated RBCs (% of RBCs)	Reticulocytes (%)	Diameter (μm)
12	8.0–10.0	33	1.5	180	60	34	5.0–8.0	40	10.5
16	10.0	35	2.0	140	45	33	2.0–4.0	10–25	9.5
20	11.0	37	2.5	135	44	33	1.0	10–20	9.0
24	14.0	40	3.5	123	38	31	1.0	5–10	8.8

34	15.0	47	4.4	118	38	32	0.2	3–10	8.5

Data from Oski FA, Naiman JL: *Hematologic problems in the newborn*, ed 3, Philadelphia, 1982, WB Saunders.
Hb, Hemoglobin.

These changes are largely the result of differences in RBC mass (early clamping, 31 mL/kg; delayed clamping, 49 mL/kg). The blood volume in premature infants (89 to 105 mL/kg) is slightly greater than that in term infants, but this difference is due in large part to an increased plasma volume (Usher and Lind, 1965). The RBC mass in premature infants, expressed in milliliters per kilogram, is the same as in term newborns.

FETAL AND NEONATAL HEMOGLOBIN FUNCTION

A variety of hemoglobins are present during fetal and neonatal life (see Hemolysis Due to Hemoglobin Disorders, later). Fetal hemoglobin is the major hemoglobin in utero, whereas hemoglobin A is the normal hemoglobin of extrauterine life. A single RBC may contain both hemoglobin F and hemoglobin A in varying proportions, depending on gestational and postnatal age. One major difference between hemoglobins A and F is related to oxygen transport.

The transport of oxygen to peripheral tissues is regulated by several factors, including blood oxygen capacity, cardiac output, and hemoglobin-oxygen affinity. (1) Oxygen capacity is a direct function of hemoglobin concentration (1 g hemoglobin combines with 1.34 mL oxygen). (2) Compensatory changes in cardiac output can maintain normal oxygen delivery under conditions in which oxygen capacity is significantly reduced. (3) The oxygen affinity of hemoglobin also influences oxygen delivery to tissues. Hemoglobin A is 95% saturated at an arterial Po_2 of 100 mm Hg, but this decreases to 70% to 75% saturation at a venous Po_2 of 40 mm Hg. The difference in O_2 content at arterial and venous oxygen tensions reflects the amount of oxygen that can be released. Changes in hemoglobin affinity for oxygen can influence oxygen delivery (Oski and Delivoria-Papadopoulos, 1970) (Figure 77-1). At any given Po_2, more oxygen is bound to hemoglobin when oxygen affinity is increased. Stated in physiologic terms, increased hemoglobin-oxygen affinity reduces oxygen delivery, whereas decreased hemoglobin-oxygen affinity increases oxygen release to peripheral tissues.

The oxygen affinity of hemoglobin A in solution is greater than that of hemoglobin F. Paradoxically, however,

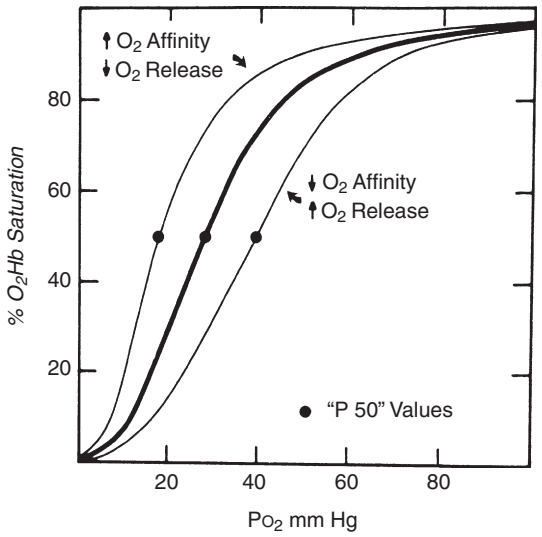

FIGURE 77-1 The oxygen dissociation curve for normal adult hemoglobin (***bold** line)*. The percent oxygen saturation (ordinate) is plotted for arterial oxygen tensions between 0 and 100 mm Hg (abscissa). As the curve shifts to the right, more oxygen is released at any given Po_2. Conversely, as the curve shifts to the left, more oxygen is retained on hemoglobin at any given Po_2. The "P 50" refers to that Po_2 in which hemoglobin is 50% saturated with oxygen. This term is useful in comparing the oxygen affinities of different hemoglobins. *(From Oski FA, Delivoria-Papadopoulos M: The red cell, 2,3-diphosphoglycerate, and tissue oxygen release*, J Pediatr *77:941-956, 1970.)*

whole blood from normal children (hemoglobin A) has a lower oxygen affinity than that of neonatal blood (hemoglobin F) (Allen et al, 1953). This difference is related to an intermediate of RBC metabolism, 2,3-diphosphoglycerate (2,3-DPG). This organic phosphate compound interacts with hemoglobin A to decrease its affinity for oxygen, thereby enhancing O_2 release. Fetal hemoglobin does not interact with 2,3-DPG to any significant extent (Bauer et al, 1968); consequently, cells containing hemoglobin F have a higher oxygen affinity than those containing hemoglobin A. The increased oxygen affinity of fetal RBCs is advantageous for extracting oxygen from maternal blood within the placenta.

A few months after birth, infant blood acquires the same oxygen affinity as that of older children (Figure 77-2). The

postnatal decrease in oxygen affinity is due to a reduction in hemoglobin F and an increase in hemoglobin A (which interacts with 2,3-DPG). Oxygen delivery (the difference in arterial and venous O_2 content) actually increases while oxygen capacity (hemoglobin concentration) decreases during the 1st week of life (Figure 77-3). This enhanced delivery is largely a reflection of the decreased oxygen affinity of infant blood (Delivoria-Papadopoulos et al, 1971). The oxygen affinity of blood from premature infants is higher than that of term infants, and the normal postnatal changes (decrease in oxygen affinity, increase in oxygen delivery) occur much more gradually in premature infants (see Figure 77-3).

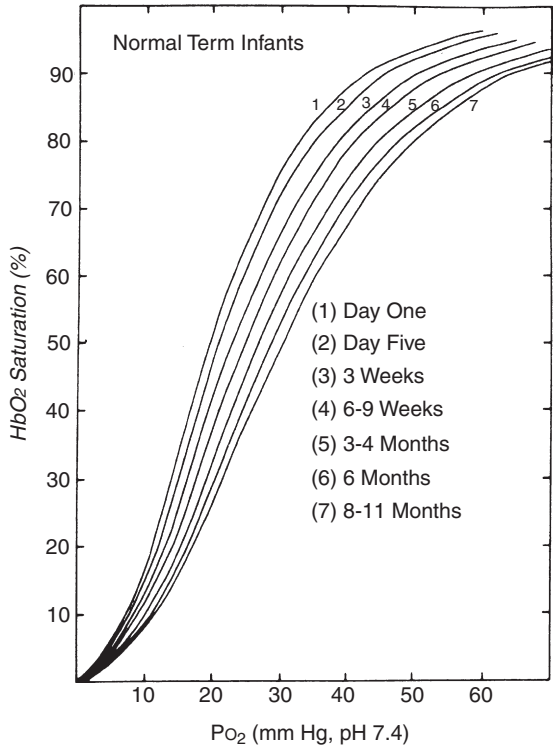

FIGURE 77-2 The oxygen affinity of blood from term infants at birth and at different postnatal ages. The gradual rightward shift of the oxygen saturation curve indicates increased oxygen release from hemoglobin as infants get older. This decreased oxygen affinity is due to a decrease in hemoglobin F and an increase in hemoglobin A. *(From Oski FA, Delivoria-Papadopoulos M: The red cell, 2,3-diphosphoglycerate, and tissue oxygen release,* J Pediatr *77:941-956, 1970.)*

GENERAL APPROACH TO ANEMIC INFANTS

MEDICAL HISTORY AND PHYSICAL EXAMINATION

The cause of anemia frequently can be ascertained by medical history and physical examination. Particular importance is given to family history (anemia, cholelithiasis, unexplained jaundice, splenomegaly), maternal medical history (especially infections), and obstetric history (previous pregnancies, length of gestation, method and difficulty of delivery). The age at which anemia becomes manifest also is of diagnostic importance. Significant anemia at birth is generally due to blood loss or alloimmune hemolysis. After 24 hours, internal hemorrhages and other causes of hemolysis become evident. Anemia that appears several weeks after birth can be caused by a variety of conditions, including abnormalities in the synthesis of hemoglobin beta chains, hypoplastic RBC disorders, and the physiologic anemia of infancy or prematurity.

Infants with anemia resulting from chronic blood loss may appear pale, without other evidence of clinical distress. Acute blood loss can produce hypovolemic shock and a clinical state similar to severe neonatal asphyxia. Newborns with hemolytic anemia frequently show a greater-than-expected degree of icterus. In addition, hemolysis often is associated with hepatosplenomegaly, and in cases resulting from congenital infection, other stigmata may be present.

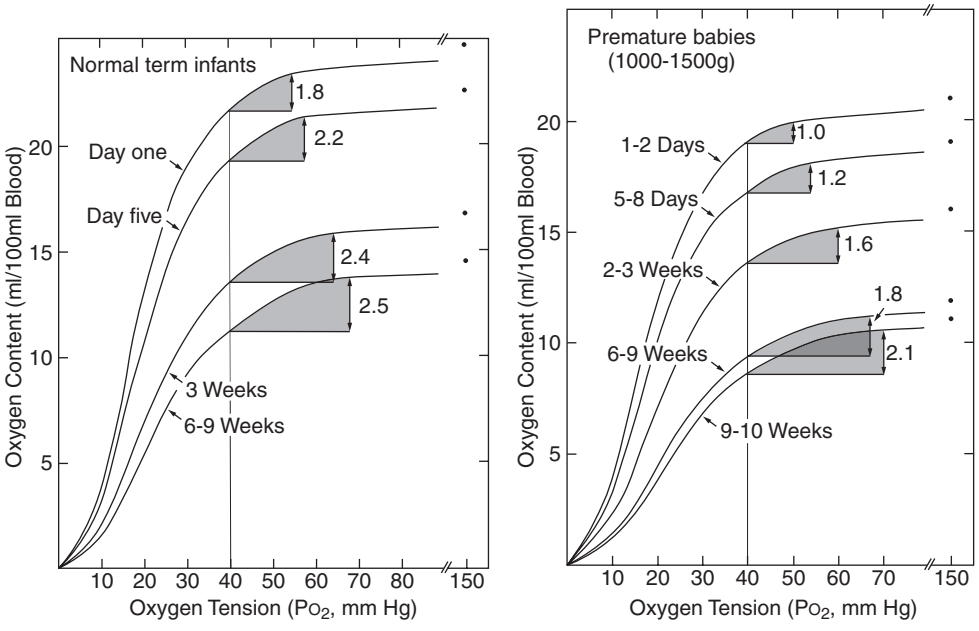

FIGURE 77-3 Oxygen delivery in normal term and premature infants. Oxygen content (a function of total hemoglobin) is on the ordinate. Oxygen tension is on the abscissa. Oxygen delivery is measured by the difference in oxygen content at arterial (100 mm Hg) and venous (40 mm Hg) oxygen tensions. For both term and premature infants, oxygen delivery *(shaded areas)* increases with age. This occurs despite a decrease in oxygen content. *(From Delivoria-Papadopoulos M, Roncevic NP, Oski FA: Postnatal changes in oxygen transport of term, premature, and sick infants: the role of red cell 2,3-diphosphoglycerate and adult hemoglobin,* Pediatr Res *5:235-245, 1971.)*

TABLE 77-2 Differential Approach to Anemia in the Newborn Period

Hemoglobin	Reticulocytes	Bilirubin	DAT	Clinical Considerations
Decreased	Normal/decreased	Normal	Negative	Physiologic anemia of infancy and prematurity Hypoplastic anemia
Decreased	Normal/increased	Normal	Negative	Hemorrhagic anemia
Decreased	Normal/increased	Increased	Positive	Immune-mediated hemolysis
Decreased	Normal/increased	Increased	Negative	Acquired or hereditary red blood cell defects Enclosed hemorrhage with resorption of blood DAT-negative ABO incompatibility

DAT, Direct antiglobulin test (previously known as direct Coombs' test).

TABLE 77-3 RBC Values in Term and Premature Infants During the First Week of Life

	Hb (g/100 mL)	Hct (%)	Reticulocytes (%)	Nucleated RBCs (cells/1000 RBCs)
Term				
Cord blood	17.0 (14–20)	53.0 (45–61)	<7	<1.00
Day 1	18.4	58.0	<7	<0.40
Day 3	17.8	55.0	<3	<0.01
Day 7	17.0	54.0	<1	0
Premature (Birthweight <1500 g)				
Cord blood	16.0 (13.0–18.5)	49	<10	<3.00
Day 7	14.8	45	<3	<0.01

Hct, Hematocrit; *Hb*, hemoglobin; *RBCs*, red blood cells.

LABORATORY EVALUATION OF ANEMIA

A simple classification of neonatal anemia based on physical examination and basic laboratory tests is presented in Table 77-2. More extensive RBC testing is discussed elsewhere (de Alarcón et al, 2005).

Red Blood Cell Count, Hemoglobin, Hematocrit, and Red Blood Cell Indices

RBC values during the neonatal period are more variable than at any other time of life. The diagnosis of anemia must therefore be made in terms of "normal" values appropriate for gestational and postnatal ages. The mean cord blood hemoglobin of healthy term infants ranges between 14 and 20 g/100 mL (Table 77-3). Shortly after birth, however, hemoglobin concentration increases. This increase is both relative (owing to a reduction of plasma volume) and absolute (owing to placental RBC transfusion). Failure of hemoglobin to increase during the first few hours of life may be the initial sign of hemorrhagic anemia. RBC values at the end of the 1st week are virtually identical to those seen at birth. Anemia during the 1st week of life is thus defined as any hemoglobin value less than 14 g/100 mL. A significant hemoglobin decrease during this time, although within the normal range, is suggestive of hemorrhage or hemolysis. For example, 14.5 g hemoglobin at 7 days of age is abnormal for a term infant whose hemoglobin was 18.5 g at birth. A slight hemoglobin reduction normally occurs in premature infants during the 1st week of life. Beyond the 1st week, however, the hemoglobin concentration decreases in both term and premature infants (see Physiologic Anemia of Infancy and Prematurity, later).

The electronic equipment used for blood counts also gives statistical information regarding erythrocyte size (MCV) and hemoglobin content (MCH). The normal MCV in older children ranges from 75 to 90 fL. MCV values of less than 75 fL are considered microcytic, whereas those over 100 fL indicate macrocytosis. Normal infant RBCs are large (MCV 105 to 125 fL), and not until 8 to 10 weeks of age does cell size approach that in older children. Neonatal microcytosis is defined as an MCV of less than 95 fL at birth. The RBC hemoglobin content of neonatal cells (MCH 35 to 38 pg/cell) is greater than that seen in older children (MCH 30 to 33 pg/cell). Neonatal hypochromia is defined as an MCH of less than 34 pg/cell. Hypochromia and microcytosis generally occur together, and invariably these abnormalities are due to hemoglobin production defects. Neonatal hypochromic microcytosis is seen with iron deficiency (chronic blood loss) and thalassemia disorders (α- and γ-thalassemias). Both the MCV and MCH are higher in preterm infants as shown in Figure 77-4 (Christensen et al, 2009).

The site from which blood is obtained is important, because hemoglobin and hematocrit are higher in capillary blood than in simultaneously obtained central venous samples (up to 20%). This difference can be minimized by warming an extremity to obtain "arterialized capillary blood" (Oh and Lind, 1966). In the face of acute hemorrhage, however, central venous samples must be obtained because of marked peripheral vasoconstriction.

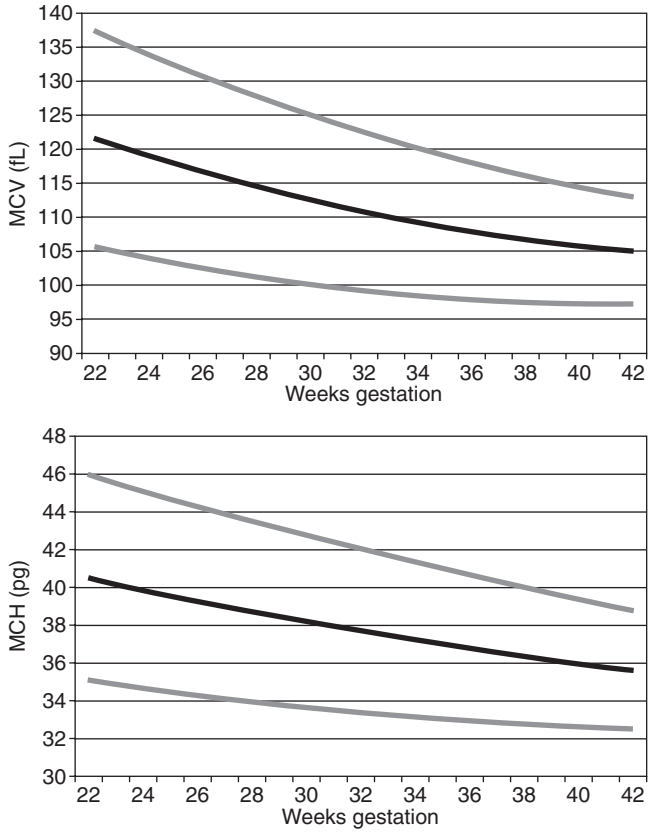

FIGURE 77-4 Reference ranges for MCV *(upper panel)* and MCH *(lower panel)* for neonates on the first day after birth. The lower line shows the 5th percentile values, the middle line shows the mean values, and the upper line shows the 95th percentile values. *From Christensen RD, Henry E, Jopling J, Wiedmeier SE: The CBC: reference ranges for neonates,* Semin Perinatol *33:3-11, 2009.*

Reticulocyte Count

The normal reticulocyte count in children and older infants is 1% to 2% of the circulating red cells. The reticulocyte count in term infants ranges between 3% and 7% at birth, but this decreases to less than 1% by 7 days of age (see Table 77-3). In premature infants, reticulocyte values at birth are higher (6% to 10%) and may remain elevated for a longer period of time. Nucleated RBCs are seen in newborn infants, but they generally disappear by the 3rd day of life in term infants and in 7 to 10 days in premature infants. The persistence of reticulocytosis or nucleated RBCs suggests the possibility of hemorrhage or hemolysis. Hypoxia, in the absence of anemia, also can be associated with increased release of reticulocytes and nucleated RBCs.

Peripheral Blood Smear

Examination of the peripheral blood smear is an invaluable aid in the diagnosis of anemia. The smear is evaluated for alterations in the size and shape of RBCs as well as abnormalities in leukocytes and platelets. Erythrocytes of older children are approximately the size of a small lymphocyte nucleus, whereas those of newborns are slightly larger. RBC hemoglobinization (e.g., hypochromia) is estimated by observing the area of central pallor, which is one third the diameter of normal RBCs and more than one half the diameter of hypochromic cells. Spherocytes are detected by the complete absence of central pallor. The degree of reticulocytosis can be estimated, because these cells are larger and have a bluish coloration.

Direct Antiglobulin Test

Most cases of neonatal hemolytic anemia are due to isoimmunization. The direct antiglobulin test (DAT), previously known as the direct Coombs' test, detects the presence of antibody on RBCs The indirect antiglobulin test, previously known as indirect Coombs' test, detects anti-RBC antibodies in the plasma.

BLOOD TRANSFUSIONS IN THE TREATMENT OF ANEMIA

A hemoglobin of 14 g/100 mL corresponds to an RBC mass of 31 mL/kg. Thus, an RBC transfusion of 2 mL/kg will increase the hemoglobin concentration by approximately 1 g/100 mL. Packed RBCs (hematocrit approximately 67%) contain 2 mL of RBCs/3 mL of packed RBCs. Whole blood (hematocrit approximately 33%) contains 2 mL of RBCs/6 mL whole blood. Thus, the transfusion of 3 mL of packed RBCs/kg or 6 mL of whole blood/kg increases hemoglobin concentration by approximately 1 g/100 mL.

Packed RBCs are the product of choice when transfusion is necessary for simple anemia, as occurs in hemolysis. If anemia is accompanied by hypovolemia from acute blood loss, volume expansion must be achieved promptly, using either whole blood, or packed RBCs and normal saline or a colloid such as 5% serum albumin (infused separately). Because of the reduced availability of whole blood, owing to the demand for its components, in most medical centers the usual choice is packed RBCs and crystalloid or colloid. The previously common practice of reconstituting RBCs with fresh frozen plasma to make "whole blood" is no longer acceptable, because the increased donor exposure increases the risk of transmitting infectious disease. When packed RBCs need to be diluted to facilitate nonurgent transfusion, isotonic saline is the preferred diluent. If exchange transfusion is needed to treat hyperbilirubinemia, the capability of albumin to improve bilirubin binding and removal is ample reason to request whole blood. Although fresh blood less than 2 days old is ideal because there is a reduced risk of hyperkalemia, this is not usually available. An acceptable substitute is packed RBCs less than 4 to 5 days old. These packed RBCs provide adequate oxygen delivery; hyperkalemia can be prevented by washing the RBCs once in saline and then reconstituting with normal saline. Washing is not required for the usually small, simple transfusions of packed RBCs, because the small volume of plasma minimizes any toxic effect of increased concentration of potassium in the plasma.

Blood currently available in most blood banks is anticoagulated with citrate-phosphate-dextrose (CPD), CPD-adenine (CPDA-1), or adenine-saline (AS-3), with a shelf life of 21, 35, or 42 days, respectively. Hematocrit usually ranges between 65% and 80% for packed RBCs. Near-normal 2,3-DPG levels are maintained for up to 12 to 14 days, which is advantageous in transfusing infants with

acute hypoxia or those receiving large volumes of blood. Hematocrits range from 55% to 65%, thus facilitating flow during infusion. The newest of these preparations, AS-3, is well tolerated by newborns even after up to 42 days of storage, so long as only small-volume transfusions are given at any one time (Strauss, 2000). Designation of a single AS-3–preserved red cell donation for use by one neonate is an effective way to limit donor exposures and reduce the risk of transfusion-associated infections (Goldman, 2001).

Preterm infants born weighing less than 1250 g are uniquely susceptible to potentially serious cytomegalovirus (CMV) infection from transfused blood, particularly if they lack immunity because their mothers are seronegative. CMV infection can be prevented by using blood products only from seronegative donors (Yeager et al, 1981). Because approximately 40% to 60% of adults are seropositive, this limits the availability of seronegative donors. Reserving seronegative blood for the minority of infants who are seronegative can reduce the demand for such donors. Alternatively, because CMV resides mainly in leukocytes, removal of such cells also can prevent transmission of the virus, and the use of high-efficiency leukocyte depletion filters (Gilbert et al, 1989) has proven effective. A potential disadvantage of using CMV-seronegative blood in CMV-positive infants receiving large amounts of blood is dilution of infant's antibody level, resulting in increased susceptibility to nursery-acquired CMV infection. Currently, a majority of neonatal services utilize leukocyte-reduced red cell products rather than relying on CMV-negative products to prevent CMV infection (Engelfreit and Reesink, 2001).

Graft-versus-host (GVH) reaction rarely follows transfusion and occurs mainly in certain newborns at risk. For this to occur, viable lymphocytes in cellular blood products must be able to engraft and react against foreign antigens on tissues of the recipient. Infants at risk include those with congenital or acquired defects of cellular immunity, those who as fetuses received intrauterine transfusion of RBCs or platelets, newborns receiving exchange transfusion following intrauterine transfusion (Naiman et al, 1969; Parkman et al, 1974), and infants receiving directed blood donations from first-degree relatives (whose genetic similarity may increase the likelihood of engraftment). Irradiation of RBCs, whole blood, platelets, and granulocytes with a minimum of 1500 rads has proved effective in preventing GVH reaction. Reports of GVH reaction after RBC transfusion in very premature infants without known risk factors (Enoki et al, 1985; Sanders et al, 1989) have prompted most neonatal services to irradiate all RBC blood products (Engelfreit and Reesink, 2001).

HEMORRHAGIC ANEMIA

Anemia frequently follows fetal blood loss, bleeding from obstetric complications, and internal hemorrhages associated with birth trauma (Box 77-1). Iatrogenic anemia due to repeated removal of blood for laboratory testing is common in premature infants. The clinical presentation of anemia depends on the magnitude and acuteness of blood loss.

Infants with anemia subsequent to moderate hemorrhage or chronic blood loss are generally asymptomatic.

BOX 77-1 Causes of Hemorrhagic Anemia in Newborns

FETAL HEMORRHAGE

Spontaneous fetomaternal hemorrhage
Hemorrhage following amniocentesis
Twin-twin transfusion
Nuchal cord

PLACENTAL HEMORRHAGE

Placenta previa
Abruptio placentae
Multilobed placenta (vasa previa)
Velamentous insertion of cord
Placental incision during cesarean section

UMBILICAL CORD BLEEDING

Rupture of umbilical cord with precipitous delivery
Rupture of short or entangled cord

POSTPARTUM NEONATAL HEMORRHAGE

Bleeding from umbilicus
Cephalhematomas, scalp hemorrhages
Hepatic rupture, splenic rupture
Retroperitoneal hemorrhages

The only physical finding is pallor of the skin and mucous membranes. Laboratory studies can range from a mild normochromic normocytic anemia (hemoglobin 9 to 12 g/100 mL) to a more severe hypochromic microcytic anemia (hemoglobin 5 to 7 g/100 mL). The only therapy required for asymptomatic children is iron (2 mg elemental iron/kg three times a day for 3 months). RBC replacement is indicated only if there is evidence of clinical distress (tachycardia, tachypnea, irritability, feeding difficulties). In most cases, increasing the hemoglobin to 10 to 12 g/100 mL removes all signs and symptoms associated with anemia. Because severely anemic infants are frequently in incipient heart failure, however, these children should be transfused very slowly (2 mL/kg/hour). If signs of congestive heart failure appear, a rapid-acting diuretic (furosemide, 1 mg/kg intravenously) should be given before proceeding with the transfusion. An alternative approach is to administer a partial exchange transfusion with packed RBCs to severely anemic infants. This approach increases the hemoglobin concentration without the danger of increasing blood volume and precipitating congestive heart failure.

Infants who rapidly lose large volumes of blood appear to be in acute distress (pallor, tachycardia, tachypnea, weak pulses, hypotension, and shock). This presentation is distinct from that seen in neonatal respiratory asphyxia (slow respirations with intercostal retractions, bradycardia, and pallor with cyanosis) (Table 77-4). Infants with respiratory problems demonstrate a marked improvement with assisted ventilation and oxygen, whereas there is little change in anemic newborns. Cyanosis is not a feature of severe anemia because the hemoglobin concentration is too low (for clinical cyanosis to be apparent, there must be at least 5 g/100 mL of deoxygenated hemoglobin). The hemoglobin concentration immediately after an acute hemorrhage may be normal, and a decreased hemoglobin may not be seen until the plasma volume has reexpanded several hours later. Thus, the diagnosis of acute hemorrhagic anemia is based

TABLE 77-4 Comparative Clinical Findings in Neonatal Asphyxia and Acute Hemorrhage

	Neonatal Asphyxia	Acute Blood Loss
Heart rate	Decreased	Increased
Respiratory rate	Decreased	Increased
Intercostal retractions	Present	Absent
Skin color	Pallor with cyanosis	Pallor without cyanosis
Response to oxygen and assisted ventilation	Marked improvement	No significant change

largely on physical findings and evidence of blood loss. It is important to recognize these clinical features because immediate therapy is required. Treatment is directed at rapid expansion of the vascular space (20 mL fluid/kg) by rapid infusion of either isotonic saline or 5% albumin, followed by either type-specific, cross-matched whole blood or packed RBCs resuspended with saline, depending on availability. In infants in whom anemia and hypoxia are severe, non-cross-matched group O, Rh-negative RBCs are an acceptable alternative to cross-matched RBCs. Infants with hypovolemic shock caused by acute external blood loss usually show marked clinical improvement after this treatment. A poor response is seen in newborns with severe internal hemorrhage.

FETAL HEMORRHAGE

Fetomaternal Hemorrhage

Significant bleeding into the maternal circulation occurs in approximately 8% of all pregnancies and thus represents one of the most common forms of fetal bleeding. Small amounts of fetal blood are lost in most cases, but in 1% of pregnancies, fetal blood loss may exceed 40 mL (Cohen et al, 1964). Fetomaternal hemorrhage occasionally follows amniocentesis and placental injury (Zipursky et al, 1963), although anemia is seen only after unsuccessful amniocentesis or when there is evidence of a bloody tap (Woo Wang et al, 1967). For this reason, infants born to mothers who have had amniocentesis should be observed closely for signs of anemia. The effects of anemia resulting from fetomaternal hemorrhage are variable. Large acute hemorrhages can produce hypovolemic shock, whereas slower, more chronic blood loss results in hypochromic microcytic anemia resulting from iron deficiency. Some newborns with severe chronic fetal anemia (hemoglobin levels as low as 4 to 6 g/100 mL) may have minimal symptoms.

An examination of maternal blood for the presence of fetal cells is necessary in any infant with suspected fetomaternal hemorrhage. Two techniques are available. The Kleihauer-Betke preparation involves examination of a stained specimen of maternal blood by microscopy following differential elution of hemoglobin A but not hemoglobin F from the red cells. Alternative, flow cytometry–based techniques are probably more accurate but are less widely available. These approaches use antibodies against fetal hemoglobin (sometimes combined with antibodies against carbonic anhydrase) or against the D antigen to distinguish fetal RBCs from adult cells (Little et al, 2005; Porra et al, 2007; Savithrisowmya et al, 2008).

Approximately 50 mL of fetal blood must be lost to produce significant neonatal anemia. This volume is greater than 1% of the maternal blood volume, and therefore fetal cells within the maternal circulation may be detected readily. Tests that depend on the presence of fetal hemoglobin are not valid when a maternal hemoglobinopathy with increased hemoglobin F levels coexists. In addition, fetomaternal ABO incompatibility may cause rapid removal of fetal RBCs, thus obscuring any significant hemorrhage. For this reason, it is important to examine maternal blood as soon as anemia from fetal hemorrhage is suspected.

TWIN-TWIN TRANSFUSION

Transfusion of blood from one monozygous twin to another can result in anemia in the donor twin and polycythemia in the recipient. Significant hemorrhage is seen only in monochorionic monozygous twins (approximately 70% of all monozygous twins). The most common form, chronic twin-to-twin transfusion (TTTS), is seen in 10% to 15% of monochorionic pregnancies (Huber and Hecher, 2004; Lopriore and Oepkes, 2008). Bleeding occurs because of vascular anastomosis in monochorionic placentas. The anemic donor twin is usually smaller than the polycythemic recipient, with a greater than 20% difference in birthweight. Polyhydramnios is frequently seen in the recipient twin and oligohydramnios is seen in the donor, and current diagnostic criteria for chronic TTTS include the demonstration by prenatal ultrasound of the twin oligopolyhydramnios sequence (TOPS). The high rate of intrauterine mortality (approximately 63% with conservative management) has spurred attempts at fetal therapy, including decompression amniocentesis, laser coagulation of vascular anastomoses, interfetal septal disruptions, and selective feticide (Seng and Rajadurai, 2000; van Gemert et al, 2001). A prospective randomized trial demonstrated that fetoscopic laser surgery had better overall survival (57%) as compared to serial amnioreduction (41%) (Senat et al, 2004). Many centers are now achieving survival rates of at least 70%, but residual vascular anastomoses can still result in polycythemia-hyperviscosity syndrome in the recipient and chronic anemia in the donor (Lopriore and Oepkes, 2008). Twin-twin transfusions should be suspected when the hemoglobin concentration of identical twins differs by more than 5 g/100 mL. However, such a difference in hemoglobin concentration does not prove there has been a twin-twin transfusion, because such a hemoglobin difference has been observed in some dichorionic twins, in whom there are no vascular anastomoses and therefore no possibility for twin-twin transfusion (Danskin and Neilson, 1989).

PLACENTAL BLOOD LOSS

Placental bleeding during pregnancy is common, but in most cases hemorrhage is from the maternal aspect of the placenta. In placenta previa, however, the thinness of the placenta overlying the cervical os frequently results in fetal

blood loss. The vascular communications between multilobular placental lobes also are very fragile and are easily subjected to trauma during delivery. Vasa previa is the condition in which one of these connecting vessels overlies the cervical os and thus is prone to rupture during delivery. Abruptio placentae generally causes fetal anoxia and death, although some infants survive but can be severely anemic. Bleeding also follows inadvertent placental incision during cesarean section (Montague and Krevans, 1966), and thus the placenta should be inspected for injury following all cesarean sections.

UMBILICAL CORD BLEEDING

The normal umbilical cord is resistant to minor trauma and does not bleed. The umbilical cord of dysmature infants, however, is weak and thus vulnerable to rupture and hemorrhage (Raye et al, 1970). In cases of precipitous delivery, a rapid increase in cord tension can rupture the fetal aspect of the cord, causing serious acute blood loss. Short or entangled umbilical cords and abnormalities of umbilical blood vessels (velamentous insertions into the placenta) are also vulnerable to rupture and hemorrhage. Bleeding from injured umbilical cords is rapid but generally ceases after a short period of time, owing to arterial constriction. The umbilical cord should always be inspected for abnormalities or signs of injury, particularly after unattended, precipitous deliveries.

HEMORRHAGE AFTER DELIVERY

Hemorrhagic anemia due to internal bleeding is occasionally associated with birth trauma. Characteristically, internal hemorrhages are asymptomatic during the first 24 to 48 hours of life, with signs and symptoms of anemia developing after this time. Cephalhematomas can be sufficiently large to cause anemia and hyperbilirubinemia, secondary to the resorption of blood. Subgaleal hemorrhages are seen infrequently, sometimes occurring after vacuum extraction is used during delivery. In contrast to cephalhematomas, subgaleal bleeding can be extensive because hemorrhage is not limited by the periosteum. Adrenal and kidney hemorrhages occasionally follow difficult breech deliveries. Splenic rupture and hemorrhage occur most commonly in association with splenomegaly, as in erythroblastosis fetalis. Hepatic hemorrhages are generally subcapsular and may be asymptomatic. Rupture of the hepatic capsule results in hemoperitoneum and hypovolemic shock. Hepatic hemorrhages are suspected when a previously healthy infant goes into shock with clinical manifestations of an increasing right upper quadrant abdominal mass, shifting dullness on percussion, and evidence of free fluid on abdominal radiographs. In contrast with newborns with acute blood loss from fetomaternal or umbilical vessel bleeding, infants with hepatic hemorrhage generally demonstrate a poor clinical response to blood replacement.

HEMOLYTIC ANEMIA

RBCs from children and adults normally circulate for 100 to 120 days. Erythrocyte survival in newborns is somewhat shorter: 70 to 90 days in term infants, 50 to 80 days in premature infants (Pearson, 1967). Hemolytic anemia, which further shortens RBC survival, may arise for many reasons (Box 77-2). Red cell destruction can occur by macrophage recognition of abnormal RBC membrane properties (extravascular hemolysis) or, alternatively, RBC destruction can occur by direct damage of the RBC in the circulation with the resultant release of hemoglobin (intravascular hemolysis). In most cases some degree of both types of hemolysis occurs.

BOX 77-2 Causes of Hemolytic Anemia During the Newborn Period

IMMUNE DISORDERS

Isoimmune: Rh and ABO incompatibility
Maternal immune disease: autoimmune hemolytic anemia, systemic lupus erythematosus
Drug-induced: penicillin

ACQUIRED RED BLOOD CELL (RBC) DISORDERS

Infection: cytomegalovirus, toxoplasmosis, syphilis, bacterial sepsis
Disseminated and localized intravascular coagulation, respiratory distress syndrome

HEREDITARY RBC DISORDERS

Membrane defects: hereditary spherocytosis, hereditary elliptocytosis
Enzyme abnormalities: glucose-6-phosphate dehydrogenase, pyruvate kinase
Hemoglobinopathies: α-thalassemia syndromes, γ/β-thalassemia

In older infants and children, the usual response to increased RBC destruction is enhanced erythropoiesis, and there may be little or no anemia if the rate of production matches the accelerated rate of destruction. In these cases of well-compensated hemolysis, the major manifestations are due to increased erythrocyte destruction (hyperbilirubinemia) and augmented erythropoiesis (reticulocytosis). During the early neonatal period, however, the increased oxygen-carrying capacity of blood (see Physiologic Anemia of Infancy and Prematurity, later) may blunt any compensatory erythropoietic activity in cases of mild hemolysis. Consequently, hyperbilirubinemia in excess of normal neonatal levels may be the only apparent manifestation of hemolysis. In most cases of significant hemolysis, however, some degree of reticulocytosis is usually present.

IMMUNE HEMOLYSIS

Placental transfer of maternal antibodies directed against fetal RBC antigens is the most common cause of neonatal hemolysis. This phenomenon is a consequence of maternal sensitization to fetal RBC antigens inherited from the father. Hemolysis occurs only in the fetus. The spectrum of clinical problems ranges from minimal anemia and hyperbilirubinemia to severe anemia with hydrops fetalis. At one time, before effective prevention of Rh sensitization was available, hemolytic disease of the newborn was responsible for more than 10,000 deaths annually in the United States (Freda et al, 1975). Since the development of immunoprophylaxis against Rh(D) sensitization, the overall incidence of alloimmune hemolysis has decreased dramatically in developed countries of the world (Figure 77-5).

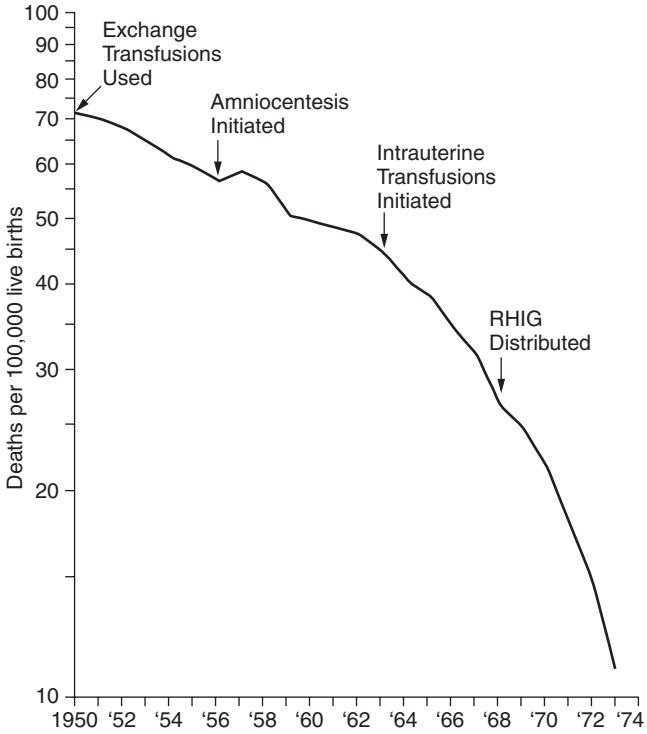

FIGURE 77-5 Infant death rates from hemolytic disease of the newborn, United States, 1950 to 1973. *(From Centers for Disease Control:* Rh hemolytic disease surveillance annual report, *Atlanta, Ga., June 1975.)*

Nevertheless, Rh incompatibility still occurs in areas where immune prophylaxis is not readily available. In the United States, most cases of alloimmune hemolysis are due to ABO maternal-fetal incompatibility with a smaller fraction resulting from sensitization to Kell, Duffy, Kidd, and other Rh antigens such as c and E.

Rh Hemolytic Disease: Erythroblastosis Fetalis

The role of Rh antibody in classic erythroblastosis fetalis was first elucidated by Levine and Katzen in 1941 (Levine et al, 1941). Several Rh antigens are recognized, each of which is detected by specific antibodies. It is known that Rh blood group antigens are determined by at least two homologous but distinct membrane-associated proteins. Two of these membrane proteins have separate isoforms (C and c; E and e), which are detected by specific antibodies (anti-C and anti-c; anti-E and anti-e). The most important of the membrane Rh proteins is the D antigen. Rh-positive RBCs are those that possess this antigen. A lowercase d is used to denote the absence of D, or Rh-negative status; it is not related to a specific antigen—no "anti-d" serum has been identified. Rh proteins are encoded by two separate genes located on chromosome 1; they are designated *RHCE* and *RHD* (Mouro et al, 1993). The *RHCE* gene encodes both the C/c and E/e proteins. The *RHD* gene encodes the Rh D proteins. The Rh-negative phenotype results from deletion of the *RHD* gene on both chromosomes. In most cases, the Rh-negative phenotype also is associated with Rh c and Rh e (i.e., Rh cde). The frequency of Rh negativity varies in different racial groups. It is high in whites (15%), lower in blacks (5%), and virtually nonexistent in Asians. The Rh-positive phenotype may result from homozygosity (DD) or heterozygosity (Dd) for the D antigen. In Rh-positive whites, approximately 44% are homozygous (DD) and 56% are heterozygous (Dd). Knowledge of differences in *RHD* genotype is important because approximately 25% of fetuses of couples with an Rh(D)-negative mother and an Rh(D)-positive father will be Rh(D)-negative.

Current understanding of the natural history of Rh sensitization is derived largely from clinical experience gained before the immunologic prevention of neonatal hemolysis was readily available. The pathophysiology of alloimmune hemolysis resulting from Rh incompatibility includes the following: an Rh-negative mother, an Rh-positive fetus, leakage of fetal RBCs into maternal circulation, maternal sensitization to D antigen on fetal RBCs, production and transplacental passage of maternal anti-D antibodies into fetal circulation, attachment of maternal antibodies to Rh-positive fetal RBCs, and destruction of antibody-coated fetal RBCs. Historically, Rh hemolytic disease was rare (occurring in 1% of cases) during the first pregnancy involving an Rh-positive fetus but increased significantly with each subsequent pregnancy. Small volumes of fetal RBCs enter the maternal circulation throughout gestation, although the major fetomaternal bleeding responsible for sensitization occurs during delivery (Zipursky et al, 1963). Once sensitization has occurred, reexposure to Rh(D) RBCs in subsequent pregnancies leads to an anamnestic response, with an increase in the maternal anti-D titer. Currently, significant hemolysis occurring in the first pregnancy indicates prior maternal exposure to Rh-positive RBCs, a consequence of fetal bleeding associated with a previous spontaneous or therapeutic abortion, ectopic pregnancy, or a variety of different prenatal procedures. On occasion the sensitization may be a consequence of an earlier transfusion in which Rh-positive RBCs were administered by mistake or in which some other blood component (e.g., platelets) containing Rh(D) RBCs was transfused.

The major factor responsible for the reduced death rate is the development of Rh immune globulin to prevent maternal sensitization. Important early observations were that fetomaternal RBC transfer (and thereby sensitization) occurs primarily during delivery and that the frequency of Rh immune hemolytic disease was much lower in ABO-incompatible pregnancies (maternal RBC type O, fetal RBC type A or B). The apparent beneficial effect of ABO incompatibility is due to the fact that maternal anti-A and anti-B antibodies recognize the corresponding A and B fetal RBCs, leading to their destruction before sensitization can occur. The practice of administering a single intramuscular dose of Rh immune globulin (300 μg) to unsensitized Rh-negative mothers within 72 hours of delivering an Rh-positive infant led to the virtual elimination of Rh(D) sensitization as a major cause of hemolytic disease in newborns (Freda et al, 1975). The few treatment failures seen were attributed to fetomaternal bleeding of greater than 30 mL at delivery or bleeding that occurred antenatally. This led to the current standard of practice of administering a full dose of Rh immune globulin to all unsensitized Rh-negative women at 28 weeks' gestation, with an additional

dose given at birth if the infant is Rh-positive. Moreover, the dose of Rh immune globulin should be increased proportionately when there is evidence of larger-than-normal fetomaternal bleeding at delivery. All women should be screened at the time of delivery using the rosette test to screen for fetal red cells (Brecher, 2002). Positive results should be followed by a quantitative test such as the Kleihauer-Betke test (Judd, 2001). In suspicious cases (e.g., with placental abruption or neonatal anemia), the volume of fetal hemorrhage can be quantified using the Kleihauer-Betke procedure. Rh immune globulin also should be administered to unsensitized Rh-negative women after any event known to be associated with increased risk of fetomaternal hemorrhage (e.g., spontaneous or therapeutic abortion, amniocentesis, chorionic villus biopsy). The risk of anti-Rh desensitization ranges from 0.6% to 5.4% when nonsensitized Rh-negative women undergo amniocentesis (Spinnato, 1992). Despite the use of antenatal and postnatal prophylaxis with Rh immune globulin, 0.1% to 0.3% of Rh-negative women with Rh-positive pregnancies develop Rh sensitization (Engelfriet et al, 2003; Koelewijn et al, 2008). A recent case-control study (Koelewijn et al, 2009) demonstrated several independent risk factors for sensitization, including nonspontaneous delivery (i.e., caesarean section or assisted vaginal delivery), pregnancy-related red cell transfusion, postmaturity (>42 weeks' gestation), and younger age at first delivery. However, in almost half of the failures, none of these risk factors could be identified.

In pregnant Rh-negative women previously sensitized to Rh(D), the transplacental passage of maternal anti-D leads to a positive DAT on Rh(D) fetal RBCs. Depending on the amount of anti-D absorbed, a variable degree of fetal hemolysis occurs, thereby leading to anemia, hepatosplenomegaly, and increased bilirubin formation. In utero, bilirubin is removed by transfer across the placenta into the maternal circulation; therefore, hyperbilirubinemia is not a problem until after delivery, when levels may increase because of immaturity of hepatic conjugating enzymes. The major threat to the fetus is severe anemia leading to hydrops fetalis and intrauterine death. The clinical severity of neonatal hemolytic disease varies.

Mild hemolytic disease is most common, manifested by a positive DAT with minimal hemolysis, little or no anemia (cord blood hemoglobin greater than 14 g/dL), and minimal hyperbilirubinemia (cord blood bilirubin less than 4 mg/dL). Aside from early phototherapy, these newborns generally require no therapy unless the postnatal rate of rise in bilirubin is greater than expected. Infants who do not become sufficiently jaundiced to require exchange transfusion are at risk of development of severe late anemia associated with a low reticulocyte count, usually at 3 to 6 weeks of age; thus, it is important to closely monitor hemoglobin levels after hospital discharge.

Moderate hemolytic disease is found in a smaller fraction of affected infants. This form is characterized by hemolysis, moderate anemia (cord blood hemoglobin less than 14 g/dL), and increased cord blood bilirubin levels (greater than 4 mg/dL). The peripheral blood may reveal numerous nucleated RBCs, decreased numbers of platelets, and occasionally a leukemoid reaction with large numbers of immature granulocytes. Infants with Rh disease also may exhibit marked hepatosplenomegaly, a consequence of extramedullary hematopoiesis and sequestration of antibody-coated RBCs. The risk of development of bilirubin encephalopathy is high if these neonates do not receive treatment. Thus, early exchange transfusion with type O Rh-negative fresh RBCs (less than 5 days old) is usually necessary, in conjunction with intensive phototherapy. This approach has been responsible for the favorable outcome for most infants with moderate alloimmune hemolysis. It is common for newborns who receive exchange transfusion to demonstrate a lower-than-normal hemoglobin concentration at the nadir of their "physiologic" anemia. Therefore, follow-up evaluation of hemoglobin for at least 2 months is important. The decrease in hemoglobin may be due in part to persistence of some anti-D antibody and destruction of the patient's own Rh(D)-positive RBCs. Also, this low hemoglobin measurement may reflect the decreased oxygen affinity and enhanced oxygen delivery of adult RBCs used for the exchange process, thereby blunting the expected erythropoietic response to hypoxia. Some studies suggest that the administration of recombinant human erythropoietin (rHuEPO) may minimize this late anemia of Rh hemolytic disease (Ovali et al, 1996; Scaradavou et al, 1993), although it is not always effective (Pessler and Hart, 2002).

Severe hemolytic disease is seen in approximately 25% of affected infants, who are either stillborn or hydropic at birth. Understanding of hydrops fetalis, originally attributed to high-output cardiac failure secondary to severe anemia, is incomplete. Two other consequences of anemia also may contribute to the edema of hydrops. One of these is low colloid osmotic pressure resulting from hypoalbuminemia, a consequence of hepatic dysfunction. The second is a capillary leak syndrome secondary to tissue hypoxia. Management of seriously affected fetuses is directed at the prevention of severe anemia and death. To accomplish this, it first is necessary to identify those fetuses at risk. An increase in the maternal anti-D titer in a previously sensitized Rh-negative woman is a good serologic measure of a fetus in potential jeopardy. Moreover, a previous history of neonatal hemolytic disease resulting from anti-D antibodies suggests that the current fetus also may be at risk. In this regard it may be useful to know the fetal Rh blood type because this identifies those Rh-negative infants who are not at risk. In many cases this can be accomplished by direct Rh typing of fetal RBCs obtained via cordocentesis. Alternatively, molecular biologic techniques can be used to determine the Rh genotype in DNA obtained from amniocytes or chorionic villus samples (Bennett et al, 1993; Fisk et al, 1994). Recently, methods have been developed to perform such analysis of free fetal DNA in maternal blood (Daniels et al, 2009). When the fetus is found to be Rh-negative, no further maternal monitoring or fetal blood studies are necessary.

An increase in the maternal titer of immunoglobulin G (IgG) anti-D indicates maternal sensitization but does not accurately predict the potential severity of fetal hemolysis. Previously, when the indirect antiglobulin test exceeded a critical threshold level (1:16 to 1:32), amniocentesis was done to perform spectrophotometric estimation of bile pigment in amniotic fluid as measured by the deviation in optical density (OD) at 450 nm. Plotting the "ΔOD_{450nm}" against fetal age provided a good correlation with the

severity of fetal hemolysis during the third trimester, and the trend of two or more values is a more reliable predictor of severity of fetal disease (Liley, 1961).

More recently, efforts have been made to use noninvasive detection of fetal anemia. Ultrasonography signs of hydrops fetalis represent a relatively late sign of fetal anemia, often not developing until Hgb values are more than 7 gm/dL below gestational age norm. However, Doppler assessment of peak velocity in the fetal middle cerebral artery (MCA), reflecting the lower viscosity associated with more severe anemia, has become the standard of care at most centers (Figure 77-6). MCA Doppler has been compared to the previous gold standard of the amniocentesis for "ΔOD_{450nm}" (Oepkes et al, 2006). In this study, 45% of infants had severe anemia at cordocentesis, defined as a hemoglobin level at least 5 standard deviations below the mean for gestational age. The MCA Doppler was both more accurate than the ΔOD_{450nm} (85% as compared with 76%) and more sensitive (88% as compared with 76%). It was suggested by the authors that more than 50% of invasive procedures might be avoided using this technique.

In severely affected fetuses, hydrops may occur as early as 20 to 22 weeks' gestation. Measurement of the peak MCA Doppler can begin as early as 18 weeks but more commonly is initiated at approximately 24 weeks, then repeated every 1 to 2 weeks, with adjustment in normal velocity with advancing gestation age to define the risk of severe anemia (Figure 77-7). When the MCA Doppler exceeds 1.5 MoM (A Zone) between 24 and 35 weeks' gestation, cordocentesis is required for direct determination of hematocrit as well as fetal blood type, DAT, reticulocyte count, and total bilirubin (Figure 77-8) (Moise, 2008b). The rate of fetal trauma and morbidity associated with cordocentesis is less than 2% (Parer, 1988; van Kamp et al, 2005). Cordocentesis should be performed with blood available for intravascular intrauterine transfusion if necessary. Such blood should be type O, RhD negative, cytomegalovirus negative, and less than 72 hours from collection; extended crossmatch is often performed with maternal blood type. Irradiation is mandatory, and many centers also perform leukoreduction. The transfusion is generally administered at approximately 20 mL per kg estimated fetal weight with a target of 40 to 50% hematocrit. Beyond 35 weeks, amniocentesis to determine both fetal lung maturity and the ΔOD_{450nm} should be performed. Induction of delivery should be considered if lungs are mature in order to decrease the risk of needing subsequent

intrauterine transfusion with their attendant risks, or postnatal exchange transfusion for hyperbilirubinemia. For a full discussion and algorithm for management of pregnant patients with RhD alloimmunization, see Moise, 2008b.

Hyperbilirubinemia (with elevation of the conjugated fraction) often develops in newborns who have received intrauterine RBC transfusions and often predicts the need for exchange transfusions. This hyperbilirubinemia reflects the severity of hemolysis and its effects on the fetal liver. In some cases, anemia may be minimal or absent, and the DAT may be negative if the Rh-negative RBCs transfused prenatally still predominate. In such cases the infant may not require exchange transfusion. Neonatal exchange transfusion, amniocentesis, selective early induction of delivery, and intrauterine fetal blood transfusions all have contributed to the declining neonatal death rate from Rh incompatibility.

ABO Incompatibility

Hemolysis associated with ABO incompatibility is similar to Rh hemolytic disease in that maternal anti-A or anti-B antibodies enter the fetal circulation and react with A or B antigens on the erythrocyte surface (Table 77-5). In persons with type A and type B blood, naturally occurring anti-B and anti-A isoantibodies largely are IgM molecules that do not cross the placenta. In contrast, the alloantibodies present in persons with type O blood also include IgG antibodies that can traverse the placenta (Abelson and Rawson, 1961). For this reason, ABO incompatibility is largely limited to type O mothers with type A or B fetuses. The presence of IgG anti-A or anti-B antibodies in type O mothers also explains why hemolysis caused by ABO incompatibility frequently occurs during the first pregnancy without prior "sensitization." ABO incompatibility is present in approximately 12% of pregnancies, although evidence of fetal RBC sensitization (i.e., positive result on DAT) is found in only 3% of births, and less than 1% of live births are associated with significant hemolysis (Kaplan et al, 1976; Zipursky et al, 1963). The relative mildness of neonatal ABO hemolytic disease contrasts sharply with the findings in Rh incompatibility. In large part, this is because A and B antigens are present in many tissues besides RBCs; consequently, only a small fraction of anti-A or anti-B antibody that crosses the placenta actually binds to erythrocytes, the remainder being absorbed by other tissues and soluble A and B substances in plasma.

Although hemolytic disease resulting from ABO incompatibility is milder than Rh disease, severe hemolysis occasionally occurs. In suspected cases of ABO incompatibility, it is essential to exclude other antibodies and other nonimmune causes of hemolysis such as glucose-6-phosphate dehydrogenase (G6PD) deficiency or hereditary spherocytosis. In most cases, pallor and jaundice are minimal (see Table 77-5). Hepatosplenomegaly is uncommon. Laboratory features include evidence of minimal to moderate hyperbilirubinemia and, occasionally, some degree of anemia. The DAT sometimes is negative, although the indirect antiglobulin test (neonatal serum plus adult group A or B RBCs) more commonly is positive. This paradox is related to the fact that fetal RBCs, compared with adult erythrocytes, have less type-specific antigen on their surface (Voak and Williams, 1971). The peripheral blood smear is characterized by marked spherocytosis that is indistinguishable from that seen in hereditary spherocytosis (see Hereditary Spherocytosis, later).

TABLE 77-5 Clinical and Laboratory Features of Immune Hemolysis Due to Rh Disease and ABO Incompatibility

	Rh Disease	ABO Incompatibility
Clinical Features		
Frequency	Unusual	Common
Pallor	Marked	Minimal
Jaundice	Marked	Minimal to moderate
Hydrops	Common	Rare
Hepatosplenomegaly	Marked	Minimal
Laboratory Features		
Blood type		
Mother	Rh(–)	O
Infant	Rh(+)	A or B
Anemia	Marked	Minimal
Direct antiglobulin test	Positive	Frequently negative
Indirect antiglobulin test	Positive	Usually positive
Hyperbilirubinemia	Marked	Variable
RBC morphology	Nucleated RBCs	Spherocytes

RBC, Red blood cell.

Hemolysis in ABO incompatibility is usually mild, presenting with some degree of hyperbilirubinemia. Of major concern in the current cost-conscious health care environment is that some infants with ABO incompatibility may be discharged home from medical establishments before significant clinical jaundice is evident. It is critical that infants with ABO incompatibility be monitored closely for evolving jaundice and hyperbilirubinemia in the first few days of life. In most cases, hyperbilirubinemia is readily controlled by phototherapy. In the minority of cases not controlled by phototherapy, exchange transfusion with group O Rh-compatible RBCs is utilized. Additional follow-up at 2 to 3 weeks of age to check for anemia in these infants is essential.

Minor Blood Group Incompatibility

With the sharp decline of hemolytic disease caused by Rh incompatibility, the proportion of cases caused by Rh c, Rh E, Kell, Duffy, and Kidd incompatibility has increased from the previous estimates of 1% to 3%, to as high as 20% (for Kell sensitization) (Geifman-Holtzman et al, 1997; Moise, 2008a). The pathophysiology of these disorders is similar to that of Rh and ABO incompatibility. The infrequency of minor group incompatibility is primarily a reflection of the lower antigenicity of these RBC antigens. Diagnosis of minor group incompatibility is suggested by hemolytic anemia with a positive DAT in the absence of

ABO or Rh incompatibility and with a negative maternal DAT. Definitive diagnosis requires identification of the specific antibody in neonatal serum or an eluate from neonatal RBCs. This is readily accomplished by testing maternal serum against a variety of known RBC antigens. With some antibodies such as Kell, antibody titer and amniocentesis findings may underestimate the severity of fetal hemolysis.

Immune Hemolytic Anemia Due to Maternal Disease

Maternal autoimmune hemolytic anemia or lupus erythematosus during pregnancy may be associated with passive transfer of IgG antibody to the fetus. The diagnosis is suggested by the presence of neonatal hemolytic disease, a positive DAT, absence of Rh or ABO incompatibility, and antiglobulin-positive hemolysis in the mother. Treatment with prednisone in the mother may reduce both maternal hemolysis and the risk of neonatal morbidity. As in other cases of neonatal hemolysis, treatment is focused on prevention of severe hyperbilirubinemia and kernicterus.

NONIMMUNE ACQUIRED HEMOLYTIC DISEASE

Infection

Cytomegalic inclusion disease, toxoplasmosis, syphilis, and bacterial sepsis all can be associated with hemolytic anemia. In most of these conditions, some degree of thrombocytopenia also exists. Generally, hepatosplenomegaly is present. In cases of bacterial sepsis, both the direct and indirect bilirubin levels may be elevated. The mechanism of hemolysis associated with infection is not clearly defined. Documentation of infection as the cause of hemolysis is made by the presence of other clinical and laboratory evidence of neonatal infections. Hemolysis caused by infections may present early in the neonatal period, or it can be delayed for several weeks.

Schistocytic Anemias

Disseminated intravascular coagulation (DIC) is discussed in Chapter 76. The hemolytic component of this disorder is secondary to the deposition of fibrin within the vascular walls. When erythrocytes interact with fibrin, fragments of RBCs are broken off, producing fragile, deformed RBCs, or schistocytes. Abnormalities of the placental microcirculation or macrovascular anomalies such as an umbilical vein varix are rare causes of congenital schistocytic anemia (Batton et al, 2000).

HEREDITARY RED BLOOD CELL DISORDERS

Membrane Defects

The customary findings in RBC membrane disorders are the presence of dominant inheritance and abnormal RBC morphology (Figure 77-9). Aside from hereditary spherocytosis, these disorders are uncommon.

Hereditary Spherocytosis

The hallmark of hereditary spherocytosis (HS) is the presence of spherocytes in the peripheral blood smear. Inherited mutations in components of the membrane cytoskeleton (spectrin, ankyrin, or band 3) weaken the stability of the interactions between the cytoskeleton and the membrane lipid bilayer, promoting vesiculation and loss of bits of the bilayer, thus leading to progressive loss of membrane surface area (Gallagher and Glader, 2009). As RBCs become more spherical, they lose flexibility and become vulnerable to entrapment in the spleen and attack by macrophages, leading to hemolysis. Removal of the spleen after 5 years of age allows spherocytes to have a near-normal life span despite their cytoskeletal defects and abnormal shape.

The clinical manifestations of HS in neonates range from the very rare presentation of hydrops fetalis with fetal death (Gallagher et al, 1997) to fully compensated, lifelong hemolysis marked by reticulocytosis but no anemia (Gallagher and Glader, 2009). Twenty-eight percent to 43% of infants are anemic at birth (Hgb <15 gm/dL) (Perrotta et al, 2008). Neonatal hemolysis or hyperbilirubinemia appears in approximately half of all affected infants (Stamey and Diamond, 1957). In fact it is often the exaggerated neonatal hyperbilirubinemia that raises the suspicion of an underlying hemolytic disorder. In many cases, other family members are affected in a pattern consistent with autosomal dominant inheritance. In 20% to 30% of cases, recessive inheritance is noted, but only homozygotes express the clinical features of spherocytosis. Occasionally, the appearance of a new case of spherocytosis in a previously unaffected family is due to spontaneous mutation.

The diagnosis of HS is suspected when spherocytes are seen on the blood smear of an infant with hyperbilirubinemia or other laboratory evidence of hemolysis. Spherocytes also are seen in ABO incompatibility. Blood typing and a DAT may support the diagnosis of ABO incompatibility, but the DAT occasionally can be negative and thus misleading. In this situation, evaluation of the family for other persons affected with spherocytosis may point to a hereditary rather than an acquired cause. Sometimes it is necessary to wait until the infant is 3 months of age or so to obtain a definitive laboratory diagnosis of hereditary spherocytosis, because, by this age, the confounding effects of maternal antibody and fetal RBCs are no longer present. Supporting evidence of HS may be the "gold standard" of an abnormal osmotic fragility test or a newer method that uses flow cytometric analysis of eosin-5′-maleimide-labeled red blood cells, with lower fluorescence levels in spherocytosis patients reflecting lower total amounts of RBC band 3 protein (Girodon et al, 2008; King et al, 2000).

The mainstay of treatment during the newborn period is directed toward management of hyperbilirubinemia, which often is present and may not peak until the infant is several days of age. Occasionally, RBC transfusions are required in the neonatal period for management of symptomatic anemia (Gallagher et al, 1997). A common occurrence is the appearance of a transient but severe anemia during the first 20 days of life due to underproduction of

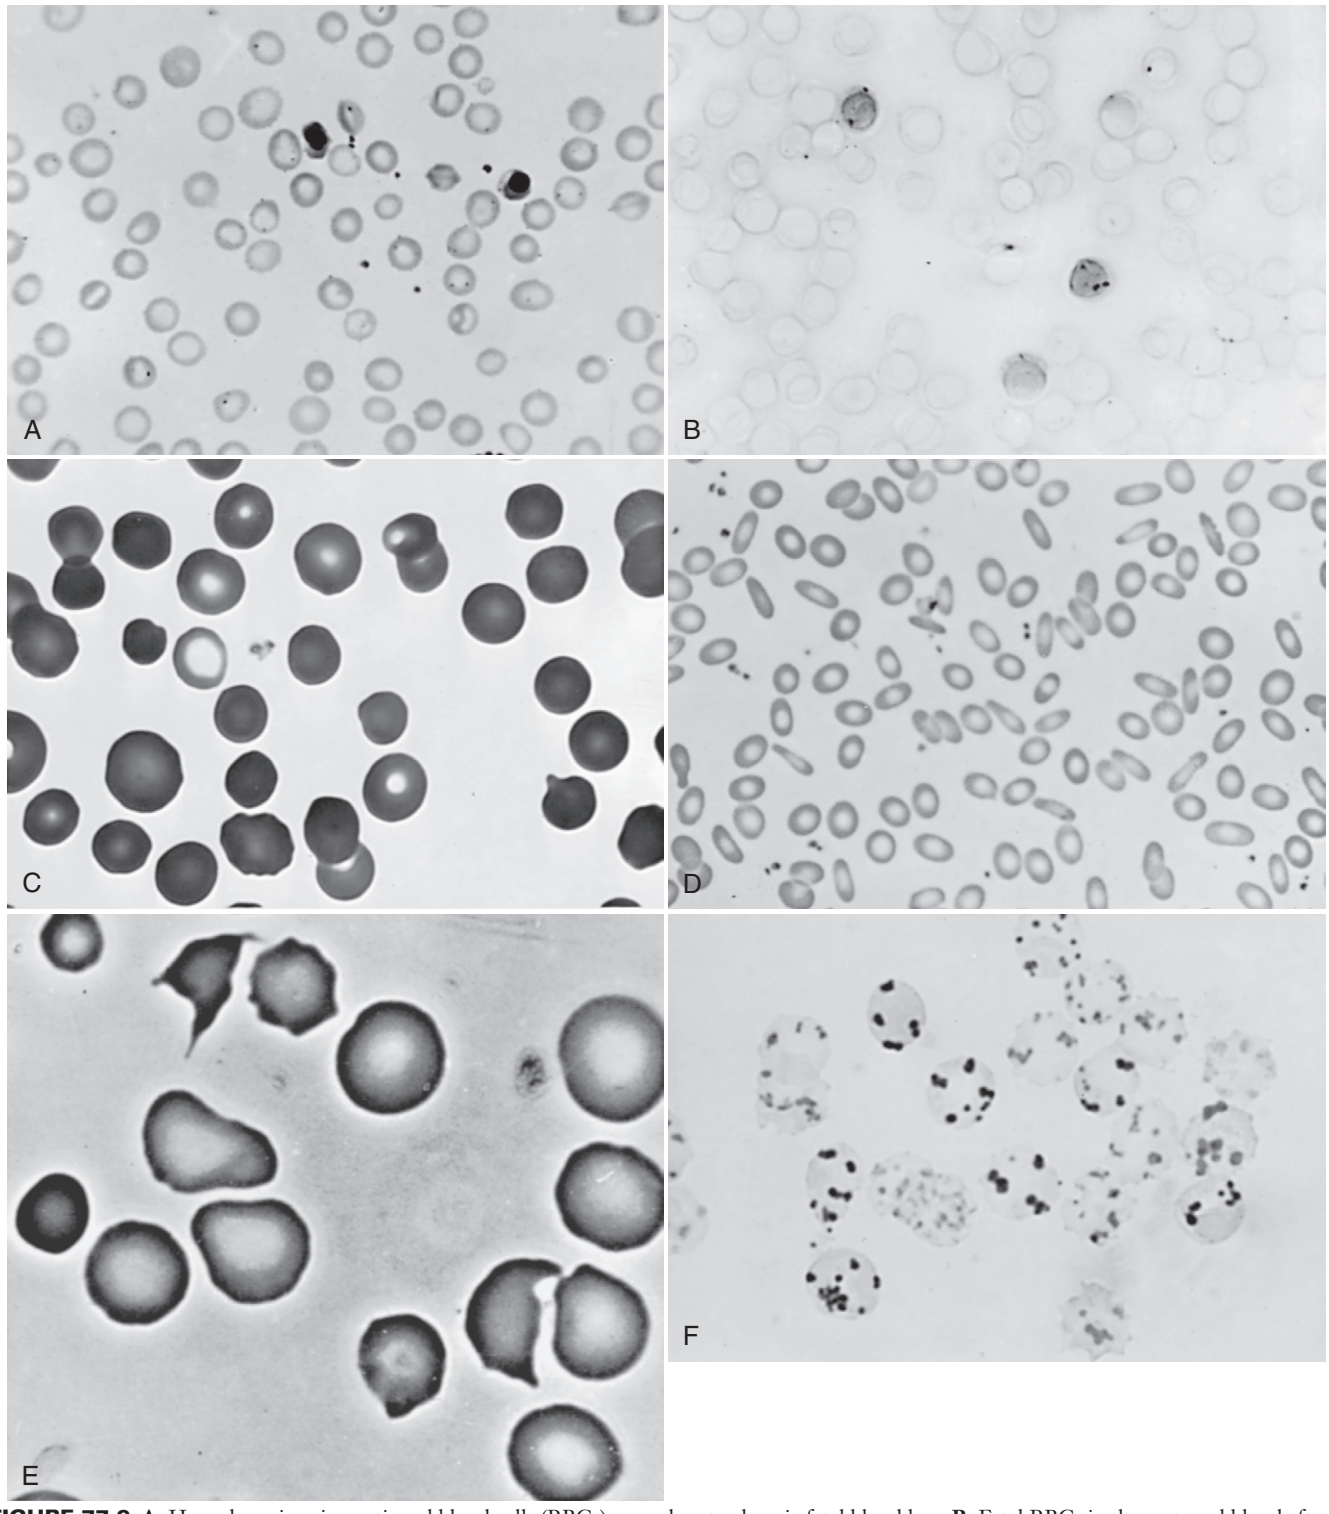

FIGURE 77-9 **A,** Hypochromic-microcytic red blood cells (RBCs) secondary to chronic fetal blood loss. **B,** Fetal RBCs in the maternal blood after a fetomaternal hemorrhage (acid-elution technique). **C,** Hereditary spherocytosis. **D,** Hereditary elliptocytosis. **E,** Glucose-6-phosphate dehydrogenase (G6PD)-deficient RBCs during acute hemolytic episode. **F,** Heinz bodies from a patient with G6PD-deficient hemolysis (stained with supravital dye).

erythropoietin in the face of continuing hemolysis (Delhommeau et al, 2000). Careful monitoring of affected infants after discharge from the nursery is warranted. Splenectomy is the definitive treatment for hereditary spherocytosis, but this is not recommended before 5 years of age because of the increased risk of overwhelming sepsis with encapsulated organisms such as *Streptococcus pneumoniae* (Diamond, 1969) that occurs following splenectomy in infants and young children. Guidelines regarding the indications for total or partial splenectomy have been reviewed (Bader-Meunier et al, 2001; Bolton-Maggs et al, 2004).

Hereditary Elliptocytosis

Hereditary elliptocytosis is an autosomal dominant, clinically heterogeneous group of disorders that are caused by mutations of the RBC membrane cytoskeletal proteins (usually spectrin or protein 4.1) that weaken skeletal protein interactions and increase RBC mechanical fragility (reviewed in Gallagher and Glader, 2009). Heterozygotes usually exhibit elliptocytes on the blood smear, but in the vast majority of instances hemolysis is absent. Homozygotes or compound heterozygotes may have sufficient weakening of the cytoskeleton to cause significant hemolysis accompanied by striking abnormalities in RBC morphology (homozygous hereditary elliptocytosis or hereditary pyropoikilocytosis).

Transient poikilocytosis and hemolysis may occur during the newborn period in infants destined ultimately to have asymptomatic elliptocytosis (Austin and Desforges, 1969). RBC membrane mechanical fragility is strikingly abnormal in these infants, probably as a consequence of the destabilizing influence of large amounts of free intraerythrocytic 2,3-DPG, a by product of the presence of fetal hemoglobin (Mentzer et al, 1987). As fetal hemoglobin levels decline postnatally in affected infants, membrane mechanical fragility lessens, hemolysis disappears, and RBC morphology undergoes a transition from poikilocytosis to elliptocytosis. Without knowledge of the membrane protein mutations present in the infant and the infant's family, it is difficult to predict at birth who will have transient poikilocytosis with ultimate recovery and who is destined to have lifelong pyropoikilocytosis with hemolysis. A practical approach to this problem is to wait 4 to 6 months to see if common HE evolves or chronic hemolysis with abnormally shaped RBCs persists.

Red Blood Cell Enzyme Abnormalities

Hyperbilirubinemia, anemia, and even hydrops fetalis can be the result of inherited RBC enzymopathies. The two most commonly encountered red cell enzyme disorders are glucose-6–phosphate dehydrogenase (G6PD) deficiency and pyruvate kinase (PK) deficiency. Overviews of these two disorders, as well as other more esoteric enzyme deficiencies, are available elsewhere (Glader 2009; Luzzato and Poggi, 2009; Mentzer, 2009) and the special features of RBC enzymopathies in the newborn period have also been summarized (Matthay and Mentzer, 1981).

Glucose-6-Phosphate Dehydrogenase Deficiency

G6PD deficiency is a sex-linked disorder that affects millions of people throughout the world, particularly in Mediterranean countries, the Middle East, Africa, and Asia. Like sickle cell trait and thalassemia, G6PD deficiency is thought to have become common because it provides a measure of protection against malaria. In most G6PD-deficient persons, hemolysis and anemia are present only episodically. Precipitating factors can include infection, exposure to medications that are potent oxidants, or to other agents such as fava beans, naphthalene, or certain petrochemical-derived substances. Rarely, hemolytic anemia is chronic rather than episodic and is present even in the absence of obvious exposure to oxidant stress. The clinical heterogeneity of G6PD deficiency is due to the different mutations, usually single amino acid substitutions, that lead to altered enzyme function (Beutler et al, 1996; Miwa and Fujii, 1996). Normal RBCs contain abundant amounts of reduced glutathione (GSH), a sulfhydryl-containing tripeptide that serves as an intracellular antioxidant, neutralizing oxidant drug metabolites and activated oxygen species released during phagocyte activation. Because of the enzyme deficiency, G6PD-deficient RBCs have a limited capacity to regenerate GSH from oxidized glutathione (Figure 77-10). In the absence of GSH, RBCs are vulnerable to oxidant injury of hemoglobin. Denatured globin precipitates termed *Heinz bodies* bind to the cell membrane, unfavorably altering its structure and function. Membrane lipid peroxidation may contribute to altered function. The ultimate result of these insults is hemolysis.

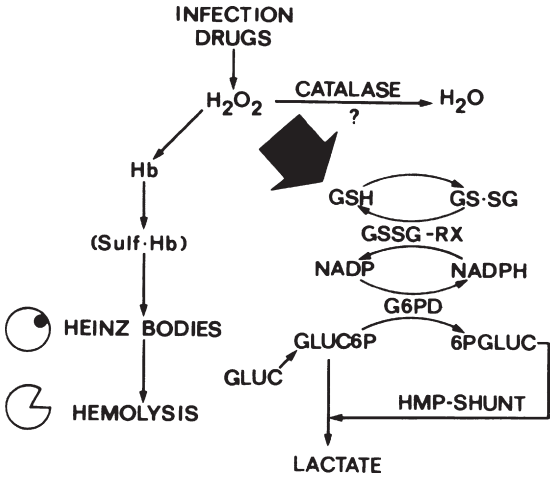

FIGURE 77-10 Glucose-6-phosphate hemolysis pathophysiology. *GSH*, Reduced glutathione; *GS-SG*, oxidized glutathione; *GSSG-RX*, glutathione reductase; *GLUC6P*, glucose-6-phosphate; *6PGLUC*, 6-phosphogluconate; *G6PD*, glucose-6-phosphate dehydrogenase; *HMP-SHUNT*, hexose monophosphate shunt.

The variant G6PD A– is responsible for nearly all of the G6PD deficiency seen in Africans (and is present in approximately 10% of African Americans). It previously was considered to be a single biochemical disorder, but is now known to be due to three different genotypes. G6PD A– affects the stability of the enzyme, causing an accelerated decline in activity during the life span of the RBC. Only in the oldest RBCs does enzyme activity reach low enough levels to create vulnerability to oxidant hemolysis. For this reason, hemolysis, if it occurs, is usually mild and self-limited. In contrast, in Asians and persons of Mediterranean or Middle Eastern descent, G6PD deficiency decreases the enzyme activity in young and old RBCs alike. Hemolysis is usually more severe and can be life threatening. It is of interest that the G6PD variants found throughout the Mediterranean and Middle East, once thought to be biochemically different, are now recognized to be due to one common single genotype. In these ethnic groups, inheritance of an as-yet-unidentified factor renders some G6PD-deficient persons susceptible to severe and even fatal episodes of hemolysis following exposure to fava beans (favism). The hemolytic factor

can be transmitted to neonates via breast milk (Kaplan et al, 1998). Favism is not seen in African-Americans with G6PD A–.

The gene for G6PD is located on the X chromosome. All of the RBCs of G6PD-deficient males are affected by the enzyme deficiency, whereas a variable fraction of RBCs of G6PD-deficient females are enzyme deficient, depending on the degree of lyonization (Lyon, 1961). Because of these differences, hemolysis due to G6PD deficiency occurs mainly in males and is much less common in females.

The diagnosis of G6PD deficiency is suggested by the appearance of a DAT-negative hemolytic anemia in association with infection or the administration of drugs. Cells that appear as if a bite had been taken from them (as a result of splenic removal of Heinz bodies) are occasionally seen on the peripheral blood smear. Supravital stains of the peripheral blood with crystal violet may reveal Heinz bodies during hemolytic episodes. Although screening tests are available, they are not as sensitive as direct assay of RBC G6PD activity. Measurement of enzyme activity may not reveal the deficiency in African Americans immediately after a hemolytic episode, because the population of enzyme-deficient cells has been eliminated. Repeating the assay at a later date is often necessary. Identification of specific G6PD mutations by DNA analysis is available, but rarely used for diagnostic purposes (Beutler, 1996; Miwa and Fujii, 1996).

In the neonatal period the major manifestation of G6PD deficiency is hyperbilirubinemia. There usually is more jaundice than anemia, and the anemia is rarely severe. Also, in contrast to classic Rh-related neonatal hyperbilirubinemia, neonatal jaundice due to G6PD deficiency rarely is present at birth, with clinical onset usually occurring between days 2 and 3 (Kaplan and Hammerman, 2004). Most infants with hyperbilirubinemia due to G6PD deficiency are of Mediterranean, Middle Eastern, or Asian descent.

In the majority of cases of neonatal hyperbilirubinemia due to G6PD deficiency, there is no obvious exposure to external oxidants. The degree of hyperbilirubinemia reflects both the increased bilirubin load presented to the liver by hemolysis of G6PD-deficient RBCs and the presence or absence of the variant form of UGT responsible for Gilbert syndrome (Kaplan et al, 2001). The relative importance of the latter is underscored by the observations that most jaundiced G6PD-deficient neonates are not anemic and that often, evidence for increased bilirubin production secondary to hemolysis is lacking (Kaplan et al, 1996, 1999).

The severity of jaundice varies widely, from being subclinical to imposing the threat of kernicterus if not treated (Johnson et al, 2009). Data from the USA Kernicterus Registry from 1992 to 2004 indicate that more than 30% of kernicterus cases are associated with G6PD deficiency. These observations have raised the question of whether testing for G6PD deficiency should be included in newborn screening programs worldwide (Kaplan and Hammerman, 2009). Neonatal screening for G6PD deficiency has been very effective in reducing the incidence of favism later in life in Sardinia (Meloni et al, 1992) and in other regions where this potentially fatal complication is common. Currently, only the District of Columbia in the United States requires such newborn screening.

Therapy for neonatal hemolysis and hyperbilirubinemia resulting from G6PD deficiency includes (1) phototherapy or exchange transfusion to prevent kernicterus, (2) RBC transfusion for symptomatic anemia, (3) removal of potential oxidants that may be contributing to hemolysis, and (4) treatment of infections using agents that do not themselves initiate hemolysis. In infants known to be G6PD deficient, prevention of severe hyperbilirubinemia by administration of a single intramuscular dose of tin-mesoporphyrin, an inhibitor of heme oxygenase, has been advocated (Kappas et al, 2001; Stevenson and Wong, 2010).

Pyruvate Kinase Deficiency

Pyruvate kinase (PK) deficiency is an autosomal recessive disorder that occurs in all ethnic groups. Although it is the most common of the Embden-Meyerhof glycolytic pathway defects, it is rare in comparison with G6PD deficiency. Hundreds of cases, mostly in northern Europeans, have been described in the literature, although many more unpublished cases also occur (Zanella and Bianchi, 2000). PK is one of the two enzymes that generate adenosine triphosphate (ATP) in RBCs. Because nonerythroid tissues have alternative means of generating ATP, clinical abnormalities in PK deficiency are limited to RBCs. More than 180 PK mutations have been defined at the nucleic acid level and many more in terms of abnormalities of the PK protein (Pissard et al, 2006; Zanella and Bianchi, 2000). Reflecting this genetic diversity, the hemolytic anemia that characterizes PK deficiency varies considerably in severity from family to family. Approximately one third of PK-deficient babies experience hyperbilirubinemia during the newborn period. Death or kernicterus may occur. Severe intrauterine anemia and hydrops fetalis have been reported (Zanella and Bianchi, 2000). In two recent cases, newborns with PK deficiency presented with neonatal cholestasis and developed progressive liver dysfunction leading to fatal hepatic failure (Raphaël et al, 2007).

The diagnosis of PK deficiency should be considered in a jaundiced newborn with evidence of nonimmune hemolysis in the absence of infection or exposure to hemolytic agents. Hemoglobinopathies and membrane disorders should be ruled out by examination of the blood smear and other appropriate diagnostic tests before proceeding to assay of RBC PK activity. RBC morphology is normal in PK deficiency, although a few dense cells with irregular margins (echinocytes) are occasionally seen. PK heterozygotes are clinically and hematologically normal but usually have roughly half the normal amount of RBC PK activity. When infants have been transfused before confirmation of diagnosis, the determination of RBC PK activity in parents may detect the heterozygous state and help lead to the diagnosis (Pissard et al, 2007).

Treatment of hyperbilirubinemia by phototherapy and exchange transfusion if necessary is usually the only therapy necessary in the newborn period. RBC transfusions for anemia occasionally are required. Splenectomy may reduce the rate of hemolysis but should be avoided in infancy and early childhood because of the high risk of infection after splenectomy.

HEMOLYSIS DUE TO HEMOGLOBIN DISORDERS

Beyond infancy the predominant hemoglobin tetramer is hemoglobin A (HbA), composed of two alpha globin chains and two beta globin chains ($\alpha_2\beta_2$). To appreciate the hemoglobinopathies that occur in newborns, however, it is necessary to understand the normal developmental changes that occur in globin synthesis during fetal and neonatal life. Embryonic hemoglobins are composed of zeta and epsilon chains. The transition from zeta to alpha globin chains is complete by the end of the first trimester. Epsilon chains disappear more slowly and are replaced first by gamma chains to form fetal hemoglobin (Hb F, $\alpha_2\gamma_2$) and next by beta chains to form hemoglobin A (Figure 77-11). The various possible combinations of these different globin chains form a number of different hemoglobin tetramers that are characteristically found in embryonic, fetal, and postnatal life (Figure 77-12).

Fetal hemoglobin is the major hemoglobin found in fetuses after the first trimester. Its replacement by adult hemoglobin A begins before birth, such that 60% to 90% of the hemoglobin found in the normal term infant is hemoglobin F. After birth, gamma chain synthesis declines rapidly as beta chain synthesis increases (see Figure 77-11) so that most newly formed hemoglobin is hemoglobin A. As RBCs made before birth are replaced postnatally, the percentage of hemoglobin F declines rapidly, reaching a level of approximately 5% by 6 months of age (Figure 77-13). Only trace amounts of the minor adult hemoglobin, hemoglobin A_2 ($\alpha_2\delta_2$), and hemoglobin Barts (γ_4) are present in cord blood. Hemoglobin Barts quickly disappears, whereas the hemoglobin A_2 level increases gradually to the adult level of 2% to 3% by 1 year of age.

Beta globin disorders such as sickle cell disease or beta-thalassemia major are not clinically apparent until several months of age, when the switch from hemoglobin F to hemoglobin A synthesis reveals the defect. In contrast, gamma globin mutations are most evident in fetal and neonatal life and then disappear by approximately 3 months of age as gamma globin synthesis wanes. Alpha globin disorders are evident at all stages of development from fetal to adult.

Thalassemia Syndromes

Thalassemias are due to absent or deficient synthesis of one normal globin chain, leading to a relative excess of the complementary or partner chain. For example, alpha-thalassemias are due to diminished synthesis of alpha globin chains, leading to an excess of beta chains (or, in the fetus, of gamma chains). The excess beta chains form tetramers (β_4 or hemoglobin H) that are unstable and can lead to hemolysis beyond infancy. The excess gamma chains also form tetramers (γ_4 or hemoglobin Barts) that have an increased affinity for oxygen but do not cause hemolysis. In beta-thalassemia, excess alpha globin chains accumulate, forming aggregates that injure the cell membrane, leading to hemolysis. In addition, the decrease in overall production of hemoglobin produces small RBCs (microcytosis) that are often filled with less than the normal amount of hemoglobin (hypochromia).

In the United States, changing immigration patterns have markedly increased the numbers of infants born with significant hemoglobinopathies. In California, analysis of newborn screening results between 1998 and 2006 demonstrated clinically significant hemoglobin genotypes in 0.05% of newborns; of these, the prevalence of alpha- and beta-thalassemia syndromes combined (28%) was almost as high as the prevalence of sickle cell disease (32%) (Michlitsch et al, 2009).

Alpha-Thalassemia

Alpha-thalassemia is of particular importance to neonatologists because its clinical manifestations are present in utero and at birth. The more severe forms of alpha-thalassemia are found in Southeast Asians (Glader and Look, 1996) and

TABLE 77-6 Alpha-Thalassemia Syndromes

		Anemia	Hemolysis	α:β Chain Synthesis	Abnormal Hemoglobins: Cord Blood	Abnormal Hemoglobins: Adult Blood
Normal	$\frac{\alpha/\alpha}{\alpha/\alpha}$	None	None	0.95–1.10	0%–1% γ_4	—
Silent carrier	$\frac{\alpha/-}{\alpha/\alpha}$	None	None	0.85–0.95	1%–2% γ_4	—
Alpha-thalassemia trait	$\frac{-/-}{\alpha/\alpha}$	Mild hypochromic Microcytic	None	0.72–0.82	5%–6% γ_4	—
Hemoglobin "H" disease	$\frac{-/-}{\alpha/-}$	Moderate hypochromic Microcytic	Moderate	0.30–0.52	20%–40% γ_4 0%–5% β_4	20%–40% β_4

less commonly in infants of Mediterranean origin, and are rare in Africans. The molecular basis for alpha-thalassemia is usually deletion of one or more of the four alpha globin genes. A thalassemic hemoglobinopathy involving the abnormal hemoglobin Constant Spring also may behave functionally as a mild form of alpha-thalassemia. Clinical severity is dictated by how many alpha globin genes are absent or nonfunctional. An infant can inherit no, one, or two alpha-thalassemia genes from each parent, giving rise to the following four clinical syndromes:

1. *Silent carrier state*. Deletion or nonfunction of a single alpha globin gene is not accompanied by any clinical or hematologic abnormalities.
2. *Alpha-thalassemia trait*. Deletion or nonfunction of two alpha globin genes, in *cis* (Asians) or *trans* (Africans), is associated with mild microcytic anemia, without hemolysis or reticulocytosis.
3. *Hemoglobin H disease*. When three of four alpha globin genes are deleted or nonfunctional, a mild to moderate hemolytic anemia is found, often aggravated by oxidant stresses just as in G6PD deficiency. The RBCs are hypochromic and microcytic and contain inclusions of hemoglobin H when appropriate staining is performed. Hemoglobin H Constant Spring can be a particularly severe syndrome with up to one third requiring regular transfusions (Vichinsky et al, 2005)
4. *Homozygous alpha-thalassemia*. Lack of all four alpha globin genes is associated with a severe intrauterine hemolytic anemia and hydrops fetalis, with massive hepatosplenomegaly, and, in most instances, fetal demise. The RBCs are very hypochromic, fragmented, and bizarre in shape. Erythroblastosis is present (Chui and Waye, 1998).

The diagnosis of the alpha-thalassemia syndromes is easily made during the newborn period by correlation of the clinical and hematologic appearance of the child with the amount of hemoglobin Barts (γ_4) present in the RBCs (Lorey et al, 2000) (Table 77-6). Screening of all newborns for hemoglobin H disease is justified in populations with a substantial number of at-risk pregnancies (Lorey et al, 2000; Michlitsch et al, 2009). The large amount of hemoglobin Barts found in the RBCs of homozygotes for alpha-thalassemia contributes to the clinical severity of the syndrome, because the increased oxygen affinity of this hemoglobin impairs oxygen release to the tissues. DNA-based diagnostic tests are available for prenatal diagnosis, which is often carried out when a pregnancy at risk for a fetus with homozygous alpha-thalassemia is identified (Chui and Waye, 1998). The increased risk of eclampsia in mothers of such fetuses is an important justification for early identification and termination of the pregnancy.

No treatment is needed for the silent carrier state or for alpha-thalassemia trait, but studies to determine the thalassemia status of other family members, particularly those in their reproductive years, are recommended so that genetic counseling (and prenatal diagnosis if indicated) can be provided. Parents of infants who have hemoglobin H disease should be instructed to avoid oxidant agents that can cause hemolysis (the same list that is given to patients with G6PD deficiency). Although these infants are usually only mildly anemic, they may experience severe episodes of hemolysis during infections or with exposure to oxidant agents. Fetuses with homozygous alpha-thalassemia that are not aborted are usually stillborn. A few affected children have been born alive and resuscitated (Lee et al, 2007), or supported with in utero transfusion before delivery (Sohan et al, 2002). Although such infants can subsequently receive chronic RBC transfusions, and a small number have undergone bone marrow transplantation (Yi et al, 2009), the long-term outcome for such infants is uncertain.

Beta-Thalassemia

Like alpha-thalassemia, beta-thalassemia is found in regions of the world where malaria was formerly endemic: Southeast Asia, India, Africa, and the Mediterranean basin. Although deletion of the beta globin locus is an occasional cause of beta-thalassemia, most cases are caused by point mutations that affect transcription, messenger RNA (mRNA) processing, or translation (Cunningham et al, 2009; Galanello, 1995; Olivieri, 1999). Two

general types of beta-thalassemia are recognized. In beta^0-thalassemia, no beta globin at all is produced by the thalassemic locus, whereas in beta$^+$-thalassemia, there is reduced but measurable output of beta globin. The severity of homozygous beta-thalassemia (or beta-thalassemia major) is greatest when two beta^0-thalassemia genes are inherited; clinical disease usually is much milder when two beta$^+$-thalassemia genes are inherited. By contrast, the inheritance of one thalassemia gene (beta thalassemia trait) is characterized by a mild microcytic anemia that needs to be distinguished from alpha thalassemia and iron deficiency. Severe beta-thalassemia is associated with lifelong hemolytic anemia, dependence on regular RBC transfusions for survival, and the gradual development of transfusion-associated hemosiderosis (Olivieri, 1999). Survival has improved, however, with improvements in iron chelation and with the use of hematopoietic stem cell transplantation for patients with available matched donors (Cunningham, 2008, Rund and Rachmilewitz, 2005).

The clinical abnormalities of beta-thalassemia are not evident at birth but first manifest only after 3 months of age, when beta globin normally becomes the dominant form of non-alpha globin synthesized. Although affected newborns appear clinically normal, the diagnosis of beta^0-thalassemia can be made at birth by detecting a complete absence of hemoglobin A, using hemoglobin electrophoresis or similar techniques. Definitive diagnosis of beta$^+$-thalassemia by these techniques, however, is not possible in the newborn period, because the reduced amount of hemoglobin A produced overlaps the range for normal babies. Direct identification of beta-thalassemia mutations by DNA diagnostic techniques is increasingly available and allows the identification at birth of all infants with beta-thalassemia major. These techniques, however, are more commonly used for prenatal diagnosis of beta-thalassemia syndromes. DNA can be obtained during midtrimester from fetal amniocytes (15 to 17 weeks) or during the first trimester from chorionic villi (9 to 11 weeks), and the assay is completed within a few days, allowing families to make informed decisions regarding termination of pregnancy (Kazazian and Boehm, 1988). The implementation of a strategy of carrier detection, genetic counseling, and prenatal diagnosis in countries where beta-thalassemia is common has led to a striking reduction in the number of births of infants with beta-thalassemia major (Cao et al, 1996). More recent advances have included preimplantation genetic diagnosis (Harteveld et al, 2009).

Hemoglobin E/Beta-Thalassemia

Hemoglobin E is a structurally abnormal hemoglobin that results from an amino acid substitution (lysine for glutamine) at the number 26 amino acid of beta globin, counting from the N terminus. Because this mutation also adversely affects mRNA processing, there is reduced output of beta globin mRNA. Hemoglobin E trait is therefore an example of a thalassemic hemoglobinopathy. Hemoglobin E carriers are microcytic but not anemic. Even hemoglobin E homozygotes have little or no anemia. However, coinheritance of hemoglobin E trait and beta^0-thalassemia trait can give rise to a transfusion-dependent form of beta-thalassemia major (Oliveri et al, 2008). As with other types of beta-thalassemia major, clinical abnormalities are not seen until the infant is 3 to 6 months of age. However, the presence of hemoglobin E is easily detected at birth by hemoglobin electrophoresis or related techniques. Infants found to have hemoglobin E need careful follow-up evaluation to exclude the possibility of hemoglobin E beta-thalassemia. DNA-based detection of the hemoglobin E mutation is feasible (Embury et al, 1990) and has been applied to both prenatal and neonatal diagnosis. Infants born to mothers with hemoglobin E beta-thalassemia have a higher risk of preterm birth, low birthweight, and fetal growth restriction (Luewan et al, 2009).

Gamma-Thalassemia

Large deletions within the beta globin gene cluster may remove both gamma globin genes ($^A\gamma$ and $^G\gamma$) as well as the delta and beta globin genes. The resulting gamma-delta-beta-thalassemia is lethal in the homozygous state but in the heterozygote produces a transient but moderately severe microcytic anemia in the newborn. Over the first few months of life, the anemia resolves to a variable extent without specific therapy, and eventually the hematologic picture is that of beta-thalassemia trait. Several different gamma-delta-beta deletions have been reported, all but one in families of European origin (Cunningham et al, 2009).

Sickle Cell Disease

The sickling hemoglobinopathies are beta globin mutations that, as with beta-thalassemia, do not become clinically evident until the infant reaches several months of age. Sickle cell anemia, the most severe of the disorders, is the result of inheritance of two beta^S mutations (substitution of valine for glutamic acid at the sixth amino acid on the beta globin chain), one from each parent. Sickle-beta^0-thalassemia, phenotypically identical to sickle cell anemia, is caused by inheritance of one beta^S and one beta-thalassemia mutation. The third common form of sickle cell disease, hemoglobin S-C disease, is somewhat milder than sickle cell anemia or sickle-beta^0-thalassemia. It is the consequence of inheritance of one beta^S mutation and one beta^C mutation (the substitution of lysine for glutamic acid at the sixth amino acid on the beta globin chain). Although no clinical abnormalities are present at birth, early diagnosis is important, because two potentially fatal but largely preventable complications may occur during the 1st year of life (Lenfant, 2002). The first is the splenic sequestration crisis, an unpredictable pooling of large numbers of RBCs in the spleen, which leads to a rapid decrease in hematocrit and, in the most severe cases, cardiovascular collapse and death. The second is overwhelming septicemia, usually caused by *S. pneumoniae*. The unusually high susceptibility to infection with encapsulated organisms such as *S. pneumoniae* is the consequence of functional asplenia, which commonly appears by 1 year of age in infants with sickle cell anemia or sickle-beta^0-thalassemia (but not until later in persons with hemoglobin S-C disease). Prompt treatment of splenic sequestration with RBC transfusions is life saving, so parents are taught to recognize early manifestations such as splenic enlargement, lethargy, or pallor.

Overwhelming sepsis can be prevented in most instances by early immunization with *Haemophilus influenzae* and conjugated pneumococcal vaccines, beginning at 2 months of age, and by institution of daily prophylactic penicillin at a dose of 125 mg twice daily (Gaston et al, 1986). It is the need to institute these prophylactic measures within the first 1 to 2 months of life that provides a compelling rationale for neonatal diagnosis of the sickling disorders. Recent data regarding the impact of these interventions have confirmed a 68% reduction in mortality from sickle cell disease for children ages 0 to 3, between 1983 and 1986 and between 1999 and 2002 (Yanni et al, 2009). In many states, all newborns are screened for these disorders, whereas in others, only high-risk ethnic groups are targeted. Usually a dried sample of blood on filter paper, collected at the same time as for other screening tests for inherited metabolic disorders, is used, but cord blood also is satisfactory. Tests that quantitate the amount of hemoglobin S, such as high-performance liquid chromatography, thin-layer isoelectric focusing, or electrophoresis on both cellulose acetate (in an alkaline buffer) and citrate agar (in an acid buffer), are valid. However, sickle solubility tests or the sodium metabisulfate "sickle prep" are not good tests because they do not clearly distinguish sickle cell disease from sickle cell trait; also, the tests are not sensitive enough to detect reliably the small percentage of hemoglobin S present in the RBCs of the newborn.

An excellent overview of issues related to newborn screening for sickle cell disease has been published by Wethers et al (1989). Extensive experience with mandatory statewide screening for all infants has been accumulated in New York (Diaz-Barrios, 1989), California (Lorey et al, 1996), and elsewhere (Wethers et al, 1989). Today, all 50 states screen for sickle cell disease (Michlitsch et al, 2009).

Infants without a hemoglobinopathy born to mothers with sickle cell disease present more of a clinical problem during gestation and the neonatal period than is the case with infants who actually have sickle cell disease. Low birthweight occurs in 28% to 42% of pregnancies (Smith et al, 1996; Thame et al, 2007) and has been correlated with gestational age and placental weight. Asymmetric growth restriction is frequent, as is intrauterine growth restriction (present in approximately 15% of cases). Spontaneous abortion, stillbirth (in 6% to 10%), preterm labor and delivery, and perinatal mortality (in approximately 15%) all are more frequent in the infants of mothers with sickle cell anemia. These problems may be traced to abnormalities of the placenta such as small size, infarction, and an increased incidence of placenta previa and abruptio placentae, which appears to be the consequence of sickle vaso-occlusive events within the maternal side of the placental circulation. They are not caused by the presence of the sickle trait, beta-thalassemia trait, or hemoglobin C trait in the infant, because no hematologic disease is associated with the carrier state for these mutations, even in adult life when they are fully expressed, except under conditions of extreme hypoxia.

One caveat regarding sickle trait blood is that blood from an adult donor who has sickle trait should not be used for exchange transfusions in the newborn, particularly if hypoxemia is present, because use of sickle trait RBCs in this setting may contribute to a fatal outcome (Veiga and Vaithianathan, 1963).

HYPOPLASTIC ANEMIA

Diamond-Blackfan Anemia

The two major causes of RBC aplasia in children are Diamond-Blackfan anemia (DBA) and transient erythroblastopenia of childhood (TEC). The latter condition, TEC, is a disease that rarely occurs before 6 months of age (Miller and Berman, 1994; Ware and Kinney, 1991), and most children with this disorder are older infants or young children. In contrast, many infants with DBA are anemic at birth or become so in the first months of life.

Also known as *congenital hypoplastic anemia*, DBA is a red cell aplasia characterized by the absence of recognizable erythroid precursor cells in the bone marrow (Lipton and Ellis, 2009). It is now considered to be a disorder of ribosome biogenesis (Dianzani and Loreni, 2008) that results in profound erythroid hypoplasia because erythroid progenitors and precursors are highly sensitive to apoptotic cell death. Although many cases are sporadic, familial, autosomal-dominant DBA has recently been estimated to account for up to 45% of cases (Orfali et al, 2004). At least 11 different ribosomal protein gene mutations have been identified in DBA patients. Approximately 25% of these are due to mutations in RPS19 on chromosome 19q (Gustavsson et al, 1997). Recent studies have identified that a significant fraction of DBA cases are linked to genes on chromosome 8p (Gazda et al, 2001). Work is ongoing to fully elucidate the relationship of these abnormalities to the pathophysiology of DBA. A working ribosomal stress hypothesis proposes that p53 is activated because of decreased ribosome protein synthesis, which leads to cell cycle arrest or apoptosis and ultimately anemia, poor growth, and congenital malformations.

Anemia is lifelong, but the onset of the disease is variable. Many affected infants are severely anemic in the newborn period, and pallor at birth or soon thereafter has been a feature of the disease in most cases. Fetal growth restriction, skeletal abnormalities, or other congenital anomalies are seen in almost one third of patients. The diagnosis of DBA is suggested by anemia and reticulocytopenia appearing in the first 6 months of life. Certain unusual features of the RBCs (macrocytosis, elevated fetal hemoglobin, increased adenosine deaminase activity) may assist in diagnosis. Also, tests for many of the DBA gene mutations are available in commercial gene diagnostic laboratories.

Many patients achieve durable remissions from anemia when treated with corticosteroids. Those who do not respond to corticosteroids require chronic RBC transfusions and are at risk of transfusion hemosiderosis. Transfusion-dependent DBA can be cured by allogeneic bone marrow transplantation from HLA-compatible siblings (Lipton et al 2006; Roy et al, 2005). The incidence of cancer is probably increased in DBA patients, based on cases reported to the Diamond Blackfan Anemia Registry (Lipton and Ellis, 2009). Although a variety of solid tumors, in particular an increased incidence of osteogenic sarcoma, have been reported, the most common malignancy

TABLE 77-7 Hemoglobin Changes During the First Year of Life

Week	Term	Premature (1.2–2.5 kg)	Premature (<1.2 kg)
0	17.0 (14.0–20.0)*	16.4 (13.5–19.0)	16.0 (13.0–18.0)
1	18.8	16.0	14.8
3	15.9	13.5	13.4
6	12.7	10.7	9.7
10	11.4	9.8	8.5
20	12.0	10.4	9.0
50	12.0	11.5	11.0
Lowest hemoglobin: mean (range)	10.3 (9.5–11.0)	9.0 (8.0–10.0)	7.1 (6.5–9.0)
Time of nadir	6–12 wk	5–10 wk	4–8 wk

*Hemoglobin concentration (g/100 mL).

reported in the registry and the published medical literature has been acute myeloid leukemia.

PHYSIOLOGIC ANEMIA OF INFANCY AND PREMATURITY

At birth, the mean hemoglobin of term infants (17 g/100 mL) is slightly greater than in premature infants (16 g/100 mL). The hemoglobin concentration in term infants subsequently decreases to a plateau at which it remains throughout the first year of life (Table 77-7). Termed *physiologic anemia of infancy*, this anemia characterized by low (relative to adult values) hemoglobin is a normal part of development and has no adverse clinical effects. A similar process (*anemia of prematurity*) occurs in premature infants, but the hemoglobin decreases more rapidly and reaches a lower nadir. After 1 year of age, there is little difference between the hemoglobin values of term and premature infants.

Physiologic Anemia of Infancy

With the onset of respirations at birth, considerably more oxygen is available for binding to hemoglobin, and the hemoglobin-oxygen saturation increases from approximately 50% to 95% or more. Furthermore, the normal developmental switch from fetal to adult hemoglobin synthesis actively replaces high-oxygen-affinity fetal hemoglobin with lower-oxygen-affinity adult hemoglobin, which can deliver a greater fraction of hemoglobin-bound oxygen to the tissues. Therefore, immediately after birth the increase in blood oxygen content and tissue oxygen delivery downregulates erythropoietin production; as a consequence, erythropoiesis is suppressed. In the absence of erythropoiesis, hemoglobin levels decrease because there is no replacement of aged RBCs as they are normally removed from the circulation. Iron from degraded RBCs is stored for future hemoglobin synthesis. The hemoglobin concentration continues to decrease until tissue oxygen needs are greater than oxygen delivery. Normally, this point is reached between 6 and 12 weeks of age, when the hemoglobin concentration is 9.5 to 11 g/dL. This physiologic hemoglobin decrease does not represent anemia in the true sense of the term; rather, it is a normal adjustment reflecting the presence of excess capability for oxygen delivery relative to tissue oxygen requirements. It is unnecessary to administer iron during this period, because it does not prevent the physiologic decrease in hemoglobin, and any iron administered is added to stores for future use. As hypoxia is detected by renal or hepatic oxygen sensors, erythropoietin production increases and erythropoiesis resumes. The iron previously stored in reticuloendothelial tissues can then be used for hemoglobin synthesis and is typically sufficient for hemoglobin synthesis, even in the absence of dietary iron intake, until approximately 20 weeks of age. In fact, the American Academy of Pediatrics recommendation that any cow milk or soy formula used to supplement breast milk be iron-fortified has the goal of preventing the late iron deficiency that can occur when the shift is made to the typical cow's-milk–based, iron-poor diet of later infancy and toddlerhood (American Academy of Pediatrics, 1999).

Anemia of Prematurity

The physiologic anemia seen in preterm infants is more profound and occurs earlier (see Table 77-7). Because symptoms may occur, the anemia of prematurity is considered nonphysiologic. The cause of anemia is multifaceted. The lower hemoglobin may be in part a physiologic response to the lower oxygen consumption in premature infants compared with that in term infants, a consequence of their diminished metabolic oxygen needs (Mestyan et al, 1964). An important component in the first few weeks of life is blood loss due to sampling for the many laboratory tests necessary to stabilize the clinical status of these infants, particularly those with cardiorespiratory problems. The erythropoietic response to anemia also is suboptimal, a significant problem because demands on erythropoiesis are heightened by the short survival of the RBCs of premature infants (approximately 40 to 60 days instead of 120 days as in adults) and the rapid expansion of the RBC mass that accompanies growth. The basis for suboptimal erythropoiesis in prematurity appears to be inadequate synthesis of erythropoietin in response to hypoxia. Figure 77-14 illustrates the magnitude of the deficiency, which, as shown by Stockman et al (1984), is greatest in the smallest, least mature infants. Because the liver is the predominant source of erythropoietin during fetal life, it has been proposed that relative insensitivity of the hepatic oxygen sensor to hypoxia explains the blunted

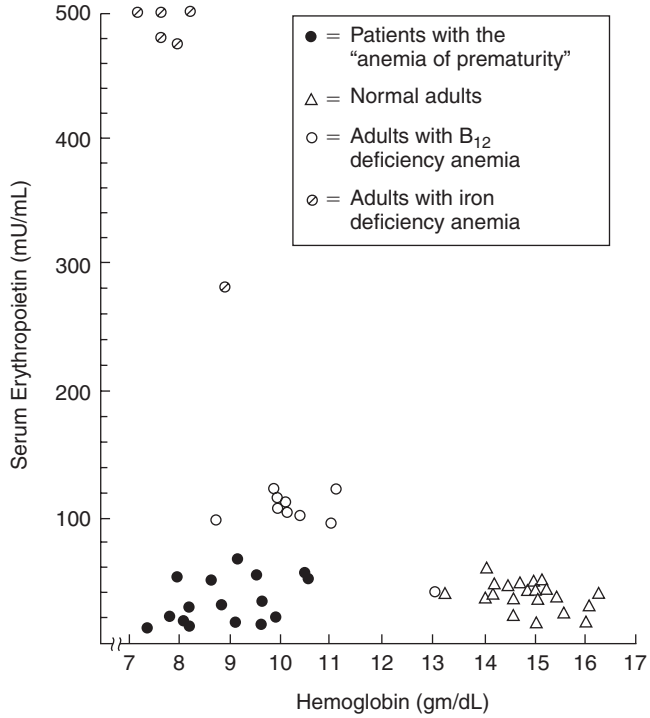

FIGURE 77-14 Hemoglobin levels and corresponding serum erythropoietin levels are shown. Values are from infants with the anemia of prematurity, normal adults, adults with vitamin B_{12} deficiency anemia, and adults with iron deficiency anemia. *(From Ross MP, Christensen RD, Rothstein G, et al: A randomized trial to develop criteria for administering erythrocyte transfusions to anemic preterm infants 1 to 3 months of age,* J Perinatol *9:246-253, 1989. Reprinted by permission of Appleton & Lange, Inc.)*

erythropoietin response seen in premature infants (Dallman, 1993). The spontaneous resolution of the anemia that occurs by approximately 40 weeks' gestational age is in keeping with a developmental switch from the relatively insensitive hepatic oxygen sensor to the renal oxygen sensor, which is exquisitely sensitive to hypoxia, because by this time the predominant site of erythropoietin synthesis has shifted to the kidneys. The problem does not lie with altered sensitivity of erythroid progenitors to erythropoietin because this has been shown to be normal (Shannon et al, 1987).

The anemia of prematurity occurs even in nutritionally replete infants, but it may be heightened by deficiencies of folate, vitamin B_{12}, or vitamin E (Worthington-White et al, 1994). Premature infants are endowed at birth with significantly less vitamin E than is present in term infants, and unless supplemental vitamin E is provided, this deficiency state persists for 2 to 3 months. Vitamin E is an antioxidant compound vital to the integrity of erythrocytes, and in its absence, these cells are susceptible to lipid peroxidation and membrane injury. One clinical consequence of vitamin E deficiency is that hemolytic anemia can occur in small premature infants (weighing less than 1500 g) at 6 to 10 weeks of age (Oski and Barness, 1967; Ritchie et al, 1968). This hemolytic anemia, which is characterized by reduced vitamin E levels and increased RBC peroxide hemolysis, rapidly disappears following vitamin E administration. A logical conclusion is that vitamin E deficiency might contribute to the anemia of prematurity in a more general sense. In fact, premature infants given daily vitamin E (15 IU/day) had higher hemoglobin levels and lower reticulocyte levels than a control group not given the vitamin (Oski and Barness, 1967). However, more recent studies found no hematologic benefit for the administration of 25 IU or 50 IU of vitamin E daily to premature infants (Pathak et al, 2003; Zipursky et al, 1987). A recent Cochrane review of the use of vitamin E in preterm infants suggested that routine vitamin E supplementation increased the hemoglobin concentration by a significant but small amount (Brion et al, 2003). In very low-birthweight infants, there was a decreased risk of retinopathy and blindness but increased risk of sepsis. This review concludes that the routine use of high-dose intravenous vitamin E, or to achieve tocopherol levels greater than 3.5 mg/dL, is not supported by evidence. Although it has become standard practice to administer vitamin E to all premature infants, the hemoglobin nadir in these babies is still lower than that in term newborns, indicating that anemia is largely caused by other factors such as erythropoietin deficiency.

The optimum management of anemia of prematurity requiring intervention beyond nutritional and vitamin support remains controversial (Bishara and Ohls, 2009; Strauss, 2006; Von Kohorn and Ehrenhranz, 2009). Primary questions include the role of erythropoietin and the application of liberal versus restrictive transfusion thresholds.

TREATMENT OF ANEMIA OF PREMATURITY WITH RECOMBINANT HUMAN ERYTHROPOIETIN

Because a relative deficiency of erythropoietin is present in the anemia of prematurity, a number of studies have evaluated the safety and efficacy of rHuEPO therapy in this setting. The optimal timing for initiation of rHuEPO therapy and the optimal dose have yet to be determined. Trials have used two different timing strategies: early treatment (before 8 days of age) and "late" treatment. The former has the goal of preventing anemia of prematurity, whereas the latter aims to treat anemia of prematurity and decrease transfusions after the acute stage. Although many studies have shown a modest decrease in RBC transfusion with either approach, there have not been significant differences between these two practices (Aher and Ohlsson, 2006; Kotto-Kome et al, 2004). Although infants require relatively high doses of rHuEPO/kg compared to adults because of more rapid clearance and higher volume of distribution, a trial of high dose (1500 unit/kg/wk) as compared to low dose (750 u/kg/wk) resulted in no difference in transfusion requirement (Maier et al, 1998). Even in very small premature infants (less than 1300 g birthweight) with the highest likelihood of needing a transfusion, the effects are minimal, except in infants with birthweight <1000 g. (Meyer et al, 2003). To optimize response to rHuEPO, infants must have adequate protein intake, receive vitamin E, and receive iron supplementation. To achieve the best results, supplemental oral iron at a dose of at least 6 to 9 mg/kg per day needs to be administered. It may be possible to use parenteral iron supplements, particularly in young very low-birthweight infants who are not able to take oral iron (Heese et al, 1990) or as a supplement to oral iron (Pollak et al, 2001).

A metaanalysis of 21 prospective controlled trials of rHuEPO treatment of the anemia of prematurity was published (Vamvakas and Strauss, 2001). Although there was considerable variation between studies, in general the efficacy of rHuEPO in reducing the need for red cell transfusions was modest. The authors concluded that it was premature to recommend rHuEPO for standard therapy for the anemia of prematurity. Given the current standard of using dedicated RBC-unit transfusion strategies, a modest rHuEPO effect is less likely to decrease the chance of exposure to multiple blood donors; in that case, the reduction of mL/kg/patient transfused or number of transfusions is less important. At this point, there is wide variation in the use of rHuEPO for very low-birthweight infants in the United States (Von Kohorn and Ehrenkranz, 2009). There is disagreement regarding the cost-benefit ratio of rHuEPO therapy (Maier et al, 1994; Shireman et al, 1994; Wandstrat and Kaplan, 1995; Zipursky, 2000).

Although recent studies in adults have raised questions about the safety of rHuEPO and have led to reductions in its use in patients with malignancy and with renal insufficiency, there are no definitive data supporting safety concerns in premature infants. Previous questions regarding neutropenia and retinopathy of prematurity have not been borne out as significant. In fact, recent interest in potential neuroprotective effects of rHuEPO has led to careful testing of three different high doses of rHuEPO in extremely low-birthweight infants ≤1000 g and ≤28 weeks of age (Juul et al, 2008). Erythropoietin treatment may have a particularly important role to play in the management of infants whose parents refuse to allow blood transfusions on religious grounds (Davis et al, 1991).

RED BLOOD CELL TRANSFUSION THERAPY IN PREMATURE INFANTS

As recently as 1991, it was estimated that of the approximately 38,000 infants born weighing less than 1500 g in the United States each year, 80% received multiple RBC transfusions (Strauss, 1991). Most transfusions given in the first several weeks of life are to replace losses from phlebotomy required for laboratory monitoring during ventilator support and other intensive care measures. After the first few weeks of life, most transfusions are given to treat the symptoms of anemia of prematurity. The risks associated with use of allogeneic RBC transfusion in premature infants include exposure to viral infections, graft-versus-host disease, electrolyte and acid-base imbalances, exposure to plasticizers, hemolysis when T antigen activation of RBCs has occurred, and immunosuppression (Strauss, 1991).
