1. Cut a piece of chromatographic support material: Whatman 3-mm chromatography paper, silica gel-coated plastic TLC sheets, or silica gel-impregnated glass fibre (ITLC) approximately 1 × 10 cm in size. Make a faint pencil mark 1.5 cm from one end.
2. Pour enough 85% methanol into a 10- to 15-cm-tall glass beaker or similar container until it is 0.5 cm deep. Cover the beaker with a petri dish lid, aluminium foil, or similar.
3. Place a 1-µl spot of the sample to be analysed onto the centre of the pencil mark on the chromatographic strip and allow it to dry.

4. Using forceps, gently place the strip upright in the beaker with the pencil mark at the lower end just above the solvent level. Cover the beaker and allow the solvent to run up the support material.
5. When the solvent is about 5 mm from the top of the strip, remove it from the beaker using forceps and lay it on a clean piece of tissue to dry.
6. Cut the strip into upper and lower halves, place each half into counting tubes, and count the tubes in a gamma counter.
7. Calculate the labelling efficiency as follows:

$$\%\ \text{Labelling efficiency} = \frac{\text{Radioactive counts on lower half of strip}}{\text{Counts on lower half counts on upper half}} \times 100\%$$

F. Measurement of the Immunoreactive Fraction of Radiolabelled Antibody

This assay has been adapted from a method published by Lindmo *et al*. (1984). Modifications include a number of simplifications that make the assay easier and quicker but which could correctly be criticised if used out of context. This modified assay is, therefore, only recommended as a "quality control check" rather than as a way of determining the real immunoreactive fraction of the antibody for which the original published method is recommended.

Solutions

1. *0.1 M phosphate buffer, pH 7.4*: Add 19 ml of 0.1 *M* sodium dihydrogen phosphate solution to 81 ml of 0.1 *M* disodium hydrogen phosphate solution. Check the pH and adjust with monobasic or dibasic solutions as required. Store at room temperature for 4 weeks.

2. *Bovine serum albumin solution*: 1% BSA in phosphate-buffered saline, pH 7.4 (1% BSA/PBS). Weigh out 1 g of BSA and dissolve by gentle continuous mixing in 100 ml of 0.1 *M* phosphate buffer, pH 7.4. Keep at 4°C for 4 weeks.

3. Cells expressing the appropriate antigen. Harvest at least 15×10^6 cells from a sufficient number of tissue culture flasks, using trypsin/EDTA or manual scraping to detach adherent cell lines. Wash the cells and resuspend them in cold 1% BSA/PBS. If required, break up small clumps of cells by repeatedly drawing them up and down in a pipette or by syringing them through a 23-gauge needle until a single-cell suspension is obtained. Measure the cell concentration with a haemocytometer or automated cell counter and dilute to a final concentration of 4×10^6 ml in cold 1% BSA/PBS.

4. Radiolabelled antibody at a concentration of 50 ng/ml in cold 1% BSA/PBS. Freshly prepare at least 4 ml.

5. *Unlabelled antibody*: 400 µg at a concentration of at least 0.5 mg/ml.

Steps

1. Place duplicate rows of 7 × 1.5-ml microcentrifuge tubes in a test tube rack. With a marker pen, label the tubes 1–7 and 8–14. Pipette 0.5 ml of cold 1% BSA/PBS into tubes 2–5 and 9–12.

2. Pipette 0.5 ml of the cell suspension into tubes 1, 2, 6, 8, 9, and 13.

3. Pipette 200 µg of unlabelled antibody into tubes 6 and 13. Mix well.

4. Briefly vortex tube 2 and transfer 0.5 ml of the contents to tube 3. Vortex tube 3 and transfer 0.5 ml to tube 4. Vortex tube 4 and transfer 0.5 ml to tube 5. Vortex tube 5 and discard 0.5 ml.

5. Repeat step 4 with tubes 9–12.

6. Pipette 250 µl of radiolabelled antibody into all tubes. Mix well.

7. Incubate the tubes for 2 h at a constant temperature (preferably 4°C but alternatively at room temperature or 37°C). Mix the tubes either constantly using a mechanical shaker or roller or about every 15 min by hand during the incubation.

8. After the incubation, leave the tubes on ice for 10 min to cool. Centrifuge tubes 1–6 and 8–13 at high speed (e.g., >1000 rpm) for 2 min. Carefully remove and discard the supernatant, taking care not to disturb the cell pellet. Pipette 0.5 ml of cold 1% BSA in PBS into each tube and quickly vortex each tube to resuspend the cell pellet. Recentrifuge and again discard the supernatant.

9. Count all tubes in a gamma counter on the appropriate isotope setting.

10. Analyse data as follows: Divide the counts in tubes 1–5 and 8–12 (bound counts) by an average of the counts in tubes 7 and 14 (total counts) in order to calculate the fraction of counts bound to the cells for each cell concentration. Average the values for duplicate tubes (1 and 8, 2 and 9, 3 and 10, 4 and 11, and 5 and 12).

11. Calculate the cell concentration in each tube (approximately 40, 20, 10, 5, and 2.5×10^5 ml).

12. Plot as y values the *reciprocal* of fraction bound (i.e., total/bound) against the *reciprocal* of cell concentrations as x values. A straight line plot should be obtained. Determine the intercept on the y axis and calculate the reciprocal. This is the immunoreactive fraction.

13. Calculate the contribution made by nonspecific binding (i.e., binding in the presence of a large excess

of unlabelled antibody) by dividing the average of the counts in tubes 6 and 13 by the average of the counts in tubes 7 and 14. This value is generally very low and the nonspecific binding contribution can therefore reasonably be excluded from the calculation of the immunoreactive fraction. If the nonspecific binding is greater that 5% of the total binding, then the causes should be identified and eliminated.

IV. COMMENTS

Many techniques have been developed in the last 50 years for labelling proteins with radioiodine but, for various reasons, most of these are now only of academic interest, at least so far as the routine labelling of antibodies is concerned. For the interested reader, a detailed review has been put together by Dewanjee (1992). The methods practised most widely are those in which the radioiodine is oxidised to a reactive intermediate positively charged species such as the hydrated iodinium ion H_2OI^+, which then reacts via electrophilic substitution for the activated protons on the phenolic ring of the tyrosine side chains. These iodinium species or related cations can be produced by reacting the radioiodide with a variety of oxidising agents, but two in particular have become the most popular: chloramine-T (*N*-chloro-*p*-toluenesulphonamide) and Iodogen (diphenylglycoluril). Methods for labelling antibodies with radioiodine using these two methods were described in Sections III,A and III,B. Both techniques have their own inherent advantages and drawbacks. The Iodogen method (Fraker and Speck, 1978) is extremely simple and largely invariable. The concentration of the oxidant is determined by its very poor solubility in aqueous solvents and therefore the only variables one can change in order to influence the reaction are incubation time and temperature. Even so, this method normally produces very acceptable labelling efficiencies of the order of 80–95%. In contrast, details of the chloramine-T method (Hunter and Greenwood, 1962) vary widely from laboratory to laboratory. Different researchers have their own favoured oxidant concentrations, incubation times, and choice of quenching reagents. This method has the (somewhat theoretical) advantage that it can be tailored for different proteins, but has the disadvantage that the reagents have to be freshly prepared prior to use and overenthusiastic attempts to improve labelling efficiencies with high concentrations of the oxidant can lead to antibody damage.

Only in rare circumstances will either labelling procedure result in labelling efficiencies approaching 100%. The consequence of this is that the reaction mixture will contain a significant proportion of unreacted "free iodide." It is normally desirable to remove this free iodine in order to provide a preparation with sufficiently high radiochemical purity. The most widely used method for the purification of labelled antibody preparations is size-exclusion chromatography on a short Sephadex column as described in Section III,D, but several alternatives, such as ion-exchange chromatography or the use of spin columns, exist, some of which are potentially more convenient. Before and after purification of the labelled antibody it is useful to measure the purity of the labelled antibody preparation, initially to check the efficiency of the labelling procedure and then later to determine the purity of your reagent. A very simple means of measuring this purity, based on ascending thin-layer chromatography, is described in Section III,E.

The main reason for labelling an antibody is to obtain a radioactive molecule that binds to a specific recognition site. It is therefore essential that the antibody retains the ability to bind to its epitope throughout the labelling procedure. The best tests to ensure that this is the case are radioligand binding assays, which measure directly the binding of the radiolabelled molecules rather than the whole population of antibody molecules in solution, most of which will not be labelled. These assays fall into two categories: those used to determine the binding affinity of the antibody and those intended to measure the proportion of labelled molecules that retain some ability to bind specifically to their epitope. For the purposes of a relatively simple check to see if the antibody remains functional after labelling, the latter type of assay is the more appropriate and a protocol describing such a test can be found in Section III,F.

Two main types of mechanism can compromise the immunoreactivity of a labelled antibody. The first is due to the effect of the steric hindrance of the large iodine atom when it is substituted into a critical tyrosine residue close to the binding site of the antibody. Although the radioiodine can potentially react with any of several tyrosine amino acids scattered throughout the antibody molecule, factors such as local charge distribution and accessibility mean that one or more residues will be labelled preferentially. If one of these sites happens to be in one of the critical CDRs, then a significant degree of antibody binding will be lost. If this happens, the number of possibilities for solving the problem are limited. It is possible that a change in pH during the labelling procedure may alter the local charge distribution and favour an alternative tyrosine residue, albeit at the risk of a lower labelling efficiency. If this does not work, then the only alternative is to

use an entirely different chemistry for radioiodination. The most well-established alternative is the Bolton and Hunter method described in Section III,C, which results in antibody labelling at the site of lysine residues.

The other type of mechanism responsible for loss of immunoreactivity is oxidation. In addition to its desired role in oxidising the radioiodide to a reactive species, the oxidant may potentially oxidise critical residues, particularly methionine, in the antibody molecule. A way to find out which of the two possible mechanisms may in fact be the cause of a loss in immunoreactivity is to perform the labelling procedure without the addition of the radioiodine and to perform an ELISA assay. If an oxidative mechanism is responsible, then immunoreactivity will still be lost, as all the antibody molecules will be affected, not only those substituted with radioiodine. If this is found to be the case then either a Bolton and Hunter approach can be pursued or an alternative electrophilic substitution method that does not subject the antibody to such strong oxidising conditions can be employed. Two approaches may work. The first is to use a milder oxidising agent, such as the lactoperoxidase system (Morrison and Bayse, 1970). The alternative is to use a modification of the Iodogen system in which the radioiodine is first oxidised in the iodogen tube but is then transferred from the oxidising environment to another tube containing the antibody (van der Laken *et al*., 1997). It is likely that both of these procedures will result in a lower labelling efficiency but either may solve the problem of oxidative damage to the antibody.

The shelf life of radioiodinated antibodies is limited by radiolysis, which causes a gradual loss in both purity and immunoreactivity. The rate of deterioration can be reduced by the addition of carrier proteins or antioxidants that scavenge the radiolytic free radicals (Chakrabarti *et al*., 1996). A concentration of 0.1–1% albumin or 0.5% ascorbic acid is commonly used and antibodies may be stored in these solutions at either 4 or –20°C for at least a month without a significant loss of quality. If stored below 0°C, then the preparation should be divided into aliquots to save repeated freezing and thawing, which tends to favour aggregation of the antibody. If stored above 0°C, provided it does not interfere with the ultimate application, sodium azide can be added to a final concentration of 0.05% to limit microbial growth.

V. PITFALLS

The most likely cause of failure of any of the labelling methods described here is the presence of impurities in the antibody solution. The best solution is to repurify the antibody by either dialysis or gel filtration into freshly prepared buffers.

The most common problem experienced with the immunoreactive fraction assay described in Section III,F is that a curve, rather than a straight line, is obtained when data are plotted. This is nearly always caused by inaccuracies in diluting and losses in washing the cells. With practice and care, the problem usually goes away.

Immunofluorescence

CHAPTER

66

Immunofluorescence Microscopy of Cultured Cells

Mary Osborn

I. INTRODUCTION

Immunocytochemistry is the method of choice for locating an antigen to a particular structure or subcellular compartment provided that an antibody specific for the protein under study is available. Immunofluorescence is a sensitive method requiring only one available antigenic site on the protein. Usually the indirect technique is used. In this technique the first antibody is unlabeled and can be made in any species. After it has bound to the antigen, a second antibody, made against IgGs of the species in which the first antibody is made and coupled to a fluorochrome such as fluoroscein isothiocyanate, is added. The distribution of the antigen can then be viewed in a microscope equipped with the appropriate filters.

Immunofluorescence as a method to study cytoarchitecture and subcellular localization gained prominence with the demonstration that antibodies can be produced to actin even though it is a ubiquitous component of cells and tissues (Lazarides and Weber, 1974). Cytoskeletal structures visualized in cells in immunofluorescence microscopy include the three filamentous systems: microfilaments, microtubules, and intermediate filaments (Figs. 1–4 and micrographs in the article by Prast *et al.*). In addition, proteins can be located to other cellular subcompartments and organelles, e.g., the plasma or nuclear membranes, the Golgi apparatus, or the endoplasmic reticulum, or to other cellular structures such as mitochondria and vesicles. Other proteins can also be localized to subcompartments of the nucleus or even of the nucleolus. In addition to its use in identifying cytoskeletal structures and organelles, immunocytochemistry has proved useful in building up a biochemical or protein chemical anatomy of a structure. Examples include the location of the microfilament-associated proteins to the stress fiber and the description of the biochemical anatomy of such structures as microvilli and stereo cilia. A third use of the technique has been to demonstrate heterogeneity in mixed cultures, e.g., of neuronal cultures (Raff *et al.*, 1978), or of other primary or secondary cell cultures (cf. Fig. 4). Immunofluorescence with selected antibodies has also been used to check the histological derivation of particular cell lines or indeed of whole cell culture collections (see Quentmeier *et al.*, 2001 and http://www.dsmz.de).

The micrographs that accompany this article show not only the beauty of some of the structures, but also some of the advantages of the technique. First, only the arrangement of the particular protein against which the antibody is made is visualized. Second, for those proteins that form part of a supramolecular structure, the arrangement of such structures throughout the cell is revealed. Third, numerous cells can be visualized at the same time, and therefore it is relatively easy to determine how the structures under study vary under particular conditions or during different phases of the cell cycle. Immunofluorescence microscopy is also a useful method to establish appropriate conditions to study a structure at higher resolution in the electron microscope.

A 1:1 correspondence has been shown for a parallel-processed or even the same specimen when studied by fluorescence microscopy and as a whole mount under the electron microscope (Osborn *et al.*, 1978b). Electron microscopic methods not only allow location of the antigen to a particular structure at higher resolution, but may also allow the determination of interactions between a structure that is immunolabeled and other unlabeled structures in the cell.

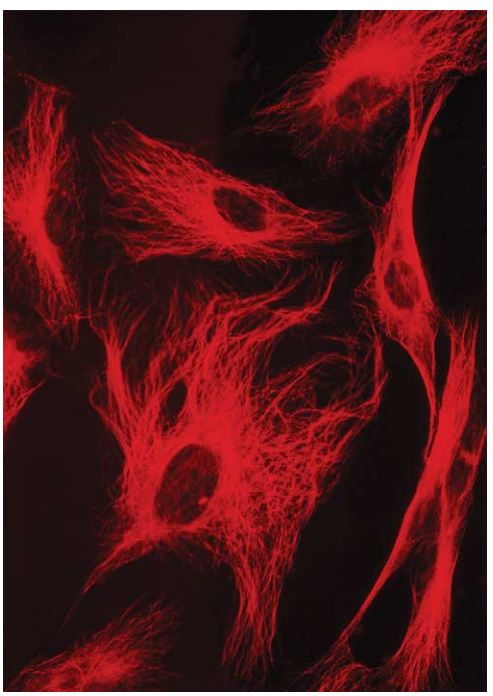

FIGURE 2 Microtubules in cells in culture revealed by staining with antibodies to tubulin followed by a rhodamine-labeled second antibody (×400).

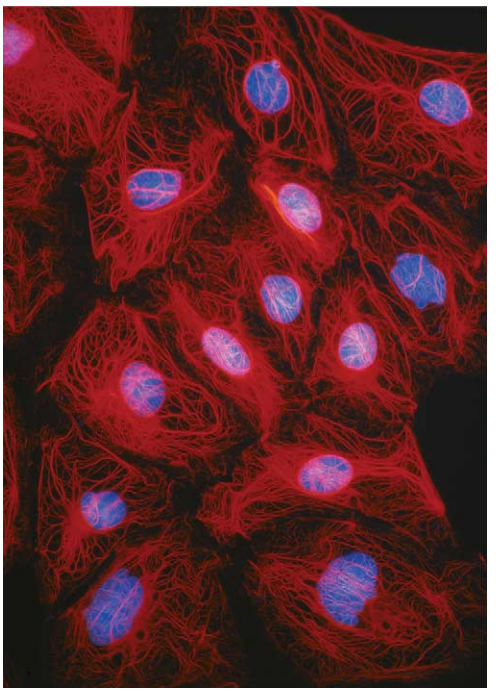

FIGURE 3 Keratin filaments in the rat kangaroo PtK2 cell line revealed by staining with antibodies to keratin and a rhodamine-labeled second antibody. DNA has been counterstained with Hoechst dye (×150).

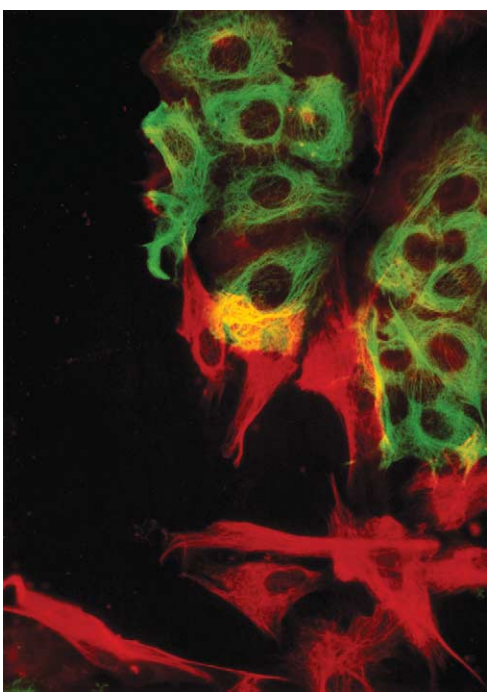

FIGURE 4 Artificial mixture of cells from the human breast carcinoma cell line MCF-7 and the human fibroblast cell line HS27 stained with an antibody to keratin (in green) and with the V9 antibody to vimentin (in red). Note that each cell type contains only a single type of intermediate filament. The yellow color results from MCF-7 and HS27 cells that lie over each other (×150).

Other reviews of immunofluorescence of cultured cells that concentrate on methods include those of Osborn (1981), Osborn and Weber (1981), and Wheatley and Wang (1981) and for live cells, Wang and Taylor (1989) and Prast *et al*. (2004). Alternatively, see Allan (2000). For an overview of the different cytoskeletal and motor proteins, see Kreis and Vale (1999). For interesting collections of color immunofluorescence micrographs from a wide variety of organisms, see Haugland *et al*. (2004) or the BioProbes newsletter (http://www.probes.com).

II. MATERIALS AND INSTRUMENTATION

A. Antibodies

Antibodies to many cellular proteins can be purchased commercially. Firms offering a variety of antibodies to cytoskeletal and other proteins include Amersham, Biomakor, Dako, Novocastra, Sigma-Aldrich, and Transduction Laboratories; other firms have specialized collections emphasizing narrower areas.

Primary antibodies today are usually monoclonal antibodies made in mice, although polyclonal antibodies made in species such as guinea pigs and rabbits are sometimes also available commercially. The appropriate dilution is established by a dilution series. Monoclonal antibodies supplied as hybridoma supernatants can often be diluted 1:1 to 1:20 for immunofluorescence or even more if other more sensitive immunocytochemical procedures are used (see also article by Osborn and Brandfass for additional information). Monoclonal antibodies supplied as ascites fluid can be diluted in the range of 1:100 to 1:1000. Use of ascites fluid at a dilution of less than 1:100 is not recommended as there are usually high titers of autoantibodies in such fluids. Polyclonal antibodies supplied as sera should be diluted in the range of 1:20 to 1:100. Note that many rabbits have relatively high levels of autoantibodies against keratins and/or other cellular proteins, so check presera. Affinity purification in which the antigen is coupled to a support and the polyclonal antibody is then put through the column usually results in a dramatic improvement in the quality of the staining patterns. Affinity-purified antibodies should work in the range of 5–20 µg/ml.

Secondary antibodies directed against IgGs of the species in which the first antibody is made are usually purchased already coupled to a fluorophore (e.g., from Jackson Laboratories http://jacksonimmuno.com, Molecular Probes http://www.probes.com and other companies listed earlier). Originally, only FITC and rhodamine-labeled antibodies were available commercially. Today there is a very wide choice of commercial antibodies coupled to different fluorophores, including AMCA, Cy2, FITC, Cy3, TRITC, phycoerythrin, RRX, Texas red, and Cy5 (see Haugland, 2004 and http://jacksonimmuno.com). Cy2 and Cy3 fluoresce in the green region of the visible spectrum, as does FITC. They are more photostable, less sensitive to pH, and are reported to give less background than many other fluorophores. Cy2 can be visualized with FITC filters and Cy3 with TRITC filters. Cy5 has an emission maximum at 670 nm and cannot be seen well by eye. Choice among the red fluorophores depends in part on the application. In addition, Molecular Probes has produced a series of Alexa Fluor dyes that cover the visible spectrum. Alexa Fluor 488 is claimed to be the best green fluoresent dye available. Alexa Fluor 555 spectra match those of Cy3, but are more fluorescent and more photostable. Alexa Fluor 647 spectra are very similar to those of Cy5. The working dilution for the secondary antibody is established by running a dilution series. Usually 1:50 to 1:150 dilutions of the commercial products are appropriate. An essential control is to check that the second antibody is negative when used alone. If nonspecific staining is present, it can sometimes be removed by absorbing the antibody on fixed monolayers of cells or on an acetone cell powder.

Antibodies other than IgMs should be stored in the freezer (–70°C for valuable primary antibodies and affinity-purified antibodies, –20°C for the rest). Antibodies should be stored in small aliquots and repeated freezing/thawing should be avoided. IgMs may be inactivated by freezing/thawing and are best kept in 50% glycerol in a freezer set at –20 to –25°C. If dilutions are made in a suitable buffer [e.g., phosphate-buffered saline (PBS), 0.5 mg/ml bovine serum albumin, 10^{-3} *M* sodium azide], diluted antibodies are stable for several months at 4°C.

B. Reagents and Other Useful Items

Methanol is of reagent grade. Formaldehyde can be diluted 1:10 from a concentrated 37% solution (e.g., Analar grade BDH Chemicals). As such solutions usually contain 11% methanol, it may be better to make the formaldehyde solution from paraformaldehyde. In this case, heat 18.5 g paraformaldehyde in 500 ml PBS on a magnetic stirrer to 60°C and filter through a 0.45-µm filter. Store at room temperature. PBS contains per liter 8 g NaCl, 0.2 g KCl, 0.2 g KH_2PO_4, and 1.15 g Na_2HPO_4, adjusted to pH 7.3 with NaOH.

Polyvinyl alcohol-based mounting media have the advantage in that although they are liquid when the sample is mounted, they solidify within hours of application. In addition, the fluorescence is stable if the sample is held in the dark and at 4°C. Samples can be reexamined and photographed after months or even years. Commonly used mounting media include Mowiol 4–88 (Calbiochem Cat. No. 475904). To make the mounting medium, place 6 g analytical grade glycerol in a 50-ml plastic conical centrifuge tube, add 2.4 g of Mowiol 4.88, and stir for 1 h to mix. Add 6 ml distilled water and stir for a further 2 h. Add 12 ml of 0.2 *M* Tris buffer (2.42 g Tris/100 ml water, pH adjusted to 8.5 with HC1 as FITC has maximal fluorescence emission at this pH) and incubate in a water bath at 50°C for 10 min, stirring occasionally to dissolve the Mowiol. Clarify by centrifugation at 1200 *g* for 15 min and aliquot. Store at –20°C; unfreeze as required. Once unfrozen, the solution will be stable for several months at room temperature. While some laboratories add antifade reagents to mounting media, we have never found this to be necessary for our applications.

Other useful items include round (12 mm) or square (12 × 12 mm) glass coverslips (thickness 1.5). Ten round coverslips fit in a petri dish of 5.5 cm diameter. For screening purposes or when a large number of samples is needed (e.g., for hybridoma screening), microtest slides that contain 10 numbered circles 7 mm in diameter (Flow Labs, Cat. No. 6041505) are useful. Tweezers (e.g., Dumont No. 7) are used to handle the coverslips. Ceramic racks into which coverslips fit (Thomas Scientific, Cat. No. 8542E40) and glass containers in which these racks fit are also needed. Glass beakers (30 ml) are used to wash the specimens. Cells growing in suspension can be firmly attached to microscope slides using a cytocentrifuge such as the Cytospin 2 (Shandon Instruments).

C. Equipment

The essential requirement is access to a microscope equipped with appropriate filters to visualize the fluorochromes in routine use. Microscopes with CCD or digital cameras so that results can be viewed directly on screen are available from several manufacturers, e.g., Zeiss. Epifluorescence, an appropriate high-pressure mercury lamp (HBO 50 or HBO 100) and appropriate filters (so that specimens doubly labeled with, e.g., fluorescein and rhodamine can be visualized) are basic requirements. Lenses should also be selected carefully. The depth of field of the lens will decrease as the magnification increases. Round cultured cells will be in focus only with a ×25 or ×40 lens, whereas flatter cells can be studied with a ×63 or ×100 lens. To enable phase and fluorescence to be studied on the same specimen, some lenses should have phase optics. Only certain lenses transmit the Hoechst DNA stain (e.g., Neofluar lenses), and this stain also requires a separate filter set.

Increased resolution particularly in the *z* direction can be obtained by confocal microscopy (see Mason, 1999). Other forms of microscopy allow a further increase in resolution, but are not widely available (see later). Some institutes are pooling their light microscopy facilities (e.g., the Advanced Light Microscope Facility at EMBL, http:/www.embl-heidelberg.de/ExternalInfo/EurALMF, which provides state-of-the-art light microscopy image analysis and support for internal groups as well as visitors to EMBL).

III. INDIRECT IMMUNOFLUORESCENCE PROCEDURE

Steps

1. Trypsinize cells 1–2 days prior to the experiment onto glass coverslips or on multitest slides that have been washed in 100% ethanol and oven sterilized. For most applications, choose coverslips or multitest slides on which cells are two-thirds or less confluent. Drain coverslip or touch to filter paper to remove excess medium, but do not allow it to dry.
2. Place coverslips in a ceramic rack and multitest slides in metal racks, and immerse in methanol precooled to –10 to –20°C. Leave for 6 min at room temperature.
3. Make a wet chamber by lining a 13-cm-diameter (for coverslips) or a 24 × 24-cm^2 petri dish (for slides) with two or three sheets of filter paper and add sufficient water to moisten the filter paper. Numbers identifying the samples can be written on the top sheet of filter paper prior to wetting it.
4. Wash the fixed specimens briefly in PBS, remove excess PBS by touching to dry filter paper, and place cell side up over the appropriate number in the wet chamber.
5. Add 5–10 µl of an appropriate dilution of the primary antibody with an Eppendorf pipette. Use the tip to spread the antibody over the coverslip without touching the cells. Replace the top of the wet chamber, transfer to a humidified incubator at 37°C, and incubate for 45 min.
6. Wash by dipping each coverslip individually three times into each of three 30-ml beakers containing PBS. Wash slides by replacing slides in metal rack and

transferring through three PBS washes (180 ml each, leave for 2 min in each). Remove excess PBS with filter paper.

7. Replace specimens in wet chamber. Add 5–10 µl of an appropriately diluted second antibody carrying a fluorescent tag. Return to 37°C incubator for a further 30–45 min.

8. Repeat step 6.

9. Identify microscope slides with small adhesive labels on which date, specimen number, antibody, or other information is written. Place slides in cardboard microslide folders (e.g., Thomas Scientific, Cat. No. 6708-M10). Mount two coverslips per slide by inverting each coverslip and placing cell side down on a drop of mounting medium placed on the slide, with a disposable ring micropipette. Cover with filter paper and press gently to remove excess mounting medium. For samples on multitest slides, use 6 × 2.5-cm glass coverslips on which a drop of mounting medium has been placed. Secure the coverslips with nail polish. Store samples in the dark in slide boxes at 4°C.

10. Documentation. Use a fast film (e.g., Kodak 35 mm Tri-X) and push the development, e.g., with Diafine (Acufine), or record the image digitally. Phase micrographs of specimens embedded in Mowiol should be made as soon as possible after mounting the specimens. The fluorescence decreases a little in the first few days, but is then stable for years if the samples are stored in the dark at 4°C.

IV. COMMENTS

Specimens should not be allowed to dry out at any stage in the procedure. If coverslips are dropped accidentally, the side on which the cells are can be identified by focusing on the cells under an upright microscope and scratching gently with tweezers.

A. Fixation

The procedure gives good results with many cytoskeletal and other antigens; however, the optimal fixation protocol depends on the specimen, the antigen, and the location of the antigen within the cell. Three requirements have to be met. First, the fixation procedure must retain the antigen within the cell. Second, the ultrastructure must be preserved as far as possible without destroying the antigenic determinants recognized by the antibody. Third, the antibody must be able to reach the antigen; i.e., the fixation and permeabilization steps must extract sufficient cytoplasmic components so that the antibodies can penetrate into the fixed cells. In the procedure just given, fixation and permeabilization are achieved in a single step, i.e., with methanol. Alternative fixation methods include the following:

1. Formaldehyde–methanol: 3.7% formaldehyde in PBS for 10 min (to fix the cells) and then methanol at –10°C for 6 min (to permeabilize the cells).

2. Formaldehyde–Triton: 3.7% formaldehyde in PBS for 10 min (to fix) and then PBS with 0.2% Triton X-100 for 1 min at room temperature (to permeabilize).

3. Glutaraldehyde: Fix in 1% glutaraldehyde (electron microscopic grade) in PBS for 15 min and then methanol at –10°C for 15 min. Immerse in sodium borohydride solution (0.5 mg/ml in PBS made minutes before use) for 3 × 4 min. Wash with PBS 2 × 3 min each. Note that the sodium borohydride step is necessary to reduce the unreacted aldehyde groups; without this step the background will be very high.

Note that formaldehyde treatment destroys the antigenicity of many antigens. Alternatively, in a very few cases, positive staining may be observed only after formaldehyde fixation. Very few antigens react after glutaraldehyde fixation.

B. Special Situations

1. Fluorescently labeled phalloidin (extremely poisonous), a phallotoxin that binds to filamentous actin, is available commercially and is usually used to reveal the distribution of filamentous actin in cells (Fig. 1). To obtain good staining patterns, fix cells for 10 min in 3.7% formaldehyde in PBS. Wash with PBS. Incubate for 1 min in 0.2% Triton X-100 in PBS and wash with PBS. Incubate with an appropriate dilution of rhodamine-labeled phalloidin (e.g., Sigma Cat. No. P-1951) for 30 min at 37°C, wash with PBS, and mount in Mowiol. Note that phalloidin staining will not work after methanol fixation (for further discussion, see article by Prast *et al.*, and Small *et al.*, 1999).

2. To stain endoplasmic reticulum, use either an antibody, e.g., ID3 against a sequence region of protein disulfide isomerase (Vaux *et al.*, 1990), or the lipophilic, cationic fluorescent dye $DiOC_6$ (3,3-dihexyloxacarbocyanine iodide, Kodak Cat. No. 14414) (Terasaki *et al.*, 1984). To stain with dye, fix for 5 min in 0.25% glutaraldehyde in 0.1 *M* cacodylate and 0.1 *M* sucrose buffer, pH 7.4. Wash. Stain for 80 s with dye, mount in buffer, and observe using a ×63 or ×100 lens and the fluorescein filter. Reticular structures should be apparent. Note that mitochondria will also be stained. To stain only mitochondria, use either an antibody, e.g., to cytochrome oxidase, or the dye rhodamine 123.

3. Special fixation procedures may also be needed for other membrane structures in cells. In addition, lectins can be used to stain carbohydrate-containing organelles, e.g., staining of Golgi apparatus with fluorescently labeled wheat germ or other agglutinins.

4. To stain DNA for fluorescent applications dyes that bind to the minor groove in DNA such as the Hoechst dyes and DAPI are usually used. To stain with Hoechst use either Hoechst 33242 (Sigma Cat. No. 2261) or Hoechst 33258 (Sigma Cat. No. B2883). Note that Hoechst 33242 can also be used to stain DNA in live cells. When bound to DNA, Hoechst dyes fluoresce bright blue (cf. Fig. 1C). To stain with Hoechst prepare a 1 m*M* stock solution in sterile water and store at 4°C. To stain cells dilute the stock solution 1:1000 in PBS to a final working concentration of 1 µ*M*. After step 8 in the immunofluorescence procedure, pipette 20–100 µl of the working solution onto each coverslip and leave for 4 min at room temperature. Wash twice with PBS, drain the coverslip, and mount in Mowiol. DNA can also be stained with DAPI, which shows a 20-fold fluorescence enhancement on binding to DNA and also gives blue fluorescence.

5. Some cellular structures, such as microtubules, are sensitive to calcium. In this case, add 2–5 m*M* EGTA to the 3.7% formaldehyde solution in Section IV,A and to the methanol in Section III, step 2.

6. Blocking steps are usually not necessary if antibodies are diluted in BSA containing buffers. If a blocking step is used it should be performed after fixation and prior to adding the first antibody. Blocking to reduce nonspecific staining is performed with 10% serum from the same host species as the labeled antibody.

7. Sometimes for cell surface components it may be advantageous to stain live cells. Expose such cells to antibody for 25 min and proceed with steps 6–8 in Section III. Then fix cells in 5% acetic acid/95% ethanol for 10 min at –10°C (Raff *et al*., 1978).

8. Another application of immunofluorescence microscopy is to monitor directly the distribution of fluorescently labeled proteins in live cells by video microscopy (e.g., Sammak and Borisy, 1988).

C. Double or Triple Immunofluorescence Mircroscopy

It is often advantageous to visualize two or three antigens in the same cell (Fig. 4). Here it is important to choose fluorophores that give good color separation, e.g., a Texas red/FITC combination will give a better separation than TRITC/FITC (see also article by Prast *et al*.). Most important is that the microscope is optimized for the fluorophores in use by the selection of the appropriate filters so that there is no overlap between the channels used to observe each of the fluorophores.

D. Stereomicroscopy

Fluorescence microscopy gives an overview of the whole cell. With practice, specimens can be seen in three dimensions when looking through a conventional microscope. Stereomicrographs can be made using a simple modification of commercially available parts (Osborn *et al*., 1978a). Today, however, confocal microscopy is the method of choice and is particularly useful for round cells, which are not in focus with the higher-power ×63 or ×100 lenses, or to document arrangements and obtain greater resolution at multiple levels in the same cell or organism (cf. Fox *et al*., 1991).

E. Limit of Resolution

Theoretically, this is ~200 nm when 515-nm wavelength light and a numerical aperture of 1.4 are used. Objects with dimensions above 200 nm will be seen at their real size. Objects with dimensions below 200 nm can be visualized provided they bind sufficient antibody, but will be seen with diameters equal to the resolution of the light microscope (cf. visualization of single microtubules in Osborn *et al*., 1978b). Objects closer together than 200–250 nm cannot be resolved by conventional fluorescence microscopy, e.g., microtubules in the mitotic spindle or ribosomes. However, some increase in the resolution of fluorescent images can be obtained using new forms of microscopy (see Hell, 2003).

F. New Developments

Immunofluorescence microscopy is an important technique not only for fixed cells (this article), but also because of the possibility of expressing GFP vectors coupled to particular constructs in living cells (see article by Prast *et al*.) and following changes in distribution by video microscopy. FRET imaging techniques (see this volume) and other novel techniques, such as the use of quantum dot ligands (e.g., Lidke *et al*., 2004), are also opening up new possibilities for more quantitative fluorescence measurements on live cells.

V. PITFALLS

Occasionally no specific structures are visualized, even though the cell is known to contain the antigen. This may be because:

1. Antibodies can be species specific. This can be a particular problem with monoclonal antibodies, which, for instance, may work with human but not with other species. If in doubt, check the species specificity with the supplier before purchase.

2. The fixation procedure may inactivate the antigen. For instance, many intermediate filament antibodies no longer react after fixation protocols such as those in Section IV,A.

3. The antigen may be present only at very low concentrations and therefore it may be necessary to use more sensitive methods to detect the antigen.

4. The antigen can be poorly fixed or extracted by the fixation procedure.

5. The antibody may not be able to gain access to the antigen, e.g., antibodies to tubulin often do not stain the midbody of the intracellular bridge.

6. The specimens may be generally fluorescent and it can be hard to decide whether this is due to specific or nonspecific staining.

Immunofluorescence Microscopy of the Cytoskeleton: Combination with Green Fluorescent Protein Tags

Johanna Prast, Mario Gimona, and J. Victor Small

Immunofluorescence microscopy is now a standard procedure for the localisation of molecules in cells (for an introduction to the method, see article by Osborn). Nevertheless, the method has its pitfalls, not least in requiring the immobilisation of cells by chemical fixation and multiple manipulations during labelling. This can lead to the loss of antigen as well as to the distortion of cell structure. Unfortunately, published pictures still appear in which distortions in cell structure are overlooked and where the conclusions drawn are consequently tenuous. Advances in live cell imaging, combined with green fluorescent protein (GFP) tags (and analogues) now provide independent methods for assessing the localisation of molecules. Nevertheless, immunofluorescence microscopy remains an important technique when used with discretion. Indeed, when applied in combination with cells expressing fluorescently tagged probes, it adds a further dimension to characterise the relative localisation of multiple components. This article provides some recipes suitable for labeling the cytoskeleton and gives examples where GFP tags and immunofluorescence can be usefully combined.

II. MATERIALS AND REAGENTS

1. *Coverslips*: Round glass coverslips 12 or 15 mm in diameter, cleaned in 60% ethanol/40% HCl (10 min), rinsed with H_2O (2 × 5 min), drained, cleaned with lint-free paper, and sterilized for tissue culture by exposure to ultraviolet light in the culture dish.

2. *Humid chamber*: Large petri dish 14 cm in diameter, or similar container with lid, containing a glass plate (around 9 cm^2) coated with a layer of Parafilm and supported on a moistened piece of filter paper on the bottom of the dish. A few drops of water on the glass plate facilitate spreading and flattening of the Parafilm.

3. *Washing reservoir*: Two multiwell dishes, 24 wells each (e.g., Nunc).

4. *Filter paper*: Whatman No. 1, 9 cm in diameter.

5. *Forceps*: Dumont No. 4 or No. 5 or equivalent watchmaker forceps.

6. *Pipettes*: Set of automatic pipettes (0–20, 20–200, 50–1000 µl) or capillary pipettes for diluting and aliquoting antibodies. Pasteur pipettes.

7. *Phalloidin*: Alexa 568- and Alexa 488-coupled phalloidins from Molecular Probes and CPITC (coumarin) phalloidin from Sigma. Store as 0.1-mg/ml stocks in methanol at –20°C.

8. *Secondary antibodies*: Commercial secondary antibodies carrying Molecular Probes Alexa 488, 568, and 350 conjugates are, in our experience, of generally good quality.

9. *Gelvatol, Vinol*: The basic ingredient of the mounting medium is polyvinyl alcohol (MW 10.000, around 87% hydrolysed), which comes under various trade names: Elvanol, Mowiol, and Gelvatol. We use Vinol 203 from Air Products and Chemical Inc.

II. PROCEDURES

Solutions

1. *0.5 M EGTA stock solution*: For 500 ml stock, weigh out 95.1 g EGTA (Sigma E-4378) into 400 ml H_2O, adjust pH to 7.0 with 1 *N* NaOH, and make up to 500 ml with H_2O. Store at room temperature in a plastic bottle.

2. *1 M $MgCl_2$ stock solution*: For 500 ml stock, weigh out 101.6 g $MgCl_2$, add H_2O to 500 ml, dissolve, and store at 4°C.

3. *Cytoskeleton buffer (CB)*: 10 n*M* MES (Sigma M-8250), 150 m*M* NaCl, 5 m*M* EGTA, 5 m*M* $MgCl_2$, and 5 m*M* glucose. For 1 liter, add the following amounts to 800 ml H_2O: MES, 1.95 g; NaCL, 8.76 g; 0.5 *M* EGTA, 10 ml; 1 *M* $MgCl_2$, 5 ml; and glucose, 0.9 g. Adjust pH to 6.1 with 1 *N* NaOH and fill up to 1 liter. Store at 4°C. For extended storage, add 100 mg streptomycin sulfate (Sigma S-6501).

4. *Phosphate-buffered saline (PBS) working solution*: 137 m*M* NaCl, 2.7 m*M* KCl, 4.3 m*M* $Na_2HPO_4{\cdot}7H_2O$, and 1.4 m*M* KH_2PO_4, pH 7.4.

5. *Triton X-100*: Make up 10% aqueous stock and store at 4°C.

6. *Glutaraldehyde (GA) stock*: Make up 2.5% solution of glutaraldehyde by diluting 25% glutaraldehyde EM grade (Agar scientific Ltd., Cat. No. R 1020 or equivalent) in CB. Readjust pH to 6.1 and store at 4°C.

7. *Paraformaldehyde (PFA) stock*: Make up a stock 4% solution of paraformaldehyde in PBS or CB (see fixative mixtures) (analytical grade Merck Cat. No. 4005). To make 100 ml, heat 80 ml of CB (or PBS) to 60°C, add 3 g paraformaldehyde, and mix 30 min. Add a few drops of 10 *M* NaOH until the solution is clear, cool, adjust pH (see appropriate mixture), and make up to 100 ml. Store in aliquots at –20°C.

8. *Fixative mixtures*: Aldehyde fixative mixtures are made up using the stock solutions given earlier to give the combinations listed under step 2.

9. *Blocking solution*: 1% bovine serum albumin and 5% horse serum in PBS.

10. *Antibody mixtures*: These are made up in PBS or in the blocking solution without serum. To remove any unwanted particles, centrifuge (10,000 *g* for 10 min) the diluted mixture before use. The antibody combinations used for this article are listed in Table I.

11. *Mounting medium*: Mix 2.4 g of polyvinyl alcohol with 6 g glycerol (87%) and then with 6 ml H_2O. After at least 2 h at room temperature, add 0.2 ml 0.2 *M* Tris–HCl, pH 8.5, to the mixture and further incubate the solution for 10 min at 60°C. Remove any precipitate by centrifugation at 17,000 *g* for 30 min. Store in aliquots at –20°C. [Antibleach agents are available that considerably reduce bleaching and thus enable multiple pictures to be taken of the same cells. We use *n*-propyl gallate (Giloh and Sedat, 1982) at 5 mg/ml or phenylenediamine (Johnson *et al*., 1982) at 1–2 mg/ml in the mounting medium. After dissolving the additive, degas mounting medium before storage.]

Steps

1. Seed the cells onto coverslips in the petri dish and allow them to attach and spread for 4–48 h in an incubator at 37°C.

2. Aspirate growth medium and rinse dish gently with PBS (warmed 37°C PBS); avoid shifting of the coverslips over each other. Aspirate PBS and replace with one of the following fixative solutions.
   a. *Fix 1*: 4% PFA/0.1% Triton X-100 in PBS for 2 min. Rinse three times with PBS. 4% PFA in PBS for 20 min. Wash 2 × 10 min with PBS.
   b. *Fix 2*: 0.5% GA/0.25% Triton X-100 in CB for 1 min. Rinse 3× with CB. 4% PFA in CB for 20 min. Wash 2 × 10 min with CB.
   c. *Fix 3*: 0.25% GA/0.5% Triton X-100 in CB for 1 min. Rinse 3× with CB. 1% GA for 15 min. Wash 2 × 10 min with CB.
   d. *Fix 4*: 4% PFA/0.3% Triton X 100/0.1% GA in CB for 15 min. Wash 2 × 10 min with CB.

3. Block: Invert each PBS coverslip onto a 30-µl drop of blocking solution on Parafilm in the humid chamber. Before transfer to drop, dry the back side of the coverslip by holding it briefly on filter paper with a pair of forceps, taking care not to allow the cell side to dry. Drain any excess solution from the cell side by touching the edge of the coverslip to the filter paper. Incubate on blocking solution for 15 min or until first antibody mixtures are prepared. (Back side of coverslip should not be wet or else coverslip will sink during the washing step.)

4. Apply drops (20–50 µl) of first antibody mixture to unused part of Parafilm and transfer coverslips to appropriate drops after draining excess blocking solution on filter paper. Replace lid on petri dish and leave at room temperature for 45–60 min.

5. Wash: To ease removal of coverslips for washing, pipette 100 µl PBS under their edge to lift them up from the Parafilm. Using forceps, transfer coverslips to a multiwell dish in which the wells are filled to the brim with PBS so that the liquid surface is flat. The coverslips will float well, cell side down, as long as the back side remains dry. (For efficient washing, transfer dish gently to a tilting rotating table for 10 min.) Repeat washing steps after transfer of coverslips to a second dish containing fresh PBS two or three times.

6. Change Parafilm in humid chamber and apply drops of second antibody mixture. Transfer coverslips

to drops after briefly draining excess with filter paper and incubate for 45 min.

7. Wash as described in step 6.

8. Mount: Add a small drop of mounting medium to a cleaned glass slide using, for example, a plastic disposable pipette tip. Drain excess (PBS) from coverslip and gently invert onto drop. *Note*: The mounting medium dries quite fast so the drops should be applied singly and not in batches. If necessary, remove excess medium after mounting by applying small pieces of torn filter paper to the coverslip edge.

9. Observe directly in a fluorescence microscope with a dry lens. An oil immersion lens can be used the next day when the mounting medium has solidified. Alternatively, the drying time can be shortened by transfer of slides to a 27°C oven.

III. CHOICE OF FIXATION FOR MULTIPLE LABELLING

Different antibodies commonly require different fixation protocols to give optimal labelling. It is therefore important to test different fixation conditions for each antibody to determine the best compromise fixation for multiple labelling. Table I lists the characterics of the commercial antibodies used in this article in terms of the intensity of label obtained with each of the four fixation protocols described for cultured smooth muscle cells (A7r5, American Type Culture Collection). In general, you should establish the strongest fixation protocol that your antibodies can tolerate and draw your conclusions accordingly.

TABLE I Characteristics of Commercial Antibodies[a]

Staining	Fix 1	Fix 2	Fix 3	Fix 4
Mc. Anti-α-actinin mouse IgM (Sigma BM-75.2) 1:500	+++	++	++	++
Mc. Antiphosphotyrosine (Santa Cruz pY99) Mouse IgG 1:1000	+++	+	++	++
Mc. Anti-α-Tubulin mouse IgG (Sigma DM1A) 1:1000	–	+++	+++	+++
Mc. Antivimentin mouse IgG (Sigma V9) 1:200	+++	+++	+++	+++

Phalloidin CPITC (Sigma) 1:25	+	+	++	++
Phalloidin Alexa 488 (Molecular Probes) 1:300	++	+++	+++	+++
***Phalloindin Alexa* 568 (Molecular Probes)** 1:300	++	+++	+++	+++

[a] **Secondary antibodies** used in this screen were as follows: (1) Rhodamine Red-conjugated donkey anti-mouse **IgM** [Affini Pure $F(ab')_2$ Fragment-Immuno Research Laboratories, Inc.] and (2) Alexa Fluor 568- and 488-conjugated goat anti-mouse **IgG** (H+L) (Molecular Probes)

IV. COMBINING IMMUNOFLUORESCENCE AND GFP TAGS

The ability to express fluorescent proteins as tags to gene products in living cells represents an important advance in localisation methods. In addition to facilitating the visualisation of protein dynamics *in vivo* with sensitive imaging systems, these tagging methods can be usefully combined with the imunofluorescence procedure. Additional flexibility is offered by the fact that the tagged protein is already fluorescent so that restrictions with the use of secondary antibodies are reduced and triple labelling is relatively straightforward. With the cytoskeleton, phalloidin is a probe of choice for actin; when applying this probe, four labels in one cell would not be problematic, given a suitable choice of fluophores (including Cy-5 in the infrared, for example).

An interesting aspect of proteins that are washed away easily during fixation is that they are retained more readily when tagged with a GFP moiety (M. Gimona, unpublished observations). This property offers an unexpected advantage of GFP-tagged probes for localisation studies with fixed cells.

Figures 1–3 show examples of cells expressing GFP-tagged proteins and then fixed and labelled with phalloidin (for actin) and a single antibody. The fixation procedure was "fixation 1" in step 2.

V. COMMENTS

We have generally aimed for fixation protocols that best preserve the actin cytoskeleton. Although stress fibers are easily preserved with most fixative protocols, the delicate peripheral lamellipodia are normally

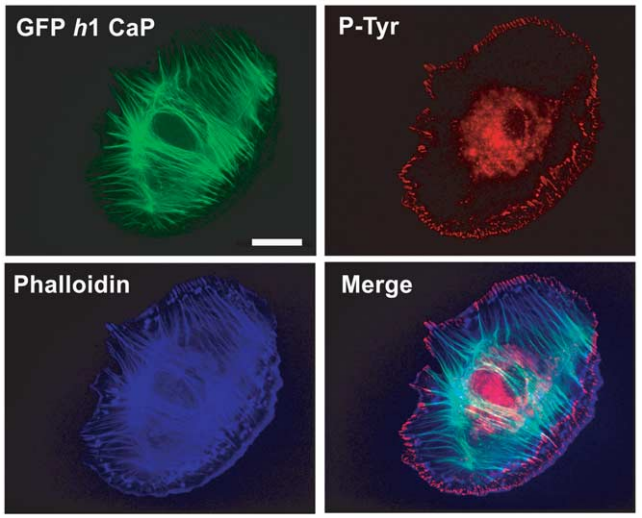

FIGURE 1 Flourescence images of an A7r5 smooth muscle cell transfected with GFP *h*1calponin (Gimona, 2003) and then counterstained with Alexa phalloidin 350 (dilution, 1:200) and mouse antiphosphotyrosine (PY99 Santa Cruz dilution 1:1000), followed by a GaM Alexa 568 as secondary antibody at a dilution of 1:750. Images were recorded on a Zeiss Axioskop fitted with an Zeiss Axiocam imaging system. All three images are combined in the merged image (bottom right). Bar: 20 µm.

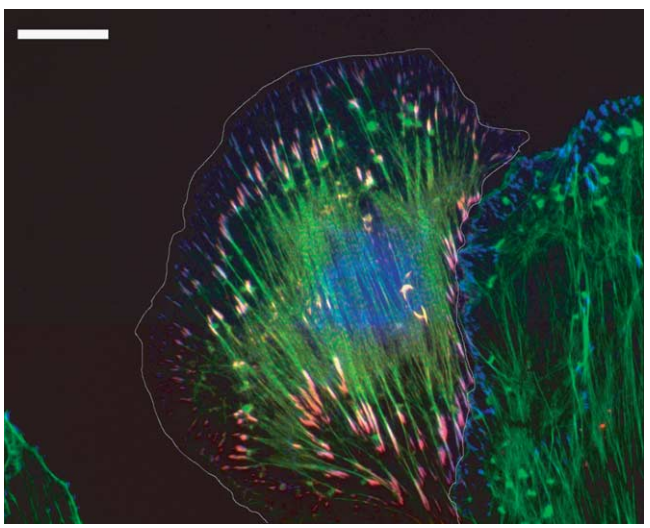

FIGURE 2 Merged fluorescence images (as Fig. 1) of an A7r5 smooth muscle cell transfected with Ds-Red zyxin (Bhatt *et al.*, 2002) to mark focal adhesions and then labelled with Alexa 488 phalloidin (dilution, 1:300) and antiphosphotyrosine (see Fig. 1) with GaM Alexa 350 at a dilution of 500 as secondary antibody. The boundary of the transfected cell is indicated by a white line. Bar: 20 µm.

distorted or lost after methanol or formaldehyde fixation. This is why glutaraldehyde is included in two of the present mixtures. A stronger glutaraldehyde fixation than what we have used here is best for lamellipodia (see, e.g., Small, 1988) but cannot be used with

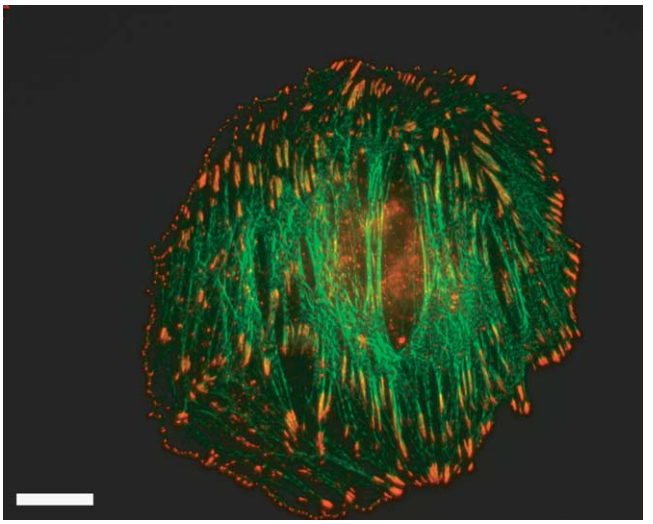

FIGURE 3 Merged fluorescence images (as Fig. 1) of an A7r5 smooth muscle cell transfected with GFP-α-actinin (Gimona *et al.*, 2003) and counterstained with mouse antiphosphotyrosine (as in Fig. 1). Bar: 20 µm.

several of the antibodies described. So again we have had to compromise. Weber and colleagues (1978) introduced the use of sodium borohydride to reduce free aldehyde groups after glutaraldehyde fixation and thereby the autofluorescence introduced by this fixative. If autofluorescence is observed, for example, in the region of the nucleus, this can be eliminated by a brief treatment (3 × 10 min) of the coverslips in ice-cold cytoskeleton buffer containing freshly dissolved sodium borohydride (0.5 mg/ml). The coverslips are rinsed three times prior to immunolabelling.

VI. PITFALLS

If problems arise from sinking of coverslips during washing, use another washing protocol, e.g., immersion of coverslips cell side up in separate petri dishes containing PBS. Damaged cells normally arise from inadvertently allowing the coverslip to dry at any stage of the procedure or by touching the cell side with filter paper. Labelling with phalloidin can be improved by including this probe also in the first antibody. Successful double or triple immunofluorescence labelling requires that the individual antibody combinations each produce intense staining with a clean background, when used alone.

Immunocytochemistry of Frozen and of Paraffin Tissue Sections

Mary Osborn and Susanne Brandfass

I. INTRODUCTION

Immunocytochemistry of tissue sections can yield valuable information as to the location of antigens. Thus it can determine whether the antigen is ubiquitous or is present only in certain tissues. It can further determine whether all cells in a given tissue are positive for a given antigen or whether the antigen is restricted to one or a few specialized cell types within the tissue. Its uses are not limited to normal tissues, and testing of tumor tissues in immunocytochemistry can yield information important for determination of tumor type. As stated in the articles on immunocytochemistry of cultured cells, choice of antibodies and of fixation method can be of critical importance. New antibodies should be tested on both frozen sections and paraffin sections of a variety of tissues in which the antigen is thought to be present. In general, more antibodies will react on frozen sections than on paraffin sections; however, morphology is better preserved in the paraffin sections.

For other reviews of methods, see Denk (1987) and Sternberger (1979), and for overviews of the use of these methods in histopathology, see Osborn and Weber (1983), Tubbs *et al.* (1986), Jennette (1989), and Osborn and Domagala (1997).

II. MATERIALS AND INSTRUMENTATION

A. Antibodies

See the article by Osborn in this volume. Establish working dilutions by running a dilution series. Usually monoclonal antibodies can be diluted 1:5 to 1:30, ascites fluid 1:100 to 1:1000, and polyclonal antibodies 1:20 to 1:40, but the dilutions depend critically on the detection technique that is employed. Dilute both primary and secondary antibodies as far as possible to save money and to avoid unspecific reactions.

B. Cryostat

Use a Leica CM1900 rapid sectioning cryostat (www.leica-microsystems.com). A useful accessory is a freezing head with variable temperature control. Use a C-knife and resharpen when necessary.

C. Tissue-tek

OCT 4583 compound from Miles Laboratories.

D. Paraffin Embedding

Automatic machines are useful only for laboratories that process a large number of samples. Check equipment for paraffin embedding in the local pathology department before purchasing.

E. Sliding Microtomes

These are relatively inexpensive and can be used with disposable knives.

F. Water Baths for Histology

These are thermostatically controlled and relatively shallow, e.g., 20 cm in diameter and 4 cm deep.

Copyright 2006, Elsevier Science (USA).
All rights reserved.

G. Microscopes

A microscope equipped with the appropriate filters to view immunofluorescence specimens is important. To view peroxidase- or streptavidin–biotin-stained specimens only a simple light microscope is required.

III. PROCEDURES

A. Cryostat Sections

1. Freezing of Tissue Blocks

Steps

1. Fill the inner beaker of the freezing apparatus with isopentane and the outer beaker with liquid nitrogen about 30 min before freezing tissues (Fig. 1). Use reagent-grade isopentane. Measure the temperature and wait until isopentane reaches –120 to –130°C. At –155°C the isopentane will freeze.
2. Dissect tissues. Cut into small blocks (~4–7 mm) using a scalpel. Place block on a prenumbered square of paper with the surface that will be sectioned furthest away from the paper. For small specimens, e.g., vessels, place a drop of Tissue-tek on the paper and then add the tissue.
3. Drop tissue blocks into iospentane. Leave for at least 30 s. Remove blocks with plastic tweezers and transfer directly to plastic vials (scintillation vials 6 × 2.5 cm work well) or metal cans (~3 × 3 cm) with screw tops that have been precooled on dry ice. Close vials and store in a –70°C freezer. Tissue blocks are stable for several years.

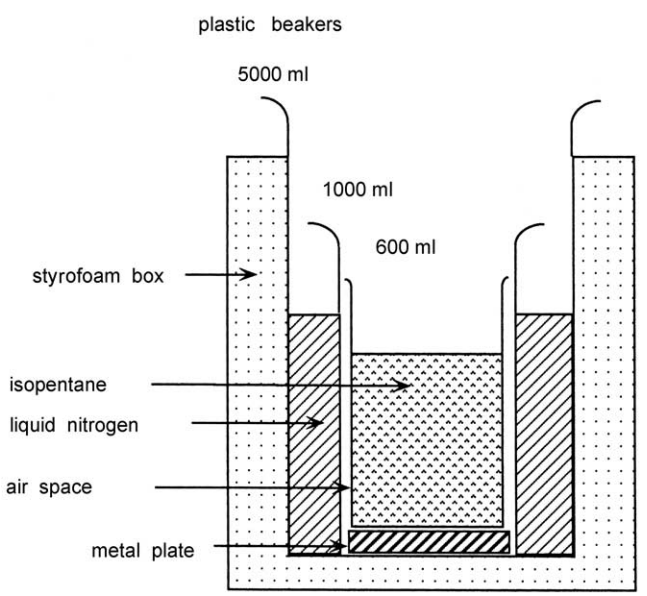

FIGURE 1 Apparatus used to freeze tissues.

2. Cutting Cryostat Sections

Stpes

1. Wash microscope slides by dipping in acetone, air dry, and store at room temperature. Store plastic tweezers and brush in the cryostat. Precool cryostat and freezing head.
2. Place Tissue-tek on precooled freezing head and mount block so that the larger side of the cut section is at 90° to the knife blade.
3. The optimal cutting temperature is different for different tissues. Most tissues cut well at –15 to –20°C. For liver, use –10°C. If the sections wrinkle as they are cut and look mushy, decrease the temperature. If the sections have cracks and look brittle, increase the temperature.
4. To cut sections use the C-knife. First trim the block to get a good cutting surface. Then adjust the section thickness to 5 µm and use the automatic advance. Now cut three or four sections so that the preset section thickness is achieved. Then bring the antiroll plate on the knife to stop the section from rolling up and to keep it flat on the knife. The antiroll plate must be parallel to the knife edge and should only protrude very slightly over the edge.
5. For optimal sections the knife and the antiroll plate must be kept clean (use a soft cloth dipped in acetone). Always clean the knife in the cutting direction and never the reverse so as not to damage the cutting edge of the knife.
6. Remove the antiroll plate and hold the microscope slide over but not touching the cut section. The section should now spring on to the slide because of the difference in temperature between knife and slide. The quality of the section can be checked using toluidine blue or hematoxylin–eosin staining (see later).
7. Dry the sections at room temperature for 30 min. Then either use directly or place in a slide box and put in a –70°C freezer. Cut sections are stable for months or years at –70°C.
8. Sections from a few tissues may not stick firmly enough to slides and may come off during subsequent processing. If this happens, try coating slides with 0.1% polylysine (e.g., Sigma Cat. No. 8920) in water.

B. Paraffin Sections

1. Embedding Tissues in Paraffin

Steps

Human material is often received from the clinic already embedded in paraffin. Protocols vary depend-

ing on the clinic, with time of fixation in formaldehyde being very variable (e.g., 4 h to over the weekend). To embed animal tissue in the laboratory, cut into 4 to 7-mm blocks and place it for 4–8 h in 3.7% formaldehyde in phosphate-buffered saline (PBS), 1 h in 50% ethanol, 2 × 1 h in 70% ethanol, 2 × 1 h in 96% ethanol, 2 × 1 h in 100% ethanol, 1 × 1 h in xylene, 1 × 2 h in xylene, and 2 × 2 h in Paraplast Plus (Shandon).

2. *Cutting Paraffin Sections*

Steps

1. To obtain very thin sections (1–2 µm), put the paraffin blocks in a freezer at –20°C for about 30 min. Mount the block in the holder of a sliding microtome. If the block cuts well do not use the automatic advance, but rely instead on the natural expansion of the block as it warms up to advance the block. If the block is not easy to cut, use the automatic advance set at a thickness of 1–2 µm. Correct adjustment of the knife and of the cutting angle is very important. Use an inclination angle (β) of 15° (Fig. 2). If the inclination angle is less than 10° the knife will not cut the block, and if it is greater than 15° the block will break.

2. Trim the block until the cutting surface is optimal. Then cut a section, using a paint brush to draw the section onto the knife so that it does not roll up.

3. Dip a second paint brush in water so that the section will adhere to it and move the section to a water bath held at 40–45°C. If the section is placed with the shiny smooth surface touching the water the warmth will smooth out the section and wrinkles will vanish!

4. Place a microscope slide under the section and, using a brush, position the section on the slide.

5. Dry the sections. For immunohistochemical methods, dry overnight at 37°C. For normal histological methods, set drying oven to 60°C so that the paraffin melts in part during the drying step and dry for 1–2 h.

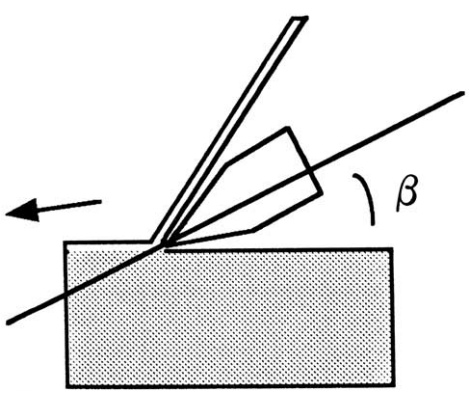

FIGURE 2 Correct adjustment of knife and of cutting angle to cut paraffin sections.

3. *Deparaffinization*

Immerse sections 2 × 10 min in xylene, 1 × 3 min in 100% ethanol, 1 × 3 min in 95% ethanol, and air dry.

4. *Trypsinization*

Some laboratories routinely use trypsinization or other proteolytic treatment of formalin-fixed, paraffin-embedded tissues prior to immunohistochemistry, e.g., 5 min in 0.1% trypsin (Sigma Cat. No. T-8128 or Dako Cat. No. S2012) in PBS at room temperature. As stressed by Ordonez *et al.* (1988), this can enhance the staining by certain antibodies but may also result in false negative staining with other antibodies. Thus, control trypsinization conditions carefully and recheck them each time a new antibody is used.

5. *Treating Sections in a Microwave Oven*

Cut sections onto Superfrost or similar slides. After deparaffinization, immerse slides in citrate buffer (2.1 g citric acid monohydrate/liter adjusted to pH 6.0 with NaOH). Microwave for two cycles of 5 min each at a setting of 650 or 700 W. Add more buffer between cycles so slides stay covered during the microwave step. Cool to room temperature (cf. Cattoretti *et al.*, 1992).

C. Histologic Staining of Sections

Stain frozen sections directly. Deparaffinize paraffin sections (see earlier), substituting a wash with distilled water for the air-drying step.

Solutions

1. *Toluidine blue:* Immerse sections in 1% toluidine blue for approximately 1 min. Wash with distilled water. Mount in water-soluble embedding medium, e.g., Glycergel (Dako Cat. No. C0563).

2. *Hemotoxylin–eosin:* Immerse sections for 10 min in Mayer's Hemalum solution (Merck). Wash for 10 min under running tap water, for 5 min in eosin (Merck), and twice with distilled water and then run through an alcohol series (e.g., 75%, 95% for 2 min each, then 100% for 5 min, then 2 × 5 min in xylol) and mount in Eukitt (Riedel de Haën Cat. No. 33949) or Entellan (Merck Cat. No. 107960).

D. Immunocytochemistry

Three methods are described in detail: immunofluorescence, the immunoperoxidase method, and the

more sensitive streptavidin–biotin method. The two latter methods have the advantage that nuclei can be counterstained with hemotoxylin and that only a simple light microscope is required to visualize the stain; however, fluorescence generally gives greater resolution.

As noted for cells, many antibodies that react well on cryostat sections may not react on the same tissue after it has been fixed in formaldehyde and embedded in paraffin. In such a case it may be advantageous to try fixing tissue, e.g., in B5, Bouin's, or Zenker's fixative or alcohol, prior to paraffin embedding. An interesting alternative is to use sections of formaldehyde-fixed, paraffin-embedded material that have been treated in a microwave oven.

For all methods mark the position of the section after fixation; either use a diamond pencil or circle the section with a water-repellent marker (Dako Cat. No. S2002). Remove excess buffer after rinsing steps with Q-tips. Use 10 µl of antibody per section. Apply with an Eppendorf pipette and use the pipette tip to spread the antibody over the section without touching the section. Several manufacturers (e.g., Dako) produce excellent protocol sheets for each immunocytochemical method.

1. Immunofluorescence

Steps

1. Fix cryostat sections or paraffin sections deparaffinized as described earlier for 10 min in acetone at –10°C. Air dry.
2. Use steps 2–9 of the protocol given in the article by Osborn in this volume for multitest slides. Nuclei can be counterstained with Hoechst dye (see Osborn's article). Positively stained cells will be green (see Fig. 3) if an FITC-labeled second antibody is used or red if a rhodamine-labeled second antibody is selected (see also the double label of a cytological sample in Fig. 4).

2. Peroxidase Staining

Steps

1. Fix cryostat sections for 10 min in acetone at –10°C, air dry, and wash in PBS.
2. Deparaffinize paraffin sections and incubate for 30 min at room temperature in 100 ml methanol containing 100 µl H_2O_2 to block endogenous peroxidase activity. Wash in PBS.
3. Incubate for 10 min at 37°C with normal rabbit serum. Drain, but do not wash after this step.
4. Incubate with primary antibody (e.g., mouse monoclonal) for 30 min at 37°C.
5. Wash three times in PBS.

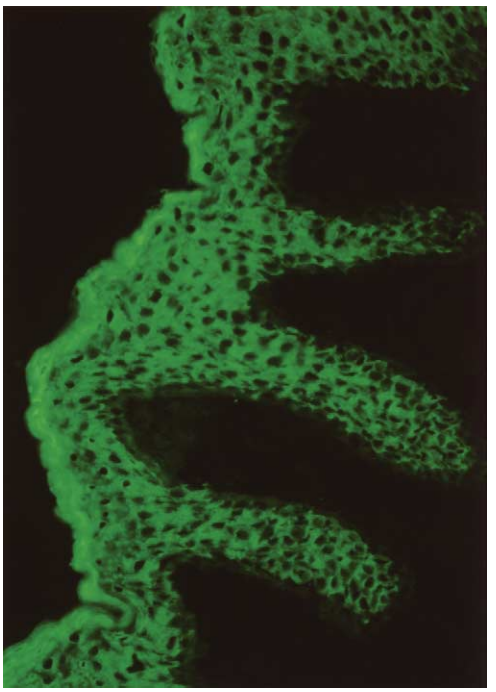

FIGURE 3 Frozen section of human skin stained with KL1 keratin antibody with FITC-labeled second antibody. Only the epidermis is stained (×150).

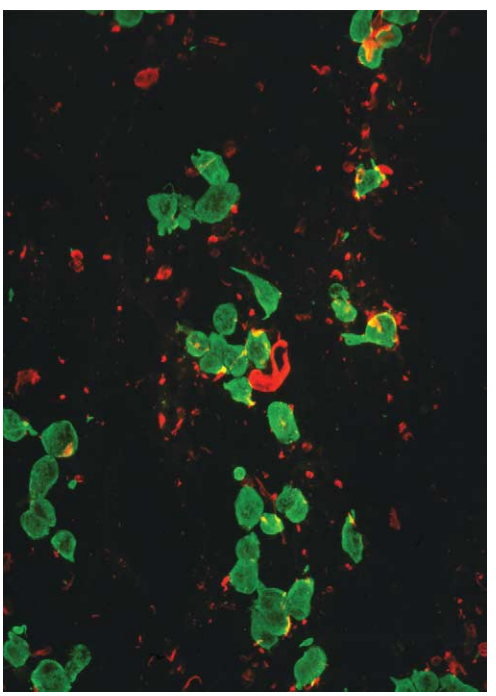

FIGURE 4 Cytological specimen from human breast carcinoma stained with a keratin antibody with FITC-labeled second antibody to show the tumor cells and with a vimentin antibody and a rhodamine-labeled second antibody to show the other cells in the specimen.

6. Incubate with second antibody coupled to peroxidase, e.g., rabbit antimouse for a monoclonal first antibody (Cat. No. P0260 from Dako diluted 1:10 to 1:20).
7. Wash three times in PBS and once in Tris buffer (6 g NaCI, 6 g Tris/liter, pH 7.4),
8. Develop for 10 min at room temperature using freshly made solutions (e.g., 0.06 g diaminobenzidine, Fluka Cat. No. 32750 in 100 ml Tris buffer, 0.03 ml H_2O_2). *Note:* Diaminobenzidine is a carcinogen; handle with care.
9. Wash in tap water.
10. Apply a light counterstain by immersing the slide in Hemalum for 1 to 10 s. Remove when staining reaches the required intensity.
11. Wash in tap water.
12. Mount in Glycergel (Dako Cat. No. C0563, http://www.dako.com).

Notes

1. Structures that are positively stained will be dark brown, whereas nuclei will be light blue (Figs. 5–7).
2. The method can be made more sensitive by using an additional step with a peroxidase–antiperoxidase complex (see Sternberger, 1979).
3. Blocking should be performed with a 5% solution of normal serum from the same host species as the labeled antibody, i.e., in this example the tissue is

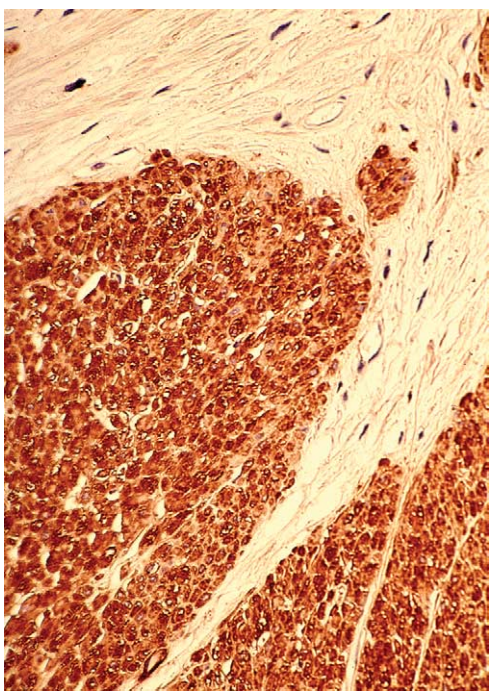

FIGURE 5 Paraffin section of human uterus stained with antibody after microwave fixation with the desmin DER 11 antibody in the peroxidase technique (×160).

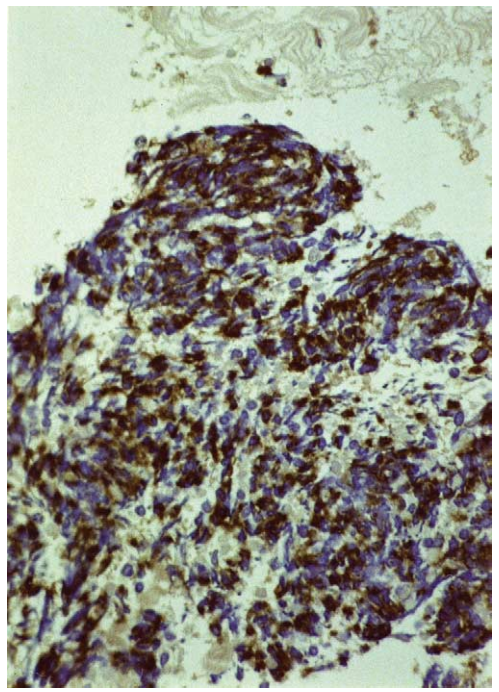

FIGURE 6 Frozen section of human rhabdomyosarcoma stained after microwave treatment with desmin antibody DEB5 and with peroxidase-labeled second antibody. Brown tumor cells are positive for desmin. Nuclei are counterstained blue (×160).

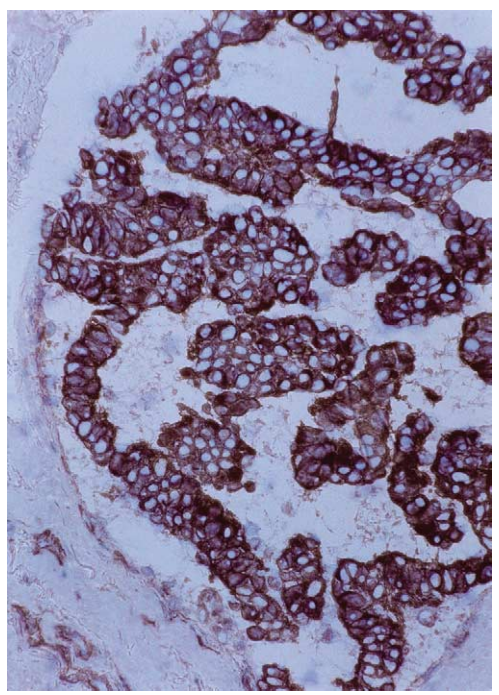

FIGURE 7 Frozen section of human breast carcinoma stained with the keratin KL1 antibody and with peroxidase-labeled second antibody. Brown tumor cells are positive for keratin. Nuclei are counterstained blue (×150).

blocked with normal rabbit serum because the labeled antibody is a rabbit antibody.
4. Bovine serum albumin (BSA) for diluting antibodies should be of high purity. Impure preparations can contain bovine IgGs that can cross-react with the labeled second antibodies.

3. *Streptavidin–Biotin Stain*

Buy the reagents separately or use the Histostain kit from Zymed Laboratories (http://www.zymed.com; Cat. No. 95-6543 for mouse primary antibody and Cat. No. 95-6143 for rabbit primary antibody). These kits are based on the strong binding between streptavidin, a 60,000-kDa protein isolated from *Streptomyces avidinii*, and biotin, a water-soluble vitamin (MW 244, $K_d = 10^{-15} M$). Instructions are given for the mouse kit.

Steps

1. Fix cryostat sections for 10 min in acetone at –10°C and air dry. Sections can be treated with 0.23% periodate for 45 s. Go to step 3.
2. Deparaffinize paraffin sections and air dry. Incubate 10 min in PBS at room temperature and then 10 min in H_2O_2 solution (nine parts methanol to one part 30% H_2O_2 in water). Wash 3 × 2 min in PBS.
3. Reduce nonspecific background staining by blocking for 10 min in 10% goat serum at room temperature (see Note 3 in Section III,D,2). Then drain but do not wash.
4. Incubate with primary antibody, e.g., mouse monoclonal antibody, in wet chamber for 30 min at 37°C.
5. Wash 3 × 2 min in PBS.
6. Add biotinylated second antibody, e.g., goat anti-mouse, for 10 min at room temperature and repeat step 5.
7. Add enzyme conjugate streptavidin–peroxidase diluted 1:20 for 5 min at room temperature. This binds to the biotin residues on the second antibody.
8. Develop by adding substrate–chromogen mixture for 5 min at 37°C or 15 min at room temperature. The enzyme peroxidase catalyzes the substrate hydrogen peroxide and converts the chromogen aminoethylcarbazole to a red, colored deposit.
9. Wash 3 × 2 min in distilled water.
10. Counterstain with Hemalum between 1 and 10 s.
11. Wash 7 min in tap water.
12. Mount in glycergel.

Notes

1. Structures that are positively stained will be red, whereas nuclei will be light blue (Figs. 8 and 9).

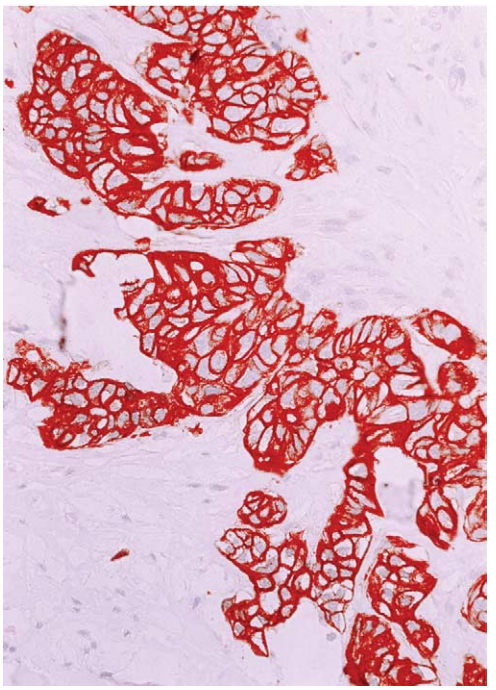

FIGURE 8 Paraffin section of human breast carcinoma stained after microwave treatment with keratin KL1 antibody in the streptavidin–biotin technique. Red tumor cells are keratin positive. Nuclei are counterstained blue (×150).

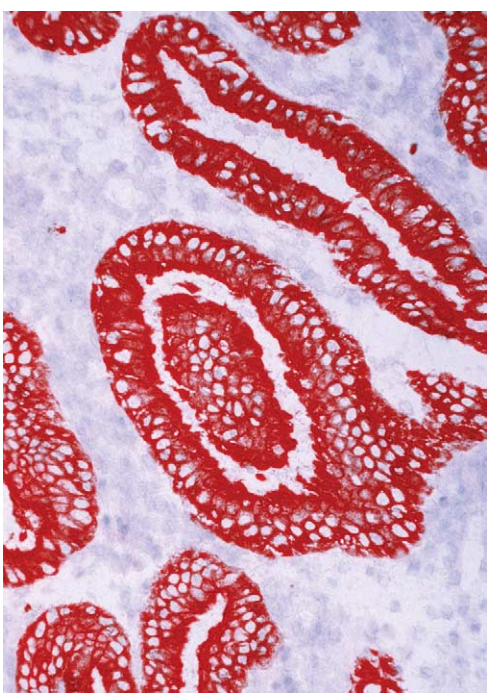

FIGURE 9 Frozen section of human uterus is stained with KL1 keratin antibody in the alkaline phosphatase–antialkaline phosphatase technique. Only epithelial cells are positive (×150).

2. The optimal dilution of primary antibody has to be determined for each antibody.
3. The streptavidin–peroxidase conjugate is the same for all species; the blocking serum and second antibody vary according to the species in which the first antibody is made.

Other Methods

1. The alkaline phosphatase–antialkaline phosphatase technique is also a very sensitive method (Fig. 8).

2. Both fluorescent and chromogenic signals can be enhanced up to 1000X with Tyramide Signal Amplification Technology (New England Nuclear). With this technique, primarily antibodies can be diluted in some instances more than 10,000-fold.

IV. COMMENTS

If possible, include (1) a positive control, i.e., a section of a tissue known to contain the antigen; (2) a negative control, i.e., a section known not to have the antigen; and (3) a reagent control, i.e., a section stained with nonimmune serum instead of the primary antibody. Ideally, the first control should be positive and the second and third controls negative. If high backgrounds are obtained, it may help to adjust the antibody concentrations by increasing the length of time for washing steps or by including 0.5*M* NaCl or 5% BSA in the antibody solutions.

Representative Cultured Cell Lines and Their Characteristics

Robert J. Hay

Virtually thousands of different cell lines have been derived from human and other metazoan tissues. Many of these originate from normal tissues and exhibit a definable, limited doubling potential. Other cell lines may be propagated continuously, as they either have become immortalized from the normal by genetic changes or have been developed initially from tumor tissue. Finite lines of sufficient doubling potential and continuous lines can both be expanded to produce a large number of aliquots, frozen, and authenticated for widespread use in research.

Resources such as the American Type Culture Collection (ATCC) have been established to acquire, preserve, authenticate, and distribute reference cell lines and microorganisms for use by the academic and industrial scientific community (Hay *et al.*, 2000). The cell biology program at the ATCC performs these functions to include human and animal cell lines with over 4000 available in 2003.

The advantages of working with well-defined cell lines free from contaminating organisms may appear obvious. Unfortunately, however, the potential pitfalls associated with the use of cell lines casually obtained and processed still require emphasis (Stacey *et al.*, 2000). Numerous occasions where lines exchanged among cooperating laboratories have been contaminated with cells of other species have been recognized since the late 1960s (Nelson-Rees *et al.*, 1974, 1981; MacLeod *et al.*, 1999). The loss of time and research funds as a result of these problems is very extensive.

Although bacterial and fungal contaminations represent an added concern, in most instances they are overt and easily detected, and therefore have less serious consequences than the more insidious contaminations by mycoplasma. That the presence of these latter microorganisms in cultured cell lines often negates research findings entirely has been stated repeatedly over the years (Barile *et al.*, 1973; Hay *et al.*, 1989). However, the difficulties of detection and the prevalence of contaminated cultures in the research community suggest that the problem cannot be overemphasized. These and related difficulties associated with the use of cell lines obtained from different sources can be avoided if one acquires stocks from a centralized cell resource that applies appropriate quality control (Hay *et al.*, 2000).

Representative human cell lines from normal and tumor tissues available from the ATCC are listed in Table I with a selection of a few of the more important characteristics. Similar data on a variety of cell lines from other animals are included in Table II. More current information on these and other cell lines, their availability, and characteristics is available online via the ATCC website at www.atcc.org.

	LoVo	CCL-229	56	M	W	Adenocarcinoma of colon	Metastasis to clevicula	F12/10	Tumorigenic; well characterized for growth kinetics and drug responses. Desmosomes shown. CEA produced
	T84	CCL-248	72	M	?	Colon carcinoma	Transplant tumor	F12DME/5	Desmosomes; receptor for peptide hormones and neurotransmitters; show vectorial transport
	NCI-H508	CCL-253	55	M	W	Cecum adenocarcinoma	Metastasis to abdo- minal wall	R10	High DOPA carboxylase; TAG-72, CA 19-9 and CEA antigens. One of a series
	FHC	RL 1831	Fetus 13 wk.	?	?	Normal	Colon	F12/DM10+	Epithelial-like; lacks keratin; limited doubling potential
	HT-29	HTB 38	44	F	W	Well-differentiated grade II adenocarcinoma	Primary	MC10	Tumorigenic; hypertriploid; 17 marker chromosomes
	Caco-2	HTB 37	72	M	W	Adenocarcinoma	Primary	EM20	Hypertetraploid; exhibits enterocyte differentiation; tumorigenic.
Duodenum (2)	FH 74	CCL-241	3- to 4-month fetus	F	?	Normal	Small intestine	DME10+	Epithelial-like; tonofibrils and microvilli; keratin –'ve
	HuTu80	HTB-40	53	M	W	Adenocarcinoma	Primary	EM10	Tumorigenic; forms well-differentiated papilloma; pseudodiploid
Embryonal carcinoma (5)	NTERA-2 cl-D1	CRL-1973	22	M	W	Testicular carcinoma	Metastasis to lung	DM10	Clone of Tera-2; pluripotent; differentiates on exposure to RA
	NCCIT	CRL-2073	Adult	M	J	Embryonal CA	Mediastinal mixed germ cell tumor	R10	Differentiates; -'ve for keratin; +'ve for vimentin and placental alkaline phosphatase
	Cates-1B	HTB-104	35	M	W	Testicular carcinoma	Metastasis to lymph node	MC15	Pseudodiploid; patient treated with cytoxan, vincristine, and actinomycin D

TABLE I (*Continued*)

Tissue/tumor (number available)	Designation	ATCC No.	Age	Sex	Race	Diagnosis	Source	Medium[b]	Comments
	Tera 1	HTB-105	47	M	W	Seminoma	Metastasis to lung	MC10	Not tumorigenic; bcl-1 mRNA
Endometrium (7)	AN3 CA	HTB-111	55	F	W	Adenocarcinoma	Metastasis to lymph node	EM10	Yields malignant, undifferentiated tumor
	HEC-1A	HTB-112	71	F	?	Adenocarcinoma stage IA	Primary tissue	MC10	Hyperdiploid; triploid variant available as HTC113
	SK-UT-1	HTB-114	75	F	W	Leiomyosarcoma grade III	Mixed Mesodermal tumor	MEM10+	Hypodiploid to hyperdiploid. Diploid line selected and available as HTB-115
	KLE	CRL-1622	64	F	W	Poorly differentiated adenocarcinoma	Primary	DM/F12–10	Tumorigenic; forms microvilli and junctional complexes
	RL95–2	CRL-1671	65	F	W	Moderately differentiated adenosquamous			Estrogen receptors; *a*-keratin; microvilli
Kidney (30)	293 [HEK293]	CRL-1573	Fetus	?	?	Normal kidney	Early passage cells exposed to sheared adenovirus 5 DNA	MEM10HS	Used extensively in virus propagation. Many variants and engineered derivatives available
	ACHN	CRL-1611	22	M	W	Adenocarcinoma	Pleural effusion	EM10	Tumorigenic; invasive
	769-P	CRL-1933	63	F	W	Clear cell adenocarcinoma	Primary	R10	Tumorigenic; colonies in soft agar; microvilli and desmosomes; hypodiploid
	HK-2	CRL-2190	Adult	M	?	Normal proximal tubular line	E6/E7 transformed	Keratinocyte serum-free medium + F12K/10	Positive for PT cell marker enzymes and other proteins
	CCD-1103 KIDTr	CRL-2304	Fetal	?	?	Normal kidney epithelia	E6/E7 transformed		Keratin and acid phosphatase positive; susceptible to coxsackie, measles, polio and syncytial virus infection
	SV7 tert	CRL-2461	63	F	?	Renal angiomyolipoma	Immortalized with SV40 large T and h-tert	DME10	For studies on tuberous sclerosis
	A-498	HTB-44	52	F	?	Kidney carcinoma	Primary tumor	MEM10	Hypertriploid line; used in virus and tumorigenicity studies
	Caki-1	HTB-46	49	M	W	Renal carcinoma	Metastasis to skin	MC10	Tumorigenic; hypertriploid
Leukemia/ lymphoma (55)	CCRF-CEM	CCL-119	4	F	W	ALL	Peripheral blood	R20	T lymphoblast; malignant in newborn hamsters; model chromosome number 45–47

TABLE I (*Continued*)

Tissue/tumor (number available)	Designation	ATCC No.	Age	Sex	Race	Diagnosis	Source	Medium[b]	Comments
	HL-60	CCL-240	36	F	W	ALL	Peripheral blood	L15/10	Neutrophilic promyelocytes differentiate when exposed to RA and others; surface receptors for Fc
	MOLT 4	CRL-1582	19	M	?	ALL	Peripheral blood	R10	Stable T cell; high Tdt; model chromosome number 95
	TUR	CRL-2367	37	M	W	Histiocytic lymphoma	Effusion	R10	Stable transfectant of U-937 resistant to both G418 and TPA
	NK-92	CRL-2407	50	M	W	Hodgkin's lymphoma	Peripheral blood	Alpha MEM/125 H/FBS	Natural killer cell line, IL-2-dependent surface markers defined series of lines available
	Loucy	CRL-2629	38	F	W	T-ALL	Peripheral blood	R10	Useful for defining role of t(16; 20) and genetic studies
	Hut 78	TIB-161	50	M	W	Sezary syndrome	Peripheral blood	R10	Mature T cell with inducer/helper phenotype; yields and responds to interleukin-2; parent to H9 cell line
Liver (13)	Hep- 3B	HB-8064	8	M	B	Hepatocellular carcinoma	Primary	EM10	Tumorigenic; produce haptoglobin; *a*-fetoprotein, albumin, a_2-macroglobulin; transferrin; fibrinogen, and other liver-specific proteins
	Hep-G2	HB-8065	15	M	W	Hepatocellular carcinoma	Primary	EM10	
	SNU-398	CRL-2233	42	M	A	Anaplastic hepatocellular carcinoma	Primary tumor	ACL4/5	Hyaline globules; HBV-DNA +'ve; HBV-RNA not expressed. One of a series of similar lines
	THLE-3	CRL-11233	Adult	?	?	Normal liver	Left lobe	BEGM	SV_{40} T antigen infected via PA317. Model for pharmacotoxicological studies
	SK-HEP-1	HTB-52	52	?	W	Adenocarcinoma	Ascites	EM10	Produces *a*-antitrypsin; has Weibel–Palade bodies and vimentin
Lung (203)	A-549	CCL-185	58	M	W	Carcinoma	Primary	F12K/15	Enzymes related to surfactant synthesis studied; lamellar inclusions but sparse.
	WI-38	CCL-75	Fetus	F	W	Normal	Primary	EM10	Euploid line, widely used in cell biology aging research, virology and vaccine manufacture. One of many normal fibroblast controls
	MRC-5	CCL-171	Fetus	M	W	Normal	Primary	EM10	Euploid line, widely used in cell biology aging research, virology and vaccine manufacture

TABLE I (*Continued*)

Tissue/tumor (number available)	Designation	ATCC No.	Age	Sex	Race	Diagnosis	Source	Medium[b]	Comments
	HLF-a	CCL-199	54	F	B	Normal	Primary	EM10	Diploid and stable; patient had epidermoid carcinoma of lung; tissue used was from site remote from cancer
	CCD-19Lu	CCL-210	20	F	W	Normal	Primary	EM10	Euploid; patient died of accidental head trauma
	NCI-H2126	CCL-256	65	M	W	Nonsmall cell lung CA	Plural effusion	HITES/5	One of an extremely large collection of human lung cancer lines and controls
	NCI-BL2126	CCL-256	65	M	W	Peripheral blood B lymphoblast line	EBV trans-formant	R10	Paired "control" for studies with NCI-H2126. Genomic DNA also available (ATCC# 45512 and 45513)
	NCI-H146	HTB-173	59	M	W	SCLC	Pleural fluid	R10	Tumorigenic; near triploid; high c-*myc* mRNA but no gene amplification; elevated biochemical markers for SCLC; keratin and vimentin positive
	NCI-H441	HTB-174	?	M	?	PapAC	Pericardial fluid	R10	Hyperdiploid; grows in soft agar; SP-A+' Clara and lamellar inclusions
	NCI-H82	HTB-175	40	M	W	SCLC	Pleural fluid	R10	Tumorigenic; near triploid, no Y, high c-*myc*; DNA and RNA, reduced amount and abnormal p53 mRNA (3.7 kb)
	NCI-H820	HTB-181	53	M	W	PapAC	Lymph node	A4	Near triploid; produces lamellar bodies and surfactants SP-A, -B and -C
	SK-LU-1	HTB-57	60	F	W	Adenocarcinoma	Primary	EM10	Tumorigenic in immunotolerant rats; hypotetraploid
Melanoma (32)	C32	CRL-1585	53	M	W	Amelanotic melanoma	Primary	EM10	Tumorigenic; hypodiploid with mode of 45
	Hs294T	HTB-140	56	M	W	Metastatic melanoma	Metastasis to lymph node	DM10	Nerve growth factor and interferon receptors; responsive to RA; tumorigenic and grows in soft agar
	MeWo	HTB-65	78	M	W	Malignant melanoma	Metastasis to lymph node	EMO	Well-studied line, XY karyottype, blood type A; HLA A2, A26, BW16, 18
	SK-MEL5	HTB-70	24	F	W	Metastatic melanoma	Metastasis to axillary node	EM10	Tumorigenic
	COLO 829	CRL-1974	45	M	W	Malignant melanoma	Subcuta-neous metastasis	R10	Prior to therapy; some melanin produced; B-cell counterpart available

TABLE I (*Continued*)

Tissue/tumor (number available)	Designation	ATCC No.	Age	Sex	Race	Diagnosis	Source	Medium[b]	Comments
	COLO 829BL	CRL-1980	45	M	W	Malignant melanoma	Peripheral blood EBV trans-formed	R10	"Control" B-cell line to CRL 1974; DNA fingerprinting confirms identity
Myeloma/ plasmacy-toma (18)	RPMI 8226	CCL-155	61	M	?	Multiple myeloma	Peripheral blood	R20	Produces λ light chains; no mature plasma cells
	U266B1	TIB-196	53	M	?	Myeloma	Perophiral	R15	IgE-A secreting
	HS-Sultan	CRL-1484	56	M	W	Plasmacytoma	Primary	R10	Produces IgG- *k*; hyperdiploid
	MC/CAR	CRL-8083	81	M	W	β-cell plasmacytoma	Peripheral blood	IDM20	Produce IgG1, have C3b complement receptors, and have normal diploid karyotype. Variant resistant to 8-aza-guanine available as CRL-8147
	NCI-H929	CRL-9068	62	F	W	Myeloma	Malignant effusion	R10+	Positive for PCA-1, transferrin receptor, and CD38. The 8q chromosomal anomaly is prevalent. Ras and C-myc RNA are expressed
Nasal septum (1)	RPMI 2650	CCL-30	52	M	?	Anaplastic SCC	Pleural effusion	EM10	Pseudodiploid with mode 46; keratin positive
Neuro-blastoma (13)	IMR-32	CCL-127	13 mo.	M	W	Neuroblastoma with organoid differentiation	Abdominal mass	EM10	Neuroblasts and large hyaline fibroblasts
	SK-N-MC	HTB-10	14	F	W	Neuroblastoma	Metastasis to supraorbital area	EM10 EM10	Pseudodiploid; dopamine hydroxlase positive
	SK-N-SH	HTB-11	4	F	?	Neuroblastoma	Metastasis to bone marrow		Hyperdiploid; dopamine hydroxylase
	BE(2)-M17	CRL-2267	2	M	?	Neuroblastoma	Metastasis to marrow	EM/F12 10	Grow in multilayer with long neuritic processes. Also as floating aggregates
	MC-IXC	CRL-2270	14	F	W	Neuroblastoma	Metastasis to supra-orbital area	EM/F12 10	High choline acetyltransferase clonal derivative of HTB-10
Ovary (11)	Caov-3	HTB-75	54	F	W	Adenocarcinoma	Primary	EM10	Extremely unusual chromosome morphology
	NIH: OVCAR-3	HTB-161	60	F	W	Progressive adenocarcinoma	Ascites	R20+	Tumorigenic; grows in soft agar; androgen and estrogen receptors
	PA-1	CRL1572	12	F	W	Teratocarcinoma	Ascites	EM10	Pseudodiploid, t(15q20q); highly malignant in nude mice
	TDV-112D	CRL-11731	42	F	W	Malignant adenocarcinoma	Primary ovary	MCDB104 and M199/15	Mutated p53, variants with deletions at 3p24 (CRL-11730 and 32)
Pancreas (19)	AsPC-1	CRL-1682	62	F	W	Metastatic carcinoma	Ascites	R20	Tumorigenic; CEA, PAA and PSA positive, hypotriploid

TABLE I (*Continued*)

Tissue/tumor (number available)	Designation	ATCC No.	Age	Sex	Race	Diagnosis	Source	Medium[b]	Comments
	SU86-86	CRL-1837	57	F	W	Pancreatic ductal adenocarcinoma	Liver metastasis	R10	Sensitivities in killer cell assays documented
	HPAF-11	CRL-1997	44	M	W	Pancreatic metastatic adenocarcinoma	Peritoneal fluid	EMIO	Highly metastatic
	MPanc-96	CRL-2380	67	M	W	Malignant adenocarcinoma	Lymph node	RI0	Transplantable to SCID mice. Recognized by autologous tumor-infiltrating leucocytes
	Capan-1	HTB-79	40	M	W	Metastatic carcinoma	Liver metastasis	R15	Tumorigenic; hypotriploid
	PANC-1	CRL-1469	56	M	W	Epitheloid ductal carcinoma	Primary	DM10	Hypertriploid
Pharynx (3)	Detroit 562	CCL-138	?	F	W	Metastatic carcinoma	Pleural fluid	EM10	Keratin positive
	FaDu	HTB-43	56	M	W	Squamous cell	Primary	EM10	Tumorigenic; desmosomes; 19 marker chromosomes
Placenta (5)	BeWo	CCL-98	Fetus	M	?	Malignant gestational choriocarcinoma	Hamster xenograft	F12-15	Secretes placental hormones, hCG, human placental lactogen, estrone, estradiol, progesterone
	JEG-3	HTB-36	Fetus	?	?	Choriocarcinoma, Edwin-Turner tumor	Hamster xenograft	EM10	Secretes hCG, human chorionic somatomammotropin, and progesterone; tumorigenic
	JAR	HTB-144	Fetus	?	?	Choriocarcinoma	Primary	R10	Secretes estrogen, progesterone, gonadotropin, and lactogen
	3A(tPA-30-1)	CRL-1583	Term	F	?	$TsA30SV_{40}$ + transformant	Normal term placenta	AMEM1O	Produce human chorionic gonadotrophin and are alkaline phosphatase positive at permissive (33) temperature. Postcrisis line available as CRL-1584
Prostate (10)	PC3	CRL-1435	60	M	W	Adenocarcinoma, grade IV	Primary	F12K-7	Tumorigenic and grows in soft agar; low acid phosphatase and steroid reductase
	LNCap.FGC	CRL-1740	50	M	W	Metastatic adenocarcinoma androgen-independent	Metastasis to supra-clavicular-lymph node	R10	Produces PSA, prostatic acid phosphatase; androgen receptors; tumorigenic
	PZ-HPV-7	CRL-2221	70	M	W	HPV-18 DNA transformed epithelium	Normal tissue peripheral prostate	KSFM	Keratins 5 and 8 positive. Not tumorigenic
	MDA Pca2b	CRL-2422	63	M	B	Prostatic adenocarcinoma	Bone	F12K/20	PSA and androgen receptor positive. Tumorigenic
	RWPE-1	CRL-11609	54	M	W	Transfected with plasmid carrying copy of HPV-18	Normal prostatic epithelia	KSFM	Nontumorigenic, positive for keratins 8 and 18. PSA develops on exposure to androgens. Transformed variants available as CRL-11610 and 11611

TABLE I (*Continued*)

Tissue/tumor (number available)	Designation	ATCC No.	Age	Sex	Race	Diagnosis	Source	Medium[b]	Comments
	DU145	HTB-81	69	M	W	Metastatic carcinoma	Metastasis to brain	EM10	Grows in soft agar; weak acid phosphatase; triploid; desmosomes
Rectum (5)	SW-837	CCL-235	53	M	W	Adenocarcinoma, grade IV	Primary	L15–10	Tumorigenic; hypodiploid
	SW-1463	CCL-234	66	F	W	Adenocarcinoma, grades II–III	Primary	L15–10	Tumorogenic; CEA positive; hypertriploid
Retinoblastoma (2)	WERI-Rb-1	HTB-169	1	F	W	Retinoblastoma	Primary	R10	Tumorigenic in rabbits; no colonies in soft agar; near diploid with 15 or 16 markers
	Y79	HTB-18	2.5	F	W	Retinoblastoma	Primary	R15	Reportedly reverse transcriptase positive
Rhabdomyosarcomas (5)	A204	HTB-82	1	F	?	Embryonal rhabdomyosarcoma	Primary	MC10	Tumorigenic; near diploid with abnormality on 22p
	HS729	HTB-153	74	M	W	Malignant rhabdomyosarcoma	Primary muscle	M5/10	Tumorigenic consistent with embryonal type
	RD	CCL-136	7	F	W	Malignant rhabdomyosarcoma	Pelvic tumor	DM10	No myofibrils but myoglobin and myosin ATPase activity; complex hyperdiploid karyology; also designated TE32 and 130T
Sarcoma (28 + genetic variants)	HT-1080	CCL-121	35	M	W	Fibrosarcoma	Acetabulum	EM10	Pseudodiploid tumorigenic. Susceptible to R0114 and FeLV. Contains activated N-ras
	HOS	CRL-1543	13	F	W	Osteogenic sarcoma	Primary	EM10	Flat morphology; sensitive to viral and chemical morphological transformation
	MES-SA	CRL-1976	56	F	W	Poorly differentiated sarcoma	Uterine tissue-hysterectomy	MCRO	Sensitive to chemotherapeutic agents. Resistant lines also available as CRL-1977 and CRL-2274
	MG-63	CRL-1427	14	M	W	Osteogenic sarcoma	Primary	EM10	Yields interferon on induction; hypotriploid with 18 or 19 markers
	SK-LMS-1	HTB-88	4	F	W	Leiomyosarcoma, grade II	Primary, vulva	EM10	Tumorigenic; hypertriploid with complex karyotype
	SW 1353	HTB-94	72	F	W	Chondrosarcoma	Primary, right humerus	L15/10	Hyperdiploid with trisomic N7 only
	U-205	HTB-96	15	F	W	Osteosarcoma	Tibia	MC15	Secretes osteosarcoma-derived growth factor similar to PDGFA chain
Skin (28)	Detroit-551	CCL-110	Fetus	F	W	Normal fibroblast	Skin	EM10	One of a series of lines from normal individuals and persons with genetic disorders

TABLE I (*Continued*)

Tissue/tumor (number available)	Designation	ATCC No.	Age	Sex	Race	Diagnosis	Source	Medium[b]	Comments
	A-431	CRL-1555	85	F	?	Epidermoid carcinoma	Primary	DM10	Tumorigenic and grows in soft agar; hypertriploid
	182-PFSK	CRL-1532	20	M	W	Normal	Skin	DM10	Apparently normal but carrying gene for hereditary adenomatosis of the colon
	MeKam	CRL-1279	10	M	W	Xeroderma pigmentosum	Skin	DM10	Xeroderma pigmentosum line from NIH. One of about 200 lines from humans with genetic disorders
	CCD 27Sk	CRL-1475	Fetus	M	B	Apparently normal fibroblasts	Skin	EM10	Established using skin from the chest area
	CD 977Sk	CRL-1900	20	F	W	Apparently normal fibroblasts	Skin	EM10	Established from skin of the breast
	CCD 966Sk	CRL-1881	78	F	B	Apparently normal fibroblasts	Skin	EM10	Established from skin of the breast
	CCD 1106 KERTr	CRL-2309	Fetus	19 wk.	W	E6/E7-transformed keratinocytes	Skin	KSFM	Epithelial specific and cytokeratin+; HLA not expressed, E6/E7 presence
	CCD 1102 KERTr	CRL-2310	Fetus	16 wk.	B	E6/E7-transformed keratinocytes	Skin	KSFM	Confirmed by PCR
Stomach (9)	AGS	CRL-1739	54	M	W	Adenocarcinoma	Primary	F12–10	No prior therapy; tumorigenic
	NCI-SNU-16	CRL-5974	33	F	A	Gastric carcinoma metastatic	Ascites	R10	DDC, CEA, and TAG-72 +'ve; muscarini and VIP receptors; c-myc amplified; one of a series of human cancer lines developed by J. Park and associates
	RF-48	CRL-1863	62	M	His-panic	Metastatic carcinoma	Primary metastasis	L15/10	Metastasis from CRL 1864 (RF-1); mucin and CEA negative
	RF-1	CRL-1864	62	M	His-panic	Metastatic carcinoma	Primary	L15/10	Stains for mucin; CEA positive Tuorigenic; hypertetraploid
	KATO-III	HTB-103	55	M	Mon-goloid		Pleural effusion	IDM10	
Submaxilla (1)	A-253	HTB-41	54	M	W	Epidermoid carcincoma	Primary	MC10	Hypotriploid; 14 marker chromosomes
Testes (3)	Cates-1B	HTB-104	34	M	W	Embryonal carcinoma	Metastasis to lymph node	MC10	Reportedly hypodiploid to diploid. See also HTB-105 and HTB-106
Thyroid (2)	SW579	HTB-107	59	M	W	SCC	Primary	L15/10	Tumorigenic
	TT	CRL-1803	77	F	W	Medullary thyroid carcinoma	Primary	F12K/10	Tumorigenic; neuropeptides produced
Tongue (4)	SCC—4	CRL-1624	55	M	?	SCC	Primary	F12/DM10	Tumorigenic; involucrin negative; hypopentaploid; positive for 40-kDa keratin. See CRL-1623 and 1629
	SCC-25	CRL-1628	70	M	?	SCC	Primary	F12/DM10	Tumorigenic, synthesizes low levels of involucrin; epidermal keratin; hypertriploid

TABLE I (*Continued*)

Tissue/tumor (number available)	Designation	ATCC No.	Age	Sex	Race	Diagnosis	Source	Medium[b]	Comments
	CAL27	CRL-2095	56	M	W	SCC	Primary	DME10	Tumorigenic; resistant to treatment with VDS, CDP, or ACTD. Cytokeratin+
Umbilicus (3)	HUV-EC-C	CRL-1730	Fetal-term			Apparently normal vascular endothelium	Umbilical vein	F12K/10+ECGS	Endothelial line; produces factor VIII; near diploid; limited life span.
	HUVE-12	CRL-2480	Fetal-term			Vascular endothelium apparently normal	Umbilical vein	F12K/10 + ECCS and heparin	Limited doubling potential. See "Wistar Special Collection" for more lines and detail
	HUVS-112D	CRL-2481	Fetal-term			Smooth muscle apparently normal	Umbilical vein	F12K/10 + ECCS and heparin	Limited doubling potential. See "Wistar Special Collection" for more lines and detail
Vulva (3)	SK-LMS-1	HTB-88	43	F	W	Leiomyosarcoma	Primary	EM10	Tumorigenic
	SW954	HTB-117	86	F	W	SCC	Primary	L15/10	Pseudodiploid
	SW962	HTB-118	64	F	W	SCC	Metastasis to lymph node	L15/10	Tumorigenic; hypertriploid with at least 15 marker chromosomes

[a] See Hay *et al*. (1992) for originators, references, and more details.

[b] Abbreviations for medium used (on the left-hand side) include (EM) Eagle's minimum essential medium; (R) RPMI 1640; (DM) Dulbecco's modification of Eagle's medium; (F12 and F12K) Ham's medium and Kaighn's modification, respectively; (IDM) Iscove's modification of Eagle's medium (L15) Leibovitz medium; (MC) McCoy's 5A medium; and (AMEM) α modification of Eagle's medium [see Hay *et al*. (1992) for formulas]. The number on the right-hand side indicates percentage of serum (usually fetal bovine) used. Additional recommended ingredients are indicated by a plus sign.

[c] SCC, squamous cell carcinoma; hGH, human growth hormone; Tdt, terminal deoxynucleotidyl transferase; hCG, human chorionic gonadotrpin; RA, retinoic acid; G6PD, glucose-6-phosphate dehydrogenase; ALL, acute lyphoblastic leukemia; SCLC, small cell lung cancer; CEA, carcinoembryonic antigen; PSA, pancreas-specific antigen; PAA, pancreas-associated antigen. See www.atcc.org for further details.

TABLE II Representative Cell Lines from Other Species (January 2003)

ATCC No.[a] (general category)	Designation	Species (No. of lines available)	Culture medium[b]	Comments
CCL-33	PK (15)	Pig (6)	MEM10	Adult kidney epithelial line. Used in virology. Keratin +. Produces plasminogen activator
CCL 34	MDCK	Canine (5)	EM10	Kidney epithelial line; model chromosomes number 78; forms domes in monolayer; used extensively in transport studies
CCL 70	CV1	African green monkey (14)	EM10	From male kidney; modal number 60; supports replication of SV40[c] and many other viruses
CCL-73	Ch1 Es (NBL-8)	Goat (3)	EM10	Continuous line from the esophagus of an adult animal. Used on studies of viruses affecting domestic animals
CCL 81	Vero	African green monkey	199-5	From adult kidney; hypodiploid (mode 58); used extensively in virus assay and production
CCL 92	3T3	Murine (129)	DM-CS10	From Swiss mouse embryo; hypertriploid (mode 68); contact sensitive; used for studies in oncogenic and viral transformation

TABLE II (*Continued*)

ATCC No.[a] (general category)	Designation	Species (No. of lines available)	Culture medium[b]	Comments
CCL-106	LLC-RK1	Rabbit (13)	199/10	Adult kidney, epithelial-like from New Zealand white animals. Viral susceptibility documented
CCL-208	4MBr-5	Rhesus monkey (8)	F12K/10	Normal, 2- to 3-year-old female animal. Bronchial epithelium. Required EGF, developed PAS-positive inclusions
CCL-209	CPAE	Bovine (101)	EM20	Enthothelial line from pulmonary artery; stable diploid karyotype; positive for angiotensin-converting activity
CRL-1476	A10	Rat (61)	DM20	Smooth muscle line from thoracic artery of a DB1X embryo; myokinase and creatine phosphokinase positive
CRL-1581	Sp2/0-Ag14	Murine	DM10	Myeloma used as fusion partner in hybridoma production; HAT sensitive; nonsecretor
CRL-1633	MDOK	Sheep (3)	EM10	From kidney of normal adult male. Epithelial-like cells support growth of several infectious viruses. Hypotetraploid
CRL-1651	COS-7	African green monkey	DM10	Transformed with origin-defective SV40; T antigen positive; suitable host in transfection studies
CRL-1711	Sf9	Fall armyworm (1)	G+10	Clonally derived from pupal ovarian tissue; susceptible to infection by baculovirus expression vectors
CRL-1721	PC12	Rat	R10HS-5	From pheochromocytoma; responsive to nerve growth factor; catecholamine; dopamine, and norepinephrine positive
CRL-1934	ES-B3	Murine	DME15 ± feeder	Stem cell line. Propagate on STO feeder layer or permit differentiation in its absence. Populations express Oct-3, SSEA-1, EMA-1, or TROMA-1 under appropriate conditions. See www.stemcells@atcc.org for more information
Patented				
CRL-8002	OKT4	Murine	IDM20	One of a series of patented hybridomas; produces monoclonal to human helper T subset
CRL-8305	FRTL-5	Rat	F12K-5+	Thyroid epithelial cell line; produces thyroglobulin; responsive to thyroid-stimulating hormone
CRL-8509	528	Murine	R10	One of a series of patented hybridomas; produces monoclonal to epidermal growth factor receptor
CRL-8873	FHCR	Murine	R12+	Hybridoma FHCR-1-2624/FH6/FHOT-1-3019; secretes monoclonal to Le^x ganglioside
CRL-10968	S4B6–1	Murine	R10	Produces monoclonal to murine interleukin-2
CRL-11422	MPRO clone 2–1	Murine	IDM + GMCSF/20	Infected with retroviral vector LRAR alpha 403SN. Neutrophil progenitor exhibits azurophilic granules, NSA7/4, chloroacetate esterase, and the RAR sequence
Hybridomas/tumor immunology Lines				
HB-55	L243	Murine	DM10	Secretes an IgG2a cytotoxic antibody to a nonpolymorphic determinant on human Ia
HB-95	WB/32	Murine	DM10	Secretes an IgG2a cytotoxic antibody that reacts with monomorphic determinants on HLA-A, -B, and -C
HB-170	R4–6A2	Murine/rat	DM10	Secretes IgG1 monoclonal to murine Interferon-γ

TABLE II (*Continued*)

ATCC No.[a] (general category)	Designation	Species (No. of lines available)	Culture medium[b]	Comments
HB-188	11B11	Murine/rat	R10	Secrets IgG1 monoclonal to murine B-cell stimulatory factor (BSF-1, interleukin-4)
HB-198 (215)	F4/80	Murine/rat	R5	Secretes rat IgG2b antibody to murine macrophages
TIB-63	$P388D_1$	Murine	R15	A phagocytic monocyte/macrophage line that produces interleukin-1 in response to PMA myelanonocyte LPS
TIB-68	WEHI-3	Murine	IDM10+	A myelomonocyte sensitive to LPS; produces colony-stimulating activity
TIB-71	RAW 264.7	Murine	DM10	A phagocytic monocyte/macrophage line; capable of antibody-dependent lysis of target cells
TIB-207	GK1.5	Murine	DM20	Secretes monoclonal to T-cell surface antigen L3T4 on a helper/inducer T-cell subset
TIB-214	CTLL-2	Murine	R10+	Clone of cytotoxic T cells dependent on interleukin-2 for proliferation

[a] Prefixes assigned to ATCC cell lines reflect the historical source of support for their addition to the collection and, to a certain extent, the degree of characterization applied. Representative certified cell lines (CCL); cell repository lines (CRL) in the general and patent collections; hybridomas in the collection supported by the National Institute for Allergy and Infectious Diseases (HB); and cells important for studies in tumor immunology (TIB) are listed. The CRL total does not include some 1900 additional cell lines in special collections. See www.atcc.org for names of originators, references, and more detail.

[b] Abbreviations for medium used (on the left-hand side) include (EM) Eagle's minimum essential medium; (R) RPMI 1640; (DM) Dulbecco's modification of Eagle's medium; (F12K) Kaighn's modification of Ham's F12; (IDM) Iscove's modification of Eagle's medium; (199) medium 199; and (G) Grace's insect medium [see Hay *et al.* (1992) for formulas]. The number on the right-hand side indicates percentage of serum used, usually fetal bovine, bovine calf (CS), or horse serum (HS). Additional recommended ingredients are indicated by a plus sign.

[c] SV40, simian virus 40; HAT, hypoxanthine aminopterin thymidine; PMA, phorbal myristic acetate; LPS, lipopolysaccharide. See www.atcc.org for further information.

Contents of Volume 2

Section 5. Membranes

Section 6. Mitochondria

Section 7. Nuclear Transport

Section 8. Chromatin Assembly

Section 9. Signal Transduction Assays

Contents of other Volumes

VOLUME 1

PART A. CELL AND TISSUE CULTURE: ASSOCIATED TECHNIQUES

Section 1. General Techniques

Section 2. Culture of Specific Cell Types: Stem Cells

Section 3. Culture of Specific Cell Types: Haemopoietic, Mesenchymal, and Epithelial

Section 15. In Situ Hybridisation

PART G. GENOMICS

Section 16. Genomics

PART H. TRANSGENIC, KNOCKOUTS, AND KNOCKDOWN METHODS

Section 17. Transgenic, Knockouts and Knockdown Methods

VOLUME 4

PART A. TRANSFER OF MACROMOLECULES

Section 1. Proteins

Section 2. Genes

Section 3. Somatic Cell Nuclear Transfer

PART B. EXPRESSION SYSTEMS

Section 4. Expression Systems

PART C. GENE EXPRESSION PROFILING

Section 5. Differential Gene Expression

Section 9. Detection of Proteins in Gels

Section 10. Gel Profiling of Posttranslationally Modified Proteins

Section 11. Protein/Protein and Protein/Small Molecule Interactions

Section 12. Functional Proteomics

Section 13. Protein/DNA Interactions

PART E. APPENDIX

Section 16. Appendix

Contributors

Numbers in parenthesis indicate the volume (bold face) and page on which the authors' contribution begins.

Mads Aaboe (**4**: 83) Clinical Biochemical Department, Molecular Diagnostic Laboratory, Aarhus University Hospital, Skejby, Brendstrupgaardvej, Aarhus N, DK-8200, DENMARK

Tanja Aarvak (**1**: 239) Dynal Biotech ASA, PO Box 114, Smestad, N-0309, NORWAY

Harindra R. Abeysinghe (**3**: 345) Department of Pathology and Laboratory Medicine, University of Rochester School of Medicine, 601 Elmwood Ave., Rm 1-6337, Rochester, NY 14642

Ruedi Aebersold (**4**: 437) The Institute for Systems Biology, 1441 North 34th Street, Seattle, WA 98103-8904

Ueli Aebi (**3**: 233, 241) ME Muller Institute for Microscopy, Biozentrum, University of Basel, Klingelbergstr. 50/70, Basel, CH-4056, SWITZERLAND

Preface

Scientific progress often takes place when new technologies are developed, or when old procedures are improved. Today, more than ever, we are in need of complementary technology platforms to tackle complex biological problems, as we are rapidly moving from the analysis of single molecules to the study of multifaceted biological problems. The third edition of *Cell Biology: A Laboratory Handbook* brings together 236 articles covering novel techniques and procedures in cell and molecular biology, proteomics, genomics, and functional genomics. It contains 165 new articles, many of which were commissioned in response to the extraordinary feedback we received from the scientific community at large.

As in the case of the second edition, the *Handbook* has been divided in four volumes. The first volume covers tissue culture and associated techniques, viruses, antibodies, and immunohistochemistry. Volume 2 covers organelles and cellular structures as well as assays in cell biology. Volume 3 includes imaging techniques, electron microscopy, scanning probe and scanning electron microscopy, microdissection, tissue arrays, cytogenetics and in situ hybridization, genomics, transgenic, knockouts, and knockdown methods. The last volume includes transfer of macromolecules, expression systems, and gene expression profiling in addition to various proteomic technologies. Appendices include representative cultured cell lines and their characteristics, Internet resources in cell biology, and bioinformatic resources for in silico proteome analysis. The Handbook provides in a single source most of the classical and emerging technologies that are essential for research in the life sciences. Short of having an expert at your side, the protocols enable researchers at all stages of their career to embark on the study of biological problems using a variety of technologies and model systems. Techniques are presented in a friendly, step-by-step fashion, and gives useful tips as to potential pitfalls of the methodology.

I would like to extend my gratitude to the Associate Editors for their hard work, support, and vision in selecting new techniques. I would also like to thank the staff at Elsevier for their constant support and dedication to the project. Many people participated in the realization of the *Handbook* and I would like to thank in particular Lisa Tickner, Karen Dempsey, Angela Dooley, Carl Soares, and Tari Paschall for coordinating and organizing the preparation of the volumes. My gratitude is also extended to all the authors for the time and energy they dedicated to the project.

Julio E. Celis
Editor

Isolation: Plasma Membrane, Organelles, and Cellular Structures

CHAPTER

1

Detergent-Resistant Membranes and the Use of Cholesterol Depletion

Sebastian Schuck, Masanori Honsho, and Kai Simons

I. INTRODUCTION

Lipid rafts have changed our view of membrane organization. Rafts are small platforms in cell membranes, composed of a specialized set of lipids (Ikonen and Simons, 1997). In the exoplasmic leaflet, rafts consist mainly of sphingolipids and cholesterol, which are connected to saturated glycerophospholipids and cholesterol in the cytoplasmic leaflet. Rafts are fluid assemblies, but they are more tightly packed and hence more ordered than the surrounding membrane. This difference is due to the more saturated hydrocarbon chains of sphingolipids and raft-associated glycerophospholipids as compared to the mostly unsaturated glycerophospholipids outside rafts. Cholesterol is thought to fill the spaces between the hydrocarbon chains of the sphingolipids, thus stabilizing rafts.

The raft concept transforms the classical membrane model (Singer and Nicolson, 1972) into a more complex system, in which proteins are embedded in a two-dimensional liquid that is itself a mosaic of lipid microdomains. Membrane proteins partition into raft and nonraft membranes according to their preferred lipid environment. Proteins with a high affinity for ordered membrane domains will mostly reside in rafts. Typical raft-associated proteins include glycosylphosphatidylinositol (GPI)-anchored proteins, doubly acylated proteins such as tyrosine kinases of the src family, and certain integral membrane proteins, especially palmitoylated ones such as caveolin and influenza virus hemagglutinin. Proteins with an intermediate affinity will move in and out of rafts, whereas proteins that do not pack well into ordered domains will be excluded from rafts.

Important for understanding the physiological functions of rafts, e.g., in signal transduction, is that their composition is dynamic and can be regulated (Simons and Toomre, 2000). Some receptors, such as the T- and the B-cell receptor (Janes *et al.*, 2000; Pierce, 2002), have a weak raft affinity in the unligated state. After ligand binding, they undergo a conformational change and/or become oligomerized, which increases their raft affinity and allows them to interact with proteins constitutively present in rafts. Other signalling molecules, such as the endothelial nitric oxide synthase, α subunits of heterotrimeric G proteins, and possibly ras, can undergo signal-induced depalmitoylation, leading to loss of raft association (Bijlmakers and Marsh, 2003; Hancock, 2003). Thus, rafts can serve to segregate signalling molecules at steady state and promote their interaction upon stimulation.

Isolation of detergent-resistant membranes (DRMs) is a simple and useful biochemical method for analyzing the possible raft association of proteins and lipids. Especially when used to monitor changes in DRM composition during processes such as exocytosis (Brown and Rose, 1992) immune cell activation and viral infection (Manes *et al.*, 2000), this technique can provide important clues about the mechanisms underlying protein sorting, signal transduation and pathogen entry into host cells (Ikonen, 2001; Simons and Toomre, 2000; van der Goot and Harder, 2001). Rafts largely resist solubilization with mild detergents due to their tight lipid packing, whereas less ordered membrane domains are disrupted. Raft proteins do not become solubilized, but remain associated with lipids. As a result, they have a lower apparent density than detergent-soluble membrane proteins and can be isolated by equilibrium density centrifugation (often referred to as "flotation"). Detergent lysates are

adjusted to high density, placed at the bottom of a density gradient, and centrifuged. Contrary to fully solubilized material, DRMs and DRM-associated proteins float up the gradient, allowing their recovery from low-density fractions. As the integrity of lipid rafts depends on cholesterol, its removal renders raft-associated proteins detergent soluble. Detergent solubility of an otherwise detergent-insoluble protein after cholesterol depletion with methyl-β-cyclodextrin (cyclodextrin) can therefore serve as an additional criterion for raft association.

However, the composition of DRMs may only imperfectly reflect the association of membrane components with lipid rafts in cell membranes (Shogomori and Brown, 2003). DRMs obtained with different detergents differ considerably in their protein and lipid content (Schuck *et al*., 2003). Different detergents clearly reflect the organization of membranes in different ways, with Triton X-100 and CHAPS seemingly being the most informative ones. In addition, the interpretation of experimental results obtained with cyclodextrin is complicated by the fact that severe cholesterol depletion may have pleiotropic effects on membrane functions. Cyclodextrin might be more effective on cell homogenate than on living cells, but the reasons for this are not completely clear (Schuck *et al*., 2003).

Finally, neither detergent insolubility nor loss of detergent insolubility after cyclodextrin treatment is a strict criterion. If a protein is detergent soluble, it may still have a weak affinity for rafts in native membranes, and persistent detergent insolubility after cholesterol depletion can be caused by the remaining cholesterol. Therefore, neither criterion allows excluding raft association.

II. MATERIALS AND INSTRUMENTATION

Standard chemicals are of the highest purity available. Minimal essential medium with Earle's salts (MEM, Cat. No. 21090-022), glutamine (Cat. No. 25030-024), and penicillin–streptomycin (Cat. No. 15140-122) are from Invitrogen. Fetal calf serum (FCS, Cat. No. A15-042) is from PAA Laboratories. One hundred-millimeter (Cat. No. 150350) and 35-mm (Cat. No. 153066) plastic tissue dishes are from Nunc. Chymostatin (Cat. No. C7268), leupeptin (Cat. No. L2884), antipain (Cat. No. A6191), pepstatin (Cat. No. P5318), DL-mevalonic acid lactone (Cat. No. M4667), and methyl-β-cyclodextrin (Cat. No. C4555) are from Sigma. Lovastatin (Cat. No. 438185) is from Merck Biosciences. Sixty percent (w/v) iodixanol (Optiprep, Cat. No. 1030061) is from Progen Biotechnik, sucrose (Cat. No. 21938) is from USB, and 10% (w/v) Triton X-100 (Surfact-Amps X-100, Cat. No. 28314) is from Perbio.

Ultraclear centrifuge tubes for an SW40 rotor (14 × 95 mm, Cat. No. 344060) and for a TLS55 rotor (11 × 34 mm, Cat. No. 347356), as well as SW 40 Ti and TLS55 rotors, are from Beckman. Ultracentrifugations are carried out using an Optima XL-100K or an Optima MAX ultracentrifuge from Beckman.

In addition, the following equipment is required: 1.5-ml microfuge tubes, cell scrapers, 15-ml plastic tubes, 25-gauge needles, and 1-ml plastic syringes.

III. PROCEDURES

A. Preparation of DRMs by Flotation on a Sucrose Step Gradient

Solutions

1. *Phosphate-buffered saline (PBS)*: 155 m*M* NaCl, 1.5 m*M* KH_2PO_4, 2.7 m*M* Na_2HPO_4, pH 7.2. To make 1 litre, dissolve 0.21 g KH_2PO_4, 0.73 g $Na_2HPO_4{\cdot}7H_2O$, and 9 g NaCl in double-distilled water and make up to 1 litre.

2. *1 M EDTA*: To make 1 litre, dissolve 372.2 g EDTA in double-distilled water by adjusting the pH to 8 with NaOH and make up to 1 litre.

3. *5× TNE:* 750 m*M* NaCl, 10 m*M* EDTA, 250 m*M* Tris–HCl, pH 7.4. To make 1 litre, dissolve 43.8 g NaCl and 30.3 g Tris in double-distilled water, add 10 ml 1 *M* EDTA, adjust pH to 7.4 with HCl, and make up to 1 litre.

4. *1000× CLAP*: To make 1 ml, dissolve 25 mg each of chymostatin, leupeptin, antipain, and pepstatin in 1 ml dimethyl sulfoxide and store at –20°C in small aliquots.

5. *TNE and TNE with protease inhibitors (TNE+)*: To make TNE, dilute 5× TNE 1:5 in double-distilled water. To make TNE+, dilute 1000× CLAP 1:1000 in TNE just before use. TNE+ has to be prepared freshly each time.

6. *56, 35, and 5% (w/w) sucrose*: To make 100 ml, dissolve 70.75, 40.29, or 5.1 g sucrose in 20 ml 5× TNE and bring to 100 ml with double-distilled water. Check refractive indices of the resulting solutions, which should be 1.266, 1.154, and 1.021, respectively. Store at 4°C.

7. *2% (w/v) Triton X-100*: To make 10 ml, dissolve 0.2 g Triton X-100 in 2 ml 5× TNE and bring to 10 ml with double-distilled water. For short-term storage, keep at 4°C and protect from light to prevent autoxidation. For long-term storage, store aliquots at –20°C.

Steps

1. Grow MDCK strain II cells in MEM with 5% FCS, 2 m*M* glutamine, and 100 U/ml penicillin and streptomycin on a 10-cm plastic tissue dish until confluent.
2. All subsequent steps are performed at 4°C unless stated otherwise. Remove culture medium and wash the cells once with PBS and once with TNE.
3. Collect the cells in 1 ml TNE with a cell scraper. Transfer suspension into a 1.5-ml microfuge tube and centrifuge for 5 min at 350×g.
4. Resuspend the cell pellet in 550 µl TNE+. Homogenize by 20 passages through a 25-gauge needle fitted on a 1-ml syringe. This treatment should break >90% of the cells without damaging nuclei (check microscopically).
5. Take 500 µl cell homogenate (about 1 mg total protein) and transfer into a new microfuge tube. Add 500 µl 2% Triton X-100. From now on, strictly avoid warming of the sample. Mix well by inverting the tube and place on ice for 30 min.
6. Transfer the sample into a 15-ml tube and bring to 40% (w/w) sucrose by adding 2 ml 56% sucrose. Mix well by inverting the tube.
7. Place the sample at the bottom of an SW40 centrifuge tube. Sequentially overlay with 8.5 ml 35% sucrose and 0.5 ml 5% sucrose.
8. Centrifuge for 18 h at 39,000 rpm (271,000×*g*) using an SW40 rotor. DRMs float to the top of the gradient during centrifugation. Carefully collect 2.5 ml from the top of the gradient with a smooth pipette.
9. To further concentrate DRMs, dilute 1:4 by adding 7.5 ml TNE and transfer into a new SW40 centrifuge tube. Following centrifugation for 2 h at 24,000 rpm (100,000×*g*) with an SW40 rotor, DRMs can be recovered from the pellet.

B. Analysis of DRMs by Flotation on a Linear Sucrose Gradient

Solutions

See Section III,A.

Steps

1–6. See Section III,A.

7. Using a gradient maker, prepare a linear 5–35% sucrose gradient in an SW40 centrifuge tube with 4.5 ml each of 35 and 5% sucrose. Cool to 4°C.
8. Place the sample under the gradient using a Pasteur pipette, disturbing the gradient as little as possible (alternatively, first transfer the sample into an SW40 centrifuge tube and then overlay with the gradient).
9. Centrifuge for 18 h at 39,000 rpm (271,000×*g*) using an SW40 rotor. Collect twelve 1-ml fractions from the top of the gradient and resuspend the pellet in 1 ml TNE. Fractions 9–12 contain the soluble material; DRMs are found in the lighter fractions.

C. Analysis of DRMs by Flotation on an Optiprep Step Gradient

Solutions

PBS, 5× TNE, TNE, and TNE+; see Section III,A.

1. *10% (w/v) Triton X-100*: To make 10 ml, dissolve 1 g of Triton X-100 in 2 ml of 5× TNE and make up to 10 ml with double-distilled water. Alternatively, use Surfact-Amps X-100.
2. *30% (w/v) iodixanol*: To make 5 ml, mix 2.5 ml Optiprep, 1 ml 5× TNE, and 1.5 ml double-distilled water.

Steps

1. Grow MDCK strain II cells to confluence on a 3.5-cm plastic tissue dish.
2. At 4°C, remove culture medium and wash the cells once each with PBS and TNE.
3. Collect and spin down the cells as in Section III,A.
4. Resuspend the cell pellet in 200 µl TNE+. Homogenize as in Section III,A.
5. Take 180 µl cell homogenate and transfer into a new microfuge tube. Add 20 µl 10% Triton X-100 solution, mix, and place on ice for 30 min.
6. Add 400 µl Optiprep to bring the sample to 40% (w/v) iodixanol and mix well by inverting the tube.
7. Place the sample at the bottom of a TLS55 centrifuge tube. Sequentially overlay with 1.2 ml 30% iodixanol and 0.2 ml TNE.
8. Centrifuge for 2 h at 55,000 rpm (259,000×*g*) with a TLS55 rotor. Collect two fractions of 1 ml each. The top fraction contains the DRMs.

D. Cholesterol Depletion of Live Cells

Solutions

PBS; see Section III,A.

1. *20* m*M lovastatin*: To make 2.5 ml, dissolve 20 mg lovastatin in 0.5 ml 100% ethanol and 0.75 ml 0.1 *M* NaOH. Incubate at 50°C for 2 h, cool briefly on ice, and adjust pH to 7.2 with HCl. Bring to 2.5 ml with double-distilled water and store aliquots at –20°C.
2. *500* m*M mevalonate*: To make 5 ml, dissolve 325 mg in 5 ml PBS. Store aliquots at –20°C.

3. *100* m*M methyl-β-cyclodextrin in MEM*: To make 1 ml, dissolve 150 mg methyl-β-cyclodextrin in MEM just before use and make up to 1 ml with MEM.

Steps

1. Grow MDCK strain II cells on a plastic tissue dish or on filter supports. For the last 48 h before the experiment, culture the cells in normal medium supplemented with 4 µ*M* lovastatin (dilute stock solution 1:5000) and 0.25 m*M* mevalonate (dilute stock solution 1:2000).
2. Wash the cells twice with PBS and add MEM containing 4 µ*M* lovastatin, 0.25 m*M* mevalonate, and 10 m*M* methyl-β-cyclodextrin. In the case of filter-grown cells, apply cyclodextrin to both the apical and the basolateral side.
3. Incubate the cells at 37°C for 30 min.

E. Cholesterol Depletion of Cell Homogenate

Solutions

PBS, TNE, TNE+, and 10% (w/v) Triton X-100; see Sections III,A and III,C.

1. *100* m*M methyl-β-cyclodextrin in TNE*: To make 100 µl, dissolve 15 mg methyl-β-cyclodextrin in TNE just before use and make up to 100 µl with TNE.

Steps

1–4. See Section III,C.
5. Take 180 µl cell homogenate and transfer into a new microfuge tube. Add 20 µl 100 m*M* methyl-β-cyclodextrin, mix, and incubate at 37°C for 30 min.
6. For subsequent DRM analysis, cool to 4°C, add 20 µl 10% Triton X-100, and incubate on ice for 30 min.
7. Add 440 µl Optiprep to bring to 40% (w/v) iodixanol. Mix and take 600 µl and continue as in Section III,C, step 7.

IV. COMMENTS

Separating DRMs from detergent-soluble material by flotation using equilibrium density centrifugation is usually preferable to pelleting. Pelleting of DRMs from detergent extracts leads to contamination with other sedimentable material, e.g., cytoskeletal components. In addition, a protein might be pelleted because of its association with the cytoskeleton rather than DRMs.

Which flotation gradient to use for DRM analysis depends on the purpose of the experiment. Continuous gradients give more information about the flotation behaviour of proteins and lipids, but to monitor changes in DRM composition after, e.g., cyclodextrin treatment, simple step gradients as in Section III,C are more convenient. Various density gradient media can be used, and the choice between sucrose and iodixanol is largely a question of personal preference. However, sucrose might be superior if lipids are to be analyzed by a very sensitive method such as mass spectrometry, as iodixanol seems to have a weak tendency to follow lipids during extraction from DRMs.

How to apply cyclodextrin strongly depends on the cell type used. Hippocampal neurons cannot be exposed to 5 m*M* cyclodextrin for longer than 20 min (Simons *et al*., 1998), whereas MDCK cells remain intact even when treated with 20 m*M* for 1 h. Hence, the conditions for cyclodextrin treatment have to be established in each case. In particular, it needs to be ensured that cholesterol is the only lipid extracted. Treating live cells will preferentially extract cholesterol from the plasma membrane and allows intracellular cholesterol transport to counteract the effects of cyclodextrin, whereas extracting cholesterol from cell homogenate will affect all cell membranes.

V. PITFALLS

Membrane solubilisation by detergent depends on the molar ratio of detergent to lipid. Therefore, this parameter, rather than detergent concentration alone, always needs to be taken into account. In the case of Triton X-100, a mass ratio of detergent to protein (taken as a measure for the molar detergent-to-lipid ratio) of greater than 5:1 seems to be necessary for maximum solubilization (Ostermeyer *et al*., 1999).

DRM-associated proteins are separated from soluble proteins by flotation gradients because of their low density; they float due to their detergent-resistant association with lipids. In contrast, the separation of DRMs from detergent micelles, which contain solubilized membrane lipids, is based largely on differences in size. Given enough time, detergent micelles will also float as a result of their low density. However, DRMs are larger than detergent micelles and therefore float up faster [the sedimentation or flotation velocity s is given by $s = V(\rho - \rho_m)/f$, where V is particle volume, ρ is particle density, ρ_m is density of the solvent, and f is friction coefficient. For a spherical particle, V is proportional to r^3, while f is proportional to r, so that s is proportional to r^2. Refer to biophysical textbooks for a more comprehensive treatment]. To avoid contamination of DRMs with detergent molecules and solubilized lipids, it is crucial to ensure that

detergent micelles are well separated from DRMs under the centrifugation conditions used. The distribution of Triton in the gradient can be measured by its absorption at 280 nm. For other detergents, their distribution can be determined semiquantitatively by thin-layer chromatography.

CHAPTER

2

Isolation and Subfractionation of Plasma Membranes to Purify Caveolae Separately from Lipid Rafts

Phil Oh, Lucy A. Carver, and Jan E. Schnitzer

I. INTRODUCTION

Cellular membranes contain distinct microdomains with unique molecular topographies, including caveolae and lipid rafts (**Fig. 1**). Caveolae are specialized flask-shaped invaginated microdomains located on the cell surface membrane of many cell types that appear to form through the polymerization of caveolin (Monier *et al.*, 1995), have a dynamin collar around their necks for fission (Oh *et al.*, 1998), and contain other molecular machinery for vesicular budding, docking, and fusion, including VAMP-2, NSF, and SNAP (Schnitzer *et al.*, 1995a). In contrast, lipid rafts are flat domains without the characteristic omega-shaped form of caveolae that suggests possible trafficking function. Unlike caveolae, which form via protein–protein interactions, lipid rafts appear to form in the membrane when highly saturated sphingolipids self-assemble with cholesterol to pack into a highly ordered lipid phase (Brown and London, 2000). Caveolae and lipid rafts may share similar lipids but a detailed compositional analysis is lacking at this time.

Although easily distinguished morphologically by electron microscopy, caveolae and lipid rafts were considered equivalent for many years because similarities in detergent solubility and density profiles made their biochemical distinction quite difficult and confounded attempts to definitively characterize the two domains. Many of caveolar preparations in wide use were isolated using one-dimensional separation techniques that rely on detergent resistance and membrane density after cell lysis (Sargiacomo *et al.*, 1993; Smart *et al.*, 1995). These preparations were later found to be heavily contaminated not only with membranes derived from intracellular organellar structures, but also with lipid rafts enriched in glycosylphosphatidyl inositol-anchored proteins (GPI-AP) derived from both the plasma membrane and intracellular membranes (Oh and Schnitzer, 1999; Schnitzer *et al.*, 1995b). As a consequence, early reports demonstrating that these low-density detergent-resistant membrane fractions were rich in both GPI-AP and caveolin concluded that caveolae constituted the GPI-AP-enriched lipid rafts in the plasma membrane (Sargiacomo *et al.*, 1993; Smart *et al.*, 1995). These data were supported by the finding that antibodies to GPI-AP can be found in caveolae by immunocytochemistry (Rothberg *et al.*, 1990; Ying *et al.*, 1992). In contrast, other reports showed that similar detergent-resistant membranes rich in GPI-AP could be isolated from cells lacking caveolin or caveolae (Fra *et al.*, 1995; Gorodinsky and Harris, 1995). In addition, it was also shown that past localization of GPI-AP in caveolae had been induced artifactually by antibody sequestration resulting from cross-linking by secondary reporter antibodies (Fujimoto, 1996; Mayor *et al.*, 1994). Thus, these early conflicting data made clear that more sophisticated methods for isolating caveolae and lipid rafts were necessary to finally defining the molecular constituents and structure of these structures.

Since the mid-1990s, caveolae and lipid rafts have been increasingly recognized as separate domains due, in part, to the development of a multidimensional membrane isolation technique. The key to this technique is the use of positively charged colloidal silica particles to coat selectively the cell surface membrane

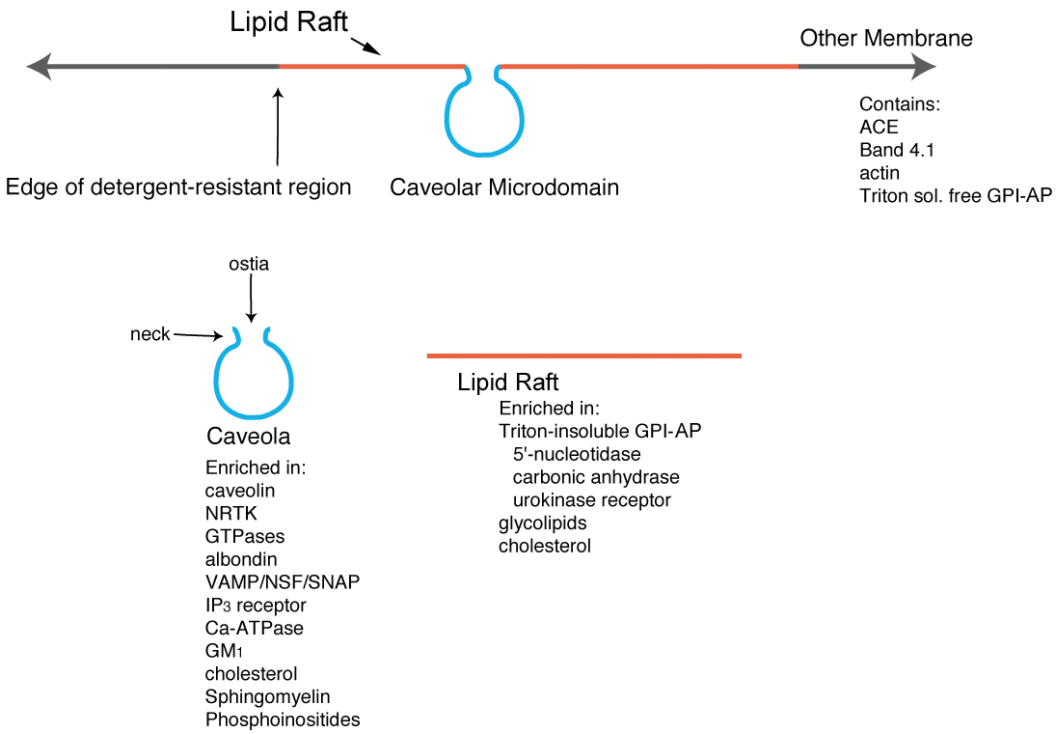

FIGURE 1 Microdomain structure of the plasma membrane. The plasma membrane contains various low-density microdomains, predominantly caveolae and lipid rafts rich in GPI-AP, that exist as distinct regions of the cell surface. Although caveolae and lipid rafts exhibit similar buoyant densities and detergent resistance, they each contain a distinct protein expression profile that differs from each other as well as from the rest of the plasma membrane proper. NRTK, nonreceptor tyrosine kinases; ACE, angiotensin-converting enzyme; VAMP, vesicle-associated membrane protein; NSF, *N*-ethylmaleimide-sensitive fusion protein; SNAP, soluble NSF attachment protein; IP3, inositol 1,4,5-trisphosphate.

before tissue/cell homogenization and centrifugation through a density gradient to yield the silica-coated plasma membranes as a membrane pellet. Intracellular membranes or membranes of other cell types (when processing tissue) are not silica coated, float on the gradient, and are thus eliminated from the pellet. This technique provides highly purified silica-coated plasma membranes largely free of other contaminating cellular membranes. Using these membranes as a starting material, it now becomes possible to isolate a nearly homogeneous preparation of caveolae (caveolin-coated small vesicles) either by physical homogenization or by physiological induction (i.e., budding) (Oh and Schnitzer, 1999; Schnitzer *et al*., 1995b, 1996). Once free of caveolae, the remaining silica-coated plasma membranes can subsequently be used to isolate detergent-resistant, caveolin-free lipid rafts (Schnitzer *et al*., 1995b).

These new preparations have revealed distinctions between the molecular constituents of caveolae and lipid rafts. Caveolae appear concentrated in caveolin but not several GPI-AP, which instead existed in lipid rafts isolated from the same plasma membranes and devoid of caveolin (Oh and Schnitzer, 1999; Schnitzer *et al*., 1995b). In addition, each microdomain contains a unique set of signaling molecules. For example, caveolae contain growth factor receptors (e.g., platelet-derived growth factor receptor), whereas lipid rafts contain immunoglobulin E receptors, T-cell receptors (TCR), and GPI-AP (Field *et al*., 1995; Gorodinsky and Harris, 1995; Liu *et al*., 1997; Montixi *et al*., 1998; Shenoy-Scaria *et al*., 1992; Stefanova *et al*., 1991; Xavier *et al*., 1998). In cells expressing caveolin and caveolae, the heterotrimeric G protein, G_q, concentrates in caveolae but not in lipid rafts, whereas G_i and G_s tend to concentrate in lipid rafts preferentially over caveolae (Oh and Schnitzer, 2001). The apparent ability of caveolin-1 to form a complex in the plasma membrane with G_q, but not G_i or G_s, appears to trap G_q effectively in caveolae and minimize its presence in lipid rafts. In cells without caveolae, G_q partitions into lipid rafts with other G proteins. These findings, discovered by tissue/cell subfractionation, were confirmed by immunofluorescence microscopy.

This article describes several protocols based primarily on a series of past studies (Brown and Rose, 1992; Oh and Schnitzer, 1999; Schnitzer *et al*., 1995b; Smart *et al*., 1995) using silica methodology to isolate first plasma membranes from tissue and cultured cells prior to further subfractionation to isolate their caveolae separately from lipid rafts rich in GPI-AP.

II. MATERIALS AND INSTRUMENTATION

A. Materials

Sodium chloride (Cat. No. BP358), potassium chloride (Cat. No. BP366), magnesium sulfate (Cat. No. BP213), glucose (Cat. No. BP350), EDTA disodium salt (Cat. No. BP120), sodium bicarbonate (Cat. No. BP328), sucrose (Cat. No. BP220), magnesium chloride (Cat. No. BP214), Tris (Cat. No. BP152), methanol (Cat. No. A412), hydrochloric acid (Cat. No. A144), sodium hydroxide (Cat. No. SS255), sodium carbonate (Cat. No. BP357), 2-mercaptoethanol (Cat. No. BP176), Tricine (Cat. No. BP315), Tween 20 (Cat. No. BP337), silver nitrate (Cat. No. S181), glacial acetic acid (Cat. No. A38), sodium phosphate dibasic (Cat. No. BP332), potassium phosphate monobasic (Cat. No. BP362), potassium phosphate dibasic (Cat. No. BP363), Tygon tubing (Cat. No. 14-169-1B), razor blades (Cat. No. 12-640), and 15-ml centrifuge tubes (Cat. No. 05-539-5) are from Fisher. HEPES (Cat. No. 737 151) and Pefabloc SC (Cat. No. 1 585 916) are from Roche Applied Science. 2-(*N*-Morpholine)ethanesulfonic acid (MES) (Cat. No. M2933), leupeptin (Cat. No. L 2884), *O*-phenanthroline (Cat. No. P9375), pepstatin A (Cat. No. P 4265), sodium nitroprusside (Cat. No. S 0501), E-64 (*trans*-epoxysuccinyl-L-leucylamido-[4-guanidino] butane) (Cat. No. E 3132), glycerol (Cat. No. G 5516), potassium acetate (Cat. No. p 3542), magnesium acetate (Cat. No. M 0631), and EGTA (Cat. No. E 4378) and from Sigma. Percoll (Cat. No. 17-0891-01) is from Amersham Biosciences. Protease inhibitor Cocktail I (2004) is from EMD Biosciences (Cat. No. 539131) Ten percent Triton X-100 (Cat. No. 28314) is from Pierce. Goat antimouse IgG–HRP conjugate (Cat. No. NA931) and goat antirabbit IgG–HRP conjugate (Cat. No. NA934) are from Amersham. Goat antimouse IgG–bodipy conjugate (Cat. No. B-2752), goat antimouse IgG–Texas red conjugate (Cat. No. T-862), goat antirabbit IgG–bodipy conjugate (Cat. No. B-2766), and goat antirabbit IgG–Texas red conjugate (Cat. No. T-2767) are from Molecular Probes. Polyacrylic acid (PAA) (Cat. No. 00627) is from Polysciences Inc. Nycodenz (Cat. No. AN-7050/BLK) is from Accurate Chemicals. Sprague Dawley rats (male) are from Charles River. SW28 tubes (Cat. No. 344058) and SW55 tubes (Cat. No. 344057) are from Beckman. Ketamine is from Fort Dodge Animal Health and xylazine is from Vedco Inc. Nitex filters 53 μm (Cat. No. 3-50/31) and 30 μm (Cat. No. 3-30/18) are from Sefar America Inc. Type "AA" homogenizer (Cat. No. 3431-E10), type "BB" homogenizer (Cat. No. 3431-E20), and type "C" homogenizer (Cat. No. 3431-E25) are from Thomas Scientific. Silk suture (3-0) is from Ethicon. Aluminum tubing (Cat. No. 89-78K101) is from McMaster-Carr. The three-way stopcock (Cat. No. 732-8103) is from Bio-Rad.

B. Instrumentation

Ultracentrifugation is carried out in a Beckman L8-80, Sorvall Pro 80, or Optima MaxE ultracentrifuge. Other centrifugation is carried out in a Brinkman Eppendorf 5415C or IEC Centra MP4R.

C. Perfusion Apparatus

On a ring stand, attach five 60-cc syringes attached to a series of five three-way stopcocks by way of Tygon tubing (0.0625 in. i.d.). The series of three-way stopcocks are attached to Tygon tubing with an stainless steel loop (0.046 in. i.d.) inserted in the middle of the tubing. The stainless-steel loop is used to regulate the temperature of the solutions perfused into the rat vasculature by emersion in temperature-controlled water. The pressure of flow is measured by a sphygmomanometer attached to the 60-cc syringes by Tygon tubing and a single hole rubber stopper. The flow for perfusion is normally 8 mm of Hg. The flow rate at 25°C is approximately 5 ml/min and at 10°C is 4 ml/min.

III. PROCEDURES

Unless otherwise specified in the protocol, all procedures should be performed at 4°C and all solutions must be kept and used ice cold.

Solutions

Buffer PM: 0.25 M sucrose, 1 m*M* EDTA, 20 m*M* Tricine in ddH_2O pH to 7.8 with NaOH (filter through 0.45-μm bottle top filter (can be stored at 4°C). For 500 ml: 42.79 g sucrose, 0.186 g EDTA (disodium salt), and 1.79 g Tricine.

Colloidal silica solution: From a 30% positively charged colloidal silica stock solution, dilute to 1% with MBS pH 6.0 [pH to 6.0 with NaOH if necessary and filter through 0.45-μm bottle top filter (can be

stored at 4°C]. For 300 ml: 10 ml stock silica in 490 ml MBS, pH 6.0, with pH strips (usually you do not have to adjust pH).

Cytosolic buffer: 25 m*M* potassium chloride, 2.5 m*M* magnesium acetate, 5 m*M* EGTA, 150 m*M* potassium acetate, 25 m*M* HEPES in ddH_2O pH to 7.4 with KOH and filter through 0.45-µm bottle top filter (can be stored at 4°C). For 500 ml: 0.93 g KCl, 0.27 g $Mg(C_2H_3O_2)_2 \cdot 4H_2O$, 0.95 g $C_{14}H_{24}N_2O_{10}$, 7.36 g $KC_2H_2O_2$, and 2.98 g HEPES.

250 mM HEPES, pH 7.4: 29.8 g in 450 ml ddH_2O, pH to 7.4 with NaOH, bring to 500 ml with ddH_2O

1M KCl: 7.46 g in 100 ml ddH_2O

20 mM KCl: 200 µl 1 *M* KCl, bring to 10 ml with ddH_2O

Mammalian Ringer's solution (without calcium): 114 m*M* sodium chloride, 4.5 m*M* potassium chloride, 1 m*M* magnesium sulfate, 11 m*M* glucose, 1.0 m*M* sodium phosphate (dibasic), 25 m*M* sodium bicarbonate in ddH_2O pH to 7.4 with HCl (filter through 0.45-µm bottle top filter (can be stored at 4°C). For 2 liters: 13.32 g NaCl, 0.67 g KCl, 0.492 g $MgSO_4 \cdot 7H_2O$, 3.96 g glucose, 0.28 g Na_2HPO_4, and 4.20 g $NaHCO_3$.

MES buffered saline (MBS): 20 m*M* MES, 135 m*M* NaCl in ddH_2O pH to 6.0 with NaOH [filter through 0.45-µm bottle top filter (can be stored at 4°C]. For 2 liters: 7.8 g MES and 14.6 g NaCl.

80% Nycodenz: 8 ml 100% Nycodenz, 200 µl 1 *M* KCl bring to 10 ml with ddH_2O

75% Nycodenz: 7.5 ml 100% Nycodenz, 200 µl 1 *M* KCl bring to 10 ml with ddH_2O

70% Nycodenz: 7 ml 100% Nycodenz, 200 µl 1 *M* KCl bring to 10 ml with ddH_2O

65% Nycodenz: 6.5 ml 100% Nycodenz, 200 µl 1 *M* KCl bring to 10 ml with ddH_2O

60% Nycodenz: 6 ml 100% Nycodenz, 200 µl 1 *M* KCl bring to 10 ml with ddH_2O

100% Nycodenz (v/w): 100 g Nycodenz in 100 ml of ddH_2O

70% Nycodenz/sucrose/HEPES: 7 ml 100% Nycodenz, 1 ml 60% sucrose, 1 ml 250 m*M* HEPES, pH 7.4, 200 µl 1 *M* KCl bring to 10 ml with ddH_2O

65% Nycodenz/sucrose/HEPES: 6.5 ml 100% Nycodenz, 1 ml 60% sucrose, 1 ml 250 m*M* HEPES, pH 7.4, 200 µl 1 *M* KCl bring to 10 ml with ddH_2O

60% Nycodenz/sucrose/HEPES: 6 ml 100% Nycodenz, 1 ml 60% sucrose, 1 ml 250 m*M* HEPES, pH 7.4, 200 µl 1 *M* KCl bring to 10 ml with ddH_2O

55% Nycodenz/sucrose/HEPES: 5.5 ml 100% Nycodenz, 1 ml 60% sucrose, 1 ml 250 m*M* HEPES, pH 7.4, 200 µl 1 *M* KCl bring to 10 ml with ddH_2O

30% Percoll in buffer PM: Mix 30 ml of stock Percoll with 70 ml of buffer PM

Phosphate-buffered saline (PBS): 137 m*M* sodium chloride, 2.7 m*M* potassium chloride, 4.3 m*M* sodium phosphate (dibasic), 1.4 m*M* potassium phosphate (monobasic) in ddH_2O pH to 7.4. For 1 liter: 8 g sodium chloride, 0.2 g potassium chloride, 0.61 g sodium phosphate (dibasic), 0.2 g potassium phosphate (monobasic).

Polyacrylic acid: From 25% stock solution, dilute to 0.1% with MBS, pH 6.0 [pH to 6.0 with NaOH and filter through 0.45-µm bottle top filter (can be stored at 4°C)]. For 500 ml: 2 ml stock 25% polyacrylic acid in 480 ml MBS, pH 6.0, pH to 6.0 and bring to 500 ml with MBS pH 6.0.

Potassium phosphate/polyacrylic acid: 4 M potassium phosphate (dibasic) 2% PAA in ddH_2O pH to 11 with NaOH. For 10 ml: 6.96 g potassium phosphate (dibasic) and 0.8 ml 25% stock polyacrylic acid.

60% sucrose (w/w): 385.95 g sucrose in 200 ml ddH_2O, add 10 ml 1 *M* KCl, after the sucrose has dissolve, bring to 50 ml with ddH_2O

Sucrose/HEPES: 250 m*M* sucrose, 25 m*M* HEPES, 20 m*M* potassium chloride in ddH_2O pH to 7.4 with NaOH and filter through 0.45-µm bottle top filter (can be stored at 4°C). For 2 liters: 171.16 g sucrose, 11.92 g HEPES and 2.98 g KCl.

60% sucrose (w/w)/20 mM KCl: 385.95 g sucrose in 200 ml ddH_2O, add 10 ml 1 *M* KCl, after the sucrose has dissolve, bring to 50 ml with ddH_2O

35% sucrose (w/w)/20 mM KCl: 5.2 ml 60% sucrose, 200 µl 1 *M* KCl, bring to 10 ml with ddH_2O

30% sucrose (w/w)/20 mM KCl: 4.4 ml 60% sucrose, 200 µl 1 *M* KCl, bring to 10 ml with ddH_2O

25% sucrose (w/w)/20 mM KCl: 3.8 ml 60% sucrose, 200 µl 1 *M* KCl, bring to 10 ml with ddH_2O

20% sucrose (w/w)/20 mM KCl: 2.8 ml 60% sucrose, 200 µl 1 *M* KCl, bring to 10 ml with ddH_2O

15% sucrose (w/w)/20 mM KCl: 2.1 ml 60% sucrose, 200 µl 1 *M* KCl, bring to 10 ml with ddH_2O

10% sucrose (w/w)/20 mM KCl: 1.3 ml 60% sucrose, 200 µl 1 *M* KCl, bring to 10 ml with ddH_2O

5% sucrose (w/w)/20 mM KCl: 0.7 ml 60% sucrose, 200 µl 1 *M* KCl, bring to 10 ml with ddH_2O

10% Triton X-100 *in PBS*

A. Purification of Silica-Coated Plasma Membranes (P)

1. Perfusion Procedure

1. Anesthetize rats with a cocktail of ketamine (60 mg/kg) and xylazine (1.6 mg/kg). Perform a tracheotomy to ventilate the lungs using a respirator.
2. Insert tubing from the perfusion apparatus into the pulmonary artery via the right ventricle and fasten

by tying a 3-0 silk suture around the artery. Cut the left atrium to allow the flow to exit.
3. Perfuse (4 ml/min) with Ringer's for 5 min starting at room temperature. After 1–1.5 min, begin lowering the temperature to ~10°C by placing the stainless-steel loop into an ice-cold bath. Gently drip ice-cold PBS over the lung to prevent drying. The remainder of the procedure should be performed at this cool temperature.
4. Perfuse MBS for 1.5 min.
5. Perfuse 1% colloidal silica solution for 1.5 min. At this point, keep the lungs inflated by replacing the tube attached to the respirator with a syringe and inflate with 3–5 ml of air.
6. Flush with MBS for 1.5 min.
7. Perfuse 0.1% PAA for 1.5 min.
8. Flush lungs with 8 ml of sucrose/HEPES with protease inhibitor Cocktail I (1×).
9. Excise lungs from the animal and keep cold by immersion in ice-cold sucrose/HEPES with protease inhibitor Cocktail I (1×).

2. Processing of the Lung

1. Finely mince the excised lung mince with a "new" razor blade on a cold aluminum block embedded in ice.
2. Add 20 ml of sucrose/HEPES with protease inhibitors and place into a type "C" homogenizer vessel.
3. Homogenize for 12 strokes at 1800 rpm in a cold (4°C) room.

3. Purification of Silica-Coated Luminal Endothelial Cell Plasma Membrane (P)

1. Filter the homogenate through a 53-µm Nytex filter, followed by a 30-µm Nytex filter.
2. Remove 200 µl from the filter solution, label "homogenate," and store at –20°C. Adjust the volume of the remaining solution to 20 ml with cold sucrose/HEPES with protease inhibitors.
3. Add an equal volume of 100% Nycodenz and mix (this is enough for two SW28 tubes). Layer onto a 70–55% continuous Nycodenz sucrose/HEPES gradient (form by placing 3 ml of 70, 65, 60, and 55 Nycodenz sucrose/HEPES and carefully swirling the solution, holding the tube at a 45° angle about 5–10 times).
4. Top with sucrose/HEPES with protease inhibitors. Spin at 15,000 rpm for 30 min at 4°C in a SW28 rotor. Aspirate off the supernatant. Resuspend the pellet in 1 ml MBS. Add equal volume of 100% Nycodenz and mix.
5. Layer onto a 80–60% continuous Nycodenz gradient (form by placing 350 µl of 80, 75, 70, 65, and 60% Nycodenz and twirling tube about 5–10 times). Top with 20 m*M* KCl. Spin at 30,000 rpm for 30 min at 4°C in a SW55 rotor. Aspirate and discard the supernatant. Resuspend the pellet in 1 ml MBS and label as "P." Store at –20°C.

4. Isolation of Silica-Coated Plasma Membranes from Cultured Cells (Monolayer)

This protocol is written for T75 flasks; alter proportionately for larger or smaller flasks. All parts of the procedure need to be performed on ice or in a 4°C room.

1. Wash cell monolayer three times with MBS.
2. Overlay with 1% ice-cold colloidal silica solution and incubate for 10 min. Wash cell monolayer three times with MBS.
3. Overlay with 0.1% PAA and incubate for 10 min. Wash cell monolayer three times with MBS.
4. Add 5 ml of sucrose/HEPES with protease inhibitors (1×). Scrape cells and place in 15-ml centrifuge tube. Centrifuge 1000 *g* for 5 min at 4°C.
5. Bring to 1 ml with cold sucrose/HEPES with protease inhibitors (1×) (you can use up to six T75 flasks per 1 ml of cold sucrose/HEPES with protease inhibitors).
6. Place in type "AA" homogenizer vessel. Homogenize with corresponding grinder for 20 strokes at 1800 rpm.
7. Remove 100 µl and label as "homogenate" and store at –20°C.
8. Add an equal volume of 100% Nycodenz and mix (SW55 tube). Layer onto a 70–55% continuous Nycodenz sucrose/HEPES gradient (form by placing 350 µl of 70, 65, 60, and 55% Nycodenz sucrose/HEPES and carefully twirling tube as described earlier).
9. Top with sucrose/HEPES with protease inhibitors. Spin at 30,000 rpm for 30 min at 4°C in a SW55 rotor. Aspirate off the supernatant. Resuspend the pellet in 1 ml MBS and label as "P." Store P at –20°C.

B. Isolation of Caveolae (V)

1. Isolation of Caveolae (V) (in the Presence of Detergent)

1. Take 900 µl "P" (as per step 5 of Section III,A,3 or step 6 of Section III,A,4), add 100 µl 10% Triton X-100, and mix. Save 100 µl "P." Mix on nutator for 10 min at 4°C. Place in type "AA" homogenizer vessel.

Homogenize with corresponding grinder for 20 strokes at 1800 rpm.

2. Bring to 40% sucrose (w/w) with 60% sucrose (w/w)/20 m*M* KCl (takes about 1.5 ml). Layer with discontinuous 35–0% sucrose (w/w)/20 m*M* KCl gradient (350 µl of 35, 30, 25, 20, 15, 10, and 5% sucrose/20 m*M* KCl and 20 m*M* KCl).

3. Spin at 50,000 rpm for 4 h at 4°C in a MLS-50 rotor.

4. Collect the band between 10 and 15% sucrose (w/w) density. Dilute the band material two to three times with MBS and spin at 15,000 rpm for 2 h at 4°C. Resuspend pellet in 100 µl MBS, pH 6.0, and label as "V."

5. Collect and resuspend membrane pellet from step 3 in 1 ml MBS and label as "P-V."

6. Store both fractions at –20°C.

2. Isolation of V′ (Detergent Free)

1. Process as in Section III,B,1 except omit the addition of Triton X-100 and homogenize for 60 strokes. Label floated caveolae as "V′" (V prime).
2. Collect and resuspend membrane pellet from step 3 in Section III,A,4 and label as "P-V.′"
3. Store V′ and P-V′ at –20°C.

C. Isolation of Budded Caveolae (V_b) (Caveolae Isolation without Physical Disruption)

1. Isolation of Rat Lung Cytosol

1. Perfuse rat lung as described in Section III,A using steps 1, 2, 3, 8, and 9 only.
2. Homogenize lung in cytosolic buffer (2–3×, v/w) for 10 strokes at 1800 rpm.
3. Spin at 35,000 rpm for 1 h at 4°C in a SW55 rotor. Place supernatant over PD-10 column and collect first peak. Aliquot (1 ml), label at "rat lung cytosol," and store at –80°C.

2. Isolation of "V_b"

1. Incubate "P" or "PM" (PM described later) (20–50 µg/ml) with rat lung cytosol (1–5 mg/ml) for 1 h at 37°C.
2. Bring to 40% sucrose (w/w) with 60% sucrose (w/w)/20 m*M* KCl solution. Layer with discontinuous 35–0% sucrose 20 m*M* KCl gradient (as described in Section III,B; 350 µl each layer).
3. Spin at 30,000 rpm overnight at 4°C in a SW55 rotor. Collect the band between 10 and 15% sucrose (w/w) density. Dilute the band material two to three times with MBS and spin at 15,000 rpm for 2 h at 4°C. Resuspend pellet in 100 µl MBS and label as "V_b."
4. Collect and resuspend membrane pellet from step 2 in 1 ml MBS and label as "P-V_b." Store at –20°C.

D. Isolation of Lipid Rafts (LR)

Isolation of LR

1. Resuspend membrane pellet (P-V) from Section III,B in 1 ml of ice-cold MBS, pH 6.0. Add equal volume of potassium phosphate/polyacrylic acid (pH should be greater than 9.5). Mix well.
2. Sonicate at maximum output for 10 bursts of 10 s each. Cool on ice between bursts. Mix using nutator at room temperature for 8 h and then sonicate as described earlier except use 5- to 10-s bursts.
3. Add Triton X-100 to a final concentration of 1%. Mix on nutator for 10 min at 4°C and then place in a type "AA" homogenizer vessel.
4. Homogenize with corresponding grinder for 30 strokes at 1800 rpm. Bring to 40% sucrose (w/w) using 60% sucrose (w/w)/20 m*M* KCl and layer with discontinuous 35–0% sucrose (w/w) with 20 m*M* KCl using 350 µl solution per layer as described Section III,A.
5. Centrifuge at 30,000 rpm overnight at 4°C in a SW55 rotor.
6. Collect band between 10 and 15% sucrose (w/w) density. Dilute the band material two to three times with MBS and centrifuge at 15,000 rpm for 2 h at 4°C. Resuspend pellet in MBS, label as "LR," and store at –20°C.
7. Collect the stripped membrane pellet from step 5 and resuspend in MBS. Label as "SP" and store at –20°C.

E. Isolation of Plasma Membrane-Enriched Fraction (PM)

Isolation of PM from Tissue

1. Perfuse rat lung as described in Section III,A using steps 1, 2, 3, 8, and 9 only.

2. Process rat lung as described in Section III,A except use 3 ml of buffer PM and type "BB" homogenizer vessel for step 2.

3. Filter the homogenate through a 53-µm Nytex filter and then through a 30-µM Nytex filter.

4. Remove 200 µl from the filter solution, label as "homogenate," and store at –20°C. Centrifuge the remaining supernatant at 1000 *g* for 10 min at 4°C. Save supernatant on ice. Resuspend the pellet in 3 ml buffer PM and repeat centrifugation. Pool the two supernatants.

5. Adjust the volume to 7 ml with buffer PM and then add 3 ml to make a 30% Percoll solution. Centrifuge at 84,000 *g* for 45 min at 4°C (no brakes) in MLS50 rotor. Collect the band around two-thirds to three-fourths from bottom of the tube. Dilute the band material two to three times with PBS and centrifuge at 15,000 rpm for 2 h at 4°C. Resuspend pellet in 100 µl PBS, label as "PM," and store at –20°C.

Isolation of PM from Cultured Cells

This protocol is written for T75 flasks, alter proportionately for larger or smaller flasks. All parts of the procedure need to be performed on ice or in a 4°C room.

1. Wash cell monolayer three times with cold buffer PM.
2. Add 5 ml of cold buffer PM with protease inhibitors (1×). Scrape cells and place in 15-ml centrifuge tube. Centrifuge at 1000 *g* for 5 min at 4°C.
3. Bring to 1 ml with cold buffer PM with protease inhibitors (1×) (you can use up to six T75 flasks per 1 ml of cold buffer PM with protease inhibitors).
4. Place in type "AA" homogenizer vessel. Homogenize with corresponding grinder for 20 strokes at 1800 rpm.
5. Remove 100 µl, label as "homogenate," and store at –20°C.
6. Centrifuge the remaining supernatant at 1000 *g* for 10 min at 4°C. Save supernatant on ice. Resuspend the pellet in 1 ml buffer PM and repeat centrifugation. Pool the two supernatants.
7. Adjust the volume to 3.5 ml with buffer PM and then add 1.5 ml to make a 30% Percoll solution. Centrifuge at 84,000 *g* for 45 min at 4°C (no brakes) in MLS50 rotor. Collect the band around two-thirds to three-fourths from bottom of the tube. Dilute the band material two to three times with PBS and centrifuge at 15,000 rpm for 2 h at 4°C. Resuspend pellet in 100 µl PBS, label as "PM," and store at –20°C.

F. Isolation of Triton-Resistant Membranes (TRM)

Isolation of TRM from Tissue

1. Perfuse rat lung as described in Section III,A using steps 1, 2, 3, 8, and 9 only.
2. Process rat lung as described in Section III,A except add 1% Triton X-100 to sucrose/HEPES solution in step 2.
3. Filter the homogenate through a 53-µM Nytex filter and then through a 30-µM Nytex filter.
4. Remove 200 µl from the filter solution, label as "homogenate," and store at –20°C. Bring the remaining supernatant to 40% sucrose (w/w)/20 m*M* KCl. Layer with discontinuous 35–0% sucrose (w/w)/20 m*M* KCl gradient (3 ml each of 35, 30, 25, 20, 15, 10, and 5% sucrose (w/w)/20 m*M* KCl and 20 m*M* KCl as described in Section III,B).
5. Centrifuge at 15,000 rpm overnight at 4°C in SW28 rotor. Collect the band between 10 and 15% sucrose (w/w) density. Dilute the band material two to three times with PBS and centrifuge at 15,000 rpm for 2 h at 4°C. Resuspend pellet in PBS, label as "TRM," and store at –20°C.

Isolation of TRM from Cells

This protocol is written for T75 flasks; alter proportionately for larger or smaller flasks. All parts of the procedure need to be performed on ice or in a 4°C room.

1. Wash cells three times with 1X PBS.
2. Scrape cells and place in 15-ml conical tube. Centrifuge at 1000 *g* for 5 min at 4°C.
3. Resuspend pellet in 1 ml of 1X PBS. Remove 100 µl, label this cellular homogenate as "H," and store at –20°C.
4. To the remaining H add Triton X-100 to 1% (100 µl of 10% Triton X-100) for a total volume of 1 ml.
5. Place in type "AA" homogenizer vessel. Homogenize with corresponding grinder for 20 strokes at 1800 rpm.
6. Bring to 40% sucrose (w/w)/20 m*M* KCl and layer with discontinuous 35–0% sucrose (w/w)/20 m*M* KCl and centrifuge as described in Section III,B.
7. Collect the band between 10 and 15% sucrose (w/w) density. Dilute the band material two to three with PBS and centrifuge at 15,000 rpm for 2 h at 4°C. Resuspend pellet in PBS, label as "TRM," and store at –20°C.

Isolation of TRM from PM

1. Isolate PM as described in Section III,E.
2. Bring pelleted PM to 1 ml with buffer PM.
3. Remove 100 µl, label as "PM," and store at –20°C.
4. To the remaining PM add Triton X-100 to 1% (100 µl of 10% Triton X-100) with a total volume of 1 ml. Mix on nutator for 10 min at 4°C.
5. Bring to 40% sucrose (w/w)/20 m*M* KCl, layer with discontinuous 35–0% sucrose (w/w)/20 m*M* KCl, and centrifuge as described in Section III,B.
6. Collect the band between 10 and 15% sucrose (w/w) density. Dilute the band material two to

three times with PBS and centrifuge at 15,000 rpm for 2 h at 4°C. Resuspend pellet in PBS, label as "TRM," and store at –20°C.

IV. POTENTIAL PITFALLS

1. When utilizing cellular membrane subfractions, a rigorous quality control protocol must be applied. It is very important that one first check the purity of the starting material to confirm that the preparation is enriched in markers of the desired membrane material and depleted in markers of other membrane-bound cellular organelles. At the very least, preparations should be checked for markers of the major microdomain components of the plasma membrane, such as caveolae, lipid rafts, adhesion complexes, and the plasma membrane proper, as well as for contaminating intracellular organellar membranes. A good plasma membrane preparation should be enriched 15- to 20-fold in cell surface marker proteins, such as caveolin-1, GPI-AP, integrins, and ion transporters. It should also be depleted by 15- to 20-fold in protein markers expressed in nuclei (ran, transportin), Golgi (p58, β-COP), lysosomes (lamp1), and mitochondria (cytochrome c). Likewise, caveolar preparations must be enriched in caveolar proteins, such as caveolin-1, Gq, and eNOS. LR should be enriched in GPI-AP but lack caveolin-1 expression. In addition, it is also very important to monitor the mass balance of all proteins. For plasma membrane preparations isolated by the silica method, this can be accomplished by examining by Western analysis the proteins left behind in the P-V fraction (containing LR and remaining plasmalemma proper) and comparing them to the protein expression in the P and V fractions to verify that the signal for all three fractions can be accounted for by the fractionation.

2. It is very important to maintain the recommended temperatures as presented in these protocols, especially when working with Triton X-100 solubilization. Any increases in temperature may solubilize a greater number of proteins, which may alter the final protein profile.

3. One needs to use the correct pH for the solutions, especially those associated with cationic silica particles, as alterations in pH will affect the binding of the silica to the luminal plasma membrane.

4. All solutions must be filtered with at least a 0.45-μm filter to ensure that they remain relatively free of contaminants and aggregates.

5. Do not mix phosphate solutions with solutions containing colloidal silica, as this will cause the silica to precipitate.

6. When perfusing rat organs, be careful to avoid getting air bubbles in the line of the perfusion apparatus, as this will interfere with the vessel lumen-coating procedure and decrease the amount of isolated material.

V. DISCUSSION

The overall goal of these procedures is to excise microdomains specifically from cellular membranes, in this case, from plasma membranes. To isolate any microdomain from a membrane, certain critical criteria are necessary to increase efficiency and purity. First, the microdomain excision must be highly selective. In most cases, however, this cannot be accomplished in one step. One must start with the appropriate highly purified membrane fraction containing the desired microdomain and then process this material to specifically excise and, if necessary, differentially isolate the desired microdomain away from other similarly excised domains.

If detergent-resistant microdomains were unique to the plasma membrane, then contamination with other organellar membranes would be rendered irrelevant. However, that seems quite unlikely given that newly synthesized GPI-AP also acquire resistance to detergent extraction upon entering the *trans*-Golgi compartment; in fact, TRM were first isolated from cultured MDCK cells as a tool for studying this maturation process (Brown and Rose, 1992). Hence, it is clearly advantageous to start with purified plasma membranes when trying to purify caveolae or other cell surface microdomains. The silica-coating method described here permits one to first isolate plasma membranes to high purity before further subfractionation to purify caveolae separately from other plasmalemmal microdomains (**Fig. 2**). To isolate the luminal endothelial cell plasma membrane directly from tissue, the tissue is first perfused with polycationic colloidal silica particles that selectively coat this luminal surface to increase the membrane density. Then, after electrostatic cross-linking and cation quenching, the tissue is homogenized and subjected to a series of centrifugations to sediment the higher density silica-coated membranes away from the other tissue components that are not silica coated and have much lower densities. Electron microscopy shows large silica-coated membrane sheets in these pellets.

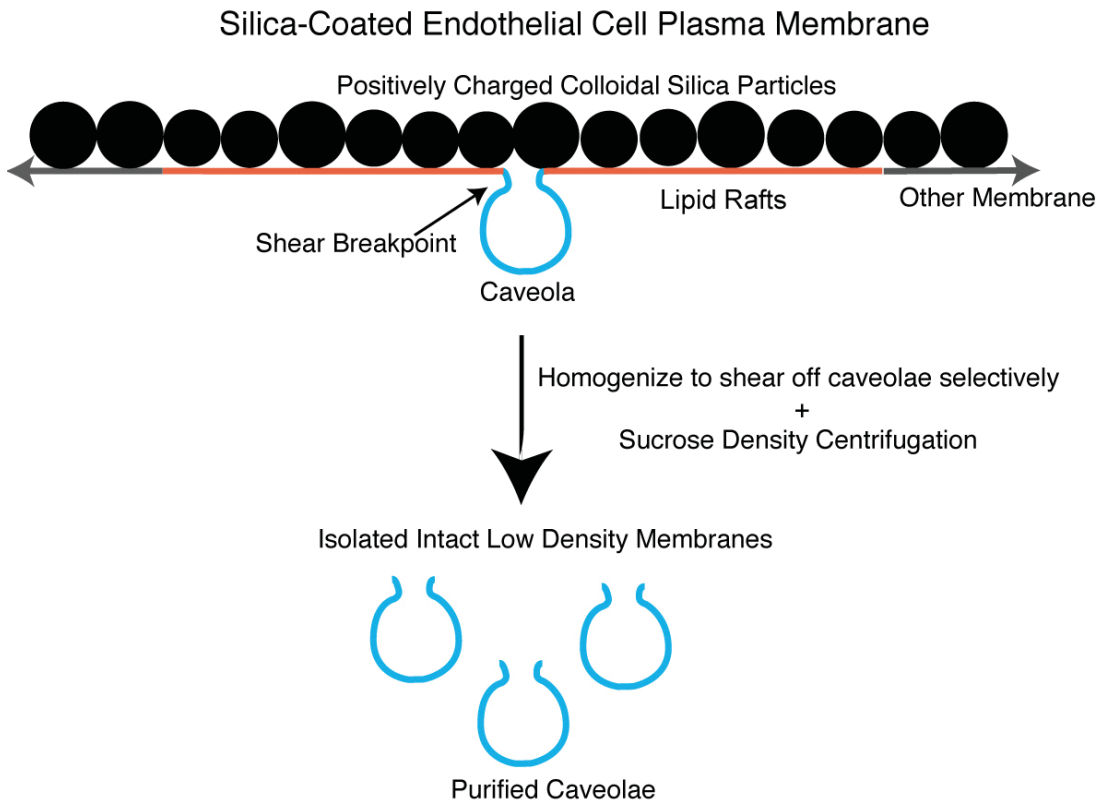

FIGURE 2 Two-step silica coating-based methodology for isolating plasma membrane caveolae. To purify endothelial plasmalemmal caveolae, the luminal endothelial cell membrane is first coated with positively charged colloidal silica particles to create a stable pellicle that specifically marks this membrane and facilitates its purification by density centrifugation of tissue homogenates. These pelleted membranes have many caveolae attached on the side of the membranes opposite to the silica coating that may be stripped from the endothelial membranes by shearing during homogenization at 4°C in the presence of Triton X-100. Further centrifugation through a sucrose density gradient yields a homogeneous population of distinct caveolar vesicles.

This procedure can also be performed on cultured cells (Schnitzer and Oh, 1996), even as a cell monolayer where the top membrane surface opposite to the plastic can be coated and purified. Using this method, the plasma membranes are enriched to levels exceeding standard subcellular fractionation techniques (e.g., Percoll) (Oh and Schnitzer, 1999) with minimal contamination from marker proteins of various intracellular organelles (nuclei, endoplasmic reticulum, Golgi, and mitochondria), as well as nonendothelial cells in the tissue (**Fig. 3B**; compare PM to P) (Schnitzer *et al*., 1995b) that are commonly present in other published preparations (Chang *et al*., 1994; Lisanti *et al*., 1994; Oh and Schnitzer, 1999; Smart *et al*., 1995).

Plasma membranes contain at least two types of microdomains, caveolae and lipid rafts, that although distinct in protein and possible lipid composition, share certain biochemical properties that often confound attempts at generating highly enriched isolates. Complicating matters further is the fact that caveolae and lipid rafts may be found on the cell surface not only as discrete entities, but also closely associated with each other, in some cases, with lipid rafts in close enough proximity to caveolae that they are essentially attached to a caveola at the annulus (**Fig. 1**) (Schnitzer *et al*., 1995b). Consequently, caveolae isolation methods that use as a starting material Triton-resistant membrane fractions (TRM) (either fractionated from whole cells or tissue) or Percoll gradient-isolated plasma membranes (PM) cannot distinguish between these very similar and sometimes associated membrane microdomains, resulting in a preparation that contains a mixture of caveolae, lipid rafts, and lipid rafts associated with caveolae (**Fig. 4**). When these preparations are examined by EM, they are revealed to contain individual caveolar vesicles in addition to

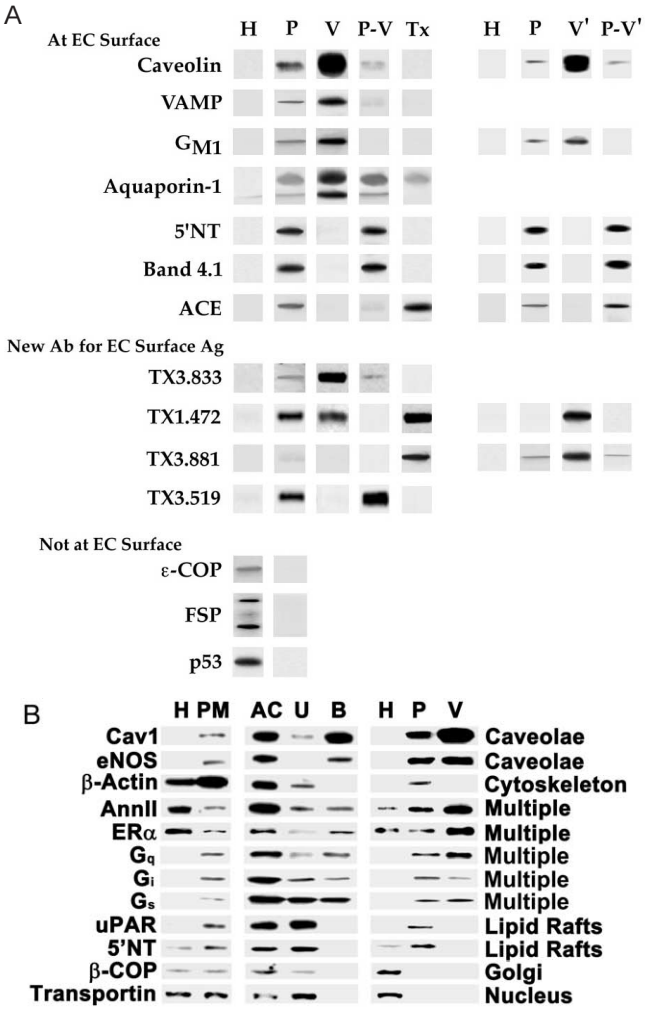

FIGURE 3 Molecular mapping of luminal plasma membrane subfractions. Proteins (5μg) from the indicated membrane fractions were subjected to SDS–PAGE followed by electrotransfer to filters for immunoblotting with antibodies to the indicated proteins. H, homogenate; P, silica-coated plasma membrane; PM, percoll-gradient isolated plasma membranes; V, caveolae [V (in the presence of Triton), V′ (in the absence of Triton)], P-V, silica-coated plasma membrane stripped of caveolae [P-V (in the presence of Triton), P-V′ (in the absence of Triton)]; Tx, Triton-soluble phase; AC, Optiprep-isolated, caveolin-enriched membranes; U, material not bound to caveolin antibody-coupled magnetic beads after immunoisolation; B, material bound to caveolin antibody-coupled magnetic beads after immunoisolation.

larger vesiculated lipid rafts (**Fig. 5A**) and even intact large vesicular lipid rafts with a caveolae attached (**Fig. 5B,C**) (Schnitzer *et al.*, 1995b). The attached caveola are usually found inside the larger vesicle, but can also be seen in an "inside-out" orientation outside the vesicle. Immunogold EM showed that the larger vesicles but not the attached caveolae could be labeled with gold-conjugated antibodies recognizing the GPI-AP carbonic anhydrase, indicating that these larger vesicles contain lipid rafts. Moreover, these preparations contain other detergent-resistant domains from other subcellular organelles and even the plasma membrane (**Fig. 3**) (Lisanti *et al.*, 1994; Oh and Schnitzer, 1999; Schnitzer *et al.*, 1995b). For instance, nuclear and Golgi marker proteins, such as transportin and β-COP, respectively, contaminate these preparations (Razandi *et al.*, 2002). Although caveolin-1 is an excellent marker for labeling caveolae selectively on the cell surface, it can also be present amply in exocytic vesicles of the trans-Golgi network. In cultured cells, such as Madin–Darby canine kidney cells, fibroblasts, or endothelial cells, it can even be found primarily in the Golgi. In addition, the membranes treated with cold Triton X-100 will also contain protein complexes resistant to detergent solubilization. For example, it is well known that plasma membrane proteins tethered to the cytoskeleton have increased resistance to detergent solubilization as do possibly other similar complexes, including focal adhesion sites and intercellular junctional complexes. Other detergent-resistant protein complexes may also float if they retain sufficient lipids. Even in cells that lack both caveolae and caveolin, TRM can readily be isolated as rich in GPI-AP. The TRM from cells with and without caveolae have very similar buoyant densities. It is apparent that the physical characteristic of vesicle buoyant density is unable to discriminate and thereby separate caveolae from LR, which clearly explains their coisolation in TRM, as well as other more recently developed detergent-free procedures (Smart *et al.*, 1995). Thus, isolation of detergent-resistant membrane microdomains yields a heterogeneous fraction consisting of a mixture of caveolar and noncaveolar components.

Caveolae can be isolated to near homogeneity using as a starting material plasma membranes prepared using the novel silica-coating procedure that bypasses the problems associated with other techniques. Examination of silica-coated plasma membranes by EM reveals that the positively charged colloidal silica particles form a strongly adherent layer over flat, noninvaginated portions of the cell surface plasma membrane (**Fig. 2**) and do not enter the caveolae, which appear amply present on the side of the endothelial cell membrane not coated with silica (**Fig. 6A**) (Oh and Schnitzer, 1998; Schnitzer *et al.*, 1995a,b). This coating serves to stabilize the flat plasma membrane, including the lipid raft domains, so that the caveolae can be selectively detached from the plasma membrane mechanically by homogenization, leaving behind the plasma membrane proper (including lipid rafts) still attached to the silica particles. The buoyant caveolae can then be floated away from the high-

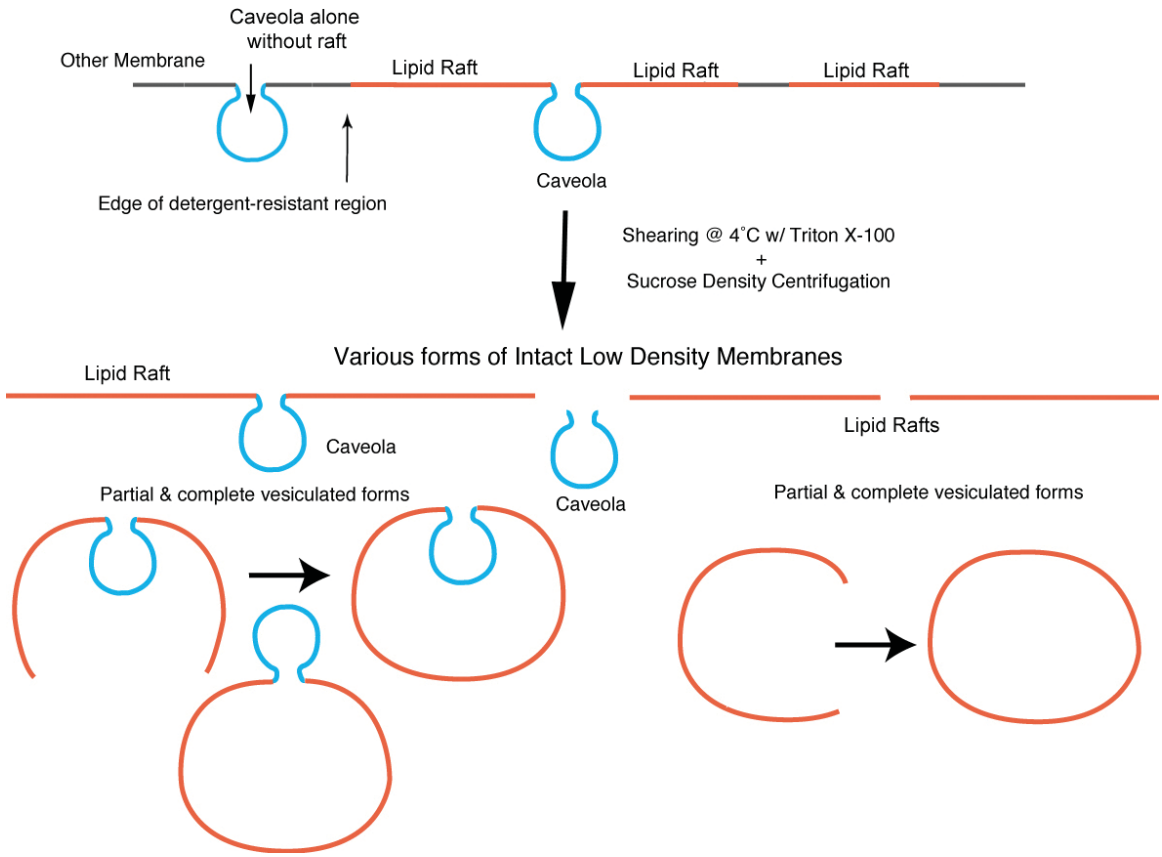

FIGURE 4 Isolation of detergent-resistant membranes without silica-coating procedure yields TRMs containing both caveolae and lipid rafts. Nonsilica-based methodologies that isolate detergent-resistant membranes by sucrose density centrifugation result in a heterogeneous preparation containing a mixture of low-density microdomains as sheets or as partial or fully vesiculated forms.

density lipid raft/silica membrane pellicle by sucrose gradient centrifugation. More than 95% of the caveolae on the silica-coated plasma membranes are removed and isolated in this manner as a rather uniform homogeneous population of distinct flask-shaped vesicles of approximately 80 nm in diameter (**Fig. 6B**) (Schnitzer *et al.*, 1995b). Biochemical analysis shows that the isolated caveolae represent specific microdomains of the cell surface with their own unique molecular topography (Schnitzer *et al.*, 1995a,b,c). They are enriched in seven caveolar markers established by immunogold EM: caveolin, Ca^{2+}-ATPase, the glycolipid GM_1, VAMP, eNOS, dynamin, and the IP_3 receptor (McIntosh and Schnitzer, 1999; Oh *et al.*, 1998; Rizzo *et al.*, 1998; Schnitzer *et al.*, 1995b,c). In contrast, 5′NT, Band 4.1, and β-actin are markedly depleted or absent from the caveolae, despite being amply present in the silica-coated plasma membrane starting material. More recent work in the laboratory has utilized these membranes successfully to generate and characterize monoclonal antibodies specific for the caveolae, as assessed by both subfractionation and immunomicroscopic analyses (McIntosh *et al.*, 2002). **Fig. 3A** shows representative immunoblots for various proteins of interest, including some of the markers discussed earlier and some of our new monoclonal antibodies.

As a test to confirm the hypothesized key role of silica coating in the isolation of caveolae separately from lipid rafts, we have performed the caveolar isolation on silica-isolated plasma membranes after removing the silica coating under high salt conditions (**Fig. 7**). The resulting caveolae preparation closely resembled the TRM fractions isolated without silica coating. GPI-linked proteins not normally associated with the highly purified V caveolar fraction, such as 5′-NT, were found in this isolate (data not shown). Furthermore, electron microscopy revealed that specimens, which appeared biochemically unpure by this criterion, contained caveolae mixed with larger vesicular structures very similar to those seen in **Fig. 5**. Thus, the uniform silica coating at the cell surface does indeed stabilize the plasma membrane by being firmly attached on one side of the membrane to most,

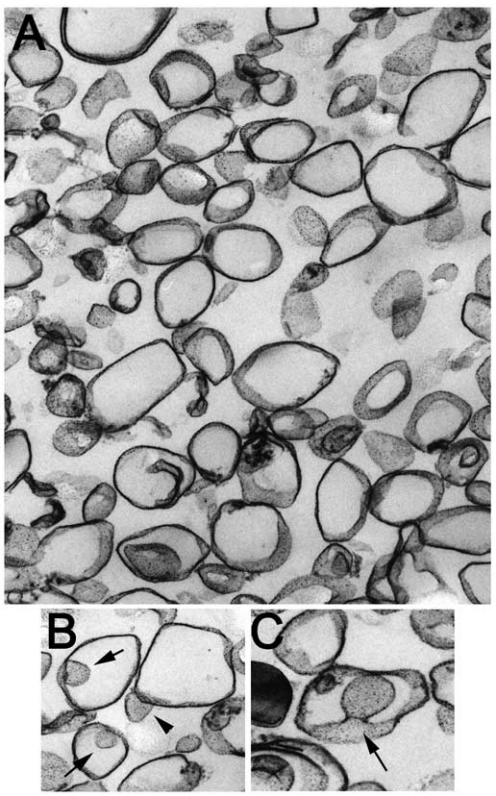

FIGURE 5 **Electron microscopy of nonsilica-isolated detergent-resistant membranes (TRMs)**. (**A**) Membranes isolated without silica consist of larger vesicles (150–700 nm diameter) interspersed with smaller caveolar vesicles (<100 nm) as well as nonvesiculated linear membrane sheets. (**B** and **C**) Caveolae were typically observed attached to a larger vesicle. Arrow: caveola within a larger vesicle. Arrowhead: "inside-out" caveola attached to a larger vesicle. Magnification: A,B = 10,000×; C = 20,000×.

if not all, nonvesiculated regions. The silica coat performs the essential function of preventing the interaction of the LR with various detergents, as well as the separation of noncaveolar detergent-resistant microdomains from the cell membranes during shearing to isolate caveolae. Without the silica coat, isolation of homogeneous preparations of caveolae is not possible.

In addition to allowing the isolation of highly purified preparations of caveolae, the stable attachment of silica particles to the detergent-resistant flat LR domains provides a means to isolate lipid rafts away from both caveolae and the plasmalemma proper (**Fig. 8**) (Schnitzer *et al.*, 1995b). Silica-coated membranes stripped of the caveolae are resedimented to form a membrane pellet (P-V) during the centrifugation and can be resuspended, treated with high salt to remove the silica coating, and used to isolate low-density, Triton-resistant lipid rafts by sucrose density centrifugation. **Figure 9** shows that each of our tissue subfractions has a distinct protein profile and that caveolae and LR differ considerably in this regard. Given that LR are difficult to follow biophysically, they currently require an operational definition based on their detergent resistance. With our strict definition and differentiation of caveolae and lipid rafts (see Section I), TRMs isolated from plasma membranes stripped of caveolae (P-V) should constitute lipid rafts. Because the starting preparation, i.e., silica-coated plasma membranes, appears minimally contaminated by intracellular membranes (Oh and Schnitzer, 1999; Razandi *et al.*, 2002), the resulting lipid raft preparation should be primarily, if not exclusively, from the cell surface. Of course, future experiments may provide further differentiation of detergent-resistant domains beyond just LR.

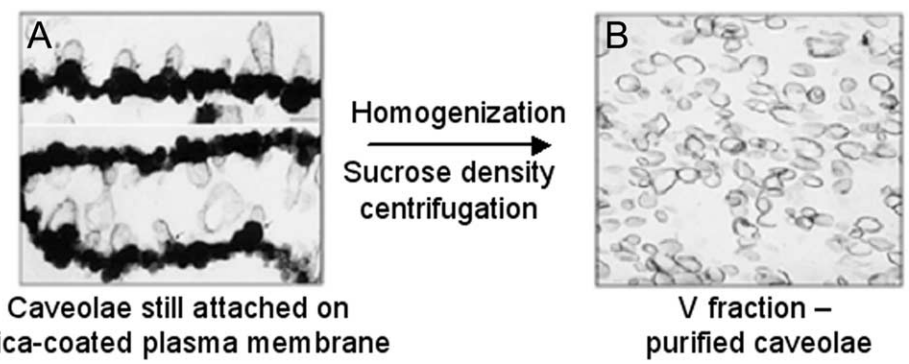

FIGURE 6 **Electron micrographs of P (A) and V (B) membrane fractions after isolation**. Electron microscopy demonstrates the presence of significant numbers of caveolae on the intracellular side of the plasma membrane not coated with silica (P fraction; A). Mechanical shearing of caveolae from the silica-coated plasma membrane yields a homogeneous population of morphologically distinct caveolae with diameters <90 nm (V fraction; B).

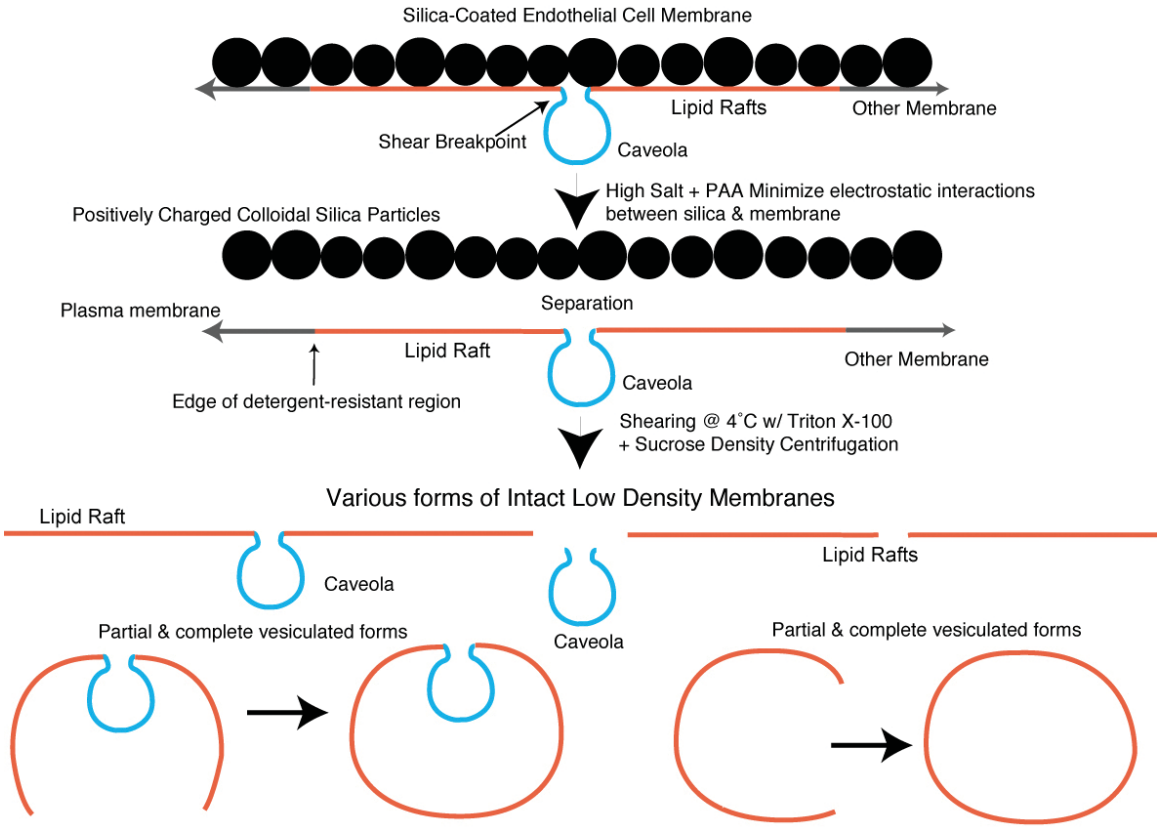

FIGURE 7 Silica coating prevents coisolation of caveolae and lipid rafts. Treatment of silica-coated plasma membranes with high salt prior to separation of caveolae by homogenization results in a heterogeneous mixture of membrane microdomains containing caveolae and lipid rafts alone or attached to each other in partial or fully vesiculated forms.

Using this methodology, we have shown that the heterotrimeric protein G_q specifically concentrates in caveolae, whereas G_s and G_i segregate preferentially to lipid rafts. These results were confirmed by dual immunofluorescence confocal microscopy to reveal that, in cultured endothelial cells, G_q but not G_i or G_s colocalized with caveolin-marked caveolae, whereas G_i and G_s, but not G_q, overlapped with folic acid receptor-marked lipid rafts (Oh and Schnitzer, 2001). In addition, we have shown that even in highly purified plasma membranes with minimal contamination from Golgi or other intracellular compartments, caveolae and GPI-anchored proteins exist distinctly at the cell surface and can actually be purified separately (Schnitzer *et al.*, 1995b). Thus, the extra dimension to the isolation process, namely the high-density silica coat, takes advantage of the distinct morphological characteristics of caveolae and lipid rafts (invaginated vs flat) and renders a new fractionation technique that is quite effective in separating two membrane microdomains of similar buoyant density.

A reconstituted cell-free system has also been developed to study further the dynamics and properties of caveolae (Schnitzer *et al.*, 1996). It shows that caveolae are dynamic structures that can be induced to bud from plasma membrane by GTP. Fission of caveolae from the plasmalemma without any physical disruption requires GTP hydrolysis and provides an alternative, and possibly more physiological, source to isolate caveolae. A comparison of GTP-induced budded caveolae with caveolae isolated via the silica-coating technique reveals that both isolates yield similar protein profiles (Schnitzer *et al.*, 1996).

Another widely used procedure leading to a similar isolate as TRM involves detergent-free sonication of plasma membranes isolated on a Percoll gradient before Optiprep gradient centrifugation to collect fractions over a wide range of densities (10–20%) (Smart *et al.*, 1995). This is then concentrated using a step gradient consisting of 5% layered over 23% to yield a caveolin-rich fraction (AC) that has been characterized as quite similar to TRM (Oh and Schnitzer, 1999). Further comparative investigation of the Optiprep-based caveolae isolate AC vs the silica-based isolate V by immunoisolation using caveolin-1 antibodies showed that ~50% vs 95%, respectively, of the material

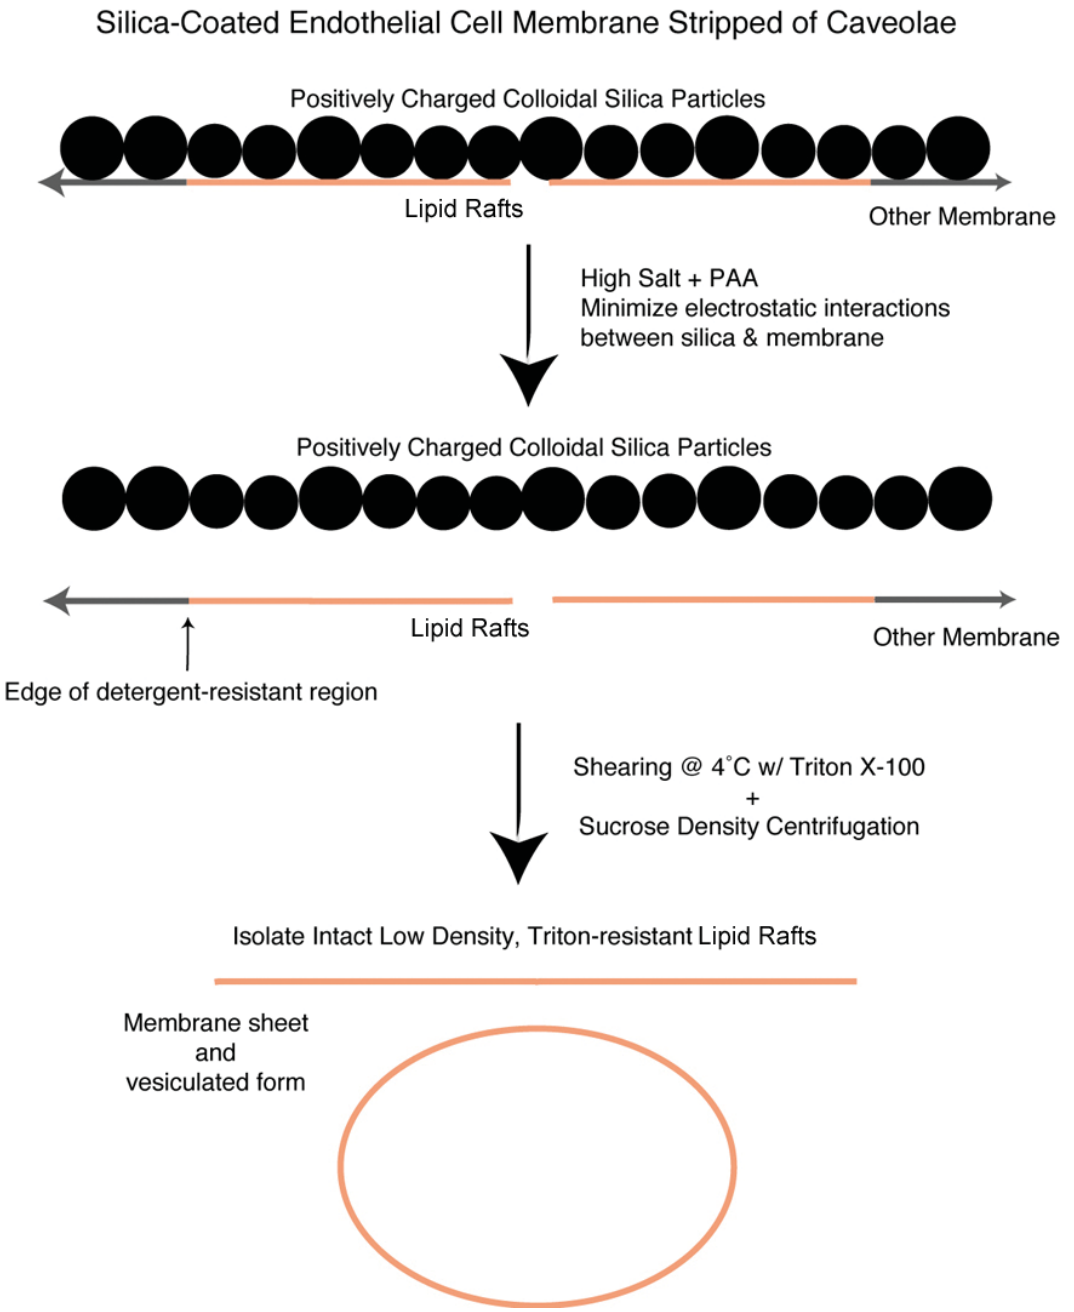

FIGURE 8 **Isolation of LR from silica-coated plasma membranes stripped of caveolae**. Because the silica coating prevents the release of detergent-resistant, GPI-anchored protein microdomains, it is possible to isolate these domains separately from caveolae. Incubation of silica-coated membranes stripped of caveolae in the presence of high salt and polyacrylic acid followed by homogenization in Triton X-100 and sucrose density centrifugation results in isolation of a membrane fraction containing membrane sheets as well as vesicles >200 nm in diameters. These membranes are enriched in GPI-AP, including 5′NT and carbonic anhydrase.

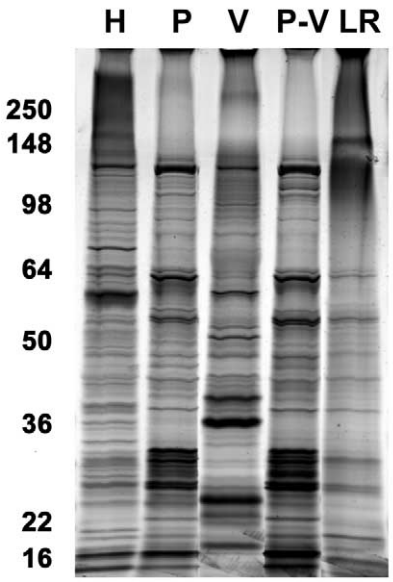

FIGURE 9 One-dimensional protein analysis of various membrane subfraction. Proteins (5μg) from the indicated membrane fractions were subjected to SDS–PAGE followed by silver staining. bound to the caveolin-1–antibody magnetic beads (Oh and Schnitzer, 1999). **Figure 3B** shows a comparative Western analysis for specific proteins in each fraction. AC clearly contains proteins of the cytoskeleton, lipid rafts, Golgi, and nucleus, but after immunoisolation, the protein profile is identical to that of silica-based caveolae isolate (**Fig. 3, compare fraction B to V**). Almost certainly the source of contamination in Optiprep-based caveolar isolates stems from the use of PM as a starting material. As discussed earlier, PM contains a mixture of cell membranes in addition to plasma membranes, such as Golgi, ER, nuclear, and mitochondrial, that are composed of multiple microdomains of different densities. Therefore, strategies that use flotation of membranes to isolate caveolae from this preparation naturally coisolate contaminating membrane fragments of similar low density to yield a caveolin-rich membrane fraction that also contains a significant amount of noncaveolar membranes. Immunoisolation should be used as a last step to validate more definitively the expression of a given protein in caveolae.

CHAPTER

3

Immunoisolation of Organelles Using Magnetic Solid Supports

Raluca Flükiger-Gagescu and Jean Gruenberg

I. INTRODUCTION

To study the molecular composition and functional properties of cellular organelles, these must first be purified. Classical *subcellular fractionation* methods are based on the physical properties of membrane-bound compartments, e.g., their density. However, many compartments have similar properties and cannot be separated from each other by such methods. *Immunoisolation*, however, allows you to affinity purify organelles using an antibody directed against a component of the compartment (Jones *et al*., 1998; Howell *et al*., 1989).

To set up an immunoisolation protocol, you first have to identify an appropriate antigen that is tightly associated with the membrane (or, even better, transmembrane) and localizes exclusively to the compartment that you wish to isolate. If the distribution of the antigen is broader, you might be able to remove unwanted organelles that contain this antigen by a prepurification step. Moreover, the antigen should be relatively abundant and its antigenic site should be well exposed on the cytoplasmic surface of the compartment.

In the absence of an ideal endogenous antigen, it is also possible to exogenously introduce a more convenient one, provided that you check thoroughly that it localizes to the correct compartment. We have transfected cells with a myc-tagged human transferrin receptor to provide a convenient marker for the *recycling endosome* (Gagescu *et al*., 2000; for a review on endocytic compartments, see Gruenberg, 2001). The myc tag allows us to use a well-characterized, high-affinity anti-myc antibody for immunoisolation, and it also provides us with an excellent means to control the specificity of the immunoisolation by carrying out all experiments in parallel with a second cell line that expresses the human transferrin receptor without the myc epitope.

Next, you need a high-affinity antibody that recognizes the native form of the chosen antigen. Because large amounts of the antibody may be needed to complete a set of experiments, it is better to use a monoclonal antibody whenever possible.

Finally, you have to choose a solid support. Of all the solid supports that we have tested, *magnetic beads* are the most convenient because of two key features: their smooth surface with low hydrophobidity ensures low nonspecific binding and they can be retrieved with a magnet, which minimizes membrane shearing when resuspending the beads.

It is possible to use either an indirect or a direct immunoisolation technique. In the first case, the antibody is bound to the organelle, and the complex is retrieved with a linker antibody that is bound to the solid support. In the second case, the antibody is first bound to a linker antibody that is bound to the solid support. The solid support with the two antibodies is then used to retrieve the organelle. Although it is slightly less convenient, the indirect immunoisolation method can, in some cases, give better results as it corresponds, to some extent, to an affinity purification of the antibody. Indeed, by incubating membranes with the antibody before adding the magnetic beads, you eliminate nonfunctional antibodies, thereby increasing the number of productive antibody–antigen interactions. Moreover, if the antigen is not well exposed, the indirect method is preferable, as it involves less steric hinderance.

Immunoisolated fractions can be analyzed by virtually any means, as the beads themselves are inert. A

small hinderance is caused by the high abundance of antibodies in the samples, which requires the use of metabolically labeled fractions to establish the general protein pattern. Most types of analysis, including Western blotting, bideminsional gel electrophoresis, lipid analysis, electron microscopy, or enzymatic assays, can be performed using standard protocols. The main limitation is that only small amounts of membranes can be isolated, so it is, for example, not possible to microsequence a protein directly from an immunoisolated fraction.

Importantly, cell-free assays can be performed with immunoisolated fractions by simply adding the reaction mix to the beads and removing it at the end of the incubation (Gruenberg and Howell, 1988). Successive steps can thus be performed more rapidly and with less damage to the membranes, as retrieval of the membranes is much simplified after each step.

II. MATERIALS AND INSTRUMENTATION

Cell scrapers (flexible rubber policemen) with a silicon rubber piece of about 2 cm, cut at a sharp angle, and attached to a metal bar can be made by your institute workshop. You need a standard low-speed cell centrifuge, Eppendorf centrifuge, and Beckman ultracentrifuges and rotors. Magnets can be purchased from Dynal Biotech (Cat. No. 120.20). A rotating wheel (e.g., Cat. No. 34526; Snijders) with a speed of about 2 rotations per minute should be used.

M450 sheep anti-mouse IgG Dynabeads (Cat. No. 110.01) and M450 goat anti-mouse IgG Dynabeads (Cat. No. 110.05) are manufactured by Dynal Biotech. It might be useful to buy Dynabeads in larger batches, as variation could occur between different lots. We find that M500 beads, which have been developed specifically for subcellular fractionation, work less well for our purposes than M450 beads, which are designed for cell isolation.

The anti-myc hybridoma cell line (Myc1-9E10.2; CRL1729) can be obtained from the American Type Culture Collection.

For the immunoisolation protocol described here, MDCK II cells were stably transfected with the pCB6 plasmid containing the human TfR with (mhTfR cells) or without (hTfR cells) a single myc tag (13 amino acids) at its cytoplasmic amino terminus. Transfection was carried out by the calcium phosphate method and was followed by selection with geneticin–sulphate (Invitrogen; Cat. No. 11811). Transfected cells should not be used for more than 8–10 passages to avoid loss of expression.

III. PROCEDURES

A. Postnuclear Supernatant

Any subcellular fractionation protocol starts with breaking the plasma membrane to release intact intracellular organelles (Howell *et al.*, 1989). This can be achieved through several methods, which are all compatible with immunoisolation. For MDCK cells, we use passage through a needle in a slightly hypotonic medium.

Steps

1. Briefly rinse the cells with ice-cold phosphate-buffered saline (PBS). Add 2.5 ml of ice-cold PBS to the dish. If MDCK cells grown on polycarbonate filters are used, add 2.5 ml of PBS to the apical side of the cells and transfer the filter to the inner side of the cool lid of the original filter support. Scrape the cells with a rubber policeman, taking care not to break them.
2. Transfer to a 15-ml Falcon tube and centrifuge at 900 rpm for 5 min.
3. Resuspend gently in 2.5 ml of HB (250 m*M* sucrose, 3 m*M* immidazole, pH 7.4) per tube and centrifuge at 2500 rpm for 10 min.
4. Add 150 µl of HB+ (HB, 1 m*M* EDTA, 1 µg/ml leupeptine, 1 µg/ml pepstatin, 1 µg/ml aprotinin, 100 µg/ml phenymethylsulfonyl fluoride) per filter and resuspend gently with a blue tip approximately eight times. Do not apply the tip to the bottom of the tube, but on the side, to minimize cell breakage while resuspending the cells. Homogenize with a 1-ml syringe and a 22-gauge needle one to three times, depending on the state of the nuclei as observed under a microscope. Nuclei should be clean of cellular material and intact (round and dark grey).
5. Dilute with 100 µl of HB+ per filter to facilitate pelleting of the nuclei and centrifuge at 2500 rpm for 10 min.
6. Preclear the postnuclear supernatant (PNS) 5 min at 13,000 rpm in an Eppendorf centrifuge.

B. Gradient Centrifugation

Before proceeding to immunoisolating the compartment of choice, a prepurification step can be useful. A simple method for partially purifying organelles is density centrifugation, e.g., on a sucrose gradient. Floatation gradients usually give purer frac-

tions, but sedimentation gradients also work well, in most cases. As our compartment of choice (the recycling endosome of MDCK cells) does not float well out of a high-density sucrose solution, we use a sedimentation gradient.

Steps

1. Form a step gradient in an SW60 ultraclear tube (Cat. No. 344062; Beckman Coulter, Inc.) by overlaying 1 ml of 20% sucrose (216.2 g/liter sucrose, 3 m*M* immidazole, pH 7.4) on top of 2.5 ml of 35% sucrose (403.0 g/liter sucrose, 3 m*M* immidazole, pH 7.4). Then add 500 µl of the precleared PNS on top of the gradient.
2. Centrifuge for 1 h at 35,000 rpm in an SW60 rotor.
3. Discard the upper band, which is often very faint. Use a 200-µl pipette to collect the lower band (usually well visible), which contains endosomes and many other membranes. Cut off about 0.5 cm of the yellow tip to avoid breaking the endosomes, which are fragile at this high sucrose density.

C. Immunoisolation

Steps

1. Preclear the antibody and the PNS for 5 min at 13,000 rpm in an Eppendorf centrifuge.
2. Add 15 µl of 9E10 culture supernatant (2 mg/ml) to 500 µl of PNS (4 mg/ml in HB+). Rotate in a cold room at 2 rpm for 45 min. Add 50 µl of 3 *M* KCl. Rotate for another 15 min.
3. Apply to a sucrose step gradient as described earlier, centrifuge, and retrieve the lower band.
4. Measure the protein concentration and use 25 µg per point for immunoisolation.
5. Use 50 µl bead slurry per point (2×10^7 beads) for the immunoisolation. Prepare the beads by washing three times with PBS/bovine serum albumin (BSA) (5 mg/ml, 0.45 µm filtered) in a 15-ml Falcon tube by centrifugation. Take the final bead pellet up in 100 µl PBS/BSA per point.
6. For each immunoisolation point, add 25 µg of membranes to an Eppendorf tube and complete to 900 µl with PBS/BSA. Keep enough endosomal fraction for Western blots (see step 3 of the protocol for sample analysis).
7. Preclear 5 min at 13,000 rpm and transfer the supernatants to new tubes.
8. Add 100 µl of bead slurry to each Eppendorf tube. Be very careful to distribute the beads equally.
9. Rotate for 2 h at 2 rpm in the cold room.
10. Retrieve the beads with a magnet. Keep the supernatants (see step 2 of the protocol for sample analysis).
11. Wash with 1 ml of PBS/BSA/0.3 *M* KCl, with 1 ml PBS/BSA, and finally with 1 ml PBS. For all washes, retrieve the beads with the magnet. Do not resuspend with a pipette as this could cause shearing of the endosomes. Instead, add the washing solution and resuspend by rotating (2 rpm) for 2 min on a wheel in the cold room. After the last wash, do not use the magnet, but pellet at 13,000 rpm. This allows one to remove the last drop of liquid so that the sample buffer is not diluted.
12. It is possible to include a carbonate wash: take up the initial bead pellet in 1 ml 0.1 *M* carbonate buffer, pH 11.0, and rotate for 15 min on the wheel. Then wash as just described.

D. Sample Analysis by Western Blotting

Steps

1. For analysis on minigels, resuspend the bead pellets in 30 µl of 1 × sample buffer. You can load the beads with the sample buffer into the wells as, unlike traces of salt or BSA, they do not perturb the migration.
2. Pellet the supernatants (unbound material) for 20 min at 200,000 *g* in a TLA100.2 rotor. Take up the pellets directly in sample buffer.
3. Dilute different amounts (e.g., 10, 25, 50%) of the starting material to 1 ml with PBS/BSA and pellet for 20 min at 200,000 *g* in a TLA100.2 rotor. Take up the pellets directly in sample buffer.
4. Load the pelleted starting material and the pelleted unbound material on the gel next to the immunoisolated fractions to calculate the yield by comparison (Fig. 1). Always include a negative control (see Section IV), as unspecific stickage may vary considerably from time to time depending on the state of

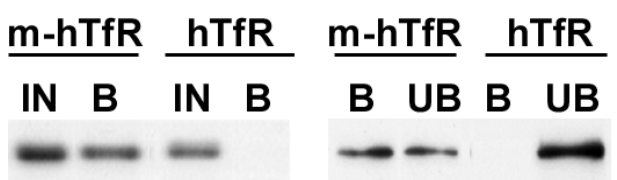

FIGURE 1 Immunoisolation of recycling endosomes. Transferrin receptor-positive endosomes were isolated as described, and fractions were analysed by Western blotting for the presence of the transferrin receptor. Yields were calculated by two means. (Left) The bound fraction (B) is compared with 50% of the starting material (IN). (Right) The bound fraction (B) is compared with the unbound fraction (UB). Both comparisons indicate a yield around 50%. In both types of analysis, a negative control is included consisting of fractions obtained in an identical manner from cells that do not contain the antigen for immunoisolation (a myc tag).

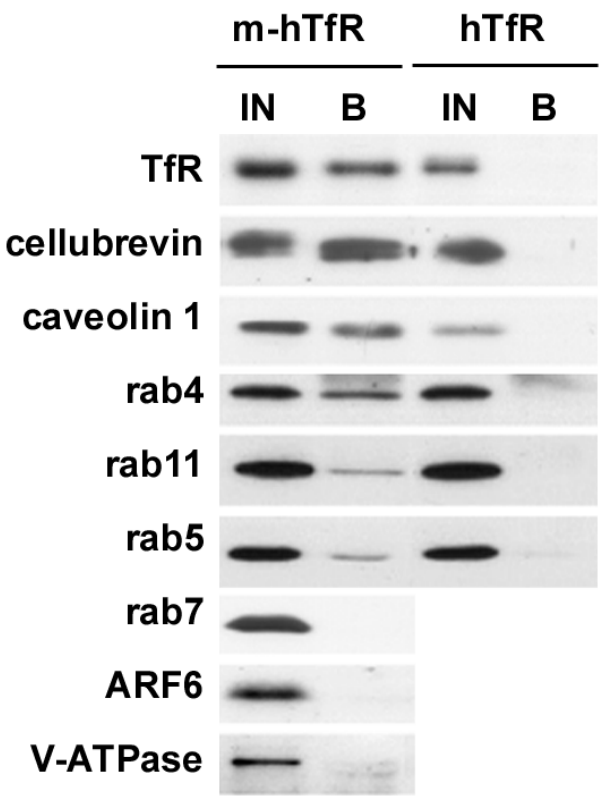

FIGURE 2 Immunoisolation of recycling endosomes. Transferrin receptor-positive endosomes were isolated as described, and fractions were analysed by Western blotting for the presence of various proteins. To estimate the yield of the immunoisolation and the degree of colocalization, bound fractions were compared with 50% of the starting material. Some markers, such as cellubrevin or caveolin 1, were isolated with similar yields as the transferrin receptor itself, indicating an excellent colocalization. Others, such as rab4, rab5, or rab11, were isolated to a lesser extent, indicating only partial colocalization. Finally, some proteins, including rab7, ARF6, and the 110-kDa subunit of the vacuolar ATPase, were absent, indicating that they do not localize to recycling endosomes.

aggregation of the starting material and on the quality of the antibody preparation.

5. Proteins that localize on the same compartment as the antigen used for immunoisolation will be isolated with a similar yield as the antigen itself, whereas proteins that only partially colocalize will be isolated with inferior yields (Fig. 2).

IV. COMMENTS

On the Importance of Negative Controls

Immunoisolation is a powerful technique for analyzing the molecular composition of organelles.

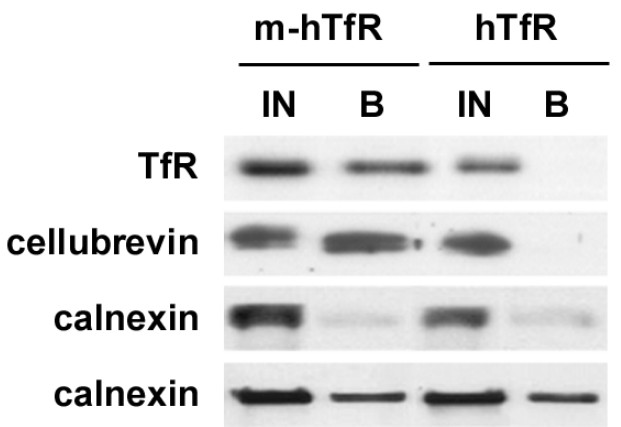

FIGURE 3 Immunoisolation of recycling endosomes. Transferrin receptor-positive endosomes were isolated as described, and fractions were analysed by Western blotting for the presence of contaminants. The ER marker calnexin is isolated with variable yields, but is always also present in the negative control (fractions from cells without the myc epitope). The transferrin receptor and cellubrevin, however, are isolated with a 50% yield in each experiment (only one experiment is shown here) and are not present in the negative control sample.

However, you can be easily misled by false positives if unspecific binding is not assessed accurately.

Whereas the components of the compartment of choice are isolated with similar yields in different experiments, contaminants are present in different proportions (Fig. 3). So to be confident that a given molecule is present in the isolated compartment, you should check that it is always isolated with similar efficiency with respect to the antigen used for immunoisolation.

In the absence of an appropriate negative control, you can use internal controls, provided that enough is known about the composition of the isolated compartment. Indeed, if several molecules that are known to be absent from the compartment are not isolated whereas several known components are isolated, you can be fairly confident that the immunoisolation is specific.

Due to its abundance in the cell, the endoplasmic reticulum is a frequent contaminant during subcellular fractionation so it may be useful to check that its known components, e.g., the transmembrane protein calnexin, are absent from your isolated fractions (Fig. 3).

As unspecific stickage varies considerably between different experiments, it is essential to always include a negative control. Frequently used negative controls consist of beads without antibodies or beads coated with irrelevant antibodies. Unfortunately, in our experience, both types of control are essentially useless. The

magnetic beads that we use never give any unspecific binding in any situation. Consequently, unspecific binding always originates from the use of suboptimal membrane or antibody preparations. Moreover, controls with irrelevant antibodies are unrepresentative, as the results are highly variable, ranging from no background stickage at all to very high stickage, depending strictly on the choice of control antibody.

We find that unspecific binding correlates best with the quality of the antibody preparation used for immunoisolation. Hence, a negative control should directly test the state of the antibody. In our experiments, this is achieved by performing all experiments in parallel with cells that express the myc-tagged human transferrin receptor and cells that express the untagged receptor. Thus, the negative control sample contains both cellular membranes and the antibody; it lacks only the 13 amino acid myc epitope.

V. PITFALLS

It is important to keep in mind that some antigen–antibody pairs just do not work for immunoisolation, either because the affinity is not high enough or because the antigen is not well exposed. If, after the first attempts, the yield is too low or the background is too high, you can try to optimize the conditions, e.g., by varying the amount of antibody, membranes, or beads. However, if you do not observe any improvement, it might be wise to simply drop this particular antigen–antibody combination and try another antibody or even another component of the compartment as the antigen for immunoisolation.

CHAPTER

4

Purification of Rat Liver Golgi Stacks

Yanzhuang Wang, Tomohiko Taguchi, and Graham Warren

I. INTRODUCTION

The study of intracellular organelles has been facilitated greatly by their purification from cellular homogenates. Such protocols yield an abundant source of material for both structural and functional studies. This article describes some simple protocols derived from several earlier methods (Leelavathi *et al*., 1970; Fleischer and Fleischer, 1970; Hino *et al*., 1978) for obtaining highly purified Golgi stacks from rat liver and for determining their relative purity over the homogenate.

II. MATERIAL AND INSTRUMENTATION

Centrifugation is carried out using an L8-70M or Optima LE-80K ultracentrifuge and either a SW-28 rotor (Cat. No. 342204) containing ultraclear tubes (Cat. No. 344058) or a SW-41 rotor (Cat. No. 331336) containing ultraclear tubes (Cat. No. 344059) from Beckman Coulter Inc. A 150-µm-mesh stainless-steel laboratory test sieve (Cat. No. 200SBW.150) and a stainless-steel receiver (Cat. No. 200BRASREC) are from Endecotts Ltd. A 0–50% Delta refractometer (Cat. No. 2–70) is from Bellingham and Stanley Ltd. Scintillation counter LS6500, spectrophotometer DU530 is from Beckman Coulter Inc.

Potassium phosphate dibasic (Cat. No. 3252), potassium phosphate (Cat. No. 3246), sucrose (Cat. No. 4072), magnesium chloride (Cat. No. 2444), concentrated hydrochloric acid (Cat. No. 9535), and dimethyl sulfoxide (DMSO, Cat. No. 9224) are from J. T. Baker. Tris (Cat. No. AB02000), SDS (Cat. No. AB01920), and β-mercaptoethanol (Cat. No. AB01340) from American Bioanalytical. The Bio-Rad protein assay (Cat. No. 500-0006) is from Bio-Rad. Manganese chloride (Cat. No. M-3634), Triton X-100 (Cat. No. T-9284), phosphotungstic acid (Cat. No. P-4006), ovomucoid (Cat. No. T-2011), ATP (Cat. No. A-7699), UDP-galactose (Cat. No. U-4500), pepstatin A (Cat. No. P-5318), and sodium cacodylate (Cat. No. C4945) are from Sigma. Complete EDTA-free tablet (protease inhibitor cocktail tablets, Cat. No. 1 873 580) is from Roche. [^{3}H]UDP-galactose with a specific activity of 30–50 Ci/mmol (Cat. No. NET758) is from NEN Research products. Ethyl alcohol (190 proof, ACS/USP grade) is from Pharmco products, Inc. Scintillation fluid (Opti-Fluor, Cat. No. 6013199) is from Packard BioScience. All reagents are of analytical grade or better. The water used is double distilled and filtered.

III. PROCEDURES

A. Purification of Rat Liver Golgi Stacks

Solutions

1. *0.5 M potassium phosphate buffer, pH 6.7:* Make up 500-ml solutions of 0.5 *M* anhydrous K_2HPO_4 (43.55 g) and 0.5 *M* anhydrous KH_2PO_4 (34.02 g). To 400 ml of the latter, gradually add the former until the pH reaches 6.7. Store at 4°C.
2. *2 M sucrose:* Dissolve 342.3 g in water prewarmed to 50°C. Make up to a final volume of 500 ml and store at 4°C.

TABLE I Buffers A–E

Buffer	A	B	C	D	E
Sucrose concentration (*M*)	0	0.25	0.5	0.86	1.3
0.5 *M* phosphate buffer, pH 6.7 (ml)	10	10	20	20	10
2 *M* sucrose (ml)	—	6.25	25	43	32.5
2 *M* $MgCl_2$	0.125	0.125	0.25	0.25	0.125
Water	39.9	33.6	54.8	36.8	7.4
Total volume (ml)	50	50	100	100	50
Sucrose % (w/w)	0	8.6	16.0	26.4	38.6
Refractive index	1.333	1.346	1.357	1.375	1.397

3. *2 M $MgCl_2$:* Dissolve 40.7 g of $MgCl_2 \cdot 6H_2O$ in water to a final volume of 100 ml. Store at room temperature.

4. *Protease inhibitors:* Directly dissolve one EDTA-free tablet in 50 ml solution and then add 50 µl pepstatin A (5 m*M* stock). To prepare the stock solution of pepstatin A, dissolve 3.43 mg of the powder in 1 ml DMSO and store at –20°C.

5. *Gradient buffers:* Make up buffers A–E from the preceding three stock solutions and cold water as shown in Table I. Fifty milliliters of each buffer A, B, and E and 100 ml of buffers C and D are needed for a medium-scale preparation. EDTA-free protease inhibitor tablet (1 tablet per 50 ml buffer) and pepstatin A (5 µM) are added to buffer C and D. We normally make 500 ml buffer C without protease inhibitors (which are expensive) for washing the liver. The water should be precooled to 4°C overnight to ensure that all the buffers are ice cold.

It is very important to be as accurate as possible when mixing various components and to check the refractive index of each buffer using a refractometer. The final refractive index should be adjusted to within ±0.5% sucrose (about 0.001 in refractive index) for buffers C and D in particular.

1. Standard Protocol (Medium-Scale Preparation)

This common protocol is used for general biochemical studies of Golgi membranes. It suffices for many electron microscopy studies as well.

Steps

1. Starve six female Sprague–Dawley rats (body weight 150–200 g) for 24 h.

2. After killing the rats with CO_2, rapidly remove the livers into large volume of ice-cold buffer C without protease inhibitors. This cools the liver and washes off the blood. Then transfer the livers into ice-cold buffer C with protease inhibitors. Mince into small pieces (approximately 4–5 mm in diameter) with a pair of scissors (Fig. 1A). Put the livers into a 50-ml Falcon tube.

3. Check the weight of livers, which is normally 40–45 g. A maximum of 50 g liver can be used for 12 gradients.

4. Homogenize the tissue by gently pressing through a 150-µm-mesh stainless-steel sieve with the bottom of a 250-ml conical flask using a rolling action (Fig. 1B). Adding a small amount of buffer C (with protease inhibitor) to the sieve will make it easier to press the liver through the mesh (Fig. 1C). Pool the homogenate (Fig. 1D) into a 50-ml Falcon tube; the final volume should be about 50 ml. Keep 200 µl on ice for enzyme assay.

5. Gradients (Fig. 2A):
   a. Place 6 ml of buffer D in each of the 12 SW-41 ultraclear tubes (size 14 × 89 mm).
   b. Overlay 4.5 ml of homogenate.
   c. Overlay 1.8 ml of buffer B and balance the tubes to within 0.01 g.

6. Centrifuge at 29,000 rpm in a SW-41 rotor for 60 min at 4°C.

7. Aspirate and discard the lipid at the top and the cytosol (colored red by hemoglobin) and collect Golgi fractions that accumulate at the 0.5/0.86 *M* interface (cloudy band) with a plastic Pasteur pipette (Fig. 2B).

8. Pool the fractions in a 50-ml Falcon tube. Typically, the total volume is about 15 ml with a refractive index of about 1.370 (0.77 *M* sucrose). Keep 200 µl on ice for enzyme assay. Adjust the Golgi sample to 0.25 *M* sucrose (refractive index 1.345) using buffer A. Make up to 50 ml with buffer B if necessary.

9. For the second gradient (Fig. 2C), put 1 ml of buffer E followed by 2 ml of buffer C into each tube and then overlay 8.0 ml of the diluted Golgi fractions.

10. Centrifuge at 8000 rpm in a SW-41 rotor for 30 min at 4°C.

11. Aspirate and discard the supernatant and collect the membranes (thin band) at the 0.5 *M*/1.3 *M*

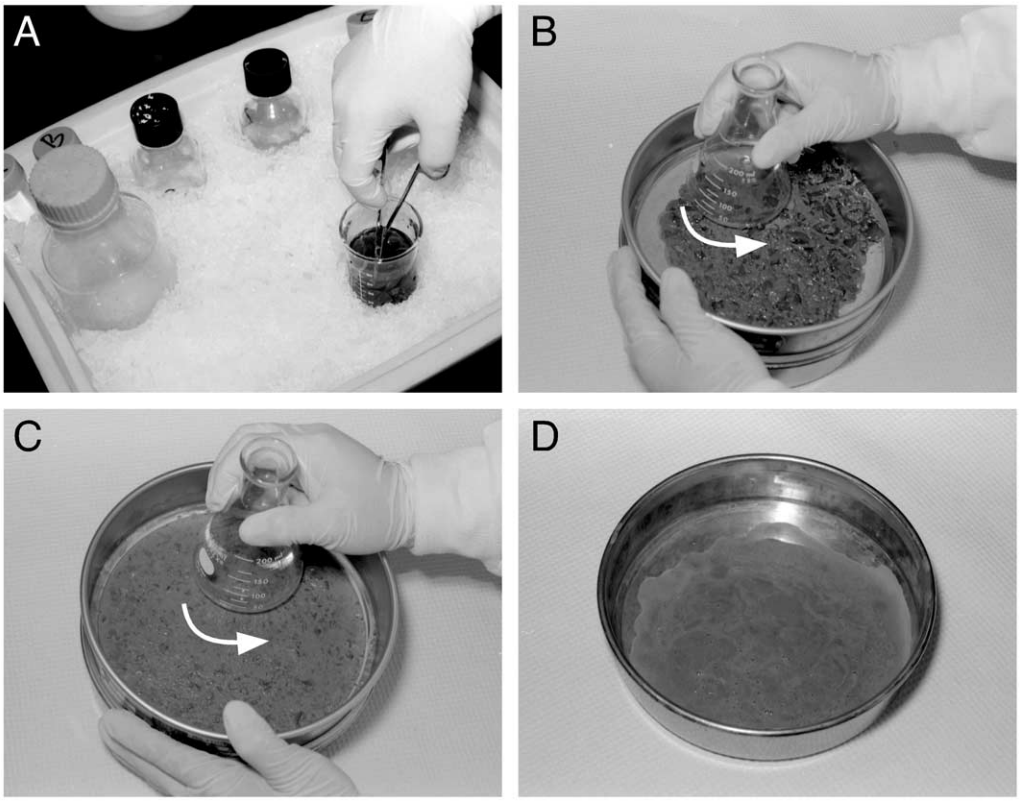

FIGURE 1 Steps in homogenizing rat liver. (A) Mince rat liver in ice-cold buffer C. (B and C) Gently press the liver through the metal mesh. (D) Homogenate in the sieve receiver.

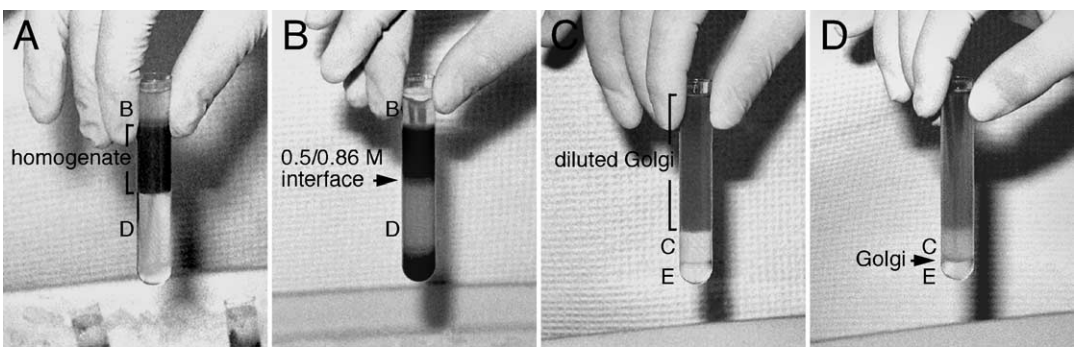

FIGURE 2 Sucrose gradients for Golgi purification from rat liver. (A) Liver homogenate was first loaded onto a 0.86*M* sucrose cushion (buffer D) and overlaid with 0.25*M* sucrose (buffer B). Letters on the left indicate sucrose buffers used to make the gradients. (B) After ultracentrifugation, Golgi stacks are enriched at the 0.5/0.86*M* interface. (C) Crude Golgi sample from the first gradient was loaded onto the second gradient. (D) After centrifugation, Golgi stacks form a thin band at the 0.5/1.3*M* interface and can be collected using a Pasteur pipette.

sucrose interface (Fig. 2D). Gently mix the Golgi membranes (about 1.5–2 ml) with 1 volume buffer A. Final volume is 3–4 ml. Check the protein concentration by the Bradford assay (Bio-Rad); typically this is 1–2 mg/ml.

12. Aliquot and freeze samples in liquid nitrogen and then store at –80°C. Samples can be thawed and frozen twice without significant loss of enzymatic activity or loss of morphology.

2. *Large-Scale Preparation*

This protocol ensures large amounts of Golgi membranes with minimal contamination by other membranes. However, stacked cisternal structures may be

less well preserved. The addition of protease inhibitors during the procedure is optional (see Section IV). Two consecutive spins at high speed are used to accommodate the large amount of homogenate used.

Steps

1. Use 8–12 female rats depending on size and requirement. Starve for 24 h. Kill the rats and ensure that all subsequent steps are performed as quickly as possible.
2. Rapidly remove the livers into 250 ml of ice-cold buffer C (without protease inhibitors) while swirling to speed cooling.
3. Weigh the livers, transfer to fresh buffer C, and mince the tissue into small pieces (about 5 mm in diameter) with a pair of scissors (Fig. 1A).
4. Homogenize the tissue by gently pressing through a 150-µm-mesh stainless-steel sieve using the base of a 250-ml conical flask (Figs. 1B and 1C). Take 100 µl of the homogenate for assay and record the total volume. The final volume for up to 100 g of liver should be about 120 ml, which is the maximum for six gradients.
5. Gradients:
   a. Place 16 ml buffer D in each of the six SW-28 ultraclear tubes.
   b. Overlay each gradient with 18–20 ml of the homogenate.
   c. Finally overlay with buffer B to top up and balance the tubes.
6. Centrifuge at 28,000 rpm in a SW-28 rotor for 60 min at 4°C.
7. Aspirate the lipid and collect Golgi fractions that accumulate at the 0.5/0.86 *M* interface between buffers C and D. About 3–4 ml should be collected from each gradient.
8. Pool the fractions and dilute to 0.5 *M* sucrose using buffer A. Check the refractive index: 0.5 *M* sucrose reads 1.357. Record the volume and keep 100 µl for enzyme assay. The total volume should be about 40 ml and should not exceed 60 ml.
9. For the second gradient, add 2 ml buffer E into SW-41 tubes and overlay 8–10 ml diluted Golgi sample. Spin at 8000 rpm for 30 min at 4°C.
10. Aspirate and discard supernatant as before. Collect membranes at the 0.5/1.3 *M* sucrose interface. Gently mix the Golgi sample (about 2.5 ml) with 1 volume buffer A. Final volume is about 5 ml. Check the protein concentration by the Bradford assay (Bio-Rad), which should typically be about 2 mg/ml.
11. Aliquot and freeze samples in liquid nitrogen and store at –80°C.

B. Determination of β-1,4-Galactosyltransferase Activity

The relative purification of the Golgi stacks can be assessed by measuring the increase in specific activity of the Golgi enzyme β-1,4-galactosyltransferase (GalT) over that of the whole liver homogenate. The enzyme assay used here is that of Bretz and Staubli (1977), which measures the addition of tritiated galactose onto the oligosaccharides of an acceptor protein, ovomucoid.

Solutions

1. *0.4 M sodium cacodylate, pH 6.6*: Dissolve 17.1 g in 150 ml of water and adjust the pH to 6.6 with HCl. Make up to 200 ml and store at room temperature.
2. *175 mg/ml ovomucoid*: Dissolve 1 g in water and make up to a final volume of 5.7 ml. Filter through a 0.45-µm nitrocellulose filter, aliquot, and store at –20°C.
3. *10 mM UDP-galactose*: Dissolve 25 mg in a final volume of 4.4 ml of water. Aliquot and store at –20°C.
4. *10% (w/v) Triton X-100*: Dissolve 10 g in 80 ml of water and make up to 100 ml. Store at 4°C.
5. *0.2 M ATP*: Dissolve 605 mg in 3 ml of water. Adjust the pH to 6.5–7.0 with 1 *M* NaOH and make up to a final volume of 5 ml with water. Aliquot and store at –20°C.
6. *2 M* $MnCl_2$: Dissolve 9.9 g of $MnCl_2 \cdot 4H_2O$ in 15 ml of water and make up to 25 ml. Store at 4°C.
7. *1% phosphotungstic acid/0.5 M HCl (PTA/HCl)*: Dissolve 5 g of phosphotungstic acid in 400 ml of water. Add 22 ml of concentrated HCl and make up to 500 ml with water. Store at 4°C.
8. *5% (w/v) SDS*: Dissolve 5 g of SDS in 80 ml of water and make up to 100 ml. Store at 4°C.
9. *2 M Tris*: Dissolve 24.2 g of Tris in 70 ml of water and make up to 100 ml. Store at room temperature.
10. *Assay mixture*: Make up a fresh batch of the assay mixture from the aforementioned stocks as follows: 200 µl sodium cacodylate, 6 µl β-mercaptoethanol, 200 µl ovomucoid, 40 µl UDP-galactose, 40 µl Triton X-100, 20 µl ATP, 40 µl $MnCl_2$, 10 µl [^{3}H]UDP-galactose, and 1040 µl of water. The concentration of UDP-galactose in the assay mixture is 0.25 m*M*.

Steps

1. Once the Golgi preparation has been completed, make 1:20 dilutions of the homogenate, intermediate, and Golgi fractions using water.

2. Add 80 µl of assay mixture (in duplicate) to screw-capped Eppendorf tubes containing 20 µl of the diluted samples or water (blanks). Vortex and incubate at 37°C for 30 min.
3. Stop the reaction by adding 1 ml of ice-cold PTA/HCl and spin at 13,000 rpm on a bench-top centrifuge for 10 s.
4. Aspirate and discard the supernatants. Add 1 ml of PTA/HCl. Resuspend the pellets by vortexing and spin as in step 3.
5. Aspirate and discard the supernatants. Add 1 ml of ice-cold 95% ethanol and resuspend the pellets as in step 4.
6. Spin as in step 3 and discard the supernatant. Resuspend the pellets in 50 µl of 2 *M* Tris followed by 200 µl of 5% SDS. Shake or vortex until dissolved.
7. Add 10 µl of assay mixture (containing 2.5 nmol of UDP-galactose), 40 µl of water, and 200 µl of 5% SDS to a fresh tube. This allows determination of the [^{3}H]UDP-galactose-specific activity in the mixture.
8. Add 1 ml of scintillation fluid to each sample. Vortex and count in a scintillation counter using the tritium channel.

C. Determination of Protein Concentration

Steps

1. While the GalT assays are incubating, make up the following dilutions of the three samples with water: 1:100 for the homogenate, 1:20 for the intermediate fraction, and 1:2 for the Golgi fraction.
2. Prepare a diluted Bio-Rad protein assay solution (fivefold dilution with water)
3. Aliquot 10 µl of each of the diluted samples in duplicate into 1-ml cuvettes using 10 µl water as a blank. Also aliquot 10 µl of 0.1, 0.2, 0.4, and 0.8 mg/ml of bovine serum albumin (BSA) for preparation of a standard curve.
4. Add 990 µl of the diluted Bio-Rad protein assay solution, mix well, and measure the absorbance at 595 nm.

D. Calculations of Purification Tables

Steps

1. Construct a protein standard curve by plotting the absorbance of each standard against the concentration of BSA. Calculate the slope (m) and the intercept at the ordinate axis (c).

$$\text{Protein concentration (mg/ml)} = \frac{(\text{sample absorbance} - c) \times \text{dilution}}{m}$$

$$\text{Total protein (mg)} = \text{Protein concentration (mg/ml)} \times \text{volume (ml)}$$

2. Calculate the specific activity (SA) of [^{3}H]UDP-galactose in the assay mixture as

$$\text{SA[}^3\text{H]UDP-galactose (dpm/nmol)} = \frac{\text{dpm of standard} - \text{blank}}{2.5\,\text{nmol}}$$

10 µl assay mixture contains 2.5 nmol of UDP-galactose (Section III,B, step 7).

3. Calculate the GalT activity in each sample as

$$\text{GalT activity concentration (nmol/h/ml)} = \frac{\text{average dpm} - \text{blank}}{\text{SA[}^3\text{H]UDP-galactose}} \times \frac{1}{0.02\,\text{ml}} \times \frac{1}{0.5\,\text{hr}} \times 20\ \text{(dilution factor)}$$

$$\text{Total GalT activity (nmol/h)} = \text{GalT activity concentration (nmol/h/ml)} \times \text{volume (ml)}$$

4. Calculate the SA of GalT by dividing its concentration by the protein concentration of the same sample to give SA in nanomoles per hour per milligram at 37°C.
5. The yields of Golgi membranes can be calculated from the ratio between the total GalT activity in the Golgi fractions and that of the homogenate.
6. The purification fold is the factor by which the SA of GalT increases in the Golgi fractions over the homogenate.

Table II was compiled using the results of 10 separate purifications, presented as the mean ± SEM for each parameter. As a consequence that the specific activity, yield and purification fold are only approximately related, arithmetically, to GalT and protein concentrations.

IV. COMMENTS

This protocol typically yields Golgi membranes that are purified 80- to 100-fold over the homogenate, as depicted in Table II. The Golgi preparations contain very little lysosomal or endoplasmic reticulum contamination as assessed by assay of β-*N*-acetylhexosaminidase (Landegren, 1984) and rotenone-insensitive NADH-cytochrome c reductase (Sottocasa *et al.*, 1967). The stacked nature of these Golgi membranes can be confirmed by examination of preparations by electron microscopy (Fig. 3). Samples

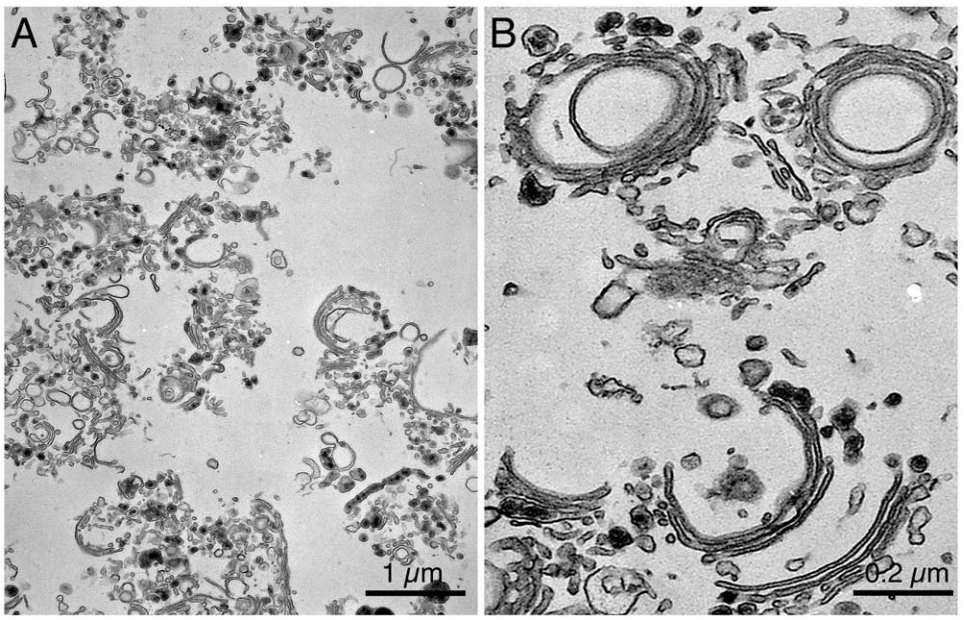

FIGURE 3 Representative micrographs of a typical rat liver Golgi preparation showing stacked membranes at low (A) and high (B) magnification. Bars: 1 μm (A) and 0.2 μm (B).

TABLE II Enrichment of the Golgi Marker β-1,4-Galactosyltransferase (GalT) over the Homogenate in Both the Intermediate Fraction (0.5/0.86 *M* Interphase) and the Golgi Preparation

Fraction	Volume (ml)	[Protein] (mg/ml)	Total GalT (nmol/h)	Specific activity (nmol/h/mg)	Yield of GalT (%)	Purification (-fold)
Homogenate	48.4 ± 2.7	103 ± 16	26,000 ± 700	5.3 ± 1.4	100.0	1.0
0.5/0.86 *M* interface	17.6 ± 2.1	12.9 ± 3.9	5350 ± 360	23.6 ± 1.6	20.2 ± 1.2	4.5 ± 0.4
Golgi	4.6 ± 0.6	1.5 ± 0.2	3560 ± 160	520 ± 22.8	13.7 ± 0.4	97.4 ± 4.2

are fixed in suspension by the method described by Pypaert *et al*. (1991).

The addition of protease inhibitors, although not essential, is recommended, especially when the Golgi protein of interest is known to be sensitive to proteases. The addition of protease inhibitors can reduce the apparent purification factor, although the reasons are not clear.

V. PITFALLS

1. As with many organelle purification procedures, it is vital to keep all solutions at 4°C during the whole protocol to prevent excessive protease digestion. If possible, steps 3–5 should be performed in a cold room. The addition of a protease inhibitors helps limit sample proteolysis.

2. All steps should be carried out as quickly as possible, and the entire procedure, from killing of the rats to freezing of the final samples, should take approximately 3–3.5 h.

3. Gradients should not be overloaded by increasing the concentration of the homogenate, as this increases the amount of mitochondrial contamination.

4. The final Golgi pellet should be white. A brown pellet indicates the presence of contaminating mitochondria. Lowering the concentration of the homogenate reduces such contamination.

5. The 150-μm sieve will become clogged with connective tissue after excessive use. This can be removed after each preparation by soaking the sieve in 4 *M* NaOH for 20–30 min followed by washing with

copious amounts of water and brushing. Prolonged soaking in 4 *M* NaOH attacks the glue used in binding the mesh to the wall of the sieves and should therefore be avoided.

Acknowledgments

The authors thank the former and current members of the Warren laboratory for contributions to the development of these methods, Henry Tan for providing the photographs in Fig. 1 and 2, and Matthew Beard for critical reading of the manuscript.

Isolation of Rough and Smooth Membrane Domains of the Endoplasmic Reticulum from Rat Liver

Jacques Paiement, Robin Young, Line Roy, and John J. M. Bergeron

I. INTRODUCTION

Subcellular fractionation from tissue homogenates have contributed extensively to our understanding of organelle structure and function. This article provides details of a tissue fractionation protocol evolved from several earlier methods (Paiement *et al.*, 1980; Paiement and Bergeron, 1983; Lavoie *et al.*, 1996), for the purification of rough microsomes, corresponding to derivatives of the rough endoplasmic reticulum, and for the purification of smooth microsomes, corresponding to derivatives of the smooth endoplasmic reticulum. The latter constitute a subcompartment of the transitional endoplasmic reticulum of hepatocytes (Lavoie *et al.*, 1996, 1999; Roy *et al.*, 2000).

II. MATERIALS AND INSTRUMENTATION

Sucrose solutions (0.25, 0.86, 1.0, 1.38, and 2.0 *M* solutions needed)[1]
Sucrose–Imidazole (0.25 m*M* sucrose, 3 m*M* imidazole, pH 7.4)
100-ml Beaker
Lint-free tissues (e.g., Kimwipes)
Surgical scissors
Potter–Elvehjem tissue grinder with ribbed Teflon pestle (50-ml capacity)
Nylon mesh (150 µm mesh, Thompson B & SH Co. Ltd., 8148 Devonshire, Montreal, Canada)
Glass funnel (60° funnel angle, 100 mm diameter)
100-ml graduated cylinder
Refrigerated low-speed centrifuge with fixed angle rotor (e.g., Beckman-Coulter Avanti J-20 with JA 25.50 rotor or equivalent)
Pasteur Pipettes
Loose-fitting Dounce homogenizer (7- and 15-ml capacity, with Wheaton type B piston, at least two of each)
Graduated conical tube
Parafilm
2.0-ml glass syringes with blunt-end syringe needles (10 cm long, 2 mm diameter)
Ultracentrifuge with swinging bucket and fixed-angle rotors (e.g., Beckman L-70 with SW60 and Ti50 rotors)

III. PROCEDURES

1. Rats must be fasting for 12 to 24 h prior to sacrifice.
2. Use two male rats of 300- to 400-g body weight (one liver weighs approximately 9 g).
3. Sacrifice rats via decapitation[2] and excise livers (free of connective tissue) and place in petri dish containing ice-cold 0.25 *M* sucrose.

[1] Densities of sucrose stock solutions should be checked for proper density with a refractometer.

[2] Animal sacrifice must be carried out according to the "*Guide to the Care and Use of Experimental Animals of the Canadian Council on Animal Care*" or equivalent protocol required by the country concerned.

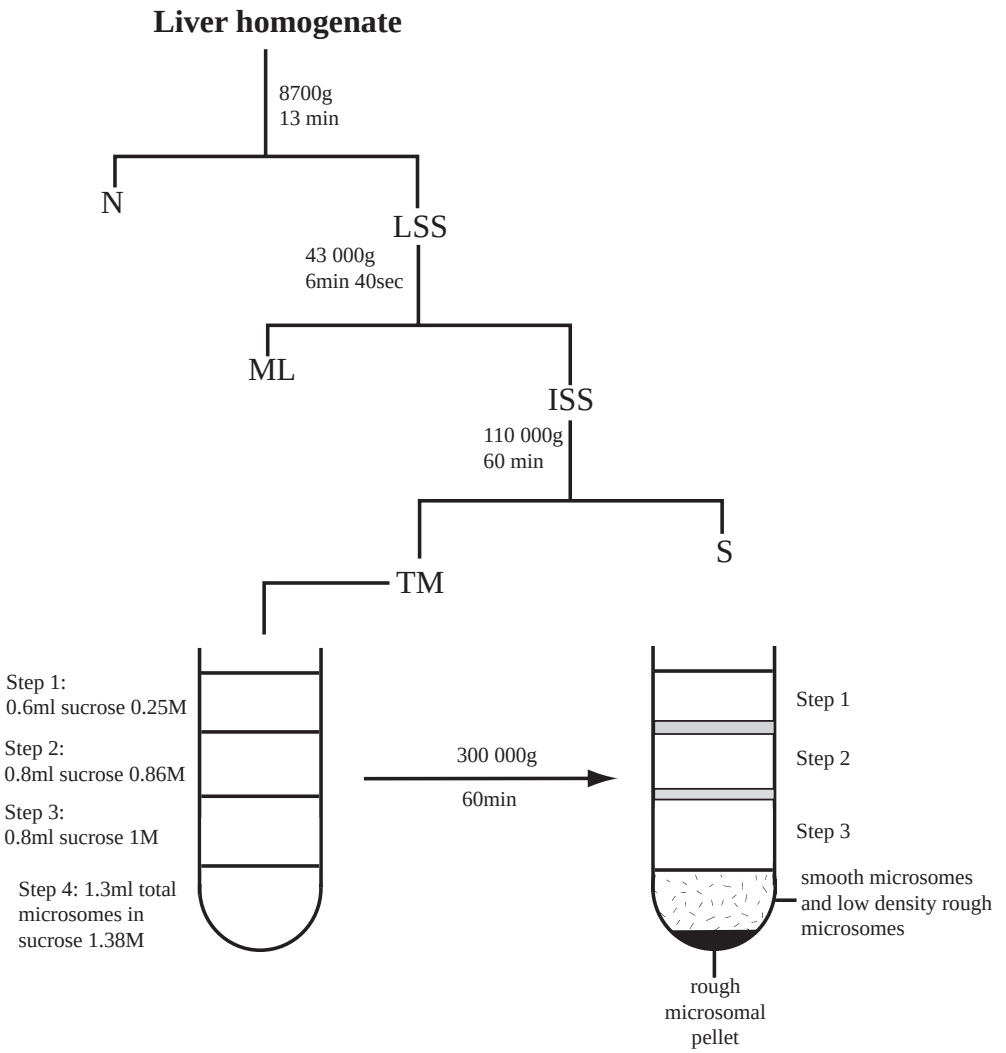

FIGURE 1

4. Blot the livers using lint-free tissues and transfer to a preweighed beaker containing ice-cold 0.25*M* sucrose and weigh (weight of two livers together should be a minimum of 18 g).

5. Blot the livers using lint-free tissues and chop them finely with scissors. Allow the pieces to fall into the mortar of the tissue grinder.[3]

6. Add a volume of ice-cold 0.25*M* sucrose, which is equivalent to 2.5 times the weight of the livers (e.g., 18.0 g × 2.5 = 45.0 ml).

7. Homogenize using the ribbed Teflon pestle for 20 strokes (down and up is one stroke) at 2850 rpm (mortar should be kept in plastic beaker filled with ice throughout homogenization process).

8. Filter the homogenate through the nylon mesh folded over four times in the glass funnel.[4]

9. The total homogenate at this point should be approximately 54 ml (45 ml sucrose plus about 9 ml liver tissue) and should be separated into 4 × 15 ml tubes.

10. Centrifuge in a Beckman-Coulter JA 25.50 fixed angle rotor that is precooled to 4°C at 8700 *g* for 13 min to sediment cellular debris and nuclei.

11. Transfer the supernatant [low-speed supernatant (LSS fraction), see Fig. 1] into three polycarbonate screw top tubes (10-ml capacity).

[3] Steps 5 to 8 are carried out in a cold room.

[4] The homogenate should not be squeezed through the nylon mesh, but instead stirred gently with a glass rod to facilitate the homogenate passing through the mesh.

12. Centrifuge in a Ti50 fixed angle rotor at 43,000 *g* for 6 min 40 s [press the stop button of the centrifuge at exactly 6 min 40 s. Complete stop (with brakes) should occur by about 10 min 20 s after the start of centrifugation].

13. With a Pasteur pipette, recover the supernatant [intermediate-speed supernatant (ISS fraction), see Fig. 1] and a portion of the flocculent layer that is covering the pellet (ML fraction, containing lysosomes and mitochondria).

14. Centrifuge the ISS fraction in a Ti50 rotor at 110,000 *g* for 60 min.

15. Discard supernatant (S fraction, see Fig. 1).

16. Resuspend the pellets in 1.38 *M* sucrose.[1] Recovery of total microsomes (TM) in the pellets is done as follows.

a. Add 0.5 ml of 2.0 *M* sucrose[1] to the first centrifuge tube and resuspend the microsomal pellet using a blunt-ended glass rod.
b. Transfer the suspension to subsequent tubes, resuspending the microsomal pellet with the glass rod in each one before transferring on to the next.
c. After resuspension is complete, rinse all centrifuge tubes with 2.0 *M* sucrose and transfer to a 7-ml Dounce.
d. Repeat rinsing as needed. However, do not exceed an accumulation of 5 ml in the Dounce.
e. Gently homogenize the resuspensions in the Dounce using the piston.

17. Measure volume using a graduated conical tube.

18. Rinse both the centrifugation tubes and the Dounce with 1 ml 2.0 *M* sucrose,[1] which is transferred to the conical tube and mixed in gently by covering the top of the tube with parafilm and inverting the tube two or three times. Repeat once.

19. Use a refractometer to adjust the density to 1.38 *M* by adding 0.25 or 2.0 *M* sucrose[1] to the TM resuspension as needed.

20. Bring the volume of the TM resuspension to 9.8 ml using the 1.38 *M* sucrose[1] stock.

21. Prepare six sucrose gradients using 4.0-ml tubes destined for the Beckman SW60 rotor as follows.

a. Carefully place 0.6 ml of 0.25 *M* sucrose[1] in the bottom of a Beckman SW60 tube with a glass syringe and blunt-ended needle.
b. Using a new syringe and needle, gently place the needle at the bottom of the tube and very gently inject 0.8 ml of 0.86 *M* sucrose[1] underneath previous layer.
c. Place a third syringe and needle carefully at the bottom of the tube and inject 0.8 ml of 1.0 *M* sucrose[1] very gently underneath the previous two layers.
d. Using a fourth new syringe and needle, very gently insert needle to the bottom of the tube again and very carefully inject 1.4 ml of TM fraction to produce the bottom layer of the gradient (see Fig. 1).
e. Repeat steps a–e for all six tubes.

22. Centrifuge gradients in a SW60 swinging-bucket rotor at 53,000 rpm (300,000 *g*) for 60 min.

23. For smooth microsomes (SM):

a. Carefully extract the top half of the bottom step (see step 4 in Fig. 1) using a Pasteur pipette and place in a Ti50 centrifuge tube.
b. Add 0.25 *M* sucrose–imidazole until tube is filled and mix gently.

24. For rough microsomes (RM):

a. Discard all gradient steps in all tubes.
b. Turn tubes upside down on a lint-free tissue for approximately 30 s to allow residual supernatant to drip out.
c. Wipe edges of tube (above pellet) using a lint-free tissue wrapped around a glass rod.
d. Resuspend pellets using a 15.0-ml Dounce and rinse tubes with sucrose–imidazole (using the same sequential rinsing method as described in Steps 16a to 16e). Transfer resuspended rough microsomes to a Ti50 tube.
e. Once sequential rinsing is done, add sucrose–imidazole to tube so that the final volume of sucrose–imidazole added is equivalent to approximately 11 ml.

25. Divide both SM and RM separately into two equal portions in Beckman Ti50 tubes and centrifuge at 140,000 *g* for 60 min.

26. Discard supernatants and resuspend as follow:

a. Resuspend the rough microsomal pellet in 2.0 ml sucrose–imidazole.
b. Resuspend the smooth microsomal pellet in 3.0 ml sucrose–imidazole.

27. Aliquot microsomal fractions into 60-, 110-, and 210-µl portions and store at –80°C in hermetically sealed tubes until needed.

IV. COMMENTS

The "rough" nature of the derivatives of the rough endoplasmic reticulum can be confirmed by examination of preparations by electron microscopy (Fig. 2). Samples were fixed in suspension and processed as

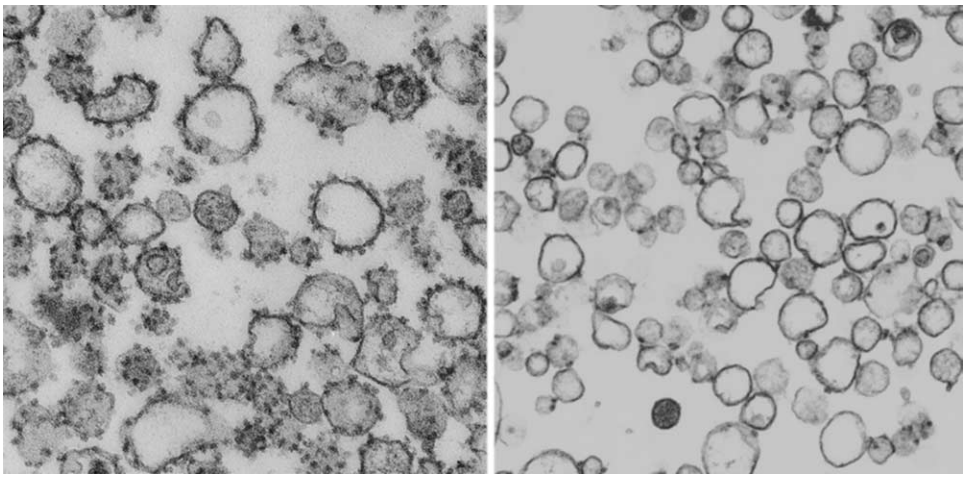

FIGURE 2

described previously (Paiement *et al*., 1980). Classical rough microsomes are shown in Fig. 2A and contain greater than 80% rough vesicles as determined by quantification of the number of vesicles with associated ribosomes. In Fig. 2B the microsomal fraction consists of approximately 60% smooth microsomal vesicles and 40% rough microsomal vesicles, which have few (one to four) ribosomes associated with their limiting membranes. Both microsomal fractions were shown previously to be enriched in enzyme markers for the endoplasmic reticulum and reduced in enzyme markers for Golgi and plasma membrane derivatives (Paiement *et al*., 1980; Paiement and Bergeron, 1983; Lavoie *et al*., 1996, 1999; Roy *et al*., 2000).

V. NOTES

This procedure takes approximately 12 h. All samples should be kept on ice at all times throughout this protocol. All centrifugations should take place at 4°C.

CHAPTER

6

Purification of COPI Vesicles

Fredrik Kartberg, Johan Hiding and Tommy Nilsson

I. INTRODUCTION

This article describes the *in vitro* assay that was developed for the faithful formation, isolation, and characterisation of COPI-derived vesicles from highly purified rat liver Golgi membranes (Lanoix *et al*., 1999, 2001). These vesicles normally form from Golgi cisternae carrying material from cisterna to cisterna, as well as from the *cis* face of the Golgi stack to the endoplasmic reticulum. Although the exact mechanism for vesicle formation and cargo incorporation is still debated, the fundamental coat components, as well as the basic principles of vesicle formation, have been clear for some time. ADP-ribosylation factor 1 (Arf1), a small GTPase of the Ras family, is first loaded with GTP via its guanine exchange factor (GEF) at the cisternal membrane. This allows Arf1 to recruit coatomer (COPI) to the donor membrane. The functional cycling of coatomer on the Golgi membrane is thought to drive cargo incorporation into the forming vesicle, as well as membrane deformation and the subsequent budding of a COPI-coated vesicle. The hydrolysis of GTP by Arf1, stimulated by a GTPase-activating protein (GAP), is then thought to trigger vesicle uncoating, producing a transport intermediate capable of fusing with target membranes (Barlowe, 2000). By adding a nonhydrolysable analog of GTP to *in vitro* budding reactions, vesicles form but retain their coat, making them easier to isolate and analyse. The first *in vitro* COPI vesicle budding assays indeed relied on GTPγS for this purpose.

The following protocols are a modifications of the COPI-vesicle budding assay first described by Warren and co-workers (Sonnichsen *et al*., 1996). The main difference is that here we allow for GTP hydrolysis. This offers the possibilty to study vesicle formation in conditions that are more physiological by circumventing the previous need for GTPγS. Important observations have been made using this strategy. First, analysis of the protein content shows a preferential incorporation of resident proteins into COPI vesicles (Lanoix *et al*., 1999). Second, the mechanism of formation seems to depend on GTP hydrolysis by Arf1 and cargo incorporation is linked to GAP (Lanoix *et al*., 1999, 2001). The coupling between GAP and cargo incorporation effectively gives rise to a kinetic proofreading mechanism ensuring that vesicles only form when sufficient and correct cargo has been selected (Weiss and Nilsson, 2003).

To summarise: Golgi stacks are purifed from rat liver and are incubated together with rat liver cytosol at 37°C. By adding the recombinant α-SNAP^{dn} mutant to the reaction the heterotypic fusion between formed vesicles and acceptor compartments is blocked (Barnard *et al*., 1997). In this way only one round of vesicle formation is reconstituted. After terminating the reaction, slowly sedimenting vesicles are separated from heavier donor membranes by medium speed centrifugation. The COPI-derived vesicles are then recovered using high speed centrifugation onto a two-step sucrose cushion. Following resuspension, vesicles may then be used for a variety of biochemical or morphological purposes, such as analysis of protein or lipid content, processed for electron microscopy or used in other functional assays.

II. MATERIALS AND INSTRUMENTATION

Guanosine 5′-triphosphate lithium salt (GTP) (Cat. No. G-5884), guanosine 5′-[γ-thio]triphosphate tetralithium salt (GTPγS) (Cat. No. G-8634), benzamidine–HCl (Cat. No. B-6506), leupeptine (Cat. No. L-2884), and soybean trypsin inhibitor (Cat. No. T-9128) are from Sigma. KOAc (Cat. No. 104820), $MgCl_2$ (Cat. No. 105833), KCl (Cat. No. 104936), NaOH (Cat. No. 106469), and KOH (Cat. No. 105021) are from Merck. HEPES (Cat. No. 05288) and dithiothreitol (DTT, Cat. No. 4010-1) are from Biomol. ATP (Cat. No. 127523), creatine phosphate (Cat. No. 621714), and creatine kinase (Cat. No. 127566) are from Roche. Ultrapure sucrose (Cat. No. 21938) is from USB. The protein assay dye reagent (Cat. No. 500-0006) is from Bio-Rad. Bovine serum albumin (BSA, Cat. No. 23209) is from Pierce. The ECL Western blotting detection reagent (Cat. No. RPN2109) is from Amersham Biosciences. Water is of double-distilled grade (ddH_2O).

Ultracentrifugation is carried out using an Optima MAX-E tabletop ultracentrifuge using a TLA-100.2 rotor (Cat. No. 362046) with polycarbonate centrifugation tubes 11 × 34 mm with a 1-ml capacity (Cat. No. 343778), a TLA-55 rotor (Cat. No. 366752) with polyallomer tubes 9.5 × 38 mm with a 1.5-ml capacity (Cat. No. 357448), or a Optima XL-100K ultracentrifuge using a SW-60 rotor (Cat. No. 335649) with ultraclear centrifuge tubes 11 × 60 mm (Cat. No. 344062) from Beckman. Medium-speed centrifugation is carried out in a Biofuge (Cat. No. 75005510) from Heraeus using microcentrifuge tubes with a 1.5-ml capacity (Cat. No. 96.75114.9.01) from Treff lab. Round-bottom test tubes with a 14-ml capacity (Cat. No. 352006), needles 18G × 3 1/2 (Cat. No. 405184), thin needles 0.4 × 19 (Cat. No. 302200), 5-ml syringes (Cat. No. 309603), and 1-ml syringes (Cat. No. 309602) are from BD Biosciences. Glass micropipettes (Cat. No. 708757) are from BRAND. The rubber adaptor between micropipettes and syringes is homemade. A standard laboratory vortex and heating block or water bath are used for incubations at 37°C. P-10, P-20, P-100, P-500, and P-1000 pipettes are from Gilson.

III. PROCEDURES

Purification of Golgi membranes and cytosol from rat liver is described in the article by Wang *et al*. The concentration of the Golgi membrane aliquots should be at least 1 mg/ml and the concentration of rat liver cytosol aliquots at least 30 mg/ml to accommodate the final volume of the reaction. Purification of a 10-mg/ml (approximately) stock of the His_6-tagged α-$SNAP^{dn}$ mutant is performed as described (Barnard *et al*., 1997).

Protein concentration determination is performed using the Bio-Rad version of the Bradford protein assay reagent and BSA as a standard. One-dimensional SDS–polyacrylamide gel electrophforesis (SDS-PAGE) is carried out according to Laemmli (1970). Western blotting is carried out according to Towbin *et al*. (1979). Antibodies are revealed using chemiluminescence.

A. Small-Scale Purification

Solutions

1. *KOAc assay buffer*: 25 m*M* HEPES, 115 m*M* KOAc, and 2.5 m*M* $MgCl_2$, pH 7.0. To make 0.5 litre, dissolve 3.0 g of HEPES, 5.6 g of KOAc, and 0.1 g of $MgCl_2$ in 450 ml water. Adjust pH to 7.0 with 1 *M* KOH and bring to a total volume of 0.5 litre with water. Aliquot and store at –20°C.

2. *10× ATP-regenerating system*: 26 m*M* of ATP, 100 m*M* of creatine phosphate, and 116 U/ml of creatine kinase. (*A*) Dissolve 0.1 g of ATP in 370 µl of KOAc assay buffer. Adjust pH to 7.0 with 1 *M* NaOH and bring to a total volume of 700 µl with KOAc assay buffer. (*B*) Dissolve 223 mg of creatine phosphate in a total volume of 2.3 ml KOAc assay buffer. (*C*) Dissolve 1 mg of creatine kinase in 333 µl of KOAc assay buffer and 333 µl of glycerol. (D) Combine the solutions and add 3.3 ml of KOAc assay buffer. Aliquot, snap freeze in liquid nitrogen, and store at –80°C.

3. *GTP stock solution:* 40 m*M* GTP. Dissolve 24 mg of GTP in 1 ml of water. Aliquot and store at –20°C.

4. *GTPγS stock solution*: 2 m*M* GTPγS. Dissolve 5 mg of GTPγS in a final volume of 4 ml water. Aliquot and store at –20°C.

5. *100× protease inhibitor cocktail*: 50 m*M* benzamidine–HCl, 500 µg/ml leupeptine, and 200 µg/ml soybean trypsin inhibitor. Dissolve 39.2 mg of benzamidine–HCl, 2.5 mg of leupeptine, and 1 mg of soybean trypsin inhibitor in water to a final volume of 5 ml. Aliquot and store at –20°C.

6. *DTT stock solution*: 100 m*M* DTT. Dissolve 1.5 mg of DTT in 1 ml of water. Aliquot and store at –20°C.

7. *3 M KCl*: Dissolve 22.5 g KCl in 100 ml water. Filter sterilise with a 0.22-µm filter and store at 4°C.

8. *30% sucrose KOAc assay buffer*: 25 m*M* HEPES, 115 m*M* KOAc, 2.5 m*M* $MgCl_2$, and 30% (w/w) sucrose, pH 7.0. To make 50 ml, dissolve 0.3 g HEPES, 0.56 g KOAc, 10 mg $MgCl_2$, and 16.9 g sucrose in 45 ml of water. Adjust pH to 7.0 with 1 *M* KOH and bring to

a final volume of 50 ml with water. Aliquot and store at –20°C.

9. *50% sucrose KOAc assay buffer*: 25 m*M* HEPES, 115 m*M* KOAc, 2.5 m*M* $MgCl_2$, and 50% (w/w) sucrose, pH 7.0. To make 50 ml, dissolve 0.3 g HEPES, 0.56 g KOAc, 10 mg $MgCl_2$, and 30.7 g sucrose in 45 ml of water. Adjust pH to 7.0 with 1 *M* KOH and bring to a final volume of 50 ml with water. Aliquot and store at –20°C.

Order of operation

1. Thaw 500 µl of rat liver cytosol and dilute by adding 1 ml of KOAc assay buffer. Centrifuge the diluted cytosol for 1 h at 157,000 g_{max} at 4°C (60,000 rpm in a TLA 100.2 rotor).

2. Transfer the supernatant to microcentrifuge tubes with 1.5-ml capacity and centrifuge for 15 min at 16,000 *g* at 4°C (13,000 rpm in Biofuge) to further clear the cytosol.

3. Determine the protein concentration of the diluted cytosol and the Golgi membrane fraction used in the assay.

4. Just before mixing the assay mixture, dilute the His_6-tagged α-$SNAP^{dn}$ mutant to 1 mg/ml in KOAc assay buffer prewarmed to 37°C. Keep at 37°C until use.

5. Mix the assay mixture by adding the following reagents to a microcentrifuge tube with 1.5-ml capacity according to Table I.

6. Add KOAc assay buffer so that the final assay volume is 250 µl.

7. Vortex the tube *very briefly* (not more than 1 s) to mix the assay mixture.

8. Incubate for 30 min at 37°C.

9. Terminate the reaction by placing the tube on ice.

10. To detach vesicles from membranes, raise the salt concentration to 250 m*M* by adding 23 µl of a 3 *M* stock solution of KCl to the reaction.

TABLE I Standard Assay Mixture for the Small-Scale Purification Protocol

Reagent	Amount	Final concentration
10× ATP-regenerating system	25 µl	1×
GTP stock solution[a]	3.1 µl	0.5 m*M*
DTT stock solution	2.5 µl	1 m*M*
100× protease inhibitor cocktail	2.5 µl	1×
α-$SNAP^{dn}$ mutant (1 mg/ml)	4.5 µl	0.5 µ*M*
Diluted rat liver cytosol	1250 µg	5 mg/ml
Golgi membranes	40 µg	40 µg

[a] For blocking GTP hydrolysis, replace with 2.5 µl of GTPγS stock solution (20 µ*M* final concentration).

11. To separate donor membranes from slowly sedimenting vesicles, centrifuge for 15 min at 16,000 *g* at 4°C (13,000 rpm in a Biofuge).

12. Transfer the medium-spin supernatant to a polyallomer centrifugation tube with 1.5-ml capacity without disturbing the membrane pellet.

13. Create a two-step sucrose cushion by adding 50 µl of 30% (w/w) sucrose KOAc assay buffer very carefully to the side of the tube, just below the surface of the supernatant followed by 5 µl of 50% (w/w) sucrose KOAc assay buffer.

14. To collect vesicles, centrifuge for 45 min at 126,000 g_{max} at 4°C (45,000 rpm in a TLA-55 rotor).

15. Vesicles are found in the 30/50% sucrose interface. Carefully aspirate all but 20 µl of the contents in the tube with a thin needle connected to a vacuum.

16. For analysis of protein content by SDS–PAGE and Western blotting, add 20 µl of 2× sample buffer to the tube, vortex to mix, and resuspend vesicles thoroughly by pipetting up and down with a P-20 Gilson pipette for 1 min. To ensure that all vesicles are resuspended properly, place the tube in a thermomixer and shake at maxiumum speed for 15 min at 4°C. For analysis of vesicle fractions by other methods, use KOAc assay buffer instead of sample buffer.

17. For analysis of protein content by SDS–PAGE and Western blotting, boil sample for 5 min at 95°C and load the entire sample (40 µl) onto a 1.5-mm SDS–PAGE gel. On the same gel run 1, 2, 4, and 8 µg of Golgi membranes (corresponding to 2.5, 5, 10, and 20% of starting membranes used in assay) to create a standard of Golgi proteins for analytical purposes. Analyse the protein content in the vesicle fractions using specific antibodies.

B. Large-Scale Purification

Solutions (in Addition to Those Described in Section III.A)

1. *20% sucrose KOAc assay buffer 0.5 M KCl:* 25 m*M* HEPES, 115 m*M* KOAc, 2.5 m*M* $MgCl_2$, and 20% (w/w) sucrose, pH 7.0. To make 50 ml, dissolve 0.3 g HEPES, 0.56 g KOAc, 10 mg $MgCl_2$, 1.9 g KCl, and 10.8 g sucrose in 45 ml of water. Adjust pH to 7.0 with 1 *M* KOH and bring to a final volume of 50 ml with water. Aliquot and store at –20°C.

2. *50% sucrose KOAc assay buffer 0.5 M KCl:* 25 m*M* HEPES, 115 m*M* KOAc, 2.5 m*M* $MgCl_2$, and 55% (w/w) sucrose, pH 7.0. To make 50 ml, dissolve 0.3 g HEPES, 0.56 g KOAc, 10 mg $MgCl_2$, 1.9 g KCl, and 30.7 g sucrose in 45 ml of water. Adjust pH to 7.0 with 1 *M* KOH and bring to a final volume of 50 ml with water. Aliquot and store at –20°C.

3. *65% sucrose KOAc assay buffer 0.5 M KCl:* 25 m*M* HEPES, 115 m*M* KOAc, 2.5 m*M* $MgCl_2$, and 65% (w/w) sucrose, pH 7.0. To make 50 ml, dissolve 0.3 g HEPES, 0.56 g KOAc, 10 mg $MgCl_2$, 1.9 g KCl, and 42.8 g sucrose in 45 ml of water. Adjust pH to 7.0 with 1 *M* KOH and bring to a final volume of 50 ml with water. Aliquot and store at –20°C.

Order of operation

1. Thaw 2.5 ml of rat liver cytosol and dilute it by adding 5 ml of KOAc assay buffer. Centrifuge the diluted cytosol for 1 h at 157,000 g_{max} at 4°C (60,000 rpm in a TLA 100.2 rotor).
2. Transfer the supernatant to microcentrifuge tubes with 1.5-ml capacity and centrifuge for 15 min at 16,000 *g* at 4°C (13,000 rpm in Biofuge) to further clear the cytosol.
3. Pool supernatants and determine the protein concentration of the diluted cytosol and the Golgi membrane fractions used in the assay.
4. Just before mixing the assay mixture, dilute the His_6-tagged α-$SNAP^{dn}$ mutant to 1 mg/ml in KOAc assay buffer prewarmed to 37°C. Keep at 37°C until use.
5. Mix *five* standard assay mixtures by adding the following reagents to five round-bottom test tubes with 14-ml capacity according to Table II.
6. Add KOAc assay buffer up to 2.5 ml final reaction volume in each tube.
7. Vortex the tubes very briefly (not more than 1 s) to mix the assay mixture.
8. Incubate for 30 min at 37°C.
9. Terminate the reaction by placing tubes on ice.
10. To detach vesicles from membranes, raise the salt concentration to 250 m*M* by adding 230 µl of a 3 *M* stock solution of KCl to each of the five tubes.
11. To separate donor membranes from slowly sedimenting vesicles, divide the content of each tube into 0.3-ml fractions into several (around 40 in total) microcentrifuge tubes with 1.5-ml capacity and centrifuge for 15 min at 16,000 *g* at 4°C (13,000 rpm in Biofuge).
12. Pool the medium spin supernatants (around 12 ml in total volume) in a round-bottom test tube without disturbing the membrane pellets.
13. Prepare four two-step sucrose cushions by adding 800 µl of 20% (w/w) sucrose KOAc assay buffer 0.5 *M* KCl to an ultraclear SW-60 centrifuge tube and then underlay this with 150 µl of 50% (w/w) sucrose KOAc assay buffer 0.5 *M* KCl using a micropipette connected to a 1-ml syringe. Onto each gradient overlay 3 ml of the pooled supernatant using a 5-ml syringe connected to a needle.
14. To collect vesicles, centrifuge for 3 h at 407,000 g_{max} at 4°C (55,000 rpm in a SW-60 rotor).
15. Vesicles are found in the 20/50% sucrose interface. Carefully aspirate all but 500 µl of the contents in the tube with a thin needle connected to a vacuum.
16. Collect the vesicles by removing 300 µl from the bottom of each tube using a micropipette connected to a 1-ml syringe.
17. Pool these vesicle fractions into a new round-bottom test tube and adjust the sucrose concentration to approximately 55% sucrose (w/w) KOAc assay buffer 0.5 *M* KCl by adding 1550 µl 65% sucrose (w/w) KOAc assay buffer 0.5 *M* KCl.
18. To further purify vesicles by floatation, prepare a step sucrose gradient in an ultraclear SW-60 centrifuge tube. Start with the 20% sucrose (w/w) KOAc assay buffer 0.5 *M* KCl. This is underlaid with 50% sucrose (w/w) KOAc assay buffer, which is underlaid with the sample containing the vesicles in 55% sucrose using a micropipette connected to a syringe in the following order:
    i. 500 µl 20% sucrose (w/w) KOAc assay buffer 0.5 *M* KCl
    ii. 750 µl 50% sucrose (w/w) KOAc assay buffer 0.5 *M* KCl
    iii. 2750 µl 55% sucrose (w/w) KOAc assay buffer 0.5 *M* KCl sample from previous step.
19. To float vesicles, centrifuge for 16 h at 337,000 g_{max} at 4°C (50,000 rpm in a SW-60 rotor).
20. Collect vesicles by removing 100-µl fractions from the top of the gradient. The layer of vesicles at the interface is between 20/50% sucrose.

TABLE II Standard Assay Mixture for the Large-Scale Purification Protocol

Reagent	Amount	Final concentration
10× ATP-regenerating system	250 µl	1×
GTP stock solution[a]	31 µl	0.5 m*M*
DTT stock solution	25 µl	1 m*M*
100× protease inhibitor cocktail	25 µl	1×
α-$SNAP^{dn}$ mutant (1 mg/ml)	45 µl	0.5 µ*M*
Diluted rat liver cytosol	12.5 mg	5 mg/ml
Golgi membranes	400 µg	400 µg

[a] For blocking GTP hydrolysis, replace with 25 µl of GTPγS stock solution (20 µ*M* final concentration).

IV. Comments

The small-scale protocol is useful for comparing a variety of reaction conditions in one experiment. The recovery of various proteins in the vesicle fractions is

compared to the amount of protein in the protein standard on the gel. For any condition that is tested it is strongly recommended to always run controls containing GTP and GTPγS and one at 4°C. Comparing these three control conditions with the one tested usually gives a good indication of the effect that the particular condition has. The large-scale protocol gives a higher amount of vesicles and is more suitable when more material is needed, for example protein analysis through proteomics.

V. PITFALLS

1. Unless specified, all steps should be carried out on ice to minimise protein degradation. Aliquots for one-time use should be thawed and kept on ice until use.
2. Pipetting of Golgi membranes should be minimised to avoid shearing. Mix these aliquots by tapping carefully on the side of the tube.
3. Once the protein concentration of a certain batch of purifed Golgi membranes and cytosol has been established, it is not necessary to perform the protein concentration determination in step 3 of the protocols.
4. The sucrose content of the various buffers should be verified with a refractometer.
5. Aspiration steps may represent a source of variation. Take special care during these steps.

Acknowledgments

The authors thank Dr. Joel Lanoix for developing this assay and Nilsson group members for providing critical comments of the manuscript.

Purification of Clathrin-Coated Vesicles from Bovine Brain, Liver, and Adrenal Gland

Robert Lindner

I. INTRODUCTION

Clathrin-coated vesicles are intermediates in several selective membrane transport processes in eukaryotic cells (for review, see Bonifacino and Lippincott-Schwartz, 2003; Brodsky *et al*., 2001; Schmid, 1997). They are derived from clathrin-coated membrane regions on the plasma membrane, the TGN, endosomes (Stoorvogel *et al*., 1996), and possibly also lysosomes (Traub *et al*., 1996) by a process of invagination and fission. In addition to the main structural protein clathrin, a three-legged molecule composed of one heavy and one light chain per leg, a number of other proteins have been isolated from clathrin-coated vesicles: most prominent are the adaptor protein (AP) complexes, heterotetramers consisting of two heavy chains, an intermediate chain, and a light chain (for review, see Kirchhausen, 1999). AP-1 and AP-2 complexes link clathrin to specific membrane areas by binding to clathrin N-terminal domains and to cytosolic tails of transmembrane receptors. The recently discovered AP-3 and AP-4 complexes appear to function independently of clathrin and are not enriched in clathrin-coated vesicles. Furthermore, clathrin-coated vesicles contain monomeric adaptor proteins, such as AP 180 and members of the epsin family. These interact with coat components via their poorly structured C-terminal regions (Kalthoff *et al*., 2002) and with phosphoinositides of the membrane via their N-terminal ENTH domain (for review, see De Camilli *et al*., 2002). Also present are accessory proteins such as auxilins that provide a J-like domain for the recruitment of Hsc70 to clathrin, thereby serving to initiate the removal of the clathrin coat (Ungewickell *et al*., 1995). A novel bilayered clathrin coat without curvature has been described on multivesicular endosomes (Raiborg *et al*., 2002; Sachse *et al*., 2002). It contains the monomeric clathrin adaptor protein HRS and appears to be involved in the sorting of ubiquitinated membrane proteins to internal vesicles. This flat structure probably does not to give rise to coated vesicles.

Since the first report on the purification of clathrin-coated vesicles (Kanaseki and Kadota, 1969), a variety of protocols have been published. Most recent protocols are based on a purification procedure introduced by Campbell *et al*. (1984). This procedure rapidly provides crude clathrin-coated vesicles that are well suited for the preparation of various coat proteins (Ahle *et al*., 1988; Ahle and Ungewickell, 1990; Lindner and Ungewickell, 1991). This basic protocol has been further improved by the introduction of a centrifugation step involving a sucrose/D_2O cushion (Maycox *et al*., 1992). By this step, contaminations of smooth membrane vesicles are reduced further. A similar procedure has been used to purify rat brain clathrin-coated vesicles for proteomic characterization (Wasiak *et al*., 2002).

This article describes a purification protocol for bovine brain-coated vesicles that includes a sucrose/D_2O step gradient at the end. With appropriate volume adjustments, the protocol can also be used for the purification of coated vesicles from other species such as pigs or rats. For the preparation of clathrin-coated vesicles from other organs (adrenal gland, liver), some modifications in the protocol are suggested.

II. MATERIALS AND INSTRUMENTATION

Ficoll 400 (Cat. No. 17-0400-02) is from Pharmacia; sucrose (Cat. No. BP 220-1) is from Fisher Scientific; D_2O (Cat. No. 15,188-2) is from Aldrich; EGTA (Cat. No. E-3889), MES (Cat. No. M-3023), and phenylmethylsulfonyl fluoride (PMSF, Cat. No. P-7626) are from Sigma. All other reagents are from Sigma or Fisher in analytical grade.

Biological material is obtained from an local abattoir within 1 h of slaughter and is kept on ice until further processing (1–2 h). Fresh and cleaned material can be frozen in liquid nitrogen and stored at –80°C for several months. It is helpful to cut the tissue into small pieces before freezing. This supports a rapid drop of temperature in the tissue and minimizes ice crystal formation. The latter process reduces yield and purity of the following preparation, probably due to the destruction of membrane vesicles and liberation of proteolytic activities.

For homogenization of the tissue, a Waring commercial blender (VWR International, Cat. No. 58977-169) is used. Membrane pellets are resuspended with Potter–Elvehjem homogenizers of various sizes (10–55 ml) obtained from Fisher Scientific (Cat. No. 08414-14 A to D). The metal shaft of the larger homogenizers is attached to a variable-speed overhead drive so that the pestle can be rotated.

Low-speed centrifugations are done in a Sorvall RC-5B centrifuge using GS-3, GSA, or SS-34 heads. High-speed centrifugations are performed with Beckman Ti 45, Ti 35, and SW 28 rotors in conventional ultracentrifuges. For fixed angle ultracentrifugation rotors, Beckman polycarbonate bottles with screw caps (Cat. No. 355622) are used and for the SW 28 rotor open-top ultraclear tubes (Cat. No. 344058) are used.

III. PROCEDURES

A. Cleaning of Bovine Brain Cortices

Solutions

Phosphate-buffered saline (*PBS*): 137 m*M* NaCl, 2.7 m*M* KCl, 8.2 m*M* Na_2HPO_4, 1.9 m*M* KH_2PO_4, 0.02% NaN_3, pH 7.0. To make 1 liter of 10× PBS (stock solution), dissolve 80 g NaCl, 2 g KCl, 2.58 g KH_2PO_4, 11.64 g Na_2HPO_4, and 0.2 g NaN_3 in double-distilled water. Adjust the pH to 7.0 (if necessary) and bring the volume to 1 liter. Dilute this stock solution 1:10 with double-distilled water and chill to 4°C prior to use. Approximately 2–3 liters of 1× PBS are needed per kilogram tissue.

Steps

1. Separate the cerebellum and the lower part of the brain from the cortex.
2. Take a hemisphere of the cortex, place it in an ice bucket covered with plastic wrap, and remove the meninges along with blood vessels contained therein using forceps.
3. Collect the cleaned cortex hemispheres in a preweighed beaker on ice. Determine the weight of the tissue and estimate the volume of homogenization buffer needed in Section III,B (approximately 1 liter per kg of tissue).
4. Wash the cortex hemispheres with cold PBS several times to remove the remaining blood. To do this, fill the beaker containing the hemispheres with PBS, mix gently, and pour the liquid off. It is helpful to use a household sieve at this step. Repeat the washes until the blood is removed.
5. If you want to store the brain tissue for later processing, cut it into small pieces after the washing step and freeze it in liquid nitrogen. Store frozen material at –80°C. Otherwise continue with Section III,B.

B. Homogenization

Solutions

1. *Buffer A*: 0.1 *M* MES, 1.0 m*M* EGTA, 0.5 m*M* $MgCl_2$, 0.02% NaN_3, pH 6.5. To make 1 liter of 10× buffer A (stock solution), dissolve 195.2 g MES, 3.8 g EGTA, and 1.0 g $MgCl_2$ in double distilled water. Adjust the pH with 10 *N* NaOH to 6.5, add 2 g NaN_3, and bring the volume to 1 liter. Do not add NaN_3 prior to the adjustment of the pH because MES is acidic and may release HN_3. To prepare 1× buffer A for homogenization, dilute the stock solution 1:10 with double-distilled water, chill to 4°C, and supplement with 0.1 m*M* PMSF prior to use. Prepare about 3 liters buffer A per kilogram tissue.
2. *Protease inhibitor* (*PMSF stock solution, 1000× = 0.1 M*). To make 10 ml, dissolve 174 mg PMSF in 10 ml pure methanol, aliquot, and store at –20°C. Dilute 1:1000 to get a working concentration of 0.1 m*M*. Note that PMSF will hydrolyze in water and that it is not soluble in this solvent at high concentrations.

Steps

1. Fill the cup of a Waring commercial blender with 300–400 g of washed tissue and an equivalent amount of cold buffer A containing 0.1 m*M* freshly added

PMSF. Do not fill the cup up to the top, but leave space below the rim.

2. Homogenize the tissue by three to six bursts of 10–15 s duration with the setting on maximum speed. The number of bursts required to give a good homogenization varies: for brain, usually three bursts are sufficient, whereas other organs, especially adrenal glands, require more (see Section IV). Do not increase the length of the bursts but their number to prevent heating of the homogenate.

C. Differential Centrifugations

1. Preparation of Postmitochondrial Supernatants

Steps

1. Pour the homogenate into buckets of a Sorvall GS-3 or GSA rotor, balance the buckets, and centrifuge them in the precooled rotor at 7000 rpm (about 8000 *g* in both types of rotors) for 50 min at 4°C.

2. Pour the turbid supernatants through a funnel with several layers of gauze to separate floating lipids from the supernatant.

3. The bulky pellets (up to a third of the total volume) should be resuspended with an at least equivalent volume of cold homogenization buffer and recentrifuged under the aforementioned conditions.

4. Discard the pellets after the second centrifugation and keep the combined supernatants on ice.

2. Preparation of Microsomal Pellets

Steps

1. Fill the postmitochondrial supernatant into the tubes for a Beckman Ti 35 or Ti 45 rotor, balance the tubes, and ultracentrifuge them at 32,000 rpm at 4°C for 1.6 h (Ti 35) or at 40,000 rpm for 1 h (Ti 45) in precooled rotors.

2. After centrifugation, discard the clear supernatant and either refill the tubes with postmitochondrial supernatant for the next spin (leave the first pellet in the tube without resuspending it to save time) or remove the microsomal pellets when all the postmitochondrial supernatant has been centrifuged or pellets from three to four ultracentrifugations have been collected in one tube.

3. Resuspend the pellets with 1–2 volumes of buffer A supplemented with 0.1 m*M* PMSF using a 10-ml glass pipette in the reverse orientation (the wide top end down) and then homogenize thoroughly by 10–15 strokes in a Potter–Elvehjem device (overhead drive at slow rotation).

3. Preparation of Crude Clathrim-Coated Vesicles from Microsomal Pellets

Solution

12.5% Ficoll–sucrose: To make 1 liter, dissolve 125 g sucrose and 125 g Ficoll 400 in buffer A, pH 6.5, and stir overnight in the cold room. Ficoll 400 dissolves only slowly! Keep at 4°C.

Steps

1. Mix the well-homogenized microsomes with the same volume of Ficoll–sucrose solution and fill into open tubes suitable for an SS-34 Sorvall rotor. Centrifuge the tubes at 43,000 *g* (19,000 rpm) and 4°C for 40 min in a precooled rotor.

2. After centrifugation, pour the supernatants containing the clathrin-coated vesicles through a funnel with gauze to remove floating lipids. The compact sediment (about a fifth of the total volume) will stay in the tube and can be discarded.

3. Dilute the combined supernatants with 3–4 volumes of cold buffer A containing 0.1 m*M* PMSF.

4. Concentration of Crude Clathrim-Coated Vesicles by Pelleting

Steps

1. Ultracentrifuge the coated vesicles in the diluted Ficoll–sucrose solution as described in Section III,C,2. The pellets obtained in this step are considerably smaller than the microsomal pellets. The color usually varies from yellowish-white to brown and is most likely due to contaminating ferritin (Kedersha and Rome, 1986).

2. Pour off the supernatants and carefully remove the pellets from the tubes with a spatula. Use a small volume of buffer A + PMSF to wash off material still attached to the walls of the tube.

3. Homogenize the combined pellets in about 20 volumes of buffer A + PMSF per bovine brain using first a 10-ml glass pipette in the reverse orientation (the wide top end down) and then homogenize very thoroughly by 10–15 strokes in a Potter–Elvehjem device (overhead drive at slow rotation).

5. Removal of Aggregated Material

Steps

1. Fill the crude clathrin-coated vesicles into open tubes for an SS-34 Sorvall rotor. Centrifuge the tubes at 20,000 *g* (13,000 rpm) at 4°C for 10 min in a precooled rotor.
2. After centrifugation, retrieve, pool and place the supernatants on ice. Discard the pellets.

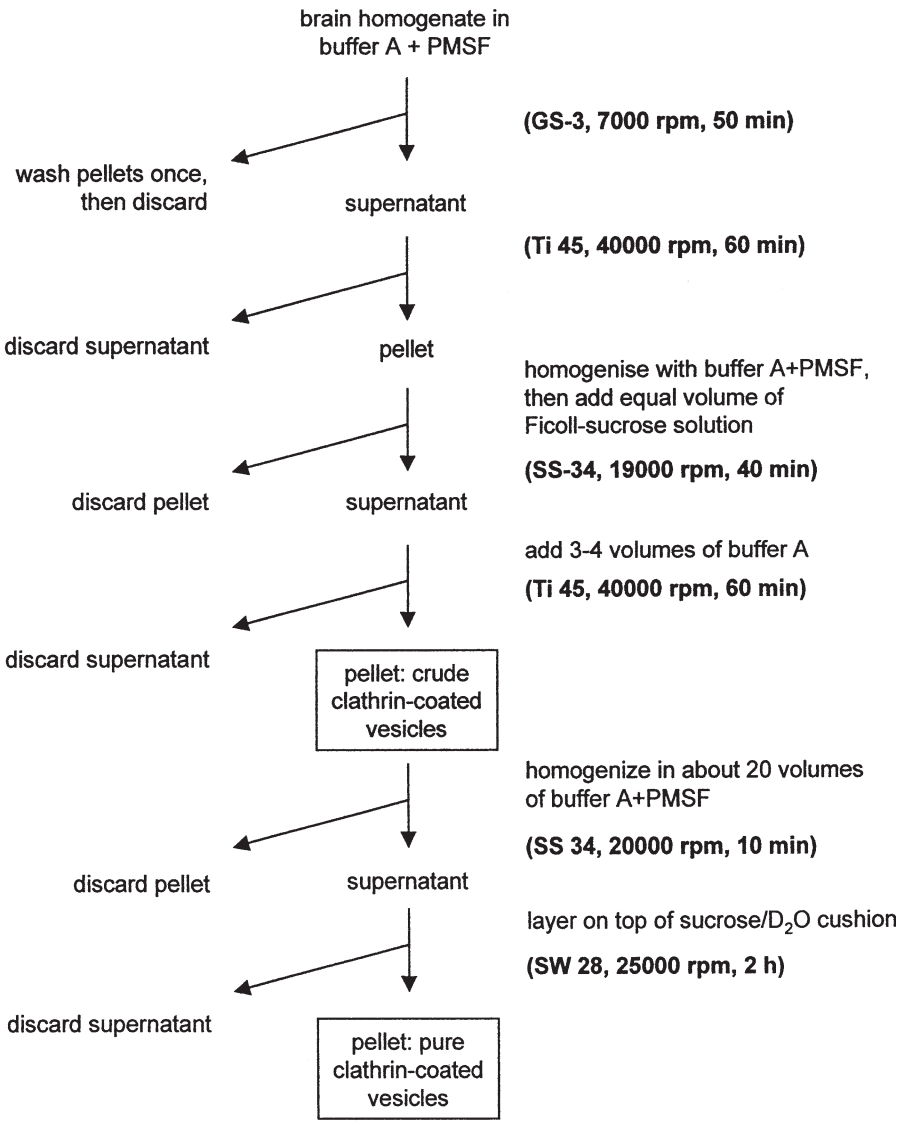

FIGURE 1 Purification scheme for clathrin-coated vesicles.

6. Removal of Smooth Membrane Contaminants

Solutions

1. *Buffer A/D_2O*: 0.1 *M* MES, 1.0 m*M* EGTA, 0.5 m*M* $MgCl_2$, 0.02% NaN_3, pH 6.5. To make 1 liter of 1× buffer A in D_2O, dissolve 19.5 g MES, 0.38 g EGTA, and 0.10 g $MgCl_2$ in D_2O. Adjust the pH with 5–10 *N* NaOH solution (prepared in D_2O as well) to 6.5, add 2 g NaN_3, and bring the volume to 1 liter using D_2O. Do not add NaN_3 prior to the adjustment of the pH because MES is acidic and may release HN_3. Chill to 4°C and supplement with 0.1 m*M* PMSF prior to use.
2. *Sucrose/D_2O solution*: 8% (w/v) sucrose in buffer A/D_2O. To make 200 ml, dissolve 16 g sucrose in buffer A/D_2O and adjust the volume with the same buffer. Keep on ice.

Steps

1. Precool an SW 28 rotor and the buckets.
2. Pour 30 ml of the sucrose/D_2O solution per SW 28 centrifugation tube (open top, ultraclear, Beckman #344058). Place the tubes on ice. Carefully overlay 5 ml of the coated vesicles from Section III,C,5 per tube.
3. Balance the tubes and assemble the buckets and the rotor. Spin the rotor in an ultracentrifuge at 110,000 *g* (25,000 rpm) at 4°C for 2 h.
4. Remove the supernatants and resuspend the pellets in 5–10 volumes of buffer A plus PMSF using a pipette and a suitable homogenizer.
5. Material obtained after this step can either be used directly or be frozen in liquid nitrogen and stored at –80°C.

IV. COMMENTS

Following this protocol (for summary, see Fig. 1), near homogeneous preparations of clathrin-coated vesicles are obtained from bovine brain. The yields usually are about 50–100 mg clathrin-coated vesicles/kg brain cortex.

For the preparation of various coat proteins, such as clathrin or the adaptor complexes, crude clathrin-coated vesicles obtained in Section III,C,4 are a good starting material of sufficient purity (80–90% pure, 100–120 mg/kg bovine brain). For a typical electrophoresis pattern of a Tris extract of crude bovine brain clathrin-coated vesicles as described in Section III,C,4, see Fig. 2.

This basic protocol can also be used with other organs rich in clathrin-coated membranes, such as adrenal glands, liver, or placenta. For adrenal glands, a more thorough homogenization (usually 6 or more 10-s bursts in a Waring commercial blender) is required to break up the very resistant capsule material.

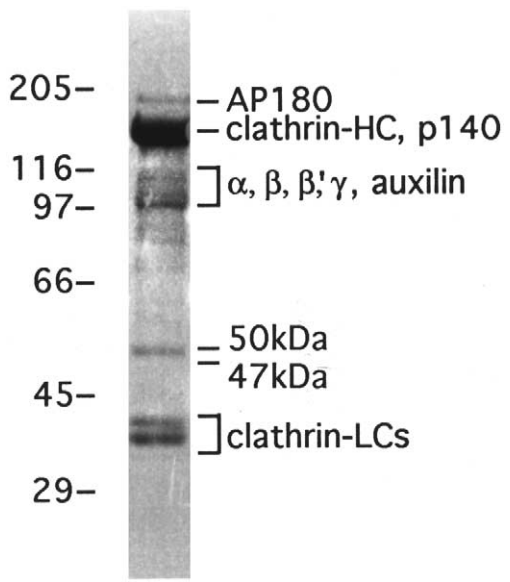

FIGURE 2 Coat proteins obtained by Tris extraction of a crude clathrin-coated vesicle preparation from bovine brain as described in the text. Coated vesicles were incubated in 0.5*M* Tris, pH 7.0, to release the peripheral membrane proteins and were then ultracentrifuged to remove the membranes. Approximately 12 µg Tris extract was electrophoresed in a low-Bis SDS–polyacrylamide gel (for details, see Lindner and Ungewickell, 1992). Note that in this gel system the brain-specific, clathrin-associated protein AP180 is well resolved from the clathrin heavy chain. Both AP180 and auxilin are only detectable in brain-derived, clathrin-coated vesicles. In nonneuronal tissues, homologues are expressed (CALM for AP180 and GAK/auxilin2 for auxilin).

Clathrin-coated vesicle preparations from liver usually contain a considerable amount of ribonucleoprotein complexes termed vaults. It is advisable to remove these structures by velocity centrifugation on 5–40% sucrose gradients as an additional step after the preparation described earlier (for details, see Kedersha and Rome, 1986). Vaults are at least partially dissociated by the conventional extraction methods for clathrin coat structures and thus contaminate coat protein extracts.

For the preparation of fusion-competent, clathrin-coated vesicle from cell culture cells, a more elaborate protocol has been described (Woodman and Warren, 1991)

V. PITFALLS

Do not mix the Ficoll–sucrose solution to microsomal pellets obtained in Section III,C,3 before thorough homogenization of the pellets. The high viscosity of the Ficoll–sucrose solution prevents proper homogenization.

In order to quantitatively pellet the clathrin-coated vesicles from the supernatant after centrifugation in Ficoll–sucrose, dilute with a *minimum* of 3 volumes of buffer A + PMSF to decrease both the density and the viscosity of the supernatant.

Isolation of Latex Bead- and Mycobacteria-Containing Phagosomes

Mark Kühnel, Elsa Anes, and Gareth Griffiths

I. INTRODUCTION

Phagocytosis is a crucial mechanism by which specialized cells, especially macrophages, neutophils, and dendritic cells, remove ingested debris, dead cells, and pathogens from the body. Many pathogens are killed within the phagosome (phagolysosome) as a consequence of fusion between this organelle and lysosomes, which delivers hydrolases and the proton ATPase into the phagosome. An important technical advance has been the use of nondegradable latex beads as phagosome marker: these have facilitated studies both in cells and *in vitro* after phagosome isolation. This article describes how latex bead phagosomes are isolated for *in vitro* studies. It also summarizes recent approaches developed for the more difficult problem of isolating phagosomes containing live and killed mycobacteria.

II. BACKGROUND

In 1967 in Edward Korn's group a simple but crucial innovation for both phagosome analysis and the study of membrane organelles in general was introducted (Weisman and Korn, 1967a,b). They fed *Acanthamoeba* with latex beads and, following gentle homogenisation, could isolate a remarkably pure fraction of latex bead phagosomes (LBP) by a single centrifugation step using a discontinuous sucrose gradient. For efficient uptake of beads into (mostly) single bead phagosomes, the beads had to be between 0.13 and 0.26 µm (smaller and larger beads were taken in more ineffectively) (summarized by Desjardins and Griffiths, 2003). Although this system was used intermittently in subsequent years, the method was not used extensively until reintroduced by Desjardins *et al*. (1994a,b). Since that time we have mostly focused on the use of 1-µm latex beads conjugated with avidin or fish skin gelatin that are taken up by J774 macrophages. LBP functions can be monitored easily within macrophages, and *in vitro* assays are available to monitor the following phagosome functions: fusion with endocytic organelles (Jahraus *et al*., 1998, 2001), microtubule binding and motility (Blocker *et al*., 1996, 1997, 1998), binding to F-actin (Al Haddad *et al*., 2001), and *de novo* actin assembly (Dejardins *et al*., 1994; Defacque *et al*., 2000; Anes *et al*., 2003).

A recent proteomic analysis by Desjardins and collages has revealed that LBP from J774 cells have about 1000 proteins, of which ≈600 have already been identified (Garin *et al*., 2001; Desjardins and Griffiths, 2003). They also contain at least 100 different lipids (Kuehnel *et al*., 2004; Anes *et al*., 2003).

Since 1994 a large number of papers have appeared in which LBP have been analyzed in different cells or have been used after isolation. By October 2003, Medline listed 73 papers that involved LBP; the actual number is certain to be significantly larger, as LBP are often used as controls for pathogen-containing phagosomes and are often not mentioned in the titles or abstracts to these papers.

An enormous advantage of the use of latex beads is the ease by which thy can be conjugated to selected proteins, such as IgG, or complement. In an agreement with the "zipper hypothesis" originally put forward by Silverstein and colleges in the 1970s (see Greenberg and Silverstein, 1993), such beads form a phagosome in which the receptor for the bound ligand is concentrated. A large body of evidence argues that

Copyright 2006, Elsevier Science (USA).

phagosomes enriched in different receptors can show significant differences in their intracellular behaviour. Such differences are likely to become more clear in future studies.

This article summarizes the methods used to prepare different beads and to isolate the ensuing phagosomes. No other membrane organelle in the cell can be prepared with such ease and to such high purity after a single purification step. We subsequently discuss our recent efforts in isolating phagosomes enclosing mycobacteria, an approach first initiated by Chakraborty et al (1994).

III. PROCEDURES

A. Preparations of Latex Beads for Internalisation

Latex beads, either "naked" or coated with substances of interest, can be used for the generation of phagosomes. Our standard system uses avidin-coated latex beads. For coating beads with avidin, incubate 100 µl of latex beads (10%, w/v) with 100 µl 0.5 *M* MES buffer, pH 6.8, 722 µl of distilled water, and 50 µl of avidin (10 mg/ml in water) for 15 min on a rotating wheel. Add 14 µl of 10 mg/ml *N*-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide hydrochloride (EDAC) and allow incubation for another 1.5 h. Subsequently, add another 14 µl EDAC to the reaction and incubate for a further 1.5 h. Stop the reaction by adding 1% Triton X-100 in 10 m*M* Tris pH 9.4. Pellet the beads by centrifugation in a desktop centrifuge at full speed (13,000×*g*) and then resuspend in Triton/tris buffer. Subsequently, wash the beads three times in phosphate-buffered saline (PBS) (each time followed by a centrifugation step) and store at 4°C in PBS containing a nonspecific protein; we use 0.03% fish skin gelatin (Sigma G7765) and 0.02% sodium azide. If determination of protein content on the beads is necessary, an aliquot of beads can be taken for protein measurement before adding the storage solution.

B. Internalisation of Latex Beads

For isolation of LBP, grow 20 × 20-cm petri dishes of macrophages (in our case J-774A.1 macrophages are used) in 50 ml of culture medium supplemented with 10% fetal calf serum (FCS) and 2 m*M* glutamine until the needed density of cells is reached. Use J774 macrophages at 50×10^6 cells per dish. For internalisation, dilute 1 ml of beads with 25 ml of Dulbecco's Modified Eagle's Medium (DMEM) per dish. Uptake is routinely allowed for 1 h on a shaker at 5% CO_2 at 37°C. Remove non internalised beads by intensive washing of the cells with PBS at 37°C. Thereafter, incubate cells with internalized beads until the desired phagosome age is reached in the presence of DMEM at 37°C and 5% CO_2.

C. Cell Lysis and Latex Bead Phagosome Isolation

Harvest cells by adding 20 ml PBS to the dish and scraping them with a suitable cell scraper. We use cell scrapers from Sarstedt (Nümbrecht, Germany). Collect cells in 50-ml tubes and centrifuge at 1000×g for 10 min, resuspend in 5 ml of homogenization buffer (HB: 0.25 *M* sucrose, 3 m*M* imidazole, pH 7.4) with protease inhibitors (Table I) and pellet again, as before. Resuspend pellets in a final volume of 1.5 ml of HB buffer and lyse using 15–20 stokes with a 1-ml syringe fitted to a 22-gauge needle. Monitor cell breakage by light microscopy. Remove nuclei and intact cells by gentle centrifugation at 800×*g* at 4°C, collect supernatants and mix gently with 62% sucrose. Prepare the gradient in ultraclear centrifugation tubes from Beckmann (Reorder NO. 344060) as follows. Overlay 3–4 ml of phagosome/62% sucrose mix with 5 ml of 25% sucrose containing protease inhibitors and overlay with 2 ml of HB buffer. Carry out centrifugation at 100,000 *g* for 60 min at 4°C. The visible band that forms between the HB buffer and 25% sucrose contains the LBP and can be collected in approximately 200 µl with a syringe by penetrating the tube wall with a 22-gauge needle (see Fig. 1). Aliquot phagosomes in 20 µl portions and store in liquid nitrogen until further use. For some purposes they can also be stored at –80°C; however, we have found that many activities are kept longer following liquid nitrogen storage.

D. Monitoring Phagosomal Integrity

If it is necessary to check the proportion of intact phagosomes, phagosomes containing avidin-coated

TABLE I Proteinase Inhibitors Used during Phagosome Isolation

Inhibitor (solvent used)	Final concentration
Pepstatin (methanol)	1 µg/ml
TLCK (methanol)	1 µg/ml
Aprotinin (water)	4 µg/ml
Leupeptin (water)	1 µg/ml
Dithiothreitol (water)	1 m*M*

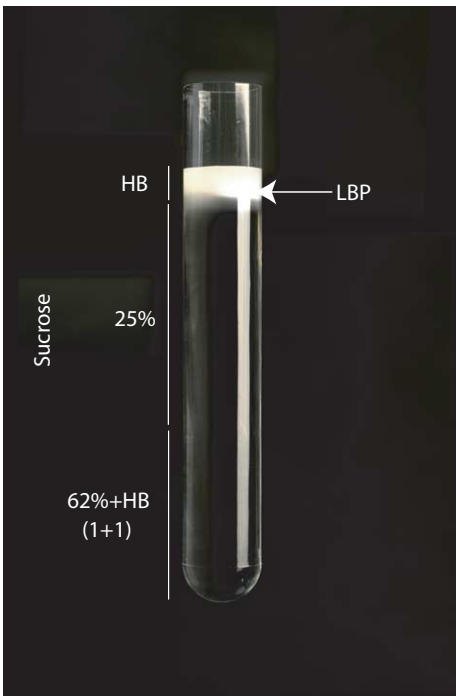

FIGURE 1

latex beads can be incubated conveniently with a suitable dye such as rhodamine–biotin 5 n*M* for 15 min at room temperature. The rationale here is that only broken phagosomes will be accessible to the label. Then the ratio of phagosomes labeled red (not intact) and nonlabelled phagosomes (intact) is determined by light microscopy. Routinely 70–80% of LBP are found to be intact in our experience.

E. Preparation of Mycobacterial Phagosomes

1. Preparation of Mycobacteria for Uptake

There are a wide range of growth characteristics among the genus *Mycobacterium*, from 3 h of generation time in *M. smegmatis*, 18–24 h of *M.tb*, and 3 to 6 days for *M. avium ssp. paratuberculosis* or *M. leprae*, which has never been cultured *in vitro*. Usually, Middlebrook 7H10 (solid agar medium, Difco) or 7H9 (liquid medium, Difco) is enough for fast-growing species such as *M. smegmatis* or *M. fortuitum*, but for slow-growing species such as *M. tuberculosis*, *M. avium*, or BCG, enrich the medium with bovine serum albumin (BSA) fraction V and glucose prepared by dissolving 5 g of albumin fraction V and 2 g glucose in distilled water that is brought to the final volume of 100 ml. Sterilise this by passing it through a 0.45-µm Nucleopore filter and store in aliquots of 10 ml at 4°C. When needed, for each 90 ml of Middlebrook (7H9 or 7H10), use 10 ml OADC (albumin, dextrose, catalase and oleic acid; Difco) to supplement the medium. For *M. avium ssp. paratuberculosis*, the medium has to be supplemented with 1 mg/liter Mycobactin J.

2. Preparation of a Suspension of Mycobacterium smegmatis

Grow bacterial cultures on petri dishes containing 4.7 g Middlebrook's 7H9 broth medium, 5 g of nutrient broth, supplemented with 0.5% glucose and 0.05% Tween 80 at 200 rpm on a shaker at 37°C until the exponential grown phase (OD_{600} = 0.2) is reached (~10^8 cells/ml).

Subsequently, pellet and wash cells twice in PBS, pH 7.4, and resuspend in PBS to a final concentration of 5–10 × 10^9 cells/ml. Treat the suspension for 2 min in a water bath sonicator (room temperature) using four 30-s pulses to disperse clumps. Subsequently, bacteria should be passed through a 23-gauge needle to disrupt remaining bacterial clumps. Before infection, remove residual bacterial aggregates by low-speed centrifugation (120 *g*) for 2 min. The absence of bacterial clumps can finally be verified by light microscopy. It should be noted that some investigations have been interested in differences in the biology of mycobacteria that are taken up as aggregates rather than as individual bacteria (Schuller *et al*., 2001).

3. Preparation of a Suspension of Slow-Growing Mycobacteria such as M. tuberculosis

Inoculate 20 ml of Middlebrook's 7H9 broth medium with OADC with colonies isolated from Loewenstein Jennsen agar plates. In order to prevent the loss of lipidic virulence components, detergents such as Tween 80 should not be added the medium. Incubate the cultures at 37°C. When they reach the exponential phase growth (approximately 10–15 days) stock solutions in 10% glycerol can be preserved at –20°C up to 3 months or at –70°C for at least 1 year.

F. Killing of Mycobacteria

For some experiments it is useful to compare the biology of phagosomes containing live versus killed pathogens. Mycobacteria can be killed either by using paraformaldyde or, more easily, by heat. Suspensions resuspended in PBS (pH 7.4) are heat inactivated for 15 min at 80°C. Such treatment completely blocks growth of bacteria as determined by colony-forming units, but keeps the appearance of the bacteria intact, as viewed by electron microscopy.

G. Labelling of Mycobaceria

For many experiments it is useful to fluorescently label bacteria before uptake. For this, wash freshly harvested bacteria twice (3000×*g*) in a Eppendorf centrifuge for 3 min in ice-cold PBS, pH 7,4 and resuspend in the same buffer. After harvesting, dilute mycobacteria using PBS to a OD_{600}: 1.0. Add sulpho-NHS-FITC to a final concentration of 5 µg/ml and allow labelling to continue for 20 min on a shaker at room temperature. Non-incorporated FITC can be removed by washing in PBS plus 100 m*M* glycine. Thereafter, wash bacteria three times with PBS and immediately freeze in 100 µl aliquots at –20°C. To avoid batch variability in experiments, bacteria can be stored after labelling at –20°C up to 3 months or at –70°C for 1 year. The use of bacteria expressing GFP has emerged as a more powerful alternative to the surface labelling approach, as can be seen in numerous publications (see, e.g., Dhandayuthapani *et al*., 1995; Kremer *et al*., 1995).

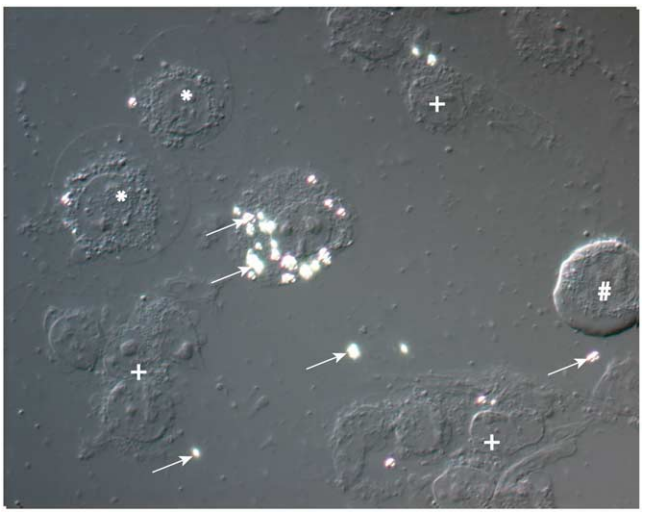

FIGURE 2 Nomarski interference microscopy image of *M. smegmatis*-infected J774 macrophages treated with a syringe equipped with a 22-gauge needle 10 times. *, cells in the process of breaking; +, nuclei with associated cell debris; #, intact cell; arrows indicate *M. smegmatis*-containing phagosomes that are phase refractile.

H. Cells Lysis and Isolation of Mycobacteria-Containing Phagosomes

The method we describe is a variation of that introduced by Chakraborty (1994). For preparing the mycobacteria-containing phagosome preparation, we usually infect macrophages of approximately 70% confluency in 245 × 245-mm dishes with mycobacteria. At desired times postinfection, wash cells in PBS. Harvest infected cells by scraping them in 20 ml of PBS and collecting them in one 50-ml tube per dish of cells and pellet by centrifugation at 800×*g* for 10 min at 4°C. Resuspend cells in 5 ml of HB with protease inhibitors and pellet again. In order to have a good lysis of the infected macrophages in the next step, cells have to be resuspended in an optimal volume of HB. As a rule of thumb, use an equal volume of HB (with inhibitors) to resuspend the pellet of cells. This should result in approximately 1 ml of suspension. Variations of this ratio can be applied to optimize breakage of cells. Lyse macrophages by approximately 30 strokes with a syringe fitted with 22-gauge needle and check the percentage of broken cells by light microscopy (Fig. 1). The process should continue until roughly 80% of the cells are broken, but with intact nuclei (Fig. 2). Subsequently, dilute the suspensions with an equal volume of HB plus inhibitors and centrifuge at 300 *g* for 10 min at 4°C and discard the pellet containing nuclei and intact cells. The postnuclear supernatant (PNS) contains the phagosomes, as well as endocytic and other organelles and cytoplasmic components. It is important to note that loss of phagosomes at this stage occurs mainly because of two reasons. First, cells are not broken properly and phagosomes are not set free in the supernatant. This can be a result of a too dilute suspension, which is more resistant to breakage, or from too gentle application or not enough strokes with the syringe. Second, phagosomes can be lost due to breakage of nuclei. This results in free DNA in the suspension that binds to phagosomes and keeps the phagosomes in the pellet together with nuclei and intact cells. As a result, cell lysis is one of the most critical stages of isolating bacterial phagosomes from macrophages.

A sucrose step gradient is then used to separate phagosomes from other organelles. For this, layer PNS on top of a discontinuous sucrose gradient in transparent centrifugation tubes consisting of 2 ml 62% sucrose, 4 ml 55%, and a 6-ml 37% (w/w) step cushion, prepared with protease inhibitors (Table I) and centrifuged at 100,000×*g* for 1 h at 4°C in Ultracentrifuge. Prepare one gradient per dish of cells. Dependent on the infection and age of the phagosomes, three different bands are found. One lies on the top of the 37% gradient, along with the majority of endocytic organelles, another in the interface between 55 and 37%, with the bacterial phagosomes, and, in the case of older (more mature) phagosomes, a third one is seen between 55 and 62% sucrose (Fig. 3). Phagosomes can be recovered using a syringe fitted to a 22-gauge needle by penetrating the tube wall from the side.

If a further concentration of the preparation is needed, a second step gradient can be done. The

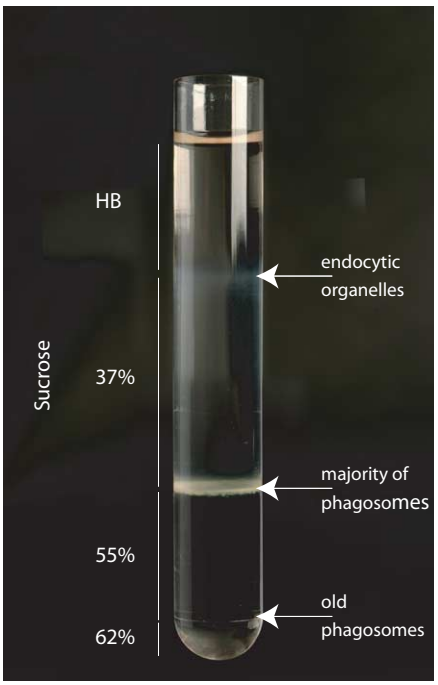

FIGURE 3

combined collected fractions (up to 2 ml) can be layered on the top of 2 ml 55% sucrose and centrifuged again at 100,000×*g* for 30 min at 4°C. The band on the top of the 55% sucrose contains the phagosomes and is collected as described earlier. Phagosomes can be used directly or stored in aliquots in liquid nitrogen until further use.

The successful isolation of intact phagosomes also depends on minimizing the interaction of phagosomes with tube surfaces. One must avoid pelleting the phagosomes until the final stage in the isolation.

IV. FINAL COMMENT

Latex bead phagosomes have emerged as a powerful model membrane organelle system that can be used to analyse many functions that are general properties of many intracellular membrane organelles, such as membrane fusion, their interaction with actin or microtubules, or acidification. The same particles can be used conveniently for *in vitro* analysis or for complementary studies in cells. In principle, any ligand that binds to cell surface receptors can be conjugated to beads in order to enrich for specific receptors in the phagosomes. It should be noted that the size of the particle is an important consideration; for phagocytosis, there is a minimum size (usually 0.2–0.3 µm in diameter) as well as a maximum size that depends on the cell type (for cultures macrophages, this is usually around 5 µm in diameter); for more details, see Desjardins and Griffiths (2003). A survey of the literature, as well as our own experience, convinces us that LBP are an excellent model system that behave similarly to phagosomes containing microorganisms that can be killed by macrophages (such as *M. smegmatis*; see Anes *et al*., 2003). LBP have also been used extensively as control phagosomes for analyses of pathogen-enclosing phagosomes; the latter usually modify the intracellular behaviour of the phagosome in a manner that facilitates the survival and growth of the pathogens. A key question that needs to be addressed individually for each intraphagosomal pathogen is how the pathogen manages to by-pass the normal phagosomal killing mechanisms. Also for this question the use of latex beads can be invaluable, as suspected pathogen surface "virulence" factors that bind to cell surface receptors can be conjugated to beads to see if and how the intracellular trafficking and molecular composition of the phagosome differ from control bead phagosomes.

For many questions there will be an increasing need to isolate pathogen-enclosing phagosomes. For no pathogen until now is it possible to enrich its phagosome to the same level of purity as is obtained routinely for the LBP. The method described here for isolating mycobacterial phagosomes can be taken as one of the current state-of-the-art methods in use. There is now a serious need to improve existing methods and to find new approaches that can provide more pure preparations of functionally intact pathogen phagosome preparations that will be important for protein and lipid analysis in the future.

CHAPTER

9

Isolation of Peroxisomes

Alfred Völkl and H. Dariush Fahimi

I. INTRODUCTION

The investigation of unique functional and structural aspects of peroxisomes (PO) requires the preparation of highly purified fractions of this organelle. This is, however, hampered by two serious problems: (1) the relative paucity of PO (2% of total liver protein) and (2) their considerable fragility. Thus, mild homogenization conditions minimizing mechanical, hydrostatic, and osmotic stress have to be sustained.

In general, the isolation of PO is accomplished in three steps: (a) homogenization of the tissue or disruption of the cells; (b) subfractionation of the homogenate by differential centrifugation usually according to the classical scheme of de Duve *et al*. (1955); and (c) isolation of purified peroxisomes by density gradient centrifugation of the so-called light mitochondrial (λ) fraction.

Homogenization is commonly carried out in an isotonic medium (e.g., see Section III,A,1) at low salt concentrations to avoid aggregation. Addition of a chelator (e.g., EDTA), however, is feasible, as it prevents the aggregation of microsomes that may contaminate PO. Moreover, the homogenization buffer (HB) should be supplemented with antioxidants (dithiothreitol, DTT), as well as protease inhibitors (phenylmethylsulfonyl fluoride, PMSF; ε-aminocaproic acid) to block oxidative and proteolytic activities in the course of the isolation procedure.

For the purification of PO by density gradient centrifugation, three approaches have been developed. In the classic procedure (Leighton *et al*., 1968), sucrose gradients and the specialized type Beaufay rotor were employed. A self-generating Percoll gradient in conjunction with a vertical rotor is used for the isolation of PO under isotonic conditions (Neat *et al*., 1980). The most straightforward approach to obtain highly purified PO makes use of iodinated gradient media such as metrizamide, nycodenz or Optiprep in combination with a vertical rotor (Völkl and Fahimi, 1985; Hartl *et al*., 1985; van Veldhoven *et al*., 1996). In the latter media, PO band at the quite high density of 1.24 g/cm^3 because of their permeability to low molecular weight compounds (van Veldhoven *et al*., 1983), well separated from lysosomes as well as from mitochondria and microsomes.

The method described in this article is a modification of the protocol established for the isolation of highly purified (>98%) PO from normal rat liver (Völkl and Fahimi, 1985). Meanwhile, it has been applied to livers and kidneys of several other mammalian species (Fahimi *et al*., 1993; Zaar *et al*., 1992), as well as for the isolation of PO from cell cultures (Schrader *et al*., 1994). With an additional differential centrifugation step, even peroxisomal subpopulations may be isolated according to this protocol, as has been demonstrated by Lüers *et al*. (1993).

II. INSTRUMENTATION AND MATERIALS

A. Instrumentation

1. Perfusion device (self-made)
2. A 30-ml Potter–Elvehjem tissue grinder (Cat. No. 1931 05145) with a loose-fitting Teflon pestle (Cat. No. 1931 05155; clearance 0.10–0.15 mm) and a motor-driven homogenizer (Cat. No. 5308 50001) are from Migge, 69123 Heidelberg, FRG.

Copyright 2006, Elsevier Science (USA).

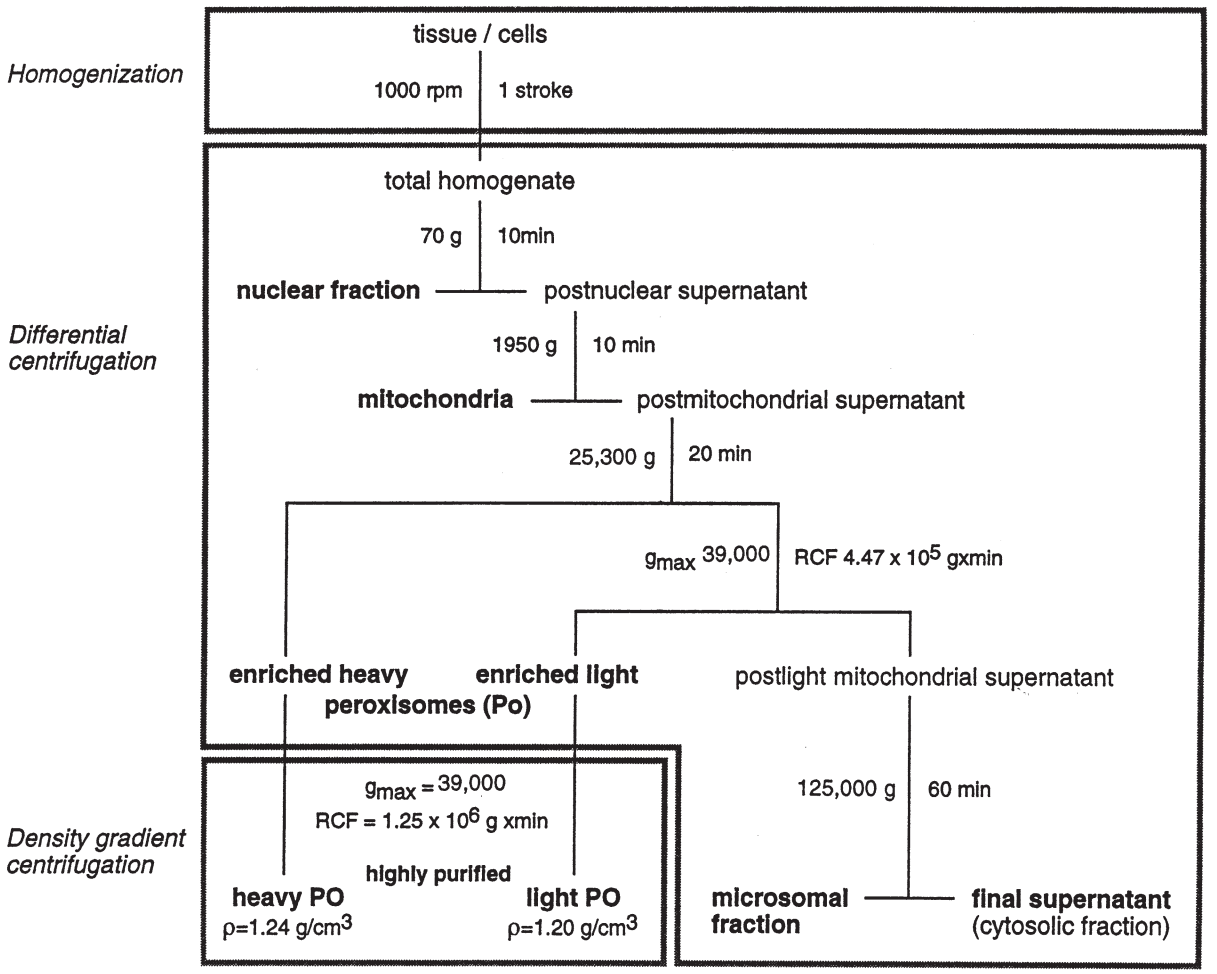

FIGURE 1 Flowchart for the isolation of highly purified (>98%) peroxisomes from rat liver.

3. Refrigerated low- and high-speed centrifuge (e.g., Beckman TJ-6 and J 2-21); ultracentrifuge (e.g., Beckman L90) with corresponding rotors (e.g., Beckman JA-20; VTi 50).
4. Refractometer

B. Chemicals

Morpholinopropane sulfonic acid (MOPS, Cat. No. 29 836), PMSF (Cat. No. 32 395), and DTT (Cat. No. 20 710) are from Serva (Heidelberg, FRG). Ethanol (Cat. No. 8006) and NaCl (Cat. No. 0277) are from J. T. Baker (Deventer, Netherlands). EDTA (Cat. No. E 2628-2) is from Max Keller (Mannheim, FRG), ε-aminocaproic acid (Cat. No. 62 075) is from Riedel-de Haen (Seelze, FRG), sucrose (Cat. No. 4621) is from Roth (Karlsruhe, FRG), and metrizamide (Cat. No. 10o 1983N) is from Life Technologies (76344 Eggenstein-Leopoldshafen).

C. Animals

Female rats of 220–250 g body weight, starved overnight

III. PROCEDURES (FIG. 1)

A. Perfusion and Homogenization

Solutions

1. *Homogenization buffer (HB)*: To make 1 liter, dissolve 85.56 g of sucrose (250 m*M*), 1.046 g of MOPS (5 m*M*), 0.372 g of EDTA–Na_2 (1 m*M*), and 1 ml of ethanol (0.1%) in distilled water, adjust pH to 7.2 with NaOH, and add water up to 1 liter. Store at 4°C. Prior to use add per 100 ml: 0.2 µl of 0.1 *M* PMSF, 0.1 ml of 1 *M* ε-aminocaproic acid, and 20 µl of 1 *M* DTT.

2. Saline (0.9%): To make 1 liter, dissolve 9 g of NaCl in distilled water and adjust to a total volume of 1 liter.

Steps

1. Anesthesize the animal (e.g., by ip injection of chloralhydrate).
2. Weigh the animal, open abdominal cavity, and perfuse liver with 0.9% saline via the portal vein until all blood is drained away.
3. Remove liver, dissect connective tissue, and weigh and cut liver into small pieces collected in a Potter tissue grinder held in an ice bath containing 3 ml/g (wet liver weight) of ice-cold HB.
4. Homogenize tissue with a loose-fitting pestle, applying a single down-and-up stroke at 1000 rpm.
5. Pour homogenate into a 50-ml centrifuge tube.

B. Subcellular Fractionation

Solution

HB as described in Section III,A.

Steps

1. To remove debris, unbroken hepatocytes, and blood cells, as well as most of nuclei, centrifuge the total homogenate at 70 *g* for 10 min in a refrigerated low-speed centrifuge.
2. Carefully pour off the supernatant (loose pellet !), resuspend pellet in 2 ml/g of ice-cold HB, rehomogenize, and spin again under the same conditions.
3. Pour off the second supernatant and combine it with the first one (postnuclear supernatant); discard the pellet.
4. Centrifuge postnuclear supernatant at 1950 *g* for 10 min in a refrigerated high-speed centrifuge.
5. Decant supernatant (firm pellet), resuspend pellet manually in 1 ml/g of ice-cold HB using a glass rod, and spin again at 1950 *g*. The final pellet (heavy mitochondrial fraction) contains the majority of ***mitochondria***, large microsomal sheets, and some remaining nuclei. The combined supernatants represent the postmitochondrial supernatant.
6. Subject the latter to 25,300 *g* for 20 min; remove supernatant, including the reddish fluffy layer by suction; resuspend pellet in about 10 ml of ice-cold HB using a glass rod; and recentrifuge at 25,300 *g* for 15 min. Resuspend the final pellet in 5 ml of ice-cold HB again by means of a glass rod, which comprises the ***enriched heavy peroxisomal*** = light mitochondrial (λ) fraction. The corresponding supernatant may be either used directly to prepare a microsomal fraction and a final supernatant (soluble proteins mostly of cytosolic origin) or processed further for the isolation of "light PO."
7. To this extent it is centrifuged at an integrated relative centrifugal force (RCF) of $4.47 \times 10^5\, g$ min (g_{max} = 39,000). Resuspend the pellet thus obtained in 5 ml of ice-cold HB using a glass rod; this pellet represents the ***enriched light peroxisomal fraction*** (Luers *et al.*, 1993).

C. Metrizamide Density Gradient Centrifugation

Solutions

1. *Gradient buffer (GB):* To make 1 liter, dissolve 1.046 g of MOPS (5 m*M*), 0.372 g of EDTA–Na_2 (1 m*M*), and 1 ml of ethanol (0.1%) in distilled H_2O, adjust with NaOH to pH 7.2, and add H_2O up to 1 liter. Store at 4°C. Prior to use add per 100 ml: 0.2 ml of 0.1 *M* PMSF, 0.1 ml of 1 *M* ε-aminocaproic acid, and 20 µl of 1 *M* DTT.
2. Metrizamide solutions (MS)
   a. *60% (w/v) stock solution*: Dissolve 60 g of metrizamide in GB by stirring. Add GB up to 100 ml. Store at 4°C.
   b. *Gradient solutions*: To prepare one gradient, take 3.78, 3.38, 3.53, 2.06, and 3.2 ml of the 60% stock solution. Add up GB to 10, 7, 6, 3, and 4 ml using a refractometer to definitely adjust densities to 1.12, 1.155, 1.19, 1.225, and 1.26 g/ml, respectively.

Steps

Preparation of a Metrizamide Gradient

1. Layer sequentially 4, 3, 6, 7, and 10 ml, respectively, of MS (1.26–1.12 g/ml) in a 40-ml centrifuge tube (e.g., Quick-seal polyallomer, Beckman) to form a discontiuous gradient.
2. Immediately freeze the gradient in liquid nitrogen and store it at –20°C.
3. Thaw the gradient quickly at room temperature using a metallic stand, thus transforming the step gradient into one with an exponential profile.

Gradient Centrifugation

1. Layer 5 ml of either the light or the heavy enriched peroxisomal fraction (corresponding to one liver of approximately 5–6 g) on top of the thawed gradient and seal the tube.
2. Centrifuge gradients in a vertical-type rotor (e.g., Beckman VTi50) at an integrated force of $1.256 \times 10^6\, g$ min (g_{max} = 39,000) using slow acceleration/deceleration modes. Under the conditions employed, ***highly purified heavy peroxisomes*** band at 1.23–1.24 g/ml and ***light peroxisomes*** band at 1.20–1.21 g/ml.

TABLE I Properties of Purified Heavy Peroxisomal Fractions from Normal Rat Liver[a]

Enzyme	mU/mg homogenate (mg/g liver)	Rate of recovery (%)	RSA
Protein	256.36 ± 82.94	0.28 ± 0.08	–
Catalase	203 ± 42.7	9.96 ± 1.92	37.67 ± 4.28
HA-oxidase	3.3 ± 0.7	9.46 ± 1.06	40.25 ± 5.83
FA β-oxidation	3.6 ± 0.96	11.18 ± 3.25	36.32 ± 5.09
β-Glucuronidase	38 ± 5.88	0.01 ± 0.01	0.07 ± 0.06
Acid phosphatase	31	0.15	0.07
Esterase	1229 ± 246.7	0.01 ± 0.01	0.09 ± 0.07
NADPH-CcR	18 ± 4.6	0.18	0.702
Cc-oxidase	127 ± 35.6	0.02 ± 0.02	0.09 ± 0.05
L-GlDH	57 ± 16.5	0.08 ± 0.02	0.679

[a] Values given are means ± SD. HA-oxidase, α-hydroxyacid oxidase; FA β-oxidation, fatty acid β-oxidation; NADPH-CcR, NADPH-cytochrome c reductase; Cc-oxidase, cytochrome c oxidase; L-GlDH, L-glutamate dehydrogenase; and RSA, relative specific activity.

3. Recover the peroxisomal fraction by means of a fraction collector; alternatively, the gradient tube can be punctured and the fraction aspirated by a syringe. Store fraction at –80°C.

4. To remove metrizamide, which interferes with the determination of some peroxisomal enzymes (e.g., urate oxidase) or of protein (Lowry method), dilute the peroxisome fraction about 10-fold with HB followed by centrifugation at 25,000 and 39,000 *g*, respectively, to pellet the organelles.

IV. OBSERVATIONS AND COMMENTS

The properties of the heavy peroxisomal fraction are listed in Table I. Estimated by the specific peroxisomal reference enzymes, it shows a purification rate of about 38-fold over the original homogenate. More than 95% of the total protein content of this fraction is contributed by peroxisomes (Völkl and Fahimi, 1985), with mitochondria and microsomes accounting for about 2% each and lysosomes for less than 1%. This is confirmed by electron microscopy, which shows that peroxisomes make up 98–99% of the fraction (Figs. 2 and 3). Many peroxisomes contain the typical inclusions of urate oxidase in the matrix (Fig. 2), but some extruded free cores are also found between the organelles. The electron-dense cytochemical reaction product of catalase after the incubation of filter preparations in the alkaline 3,3′-diaminobenzidine medium (Fahimi, 1969) is seen over the matrix of the majority of peroxisomes (Fig. 3), demonstrating their integrity and the absence of leakage of catalase.

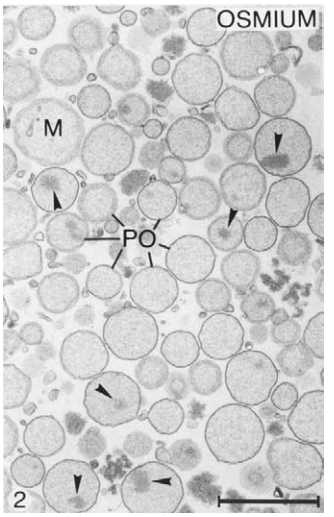

FIGURE 2 Electron microscopic appearance of isolated heavy peroxisomes after fixation in glutaraldehyde and osmium. The fraction consists almost exclusively of peroxisomes (PO) with only a rare mitochondrion (M). Many peroxisomes contain urate oxidase cores (arrowheads). Bar: 1 μm.

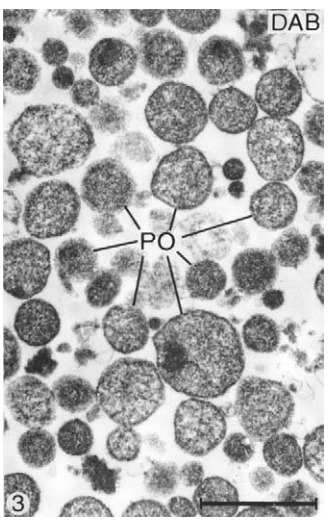

FIGURE 3 A preparation comparable to that in Fig. 2 but incubated with alkaline 3,3′-diaminobenzidine for localization of catalase (Fahimi, 1969). Note the electron-dense reaction product of catalase over the matrix of most peroxisomes. This illustrates the absence of catalase leakage, confirming their integrity. Bar: 1 μm.

The polypeptide pattern (SDS–PAGE) of rat liver heavy peroxisomes is shown in Fig. 4 (lane R) confirming their high degree of purity because of the absence of bands typical for mitochondria and microsomes. It also shows distinct differences in protein composition of hepatic peroxisomes between rat (R)

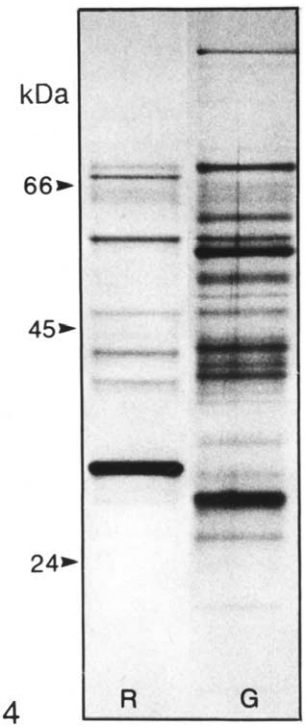

FIGURE 4 SDS–PAGE of highly purified heavy peroxisomes from rat (R) and guinea pig (G) liver. A 10–12.5% resolving gel was used, and the amounts of protein loaded per lane were (R) 2.4 µg and (G) 5.4 µg. Silver staining of polypeptide bands. M_r standards: BSA (66 kDa), ovalbumin (45 kDa), and trypsinogen (24 kDa). Note the distinct differences in the polypeptide patterns between rat and guinea pig peroxisomes.

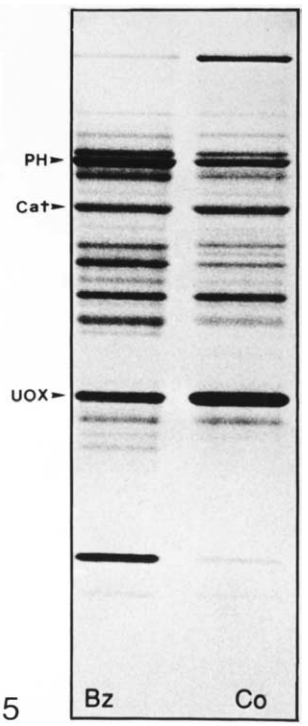

FIGURE 5 SDS–PAGE of highly purified peroxisomes from control (Co) and bezafibrate-treated (Bz) rat liver. A 10–15% resolving gel was used, and 5.0 µg of protein was loaded per each lane. Silver staining of bands. Peroxisomal polypeptides indicated by an arrowhead are PH, trifunctional protein; Cat, catalase; and UOX, urate oxidase. Note the induction of PH and the concomitant reduction of Cat and UOX in peroxisomes of Bz-treated rats. Also note that the control preparations, R in Fig. 4 and Co in Fig. 5, are not identical and that different resolving gels have been used.

and guinea pig (Fig. 4, lane G). The selective induction of specific peroxisomal proteins, such as the trifunctional protein (PH) in rats treated with hypolipidemic fibrates (lane Bz) with the concomitant reduction of catalase (Cat) and urate oxidase (UOx), is apparent in Fig. 5.

The extended procedure outlined here has been successfully employed to isolate heavy and light peroxisome subpopulations from normal and regenerating rat liver differing in density, size, shape, and enzymatic composition (Lüers *et al*., 1993). Moreover, peroxisome subsets as divergent as the former have been also obtained from the human heptoma cell line HepG2 (Schrader *et al*., 1994). However, further subpopulations, which are also present in those tissues, escape purification by conventional gradient centrifugation, most probably because their sedimentation properties are close to those of other subcellular organelles, particularly microsomes. Nevertheless, their purification has become an essential task in view of the functional significance of PO in humans in general (Wanders *et al*., 1995) and the putative importance of peroxisomal subpopulations in the biogenesis of this organelle in particular (Erdmann *et al*., 1997; Titorenko *et al*., 1997).

As an alternative to density gradient centrifugation, immune free flow electrophoresis (IFFE) has been introduced and applied successfully for the purification not only of regular PO (ρ = 1.22–1.24 g/cm^3) from a light mitochondrial fraction of rat liver, but also of PO from heavy and postmitochondrial fractions (Völkl *et al*., 1997, 1999). IFFE combines the advantages of eletrophoretic separation with the high selectivity of an immune reaction. It makes use of the fact that the electrophoretic mobility of a subcellular particle, complexed with an antibody directed against the cytoplasmic domain of one of its integral membrane proteins, is diminshed greatly, provided the pH of the electrophoresis buffer is adjusted to pH ~8.0, which is the pI of IgG molecules. The PO isolated by IFFE from the diverse hepatic subcellular fractions differed in their composition of matrix and membrane proteins as has been revealed by immunoblotting, thus supporting the view that IFFE is a valid method for the

purification of distinct subsets of the peroxisomal compartment.

CHAPTER

10

Isolation of Mitochondria from Mammalian Tissues and Cultured Cells

Erika Fernández-Vizarra, Patricio Fernández-Silva, and José A. Enríquez

I. INTRODUCTION

Isolation of mitochondria can be a necessary procedure for many purposes: (1) as a primary step for further purification of mitochondrial subcomponents; (2) to perform metabolic assays, with respiration activity analysis the most common; and (3) to perform molecular analyses on the biogenetic activity of the organelle. The mitochondrial preparations obtained using the method described herein are perfectly suitable for biogenetical studies (mitochondrial DNA, RNA, protein synthesis, and as source for respiratory complex analysis by blue-native gel electrophoresis), as well as in a variety of different assays where isolated mitochondria are required, such as assessment of respiratory enzyme activities, protein import, aminoacylation, and *in organello* footprinting. The method consists of three basic steps: (1) cell rupture, (2) differential centrifugation: first at low speed to pellet mainly nuclei and unbroken cells and then at high speed to pellet mitochondria, and (3) washing of the mitochondrial pellet in order to reduce the presence of other subcellular contaminants. Mitochondria from different sources are obtained using basically the same methodology, although some modifications must be introduced depending on the tissue type or if mitochondria are to be isolated from cultured cells. When the purity of samples is considered, there is an elimination of a good part of the contaminants when mitochondrial preparations obtained by this procedure are compared with crude mitochondrial fractions. Because this purification protocol does not make use of gradient preparation or ultracentrifugation, further purification of the organelles is recommended when mitochondria are prepared for isolation of organelle subcomponents. In summary, the method described here produces reasonably pure mitochondria in a fairly short time and with a low cost. In addition, maintenance of integrity and functionality of the organelles are guaranteed.

II. MATERIALS AND INSTRUMENTATION

Sucrose (ACS for analysis) is from Carlo Erba Reagenti (Cat. No. 477183). Sodium chloride (ACS analytical reagent, Cat. No. 727 810) is from Prolabo. Potassium cyanide (KCN; BioChemika MicroSelect; Cat No. 60178) is from Fluka. Ethylenediaminetetraacetic acid disodium salt 2-hydrate (EDTA-Na_2; for analysis-ACS; Cat. No. 131669), potassium chloride (for analysis-ACS-ISO; Cat. No. 131494), magnesium chloride 6-hydrate (for analysis-ACS-ISO; Cat. No. 131396), sulphuric acid (96%; Cat. No. 251058), trichloroacetic acid [solution 20% (w/v); Cat. No. 252373], acetic acid glacial (chemically pure; Cat. No. 211008), sodium hydrogen sulphite [solution 40% (w/v); Cat. No. 211642], sodium sulphite (anhydrous purissimum; Cat. No. 141717); dipotassium hydrogen phosphate (anhydrous for analysis; Cat. No. 121512), potassium dihydrogen phosphate (for analysis, Cat. No. 121509) and orthophosphoric acid (85% for analysis-ACS-ISO; Cat. No. 131032) are from Panreac. D-Mannitol (ACS reagent; Cat. No. M-9647), ethylene glycol-bis(β-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA; approximately 97%; Cat. No. E-4378), L-glutamic acid monosodium salt [glutamate; minimum 99% (TLC); Cat. No. G-1626], L-(-)-malic acid sodium salt [malate; 95–100% (enzymatic); Cat. No. M-1125], succinic acid disodium salt hexahydrate (succinate;

Copyright 2006, Elsevier Science (USA).
All rights reserved.

minimum 99%; Cat. No. S-2378), oxalacetic acid (approximately 98%; Cat. No. O-4126), acetyl coenzyme A trilithium salt (acetyl-CoA; approximately 95%, Cat. No. A-2181), 5-5′-ditio-bis(2-nitrobenzoic acid) or DTNB (Ellman's reagent; Cat. No. D-8130), glycerol 2-phosphate disodium salt hydrate (β-glycerophosphate; ≤ 0.1% α-isomer; Cat. No. G-6251), ammonium molybdate tetrahydrate (81–83% as MoO_3 ACS reagent; Cat. No. A-7302), β-D-glucose 6-phosphate sodium salt (crystalline, Sigma Grade; G-7879), imidazole [minimum 99% (titration), crystalline; Cat. No. I-0250], hydrogen peroxide (29–32% as H_2O_2 ACS reagent; Cat. No. H-0904), bovine serum albumin [BSA; fraction V; minimum 96% (electrophoresis); Cat. No. A-4503], and subtilisin (subtilisin A from *Bacillus* sp.; lyophilized powder, type VIII, 7–15 units/mg solid; Cat. No. P-5380) are from Sigma. Aldrich supplied the titanium (IV) oxysulfate [titanyl sulfate or $TiOSO_4$; 15% (w/v) solution in diluted H_2SO_4; Cat. No. 49,537-9] and the 4-amino-3-hydroxy-1-naphtelenesulphonic acid (aminonaphtosulphonic Acid; 98+% ACS reagent; Cat. No. 39,896-9). D-Sorbitol (high purity; Cat. No. SO0850) is from Scharlau. Tris (for analysis; Cat. No. 1.08382), hydrochloric acid fuming (37%; Cat. No. 1.00317) and 2-mercaptoethanol (for synthesis; Cat. No. 8.05740) are from Merck. BSA fraction V, fatty acid free (Cat. No. 775 827), adenosine-5′-diphosphate disodium salt (ADP; Cat. No. 127 507), cytochrome c (from horse heart, salt free, Cat. No. 103 888), and Triton X-100 (especially purified for membrane research; Cat. No. 789 704) are from Roche. For protein determination, the Bio-Rad protein assay dye reagent concentrate (450 ml; Cat. No. 500-0006) is used. Phosphate-buffered saline (PBS 1x, liquid, pH 7.4 ± 0.05; Cat. No. 10010) is from GIBCO (Invitrogen Corporation).

Elvejhem-type glass homogenisers with Teflon pestles, as well as the Dounce-type glass potter, are from local glassware providers (VidraFoc and Sumalsa). Fifty-milliliter polypropylene copolymer centrifuge tubes (Oak Ridge centrifuge tubes; Cat. No. 3119-0050) and the 0.2-µm syringe filters (Cat. No. 190-2520) are from Nalgene.

Centrifugations are performed in a Sorvall RC 5B Plus refrigerated centrifuge with the Sorvall HS-4 swinging rotor and the SS-34 fixed angle rotor. An Eppendorf 5415 C microfuge kept in the cold room is used to centrifuge the Eppendorf tubes.

Mitochondrial oxygen consumption measurements are obtained with a Hansatech CBID oxygen electrode and registered in a PC using software from Pico Technology Limited. The polytetrafluoroethylene (PTFE) membrane (ordering code: S4; thickness 0.0125 mm, width 25.4 mm, 30 m reel) is from Hansatech.

Spectrophotometric measurements are performed in a Unicam UV 500 spectrophotometer, where the temperature is kept constant by a DBS PCD 150 water peltier system. Data from these measurements are registered by a PC using the Vision 32 version 1.25 software from Unicam Limited.

III. PROCEDURES

A. Isolation of Mitochondria

1. Solutions

a. *Homogenisation medium A*: 0.32 *M* sucrose, 1 m*M* EDTA, and 10 m*M* Tris–HCl. For 1 liter, weigh 109.5 g of sucrose, dissolve in bidistilled water, and add 2 ml of 0.5 *M* disodium EDTA stock solution and 20 ml of 0.5 *M* Tris–HCl, pH 7.4. Check and adjust, if necessary, pH to 7.4 and autoclave at low pressure. Store at 4°C.

b. *Homogenisation medium AT*: 0.075 *M* sucrose, 0.225 *M* mannitol, 1 m*M* EGTA, and 0.01% BSA. For 500 ml, add 12.84 g of sucrose, 20.5 g of mannitol, and 5 ml of a stock solution of 100 m*M* EGTA. Adjust pH to 7.4 and autoclave at low pressure. Store at 4°C. Just before use add 500 µl of 10% (w/v) BSA. Once the BSA is added, the solution cannot be autoclaved again.

c. *Homogenisation medium IB 10×*: 0.35 *M* Tris–HCl, pH 7.8, 0.25 *M* NaCl, and 50 m*M* $MgCl_2$. To prepare 100 ml, add 70 ml of 0.5 *M* Tris–HCl, pH 7.8, 5 ml of 5 *M* NaCl, and 5 ml of 1 *M* $MgCl_2$. Complete to 100 ml with bidistilled water and sterilize by filtration. Store at 4°C.

d. *MAITE medium*: 25 m*M* sucrose, 75 m*M* sorbitol, 100 m*M* KCl, 0.05 m*M* EDTA, 5 m*M* $MgCl_2$, 10 m*M* Tris–HCl, pH 7.4, and 10 m*M* H_3PO_4 (pH 7.4). For 100 ml of solution weigh 0.86 g of sucrose, 1.37 g of sorbitol, and 0.74 g of KCl, dissolve, and then add 10 µl of 0.5 *M* EDTA, 500 µl of 1 *M* $MgCl_2$, 2 ml 0.5 *M* Tris–HCl, pH 7.4, and 68 µl of orthophosphoric acid. Adjust pH to 7.4 using Tris base 0.5 *M*. Sterilize by filtration through a 0.2-µm filter, make 10-ml aliquots, and store at 4°C.

e. *0.5 M EDTA*: Weigh 93.1 g of disodium EDTA, dissolve, adjust the pH to 8.0, and complete the volume to 500 ml with distilled water. Store at 4°C.

f. *0.5 M Tris–HCl pH 7.4 or pH 7.8*: For 500 ml, weigh 30.3 g of Tris and adjust pH to 7.4 or 7.8 with HCl. Store at 4°C.

g. *100* m*M EGTA*: Prepare 100 ml of this solution by weighing 3.8 g. In order to increase the solubility of EGTA, the pH has to be raised with NaOH when dissolving it. Once the EGTA is totally dissolved, complete to 100 ml with bidistilled water. Store at 4°C.

h. *1 M $MgCl_2$*: For 100 ml, weigh 2 g of magnesium chloride and dissolve. Store at 4°C.

i. *5 M NaCl*: Weigh 29.3 g of NaCl, dissolve, and adjust to 100 ml with bidistilled water.

j. *10% (w/v) or 100 mg/ml BSA*: Weigh 0.5 g of fatty acid-free BSA and dissolve in 5 ml of distilled water. Sterilize by filtration through a 0.2-µm filter and store at –20°C in 1-ml aliquots.

2. *Isolation of Mitochondria from Rat Tissues*

a. Mitochondria from Liver and Kidney

Use male Wistar rats weighing 200–300 g. It is recommended that glassware, scissors, and metal sieves be sterilized at 160°C overnight. Autoclave plastic tubes at 1 atm for 20 min.

1. Previous to the sacrifice of the animals, fill 100-ml glass beakers with enough homogenisation medium A to cover the organ to be utilised, weigh, and place them on ice.
2. Kill the animals, remove the organ of interest, and place it in a beaker with ice-cold homogenisation medium A (in this case liver or kidneys).
3. Weigh the beaker to know the amount of tissue that has been extracted.
4. Cut the tissue into small pieces with a pair of scissors.
5. Sift the tissues and wash them with more homogenisation medium in order to remove blood and connective tissue. Put them back in the beaker and repeat steps 4 and 5 three or four times until the tissue is well cleaned.
6. Add fresh homogenisation medium to the homogeniser in a proportion of 4 ml per gram of liver and 5 ml per gram of kidney.
7. Transfer the pieces of tissue to the homogeniser.
8. Homogenise with four up-and-down strokes in the Elvehjem–Potter with the motor-driven Teflon pestle at 600 rpm.
9. Transfer the homogenised tissue into the 50-ml sterile centrifuge tubes.
10. Centrifuge in the HS-4 swinging rotor at 1000 *g* (3000 rpm) for 5 min at 4°C in order to pellet unbroken tissue, cells, and nuclei.
11. Place eight Eppendorf tubes in a container with ice and fill them with supernatant from the previous step (this and the following steps are done in a cold room).
12. Centrifuge the Eppendorf tubes for 2 min at 13,000 rpm in a microfuge.
13. Using a sterile Pasteur pipette, remove the supernatant trying to draw out all the liquid and part of the light coloured fluffy layer on the top of the pellet without disturbing the darker part where mitochondria are.
14. To wash the mitochondrial fraction, add homogenisation medium A, up to 1.5 ml, to four of the eight Eppendorf tubes and resuspend. Transfer the resuspended pellet of one tube to one of the tubes without medium A and resuspend.
15. Centrifuge the four resulting tubes as described earlier.
16. Repeat steps 15, 16, and 17 so that now two tubes are centrifuged.
17. Repeat the same procedure once again until one tube, containing all the material, is left.
18. When the last tube is centrifuged and the supernatant is removed, wash the pellet by resuspending it with MAITE medium.
19. Centrifuge for 2 min at 13,000 rpm.
20. Resuspend the pellets with 1 ml of MAITE medium.

When a bigger amount of sample is needed, the procedure can be started using twice as much supernatant and then finishing with the mitochondrial preparation in two Eppendorf tubes.

b. Mitochondria from Heart

1. Follow the steps 1 to 7 described in Section III,A,2,a but instead of filling the beakers with homogenisation medium A, use homogenisation medium AT.
2. Fill the homogeniser with 10 ml of medium AT per gram of heart.
3. Homogenise with six strokes in the Elvehjem–Potter with the motor-driven Teflon pestle at 600 rpm.
4. Transfer the homogenised tissue to a sterile 50-ml centrifuge tube.
5. Centrifuge at 1000 *g* (3000 rpm) in the HS-4 swinging rotor for 5 min at 4°C.
6. Transfer the supernatant from the previous centrifugation step to a clean centrifuge tube.
7. Centrifuge at 12,000 *g* (9000 rpm) in the SS-34 fixed angle rotor for 10 min at 4°C to obtain the crude mitochondrial fraction.
8. Draw out and discard the supernatant.
9. Resuspend the pellet in 5.5 ml of homogenisation medium AT.
10. Transfer the mitochondrial suspension to four Eppendorf tubes for the washing steps in the cold room.
11. Proceed hereafter as described for liver and kidney mitochondria, but if the mitochondrial fraction is obtained from one rat heart, the final fraction has to be resuspended in a smaller volume than those from liver and kidney, usually with 0.5–0.75 ml.

An alternative isolation procedure for heart mitochondria has been described previously (McKee *et al*., 1990) where perfusion and homogenisation of the

hearts using subtilisin (0.4 mg/ml) are proposed to improve the yield, the respiratory performance, and the protein synthesis activity of the isolated organelles. In our hands, the addition of subtilisin to the homogenisation medium provides a higher yield in the preparations and increases the *in organello* transcription rate. However, no significant improvement in the rate of incorporation of a radioactive amino acid into the mitochondrial translation products could be observed. However, the electrophoretic pattern of *in organello* synthesized products reveals an abnormal accumulation of low molecular weight peptides when subtilisin is used, probably due to residual peptidase activity of the subtilisin after breaking the organelles.

c. Mitochondria from Brain

1. Again follow the same first five steps as for liver, kidney, and heart. Use homogenisation medium AT.
2. Add 5 ml of medium AT per gram of brain to the homogeniser.
3. Homogenise the pieces of brain with 10 to 15 strokes using a Dounce-type glass homogeniser with a manually driven glass pestle.
4. Transfer the homogenised tissue to a sterile 50-ml centrifuge tube.
5. Centrifuge at 1000 *g* in swinging rotor for 5 min at 4°C.
6. Transfer the supernatant from the previous centrifugation step to a clean sterile centrifuge tube.
7. Resuspend the pellet resulting from the previous centrifugation in another 5 ml of medium AT per gram of starting tissue.
8. Rehomogenise the nuclear pellet by repeating 10 to 15 strokes in the Dounce potter.
9. Transfer the homogenised nuclear pellet to the same 50-ml tube where the first centrifugation was done.
10. Centrifuge at 1000 *g* in the swinging rotor for 5 min at 4°C.
11. Remove this second supernatant and pour it into the tube with the first supernatant.
12. Centrifuge at 12,000 *g* (9000 rpm) in the fixed angle SS-34 rotor for 10 min at 4°C to obtain the crude mitochondrial fraction.
13. Wash and resuspend as described for heart mitochondria (steps 8–11).
14. Resuspended the final pellet in 0.9 ml of MAITE medium.

A great fraction of mitochondria is lost in the first nuclear pellet in whatever tissue is used; therefore, these steps (7–11) of rehomogenisation and a second centrifugation are especially necessary when isolating brain mitochondria because the homogenisation is much gentler than for the other tissues and the yield is too low when only one homogenisation step is done. The brain mitochondrial fraction obtained this way contains free as well as synaptic mitochondria. To separate free mitochondria from synaptosomes ("pinched off" synaptic ends with the synaptic mitochondria), several methods are available (reviewed in Whittaker, 1993). Partitioning in an aqueous two-phase system is recommended (Lopez-Perez, 1994).

3. Isolation of Mitochondria from Mammalian Cultured Cells

This procedure is the modified Gaines method (Enriquez and Attardi, 1996; Fernandez-Vizarra *et al.*, 2002; Gaines, 1996).

1. Harvest exponentially growing cells by trypsinization. Use the cells contained in ten to twelve 150-mm plates that are about 80–90% confluent.
2. Transfer the cells to a 50-ml Falcon tube.
3. Wash twice with cold PBS by centrifuging at 600 *g* in the clinical centrifuge for 8 min at 4°C. In the last wash, transfer the cells to a 15-ml Falcon tube and centrifuge as before.
4. Place the cells in ice. Measure the volume occupied by the packed cells.
5. Resuspend the cells in one-half of the packed cell volume of IB 0.1×. This is a hypotonic medium to facilitate the breakage of the cells.
6. Pipette the cell suspension into the homogeniser.
7. Wash the tube where the cells are with 0.1× IB using another half volume of the originally packed cells and pipette this into the homogeniser.
8. Perform four to five strokes in the homogeniser with the motor-driven Teflon pestle at 600 rpm.
9. Immediately add 1/10 of the initial volume of packed cells of 10× IB, to make the medium isotonic.
10. Transfer the homogenised cells to a 15-ml Falcon tube.
11. Centrifuge at 1600 *g* (3500 rpm) for 3 min at 4°C in the HS-4 swinging rotor to pellet unbroken cells, debris, and nuclei.
12. Draw out the supernatant and transfer it to a clean 15-ml Falcon tube.
13. Resuspend the nuclear pellet in one-half of its volume of 0.1× IB.
14. Repeat steps 6 to 11.
15. Collect the supernatant from this second round of homogenisation and centrifugation and add it to the first supernatant.
16. Centrifuge the supernatants at 1600 *g* (3500 rpm) for 3 min at 4°C in the HS-4 swinging rotor to remove remaining nuclei and unbroken cells.

17. Pipette the supernatant in (normally two) Eppendorf tubes placed in ice (this one and the following steps are performed in the cold room).
18. Centrifuge the Eppendorf tubes at 13,000 rpm in the microfuge for 1 min.
19. Wash the mitochondrial pellet with homogenisation medium 1× IB, until all the material is in one tube.
20. Remove supernatant and wash the pellet by resuspending it with homogenisation medium A.
21. Centrifuge the Eppendorf tube at 13,000 rpm in the microfuge for 1 min.
22. Remove supernatant and wash the pellet using MAITE medium.
23. Centrifuge the Eppendorf tubes at 13,000 rpm in the microfuge for 1 min.
24. Resuspend the mitochondrial pellet in the appropriate volume of MAITE medium, which is usually around 300 µl.

B. Assessment of Purity

Two different parameters have to be considered when assessing the purity of a mitochondrial fraction. One is the enrichment of the preparation in mitochondria and the other is the presence of contaminants. The enrichment in mitochondria is evaluated by measuring the activities of mitochondrial enzymes in the initial homogenate and in the final mitochondrial preparation. We usually measure two activities: the inner membrane-bound respiratory complex IV or cytochrome c oxidase (Wharton, 1967) and the mitochondrial matrix enzyme citrate synthase (Srere, 1969). Spectrophotometric measurement of individual respiratory complex activities has been reviewed previously (Birch-Machin and Turnbull, 2001; Trounce, 1996). However, to evaluate the presence and abundance of contaminants, different approaches can be proposed. The most common contaminants in a mitochondrial preparation are microsomes (mostly derived from endoplasmic reticulum), lysosomes, and peroxisomes, and their presence is monitored by the determination of specific enzyme activities present in each contaminant particle. Good examples of these activities that we have used to assess purity are glucose-6-phosphatase for endoplasmic reticulum (Morré, 1971), acid phosphatase for lysosomes (Trouet, 1974), and catalase for peroxisomes (Baudhuin, 1974). Electron microscopy morphometric analysis is good for estimating unidentified contaminants for which no enzymatic marker is available (Enriquez *et al*., 1990).

1. Treatment of Samples

Total homogenate samples that are used for spectrophotometric enzymatic activity measurements must undergo a freeze–thawing treatment in order to break the cells completely and liberate the enzymes from the subcellular particles. Crude mitochondrial fractions and mitochondrial preparations do not need such treatment, they are just divided in aliquots and kept at –70°C until they are used for the spectroscopic measurements. The single freezing and thawing step is sufficient to break them.

1. Use 1-ml aliquots of total homogenate that are in Eppendorf tubes.
2. Prepare a water bath at a temperature of 37°C.
3. Fill an appropriate container with liquid nitrogen.
4. Put the samples in the liquid nitrogen until they are completely frozen (2 min).
5. Immediately pass the samples to the water bath at 37°C and keep them there until they are thawed completely (5 min).
6. Repeat steps 4 and 5 four or five times.
7. Aliquot the homogenate in Eppendorf tubes, 50–100 µl in each tube, and keep them at –70°C.

2. Cytochrome c Oxidase Activity (EC 1.9.3.1)

Measurements of cytochrome c oxidase activity are performed spectrophotometrically using 5 µl of sample (nondiluted total homogenate or 1/10 diluted mitochondrial samples) in a final volume of 1 ml. The decrease of absorbance at 550 nm, due to the oxidation of cytochrome c, is measured for 90 s at 38°C (Wharton, 1967). Sensitivity to KCN is used to confirm that cytochrome c oxidase activity is measured.

3. Citrate Synthase Activity (EC 4.1.3.7)

To measure citrate synthase activity, use the same amount of sample as in the case of cytochrome c activity; the final reaction volume is also 1 ml. In the spectrophotometer, measure the increase of the absorbance at 412 nm due to the formation of a yellow complex of free CoA with DTNB, for 90 s at 30°C (Srere, 1969). The CoA is formed in the reaction of acetyl-CoA with oxalacetate to form citrate, catalysed by citrate synthase.

Mitochondrial enrichment assessed by these enzymatic activities in the indicated preparations is shown in Table I.

4. Glucose-6-phosphatase Activity (EC 3.1.3.9)

Glucose-6-phosphatase activity was measured according to (Morré, 1971), determining spectrophotometrically the inorganic phosphate (P_i) liberated by the enzyme from the substrate (glucose-6-phosphate). The amount of sample used is 0.1 ml, diluted 1/10 in the case of total homogenate and 1/20 for mitochon-

TABLE I Specific Activities Obtained for Two Mitochondrial Marker Enzymes: Cytochrome c Oxidase (Inner Membrane) and Citrate Synthase (Matrix)[a]

Enzyme	Source	Specific activity (units/g protein)			Purification (number of times)		Yield (%)

[a] Homogenate, total homogenate; crude, crude mitochondrial fraction, which is obtained by differential centrifugation without the washing steps; mitochondria, final mitochondrial fraction obtained as described in the text; G6pase, glucose-6-phosphatase (***EC 3.1.3.9***); acid phsp, acid phosphatase (***EC 3.1.3.2***).

dria and crude mitochondrial fractions. After a 15-min incubation at 37°C, there will be 0.1–1 µmol of P_i per milliliter. Protein is removed by TCA precipitation and centrifugation, and the amount of inorganic phosphate is measured in 1 ml of cleared supernatant.

5. *Acid Phosphatase Activity (EC 3.1.3.2)*

Incubate 1 ml of 1/10 diluted sample (total homogenate, mitochondria, or crude mitochondrial fractions) with 200 µl 0.5 *M* β-glycerophosphate, 100 µl of buffer, 100 µl of 2% (w/v) Triton X-100, and 600 µl of water for 30 min at 37°C (Trouet, 1974). Remove protein by TCA precipitation and centrifugation and measure the amount of inorganic phosphate in 1 ml of cleared supernatant.

The unit of activity is defined as the amount of enzyme liberating 1 µmol of phosphate per minute.

6. *Catalase Activity (EC 1.11.1.6)*

Catalase activity in the samples is measured using the method described in Baudhuin (1974), which is based on the formation of the yellow titanyl sulphate–H_2O_2 complex. Liver and kidney samples must be diluted (1/40 for liver and 1/10 for kidney), whereas heart and brain samples do not need to be diluted. After incubation for 10 min at 0°C and addition of the titanyl sulphate solution, measure the absorbance at 405 nm to evaluate how much of the initially added H_2O_2 is left. To calculate the activities, take into account that the reaction follows first-order kinetics and that one unit of enzyme is defined as the amount consuming 90% of the H_2O_2 present in a 50-ml reaction volume in 1 min.

Evaluation of the presence of contaminants is shown in Table II.

C. Yield of Mitochondria and Normalisation Criteria

The yield of mitochondria depends on the source of the organelles. Typically we obtain 6–9 mg of mitochondrial protein per gram of starting tissue for the liver samples, which is 5–6 mg/g for kidney, 2–3 mg/g for heart, and 3–4.5 mg of mitochondrial protein per gram of tissue in brain samples. The yield can also be calculated by the amount of mitochondrial activity (cytochrome c oxidase and citrate synthase) recovered in preparations from the total homogenate. Table I shows values obtained for the different mitochondrial preparations. The yield of mitochondria evaluated this way varies from 8% of recovery in brain to about 25% in liver.

Classically, the way of normalising mitochondrial parameters is using protein content in the sample. However, mitochondrial protein content in the different preparations is very variable. In each kind of sample, the nature and amount of contaminants vary, and even the protein composition of mitochondria is different depending on their source. In this way, specific mitochondrial enzyme activities are very different among organs; this is due to their intrinsic differences in activity and also to the different protein content in each preparation (Table I). More recently, citrate synthase activity is often taken to normalise mitochondrial parameters (Trounce, 1996), particularly respiratory chain enzyme activities, because it is considered a measurement of mitochondrial volume. However, the intertissue variation on citrate synthase specific activities is also too high and its use for normalization when comparing different sources of organelles is again questionable; i.e., when calculating the cytochrome c oxidase/citrate synthase ratio, there are significant differences between organs, with liver apparently the highest cytochrome c oxidase activity (these can easily be calculated from Table I values).

Taking all this into account, we propose that the best way to normalise mitochondrial parameters when comparing organelles from different sources is to extract mitochondrial DNA from the organelle preparations and total cell DNA from the homogenate of the same samples and quantify the amount of nuclear DNA and mitochondrial DNA. The quantification of DNA is performed easily by conventional slot blot or Southern blot and hybridisation using a specific probe for each genome (Diez-Sanchez *et al.*, 2003). Routinely we use 12S rRNA for mtDNA and 18S rRNA for nDNA using the following rat polymerase chain reaction-generated probes.

1. 12S rRNA 617-bp amplification product (12S1 forward: caccgcggtcatacgattaacc; 12S2 reverse: ctaatttgaggagggtgacggg).
2. 18S rRNA 429-bp amplification product (18S1 forward: cctcgatgctcttagctgagtg: 18S2 reverse: cagctttgcaaccatactcccc).

In this way, the parameter/nuclear DNA ratio would represent a "per cell" or "per genome" estimation and the parameter/mtDNA a "per mitochondria" or "per mitochondrial DNA" estimation. Although the mtDNA copy number per cell varies among cell types, tissues, and physiological condition, it can be monitored easily by following the mtDNA/nDNA ratio.

D. Assessment of Functionality

Mitochondria obtained using the purification protocols described here have intact membranes and are coupled. This means that electron transfer among the inner membrane complexes takes place when there is phosphorylation of ADP by the ATP synthetase; this is the main way to dissipate the proton gradient between the intermembrane space and the matrix. Mitochondrial electron transfer can be measured by oxygen consumption using an oxygen electrode (Trounce, 1996). The respiratory control ratio (RCR) is a way to determine how coupled mitochondria are The consumption of oxygen by mitochondria in the presence of electron donors (substrates) and ADP, called state 3 respiration, is measured and then compared with the respiration rate when all the ADP has been phosphorylated (state 4). When there is no difference between state 3 and state 4 respiration (RCR = 1), mitochondria are completely uncoupled, whereas RCRs higher than 4 are indicative of tightly coupled mitochondria. Another parameter to evaluate coupling using the same measurements in the oxygen electrode is the P/O ratio, which gives the moles of synthesized ATP per atom of oxygen transformed to water during oxidative phosphorylation. Coupled mitochondria usually exhibit P/O ratios higher than 2.5, approaching 3 with NAD-linked substrates, and ratios higher than 1.8, approaching 2 with succinate (Palloti and Lenaz, 2001). A detailed explanation on oxygen electrode functioning can be found in Rickwood (1987).

1. Perform measurements in the oxygen electrode using MAITE medium where mitochondria are resuspended. The final volume in the electrode chamber is 1 ml.

2. Add 10 µl of 100 mg/ml BSA and either 20 µl of 500 m*M* glutamate and 25 µl of 100 m*M* malate when measuring RCR with glutamate and malate (NAD-

TABLE III RCR and P/O Ratios in Different Mitochondrial Preparations

Source of mitochondria	Glutamate + malate		Succinate	
	RCR	P/O ratio	RCR	P/O ratio
Liver	4.0–5.7	2.0–2.6	2.8–3.4	1.3–1.7
Kidney	2.3–4.6	1.7–2.3	2.1–3.5	1.6–1.9
Heart	4.9–7.4	2.9–3.4[a]	1.3	1.4–1.8
Brain[b] (total)	1.7–2.5	1.7–2.3	1.4	1.0–1.1
Brain[c] (PH-PART)	3.4	2.4	3.4	1.8

[a] The observation with some substrates of P/O ratios higher than the theoretical value 3 is attributed to substrate-level phosphorylation (Palloti and Lenza, 2001).

[b] Low values in the coupling parameters are usually found in mitochondrial preparations from brain and can be due to the presence of synaptosomes.

[c] These parameters improve substantially after further purification by phase partition (PH-PART). Data from López-Pérez (1994).

linked substrates) or, as an alternative, 20 µl of 500 m*M* succinate.

3. Add 0.5 to 1 mg of mitochondrial protein from freshly isolated mitochondria. In the case of heart mitochondria, 0.2 mg of protein is enough to perform the assay.

4. When the chamber is closed, add 100 nmol of ADP (10 µl of ADP 10 m*M*) to stimulate mitochondria and start state 3 respiration. This addition is repeated after mitochondria return to state 4 respiration.

Values for RCR and P/O for different mitochondrial preparations are given in Table III.

IV. COMMENTS AND RECOMMENDATIONS

We would like to make a particular comment on the nature of the less commonly evaluated contaminants in the mitochondrial preparations, whose presence is variable depending on their source and that has been frequently underscored in classical preparative or metabolic assays. In addition to their utility in bioenergetic and metabolic studies, isolated organelles provide a unique tool to investigate the synthesis and expression of mtDNA in conditions that very much resemble the *in vivo* enzyme/substrate proportions, ionic composition, and integrated activity of the metabolic and biogenetic processes (Enríquez e*t al*., 1996, 1999; Enriquez and Attardi, 1996; Fernandez-Vizarra *et al*., 2002).

In this type of assay the presence of contaminants can be relevant or negligible depending on the type of investigations to be performed. For example, only brain crude mitochondria preparations contain large myelin membrane debris that can be estimated by monitoring the 2′, 3′-cyclic nucleotide 3′-phosphohydrolase (Enriquez *et al*., 1990; Olafson *et al*., 1969). They do not seem to interfere with biogenetic analyses, but can contribute to the overall protein content (see later). In addition, this crude preparation contains synaptosomes (also enclosing mitochondria). Crude mitochondrial preparations are suitable for *in organello* transcription and replication analysis when labeled UTP or dNTPs are used, as well as for protein import assays, as nucleotides or peptides do not cross the plasma membrane of synaptosomes. However, when analyzing protein synthesis and amino acylation using labeled amino acids, one should keep in mind that amino acids are also imported by synaptosomes and used by their mitochondria. Therefore, if trying to evaluate the influence of specific factors in the mitochondrial protein synthesis, one has to be aware that a relevant portion of mitochondria are protected by a plasma membrane.

Other relevant contaminants, not considered very often, are residual but partially active biogenetic components of the nucleocytoplasmic machinery, such as cytoplasmic ribosomes, transcriptionally or replicative partially active nuclear rests, or cytoplasmic aminoacyl tRNA synthetases. The use of additional purification steps using density gradient purification could reduce the presence of some of these contaminants, but it is expensive, not suitable for large-scale preparations, and, most important, can affect the functionality of the purified organelles. Protein synthesis due to contaminant cytoplasmic ribosomes is not very relevant (Fernandez-Vizarra *et al*., 2002) and it is possible to eliminate it completely using drugs that specifically inhibit cytoplasmic protein synthesis without affecting mitoribosomes such as cycloheximide or emetine. In our hands, no detectable aminoacylation of cytoplasmic tRNAs is observed when using purified organelles from cultured cells (Enríquez, 1996). The same is true for transcription in any source of mitochondria tested (Andreu *et al*., 1998; Enríquez, 1999; Enriquez *et al*., 1991, 1996; Fernandez-Vizarra *et al*., 2002; Micol *et al*., 1997), but a background of nonmitochondrial DNA is labeled when mitochondria are prepared from exponential growing cultured cells (unpublished results). To avoid this, it is recommended to add DNase (or micrococcal nuclease) during the mtDNA replication assay, as mtDNA and mtRNAs are protected by the mitochondrial double membrane. Then, as the standard DNA isolation procedure, after incubations, includes a strong step of proteinase K digestion, the DNase is fully removed before breaking

of the mitochondria. In that way only mitochondrial DNA is labeled.

V. Pitfalls

1. Always keep mitochondrial preparations on ice while they are being isolated and until they are used for biogenetical analyses or for measurements in the oxygen electrode.

2. Invert the tubes where the mitochondria are kept every once in a while in order to maintain mitochondria in suspension, avoiding sedimentation. During the incubation for activity determination, mixing is essential, as sedimentation of the organelles can make them become permanently impaired in their biogenetic activities due to a lack of oxygenation.

3. Irreversible uncoupling of mitochondria during purification can occur and is found more often when isolating brain or heart mitochondria. This is likely due to the well-known uncoupling activity of fatty acids and could be prevented by the inclusion of fatty acid-free BSA in the purification buffer.

Acknowledgments

We thank Drs. Julio Montoya, Acisclo Pérez-Martos, and Manuel, José López-Pérez for their valuable input in our work and Santiago Morales for his technical assistance. Our research was supported by the Spanish Ministry of Education PM-99-0082 grant to JAE, by the Ramón y Cajal 2001 grant to PF-S, and by a Diputación General de Aragón (CONSID B015/2001) fellowship to EF-V.

Subcellular Fractionation Procedures and Metabolic Labeling Using [^{35}S]Sulfate to Isolate Dense Core Secretory Granules from Neuroendocrine Cell Lines

Sharon A. Tooze

I. INTRODUCTION

Subcellular fractionation techniques have been developed to allow isolation of a particular subcellular compartments. Typically subcellular fractionation is used as a starting point to characterize the composition of subcellular organelles, but has also been used frequently to provide membranes for cell-free assays that reconstitute a particular intracellular event or process.

Ideally, for both purposes (characterization and cell-free assays) the subcellular compartment should be purified to homogeneity. However, this is difficult to achieve, particularly when the starting material is from cell lines where amounts are limiting. Therefore, it is realistic to aim to achieve a highly enriched fraction (defined here as greater than 90% purity) with a good yield. In addition, it is important to carefully consider the purpose of the fractionation protocol as this will dictate how critical the purity is.

To study the formation of secretory granules in the PC12 cell line, a protocol was developed to identify nascent immature granules by optimizing their separation from the donor compartment, the Golgi complex (Tooze and Huttner, 1990). A combination of velocity-controlled differential and equilibrium density centrifugation achieved a separation of immature secretory granules and the *trans*-Golgi network (TGN). This protocol was also used to obtain a population highly enriched in immature secretory granules (ISG) and one highly enriched in mature secretory granules (MSG) (Tooze *et al.*, 1991). MSGs are easier to obtain in a more purified form as MSGs are denser than other subcellular compartments. This protocol has been used to characterise the ISG and MSG (Tooze *et al.*, 1991), study low pH-dependent prohormone processing (Urbé *et al.*, 1997), clathrin coat recruitment to ISGs (Dittié *et al.*, 1996), and the role of ADP-ribosylation factor (ARF) (Austin *et al.*, 2000), sorting of proteins in the ISG (Dittié *et al.*, 1999), cell-free homotypic fusion (Urbé *et al.*, 1998; Wendler *et al.*, 2001), and the recruitment of lipid kinases to ISGs (Panaretou and Tooze, 2002). This protocol has also been used by other researchers to investigate sorting sequences in regulated secretory proteins (Krömer *et al.*, 1996) and with, for example, the AtT20 cell line (Eaton *et al.*, 2000).

II. MATERIALS AND INSTRUMENTATION

PC12 cells are maintained in growth medium consisting of 10% horse serum, 5% fetal calf serum, and Dulbecco's modified Eagle's medium (DMEM) with 3.5 g/liter glucose, penicillin/streptomycin, and 4 m*M*

Copyright 2006, Elsevier Science (USA).
All rights reserved.

glutamine (note this is twice the standard concentration) under 10% CO_2. Reagents for cell culture are obtained from Sigma Aldrich and GIBCO.

PC12 cells are passaged once a week at a dilution of 1:6. For a standard granule preparation, nine, 245 × 245-mm confluent plates of PC12 cells are used. These plates are prepared from five, 175-cm^2 flasks harvested with trypsin, seeded, and grown for about 7 days or from nine, 175-cm^2 flasks harvested with trypsin, seeded, and grown for about 3 days.

All chemicals are available from Sigma-Aldrich, except sucrose (ultrapure grade Cat. 15503-02), which is from GIBCO.

A cell cracker (EMBL Workshop, EMBL Heidelberg, Germany) with a range of titanium balls. Assemble cell cracker with chosen ball, precool and wash cell cracker with 1 ml of homogenization buffer (HB)/protease inhibitor cocktail (pi) before use. For PC12 cells, use a 18-µm clearance.

Gradients are centrifuged in an SW40 rotor using Beckman ultraclear centrifuge tubes (Cat. No. 344060).

Velocity gradients are prepared using a BioComp gradient master (http://www.biocompinstruments.com), and equilibrium gradients are prepared using a Labconco Auto Densiflow gradient maker (http://www.labconco.com). Both velocity and equilibrium gradients are collected using the Auto Densiflow.

A cell scraper is made from a silicon rubber bung by cutting the bung with a single-sided razor blade first horizontally (across the widest part) and then vertically in half. The tip of a plastic 10-ml pipette is then inserted into the center of the cut bung.

III. PROCEDURES

A. Preparation of a Postnuclear Supernatant

Solutions

1. *Tris-buffered saline* (*TBS*): 137 m*M* NaCl, 4.5 m*M* KCl, 0.7 m*M* Na_2HPO_4, 25 m*M* Tris–HCl, pH 7.4
2. *Protease inhibitor (pi) cocktail*: 0.5 m*M* phenylmethylsulfonyl fluoride and 5-µg/ml leupeptin
3. *Homogenization buffer (HB)*: 0.25 *M* sucrose, 10 m*M* HEPES–KOH, pH 7.2, 1 m*M* EDTA, and 1 m*M* MgOAc

Steps

For preparation of sufficient postnuclear supernatant (PNS) to load six SW40 gradients, use nine 245 × 245-mm plates. All solutions must be at 4°C.

1. Place one 245 × 245-mm plate on ice.
2. Remove growth medium by decanting and wash gently twice with 40 ml TBS.
3. Wash each plate again with 40 ml TBS/pi.
4. Add 40 ml TBS/pi and remove PC12 cells from the plates by scraping with a cell scraper. Collect the suspension of cells from each plate into a 50-ml Falcon tube. Repeat for all nine plates.
5. Spin each tube for 7 min at 84 *g*. Remove supernatant and resuspend each pellet in 1 ml of HB/pi. Pool in a 50-ml Falcon tube containing 24 ml of HB/pi and divide into six 15-ml Falcon tubes.
6. Spin for 7 min at 500 *g*. Remove supernatant and resuspend each pellet in 700 µl HB/pi and pool all nine tubes of cell suspension into a 15-ml Falcon tube.
7. Using a 1-ml syringe with a 21- or 22-gauge needle, draw up 1 ml of cells and pass back and forth through the needle six to seven times. Check that cells are well dispersed by resuspending 5 µl of cells with 10 µl of trypan blue solution and monitoring by phase-contrast microscopy. Ensure that the cells are now dispersed uniformly and not still in clumps. A maximum of 20% of the cells should be permeable to trypan blue. Repeat until all the cells have been passed through the needle.
8. Using a 1-ml syringe and 21- or 22-gauge needle, draw up 1 ml of the cell suspension and place syringe on one port of the cell cracker. Place an empty syringe on the other port. Pass cells through chamber six to seven times. Check breakage with trypan blue as in step 7. Greater than 90% of the cells should be broken. Nuclei should be intact and spherical but free of subcellular membranes (see Tooze and Huttner, 1992).
9. Remove homogenate and repeat with remaining cell suspension. Rinse the cell cracker out with 1 ml of HB/pi. Pool all the homogenate into a 15-ml Falcon tube. Total volume will be between 9 and 10 ml.
10. Spin for 10 min at 1700 *g* to pellet nuclei. Remove postnuclear supernatant, avoiding the nuclear pellet. Because the interface between the supernatant and the pellet can be difficult to see, illuminate the tube from behind when removing the supernatant.
11. Respin the PNS for 5 min at 1700 *g* to ensure that all nuclear material is removed and collect the supernatant. Adjust volume if necessary to 9.0 ml.

B. Velocity Gradient Centrifugation

This method achieves separation of organelles by size rather than density. Thus, larger subcellular compartments will sediment faster during this centrifugation than smaller ones. This is the basis for the separation of ISGs and MSGs from the trans-Golgi

network (TGN). In particular, this step is essential for separation of ISGs from the TGN as these organelles have the same equilibrium density.

Solutions

Sucrose solutions: 0.3 *M* sucrose, 10 m*M* HEPES–KOH, pH 7.2, and 1.2 *M* sucrose, 10 m*M* HEPES–KOH, pH 7.2

Steps

1. Prepare the velocity gradients. Use 5.5 ml of 0.3 *M* sucrose and 6 ml of 1.2 *M* sucrose per gradient. Using the Biocomp gradient maker, perform two steps: step 1 for 10 min at a 50°C angle at 30 rpm and step 2 for 1 min at a 80°C angle at 12 rpm. If preparing the gradients manually, use a 15-ml gradient maker, gently mixing the heavy into the light. Using a narrow pipette, pump solution from the light chamber into the bottom of the tube and displace the solution upward with the heavier solutions.
2. Load 1.5 ml of PNS on top of each gradient. Spin at 25,000 rpm in a SW40 rotor at 4°C. Using maximum acceleration, allow centrifuge to reach 25,000 rpm and then spin for exactly 15 min with the brake applied at the end of the run.
3. Collect thirteen 1-ml fractions from the top. Fraction 1 will contain most of the soluble proteins from the PNS. Fractions 2–4 will contain the ISG and constitutive secretory vesicles (CSVs), fractions 5–7 will contain MSGs, and fractions 8–11 will contain TGN membranes. *Note*: There will be other subcellular membranes in these fractions so the ISGs, MSGs, and TGN fractions are only slightly enriched. Pool fractions 1–4 for preparation of ISGs and fractions 5–7 for preparation of MSGs.

C. Preparation of ISGs and MSGs by Equilibrium Gradient Centrifugation

This method achieves separation of organelles by density, allowing vesicles of the same size but different densities to be separated. ISG, which have an average diameter of 80 nm, can be separated Golgi-derived CSVs, which are reported to have a diameter of 50–200 nm (Salamero *et al*., 1990).

Solutions

Sucrose solutions: 0.8 *M* sucrose, 10 m*M* HEPES–KOH, pH 7.2; 1.0 *M* sucrose, 10 m*M* HEPES–KOH, pH 7.2; 1.2 *M* sucrose, 10 m*M* HEPES–KOH, pH 7.2; 1.4 *M* sucrose, 10 m*M* HEPES–KOH, pH 7.2; and 1.6 *M* sucrose, 10 m*M* HEPES–KOH, pH 7.2

Steps

1. Prepare equilibrium gradients. Pipette 1 ml of 1.6 *M* and then layer 2 ml of 1.4, 1.2, 1.0, and then 1.0 ml of 0.8 *M* sucrose into a SW40 tube, either by hand or using the Auto Densiflow, with probe moving upward.
2. Adjust pooled fractions from the velocity gradient to a final volume of 4 ml per gradient with 10 m*M* HEPES–KOH, pH 7.2. Load pooled fractions from velocity gradient onto prepared equilibrium gradients.
3. Spin gradients in a SW40 rotor at 25,000 rpm overnight or for at least 5.5 h at 4°C.
4. Collect twelve 1-ml fractions from the top of the gradient. If preparing ISGs, the ISGs will be found in fractions 7–9. If preparing MSGs, the MSGs will be found in fractions 10–12. These respective fractions can be pooled and aliquoted for storage for up to 6 months in liquid nitrogen.

D. Other Procedures

The centrifugation procedure can be checked by assaying for TGN, secretory granule, or other compartment-specific markers in each fraction from the velocity and equilibrium gradients. This can be done by Western blotting using antibodies to the marker proteins or by metabolic labelling. For the technique described earlier using PC12 cells, the most accurate method is posttranslational labelling of proteins with [^{35}S]sulfate on tyrosine residues (for a review, see Moore, 2003).

Protein tyrosine sulfation is a posttranslational modification found in some secretory proteins, including secretogranin II (SgII) and an unidentified constitutively secreted heparan sulphated proteoglycan (HSPG). The enzyme tyrosylprotein sulfotransferase responsible for sulfation is a resident TGN protein (Lee and Huttner, 1985). Thus, by incubating or pulsing the cells for a short period of time by the addition of [^{35}S]sulfate, proteins that contain the sulfation motif can be labelled in the TGN and can be used to identify TGN membranes. In addition, exit of sulphated proteins from the TGN into CSVs, which contain HSPG, and ISGs and MSGs, which contain SgII, can be followed accurately during the chase. Identification of CSV and ISGs by sulfate label of the specific markers, followed by subcellular fractionation, can be used to confirm that the cultured cells are correctly sorting regulated and constitutively secreted proteins into separate vesicles (Tooze and Huttner, 1990). Metabolic labelling with sulfate can also be applied more generally (Tooze, 1999). It is advisable to use a scaled down

version of the procedure described earlier to avoid having to use large amounts of radioactivity.

Solutions

1. *Labelling medium* (*sulfate-free DMEM*): DMEM is prepared by substituting $MgCl_2 \cdot 6H_2O$ for $MgSO_4 \cdot 7H_2O$ and reducing the normal concentration of cysteine and methionine to 1% of the original concentration; 0.1% dialysed horse serum; 0.05% dialysed fetal calf serum; and 2 m*M* glutamine. It is important not to include any sulphated antibiotics.
2. *[^{35}S]Sulfate* (*40–100 mCi/ml*): Amersham Biosciences (Cat. No. SJS.1).
3. *Chase medium*: growth medium supplemented with 1.6 m*M* $NaS0_4$.

Steps

To check the ability of PC12 cells to sort regulated proteins using the gradients described earlier, two 150-mm^2 dishes of PC12 cells should be prepared for each condition. Ideally the experiment should confirm the position of the TGN on the gradients, identified by a 5-min pulse of sulfate; the CSVs and ISGs, identified by a 5-min pulse followed by a 15-min chase; and the MSGs, identified by a 5-min pulse and 90-min chase. Alternatively, MSGs can be labelled using one-tenth the amount of [^{35}S]sulfate for 6 h and chased overnight.

1. Wash each 150-mm^2 dish once with labelling medium at 37°C. Replace with 20 ml labelling medium. Incubate for 20 min at 37°C to deplete endogenous sulfate.
2. Remove medium and replace with fresh medium at 37°C containing 1 mCi/ml [^{35}S]sulfate, or 0.1 mCi/ml for long-term MSG labelling. Incubate at 37°C for precisely 5 min. Dishes can be rocked gently to reduce the amount of labelling medium required. Five to 7 ml is sufficient when dishes are being rocked.
3. Remove labelling medium. To identify the TGN, transfer the dishes immediately to 4°C and add 10 ml of TBS at 4°C. To identify ISGs, add 20 ml chase medium at 37°C and return cells to incubator for 15 min. To label MSGs, add 20 ml chase medium at 37°C and return cells to incubator for 90 min. Alternatively, use the longer label-and-chase protocol for MSGs.
4. At the end of the chase period, transfer remaining dishes to 4°C, remove the chase medium, and add 10 ml TBS at 4°C.
5. Wash and harvest dishes as described previously. Pool the two dishes from each condition. Prepare a PNS as described earlier and load the PNS from both labelled 150-mm^2 dishes on one velocity gradient.
6. Collect thirteen 1-ml fractions from each gradient. Remove 30 µl from each fraction and analyse the [^{35}S]sulfate-labelled proteins by SDS–PAGE. For optimal resolution of SgII and HSPG, use a 7.5% gel.
7. Save the remaining material for equilibrium gradient centrifugation. Pool fractions 1–4 from the ISG gradient, and pool fractions 5–7 from the MSG gradient. Load each pool onto on an equilibrium gradient and continue as described in Section III.C.

IV. COMMENTS

1. It is possible to perform a cell-free budding assay to reconstitute the formation of ISGs from the TGN using this protocol and protocols described in Sections III.A and III.B.
2. The purity of ISGs and MSGs, while greater than 95% as judged by thin section electron microscopy, may allow assessment of the composition of these organelles by techniques such as two-dimensional gels or mass spectroscopy analysis using MUDPIT (Wu *et al*., 2003), for example. However, to acheive a purity approaching 100% and to confirm your results, additional techniques such as immunoisolation (Howell *et al*., 1989) with a compartment-specific marker are strongly advised.

V. PITFALLS

1. The PC12 cells are not passaged correctly and thus do not achieve maximum confluency, resulting in a very low yield of cells. The cells must be plated as single cell suspensions. This is best achieved by tituration using a flamed narrowed disposable glass pipette.
2. The cells are not completely homogenized, resulting in fewer broken cells as judged by trypan blue. This will result in a reduced yield.
3. The homogenate is very viscous. This is most likely a result of nuclei lysis during homogenization. A clean postnuclear supernatant cannot be obtained from this homogenate, and the experiment should be stopped as the subcellular organelles will not be separated properly on the gradients.

CHAPTER

12

Preparation of Synaptic Vesicles from Mammalian Brain

Johannes W. Hell and Reinhard Jahn

I. INTRODUCTION

Synaptic vesicles are secretory organelles that store neurotransmitters in presynaptic nerve endings. When an action potential arrives in the nerve terminal, the plasma membrane is depolarized, leading to the opening of voltage-gated Ca^{2+} channels. The rise in intracellular Ca^{2+} concentration leads to exocytosis of synaptic vesicles within a time interval that can be as short as 200 µs (reviewed by Südhof, 1995).

Synaptic vesicles possess several remarkable properties that distinguish them from most other organelles involved in membrane traffic. First, they are very abundant in brain tissue. Model calculations show that an average neuron contains approximately 10^6 synaptic vesicles, with a total of around 10^{17} in the human central nervous system (Jahn and Südhof, 1993). Approximately 5% of the protein in the brain is contributed by synaptic vesicles; thus, about a 20-fold enrichment from homogenate is sufficient to obtain a pure preparation. Second, synaptic vesicles are highly homogeneous in size and shape and, in addition, are smaller than most other organelles, with an average diameter of only 50 nm. Therefore, size-fractionation techniques can be applied for the isolation of synaptic vesicles. Third, synaptic vesicles do not contain a matrix of soluble proteins (Jahn and Südhof, 1993), as they recycle many times in the nerve terminal and thus can only be reloaded with nonpeptide transmitters by means of specific transport systems.

The study of synaptic vesicles has been facilitated by recent advances in understanding their protein composition. To date, more than half a dozen protein families have been shown to be localized specifically on the membrane of synaptic vesicles. With the exception of some variation due to isoforms, most of these proteins are residents of all synaptic vesicles irrespective of their neurotransmitter content or of the location of the neuron. These include synapsins, synaptophysins, synaptotagmins, SV2s, synaptobrevins/VAMPs, rabs, cysteine string proteins, synaptogyrin, and the subunits of the vacuolar proton pump (for a review, see Südhof, 1995). Rapid progress during the last few years has clarified the function of many of these proteins in membrane traffic. Synaptic vesicles are thus presently regarded as the best-characterized "model" trafficking organelle of eukaryotic cells (Südhof, 1995). Antibodies against synaptophysin and synaptobrevin/VAMP are available commercially from several sources and may be used as probes to assess synaptic vesicle purity. In addition, synaptic vesicles contain neurotransmitter transporters that are specific for neurons exhibiting the corresponding neurotransmitter phenotype. Transporters for the main neurotransmitters have been cloned and sequenced (Reimer *et al*., 2001).

Purification protocols for synaptic vesicles can be divided into three groups. The first group involves the preparation of isolated nerve terminals (synaptosomes) by differential centrifugation. The synaptosomes are subsequently lysed in order to release the synaptic vesicles. An advantage of this procedure is that small membrane fragments generated during homogenization are removed prior to vesicle extraction as synaptosomes sediment at lower *g* forces than these fragments. The first protocol described here belongs in this category. These protocols are laborious and result in relatively low yields, but the resulting synaptic vesicles preparations are of high purity. In the second group of protocols, synaptic vesicles are purified directly from homogenate, without prior isolation of synaptosomes.

Copyright 2006, Elsevier Science (USA).
All rights reserved.

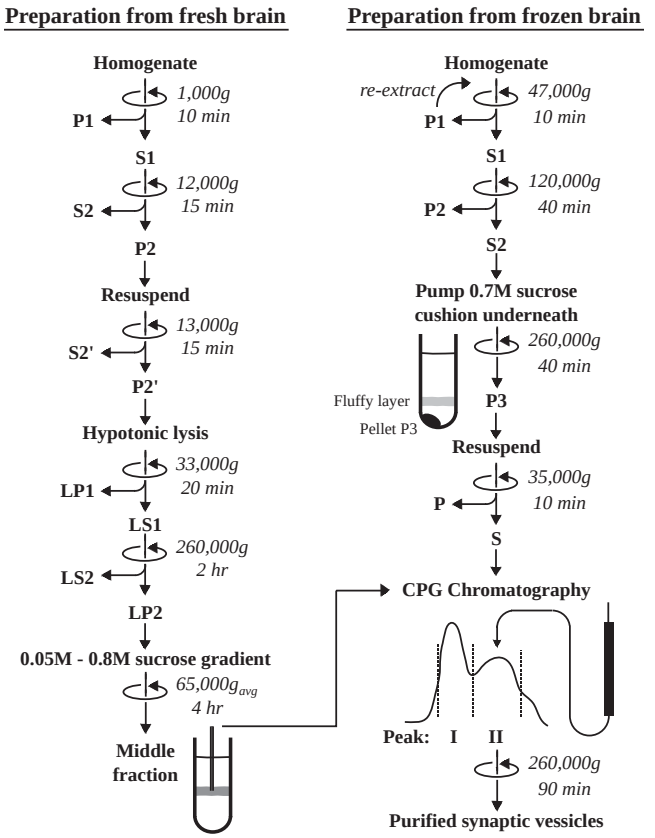

FIGURE 1 Flowchart depicting the main steps of the two preparation methods for synaptic vesicles described in the text. The final step for both methods is CPG chromatography.

In order to obtain high yields, initial homogenization is harsh in order to break up as many nerve terminals as possible, e.g., by freeze-powder homogenization, as described in the second procedure. In both cases, a combination of differential centrifugation, rate-zonal density gradient centrifugation or isopycnic density gradient centrifugation, and size-exclusion chromatography is employed for purification (Fig. 1). The third group involves immunoisolation using antibodies specific for synaptic vesicle proteins (see, e.g., Burger *et al*., 1989, Walch-Solimena *et al*., 1993). These procedures allow for the rapid isolation of small quantities of highly pure organelles from brain homogenates. However, they require access to large amounts of specific antibodies (preferably monoclonal antibodies) and are therefore not further discussed here.

II. MATERIALS AND INSTRUMENTATION

The following chemicals are used: HEPES (Research Products International, #H75030), sucrose (Sigma, # S-9378), glycine (Bio-Rad, 161-0718), phenylmethylsulfonyl fluoride (PMSF; ICN, #195381), pepstatin A (ICN, #195368), dimethyl sulfoxide (DMSO, Sigma, #D-8779), and controlled pore glass beads (CPG Inc., see Appendix). Note that the standard reagents can also be obtained from other sources.

The following instrumentation is required: loose-fitting, motor-driven glass–Teflon homogenizer (Braun, Melsungen, Germany), cooled centrifuge [Sorvall RC5 (DuPont) or comparable, SS34 rotor], ultracentrifuge with fixed angle and swing-out rotors [Beckman L80 (Beckman Instruments) or comparable, Ti70 or Ti50.2 rotor, SW-28 rotor, Ti 45 rotor] and corresponding tubes, equipment for column chromatography (peristaltic pump, UV monitor, fraction collector), gradient mixer for forming continuous sucrose gradients, filtration device for the filtration of buffers using 0.45-μ membranes (Millipore), and glass columns (see Appendix).

III. PROCEDURES

A. Preparation of Synaptic Vesicles from Synaptosomes

In this protocol (Nagy *et al*., 1976; Huttner *et al*., 1983), a crude synaptosomal fraction (P2) is first isolated by differential centrifugation. The synaptosomes are then lysed by osmotic shock and synaptic vesicles are released into the medium. After removal of synaptosomal fragments and large membranes, synaptic vesicles are sedimented by high-speed centrifugation. The resulting pellet, already five- to sixfold enriched in synaptic vesicles, is then purified further by sucrose velocity-density gradient centrifugation and size-exclusion chromatography on controlled pore glass beads (CPG). This procedure is the standard method for obtaining synaptic vesicles of the highest purity, with less than 5% contamination as judged by electron microscopy and biochemical analysis. This preparation does contain, however, endosomes derived from nerve terminals and decoated coated vesicles that lost their clathrin but retained adaptors. The degree of this contamination is probably minor but cannot be quantified easily.

Solutions

1. *Homogenization buffer*: 320 m*M* sucrose, 4 m*M* HEPES–NaOH, pH 7.3 (HEPES is optional; we found no difference when the buffer is omitted. Other buffers such as MES and slightly lower pH are also acceptable).

2. *1 M HEPES-NaOH, pH 7.4*
3. *40 mM sucrose*
4. *50 mM sucrose*
5. *800 mM sucrose*
6. *Glycine buffer*: 300 m*M* glycine, 5 m*M* HEPES–KOH, pH 7.4, degassed and filtered through a 0.45-µm filter
7. *Protease inhibitors*: 1 mg/ml pepstatin A in DMSO and 200 m*M* PMSF in dry ethanol. Keep stocks at room temperature. Add 1/1000 volume where indicated. Note that PMSF is unstable in aqueous solutions and should not be added to buffers prior to use. The PMSF stock solution should be prepared fresh every day.

Steps

After collecting the brains, all steps are carried out on ice or at 4°C.

1. Decapitate 20 rats (about 2 months old; 180–200 g body weight), remove the brains, avoiding myelin-rich areas such as corpus callosum or medulla oblongata, place into 180 ml ice-cold homogenization buffer, and homogenize in several aliquots with a loose-fitting glass Teflon homogenizer (nine strokes, 900 rpm). Add protease inhibitors.
2. Centrifuge the homogenate for 10 min at 1000 *g*max (2700 rpm, Sorval SS34 rotor), discard the resulting pellet (P1) containing large cell fragments and nuclei, and collect the supernatant (S1).
3. Centrifuge S1 for 15 min at 12,000 *g*max (10,000 rpm; SS34 rotor); remove the supernatant (S2) containing small cell fragments such as microsomes or small myelin fragments and soluble proteins. Wash the pellet (P2) by carefully resuspending in 120 ml homogenization buffer (pipette, avoiding the dark brown bottom part of the pellet that consists mainly of mitochondria) and recentrifuging at 13,000 *g*max (11,000 rpm, SS34 rotor); discard the supernatant (S2′). The resulting pellet (P2′) represents a crude synaptosomal fraction.
4. To release synaptic vesicles from the synaptosomes, resuspend P2′ in homogenization buffer to yield a final volume of 12 ml. Transfer this fraction into a glass–Teflon homogenizer, add 9 volumes (108 ml) ice-cold water and perform three up-and-down strokes at 2000 rpm. Add 1 ml of 1 *M* HEPES–NaOH, pH 7.4, and protease inhibitors.
5. Centrifuge the suspension for 20 min at 33,000 *g*max (16,500 rpm, SS34 rotor) to yield the lysate pellet (LP1) and the lysate supernatant (LS1). Using an electric pipetter, carefully remove LS1 immediately after the end of the run without disturbing LP1. It is crucial that LS1 does not get contaminated even with traces of membrane fragments from LP1 (rather, leave 1–2 ml behind in the tube). Contaminating LS1 with LP1 is the most common problem, which significantly reduces the purity of the final vesicle fraction.
6. Centrifuge LS1 for 2 h at 260,000 *g*max (50,000 rpm, Beckman 60Ti or comparable rotor). Discard the supernatant (LS2) and resuspend the pellet (LP2) in 6 ml of 40 m*M* sucrose utilizing a small, tight-fitting glass–Teflon homogenizer. Extrude the resuspended sample consecutively through a 23- and a 27-gauge hypodermic needle attached to a 10-ml syringe (avoid air bubbles).
7. Layer the suspension (3-ml aliquots) on top of a linear sucrose gradient formed from 18.5 ml of 800 m*M* sucrose and 18.5 ml of 50 m*M* sucrose (prepare two tubes containing identical gradients in advance) and centrifuge for 4 h at 65,000 *g*av (25,000 rpm, Beckman SW 28 rotor). After the run, a turbid (white-opaque) zone is visible in the middle of the gradient (in the range of 200 to 400 m*M* sucrose, best seen when viewed against a black background with light from the top). Collect these bands with the aid of a glass capillary connected to a peristaltic pump, yielding a combined volume of 25–30 ml. This fraction represents synaptic vesicles that are 8- to 10-fold enriched over the homogenate (Jahn *et al*., 1985). Note that synaptic vesicles do not reach isopycnic equilibrium during this velocity gradient-type centrifugation. Changes of angular velocity or of the run time will therefore affect the result.
8. Equilibrate a CPG-3000 column (180 × 2 cm, see Appendix) with 10 column volumes of glycine buffer (optimally done overnight before the preparation). Load the sample on top of the resin and overlay it carefully with glycine buffer without diluting the sample. Elute the column with glycine buffer at a flow rate of 40 ml/h, collecting 6- to 8-ml fractions. Monitor protein efflux at 280 nm. The first peak contains plasma membranes and some microsomes and is usually smaller than the second peak containing synaptic vesicles. If no separation into two clearly distinguishable peaks is obtained, the column may need to be repacked. Fractions of the second peak are pooled and centrifuged for 90 min at 260,000 *g*max (50,000 rpm, Beckman 60Ti rotor). The synaptic vesicle pellet should have a glassy appearance, being completely transparent and colorless. Resuspend it in the desired buffer as in step 6. The suspension is frozen rapidly (e.g., in liquid nitrogen) and stored at –70°C. Yields are typically between 2 and 3 mg of protein, based on one of the commercially available Coomassie blue protein determination kits.

Note: Size-exclusion chromatography on glyceryl-coated CPG beads or on Sephacryl S-1000 is omitted in

many protocols and, if applied, is the last step of the procedure. Both resins have a relatively low capacity, do not tolerate overloading, and require some experience in their use. Sephacryl S-1000 has higher separation capacity than CPG per gel volume, but the columns have low flow rates, do not tolerate increased pressure, and have a tendency to adsorb proteins and membrane particles, particularly during the first few separation runs in the life of the column. CPG columns are more difficult to set up and tolerate less material. However, glass beads are noncompressible and allow high flow rates, shortening separation times substantially. The experimenter who does not shy away from the effort to set up a large CPG column is rewarded with highly reliable results for many runs and exceptionally clean synaptic vesicle preparations. We utilized a CPG-3000 column (3 × 180 cm) continuously for 10 years for more than 200 synaptic vesicles preparations, with only a few repackings required, usually caused by experimental error (running dry). Column profiles and synaptic vesicle purity were highly reproducible.

B. Preparation of Synaptic Vesicles from Frozen Brain

This procedure starts with a harsh homogenization of frozen brains to efficiently break up the nerve terminals, thus releasing synaptic vesicles. Frozen brains are ground in a precooled mortar to yield a fine powder. This treatment does not affect the function or integrity of the small synaptic vesicles, but larger membrane structures are ruptured. After resuspending the tissue powder in sucrose solution, most of the cell fragments are removed by centrifugation with low and intermediate angular velocities, leaving synaptic vesicles in the supernatant. Synaptic vesicles are then sedimented at high speed through a cushion of 0.7 *M* sucrose, removing soluble proteins and membrane contaminants of lower buoyant density (mostly myelin). Synaptic vesicles are five- to sixfold enriched in the pellet and can be purified further by CPG chromatography.

The final enrichment factor for synaptic vesicles purified by this protocol is 15–20 (Hell *et al*., 1988), somewhat lower than in the previous method. However, there are several advantages. First, the tissue can be collected before the experiment and can be stored in liquid nitrogen for more than 1 year, allowing more efficient use of experimental animals. Second, the yield is severalfold higher under optimal conditions than the yield of the preparation from synaptosomes. Third, the procedure is faster, requiring only 12 h for completion, thereby allowing for higher activity of various synaptic vesicle functions such as neurotransmitter uptake.

Solutions

1. *Homogenization buffer:* 320 m*M* sucrose, degassed
2. *700 mM sucrose:* 700 m*M* sucrose and 10 m*M* HEPES–KOH, pH 7.3
3. *Resuspension buffer:* 320 m*M* sucrose and 10 m*M* HEPES–KOH, pH 7.3
4. *Glycine buffer:* 300 m*M* glycine and 5 m*M* HEPES–KOH, pH 7.3, degassed
5. *Protease inhibitors:* 1 mg/ml pepstatin A dissolved in DMSO and 200 m*M* PMSF in dry ethanol; add 1/1000 volume where indicated

Steps

After powdering the frozen brains, all steps are carried out on ice or at 4°C.

1. Decapitate 40 rats (2 months old, 180–200 g body weight); remove the brains, avoiding myelin-rich areas such as corpus callosum or medulla oblongata, and freeze immediately in liquid nitrogen. Immediate shock freezing is essential. In our experience, frozen brains available from commercial sources are usually not satisfactory for this reason.

2. To create a tissue powder, place the frozen brains into a porcelain mortar precooled with liquid nitrogen. Cover them with cheesecloth and break them carefully using a porcelain pestle. Grind to a fine powder. This step is crucial for obtaining high yields. After evaporation of the liquid N_2, suspend the powder in 320 ml ice-cold homogenization buffer (magnetic stirrer) and homogenize with a glass–Teflon homogenizer (eight strokes, 1000 rpm).

3. Centrifuge the homogenate for 10 min at 47,000 *g*max (20,000 rpm, Sorval SS-34 rotor). Collect the supernatant (S1). The pellet (P1) contains large cell fragments and nuclei, but also some entrapped synaptic vesicles. To increase the yield, reextract the pellet with 160 ml homogenization buffer by means of one slow stroke in the glass–Teflon homogenizer followed by centrifugation as described earlier. The resulting supernatant (S1′) is combined with S1.

4. Centrifuge S1 for 40 min at 120,000 *g*max (32,000 rpm, Beckman 45Ti rotor). Using an electric pipetter, collect the supernatant (S2) carefully without disturbing the pellet (P2). It is crucial that S2 is not contaminated with membrane fragments from the soft pellet P2. S2 should be clear with a reddish color. If it is turbid, it should be recentrifuged using the same conditions to remove contaminating membrane fragments.

5. To sediment synaptic vesicles through a sucrose cushion, fill 25-ml centrifuge tubes appropriate for a Beckman 60Ti rotor with 20 ml S2. Form the sucrose cushion by pumping 5.5 ml of 700 m*M* sucrose underneath S2 using a peristaltic pump and a glass capillary. Centrifuge for 2 h at 260,000 *g*max (50,000 rpm, Beckman 60Ti rotor). Remove the supernatant S3 and resuspend the pellet P3 in 6–10 ml resuspension buffer with a small, tight-fitting glass–Teflon homogenizer. Extrude the resuspended sample consecutively through a 23- and a 27-gauge hypodermic needle attached to a 10-ml syringe (avoid air bubbles). This sample represents a crude synaptic vesicles fraction. Clear the suspension by a short spin (10 min) at 35,000 *g*max (17,000 rpm, SS34) before loading onto the CPG-column.

6. Equilibrate a CPG column (see Appendix) with 10 column volumes of glycine buffer. Load the sample on top of the resin and overlay carefully with glycine buffer without disturbing the sample. A column of size 85 × 1.6 cm has a maximal capacity of 15 mg of protein, requiring several consecutive runs if all material is to be chromatographed. Elute the column with glycine buffer at a flow rate of 80 ml/h, collecting 2-ml fractions. Follow the elution of protein with a UV detector at 280 nm. The first peak, containing plasma membranes and microsomes, is usually larger than the second peak, containing synaptic vesicles. The two peaks are typically not completely separated in this protocol. The shoulder frequently observed at the end of the second peak represents soluble protein. Pool the fractions of the second peak and centrifuge for 2 h at 260,000 *g*max (50,000 rpm; 60Ti rotor). Resuspend the synaptic vesicle pellet in the desired buffer as described in step 5.

IV. COMMENTS

Scaling up or down is feasible but it should be kept in mind that changing rotors or using half-filled centrifuge tubes may affect yield and purity significantly and adversely. Contamination by other subcellular fractions (e.g., plasma membranes, mitochondria, endoplasmic reticulum) can be monitored conveniently by assaying for marker enzymes (Hell *et al*., 1988). In parallel to a decrease of these marker enzymes, proteins specific for synaptic vesicles, namely synaptophysin (p38), for which antibodies are available commercially (e.g., from Boehringer, Mannheim, Germany), should be enriched about 20- to 25-fold over homogenate (Jahn *et al*., 1985), best quantitated by immunoblotting.

Synaptobrevin is less reliable for quantification by SDS–PAGE/immunoblotting as histones present in the homogenate migrate alongside synaptobrevin/VAMP in nuclei-containing fractions (homogenate) and interfere with the signal, resulting in overestimation of the enrichment factor. The protein profile of the synaptic vesicles preparation as observed after SDS–PAGE exhibits a characteristic pattern (Huttner *et al*., 1983; Hell *et al*., 1988), with the prominent membrane proteins synaptobrevin/VAMP, synaptophysin (p38), synaptotagmin (p65), and synapsin I being clearly visible. Synaptic vesicle preparations contain various amounts of soluble proteins with affinity for membranes such as glyceraldehyde phosphate dehydrogenase, aldolase, actin, and tubulin. These proteins may be partially removed by a salt wash (resuspend synaptic vesicles in 160 m*M* KCl, 10 m*M* HEPES–KOH, pH 7.4, and centrifuge for 2 h at 50,000 rpm, 260,000 *g*max). However, this treatment also removes synaptic vesicle protein synapsin I.

The morphology of the synaptic vesicles fraction can be studied using electron microscopy (Fig. 2). Membranes can be visualized easily, e.g., by negative staining (Hell *et al*., 1988). Synaptic vesicle membranes are identified by their very uniform appearance (small vesicular profiles of approximately 50 nm diameter). Confirmation can also be obtained by immunogold labeling for the vesicle protein synaptophysin, which can be carried out conveniently on a single day when combined with negative staining (Jahn and Maycox, 1988).

APPENDIX: PREPARATION AND MAINTENANCE OF CPG COLUMNS

Controlled pore glass beads (CPG 3000, glycerol coated) are obtained from CPG Inc. Column dimensions may vary, but the diameter-to-length ratio should be at least 1 : 20–1 : 50. Use a sturdy, tension-free glass column that withstands mechanical stress during packing.

Steps

1. Resuspend CPG beads in distilled water and degas thoroughly.

2. Connect the column to a vibration device (e.g., an immobilized vortex apparatus) using a stiff, nonbreakable connection (e.g., a plastic cylinder). Attach the column with several clamps to a strong support such as a heavy stand or wall-mounted rack, with uneven spacing between the clamps to avoid the generation of waves with large amplitudes.

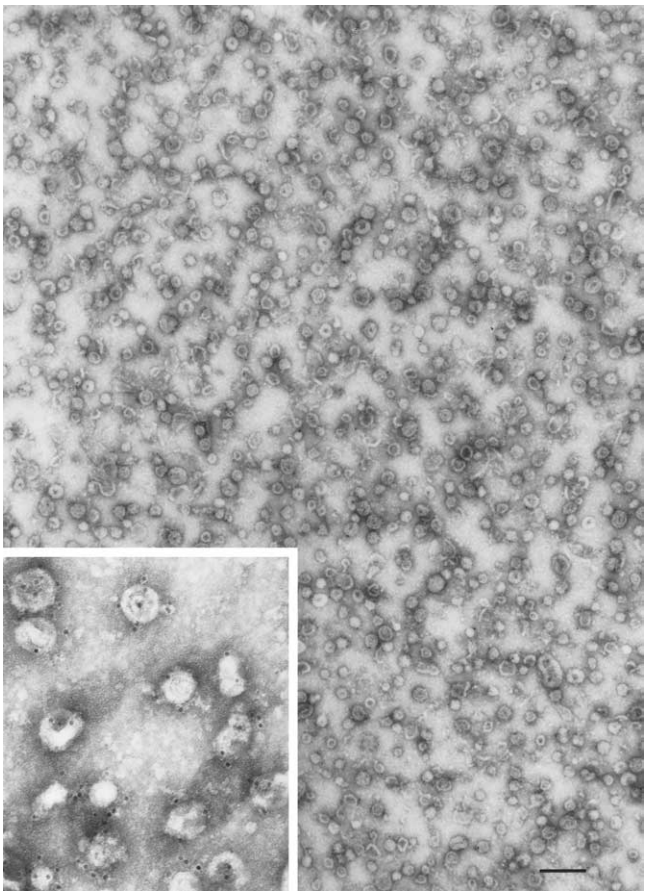

FIGURE 2 Electron micrograph showing a synaptic vesicle fraction purified by the procedure described in Section IIIB (negative staining). (Inset) Magnification of a field following immunogold labeling for the synaptic vesicle protein synaptophysin. For methods, see Jahn and Maycox (1988). Bar: 200 nm. Electron micrographs courtesy of Dr. Peter R. Maycox (London, UK).

3. Fill the column with the CPG bead slurry. Vibrate the column at a high-speed setting of the vortex apparatus and continue to add slurry. Avoid the generation of settled zones between additions. After filling, keep vibrating until the resin does not settle for at least 30 min. Packing of a small column (85 × 1.6 cm) and a large column (180 × 2 cm) requires approximately 4 and 10 h, respectively.

4. Equilibrate the column with 10 column volumes of column buffer.

5. For maintenance the column should be stored in buffer containing 0.02% sodium azide to prevent microbial growth. To avoid accumulation of debris, all samples should be cleared by a short centrifugation before loading and all buffers filtered by ultrafiltration. The column should not be allowed to run dry. If this occurs, the air may be removed by pumping large amounts of extensively degassed and temperature-equilibrated column buffer from the bottom through the column. However, if air bubbles remain, repacking is unavoidable. If contaminants accumulate (after 10–20 runs), the column can be cleaned by washing with 1–2 bed volumes of 4 *M* urea, buffered to pH 7.0, followed by extensive washing. The first run after urea cleaning results in lower yields.

Acknowledgment

The authors thank Dr. Duane D. Hall for preparation of Fig. 1.

CHAPTER

13

Preparation of Proteasomes

Keiji Tanaka, Hideki Yashiroda, and Nobuyuki Tanahashi

I. INTRODUCTION

The proteasome is a protein-destroying machine capable of degrading a variety of proteins involved in the regulation of diverse processes, such as the cell cycle, immune response, signaling cascades, and developmental programs in various eukaryotes (Hershko and Ciechanover, 1998; Kloetzel, 2001; Rock *et al*., 2002). Early studies identified the proteasome as a latent protease complex with a sedimentation coefficient of 20S, and it was accordingly named the 20S proteasome (Coux *et al*., 1996). The 20S proteasome is a barrel-like particle formed by the axial stacking of four rings made up of two outer α rings and two inner β rings, being associated in the order of αββα. The active sites reside in a chamber formed by the centers of the abutting β rings (Bochtler *et al*., 1999; Unno *et al*., 2002). The latency of the proteasome may be explained by the tertiary structure, as the center of the α ring is almost closed, preventing penetration of proteins into the inner aspect of the β ring on which the proteolytically active sites are located (Fig. 1). The 20S proteasome possesses a variety of catalytic centers that presumably contribute to the hydrolysis of multiple peptide bonds in single polypeptide substrates by a coordinated mechanism.

Subsequently, the latent 20S proteasome was demonstrated to act as a catalytic core of a large multisubunit proteolytic complex. To date, three protein factors that can stimulate 20S proteasome activity have been described. One is PA700 (also known as the 19S regulatory particle), which can be divided into lid and base complexes. The lid consists of multiple Rpn (non-ATPase) subunits, while the base consists of six proteasomal ATPases, Rpt1–Rpt6, and a few additional Rpn subunits (Finley *et al*., 1998). PA700 can associate with the 20S proteasome in an ATP-dependent manner to form the 26S proteasome with a molecular mass of ~2500 kDa, a eukaryotic ATP-dependent protease (Fig. 2), capable of degrading mainly proteins tagged with a polyubiquitin (Ub) chain, which functions as a degradation signal (Baumeister *et al*., 1998; Pickart, 2001).

Another activator of the 20S proteasome is PA28 (equivalent to the 11S regulator) (DeMartino and Slaughter, 1993; Rechsteiner *et al*., 2000). PA28 is attached independently to both ends of the central 20S proteasome ATP to form a football-like proteasome and markedly stimulates the activities of various peptidase of the 20S proteasome *in vitro*. However, unlike the 26S proteasome, PA28 fails to enhance the hydrolysis of large protein substrates with native or denatured structures, even when they are polyubiquitinated. PA28 is composed of three related proteins, named PA28α, PA28β, and PA28γ, with an overall identity of approximately 50% (Tanaka, 1998). Of these, PA28α and PA28β are induced greatly by a major immunomodulatory cytokine, interferon-γ (Tanaka and Kasahara, 1998). Intriguingly, further studies identified that the "hybrid proteasome," which comprises the 20S proteasome flanked by PA28 on one side and PA700 on the other, functions as a new ATP-dependent protease (Tanahashi *et al*., 2000).

The third proteasome activator is PA200, which is localized in the nucleus and is involved in DNA repair (Ustrell *et al*., 2002).

II. MATERIALS AND INSTRUMENTATION

Q-Sepharose (Cat. No. 17-1014-03), Q-Sepharose fast flow (Cat. No. 17-0510-10), Superdex 200 pg (Cat. No. 17-1043-01), Mono Q (Cat. No. 17-5166-01), and heparin–Sepharose CL-6B (Cat. No. 17-0467-09) can be purchased from Amersham. Bio-Gel A-1.5m (Cat. No. 151-0440) and hydroxylapatite Bio-Gel HTP (Cat. No. 130-0420) are from Bio-Rad. Polyethylene glycol 6000 (Cat. No. P-2139), ubiquitin (Ub, Cat. No. U-6253), succinyl-Leu-Leu-Val-Tyr-4-methyl-courmaryl-7-amide (Suc-LLVY-MCA, Cat. No. S-6510), and Supelco TSK-DEAE 650M is from Sigma. Amicon PM-10 and PM-30 membranes (Cat. No. 13132 and 13232) can be obtained from Millipore. Complete protease inhibitor (Cat. No. 1 697 498) is from Roche.

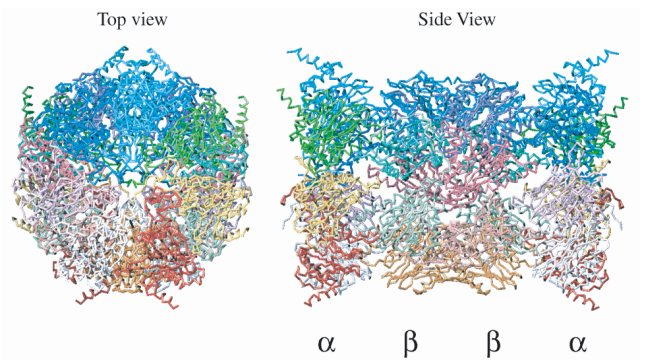

FIGURE 1 Crystal structure of the 20S proteasome from the bovine liver. For details, see Unno *et al*. (2002).

III. PROCEDURES

Solutions

1. *Buffer A:* 25 m*M* Tris–HCl (pH 7.5) containing 1 m*M* dithiothreitol (DTT) (or 10 m*M* 2-mercaptoethanol) and 20% glycerol

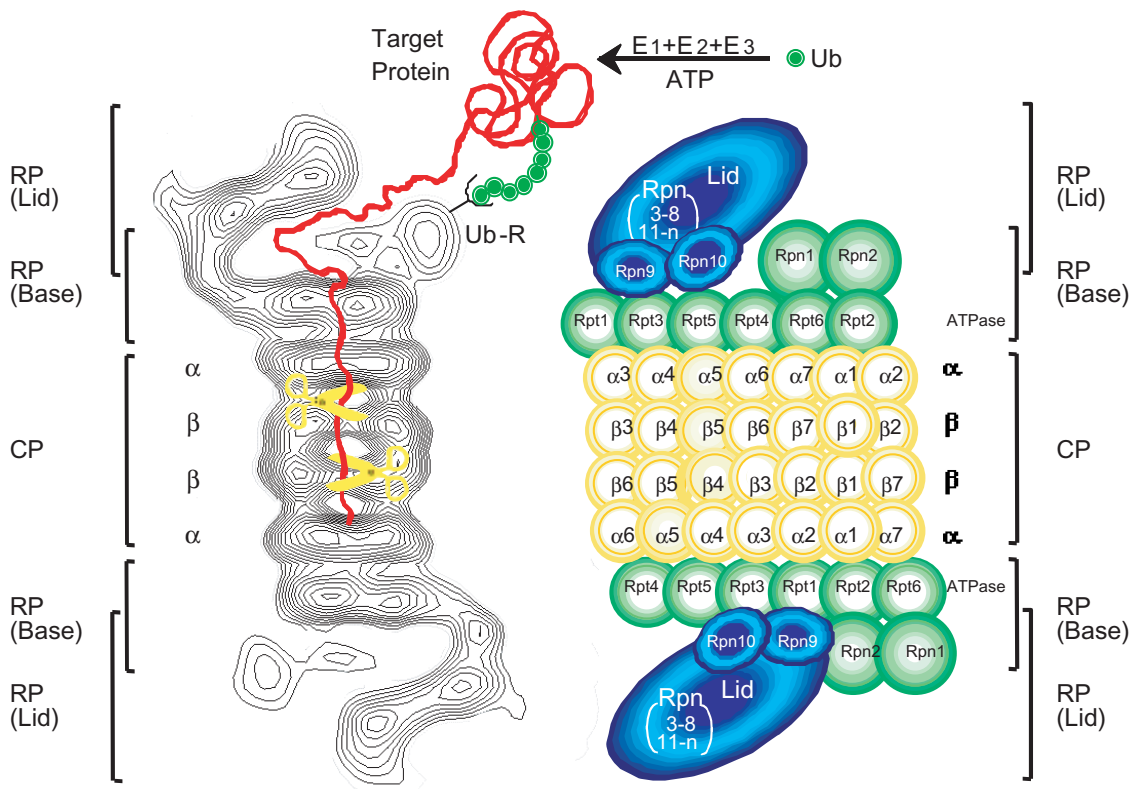

FIGURE 2 Molecular organization of the 26S proteasome. (Left): Averaged image based on electron micrographs of the complex of the 26S proteasome from rat. The α and β rings of the 20S proteasome are indicated. Photograph kindly provided by W. Baumeister. (Right): Schematic drawing of the subunit structure. Ub, ubiquitin; E1 (Ub-activating), E2 (Un-conjugating), and E3 (Ub-ligating) enzymes; CP, core particle; RP, regulatory particle; Rpn, RP non-ATPase; Rpt, RP triple ATPase; Ub-R, Ub receptor (poly-Ub binding subunit).

2. *Buffer B:* 10 m*M* phosphate buffer (pH 6.8) containing 1 m*M* DTT and 20% glycerol
3. *Buffer C:* Buffer A containing 0.5 m*M* ATP
4. *Buffer D:* Buffer B containing 5 m*M* ATP
5. *Buffer E:* 10 m*M* Tris–HCl (pH 7.0), 25 m*M* KCl, 10 m*M* NaCl, 1.1 m*M* $MgCl_2$, 0.1 m*M* EDTA, 1 m*M* DTT, and 10% glycerol
6. *Buffer F:* 10 m*M* Tris–HCl (pH 8.5), 25 m*M* KCl, 10 m*M* NaCl, 1.1 m*M* $MgCl_2$, 0.1 m*M* EDTA, 1 m*M* DTT, and 10% glycerol

A. Preparation of 20S Proteasomes

Procedures

1. Homogenize 200- to 400-g samples of animal tissues in 3 volumes of 25 m*M* Tris–HCl buffer (pH 7.5) containing 1 m*M* DTT and 0.25 *M* sucrose in a Potter–Elvehjem homogenizer. Centrifuge the homogenate for 1 h at 70,100 *g* and use the resulting supernatant as the crude extract.

2. Add glycerol at a final concentration of 20% to the crude extract. Then mix the extract with 500 g of Q-Sepharose that has been equilibrated with buffer A. Wash the Q-Sepharose with the same buffer on a Büchner funnel and transfer to a column (5 × 60 cm). Wash the column with buffer A, elute the material with 2 liters of a linear gradient of 0–0.8 *M* NaCl in the same buffer, and measure the activity of proteasomes using Suc-LLVY-MCA as a substrate (for details, see Section IV).

3. Pool fractions containing 20S proteasomes from the Q-Sepharose column and add 50% polyethylene glycol 6000 (adjust to pH 7.4) at a final concentration of 15% with gentle stirring. After 15 min, centrifuge the mixture at 10,000 *g* for 20 min, dissolve the resulting precipitate in a minimum volume (approximately 50 ml) of buffer A, and centrifuge at 20,000 *g* for 10 min to remove insoluble material.

4. Fractionate the material precipitated with polyethylene glycol on a Bio-Gel A-1.5m column (5 × 90 cm) in buffer A. Collect fractions of 10 ml and assay their proteasome activity. Pool fractions of 20S proteasomes.

5. Apply the active fractions from the Bio-Gel A-1.5m column directly to a column of hydroxylapatite equilibrated with buffer B. Wash the column with the same buffer and elute the material with 400 ml of a linear gradient of 10–300 m*M* phosphate. Collect fractions of 4 ml. Elute the 20S proteasomes with about 150 m*M* phosphate.

6. Combine the active fractions from the hydroxylapatite, dialyze against buffer A, and apply to a column of heparin–Sepharose CL-6B equilibrated with buffer A. Wash the column with the same buffer until the absorbance of the eluate at 280 nm returns to baseline. Then eluate with 200 ml of a linear gradient of 0–0.4 *M* NaCl in the same buffer and collect fractions of 2 ml. Eluate the 20S proteasomes with approximately 75 m*M* NaCl.

7. Pool the fractions with high proteasomal activity, dialyze against buffer A, and concentrate to about 5 mg/ml protein by ultrafiltration in an Amicon cell with a PM-10 membrane. The enzyme can be stored at –80°C for at least 2 to 3 years.

B. Preparation of 26S Proteasomes

Procedures

1. Homogenize 200- to 400-g samples of animal tissues in 3 volumes of 25 m*M* Tris–HCl buffer (pH 7.5) containing 1 m*M* DTT, 2 m*M* ATP, and 0.25 *M* sucrose in a Potter–Elvehjem homogenizer. Centrifuge the homogenate for 1 h at 70,100 *g* and use the resulting supernatant as the starting material.

2. Recentrifuge the crude supernatant for 5 h at 70,100 *g* to obtain 26S proteasomes, which precipitate almost completely. Dissolve the precipitate in a suitable volume (40–50 ml) of buffer C and centrifuge at 20,000 *g* for 30 min to remove insoluble material.

3. Apply samples of the preparation from step 2 to a Bio-Gel A-1.5m column (5 × 90 cm) in buffer C. Collect fractions of 10 ml and assay the 26S proteasome activity in the fractions (for the assay, see Section IV). Pool fractions of 26S proteasomes.

4. Add ATP at a final concentration of 5 m*M* to the pooled fractions of 26S proteasomes from the Bio-Gel A-1.5m column. Apply a sample directly to a hydroxylapatite column with a 50-ml bed volume that has been equilibrated with buffer D. Recover the 26S proteasomes in the flow-through fraction because they do not associate with this column in the presence of 5 m*M* ATP. Approximately 70% of the proteins, including free 20S proteasomes, bind to the hydroxylapatite resin.

5. Apply the flow-through fraction from the hydroxylapatite column to a Q-Sepharose column that has been equilibrated with buffer C without ATP and washed with 1 bed volume of buffer C. Wash the column with 5 bed volumes of buffer C and elute the adsorbed materials with 300 ml of a linear gradient of 0–0.8 *M* NaCl in the same buffer. Collect fractions of 3.0 ml of eluate. Proteins with the ability to degrade Suc-LLVY-MCA with or without 0.05% SDS are eluted with about 0.4 *M* NaCl as a single symmetrical peak. ATPase activity and the ATP-dependent activity necessary to degrade ^{125}I-labeled lysozyme–Ub conjugates are observed at the same position as the peptidase

activity and are eluted as superimposable symmetrical peaks, which suggests a specific association of ATPase with the 26S proteasome complex. Collect the protein in fractions exhibiting high activity.

6. Concentrate the 26S proteasome fraction obtained by Q-Sepharose chromatography to 2.0 mg/ml by ultrafiltration with an Amicon PM-30 membrane and subject samples of 2.0 mg of protein to 10–40% glycerol density gradient centrifugation (30 ml in buffer C containing 2 m*M* ATP). Centrifuge for 22 h at 82,200 *g* in a SW rotor and collect 1-ml fractions from the bottom of the centrifuge tube. A single major peak of peptidase activity, obtained in the absence of SDS, is eluted around fraction 15, but when the activity is assayed with 0.05% SDS, another small peak is observed around fraction 20. The latter peak corresponds to the elution position of 20S proteasomes. ATPase activity is observed at the same position as peptidase activity. Activity for ATP-dependent degradation of ^{125}I-labeled lysozyme–Ub conjugates is also observed as a single symmetrical peak, coinciding in position with the ATPase and peptidase activities in the absence of SDS. No significant ^{125}I-labeled lysozyme–Ub conjugate-degrading activity is detected in fractions of 20S proteasomes. Pool fractions 12–16 and store at –80°C.

Preparation of PA700

Steps for homogenization, ultracentrifugation, and Bio-Gel A-1.5m gel filtration are similar to those used for the preparation of 26S proteasomes. Apply the pooled fractions of the 26S proteasome from the Bio-Gel A-1.5m column directly to a hydroxylapatite column with a 50-ml bed volume that has been equilibrated with buffer C. Wash the column with the same buffer and elute the adsorbed materials with 300 ml of a linear gradient of 10–300 m*M* phosphate. Collect 3.0-ml fractions of eluate. Note that the 26S proteasome can be adsorbed in the hydroxylapatite column under a low concentration of ATP and that the 20S proteasome and PA700 regulatory complex can be eluted separately at different phosphate concentrations of approximately 150 and 50 m*M*, respectively. The 20S proteasome is detected by measuring the Suc-LLVY-MCA-degrading activity with 0.05% SDS as described earlier, whereas the PA700 complex is monitored by immunoblotting with antibodies against their subunits. Collect protein in fractions containing the PA700 complex from hydroxylapatite chromatography, concentrate it to 2.0 mg/ml by ultrafiltration with an Amicon PM-30 membrane, and subject samples of 1.0–2.0 mg of protein to 10–30% glycerol density gradient centrifugation, similar to step 6 used in preparation of the 26S proteasome. Collect 1-ml fractions from the bottom of the centrifuge tube. The PA700 complex can be monitored by ATPase activity and/or the aforementioned immunoblotting analysis. Pool fractions 14–18 containing PA700 complex and store at –80°C.

C. Preparation of Football Proteasomes

Procedures

1. Perfuse animal tissues with 25 m*M* Tris–HCl buffer (pH 7.5) containing 1 m*M* DTT, 1 m*M* pheryhrethylsulforyl fluoride (PMSF), 20 µg/ml E64, and 0.25 *M* sucrose and then homogenize in 3 volumes of the same buffer in a Potter–Elvehjem homogenizer. Centrifuge the homogenate for 1 h at 70,100 *g* and use the resulting supernatant as the crude extract.

2. Apply the crude extract directly to a Q-Sepharose column that has been equilibrated with buffer A. Wash the column with 5 bed volumes of buffer A and elute the adsorbed materials with a linear gradient of 0–0.8 *M* NaCl in the same buffer. For detection of PA28, the activator of 20S proteasome, the hydrolysis of Suc-LLVY-MCA is assayed after preincubation for 10 min at 4°C with approximately 0.5 µg of the latent 20S proteasome purified as described in Section IIIA. Eluate the PA28 activator with about 0.3 *M* NaCl. The endogenous activities of 20S and 26S proteasomes are monitored by assaying Suc-LLVY-MCA degradation with or without 0.05% SDS, respectively, which are coeluted at approximately 0.45 *M* NaCl.

3. Combine the PA28 fractions from the Q-Sepharose column, dialyze against buffer A, and apply it to a heparin–Sepharose CL-6B column that has been equilibrated in the same buffer. Recover PA28 in the flow-through fraction, as it does not bind to this resin.

4. Apply the flow-through fraction from the heparin–Sepharose CL-6B column directly to the hydroxylapatite column that has been equilibrated with buffer B. Wash the column with 5 bed volumes of the same buffer and elute the adsorbed material with a linear gradient of 10–200 m*M* phosphate. Pool fractions of PA28.

5. Concentrate the PA28 activator from the hydroxylapatite column to 2.0 mg/ml by ultrafiltration with an Amicon PM-10 membrane. Incubate the PA28 with the purified 20S proteasome (about 0.5 mg) for 30 min at 4°C to form the PA28–20S proteasome complex and subject 2.0-mg samples of protein to 10–40% glycerol density gradient centrifugation in a manner similar to step 6 used in preparation of the 26S proteasome. Note that excess PA28 should be used for association with the 20S proteasome because the PA28–20S proteasome complex is hardly separated from the 20S proteasome,

unlike the PA28 complex, by density gradient centrifugation analysis. Collect 1-ml fractions from the bottom of the centrifuge tube. The PA28–20S proteasome complex is monitored by assaying Suc-LLVY-MCA degrading activity. Pool fractions 14–18 and store at –80°C.

Preparation of PA28

Apply the PA28–20S proteasome complex from the glycerol density gradient centrifugation, the final material for preparation of football proteasomes, directly to a Q-Sepharose column that has been equilibrated in buffer A and wash extensively with the same buffer. Elute the adsorbed material with a linear gradient of 0–0.8 *M* NaCl in the same buffer because the 20S proteasome and PA28 are separated by this column operation. Eluate the PA28 activator with about 0.3 *M* NaCl (for details, see step 2). Pool fractions containing PA28 and store at –80°C.

Preparation of Hybrid Proteasomes

Hybrid proteasomes can be reconstituted by purified PA28 (or recombinant PA28α) and 26S proteasomes. Incubate 26S proteasomes (single- and double-capped PA700–20S proteasome complexes) with PA28 or PA28α at 37°C for 15–30 min in 20 m*M* Tris–HCl (pH 7.5) buffer containing 2 m*M* ATP, 5 m*M* $MgCl_2$, and 1 m*M* EDTA (Kopp *et al.*, 2001; Cascio *et al.*, 2001).

D. Preparation of PA200

Procedures

1. Homogenize a 125-g sample of animal tissues in 2.4 volumes (300 ml) of 10 m*M* Tris–HCl buffer (pH 7.5) containing 1 m*M* DTT, 0.25% Triton X-100, and three Complete protease inhibitor tablets in a Waring blender. Centrifuge the homogenate for 1 h at 100,000 *g* and use the resulting supernatant as the crude extract.

2. Apply the crude extract (400 ml) directly to TSK-DEAE (1.6 × 50 cm) that has been equilibrated with buffer E. Wash the column with buffer E and elute the material with a 1 liter linear gradient from 35 to 300 m*M* KCl in the same buffer. The proteasome activity is detected by measuring the Suc-LLVY-MCA-degrading activity. Monitor PA200 by immunoblotting with antibody PA200.

3. Dilute pool fractions containing PA200 from the DEAE column by twofold with buffer F and apply to 5 ml of Q-Sepharose fast flow resin equilibrated with buffer F. Elute bound proteins with 10 ml of 0.5 *M* KCl in the same buffer.

4. Apply the elution fractions from Q-Sepharose resin to a Superdex 200-pg (2.6 × 60 cm) column that has been equilibrated with buffer E containing 250 m*M* KCl and 5% glycerol. Pool fractions containing PA200.

5. Dilute fractions from the size column threefold with 5% glycerol in buffer F and apply to a Mono Q column (0.5 × 5 cm). Wash the column with the same buffer and resolve in 12 column volumes at 30 m*M*/ml from 35 to 200 m*M* KCl and then reduce the gradient to 20 m*M*/ml from 200–400 m*M* KCl and increase to 30 m*M*/ml from 400–500 m*M* KCl.

6. Subject samples of the Mono Q pools to 5–20% glycerol density gradient centrifugation (30 ml in buffer E containing Complete protease inhibitor tablets). Centrifuge for 19 h at 85,500 g in a SW28 rotor and collect 1-ml fractions from the bottom of the centrifuge tube. Monitor PA200 by measuring Suc-LLVY-MCA degradation for incubation of indicated fractions with 200 ng of purified proteasome and/or an immunoblotting analysis. Pool fractions containing PA200 and store at –80°C.

IV. COMMENTS

Various fluorogenic peptides are suitable for the measurement of 20S proteasomal activity because proteasomes show broad substrate specificity. However, Suc-LLVY-MCA is recommended as a sensitive substrate. Latent 20S proteasomes can be activated in various ways (Coux *et al.*, 1996). We recommend the use of SDS at low concentrations of 0.02–0.08% for the activation of Suc-LLVY-MCA breakdown; the optimal concentration depends on the enzyme source and the protein concentration used. The fluorogenic peptide (Suc-LLVY-MCA) can be used for assay of PA700–, PA28–, PA200–20S proteasome complexes, but these are active without any treatment, unlike latent 20S proteasomes. For a specific assay, ATP-dependent degradation of polyubiquitinated ^{125}I-labeled lysozyme should be measured, although such an assay is not easy because three kinds of enzymes, E1 (Ub-activating), E2 (Ub-conjugating), and E3 (Ub-ligating) must be purified for the *in vitro* preparation of ubiquitinated substrate (for the procedures, see Tamura *et al.*, 1991). There are various E2 and E3 enzymes. Most of them have not yet been characterized for use in *in vitro*-reconstituted proteolytic systems, so it is difficult to prepare large amounts of ubiquitinated proteins for use as substrates for 26S proteasomes. Therefore, for quantitative and sensitive measurement of ATP-dependent proteolysis

activity *in vitro* in mammalian cells, ornithine decarboxylase (ODC) is a useful substrate. ODC is the only known natural substrate independent of ubiquitination for recognition and degradation by 26S proteasomes and hybrid proteasomes. Antizyme (AZ), an ODC inhibitory protein, however, is needed for the process instead of Ub, but both ODC and AZ, required for this *in vitro* degradation assay, are available as recombinant proteins (Murakami *et al*., 1999; Tanahashi *et al*., 2000). Note that AZ is not present in lower organisms, such as yeasts, and thus this assay is not fit for these cells. It is also possible that their purification is monitored by measuring ATPase activity at later steps of their purification, since the 26S proteasome and PA700 regulator complex have intrinsic ATPase activity.

Proteasomes have been purified from a variety of eukaryotic cells by many investigators. Many purification methods have been reported, but no special techniques are necessary because 20S proteasomes are very stable and abundant in cells, constituting 0.5–1.0% of the total cellular proteins. The procedures used for the purification of 20S proteasomes obviously differ, depending on whether they are small or large operations. For their isolation from small amounts of biological materials, such as cultured cells, 10–40% glycerol density gradient centrifugation analysis is very effective. 20S proteasomes are present in a latent form in cells and can be isolated in this form in the presence of 20% glycerol. For their isolation in high yield, a key point is to keep them in their latent form because their activation results in autolytic loss of a certain subunit(s) and marked reduction of enzymatic activities, particularly their hydrolyses of various proteins. Accordingly, all buffers used contain 10–20% glycerol as a stabilizer. Furthermore, a reducing agent is required because 20S proteasomes precipitate in its absence. All purification procedures are performed at 4°C, but operations in a high-performance liquid chromatography (HPLC) apparatus can be carried out within a few hours at room temperature.

For purification of the 26S proteasome, ATP (0.5 or 2 m*M*), together with 20% glycerol and 1 m*M* DTT, should be added to all solutions used because they strongly stabilize the 26S proteasome complex; the purified enzyme is stable during storage at –70°C for at least 6 months in the presence of 2 m*M* ATP and 20% glycerol. Other drastic chromatographs should be avoided because these operations may result in dissociation of the 26S complex into its constituents. Alternative methods of purification of the PA28 and PA700 regulatory complexes have been reviewed by DeMartino and Slaughter (1993).

It should be noted that the hybrid proteasome is prepared by an *in vitro* reconstitution system using purified 26S proteasomes and PA28 (Kopp *et al*., 2001; Cascio *et al*., 2001) because it is hardly separated from 26S proteasomes by conventional chromatographic techniques (Tanahashi *et al*., 2000). In addition, PA200 is found both in complexes of the homologous type PA200–20S proteasome-PA200 and in complexes that also contain PA700, as PA700-20S proteasome-PA200 (Ustrell *et al*., 2002). To date, the procedures to separate the diverse forms of active proteasomes individually from cells and tissues have not yet been established.

CHAPTER

14

Preparation of Cilia from Human Airway Epithelial Cells

Lawrence E. Ostrowski

I. INTRODUCTION

For many years, the biochemical analysis of cilia, and flagella has focused primarily on organisms that are easy to grow and maintain in the laboratory and from which axonemal structures can be isolated in large quantities with a high degree of purity. For example, the isolation of flagella from *Chlamydomonas* in response to pH shock was described as early as 1972 (Witman *et al*., 1972) and cilia were isolated from *Tetrahymena* using dibucaine in 1974 (Thompson *et al*., 1974). While studies of these and other organisms have provided a wealth of valuable information concerning the structure and function of these fascinating axonemal structures, it is clearly important to also investigate the structure, function, and regulation of mammalian, especially human, cilia and flagella. While the axoneme of mammalian sperm has been isolated by a number of techniques (e.g., San Agustin and Witman, 1995), only a few reports detail isolations of mammalian cilia from the airway. This probably reflects in part the difficulty of obtaining sufficient quantities of suitable starting material and the inherent difficulties encountered when working with whole tissues.

In the last several years, the techniques used for culturing airway epithelial cells from both animal and human tissue have improved significantly. When cultured at an air/liquid interface on a collagen matrix and provided with suitable media, these cells have been shown to undergo ciliogenesis *in vitro*. In addition, human cells can be expanded for one or two passages and maintain their ability to differentiate, thus increasing the number of ciliated cells obtained. By culturing human airway epithelial cells under these conditions and modifying a technique originally described by Hastie *et al*.(1986) for isolating cilia from porcine trachea, it is possible to routinely produce highly enriched preparations of human ciliary axonemes. Although these preparations are not completely free of contamination by other cellular structures, they are suitable for many biochemical studies (Zhang *et al*., 2002; Reed *et al*., 2000; Ostrowski *et al*., 2002; Kultgen *et al*., 2002). Because this procedure utilizes a detergent, most of the ciliary membranes and soluble proteins are removed during the isolation, and the recovered material consists primarily of ciliary axonemes and their attached structures (dynein arms, radial spokes, etc.). Modifications of the procedure have been described that allow for at least partial recovery of ciliary membranes (Hastie *et al*., 1990; Salathe *et al*., 1993) from *in vivo* samples; these have not yet been tested extensively in the *in vitro* model. It should also be emphasized that the starting material for this procedure is well-differentiated, heavily ciliated airway cultures (Fig. 1A) grown under the conditions described in detail by Bernacki *et al*. (1999) and Randell *et al*. (2001) (and references therein). If the cultures are not completely confluent and heavily ciliated, the resulting preparation often contains a significant amount of cellular debris. The use of a nonionic detergent in the presence of calcium causes the cilia to be removed from the cell at a point just above the apical membrane, leaving the basal bodies intact (Figs. 1B and 1C).

II. REAGENTS AND SOLUTIONS

Protease inhibitor cocktail (P8340), dithiothreitol (DTT, D-9779), and Triton X-100 (T-8787) are from

Copyright 2006, Elsevier Science (USA).
All rights reserved.

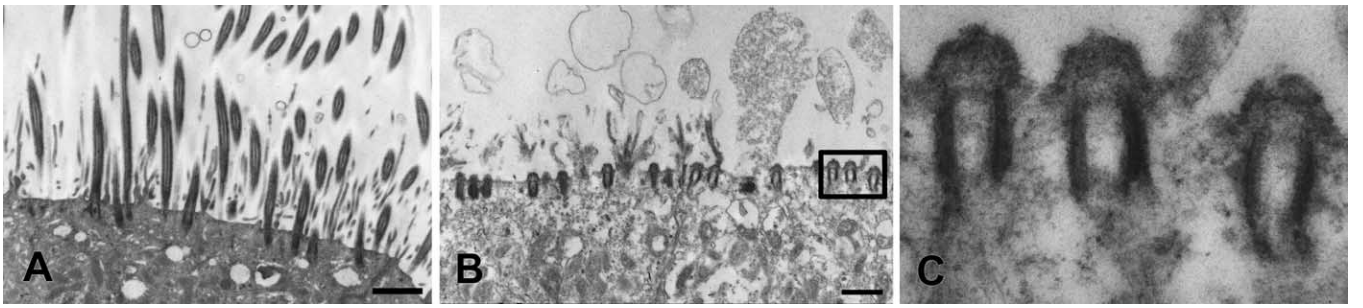

FIGURE 1 Electron micrographs of ciliated cultures of human airway epithelial cells before (A) and after (B and C) isolation of cilia. (A) A heavily ciliated culture after 6 weeks of culture. (B) A parallel culture fixed immediately after removal of cilia. Note the intact basal bodies, which are shown at higher magnification in C. Scale bar in A and B: 2.5 µm.

Sigma. β-Mercaptoethanol (0482) is from Amresco. The protease inhibitor cocktail is thawed upon arrival and frozen in small aliquots (100–200 µl). A 10% solution of Triton X-100 is made in sterile distilled water and stored in the refrigerator for no longer than 1 month. DTT is conveniently frozen in small aliquots at 100 m*M*. All other chemicals are standard laboratory reagents and can be obtained from most laboratory suppliers.

1. *Deciliation buffer (DB)*: 10 m*M* Tris–HCl (pH 7.5), 50 m*M* NaCl, 10 m*M* $CaCl_2$, 1 m*M* EDTA, 0.1% Triton X-100, 7 m*M* β-mercaptoethanol, and 1% protease inhibitor cocktail. Prepare a stock solution *without* protease inhibitor, β-mercaptoethanol, or Triton X-100. Sterile filter and store in the refrigerator. Before starting the procedure, add to 4.9 ml of the stock solution 50 µl of freshly thawed protease inhibitor cocktail, 50 µl of 10% Triton X-100, and 2.45 µl of β-mercaptoethanol.

2. *Resuspension buffer (RB)*: 30 m*M* HEPES (pH 7.3), 25 m*M* NaCl, 5 m*M* $MgSO_4$, 1 m*M* EGTA, 0.1 m*M* EDTA, 1 m*M* DTT, and 1% protease inhibitor cocktail. Prepare a 10× stock solution *without* protease inhibitor and DTT (300 m*M* HEPES, 250 m*M* NaCl, 50 m*M* $MgSO_4$,10 m*M* EGTA, 1 m*M* EDTA), sterile filter, and store in the refrigerator. Before starting the isolation procedure, dilute an aliquot to 1X with sterile water. To 4.9 ml of diluted stock, add 50 µl of freshly thawed protease inhibitor cocktail and 50 µl of freshly thawed 100 m*M* DTT.

III. PROCEDURE

As noted earlier, this procedure starts with heavily ciliated cultures of human airway epithelial cells. Cilia can be isolated from four 30-mm Millicell-CM culture inserts (PICM03050; Millipore) at one time. The inserts are first transferred to a six-well plate for ease of manipulation. Once started, the procedure should be carried out quickly.

1. Gently wash the mucus from the apical surface of the culture with at least two rinses of 2 ml of chilled phosphate-buffered saline (PBS). Add the PBS to the surface of the culture, swirl gently, and aspirate. If the cultures are producing large amounts of mucus, perform additional washes until the visible mucus is removed. After the last wash, carefully aspirate as much fluid as possible from both apical and basolateral sides of the insert.
2. Add 300 µl of cold DB to each insert.
3. Cover the six-well plate and rock vigorously for 1 min. Tilt the plate from side to side so the solution flows back and forth. Occasionally swirling the plate so the solution washes around the edges helps remove cilia from this area of the insert. Tilt the plate slightly so that the solution collects on one edge and remove with a pipetter. Pool the solution containing the cilia from two inserts into one tube. Keep isolated cilia on ice.
4. Repeat steps 2 and 3. Pool the second collection of cilia with the first. There should be 1.2 ml per microcentrifuge tube.
5. Pellet any cellular debris by centrifuging at 1000 RCF for 1 min at 4°C. Carry out the remaining steps in a cold room.
6. Collect the cilia containing supernatant into a new tube. When starting with heavily ciliated cultures that are washed well, there will be only a very small pellet of debris, with some stringy material along the sides of the tube. Try to remove the supernatant without disturbing the pellet. We have found that spinning at higher speeds or for longer times pellets cilia

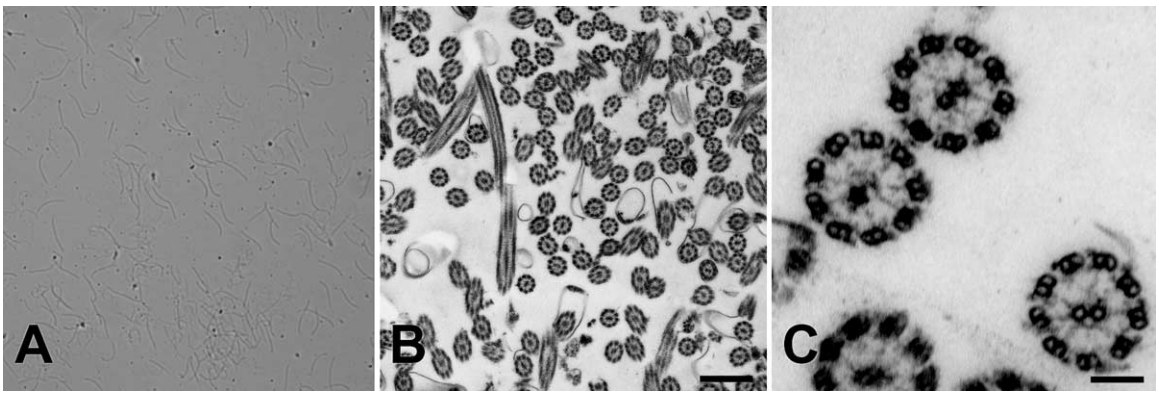

FIGURE 2 (A) Phase-contrast light micrograph of isolated cilia showing the appearance of the preparation after step 10 (original magnification, 400×). (B) Electron micrograph showing many intact ciliary axonemes after step 12. (C) Higher magnification of the same preparation as in B showing details of the isolated axonemes. Note the presence of radial spokes and dynein arms. Scale bars: 1.1 µm (B) and 0.15 µm (C).

as well as debris. Depending on the goal of the experiment (high purity or greatest recovery), the time of this centrifugation may be adjusted.

7. Pellet the ciliary axonemes by centrifugation at 12,000 RCF for 5 min at 4°C. After this centrifugation, a compact white pellet should be obtained. Carefully remove the supernatant and discard.

8. Resuspend the ciliary axonemes in 0.5 ml of RB buffer/insert (1.0 ml per tube). The pellet does not go into solution readily and must be pipetted gently to disrupt. While a homogeneous solution is desired, small clumps of material do not seem to affect the results.

9. Optional: To remove ciliary membranes, add 50 µl of 10% Triton-X 100 (final concentration of 0.5%) and incubate the solution on ice for 15 min. Repeat steps 7 and 8.

10. Withdraw and spot 5 µl of the solution onto a slide, coverslip, and examine by phase-contrast microscopy at 40× magnification. The axonemes should be readily visible as individual strands, with little cellular debris present (Fig. 2A).

11. If a protein determination is desired, remove an aliquot to a separate tube (typically 10%, or 100 µl). Pellet the cilia in both the sample and the protein determination tube by centrifugation at 12,000 RCF for 5 min at 4°C.

12. Remove as much of the supernatant as possible and freeze the pellets at –80°C until needed.

IV. NOTES

1. Protein concentration is determined using the BCA protein assay kit (Pierce, Rockford, IL). To solublize the axonemes, the pellet is dissolved in 0.5% SDS before performing the assay. The protein values obtained provide estimates of how much protein is in the cilia pellet. Although the amount of ciliary axonemes recovered varies with the degree of ciliated cell differentiation, each insert typically yields about 50 µg of protein.

2. The microscopic examination of the preparation in step 10 provides a simple and rapid qualitative estimate of the purity of the axonemes recovered.

3. Cilia isolated by this procedure can be reactivated by the addition of ATP to the cilia suspension obtained after step 10. ATP is added to an aliquot of the cilia and the reactivation is observed by phase-contrast microscopy (Hastie *et al*., 1986).

4. For detailed analysis, the pelleted axonemes can be fixed in 2% formaldehyde/2% glutaraldehyde with 0.5% tannic acid (Hayat, 1989) and examined by transmission electron microscopy. An example of a routine preparation of isolated axonemes examined by electron microscopy is shown in Figs. 2B and 2C.

5. A problem sometimes encountered has been the fragmentation of the axoneme into individual microtubules. While the cause of this phenomena has not been identified, proteolytic degradation or the use of old or improperly made solutions seems to be a likely cause. When this is observed, fresh solutions should be prepared and the procedure repeated to verify that intact axonemes are obtained.

Acknowledgments

This work was funded in part by NIH Grant HL63103 from the National Heart, Lung, and Blood Institute. The author thanks Dr. Scott Randell and the

members of the Cell and Tissue Core Facility for helpful discussions and providing the human airway epithelial cells, Kim Burns and the members of the Histology Core Facility for providing electron microscopy services, Kerri Kendrick for preparing the illustrations, and Dr. William Reed for helpful suggestions concerning the cilia isolation protocol.

Isolation of Nucleoli

Yun Wah Lam and Angus I. Lamond

I. INTRODUCTION

The human nucleolus is a prominent nuclear substructure assembled around tandemly repeated ribosomal genes (rDNA genes) on chromosomes 13, 14, 15, 21, and 22 and is the site of rDNA transcription and ribosome subunit synthesis (reviewed by Shaw and Jordan, 1995). Visualised under electron microscopy, the nucleolus is separated morphologically into three distinct substructures: fibrillar centres (FC), which are surrounded by dense fibrillar components (DFCs), and granular components (GC) (Shaw and Jordan, 1995). Its high density and structural stability allow effective purification using a straightforward procedure. Following the initial successful attempts to purify nucleoli from human tumour cells and rodent liver cells in the early 1960s (e.g., Muramatsu *et al*., 1963), numerous studies have reported on the characterization of isolated nucleoli. Nucleoli have been purified from a large variety of mammalian tissues, including liver, brain (Banks and Johnson, 1973), and thyroid (Voets *et al*., 1979), and from cells of nonmammalian species such as Xenopus (Saiga and Higashinakagawa, 1979) and Tetrahymena (e.g., Matsuura and Higashinakagawa, 1992). The ability to isolate nucleoli in large scale provides an excellent starting material for identifying, purifying, and studying nucleoli and has contributed significantly to the understanding of this nuclear structure.

The following protocol is based on one of the earliest published procedures for isolating nucleoli from cultured human cells (Muramatsu *et al*., 1963). This is a very robust procedure in which isolated nuclei are subjected to sonication whose power is adjusted so that nucleoli remain intact while the rest of nuclei are fragmented. Then nucleoli are isolated by spinning through a density gradient, exploiting their high density compared with other nuclear components. Detailed analysis using highly sensitive mass spectrometric techniques (Andersen *et al*., 2002) indicated that this method was a reproducible and efficient way to produce highly purified nucleoli.

II. PROCEDURES

Solutions

All solutions are supplemented with Complete protease inhibitor tablet (Roche, Cat. No. 1-873-580) at the final concentration of 1 tablet/50 ml).

Phosphate-buffered Saline (PBS)
Buffer A: 10 m*M* HEPES, pH 7.9, 10 m*M* KCl, 1.5 m*M* $MgCl_2$, 0.5 m*M* dithiothreitol (DTT)
S1 solution: 0.25 *M* sucrose and 10 m*M* $MgCl_2$
S2 solution: 0.35 *M* sucrose, 0.5 mM $MgCl_2$
S3 solution: 0.88 M Sucrose, 0.5 mM $MgCl_2$

See "Notes" on making stock sucrose solution.

Steps

1. Seed HeLa cells (ATCC number: CCL-2) onto 10 × 14-cm petri dishes and culture at 37°C in 5% CO_2 in Dulbecco's modified Eagle medium (DMEM) containing 4 m*M* L-glutamate, 4.5 mg/ml glucose, and 0.11 mg/ml sodium pyruvate (Invitrogen UK, Cat. No: 41966-029), supplemented with 100 U/ml penicillin and 100 µg/ml streptomycin [1% (v/v) penicillin/streptomycin solution, Invitrogen UK, Cat. No: 15140-122] until >90% confluence (approximately 10^7 cells per

Copyright 2006, Elsevier Science (USA).
All rights reserved.

dish). This number of HeLa cells consistently provides nucleoli with excellent yield and purity. It is possible to scale down the preparation, although the purity of isolated nucleoli may suffer. Make sure you monitor every step using a phase-contrast microscope (see later). One hour before nucleolar isolation, replace with fresh, prewarmed medium.

2. Harvest cells by trpysinization. Rinse each dish three times with prewarmed PBS and, on removal of the last rinse, add 2 ml of trypsin–EDTA solution (Invitrogen UK, Cat. No: 25300-054) per dish. Swirl the dishes to make sure the trypsin–EDTA is distributed evenly and return the dishes to the incubator for about 5 min. Check under a phase-contrast microscope that all the cells are detached. Prolong incubation if needed. Into each dish add 8 ml of prewarmed medium and pipette up and down so that all the cells are collected as a single-cell suspension. Pool all the harvested cells into 2 × 50-ml Falcon tubes. For some strains of HeLa cells, it is also possible to harvest the cells by scraping them in 5 ml ice-cooled PBS per dish. Because scraping may lead to an impure nucleolar preparation in some HeLa strains, it is not recommended as the method of first choice.

3. Wash three times with ice-cold PBS at 218 *g* (1000 rpm, Beckman GS-6 centrifuge, GH-3.8 rotor) at 4°C.

4. After the final PBS wash, resuspend the cells in 5 ml of buffer A and incubate the cells on ice for 5 min. Put a small drop of the cell suspension on a glass slide and check under a phase-contrast microscope, such as a Zeiss Axiovert 25, using a 20× objective. The cells should be swollen, but not burst (Fig. 1). Nucleoli of cultured mammalian cells disassemble at 37°C in hypotonic conditions (Zatsepina *et al*., 1997). It is therefore imperative to keep the cell suspension on ice during this step.

5. Transfer the cell suspension to a precooled 7-ml Dounce tissue homogenizer (Wheaton Scientific Product Cat. No: 357542). Homogenize 10 times using a tight pestle ("A" specification: 0.0010–0.0030-in. clearance) while keeping the homogenizer on ice. The number of strokes needed depends on the cell type used (see Section III). It is therefore necessary to check the homogenized cells under a phase-contrast microscope after every 10 strokes. Stop when >90% of the cells are burst, leaving intact nuclei, with various amounts of cytoplasmic material attached. In most cases, the presence of this cytoplasmic contamination does not affect the final purity of the isolated nucleoli (Fig. 2). Centrifuge the homogenized cells at 218 *g* (1000 rpm, Beckman GS-6 centrifuge, GH-3.8 rotor) for 5 min at 4°C. The pellet contains enriched, but not highly pure, nuclei.

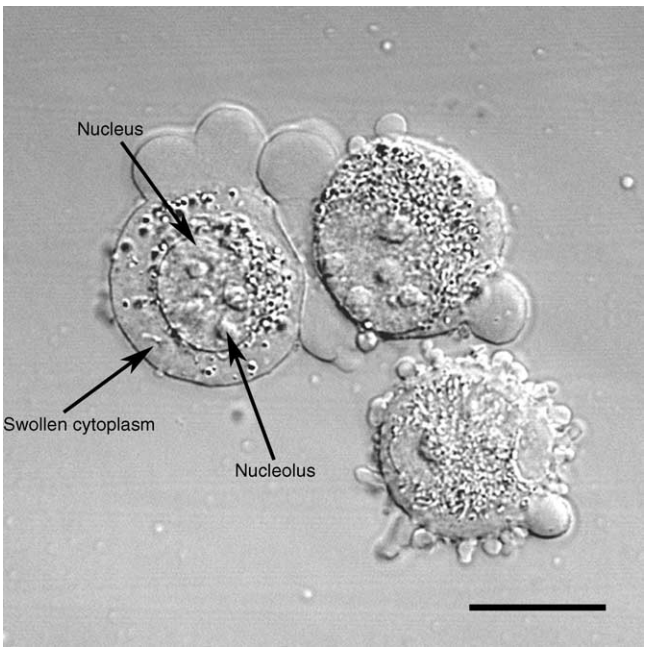

FIGURE 1 HeLa cells after step 4. Note the swollen cytoplasm and prominent nucleoli. Bar: 10 µm.

6. Resuspend the pellet with 3 ml S1 solution (Fig. 3). The pellet should be resuspended readily by pipetting up and down. A pellet that cannot be resuspended contains lysed nuclei and should be discarded. Layer the resuspended pellet over 3 ml of the S2 solution. Take care to keep the two layers cleanly separated. Centrifuge at 1430 *g* (2500 rpm, Beckman GS-6 centrifuge, GH-3.8 rotor) for 5 min at 4°C. This step results in a cleaner nuclear pellet (Fig. 3). Resuspend the pellet with 3 ml of the S2 solution by pipetting up and down.

7. Sonicate the nuclear suspension with six 10-s bursts (with 10-s intervals between each burst) using a Misonix XL 2020 sonicator fitted with a microtip probe and set at power setting 5 (Fig. 4A). Check the sonicated nuclei under a phase-contrast microscope. There should be virtually no intact cells and nucleoli should be readily observed as dense, refractile bodies (Fig. 4B). The optimal sonication time depends on the cell type used. If you attempt to isolate nucleoli from a cell type from the first time, it is necessary to check the sonicated material under a microscope after every 10 sec of sonication. Oversonication leads to destruction of nucleoli.

8. Layer the sonicated sample over 3 ml of the S3 solution and centrifuge at 3000 *g* (3500 rpm, Beckman GS-6 centrifuge, GH-3.8 rotor) for 10 min at 4°C (Fig. 5). The pellet contains nucleoli, whereas the supernatant can be retained as the "nucleoplasmic fraction" (Fig. 5).

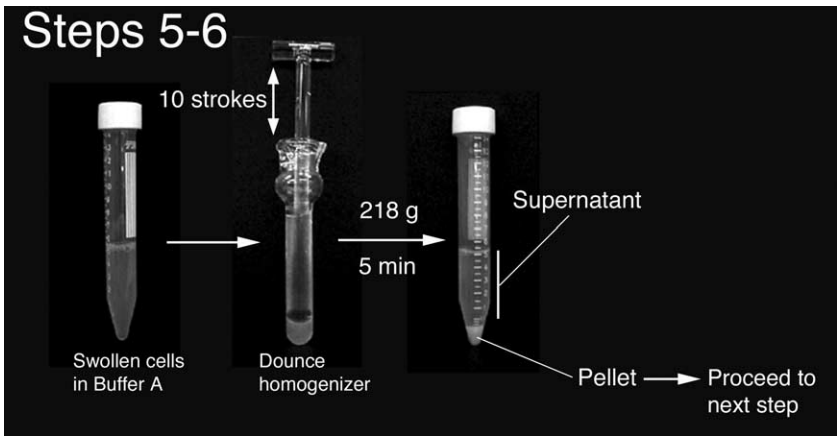

FIGURE 2 Steps 5 and 6 of the procedure.

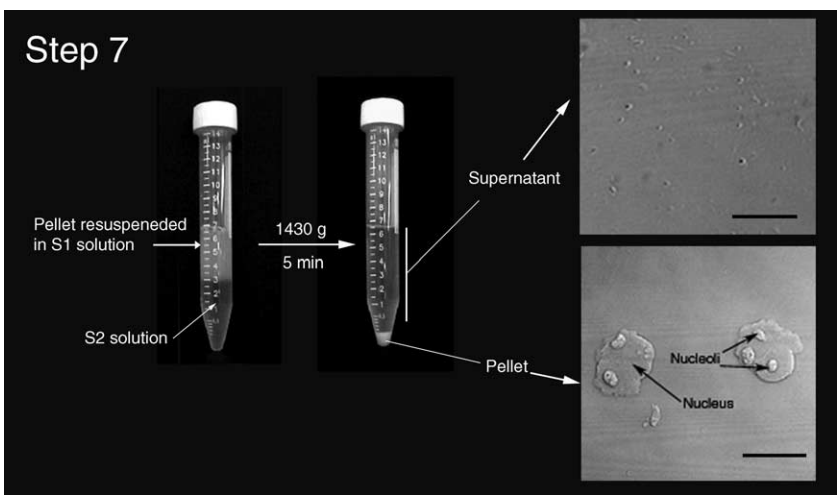

FIGURE 3 Step 7 of the procedure. Note the clear boundary between S1 and S2 layers before centrifugation. (Insets) DIC images of the supernatant and pellet. Note prominent nucleoli inside nuclei in the pellet. Bars: 10 μm.

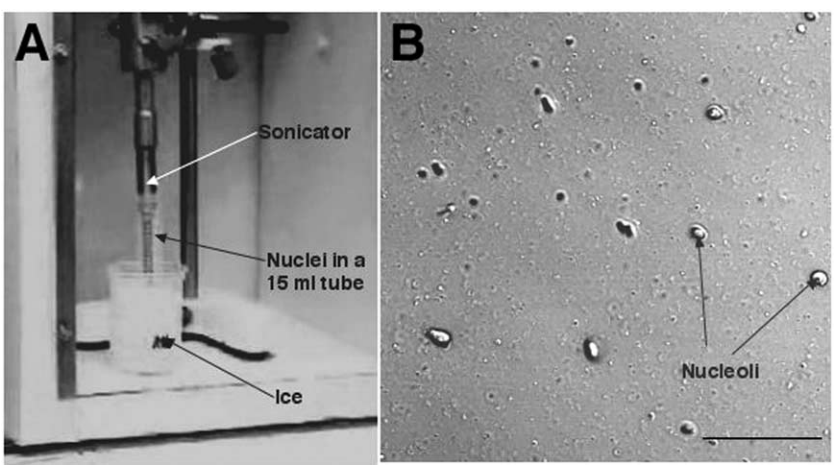

FIGURE 4 (A) Setup for sonication. (B) DIC image of sonicated nuclei. Note the presence of prominent nucleoli. Bar: 10 μm.

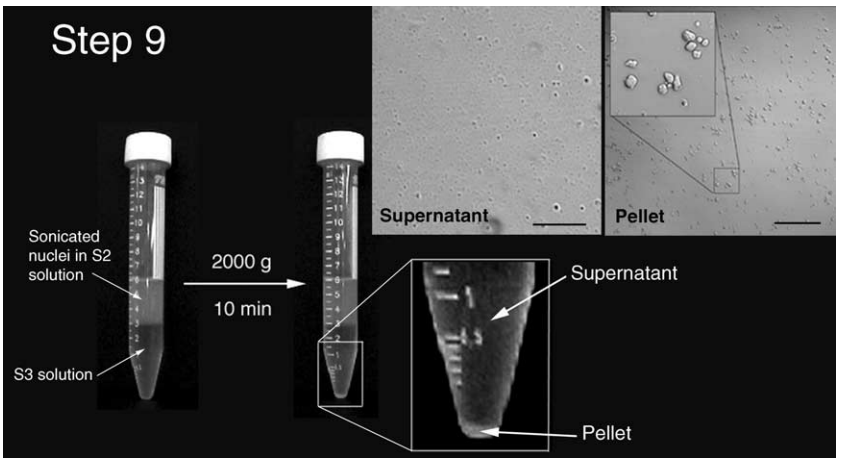

FIGURE 5 Step 9 of the procedure. Note the clear jboundary between S2 and S3 layers before and after centrifugation. The pellet should be small but visible. (Insets) DIC images of the supernatant and pellet. The pellet should contain purified nucleoli. Bars: 10 µm (left inset) and 20 µm (right inset).

9. Resuspend the nucleoli with 0.5 ml of the S2 solution, followed by centrifugation at 1430 *g* (2500 rpm, Beckman GS-6 centrifuge, GH-3.8 rotor) for 5 min at 4°C. The pellet contains highly purified nucleoli. Check under a phase-contrast microscope to ensure that this preparation contains only highly purified nucleoli without any other material (Fig. 5). Nucleoli can be resuspended in 0.5 ml of the S2 solution and stored at –80°C.

III. NOTES

1. Making 2.55 M Sucrose Stock

Here is a protocol for preparing a sucrose stock solution (Cline and Ryel, 1971) suitable for the nucleolar isolation protocol. The resulting solution is 2.55 *M*, or 66% by weight. Its density is 1.3224 g/cm^3 at 20°C, and its refractive index is 1.4558. The stock solution is stable indefinitely at 4°C. This procedure can be carried out at room temperature. There is no need to heat up the solution to help dissolve the sucrose. Heating up an incompletely dissolved sucrose solution can lead to charring of sucrose and affect the quality of the sucrose solution.

1. Weigh out 1710 g sucrose (BDH). Keep it aside in a clean container.
2. Put exactly 900 ml water and a magnetic bar in a 5 litre beaker. Put the beaker on a stirrer and start stirring.
3. Add one-third of the sucrose into the beaker. Make sure the magnetic bar is rotating freely. Stir for 1 h.
4. Add another one-third of the sucrose into the solution. Again make sure the rotation of the stir bar is not impaired. Stir for another 1 h.
5. Add the remaining sucrose. Stir for another 1 h or until all the sucrose has gone into solution. The final volume should be exactly 2 litres.

2. Sonication

We use a Misonix 2020 sonicator fitted with a microtip at power setting 5. To ensure reproducible soncation, the following points should be followed.

i. It is necessary to tune the sonicator every time after you change the probe. Follow the manufacturer's manual for the tuning procedure.

ii. Sonication produces intense and localized heat in your solution. If you are concerned about the heating, the correct way to reduce heating is to shorten the sonication time and to increase the intermission between bursts. Keeping the tube on ice or performing the sonication in the cold room is helpful, but is not the most effective way of heat control.

iii. If the probe is too close to the liquid surface, it produces a foam and reduces the efficiency of sonication. Make sure the probe is well submerged in the solution, about 5 mm above the bottom of the tube. Do not, however, touch the bottom or the wall of the tube with the probe.

iv. A sonicator probe that has been used repeatedly develops pits on its end. The sonication efficiency gradually decreases as time goes on. Therefore, the sonication time recommended here can only be used as a guideline. Always monitor the outcome of sonication using a phase-contrast microscope. You may

need to adjust the sonication time to maintain the efficiency, especially if the probe is getting old. Change the probe when the efficiency is noticeably down.

3. Analysis of Isolated Nucleoli

i. To immunolabel purified nucleoli, spot about 5 µl of the nucleolar suspension onto a polylysine-coated slide (BDH Cat. No: 406/0178/00) and air dry the spot. Rehydrate the slide in PBS for 5 min before carrying out a standard immunostaining procedure.

ii. To separate nucleolar proteins on a gel, resuspend directly either in Laemmli SDS sample buffer or in your preferred buffer. The high concentration of nucleic acid in isolated nucleoli makes the lysed sample very viscous. The sample can be clarified by passing through a QIAshredder spin column (Qiagen Cat. No: 79654). Nucleoli can also be extracted with RIPA buffer (150 m*M* NaCl, 1% NP40, 0.5% deoxycholate, 0.1% SDS, 50 m*M* Tris, pH 8.0, Complete protease inhibitor cocktail). Immunoprecipitations can be performed from nucleolar lysates prepared in RIPA buffer.

4. Adapting Nucleolar Isolation Protocol to Use with Other Cell Types

The aforementioned protocol can be adapted readily to other cell types. Apart from HeLa cells, we have used this protocol, with minor modifications, to isolated nucleoli from MCF-7 (human breast epithelium), WI-38 (human fibroblast), IMR-32 (human neuroblastoma), HL60 (human promyelocytic leukemia), and plant *Arabidopsis thalina* cells. When adapting the protocol to a different cell type, make sure that you control each step by carefully checking the products after each step under a phase-contrast microscope. For example, different cell types may require a different homogenization (step 4) and/or sonication strength (step 7). The concentration of $MgCl_2$ also appears crucial to the purity of the isolated nucleoli. If the isolated nucleoli are not pure enough, try lowering the concentration of $MgCl_2$ in the S2 and S3 solutions. If the yield is poor or if nucleoli look fragmented, use more $MgCl_2$.

Purification of Intermediate-Containing Spliceosomes

Melissa S. Jurica

I. INTRODUCTION

The spliceosome is the dynamic macromolecular machine responsible for removing intervening sequences (introns) from pre-mRNA transcripts. *In vitro* studies have been used to define a pathway of a spliceosome assembly consisting of several intermediate subcomplexes (Moore *et al.*, 1993). Isolating any one of these splicing complexes for subsequent characterization, and structural analysis requires a means to accumulate that specific complex (Jurica and Moore, 2002). A number of methods for purifying complexes along the spliceosome assembly pathway have been described (Das *et al.*, 2000; Hartmuth *et al.*, 2002; Jurica *et al.*, 2002; Makarov *et al.*, 2002; Zhou *et al.*, 2002). These protocols use similar approaches of combining size fractionation and affinity purification to isolate *in vitro*-assembled splicing complexes under native conditions. Presented here is a procedure developed for isolating intact splicing complexes arrested between the first and the second chemical steps of splicing (Jurica *et al.*, 2002).

Spliceosomes are assembled on an *in vitro*-transcribed splicing substrate from components present in the nuclear extract of HeLa cells. Using a substrate with a mutation at the 3′ splice site, complex assembly is arrested by a block at the second step of splicing. The substrate also contains binding sites for an RNA-binding protein that serves as an affinity tag. Purification of arrested spliceosomes is carried out in three steps: (1) RNase H digestion of excess pre-mRNA substrate, (2) size-exclusion chromatography, and (3) affinity selection via the RNA-binding adapter protein (Fig. 1). Digestion serves to improve the ratio of fully assembled complexes to earlier species by targeting substrate molecules not fully assembled into spliceosomes. Cleavage is mediated by endogenous RNase H present in nuclear extracts and DNA oligonucleotides targeted to the last 30 nucleotides of the 5′ exon in the pre-mRNA substrate, a region protected from digestion in arrested complexes, but accessible in earlier ones (Reichert *et al.*, 2002). Size exclusion employs a small sizing column to quickly separate a splicing reaction into basically two fractions: larger molecules, including the spliceosomes, that are excluded by the sizing resin and elute in the void volume, and smaller molecules that can enter the pores of the resin and are retained on the column, such as the bulk of nuclear extract proteins, degraded RNA, and unbound affinity adapter protein. Affinity selection is mediated by binding sites for the bateriophage MS2 coat protein in the pre-mRNA substrate. The substrate can then be bound to a fusion of MS2 and maltose-binding protein (MBP). The MS2:MBP serves as an affinity adapter so that spliceosomes assembled on the tagged substrate can be captured by amylose resin and eluted under native conditions with maltose. The main objectives in developing this protocol were to isolate homogeneous splicing complexes in the quantities (~100 µl) and concentrations (5–50 n*M*) useful for both biochemical characterization and electron microscopy analysis.

II. MATERIALS AND INSTRUMENTATION

HEPES (Cat. No. H-3375), EDTA (Cat. No. E-5134), isopropyl-β-D-thiogalactoside (IPTG, Cat. No. I-5502), maltose (Cat. No. M-5895), phenylmethylsulfonyl flouoride (PMSF, Cat. No. P-7626), L-glutamic acid,

Copyright 2006, Elsevier Science (USA).
All rights reserved.

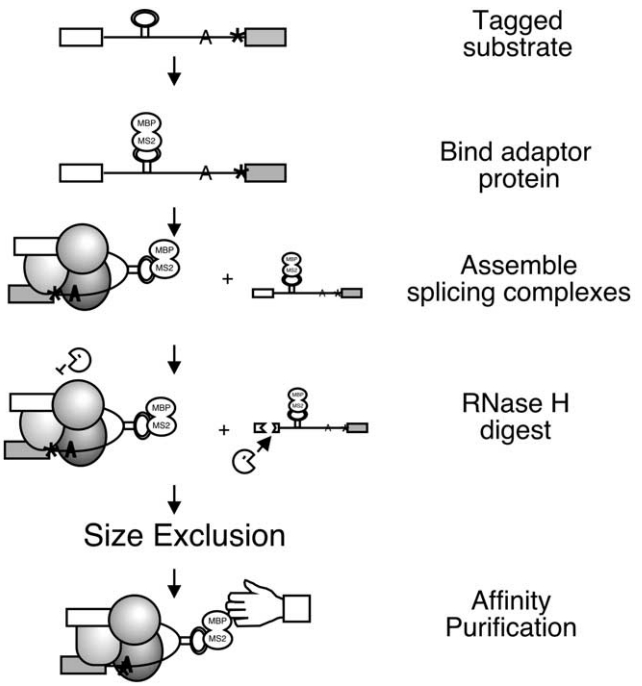

FIGURE 1 Purification scheme.

monopotassium salt (Cat. No. G-1501), Nonidet P-40 (Cat. No. N-6507), heparin (Cat. No. H-3900), phosphocreatine (Cat. No. P-7936), yeast tRNA (Cat. No. R-9001), Trizma base (Cat. No. T-1503), and formamide (Cat. No. 47671) are from Sigma. Tris–HCl (Cat. No. BP153), glycerol (Cat. No. G33), magnesium acetate (Cat. No. M13), and potassium chloride (Cat. No. P217) are from Fisher. Adenosine triphosphate (Cat. No. 27-2056-01), HiTrap heparin column (Cat. No. 17-0407-01), and S-400 Sephacryl (Cat. No. 217-0609-10) are from Amersham Biosciences. RNasin (Cat. No. N2515) is from Promega, and amylose resin (Cat. No. E8021) is from New England Biolabs. Acrylamide (Cat. No. EC-852) is from National Diagnostics, and urea (Cat. No. 821527) is from ICN. The splicing substrate is generated by *in vitro* runoff transcription under standard conditions (Moore and Query, 1998) from construct MJM273. MJM273 is derived from an AdML gene construct containing a single intron with an extended polypyrimidine tract, an AG->GG 3′ splice site mutation (Anderson and Moore, 1997; Gozani *et al*., 1994), and contains a tag of three MS2-binding sites located in the intron between the 5′ splice site and the branch point (Jurica *et al*., 2002). The substrate is transcribed with T7 RNA polymerase, radiolabeled uniformly using [α-^{32}P]UTP and capped with G(5′)ppp(5′)G. The RNA should be gel purified and quantified by comparison with the specific activity of the transcription reaction. Nuclear extract is derived from HeLa cells as outlined in Dignam *et al*. (1983) and stored in 400-µl aliquots at –80°C. DNA oligonucleotides for RNase H-mediated digestion were synthesized with the following sequences: oligo1 (5′-AGCTGGCCCTCG-3′), oligo2 (5′-CAGACAGCGATG-3′) and stored in 100 µ*M* aliquots of 100 µl at –20°C.

The FPLC (Cat. No. 18-1118-67) is from Amersham Biosciences, and the Centricon-10 (Cat. No. 4205) and Kontes Flex-column (Cat. No. K420401-1010) are from Fisher. Mobicols (Cat. No. M1002) and filter (Cat. No. M2135) are obtained from Mo Bi Tec, LLC, and low-adhesion microcentrifuge tubes (Cat. No. 1415-2600) are from USA Scientific. Gel plates, combs, spacers, and electrophoresis rigs are homemade. Power supplies are from Thermo EC (EC3000) or similar, and the phosphorimager is from Molecular Dynamics.

III. PROCEDURES

A. Purification of Spliceosomes

Solutions

1. *Potassium glutamate:* 1 *M*, pH 7.5. To make 50 ml, dissolve 9.26 g of L-glutamic acid, monopotassium salt in 35 ml of H_2O, and adjust the pH to 7.5 with 10 *N* potassium hydroxide. Complete to 50 ml with H_2O and filter sterilize. Store at 4°C.
2. *Magnesium acetate:* 1 *M* pH 7.5. To make 50 ml, dissolve 10.72 g of magnesium acetate in 35 ml of H_2O and adjust pH to 7.5 with sodium hydroxide. Complete to 50 ml with H_2O and filter sterilize. Store at room temperature.
3. *Creatine phosphate:* 250 m*M*. To make 5 ml, dissolve 319 mg phosphocreatine disodium salt in 5 ml of H_2O. Store at –20°C in 1-ml aliquots. Keep a 100-µl working aliquot at –20°C.
4. *Yeast tRNA:* 5 mg/ml. Add 5 ml of H_2O to a 500 unit bottle of Sigma yeast tRNA and store at –20°C. Keep a 100-µl working aliquot at –20°C.
5. *Heparin:* 10 mg/ml. Make a 1-ml stock by dissolving 10 mg heparin in 1 ml H_2O and filter sterilize. Store at 4°C.
6. *Maltose:* 0.5 M. To make 50 ml, dissolve 9 g of maltose in 40 ml of H_2O and complete to 50 ml. Filter sterilize and store at room temperature.
7. *5x SB:* 0.75 *M* KCl, 25 m*M* EDTA, 100 m*M* Tris, pH 7.9. Make 50 ml with 18.75 ml of 2 *M* KCl stock solution, 2.5 ml of 0.5 *M* of EDTA stock solution, 5 ml of 1 *M* Tris, pH 7.9, stock solution, and 23.75 ml of H_2O. Store at room temperature.
8. *SB-N:* 150 m*M* KCl, 20 m*M* Tris, pH 7.9, 5 m*M* EDTA, 1 m*M* dithiothreitol (DTT), and 0.5% NP-40.

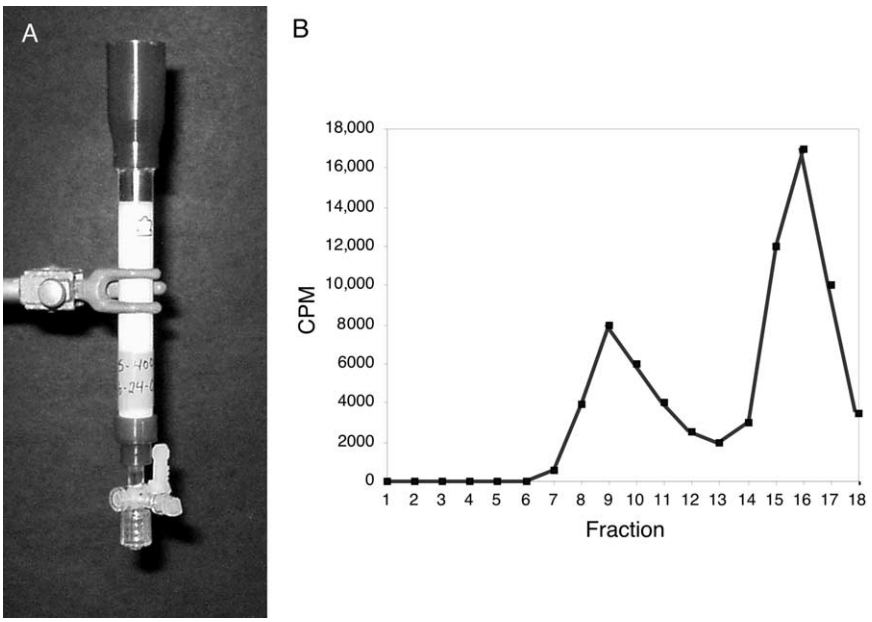

FIGURE 2 (A) Size-exclusion column. (B) Elution profile of size-exclusion column measured with a Gieger counter.

Make 50 ml fresh for each preparation with 10 ml of 5 × SB, 50 µl of 1 *M* DTT stock solution, 250 µl of 10% NP-40 stock solution, and 39.7 ml of H_2O. Keep at room temperature.

9. *SB:* 150 m*M* KCl, 20 m*M* Tris, pH 7.9, 5 m*M* EDTA, and 1 m*M* DTT. Make 15 ml fresh for each preparation with 3 ml of 5 × SB, 15 µl of 1 *M* DTT stock solution, and 12 ml of H_2O. Keep on ice.

10. *SB-M:* 150 m*M* KCl, 20 m*M* Tris, pH 7.9, 5 m*M* EDTA, 1 m*M* DTT, and 10 m*M* maltose. Make 1 ml fresh for each preparation with 200 µl of 5 × SB, 1 µl of 1 *M* DTT stock solution, 20 µl of 0.5 *M* maltose, and 779 µl of H_2O. Keep on ice.

Steps

1. At room temperature, pour 5 ml of S-400 resin equilibrated and resuspended in an equal volume of SB-N into a 1.0 × 10-cm glass column. Allow the resin to settle by gravity flow until the buffer is near the top of the column bed. This sizing column can be used multiple times by washing with 10 ml of SB-N before each use (Fig. 2A).

2. Set up a 1-ml splicing reaction as described in steps 3 and 4 to contain final concentrations of the following: 10 n*M* splicing substrate (MJM273), 500 n*M* MS2-MBP, 80 m*M* potassium glutamate, pH 7.5, 2 m*M* magnesium acetate, pH 7.5, 2 m*M* ATP, 5 m*M* creatine phosphate, 0.05 mg/ml yeast tRNA, 1% RNasin, and 40% nuclear extract.

3. First, place 50 µl substrate (0.2 pmol/µl) in a low-adhesion microcentrifuge tube. Heat at 95°C for 1 min and then place on ice to cool. Add 10 µl MS2-MBP (50 µ*M*) and mix by flicking. Incubate on ice for 5 min.

4. In a second tube, add the following in order: 381 µl H_2O, 80 µl potassium glutamate (1 *M*, pH 7.5), 2 µl magnesium acetate (1 *M*, pH 7.5), 20 µl ATP (100 m*M*), 20 µl creatine phosphate (250 m*M*), 10 µl tRNA (5 mg/ml, yeast), 10 µl RNasin, contents of the first tube (substrate plus MS2-MBP), and 400 µl nuclear extract. Mix by flicking the tube gently. (Place a 5-µl aliquot of the reaction on ice as a 0′ time point for RNA denaturing gel analysis.)

5. Aliquot 200 µl into five tubes. Incubate tubes at 30°C for 60 min to assemble spliceosomes. (Place a 5-µl aliquot of the reaction on ice as a 60′ time point for RNA denaturing gel analysis.)

6. During this incubation, assemble the MoBiCol column by placing a small filter in the bottom of the column. The column can be supported in a microcentrifuge tube on ice. Add 200 µl of amylose resin equilibrated and resuspended in an equal volume of SB-N. Allow the buffer to drain by gravity flow (Fig. 3A).

7. After the 60′ incubation add 2 µl each of oligo 1 and oligo 2 (100 µ*M*) to each tube of the splicing reaction. Mix by flicking the tube gently. Incubate tubes at 30°C for 20 min to induce RNase H digestion. (Place a 5-µl aliquot of the reaction on ice as an 80′ time point for RNA denaturing gel analysis.)

8. Add 10 µl of heparin (10 mg/ml) to each tube. Mix by flicking the tubes gently. Incubate tubes at 30°C for 5 min.

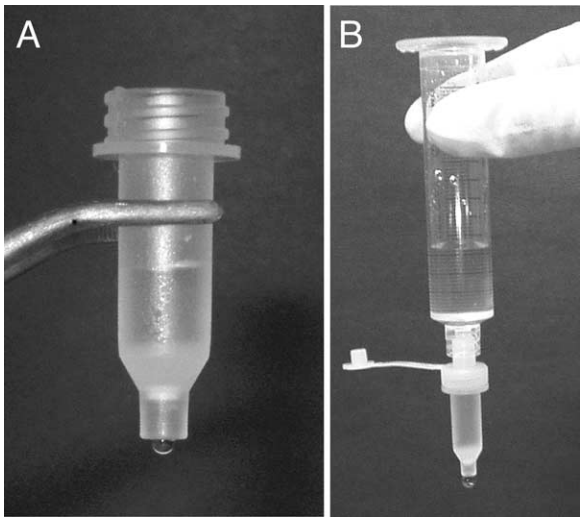

FIGURE 3 (A) Amylose affinity resin in a small MoBiCol column. (B) Setup for washing the amylose column.

9. Run the sizing column by gravity flow until the buffer head just reaches the top of the resin bed. Pool the splicing reactions from the five tubes and carefully load onto the sizing column. Run the column until the resin bed is exposed and load 500 µl SB-N to wash the column wall. Again run the column until the resin bed is exposed.

10. Run 10 ml of SB-N through the column, taking 500-µl fractions in tubes on ice. Gravity flow should be about ~0.4 ml/min. Collect 18–20 fractions total.

11. Count the fractions for the radioactively labeled the splicing substrate with a Geiger counter. There should be two peaks of radioactivity, with the first smaller peak (usually within the first 11 fractions) containing splicing intermediates (spliceosomes) and the larger second peak containing degraded splicing substrate (Fig. 2B). (This can be checked by taking 10-µl aliquots of the fractions for RNA denaturing gel analysis.)

12. Pool the first peak (usually ~2 ml) and flow this through the amylose column by gravity. Collect the column flow-through in tubes on ice and reapply to the amylose column. To wash the column, attach a 10-ml syringe barrel to the top of the column using a luer adaptor cap and place in a 15-ml Falcon tube. Fill the syringe with 10 ml of cold SB to wash the column by gravity flow at 4°C (Fig. 3B).

13. Elute the splicing complexes by pipetting 50-µl aliquots of SB-M onto the amylose resin and taking fractions dropwise into tubes on ice. Count the fractions for the radioactively labeled splicing substrate with a Geiger counter. The complexes should be contained within the first 100 µl of elution.

B. Purifying Affinity-Tag Adapter Protein, MS2-MBP

The affinity-tag adapter protein is a recombinant MS2-MBP fusion expressed in *Escherichia coli* (construct a gift from Josep Vilardell). This fusion places MBP N-terminal to MS2. The MS2 portion carries a double mutation (V75Q and A81G) that prevents oligomerization (LeCuyer *et al.*, 1995). Single-step purification of MS2-MBP over an amylose column yields a single band on a Coomassie-stained gel, but the A_{280}/A_{260} ratio (<1) reveals that a significant amount of bound nucleic acid remains as a contaminant. Heparin chromatography as a second purification step eliminates this contaminant.

Solutions

1. *AB1*: 20 m*M* HEPES, pH 7.9, 200 m*M* KCl, and 1 m*M* EDTA. Make 500 ml by combining 10 ml of 1 *M* HEPES, pH 7.9, stock solution, 50 ml of 2 *M* KCl stock solution, 1 ml of 0.5 *M* EDTA stock solution, and 439 ml of H_2O.
2. *AB2*: 20 m*M* HEPES, pH 7.9, 5 m*M* KCl, and 1 m*M* EDTA. Make 500 ml by combining 10 ml of 1 *M* HEPES, pH 7.9, stock solution, 1.25 ml of 2 *M* KCl stock solution, 1 ml of 0.5 *M* EDTA stock solution, and 487.75 ml of H_2O.
3. *ABE*: 20 m*M* HEPES, pH 7.9, 5 m*M* KCl, 1 m*M* EDTA, and 10 m*M* maltose. Make 100 ml by combining 2 ml of 1 *M* HEPES, pH 7.9, stock solution, 0.25 ml of 2 *M* KCl stock solution, 200 µl of 0.5 *M* EDTA stock solution, 2 ml of 0.5 *M* maltose, and 474.75 ml of H_2O.
4. *PMSF*: 100 m*M*. To make 5 ml, dissolve 87.1 mg PMSF in 5 ml of ethanol. Store at 4°C.
5. *IPTG*: 1 *M*. To make 10 ml, dissolve 1.19 g of IPTG in 5 ml of H_2O. Store in 1-ml aliquots at –20°C.
6. *HB1*: 20 m*M* HEPES, pH 7.9, and 1 m*M* EDTA. Make 500 ml by combining 10 ml of 1 *M* HEPES, pH 7.9, stock solution, 1 ml of 0.5 *M* EDTA stock solution, and 489 ml of H_2O.
7. *HB2*: 20 m*M* HEPES, pH 7.9, 1 *M* KCl, and 1 m*M* EDTA. Make 500 ml by combining 10 ml of 1 *M* HEPES, pH 7.9, stock solution, 250 ml of 2 *M* KCl stock solution, 1 ml of 0.5 *M* EDTA stock solution, and 239 ml of H_2O.

Steps

1. Inoculate a 5-ml culture of Luria broth (LB) with single bacterial colony of DH5α cells transformed with a plasmid expressing MS2-MBP and grow overnight to saturation at 37°C with shaking. The next morning, inoculate 1 liter of LB plus 2% glucose with the 5-ml culture. Grow the cells at 37°C with shaking to an OD_{600} of ~0.5 and then induce expression of the protein

by adding 1 ml of 1 *M* IPTG. Continue to grow the cells for 2–3 h and harvest by centrifugation at 6000 rpm for 10 min. Pour off the supernatant, freeze the cell pellet, and store at –20°C.

2. Thaw and resuspend ~1 g cells in 10 ml cold AB1 plus 200 µl PMSF. Break open the cells by sonication on ice. Centrifuge for 30 min at 15,000 rpm at 4°C.

3. Perform all the following steps of purification at 4°C. Load the supernatant on a –5-ml amylose column equilibrated with AB1, running the column at 0.3 ml/min. Wash the column with 40 ml of AB1, followed by 10 ml of AB2 to lower the salt concentration in preparation for heparin chromatography.

4. Elute the protein with 20 ml of ABE, taking 1-ml fractions. Check the OD_{280} of the fractions and pool the peak fractions. (The column can be cleaned with 5 ml of 0.1% SDS and reequilibrated with AB1 for future use.)

5. Concentrate the pooled peak fraction to ~1 ml in a Centricon-30.

6. On an FPLC, equilibrate a 1-ml heparin column with a mixture of HB1 and HB2 to 5 m*M* KCl. Load the concentrate on the column and wash with 5 ml at 5 m*M* KCl.

7. Run a gradient from 5 to 400 m*M* KCl over 10 column volumes. The MS2-MBP protein elutes at ~60 m*M* KCl. Pool peak fractions and concentrate to ~500 µl in a Centricon-30. Add glycerol to 10% and freeze at –20°C in 100-µl aliquots.

8. Determine the protein concentration for MS2-MBP. An OD_{280} of 1 corresponds to 16.5 µ*M* or 0.89 mg/ml.

C. Denaturing Gel Analysis and Quantification

Solutions

1. *Splicing dilution buffer*: 100 m*M* Tris, pH 7.5, 10 m*M* EDTA, 1% SDS, 150 m*M* NaCl, and 0.3 M NaAc, pH 5.2. To make 50 ml, combine stock solutions of 5 ml of 1 *M* Tris, pH 7.5, 1 ml of 0.5 *M* EDTA, 5 ml of 10% SDS, 3.75 ml of 2 *M* NaCl, 5 ml of 3 *M* NaAc, pH 5.2, and 30.25 ml of H_2O. Store at room temperature.

2. *Acrylamide solution*: 15% acrylamide (29:1 acrylamide:bis-acrylamide), 8 *M* urea, and 1 × TBE. To make 500 ml, dissolve 240.24 g of urea in 100 ml of stock solution of 5 × TBE and 187.5 ml of 40% acrylamide solution with stirring over low heat. Complete to 500 ml with H_2O and filter. Store in the dark at room temperature.

3. *FEB*: 94% formamide, 20 m*M* EDTA, 0.01% cyan blue, and 0.01% bromphenol blue. To make 10 ml, combine 9.4 ml of formamide, 0.4 ml of 0.5 *M* EDTA, 0.1 ml of 1% cyan blue, and 0.1 ml of 1% bromphenol blue stock solutions. Store 1-ml aliquots at –20°C.

Steps

1. To prepare the time point aliquots taken during the spliceosome purification for electrophoresis, remove the tubes from ice and add 95 µl of splicing dilution buffer. Then add 100 µl of phenol:chloroform:isoamyl alcohol (25:24:1, pH 4.5) stock solution. Vortex well and spin at 14,000 rpm in a microcentrifuge for 10 min at room temperature. (If taken, aliquots from the sizing column elution should be treated similarly.)

2. Take the top 90 µl, avoiding the interface, and place in a new tube. To this add 3 volumes ethanol and invert to mix. Place at –70°C for 30 min. Discard the lower layer.

3. Spin tubes in a microcentrifuge at 14,000 rpm for 30 min at 4°C. Remove the ethanol with a pipettor and wash the pellet with 100 µl of 70% ethanol. Dry the pellet.

4. Resuspend the pellet in 5 µl of FEB. Load 2.5 µl on the denaturing acrylamide gel.

5. To prepare elution samples, add 4 µl of FEB to 1 µl of elution aliquots. Load 2.5 µl on the gel.

6. To prepare standard, add 39 µl of FEB to 1 µl of 10 n*M* splicing substrate used during the purification. Load 1 µl on the gel.

7. Assemble a gel mold using 20 × 25-cm glass plates with 0.1-mm spacers and comb. Pour the gel using 25 ml acrylamide solution and polymerize with 75 µl of 20% APS and 25 µl of TEMED stock solutions. Allow the gel to set for at least 30 min.

8. Assemble the gel on a gel rig with TBE buffer stock. Prerun at 30 W for 30 min.

9. Prior to loading on the gel, incubate the samples at 95°C for 1 min and then place on ice.

10. After rinsing out the wells, load samples and standard. Run the gel at 30 W for 2 h. The cyan blue should migrate to near the bottom of the gel.

11. Take down the gel onto a piece of exposed X-ray film and cover with plastic wrap. Expose to a phosphorimager plate overnight.

12. To quantify the concentrations of the purified spliceosomes, the specific activity of the labeled splicing intermediates should be compared to the standard. (Figure 4)

IV. PITFALLS

1. Starting with 10 pmol of pre-mRNA substrate, this protocol generally yields 0.3–0.5 pmol of purified

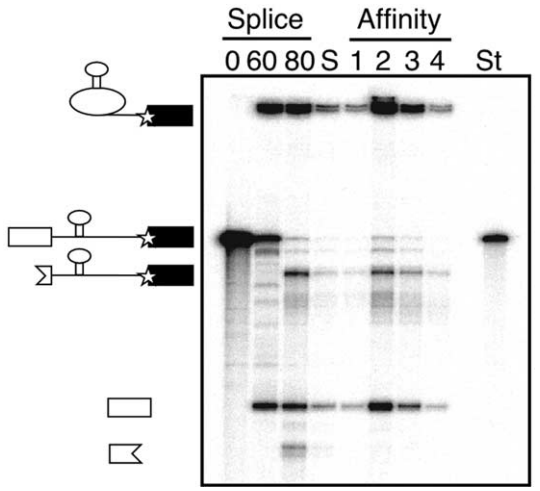

FIGURE 4 Example of denaturing gel (15% polyacrylamide) analysis of substrate RNA during purification. Time points taken during the splicing reaction (0 and 60 min) and after RNase H digestion (80 min), size-exclusion peak fraction (S), affinity column elutions (1–4), and standard used for quantification (St) are shown. The positions of MS2-tagged pre-mRNA, lariat intermediate, 5′ exon, and RNase H digestions products are indicated.

complexes. The yield is highly dependent on the efficiency of the first step of splicing in the reactions. Nuclear extracts can differ in their splicing efficiencies, and therefore titrations of potassium glutamate and magnesium acetate concentrations should be performed to maximize splicing efficiency for a given nuclear extract preparation.

2. The final buffer conditions for the purification were chosen with electron microscopy studies in mind. We found that the splicing complexes tended to aggregate when 2 m*M* $MgCl_2$ was present in the buffer instead of the 5 m*M* EDTA. Although some spliceosome proteins are disassociated in the presence of EDTA, the core splicing components remain intact (Jurica *et al.*, 2002).

3. We have yet to find a method to concentrate spliceosomes after purification, as the complexes adhere to the membranes of all concentration devices tested. By using the very small amount of affinity resin with a column geometry, the spliceosomes can be eluted at a high enough concentration for structural and biochemical analyses without further concentration. Typically peak elution fractions of 15–50 µl containing 5 to 15 n*M* splicing intermediates are obtained.

4. Contamination of reagents, tubes, and so on by RNases is always a concern when handling RNA. Care should be taken to wear clean gloves during the purification and, if possible, to designate reagents, tips, tubes, and so on as being for RNA use only.

CHAPTER

17

Isolation of Cajal Bodies

Yun Wah Lam and Angus I. Lamond

I. INTRODUCTION

The Cajal body (CB) is a subnuclear organelle involved in the biogenesis of snRNPs and snoRNPs. It was first described by Ramon-y-Cajal as the "nucleolar-accessory body" in silver nitrate-stained neuronal cells (Cajal, 1903). Later, electron microscopy studies on neuronal cells showed that this nuclear domain sometimes resembled a ball of coiled threads 0.15 to 1.5 μm in diameter. The identification of CBs in the fluorescence microscope was facilitated by the discovery of p80 coilin, a human autoantigen that is enriched in the CB (Andrade *et al.*, 1991). Antibodies against human p80 coilin label CB-like nuclear foci in a wide spectrum of organisms, showing that the CB is a highly conserved structure. While various lines of experiment suggest a role of the CB in snRNA and snoRNA maturation (reviewed by Gall, 2000), CBs also contain proteins involved in other pathways, such as nucleolar functions, tumourigenesis, and cell cycle regulation (Sleeman and Lamond, 1999; Jacobs *et al.*, 1999; Liu *et al.*, 2000, Ma *et al.*, 2000). Therefore, CBs may also have other cellular functions that remain to be characterized.

This article describes an effective procedure for the large-scale isolation of CBs from mammalian somatic cell nuclei (Lam *et al.*, 2002). The procedure involves disrupting HeLa cell nuclei by sonication, treatment with detergent, nuclease, and polyanion, and subsequent density gradient fractionation. Density separation is carried out using Percoll, a silica sol coated with polyvinylpyrolidone, which generates a density gradient on ultracentrifugation. It results in the enrichment of particles containing known CB factors that are comparable in size, morphology, and composition to CBs detected *in situ*. These particles, therefore, correspond to isolated CBs. Judging by both immunofluorescence and immunoblotting analyses, we estimate that this protocol provides an enrichment factor of at least 750-fold for isolated CBs, as compared to intact nuclei. The protocol is reproducible and can be carried out on a sufficiently large scale to generate sufficient material for biochemical analysis.

II. BUFFERS AND SOLUTIONS

All solutions are supplemented with Complete protease inhibitor tablet (Roche, Cat. No. 1-873-580) at a final concentration of 1 tablet/50 ml).

S1 solution: 0.25 *M* sucrose and 10 m*M* $MgCl_2$
S2 solution: 0.35 *M* sucrose and 0.5 m*M* $MgCl_2$
S3 solution: 0.5 *M* sucrose and 25 m*M* Tris–HCl, pH 9.0
SP1 buffer: 1 *M* sucrose, 34.2% Percoll, 22.2 m*M* Tris–HCl, pH 7.4, and 1.11 m*M* $MgCl_2$
SP2 buffer: 20% Percoll, 10 m*M* Tris–HCl, pH 7.4, 1% Triton X-100, and 0.5 mg/ml heparin
HT buffer: 10 m*M* Tris–HCl, pH7.4, 1% Triton ×100, and 0.5 mg/ml heparin

See Section IV on making sucrose stock solution.

III. PROCEDURES

All procedures should be performed either on ice or at 4°C.

Copyright 2006, Elsevier Science (USA).
All rights reserved.

A. Sonication

1. Prepare the starting material of 2.5×10^9 HeLa nuclei. Suitable HeLa nuclei can be purchased from CIL Biotech (Mons, Belgium; Cat. No. CC-01-30-25). Add S1 solution to thawed nuclei to a final volume of 30 ml. Mix thoroughly but avoid vigorous vortexing.

2. Divide the diluted nuclei into 2×15 ml portions. Overlay each portion onto 15 ml of the S2 solution in a 50-ml Falcon tube. Make sure the interface of the two layers is sharp (Fig. 1).

3. Centrifuge at 1430 g (2500 rpm, Beckman GS-6 centrifuge, GH-3.8 rotor) for 5 min at 4°C.

4. Carefully decant the supernatant. The pellets should be solid and firm (Fig. 1). Resuspend each pellet with the S2 solution so that the final volume is 30 ml. The pellets should resuspend easily. A pellet that cannot be resuspended completely indicates the presence of lysed nuclei and should be discarded.

5. Divide resuspended nuclei into 10×3-ml portions, each in a 15-ml Falcon tube. In our experience, sonication is more effective with this sample size.

6. Sonicate each aliquot using a tuned sonicator (Misonix XL 2020) for 3×6 s, with a 6-s intermission between each burst. See Section IV on sonication.

7. Examine the sonicated nuclei under a phase-contrast microscope. The majority of nuclei should have been lysed, while nucleoli should be clearly visible. If the percentage of unlysed nuclei is too high (over 5%), sonicate again for 2–3 s and then reexamine under the microscope. Stop at the point when most nuclei are lysed. Over sonication disrupts CBs. The conditions used to sonicate HeLa nuclei not only maintain the structure of CBs, but also that of nucleoli (see Chapter 15, this volume). PML bodies, and splicing speckles. This indicates that, under suitable conditions, many nuclear domains remain intact even after the overall nuclear structure is destroyed.

B. Removal of Nucleoli

8. Pool the 10 aliquots back together. Measure the volume. Add 0.42× volume of 2.55 *M* sucrose to sonicated nuclei so that the final sucrose concentration is now 1 *M*. Mix thoroughly but do not vortex. Divide the mixture into two portions, approximately 20 ml each, in two 50-ml Falcon tubes (Fig. 2).

9. Centrifuge at 3000 g (3500 rpm, Beckman GS-6 centrifuge, GH-3.8 rotor) for 10 min at 4°C.

10. A small pellet should be visible in each tube (Fig. 2). This pellet contains nucleoli and unlysed nuclei, while the supernatant is nucleoplasm containing CBs. Using a pipette, collect the supernatant carefully. Do not decant, as the pellets are not firm. Stop when you are about 5 mm above the pellet. This is the region where the distinction between the pellet and the supernatent is blurred. This part of the supernatant should not be included in subsequent steps.

11. To collect nucleoli for other experiments, resuspend the pellet with 3 ml S2. Sonicate the mixture for 3×10 s. Proceed from step 7 of the nucleolar isolation protocol (see article by Lam and Lamond).

C. Gradient One

12. Measure the volume of the supernatant. Add 0.82× volume of SP1. For example, in a typical experiment, mix 37 ml of the supernatant with 30.27 ml SP1. Add 0.05× volume of 20% Triton X-100 (3.36 ml in the aforementioned example). Mix thoroughly but do not vortex.

13. Divide the mixture into precooled SW41 ultracentrifuge tubes (Fig. 3). The volume of the sample should fit six tubes perfectly. Balance the tubes carefully. Load the tubes into a precooled SW41 rotor. Transfer the rotor to a precooled ultracentrifuge.

14. Ultracentrifuge at 37,000 rpm for 2 h.

15. A loose pellet can be seen resting on the Percoll precipitate at the bottom of each tube (Fig. 3). This pellet contains most of the Cajal bodies. Carefully pipette away the turbid supernatant. Do not decant. Stop when you are 5–6 mm above the pellet. Keep the supernatant labeled as fraction 1S. Use a P1000 pipette and resuspend the pellets in the remaining supernant. Transfer the resuspended pellets to a 15-ml Falcon tube. This is fraction 1P. Measure the final volume of fraction 1P. In a typical experiment, the final volume is about 5 ml. In fraction 1P, the CBs present are mostly entangled with large pieces of chromatin, as revealed by DAPI staining. Nucleoli that have not been removed in the first step are also a significant contaminant.

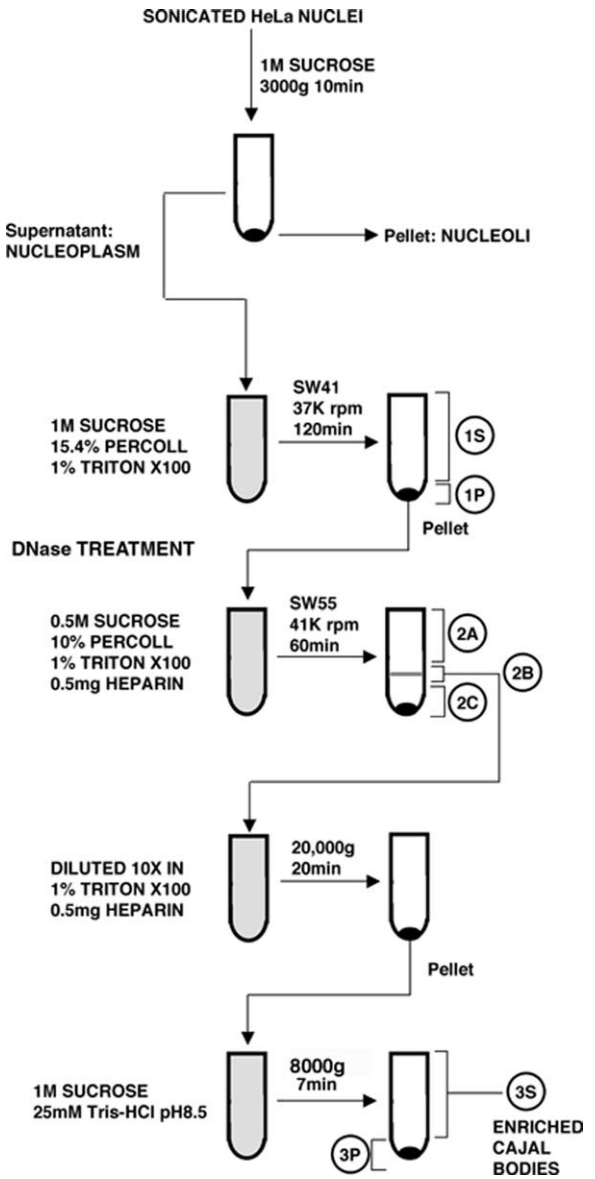
D. Gradient Two

16. Add 600 units of DNase1 (Sigma Cat. No. D4527; 20,000 units/ml) to fraction 1P. Mix with a rotating wheel for 1 h at room temperature.

17. Add 0.05× volume of heparin (10 mg/ml). The mixture should become more transparent on mixing.

18. Add 1× volume of SP2. Mix gently with a rotating wheel for 1 min.

19. Load the mixture in precooled tubes suitable for SW55 rotor (Fig. 4). In a typical experiment, the mixture fits two tubes perfectly. Ultracentrifuge at 45,000 rpm for 1 h.



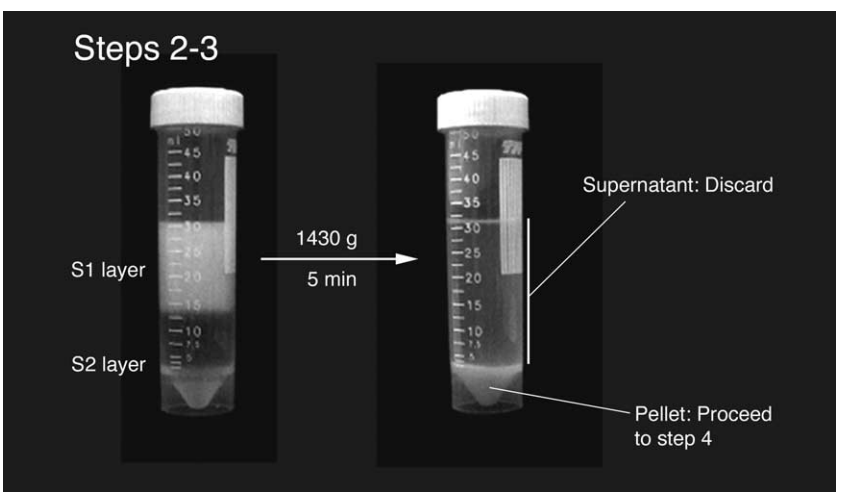


FIGURE 1 Steps 2–3 of the procedure. Note the clear boundary between S1 and S2 layers before centrifugation.

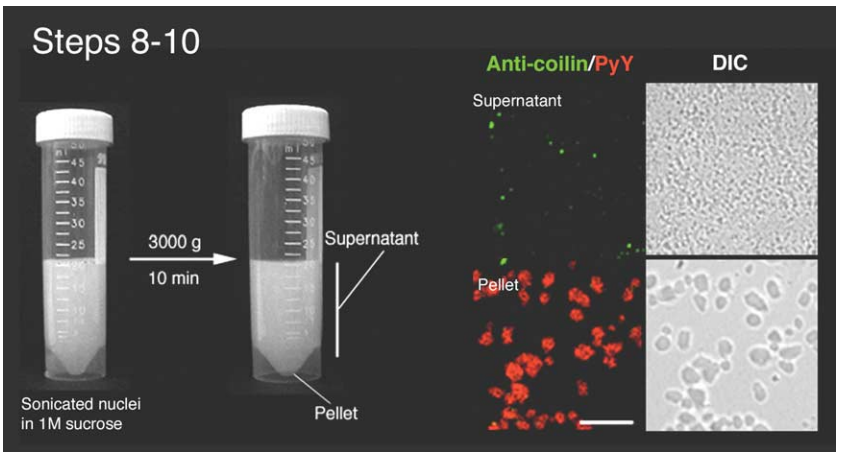

FIGURE 2 Steps 8–10 of the procedure. Note the small pellet after centrifugation. (Right) Microscope images of the supernatant and pellet. Anticoilin antibodies (5P10, green) and pyronin Y (red) were used to label CBs and nucleoli, respectively. Bar: 10 µm.

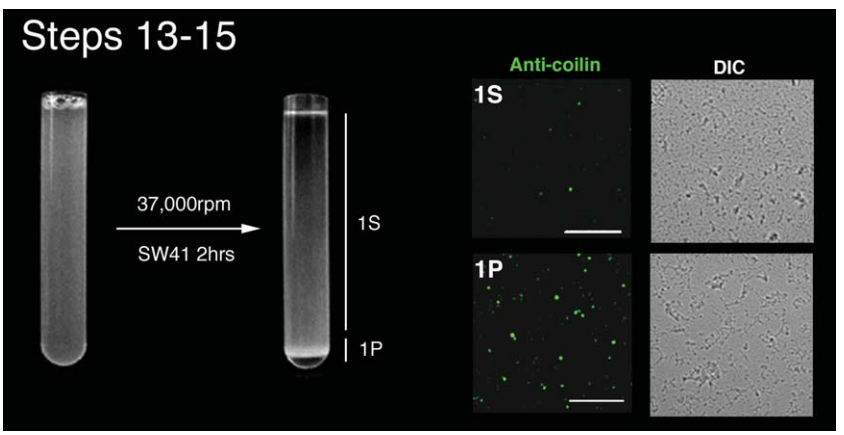

FIGURE 3 Steps 13–15 of the procedure. Note the loose pellet (1P) after centrifugation. Immunofluorescence (right) shows that most CBs are in 1P. Bar: 10 µm.

20. Three bands should be visible (Fig. 4). A broad white band floats on the top, a thin white band at the middle, and a pellet resting on the Percoll precipitate at the bottom. Using a P1000 pipette, very carefully unload the gradient from the top. Take the top band and go on until you are 2–3 mm above the middle band. This is fraction 2.1. Using a new pipette tip, take the middle band (fraction 2.2). Finally, resuspend the pellet using the remaining part of the gradient. This is fraction 2.3. For each 5-ml gradient, typical volumes of the three fractions are fraction 2.1, 2.5 ml; fraction 2.2, 1 ml; and fraction 2.3, 1.5 ml. Most of the CBs are contained in fraction 2.2 in the middle of the gradient, where the resolution is the greatest.

E. Concentration and Final Enrichment of Cajal Bodies

21. Add 10× volume of HT buffer into fraction 2.2. Mix well using a rotating wheel.

22. **Either** load the diluted fraction into 2 × SW41 tubes and ultracentrifuge at 12,000 rpm for 15 min **or** divide the mixture into 20 × 1.5-ml Eppendorf tubes and centrifuge at 14,000 rpm for 15 min in an Eppendorf centrifuge (Fig. 5).

23. Remove the supernatant carefully. Resuspend the pellet in 0.5 ml HT buffer. Pool all the resuspended pellets into a single tube and centrifuge again as described earlier. The final pellet should be visible, but very small. Remove the supernatant carefully .

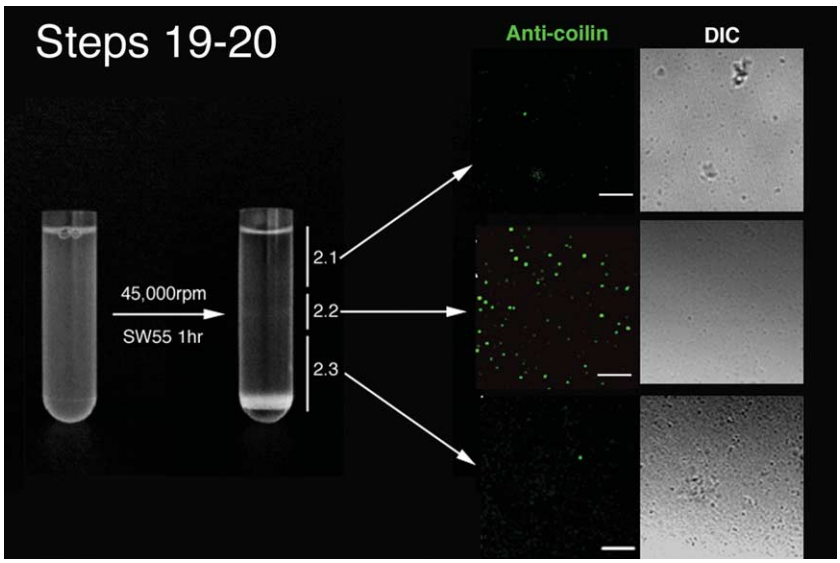

FIGURE 4 Steps 19 and 20 of the procedure. Note the thin band (2.2) in the middle of the gradient after centrifugation. Bar: 10 µm.

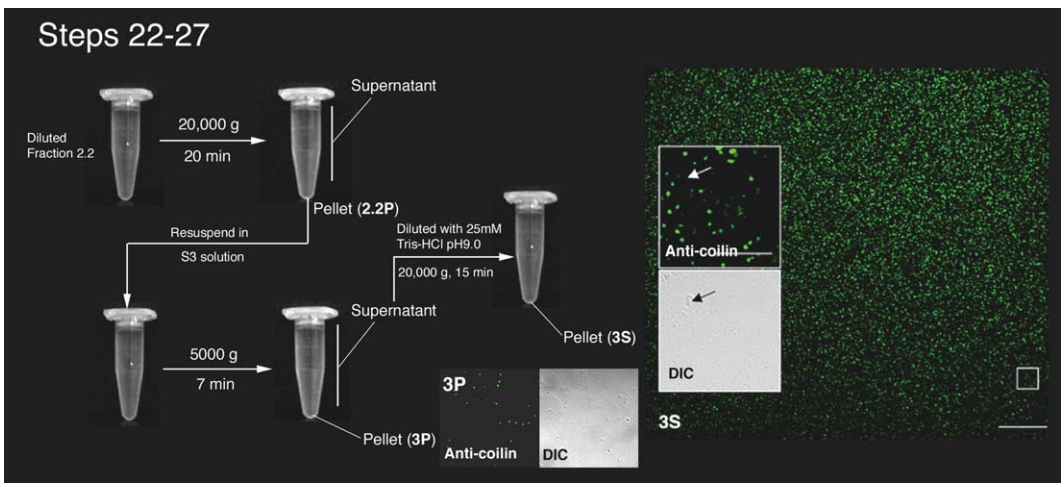

FIGURE 5 Steps 22–27 of the procedure. Most CBs are found in fraction 3S. (Inset) Arrows indicate the presence of a small amount of coilin-negative material in 3S. Bars: 25 µm (large inset) and 10 µm (small insets).

24. Resuspend the pellet with 0.5 ml S3 solution. The pellet detaches from the bottom of the tube and is resuspended on pipetting up and down.

25. Spin down the resuspended pellet in an Eppendorf centrifuge at 8000 rpm for 5 min. A visible pellet should be seen. Carefully take the supernatant and transfer it to a new Eppendorf tube. Repeat spinning the supernatant at 8000 rpm for 5 min. Carefully take the supernatant and transfer it to a new Eppendorf tube.

26. Combine the pellets. Label this fraction 3P.

27. Dilute the supernatant with 10× volumes of 25 m*M* Tris–HCl, pH 9.0. Divide the diluted supernatant into 3 × 1.5-ml Eppendorf tubes. Centrifuge at 14,000 rpm for 15 min. Remove the supernatants carefully, leaving about 0.1 ml at the bottom of each tube. Pipette the remaining supernatants up and down, resuspending the small pellet. Mix the contents of the three tubes together. Fill up the tube with 25 m*M* Tris–HCl, pH 9.0, and centrifuge again at 14,000 rpm for 15 min. Remove the supernatant carefully, leaving about 20 µl in the tube. Pipette the remaining super-

natants up and down to resuspend the small pellet. Label this fraction 3S. This fraction contains enriched CBs.

IV. NOTES

1. Making 2.55 M Sucrose Stock

Here is a protocol for preparing a sucrose stock solution (Cline and Ryel, 1971) suitable for the nucleolar isolation protocol. The resulting solution is 2.55 *M*, or 66% by weight. Its density is 1.3224 g/cm^3 at 20°C, and the refractive index is 1.4558. The stock solution is stable indefinitely at 4°C. This procedure can be carried out at room temperature. There is no need to heat up the solution to help dissolve the sucrose. Heating up an incompletely dissolved sucrose solution can lead to charring of sucrose and affect the quality of the sucrose solution.

1. Weigh out 1710 g sucrose (BDH). Keep it aside in a clean container.
2. Put exactly 900 ml water and a magnetic bar in a 5-litre beaker. Put the beaker on a stirrer and start stirring.
3. Add one-third of the sucrose into the beaker. Make sure the magnetic bar is rotating freely. Stir for 1 h.
4. Add another one-third of the sucrose into the solution. Again make sure the rotation of the stir bar is not impaired. Stir for another 1 h.
5. Add the remaining sucrose. Stir for another 1 h or until all the sucrose has gone into solution. The final volume should be exactly 2 litres.

2. Sonication

We use a Misonix 2020 sonicator fitted with a microtip at power setting 5. To ensure reproducible soncation, the following points should be followed.

i. It is necessary to tune the sonicator every time after you change the probe. Follow the manufacturer's manual for the tuning procedure.

ii. Sonication produces intense and localized heat in the solution. If you are concerned about the heating, the correct way to reduce heating is to shorten the sonication time and to increase the intermission between bursts. Keeping the tube on ice or performing the sonication in the cold room is helpful, but is not the most effective way of heat control.

iii. If the probe is too close to the liquid surface, it produces a foam and reduces the efficiency of sonication. Make sure the probe is well submerged in the solution, about 5 mm above the bottom of the tube. Do not, however, touch the bottom or the wall of the tube with the probe.

iv. A sonicator probe that has been used repeatedly develops pits on its end. The sonication efficiency gradually decreases as time goes on. Therefore, the sonication time recommended here can only be used as a guideline. Always monitor the outcome of sonication using a phase-contrast microscope. You may need to adjust the sonication time to maintain the efficiency, especially if the probe is getting old. Change the probe when the efficiency is noticeably down.

3. Analysis of the Enriched Cajal Body Fraction

i. To immunolabel the isolated CBs, spot about 5 µl of fraction 3S onto a polylysine-coated slide (BDH Cat. No. 406/0178/00) and air dry the spot. Rehydrate the slide in PBS for 5 min before using the standard immunostaining procedure.

ii. To separate and analyse the proteins by SDS–PAGE, resuspend directly either in Laemmli SDS sample buffer or in your preferred buffer.

Replicon Clusters: Labeling Strategies for the Analysis of Chromosome Architecture and Chromatin Dynamics

Dean A. Jackson, Chi Tang, and Chris Dinant

I. INTRODUCTION

In all eukaryotes, the maintenance of genetic integrity requires that DNA replication is controlled precisely to ensure that a perfect set of chromosomes passes to each of the daughter cells during cell division. Mammalian chromosomes are so long that DNA synthesis must initiate at many positions on each in order to complete S phase in the observed time frame—typically 8–10 h. Direct observation of sites of DNA synthesis on spread DNA fibres shows that initiation events are spaced roughly 150 kb apart, giving ~1000 on a typical human chromosome. However, the initiation events are not performed simultaneously at all sites at the onset of S phase. Instead, small groups of origins within replicon clusters are activated at the onset of the replication programme such that only about 10% of possible origins operate at this time. Replication proceeds from these early origins until some unknown switch—probably related to changes in chromatin structure that arise during this first phase of synthesis—allows new sets of replicons to be activated. Different banks of replicons are activated in this progressive fashion until the replication process is complete.

During each phase of synthesis small clusters of replicons are activated together (Fig. 1). These clusters typically contain two to five adjacent replicons and appear to form stable units of **chromosome structure**, with ~0.5–1 Mbp DNA (Jackson and Pombo, 1998; Ma *et al*., 1998; Zink *et al*., 1998; Cremer and Cremer, 2001). The ability to label replicon clusters in mammalian cells to reveal DNA or replication foci provides an outstanding opportunity to analyse many aspects of chromosome architecture and chromatin function. The basic principle behind the approach is facile and relies on the use of modified DNA precursor analogues that can be incorporated into DNA in place of the natural precursor and subsequently detected to reveal sites of incorporation. **Bromodeoxyuridine** (BrdU) was the first compound to find common use in this approach (Dolbeare, 1995). BrdU can be added to culture medium—or indeed introduced by injection into whole animals—and is incorporated into DNA in place of thymidine. Patterns of incorporation can subsequently be visualised. Initially, low resolution techniques were used that relied on the variable biochemical properties of the BrdU-containing chromatin. The subsequent use of immunostaining techniques using antibromo antibodies (Gratzner, 1982) and fluorescence-based detection systems revolutionised the analysis of replicon clusters labelled in this way. In the seminal experiment, Nakamura *et al*. (1986) used BrdU incorporation **and indirect immunofluorescence** to show that early replication in rat embryonic fibroblasts occurred at some 130 sites that were each estimated to contain at least 10 active replicons. Further studies have defined a replication programme (Fig. 2), with characteristic patterns of synthesis correlating with the duplication of specific regions of the genome at different times during S phase (Nakayasu and Berezney, 1989; Humbert and Usson, 1992; O'Keefe *et al*., 1992; Hozák *et al*., 1994). The activation of specific groups of replicons also correlates with the structured assembly of active replication centres—also

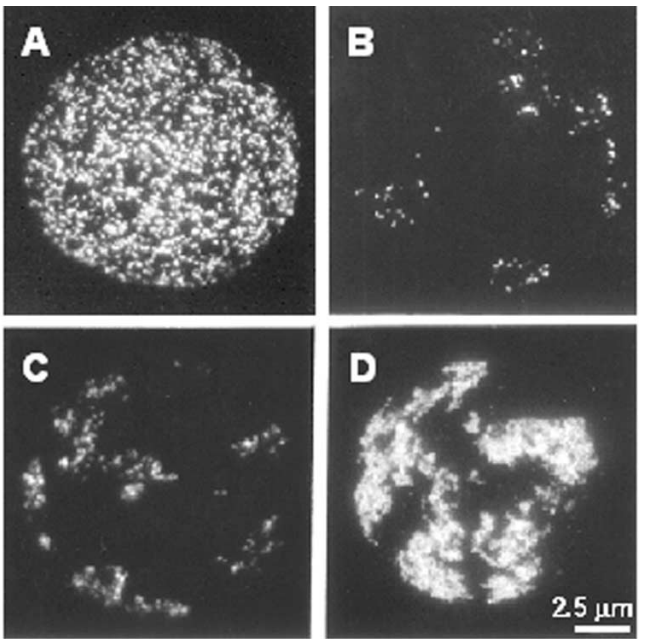

FIGURE 1 Chromosome territories in mammalian cells. HeLa cells were labelled with BrdU at the onset of S phase for 20 min (A and B), 3 h (C), and 10 h (D). Cells were attached to glass slides using the standard chromosome spreading technique, and BrdU-containing sites were visualised by immunofluorescence immediately after labelling (A) or 5 days later (B–D). Note the structure of individual replication foci and their organisation in individual chromosome territories (B–D). (D) Individual territories are labelled throughout S phase so that the boundary of each territory is seen. Bar: 2.5 μm. For details, see Jackson and Pombo (1998).

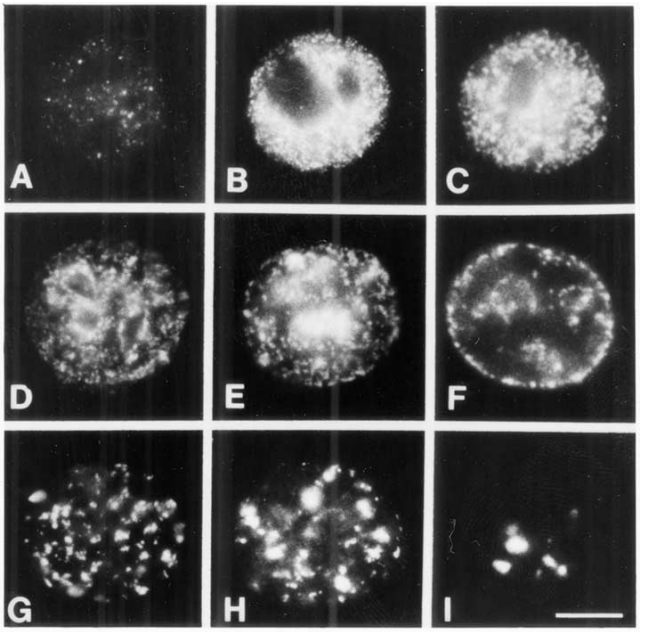

FIGURE 2 The S-phase programme. During S phase, different classes of DNA elements are replicated at specific times. Chromatin with the majority of transcribed genes is replicated over the first ~4 h of the S phase. During this period, active sites of DNA synthesis are in discrete foci dispersed throughout the nuclear interior (A–C). These are designated early or type 1 replication patterns. During mid-S phase (D–F) replication switches to peripheral inactive chromatin. These mid-S phase patterns are also referred to as type 2 (D and E) and type 3 (F) patterns. During late S phase (G–I) the replication of extended blocks of constitutive heterochromatin occurs throughout the nuclear interior. These late S phase patterns are also referred to as type 4 (G–H) and type 5 (I) patterns. Encapsulated HeLa cells were synchronised at the onset of S phase, and replication sites were labelled at 1-h intervals for 10 h. Images shown are replication sites labelled in permeabilised cells using biotin-dUTP. For details, see Hozak *et al*. (1994) and O'Keefe *et al*. (1992). Bar: 5 μm.

called replication "factories" (Hozák *et al*., 1993)—in the vicinity of active foci. These replication factories are assembled transiently at the appropriate sites in response to factors that determine the progress of S phase. The distribution of active sites appears to be influenced by fundamental features of nuclear structure. Many proteins involved in the replication machinery have targeting signals that direct their association with the active sites. The sites are dynamic, however, and can be shown using green fluorescent protein (GFP)-tagged replication proteins, such as proliferating cell nuclear antigen (PCNA) (Leonhardt *et al*., 2000), to assemble shortly before synthesis begins and disassemble as replication within a particular factory is complete.

Chromosome Structure and Dynamics

Mammalian chromosomes are highly structured. This is evident from the fact that their condensation during mitosis occurs in such a way that specific chromosomes from different cell types can be readily recognised if they are stained in specific ways. The banded chromosomal patterns revealed by stains such as Giemsa correlate with differences in gene density (transcriptionally active R bands have roughly fourfold the gene density of G bands), slight differences in base composition (R bands are commonly 3–5% more GC rich), and variations in chromatin structure (antibodies that recognize histone modification associated with gene activity stain R bands). Fundamental features of this organization persist during interphase when individual chromosomes maintain spatially discrete nuclear "territories" (Cremer and Cremer, 2001).

In mammalian nuclei, chromatin is locally dynamic but only over short distances, typically <100 nm. Long-range movement is constrained, and the best models for the corresponding organisation predict randomly arrayed structural subunits of roughly 1 Mbp DNA

(Cremer and Cremer, 2001), the typical size of DNA foci. The possibility that clusters of replicons act as stable cohorts that determine chromosome architecture and drive critical aspects of chromatin function, such as the replication programme, is an exciting insight that emphasises the importance of structure–function relationships.

In order to study this in living cells, strategies have been developed to label DNA foci with fluorescent precursor analogues so that it is now possible to perform detailed studies of the dynamic relationships between different foci and explore if these structures dictate fundamental features of chromosome structure and function.

II. MATERIALS AND INSTRUMENTATION

Solutions are prepared in molecular biology grade water from BDH Laboratory Supplies (Cat. No. 443847D). Cell culture media from Sigma-Aldrich are modified as required by the cells under study. For many purposes it is convenient to use HeLa cells grown in Dulbecco's MEM (Cat. No. D 5546) supplemented with penicillin and streptomycin (Cat. No. P 0781), sodium pyruvate (Cat. No. S 8636), glutamine (Cat. No. G 7513), and 5% foetal bovine serum (Cat. No. F 7524). Reagents for *in vitro* labelling are from Sigma-Aldrich: potassium acetate (Cat. No. P 5708), potassium chloride (Cat. No. P 9333), disodium hydrogen phosphate (Cat. No. S 7907), potassium hydrogen phosphate (Cat. No. P 9791), magnesium chloride (Cat. No. M 1028), adenosine triphosphate (Cat. No. A 7699), dithiotheritol (Cat. No. D 5545), phenylmethylulfonyl fluoride (PMSF; Cat. No. P 7626), deoxynecleoside triphosphate set (Cat. No. DNTP-100), nucleoside triphosphates (Cat. Nos. A 6559; C 8552; G 3776; U 1006), phosphate-buffered saline (PBS; Cat. No. P 4417), Triton X-100 (Cat. No. T 9284), saponin (Cat. No. S 7900), digitonin (Cat. No. D 1407), lysolecithin (Cat. No. L 4129), DNase I (Cat. No. D 7291), hydrocholric acid (Cat. No. H 1758), sodium borate (Cat. No. B 0127), acetic acid (Cat. No. A 0808), methanol (Cat. No. M 3641), low melting agarose (type VII-A; Cat. No. A 0701), poly-L-lysine (Cat. No. P 4707), bovine serum albumin (fraction V; Cat. No. A 4503), Tween 20 (Cat. No. P 7949), trypan blue (Cat. No T 8154), Hanks' balanced salt solution (HBSS; Cat. No. H 9269), and 4′,6-diamidine-2-phenylindole dihydrochloride (DAPI; Cat. No. D 8417). Inhibitors used for cell cycle studies are from Sigma-Aldrich: thymidine (Cat. No. T 1895), aphidicolin (Cat. No. A 0781), nocodazole (Cat. No. M 1404), and colcemid (Cat. No. D 7385). The protease inhibitor set (Cat. No. 1 206 893) and FuGene 6 (Cat. No. 1 815 091) are from Roche Applied Science. Liquid paraffin (Cat. No. 29436) is from BDH. The electron microscopy grade 16% paraformaldehyde solution is from Electron Microscopy Sciences (Cat. 15710-S). Vectashield is from Vector Laboratories (Cat. H 1000). TOTO III iodide is from Molecular Probes (Cat. T-3604). Different DNA precursor analogues that may be used to label DNA foci are indicated in Table I, and antibodies used for indirect immunolabelling are detailed in Table II. Plastics for cell culture are from Nunc, and prewashed glass slides and coverslips are from BDH. Culture dishes for live cell imaging are from IWAKI (Cat. 3911-035) or MatTek Corporation (Cat. P35GC-0-14-C), and coverslips with location grids are from MatTek Corporation (Cat. P35G-1.5-7-C-grid). Radioactive nucleotides are from Amersham Biosciences.

The routine procedures described later are commonly used to analyse **replication foci** at the single cell level. Accordingly the output will be recorded using light microscopy with epifluorescence capabilities. Many commercially available light microscopes are capable of generating the necessary output; the particular choice will depend both on the instrumentation that is readily available and on the specific aims of the analysis. For high-resolution work, an advanced machine such as the Zeiss LSM 510 or equivalent from other manufacturers should be used. For many applications it will be adequate to use a much simpler microscope equipped with a CCD camera. Certain labelling strategies can be adapted to study cell cycle parameters using flow cytometry techniques. Finally, if specific emphasis needs to be placed on the extent of DNA synthesis, it is often necessary to perform a single cell analysis in conjunction with radiolabelling. The incorporation of (^{32}P)dNTPs into DNA is measured using a scintillation counter.

III. PROCEDURES

A. Labeling Replication Foci in Cells Growing in Culture

5-Bromo-2′-deoxyuridine is phosphorylated by cells to give BrdUTP and this precursor is incorporated into DNA in place of dTTP.

Solutions

1. Prepare appropriate culture medium—as required by cells under investigation.

TABLE I DNA Precursor Analogues Used to Label DNA Foci[a]

Modified analogue	Supplier (Cat. No.)	Detection	Comments
5-Bromo-2′-deoxyuridine	Sigma (B 9285)	Indirect IF	Excellent
5-Fluoro-2′-deoxyuridine	Sigma (F 8791)	Indirect IF	Moderate detection
5-Chloro-2′-deoxyuridine	Sigma (C 6891)	Indirect IF	Used in double labelling
5-Iodo-2′-deoxyuridine	Sigma (I 7125)	Indirect IF	Used in double labelling
5-Bromo-2′-deoxyuridine 5′-triphosphate	Sigma (B 2506)	Indirect IF	Excellent in permeabilised cells
Biotin-16-dUTP	Roche (1 093 070)	Indirect IF	Excellent in permeabilised cells
Digoxigenin-11-dUTP	Roche (1 093 088)	Indirect IF	Excellent in permeabilised cells
Fluorescein-11-dUTP	Amersham (RPN2121)	Direct by lm[b]	Excellent
Rhodamine-4-dUTP	Amersham (RPN2122)	Direct by lm	Excellent
Cy3-dUTP	Amersham (PA53022)	Direct by lm	Excellent
Cy5-dUTP	Amersham (PA55022)	Direct by lm	Good
Cy3.5-dUTP	Amersham (PA53521)	Direct by lm	Some cytoplasmic binding
Fluorescein-12-dUTP	Roche (1 373 242)	Direct by lm	Excellent
Alexa 488-5-dUTP	Mol. Probes (C-11397)	Direct by lm	Excellent—as fluorescein
Alexa 532-5-dUTP	Mol. Probes (C-11398)	Direct by lm	Strong binding in cytoplasm
Alexa 546-14-dUTP	Mol. Probes (C-11401)	Direct by lm	Excellent—very similar to Cy3
Alexa 568-5-dUTP	Mol. Probes (C-11399)	Direct by lm	Good
Alexa 594-5-dUTP	Mol. Probes (C-11400)	Direct by lm	Good

[a] A selection of precursors used to visualise DNA foci either in living cells or *in vitro* after cell permeabilisation. Note that fluorescent analogues can be used to label foci in permeabilised cells, when they can be visualised directly by lm without further processing, or *in vivo*, providing they can be delivered into the cells.

[b] Light microscopy.

2. Prepare stock solution of desired replication precursor analogue (Table I; e.g., BrdU) in medium. For most purposes, it is convenient to prepare a 100× stock. Labelling is usually performed at 10–50 µ*M* BrdU, depending on the duration of labelling. Higher concentrations may be used for very short pulses, although concentrations in excess of 50 µ*M* may lengthen the cell cycle. IdU is much less soluble than BrdU and should be made as a 10× stock.

1. Adherent Cells

Steps

1. Place clean, sterile 13-mm glass coverslips in a 60-mm petri dish and coat with poly-L-lysine by applying a drop of sterile 0.01% solution for 1 h.
2. Rinse coverslips with medium and seed ~2×10^5 cells in 2 ml fresh medium and grow for 16–24 h or until cells reach ~50% confluency.
3. Replace medium with fresh medium containing 10–50 µ*M* BrdU and incubate for 1–10 h. The concentration should be modified according to the labelling time required—use lower concentrations for longer labelling periods. For very short pulse labels, concentrations in the range of 50–200 µ*M* BrdU can be used.
4. Rinse samples in PBS at room temperature and prepare for immunolabelling.

2. Nonadherent Cells

Nonadherent cells can be labelled directly in suspension in medium. However, for many *in vivo* and *in vitro* applications it is convenient to use cells encapsulated in **agarose microbeads** (Jackson and Cook, 1985). For some applications, particularly high-resolution analyses using electron microscopy (e.g., Hozak *et al.*, 1993), it is also convenient to perform experiments on adherent cells that are encapsulated after removing from the surface on which they normally grow. Use the following steps to encapsulate cells.

Steps

1. Warm 10 ml liquid paraffin to 37°C.
2. Heat 0.25 g low-gelling agarose in 10 ml PBS at ~95°C until dissolved and cool to 37°C.
3. Resuspend ~10^7 cells (a final cell density of 2×10^6 cells/ml beads is ideal for this application, although a wide range can be used) in 4 ml PBS at 37°C in a 100-ml round-bottomed flask.
4. Add 1 ml agarose solution at 37°C to 4 ml cell suspension at 37°C and mix thoroughly.
5. Add 10 ml paraffin at 37°C, seal flask with plastic film, and immediately shake (by hand or at 800 cycles/min using a flask shaker) until a creamy emulsion forms (~15 s).

6. Cool flask by periodic rotation in ice-cold water for 10 min; this allows spherical droplets of molten agarose suspended in the paraffin to gel.
7. Add 35 ml ice-cold PBS, mix, and transfer to a 50-ml plastic centrifuge tube.
8. Pellet microbeads by spinning at 1000 rpm on a bench centrifuge at 20°C.
9. Aspirate the supernatant and wash pelleted microbeads once in PBS. If some beads remain at the water/paraffin interface, remove most paraffin, mix thoroughly, and respin.
10. Encapsulated cells can now be regrown in medium or permeabilised directly.

Incorporate BrdU or alternative precursor analogue into encapsulated cells as follows.

Steps

1. Use cells adapted for suspension culture or cells encapsulated in agarose microbeads at a density of ~2 $\times 10^6$/ml and grow in fresh medium for at least 1 h.

2. Add 10–50 µ*M* BrdU for 1–10 h; use a higher concentration if shorter pulse times are required (see earlier discussion).

3. As an optional step, double labelling can be performed using iododeoxyuridine (IdU) and chlorodeoxyuridine (Aten *et al.*, 1992) or IdU and BrdU (Jackson and Pombo, 1998). After the first pulse, e.g., 20 µ*M* BrdU for 1 h, wash samples once in fresh medium by centrifugation (1000 rpm) and resuspension and add medium with a second precursor for a second pulse, e.g., 20 µ*M* IdU for 1 h.

4. Wash in PBS at room temperature and prepare for immunolabelling. The routine procedure for washing agarose microbeads is facile. Beads pellet readily during centrifugation at ~1000 rpm in a benchtop centrifuge for 1–2 min. The supernatant can then be aspirated (with care no beads should be lost) and the bead pellet resuspended in any solution of choice.

3. *Labeling* in Vitro

For many applications, labelling *in vitro* using **permeabilised cells** provides an appealing versatility. A major advantage of this option is that replication elongation rates can be manipulated precisely by adjusting the concentration of the precursor pools, incubation time, and temperature. It is also convenient to use a much wider variety of modified precursors (Table I), as permeabilised cells do not restrict access of the dNTPs to the nucleus. The chromatin structure is especially sensitive to changes in its ionic environment, and the choice of the buffer to use with permeabilised cells is particularly important. Many buffers are in common use, but the following "physiological buffer" (PB) is useful for preserving critical features of nuclear structure and function.

Solutions

1. Prepare PB containing 100 m*M* KCH_3COOH, 30 m*M* KCl, 10 m*M* Na_2PO_4, 1 m*M* $MgCl_2$, 1 m*M* Na_2ATP, 1 m*M* dithiothreitol, and 1 m*M* PMSF and add 100 m*M* KH_2PO_4 as required to give pH 7.4. Protease and nuclease inhibitors should be added to suit the demands of particular experiments.

2. In PB, prepare 10× concentrated initiation mix to give the following final concentrations: 250 µ*M* dATP, 250 µ*M* dCTP, 250 µ*M* dGTP, 100 µ*M* CTP, 100 µ*M* GTP, 100 µ*M* UTP, and 10–100 µ*M* TTP analogue (Table I), plus $MgCl_2$ at a molarity equal to that of the triphosphates.

Comments and Pitfalls

Various combinations of monovalent anion can be used. Different chloride/acetate/glutamate (or polyglutamate) combinations support similar rates of replication. However, acetate/glutamate is preferred to the smaller Cl^-, which is more damaging to the tertiary protein structure. The concentration of divalent cations must be controlled carefully. As little as 0.5 m*M* free Mg^{2+} causes the visible (by EM) collapse or aggregation of chromatin. The equimolar Mg/ATP combination used here preserves the chromatin structure and supports the action of Mg-dependent enzymes. Dithiothreitol, protease inhibitors, and ribonuclease inhibitors protect the sample and preserve cell morphology.

Steps

1. Prepare cells on coverslips or encapsulated in agarose microbeads as described earlier.
2. Wash samples in ice-cold PB to remove medium and permeabilise for ~2 min using 0.01–0.1% of a suitable detergent.
3. Wash cells three times in ice-cold PB to remove the detergent.
4. Incubate coverslips or microbeads in PB at 33°C for 5 min.
5. Add one-tenth volume of 10× IM, mix, and incubate at 33°C for 2–60 min.
6. Wash three times in >10 volumes ice-cold PB and proceed to fix and label.

Comments and Pitfalls

The choice of detergent will depend on the requirements of a particular experiment. We commonly use

saponin at 0.01%, as this preserves nuclear structure and supports endogenous levels of DNA or RNA synthesis. The extent of lysis is critical. To define conditions, use a twofold dilution series of detergent in PB and assess the level of permeabilisation using trypan blue exclusion (add 50 µl 1% trypan blue in PB to a coverslip or 50 µl packed microbeads; after 2 min, inspect by light microscopy; score percentage permeabilised, dark-blue cells). Choose the detergent concentration that permeabilises ~95% cells. If cells detach from coverslips during washing, use a lower concentration of detergent. The following (and related) detergents can be used (guideline concentrations are indicated): 0.02–0.05% Triton X-100; 0.01–0.02% saponin; 0.01–0.02% digitonin; and 0.02–0.05% lysolecithin.

The concentration of modified precursor and duration of labelling can be adjusted to suit individual requirements. The following provides some guidelines. Fifteen-minute incubations with 20 µ*M* biotin- or digoxigenin-coupled precursors give good indirect immunofluorescence signals, and longer incubations give correspondingly stronger signals. Five- and 2-min incubations with 100 µ*M* biotin-16-dUTP allow detection by light and electron microscopy, respectively, using standard detection protocols. Incorporated labels can be detected after ~30-min incubations with 20 µ*M* fluorescent precursors. Overall levels of incorporation can be quantitated by incorporating a radioactive trace—typically [P^{32}]dCTP—into the reaction; use ~50 µCi/ml [P^{32}]dCTP and reduce dCTP pool to ~10 µ*M*.

If inhibitors are to be used, incubate them for 15 min at 0°C prior to the addition of 10× IM.

B. Chromosome and Nuclear Spreads

Samples labelled in suspension can be fixed onto a glass surface using a standard **chromosome spreading** technique (Fig. 1).

Solutions

1. Hanks balanced salt solution (HBSS).
2. Prepare 0.075 *M* KCl in distilled water.
3. Prepare 3:1 (v/v) methanol:acetic acid fixative.

Steps

1. In a 10-ml plastic tube, wash cells labelled with DNA precursor analogue once in HBSS at room temperature. Resuspend the cell pellet in 0.075 *M* KCl (0.5–1 × 10^6 cells/ml) and incubate at 37°C for 15 min to swell the cells.

2. Using 2–5 ml of swollen cell suspension in a 10-ml plastic centrifuge tube, prefix cells by adding 3 drops/ml of methanol/acetic acid (3:1)—add the fixative dropwise from a Pasteur pipette while agitating the cell suspension gently. Leave the mix at room temperature for 15 min.

3. Pellet cells at 1000 rpm, aspirate the supernatant gently, and resuspend the pellet (by gentle agitation of the tube) in methanol/acetic acid (3:1). Stand at room temperature for 1 h.

4. Pellet the sample once more and resuspend cells in fresh methanol/acetic acid at 2 × 10^6 cells/ml. Spread immediately.

5. Glass slides should be rinsed in detergent (e.g., Decon 90), washed extensively in double-distilled water, and chilled to 4°C in water. Take a chilled slide, drain off excess water, and hold the slide at a ~30° angle against a work surface. Immediately drop 2–3 drops of the cell suspension from a Pasteur pipette onto the centre of the slide. The organic solvent and fixed cells will spread in the water film to cover most of the slide.

6. Place the slide on paper towels soaked in iced water and allow to dry. The dried slides can be stored in a fridge for many days before immunolabelling.

Comments and Pitfalls

If the analysis requires significant numbers of mitotic cells, it is usual to begin by growing cells for 30–60 min in medium supplemented with colcemid (50 ng/ml). This drug disrupts microtubule function and blocks cells in metaphase.

Hydrodynamic properties of the drying spread have a significant impact on the quality of mitotic spreads. Reproducibly high-quality spreads are usually obtained if the speed of drying is controlled by placing slides on cold, damp paper towels.

C. DNA Fibre Spreads

Many important aspects of the biology of replication clusters, as well as fundamental features of the replication process, can be studied using appropriately labelled **DNA fibre spreads** (Jackson and Pombo, 1998; Takebayashi *et al*., 2001).

Solutions

1. Prepare PBS in distilled water.
2. Prepare lysis mix with 0.5% (w/v) SDS, 200 m*M* Tris–HCl (pH 7.4), and 50 m*M* EDTA in distilled water.
3. Prepare 3:1 (v/v) methanol:acetic acid fixative.

Steps

1. Harvest cells labelled with the appropriate DNA precursor analogue (or analogues for multiple labelling) and resuspend in PBS at 10^6 cells/ml.

2. Take a clean glass slide and place 2 µl of the cell suspension on the slide, about 2 cm from one end. Leave the sample to stand for about 10 min so that the cells settle on to the glass surface; do not allow the sample to dry completely.
3. Add 5 µl of lysis mix to the cell sample and let stand for 5 min at room temperature to lyse the cells.
4. Tilt the slide to a ~20° angle so that the cell lysate flows as a uniform smear to the bottom of the slide (the smear will be about 4 cm).
5. Lie the slide on a flat surface and allow the spread sample to dry.
6. Fix the sample by immersing the slide in methanol/acetic acid (3:1) for 5 min.
7. Remove slides from the fixative and allow them to dry. The dried slides can be stored in a fridge for many days before immunolabelling.

D. Immunolabeling Procedures

Cell structures with incorporated DNA precursor analogues must be stabilised by fixation prior to immunolabeling. For light microscopy techniques, paraformaldehyde is the fixative of choice. Samples treated with methanol/acetic acid can be stained directly, although for some applications it is also advantageous to postfix samples with paraformaldehye. Fixation and immunolabeling procedures used for electron microscopy are specialised and beyond the scope of this article. For details of these techniques, see Hozák *et al*. (1993, 1994).

Solutions

1. Prepare PBS or physiological buffer (PB; see earlier discussion) in distilled water.
2. Prepare 4% paraformaldehyde in PBS or PB.
3. Prepare 0.25% Triton X-100 in PBS or PB.

1. Cells on Glass

Steps

1. After rinsing in PBS, place coverslips or slides in 4% paraformaldehyde for 10 min at room temperature. Permeabilised cells labelled *in vitro* should also be fixed in this way but must be first washed in buffer to remove unincorporated precursors.

2. Wash samples twice with PBS.

3. Permeabilise cells by incubation in 0.25% Triton X-100 in PBS for 2 min at room temperature—this improves subsequent access of the antibodies.

4. Wash gently in PBS (three changes over 5 min). Samples can now be labeled with antibodies.

2. Encapsulated Cells

Steps

1. After labelling *in vitro*, remove unincorporated precursors by washing beads three times in 10 volumes ice-cold PB for 15 min.
2. Permeabilise by incubating in 0.25% Triton X-100 in PB for 10 min at 0°C.
3. Wash three times in 10 volumes ice-cold PB.
4. Fix in ice-cold 4% paraformaldehyde in PB for 10 min.
5. Wash three times in 10 volumes ice-cold PBS. Samples can now be labelled with antibodies as described later.

3. Antibody Binding

Commercial anti-BrdU antibodies (Table II) react poorly with BrdUMP in native DNA. Binding is increased 10- to 20-fold if DNA is first denatured.

i. Acid Denaturation

Solutions

1. Prepare 2 *M* HCl by diluting concentrated acid in distilled water.
2. Prepare 0.1 *M* $Na_2B_4O_7$ dissolved in distilled water.
3. PBS/BSA/Tween is PBS containing 0.5% BSA and 0.1% Tween 20.

Steps

1. Rinse slides or coverslips in distilled water.

2. Denature DNA in 2 *M* HCl for 1 h at room temperature.

3. Rinse five times in 0.1 *M* $Na_2B_4O_7$ to remove acid.

4. Rinse twice in PBS/BSA/Tween and incubate samples with PBS/BSA/Tween for 1–2 h in a humid atmosphere at room temperature to block nonspecific-binding sites.

5. Add first antibody, cover sample with a few drops of PBS/BSA/Tween and 1/50 to 1/500 dilution (determine empirically) anti-BrdU antibody, and incubate 1–2 h in a humid atmosphere at room temperature.

6. Wash five times in PBS/BSA/Tween at room temperature for 1 h.

7. Add second antibody. Cover the sample with a few drops of PBS/BSA/Tween and 1/500 to 1/1000 dilution of the labelled second antibody (Table II) and incubate 1–2 h in a humid atmosphere at room temperature. The second antibody should be selected to react with antibodies from the species in which the first antibody was developed (Table II).

TABLE II Antibodies Commonly Used to Label DNA Foci and Sites of DNA Synthesis[a]

Antibody—clone	Supplier (Cat. No.)	Reactivity/crossreactivity	Comments
M anti-Br—mab—IU-4	Caltag (MD5100)	+++ BrdU+/IdU+/F/ClduU+	Used in double labelling
M anti-Br—mab—BR-3	Caltag (MD5200)	++ BrdU+/IdU$^-$	
M anti-Br—mab BMC9318	Roche (1 170 376)	++ BrdU+/IdU+	
M anti-Br—mab—B44	Becton Dickinson (347580)	+ BrdU+/IdU+	
M anti-Br—mab—BU-33	Sigma (B 2531)	+ BrdU+/IdU+	
R anti-Br—mab—BU1/75	Sera-Labs (MAS 250p)	+ BrdU+/IdU–	Used in double labelling
S anti-Br—polyclonal	Biodesign (M20105S)	+++ BrdU +F/Cl/IdU	Useful with other M antibodies
G antibiotin—polyclonal	Sigma (B 3640)	+++ Biotin	Excellent *in vitro*
M antibiotin—c33	Roche (1 297 597)	+++ Biotin	Excellent *in vitro*
M antidigoxigenin—mab—1.71.256	Roche (1 333 062)	+++ Digoxigenin	Excellent *in vitro*
S antidigoxigenin—polyclonal	Roche (1 333 089)	+++Digoxigenin	Excellent *in vitro*
M anti-PCNA—PC10	Sigma (P 8825)	+++PCNA	After methanol fixation
H anti-PCNA—autoimmune	Alpha Labs (6006)	+++PCNA	After paraformaldehyde fixation
Fluorochrome-conjugated secondary antibodies	Jackson Labs (see catalogue)	+++M/R/G/S/H determined by first antibody	

[a] A selection of reagents used commonly to visualise DNA foci and sites of DNA synthesis. Antibodies that bind to BrdU in DNA are available from many commercial sources. A selection of commonly used antibodies is given. The species are M, mouse; R, rat; S, sheep; G, goat; and H, human. Secondary antibodies that are labelled with a wide range of fluorochromes are available from many commercial sources. Appropriate reagents should be chosen as determined by the primary antibody or antibodies—if multiple labelling is required. Jackson Laboratories have an excellent range of reagents and supply absorbed ML antibodies that should be used for multiple labelling.

8. Wash five times in PBS/BSA/Tween at room temperature for 1 h.
9. Prepare samples for microscopy using an appropriate mountant (e.g., Vectashield) and seal coverslips with nail varnish.
10. Inspect samples using a suitable microscope.

Comments and Pitfalls

Fluorochrome-coupled second antibodies give high resolution and can be analyzed using confocal-scanning light microscopes and sensitive charge-coupled device (CCD) cameras. Fluorescence-based detection systems also allow convenient multiple labelling (e.g., Aten *et al*., 1992; Jackson and Pombo, 1998; Schermelleh *et al*., 2001). As an alternative, it is also possible to detect the location of the incorporated precursor using enzyme-coupled second antibodies (such as alkaline phosphatase). This approach is used in routine histology of tissue sections but generally offers lower resolution.

ii. Nuclease-Dependent Denaturation. Acid denaturation is accompanied by some loss of morphology. If morphological considerations are critical, nuclease-dependent detection systems are preferred.

Solution

PBS/BSA/Tween is PBS containing 0.5% BSA and 0.1% Tween 20.

Steps

1. Rinse slides or coverslips once in PBS, twice in PBS/BSA/Tween, and incubate in PBS/BSA/Tween for 1 h at room temperature.
2. Add first antibody, cover samples with a few drops of PBS/BSA/Tween, 1/50 to 1/500 dilution anti-BrdU antibody, and 50 µg/ml DNase I (Sigma), and incubate 1–2 h in a humid atmosphere at 37°C.
3. Perform steps 6–11 as following acid denaturation described earlier.

iii. Encapsulated Cells

Solutions

1. PBS/BSA/Tween is PBS containing 0.5% BSA and 0.1% Tween 20.
2. 0.02 mg/ml DAPI in sterile distilled water—this is a 1000× stock.

Steps

1. Wash beads containing fixed cells twice in ice-cold PBS/BSA/Tween and incubate in PBS/BSA/Tween for 1 h at 0°C.
2. Add first antibody, mix 100 µl beads with 400 µl PBS/BSA/Tween containing 1/50 to 1/500 dilution of appropriate first antibody, and incubate at 0°C for 2 h with periodic mixing.

3. Wash three times in 10 volumes ice-cold PBS/BSA/Tween for 30 min.

4. Add second antibody, mix the bead pellet with 400 µl PBS/BSA/Tween containing 1/500 dilution of appropriate fluorochrome-coupled second antibody (Table II), and incubate at 0°C for 2 h with periodic mixing.

5. Wash three times in 10 volumes ice-cold PBS/BSA/Tween for 30 min.

6. Wash three times in 10 volumes PBS at room temperature with 5 min between washes; add 0.02 µg/ml DAPI or 1/250 dilution TOTO III iodide (fluorescence in the far red spectrum) to second wash.

7. Mount by mixing 5 µl beads with an equal volume of mounting medium (Vectashield), apply coverslip with gentle pressure to eliminate excess fluid, and seal with nail varnish.

8. Inspect samples using a suitable microscope.

E. Patterns of DNA Synthesis

The techniques detailed earlier allow visualisation of labeled DNA foci. These foci can be analysed by indirect immunolabeling either immediately after incorporation or many hours later. If the precursor analogue (e.g., BrdU) is added to cells for <30 min and indirect immunolabeling is performed immediately, most labeled sites will correspond with sites of ongoing DNA synthesis. This can be confirmed by labeling DNA foci (as described earlier) in conjunction with a marker for the replication factory. Antibodies to PCNA are generally used for this purpose. Cells labeled either *in vivo* (Nakamura *et al*., 1986) or *in vitro* (Nakayasu and Berezney, 1989) to reveal the sites of nascent DNA synthesis display a few hundred discrete nuclear sites, with patterns that are characteristic of different stages of S phase (O'Keefe *et al*., 1992; Humbert and Usson, 1992). Foci labeled after very short incubations are associated with massive protein complexes (Hozák *et al*., 1993) where many replicons are duplicated together.

1. Labeling Sites of Ongoing DNA Synthesis

While nascent sites of DNA synthesis can be labeled in living cells using short pulse labels of appropriate analogues (e.g., BrdU), for technical reasons it is preferable to label nascent sites *in vivo* using permeabilised cells. The major advantages of *in vitro* labeling are that precursors dNTP (e.g., biotin-dUTP) can be used directly and that soluble pools of unassembled replication proteins are lost during cell lysis.

Solutions

1. Physiological buffer as detailed earlier.
2. 0.2% (w/v) saponin in PB—this is a 20× stock lysis solution.
3. 10× IM mix as indicated earlier supplemented with 20 µ*M* biotin-dUTP.
4. 4% paraformaldehyde in PB.

Steps

1. Permeabilise cells growing on coverslips or encapsulated in agarose microbeads and label for 15–30 min with a suitable labelled precursor analogue as described earlier. Biotin-dUTP is recommended for this application, although it may be convenient to label the nascent DNA directly using a fluorescent precursor analogue (Table I).

2. If biotin-dUTP is used, wash samples three times in PB to remove the unincorporated precursor and fix the samples in 4% paraformaldehyde in PB as described earlier.

3. Visualise sites of incorporation as described earlier, using an antibody to biotin (Table II).

4. The engaged replication machinery can be visualised in the same samples using an antibody to a protein component such as PCNA using the standard indirect immunolabelling technique: in PBS/BSA/Tween add 1/500 dilution of the first anti-PCNA antibody for 1–2 h, wash with PBS/BSA/Tween, and then apply appropriate fluorescently labelled second antibodies in PBS/BSA/Tween as described earlier. Wash the samples and mount as described earlier.

Comments and Pitfalls

PCNA antibodies can be used to visualise assembled replication proteins. The antibody from Alpha Laboratories is a human autoimmune serum and can be applied to samples directly. PC10, a mouse monoclonal antibody, reacts poorly with PCNA at replication sites fixed in paraformaldehyde. To use this reagent, samples should be fixed by incubating for 10 min in methanol at –20°C.

F. Chromosome Dynamics and Live Cell Techniques

Many directly labeled fluorescent analogues of DNA synthesis precursors can be used to visualise **replication foci in living cells** (Pepperkok and Ansorge, 1995; Zink *et al*., 1998; Manders *et al*., 1999). However, one limitation of this approach arises from the inability of these charged molecules to cross the cell membrane. Many techniques have been evaluated to address this problem. Microinjection (Pepperkok and

Ansorge, 1995; Zink *et al*., 1998) is an obvious possibility but this is technically tedious and only ideally suitable for labelling small numbers of cells. Other alternatives include bead loading (Manders *et al*., 1999) scratch loading (Schermelleh *et al*., 2001) and the use of synthetic carrier complexes.

1. Scratch Loading

Solutions

1. Culture medium—as required for the specific cell type under study.
2. Culture medium supplemented with 10–20 µ*M* dNTP analogue (Table I).

Steps

1. Cells should be 50–75% confluent and growing on glass coverslips or culture dishes with glass inserts.
2. Remove the medium and apply medium with fluorescent analogue—use 10 µl for each 13 mm diameter and proportionally more if larger samples are used.
3. Use the tip of a fine hypodermic needle to scratch a series of parallel lines across the coverslip surface —it is convenient to use lines separated by about 0.5–1 mm.
4. After 1 min, add 0.5 ml of prewarmed medium and let stand in incubator for 30 min.
5. Finally, wash in medium to remove any unincorporated precursors, add medium to normal growth conditions, and return culture dish to a humidified incubator until use.

2. Carriers

Carrier-mediated delivery of fluorescent nucleotides (Table I) can be performed as follows.

Solutions

1. For each coverslip, prepare 3 µl of the transfection reagent FuGENE 6 mixed with 12 µl PBS and incubate at 4°C for 5 min.
2. Add 1.5 µl of the desired fluorescent nucleotide analogue, mix, and incubate at 4°C for 20 min.

Steps

1. Grow cells on 13-mm coverslips coated with poly-L-lysine as described earlier.

2. Pipette the fluorescent nucleotide carrier complex (16.5 µl) onto a piece of parafilm and place the coverslip (cell face down) on the droplet for 15 min at 4°C.

3. Rinse the cells in full medium, replace with fresh medium, and return samples to an incubator prior to analysis or further labelling treatments.

4. If further analogues are to be used, simply repeat the procedure at the desired time interval. Note, however, that repeated applications do influence cell viability, which is particularly pronounced if two or more analogues are added consecutively without allowing cells time to recover. Good results are obtained if the separation between applications is at least 2 h.

5. Samples can be inspected directly following incorporation; using this technique, fluorescent nucleotides introduced into an S-phase cell are consumed in ~30 min. For live cell experiments, transfer the labelled cells into culture dishes with poly-L-lysine-coated glass coverslip inserts. Culture dishes with gridded coverslips are also of use for relocating individual cells during long-term analysis.

6. Inspect samples using a convenient microscope adapted for live cell imaging.

In living cells, studies of the dynamics of DNA foci and their association with replication machinery can be performed by labelling DNA foci in cells that have a component of the replication machinery, such as PCNA, tagged with GFP (Leonhardt *et al*., 2000).

G. Cell Cycle Analysis

In vertebrates, important features of the replication process have been revealed using cell populations that have been synchronised at critical points of the cell cycle. Two points in the cycle are generally amenable to **cell synchronisation**. First, reagents that disrupt microtuble function (e.g., nocodazole or colcemid) allow cells to accumulate in mitosis. Cells that generally grow as adherent monolayers can be purified in mitosis using simple shake-off techniques that dislodge only mitotic cells. Many compounds can be used to accumulate cells at or close to the beginning of S phase. Aphidicolin is the reagent of choice, as inhibition is readily reversible and low concentrations added to medium specifically inhibit the elongation phase of DNA synthesis. The following protocol was used to demonstrate the efficiency with which human replicons are activated in different cell cycles (Jackson and Pombo, 1998).

Solutions

1. Full medium, as required by cells under study—serum should be added to support optimal growth.
2. 250 m*M* thymidine in sterile distilled water—this is a 100× stock solution.
3. 50 µg/ml nocodazole in sterile distilled water—this is a 1000× stock solution.
4. 5 mg/ml aphidicolin in DMSO—this is a 1000× stock solution.

5. 10–100× stock solution of required DNA synthesis precursor analogue (Table I) in medium.

Steps

1. Synchronise cells in mitosis by incubating sequentially in medium supplemented with (i) 2.5 m*M* thymidine for 24 h; (ii) no additive for 12 h; (iii) 2.5 m*M* thymidine for 12 h; (iv) no additive for 10 h; and (v) 50 ng/ml nocodazole for 4 h. To remove inhibitors, remove medium, wash cells once in fresh medium for 5 min, and replace with fresh medium.

2. Wash cells to remove nocodazole and incubate in fresh medium for 4–7 h.

3. Add 5 µg/ml aphidicolin for 2–3 h.

4. Wash cells in fresh medium supplemented with a suitable precursor analogue (e.g., BrdU) and incubate for 15–30 minutes as described previously. This will pulse-label DNA foci in cells accumulated at the onset of S phase.

5. Return cells to fresh full medium.

6. After a specified time, typically 1–5 h, samples can be pulse labelled further in medium supplemented with a second precursor analogue (e.g., IdU).

7. Alternatively, from 12 h to many days later, steps 1–5 can be repeated using a second precursor analogue (e.g., IdU).

8. Indirect immunodetection of the two incorporated analogues can now be performed on fixed cells or spread DNA fibres as detailed earlier.

Comments and Pitfalls

Timings must be determined empirically, as different cell lines each have characteristic cell cycle parameters. Trial experiments should be performed to establish the time interval between releasing cells from mitosis and the onset of S phase. For most mammalian cell lines, cells synchronised in mitosis enter S phase after 5–10 h. Because G1 is the most variable period of the cell cycle, additional aphidicolin treatment is required to accumulate cells at the very beginning of S phase. Conditions should be used that give 20–50% cells undergoing replication.

The same approach can be applied using directly labelled analogues for live cell imaging.

Using a combination of pulse labelling and fluorescent *in situ* hybridisation (FISH) on DNA fibres, it is also possible to analyse where DNA synthesis initiates at specific chromosomal loci (Takebayashi *et al*., 2001).

H. Reconstituting Replication Sites

The protocols detailed earlier have been developed to visualise DNA foci and sites of nascent DNA synthesis in intact or permeabilised cells. For some applications it is convenient to extend our knowledge of the replication process using systems that are amenable to manipulation *in vitro*. While it is beyond the scope of this article to cover these applications in detail, the authors would like to comment on their potential merits. The best system in vertebrates takes advantage of the ability of *Xenopus laevis* egg extracts to assemble nuclei when incubated with a suitable DNA (commonly from sperm). Reconstituted nuclei are formed that perform a single but complete round of DNA synthesis, which begins about 30 min after mixing. Importantly, as the extracts can be manipulated by the removal or addition of replication or cell cycle components, this provides an excellent opportunity to study pathways of activation and assembly of the replication machinery. Mammalian nuclei cannot be assembled from basic components in the same way, although it is possible to manipulate assembly of the replication machinery using permeabilised cells from the late G1 phase of the cell cycle mixed with extracts derived from S-phase cells.

Isolation of Chromosomes for Flow Analysis and Sorting

Nigel P. Carter

I. INTRODUCTION

The bivariate analysis of mammalian chromosomes using the flow cytometer was first described by Gray and colleagues in 1979. In this method, metaphase chromosomes are released into a stabilising buffer and stained with two dyes, Hoechst 33258 (with specificity for AT-rich regions of DNA) and chromomycin A3 (specificity for GC-rich DNA) and then analysed or sorted using the flow cytometer. However, the technique has remained a somewhat specialist application limited to a relatively small number of laboratories. One reason for this is the requirement for the flow cytometer to be equipped with two large water-cooled and expensive lasers in order to excite the two dyes. However, arguably the most critical factor is the isolation of intact metaphase chromosomes from actively dividing cells. Several chromosome isolation procedures have been described (Sillar and Young 1981; van den Engh *et al*., 1984, 1985, 1988; general reference, Gray, 1989). Of these procedures, methods based on the stabilisation of chromosomes with polyamines (Sillar and Young, 1981) have proved to be most reliable for not only flow karyotype resolution, but also for the generation of high molecular weight DNA from sorted chromosomes. This article describes the procedure for isolating chromosomes from human lymphoblastoid cell lines using a polyamine buffer.

II. MATERIALS

Spermine tetrahydrochloride (Cat. No. S2876), spermidine trihydrochloride (Cat. No. S2501), Hoechst 33258 (Cat. No. B2883), chromomycin A3 (Cat. No. C2659), gentian violet (Cat. No. G2039), propidium iodide (Cat. No. P4170), Triton X-100 (Cat. No. X100), Trizma base (Tris-base, Cat. No. T6791), EGTA (Cat. No. E3889), EDTA (Cat. No. E5134), potassium chloride (Cat. No. P9541), sodium chloride (Cat. No. S3014), sodium sulphite (Cat. No. S8018), trisodium citrate (Cat. No. C3434), RPMI1640 medium (Cat. No. R8758), L-glutamine/penicillin/streptomycin solution (Cat. No. G6784), dithiothreitol (Cat. No. D9779), and magnesium sulphate (Cat. No. M2773) are obtained from Sigma. Foetal bovine serum (Cat. No. 16000-044) is obtained from Gibco. Invitrogen Corp.

III. PROCEDURES

A. Tissue Culture and Chromosome Preparation

Solutions

1. *Culture medium*: To 500 ml of RPMI 1640 medium add 100 ml of foetal bovine serum and 5 ml of L-glutamine/penicillin/streptomycin additive.
2. *Polyamine buffer and stain stock solutions*
   a. Dissolve 1.18 g of Tris-base and 832 mg of EDTA in sterile distilled water, adjust pH to 8.0, and bring final volume to 100 ml.
   b. Dissolve 1.18 g of Tris-base and 190 mg of EGTA in sterile distilled water, adjust pH to 8.0, and bring final volume to 100 ml.
   c. Dissolve 5.96 g of potassium chloride in sterile distilled water and bring final volume to 100 ml.

Copyright 2006, Elsevier Science (USA).
All rights reserved.

d. Dissolve 1.17 g of sodium chloride in sterile distilled water and bring final volume to 100 ml.

Solutions should be sterile filtered and stored at 4–10°C for up to 1 month.

e. Dissolve 1.39 g of spermine tetrahydrochloride in sterile distilled water and bring final volume to 10 ml. Aliquot and store at –20°C.
f. Dissolve 2.55 g of spermidine trihydrochloride in sterile distilled water and bring final volume to 10 ml. Aliquot and store at –20°C.
g. Dissolve 1 g of dithiothreitol in sterile distilled water and bring final volume to 21.6 ml. Sterile filter and store at 4–10°C.
h. Dissolve 3.15 g of sodium sulphite in sterile distilled water and bring final volume to 100 ml. Do not store.
i. Dissolve 2.94 g of trisodium citrate in sterile distilled water and bring final volume to 100 ml. Do not store.
j. Dissolve 10 mg of Hoechst 33258 in sterile distilled water and bring final volume to 10 ml. Sterile filter and store in the dark at 4–10°C.
k. Dissolve 5 mg of chromomycin A3 in ethanol and bring final volume to 2.5 ml. Aliquot and store at –20°C.
l. Dissolve 1 mg of propidium iodide in sterile distilled water and bring the final volume to 10 ml.
m. Dissolve 1.2 g of magnesium sulphate in sterile distilled water and bring final volume to 100 ml. Sterile filter and store at 4–10°C.
n. Add 1 ml of glacial acetic acid and 10 mg of gentian violet to sterile distilled water and bring the final volume to 100 ml (Turck's stain). Store at 4–10°C.

Steps

1. Grow 20 ml of the lymphoblastoid cell line to near confluence and add a further 30 ml of medium to the flask, gently breaking up any cell clumps. Incubate for 24 h.

2. Add 0.5 ml of colcemid and mix gently. Incubate for 6 h.

3. Transfer the cell suspension to a 50-ml centrifuge tube and centrifuge at 200 *g* for 10 min. Decant the supernatant and place the tube, inverted, on an absorbent paper tissue.

4. Dilute 4.7 ml of stock 800 m*M* potassium chloride solution to 50 ml with sterile distilled water and filter through a sterile 0.2-µm filter. Add 10 ml to the cell pellet and resuspend gently. Incubate at room temperature for 15 min.

5. Monitor swelling by staining 10 µl of the cell suspension with an equal volume of Turck's stain and viewing in a haemocytometer using phase-contract microscopy. Monitor cell bursting by staining 20 µl of the cell suspension with 1 µl of propidium iodide solution and viewing in a haemocytometer using fluorescence microscopy.

6. To make the polyamine buffer, mix together 10 ml of each of the four stock solutions (a–d), 50 µl of spermine tetrahydrochloride, 50 µl spermidine trihydrochloride, 250 µl of Triton X-100, 500 µl of dithiothreitol, and 50 ml of sterile distilled water, adjust pH to 7.2 with hydrochloric acid, and bring the final volume to 100 ml. Pass through a sterile 0.2-µm filter.

7. Centrifuge cell suspension at 400 *g* for 10 min, decant supernatant, and invert the tube on a paper tissue. Add 3 ml of the polyamine buffer, resuspend gently, and incubate on ice for 10 min.

8. Vortex the cell suspension for 10 s at a speed that produces a swirling film of suspension around the wall of the tube.

9. Monitor the chromosome release by staining 20 µl of the cell suspension with 1 µl of propidium iodide solution and viewing in a haemocytometer using fluorescence microscopy. Check that the majority of chromosomes are free in solution and not clumped. If clumps are apparent, vortex for periods of 5 s until few clumps are present. Too vigorous or too long vortexing will increase the number of broken chromosomes and debris.

10. Centrifuge 850 µl of the chromosome suspension at 100 *g* for 1 min. Transfer 740 µl of the supernatant to a tube suitable for use on the flow cytometer and add 20 µl of chromomycin A3, mixing immediately.

11. Add 20 µl of magnesium sulphate. Dilute 5 µl of Hoechst with 45 µl of sterile distilled water and add 20 µl to the chromosome suspension and mix well. Incubate for at least 2 h on ice.

12. Add 100 µl of trisodium citrate and 100 µl of sodium sulphite to the stained chromosome preparation 15 min prior to analysis.

IV. COMMENTS

The procedure detailed in this article is directly applicable, with minor modification, to any actively dividing preparation of cells. Care should be taken to block the cells at a time during cell culture when the

maximum number of cells are actively dividing and the time of incubation in colcemid should be adjusted to be approximately three-fourths of the time that the cells spend in the S phase of the cell cycle. Some cell types are resistant to disruption by vortexing (e.g., fibroblasts) and require gently syringing to release chromosomes into solution. The flow cytometer should be aligned according to the manufacturer's procedures such that the chromosomes first pass through the multiline ultraviolet beam required for Hoechst excitation and then, after the appropriate spatial separation, through the deep blue beam (457.9 nm) required for excitation of chromomycin. A nozzle orifice diameter of 50–70 µm is recommended.

V. PITFALLS

Poor preparations that generate flow karyotypes without good separation of peaks are invariably produced when a low mitotic index is produced. Attention must be paid to culture conditions and the timing of subculturing and colcemid blocking to generate the highest mitotic index possible.

Vital Staining of Cells with Fluorescent Lipids

Toshihide Kobayashi, Asami Makino, and Kumiko Ishii

I. INTRODUCTION

Although a number of fluorescent lipid analogs are now available, only a limited set of the molecules are frequently employed for cell biology. Because most of these molecules are less hydrophobic than naturally occurring counterparts, they are easily partitioned to cell membranes when added to the medium. This property and bulk fluorophore alter both physical and biological properties of the lipids. Therefore, the intracellular behavior of fluorescent lipids is not always the same as that of endogenous lipids. In this context, the results need to be evaluated carefully. However, together with appropriate control, fluorescent lipids are very useful tools to follow dynamics of membrane lipids.

II. MATERIALS AND INSTRUMENTATIONS

6-((*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino) hexanoyl)sphingosylphosphorylcholine (C6-NBD-SM, MW 740.88, Cat. No. N3524), 6-((*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)hexanoyl)sphingosine (C6-NBD-Cer, MW 575.75, Cat. No. N1154) and *N*-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-pentanoyl)sphingosine (C5-BODIPY-Cer, MW 601.63, Cat. No. D3521) are from Molecular Probes. 12-((*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)amino)dodecanoyl)sphingosine (C12-NBD-Cer, MW 659.90, Cat. No. N9158) is from Sigma. 1-Palmitoyl-2-(6-((7-nitro-2-1,3-benzoxadiazol-4-yl)amino)hexanoyl)-*sn*-glycero-3-phospho-L-serine (ammonium salt) (C6-NBD-PS, MW 790.85, Cat. No. 810192) is obtained from Avanti. Structures of fluorescent lipids are summarized in Fig. 1.

Dulbecco's modified Eagle's medium (DMEM, Cat. No. 11885-084) is obtained from Invitrogen. Dulbecco's modified Eagle's medium/nutrient mixture F-12 Ham, without phenol red (DMEM F-12, Cat. No. 6434), is from Sigma. Thirty-five-millimeter glass-bottom culture dishes are from Matsunami Glass (noncoat, Cat. No. 111100) or from IWAKI (Asahi Technoglass Scitech Division IWAKI brand, Cat. No. 3911-035) and 60-mm culture dishes are from Nunc. Dulbecco's phosphate-buffered saline (-) (PBS, Cat. No. 14249-95) and sodium dithionite (sodium hydrosulfite, Cat. No. 31509-55) are from Nacalai Tesque. Brefeldin A (Cat. No. G-405) is from BIOMOL. The stained cells are examined under a Zeiss LSM 510 confocal microscope equipped with C-Apochromat 63XW Korr (1.2 n.a.) objective.

III. PROCEDURES

A. Fate of Different NBD-Labeled Lipids Introduced into Plasma Membranes of Cultured Fibroblasts

This procedure describes the methods used to follow the fate of fluorescent lipids inserted into the outer leaflet of the plasma membranes. The fate of fluorescent lipids is different depending on the hydrophilic head group of the lipids.

Copyright 2006, Elsevier Science (USA).

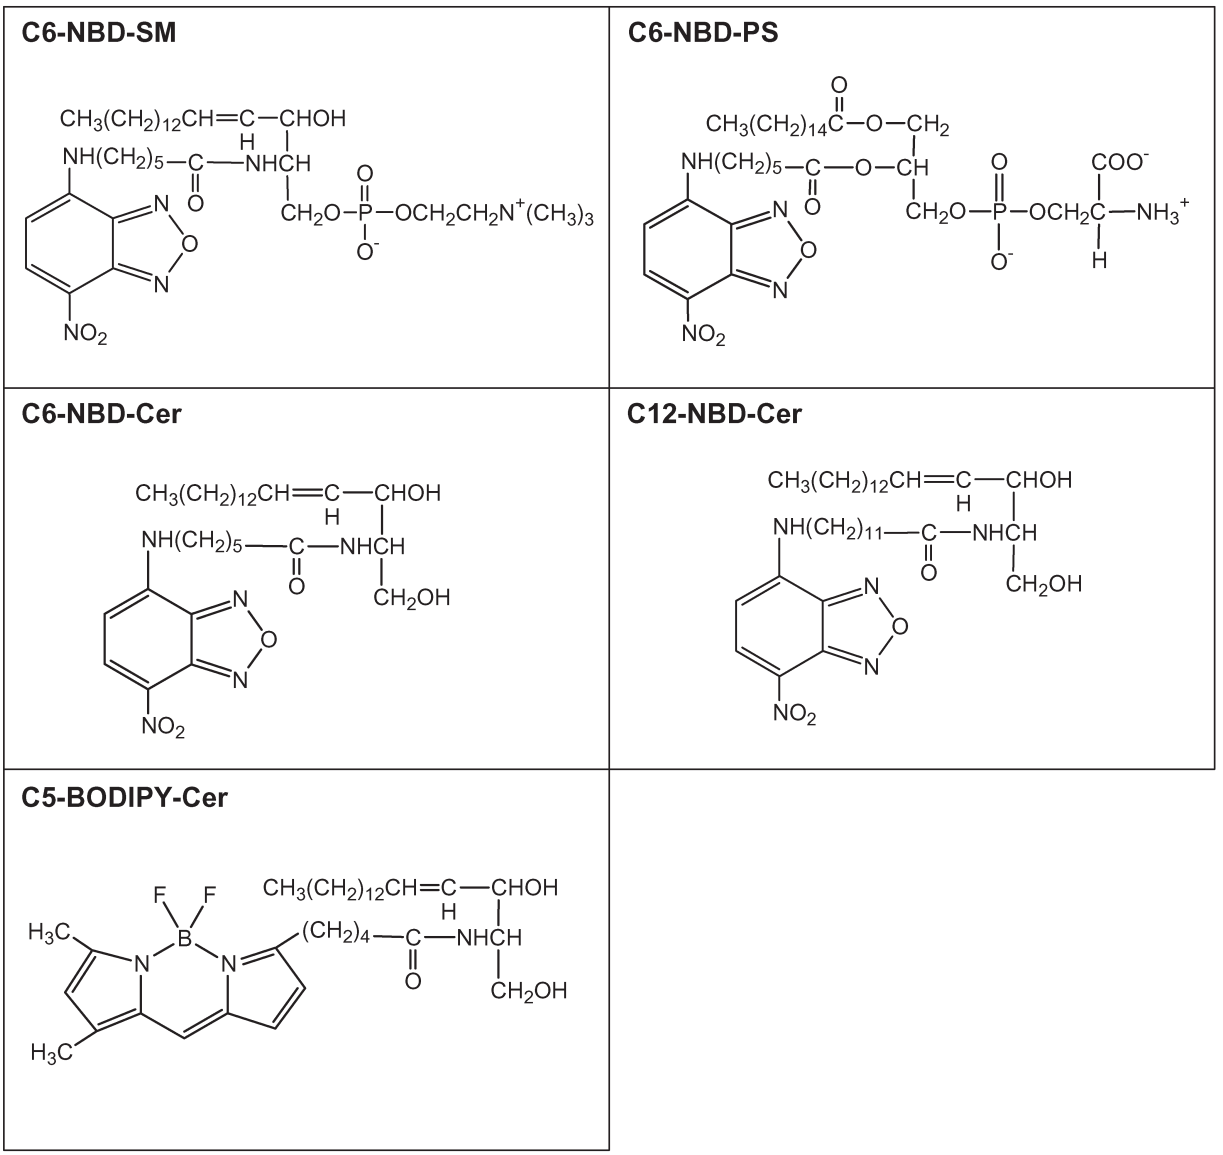

FIGURE 1 Structures of fluorescent lipids described in the text.

Solutions of Fluorescent Lipids

Stock solutions (1 mg/ml) of fluorescent lipids are prepared by dissolving C6-NBD-PS in chloroform and C6-NBD-SM in ethanol. The chloroform stock solution should be kept in screw-capped (Teflon-lined) glass tubes. The ethanol solution can be stored in either glass or plastic tubes. Stock solutions are stored at –20°C. An aliquot of a stock lipid solution is dried, first under a stream of nitrogen and then *in vacuo*. The dried lipid is then dissolved in DMEM to give final concentration 4 μ*M*. The solution is vortexed and kept at 4°C before use.

Steps

1. Grow HeLa cells in duplicate on 35-mm glass-bottom culture dishes for 1–2 days to reach 50–80% confluency.
2. Wash cells twice with ice-cold DMEM.

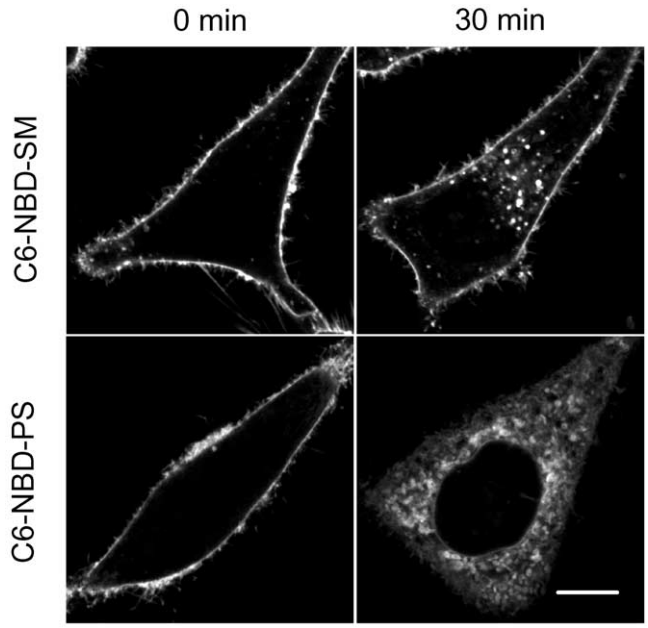

FIGURE 2 HeLa cells labeled with C6-NBD-SM or C6-NBD-PS for 30 min at 4°C (0 min) or 4°C treatment followed by a 30-min incubation at 37°C (30 min). Bar: 10 μm.

3. Incubate cells for 30 min at 4°C with 1 ml DMEM containing 4 μ*M* C6-NBD-SM or C6-NBD-PS.
4. Wash one dish twice with ice-cold DMEM F-12 and then add 1 ml ice-cold DMEM F-12. Record fluorescence images under a confocal microscope (Fig. 2, "0 min").
5. Wash the other dish twice with ice-cold DMEM and then add 1 ml prewarmed (37°C) DMEM.
6. Incubate cells for 30 min at 37°C in a CO_2 incubator.
7. Wash cells twice with DMEM F-12 at room temperature.
8. Add 1 ml DMEM F-12 and observe cells under a microscope (Fig. 2, "30 min").

Comments

C6-NBD-SM (Koval and Pagano, 1989) and C6-NBD-PS (Martin and Pagano, 1987) were first introduced by Pagano and co-workers. At low temperature (2 or 4°C), both fluorescent lipids are transported from the medium to the outer leaflet of the plasma membranes of cultured cells via spontaneous transfer of the lipids. Warming up of cells induces ATP-dependent transbilayer movement (flip-flop) of C6-NBD-PS (Martin and Pagano, 1987). In mammalian cells, the energy-dependent transbilayer movement of lipids is observed only with amino phospholipids such as phosphatidylserine and phosphatidylethanolamine (Devaux *et al.*, 2002). Flip-flop is observed as low as 7°C. Once internalized, C6-NBD-PS is transported spontaneously to intracellular membranes. Unlike C6-NBD-PS, C6-NBD-SM stays on the outer leaflet of the plasma membrane and is internalized by endocytosis. It is postulated that C6-NBD-SM is a marker for the bulk flow of membranes after endocytosis (Mayor *et al.*, 1993). C6-NBD-SM is also used together with C6-NBD-labeled glycolipids to study polarized lipid transport in hepatoma cells (Maier *et al.*, 2002). Because DMEM F-12 contains HEPES, the pH keeps constant during incubation outside the CO_2 incubator. We use phenol red-free DMEM F-12 when we take images under a microscope. BODIPY-labeled lipids (Pagano and Chen, 1998) and pyrene-labeled lipids (Somerharju, 2002) are also used for the similar purpose. The fluorescent cholesterol analog dihydroergosterol is introduced to follow the fate of cell surface cholesterol (Mukherjee *et al.*, 1998).

B. Measurement of Recycling of NBD-Labeled Sphingomyelin Using Dithionite

The dithionite method is a simple procedure used to bleach NBD located outside cells. With this procedure, it is possible to quantitate the appearance of NBD-lipid to the plasma membrane.

1. Cellular Distribution of Fluorescent Lipids

Solutions

The fluorescent lipid solution is prepared as described in Section III,A. Sodium dithionite solution is prepared by diluting a freshly made 1 *M* aqueous stock solution with DMEM (final concentration: 50 m*M*).

Steps

1. Grow HeLa cells in triplicate on 35-mm glass-bottom culture dishes for 1–2 days to reach 50–80% confluency.
2. Wash cells twice with ice-cold DMEM.
3. Incubate cells for 30 min at 4°C with 1 ml DMEM containing 4 μ*M* C6-NBD-SM.
4. Wash cells twice with ice-cold DMEM and then add 1 ml prewarmed (37°C) DMEM.
5. Incubate cells for 30 min at 37°C in a CO_2 incubator.
6. Wash one dish twice with DMEM F-12 at room temperature and then add 1 ml DMEM F-12 and observe under a microscope (Fig. 3, "before quench").
7. Wash the other two dishes twice with DMEM at room temperature.
8. Add 1 ml DMEM containing 50 m*M* sodium dithionite. Incubate for 1 min at room temperature.

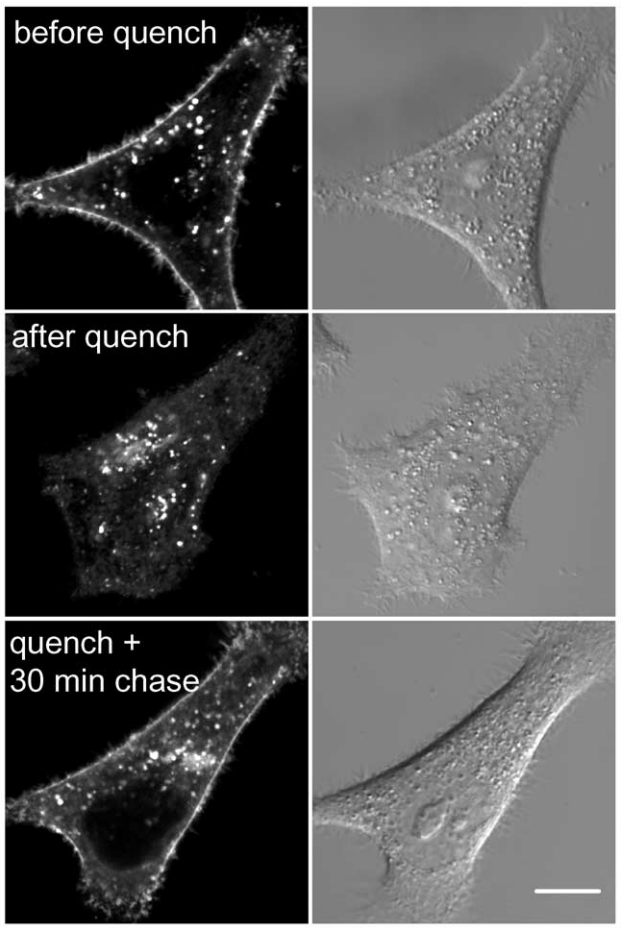

FIGURE 3 HeLa cells labeled with C6-NBD-SM for 30 min at 37°C (before quench). Cell surface fluorescent lipids are then quenched by sodium dithionite (after quench). Cells are further incubated for 30 min at 37°C (quench + 30 min chase). Bar: 10 µm.

9. Wash one dish twice with DMEM F-12 at room temperature and then add 1 ml DMEM F-12 and observe under a microscope (Fig. 3, "after quench").
10. Wash the last dish twice with DMEM at room temperature.
11. Incubate cells in 1 ml DMEM for 30 min at 37°C in a CO_2 incubator.
12. Wash cells twice with DMEM F-12 at room temperature.
13. Add 1 ml DMEM F-12 and observe under a microscope (Fig. 3, "quench + 30 min chase").

2. *Quantitation of Recycling of C6-NBD-SM*

Steps

1. Grow HeLa cells in duplicate on 60-mm culture dishes for 1–2 days to reach 50–80% confluency.
2. Wash cells twice with ice-cold DMEM.

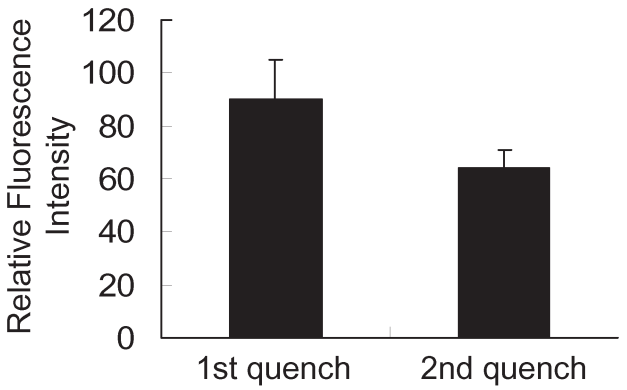

FIGURE 4 HeLa cells labeled with C6-NBD-SM for 30 min at 37°C and treated immediately with sodium dithionite (first quench) or incubated further for 30 min at 37°C in DMEM after the first dithionite treatment. Cells are then again treated with dithionite (second quench). Cells are scraped in PBS containing 1% Triton X-100. Fluorescence intensity/dish is shown. Results are mean ± SD of three experiments. The difference between the two histograms represents the NBD-lipid recycled back to the plasma membrane.

3. Incubate cells for 30 min at 4°C with 2 ml DMEM containing 4 µ*M* C6-NBD-SM.
4. Wash cells twice with ice-cold DMEM and then add 2 ml prewarmed (37°C) DMEM.
5. Incubate cells for 30 min at 37°C in a CO_2 incubator.
6. Wash cells twice with DMEM at room temperature.
7. Add 2 ml DMEM containing 50 m*M* sodium dithionite. Incubate for 1 min at room temperature.
8. Wash one dish twice with PBS at room temperature and then add 1 ml PBS containing 1% Triton X-100. Scrape cells and measure fluorescence at 535 nm with excitation at 475 nm using the Jasco FP-6500 spectrofluorometer (Fig. 4, "1st quench").
9. Wash the other dish twice with DMEM at room temperature.
10. Incubate cells in 2 ml DMEM for 30 min at 37°C in a CO_2 incubator.
11. Add 2 ml DMEM containing 50 m*M* sodium dithionite. Incubate for 1 min at room temperature.
12. Wash cells twice with PBS at room temperature and then add 1 ml PBS containing 1% Triton X-100.
13. Scrape cells and measure fluorescence at 535 nm with excitation at 475 nm using the Jasco FP-6500 spectrofluorometer (Fig. 4, "2nd quench").

Comments

Selective removal of fluorescent lipid present on the outer leaflet of the plasma membrane allows the quantitative analysis of the kinetics of lipid transport to the plasma membrane. This is achieved by extracting C6-

NBD- and C5-BODIPY-labeled phospho- and sphingolipids with BSA (Sleight and Pagano, 1984). Alternatively, one can selectively destroy NBD-labeled lipids on the outer monolayer with the water-soluble quencher dithionite (McIntyre and Sleight, 1991). The dithionite method is widely used to monitor transbilayer distribution (Nolan *et al*., 1995; Williamson *et al*., 1995) and vesicular traffic (Babia *et al*., 2001), as well as lateral mobility (Kobayashi *et al*., 1992), of NBD-labeled lipids. However, because dithionite can leak through the membrane in some cells, proper conditions have to be adapted to each specific case (Pomorski *et al*., 1994). Recycling of C6-NBD-SM is very rapid (Hao and Maxfield, 2000). The distribution of C6-NBD-SM shown here is the result of several recycling rounds of the fluorescent lipid. Internalized C6-NBD-SM is also transported to lysosomes and metabolized to C6-NBD-Cer. Transport to the degradative compartments is estimated to be 18- to 19-fold slower than the rate of C6-NBD-SM recycling (Koval and Pagano, 1990). In some cells, degradation of C6-NBD-SM occurs on the plasma membrane in a differentiation-dependent manner (Kok *et al*., 1995). Such degradation products are separated from C6-NBD-SM by thin-layer chromatography (Kobayashi and Pagano, 1989; Koval and Pagano, 1990).

C. Vital Stain of Golgi Apparatus by Fluorescent Ceramide Analogs

Fluorescent ceramide is widely used for vital staining of the Golgi apparatus (Pagano, 1989; Pagano *et al*., 1991). Dynamics of the Golgi membranes could be followed by using fluorescent ceramide.

1. Vital Stain of Golgi Apparatus by Fluorescent Ceramides

Solutions

Stock solutions (1 mg/ml) of fluorescent lipids are prepared by dissolving C6-NBD-Cer, C12-NBD-Cer, and C5-BODIPY-Cer in ethanol. An aliquot of a stock lipid solution is dried, first under a stream of nitrogen and then *in vacuo*. The dried lipid is dissolved in DMEM to give a final concentration 0.5 μ*M* (C6-NBD-Cer and C5-BODIPY-Cer) or 5 μ*M* (C12-NBD-Cer). The solutions are vortexed and kept at 4°C before use.

Steps

1. Grow HeLa cells on 35-mm glass-bottom culture dishes for 1–2 days to reach 50–80% confluency.
2. Wash cells twice with DMEM at room temperature.

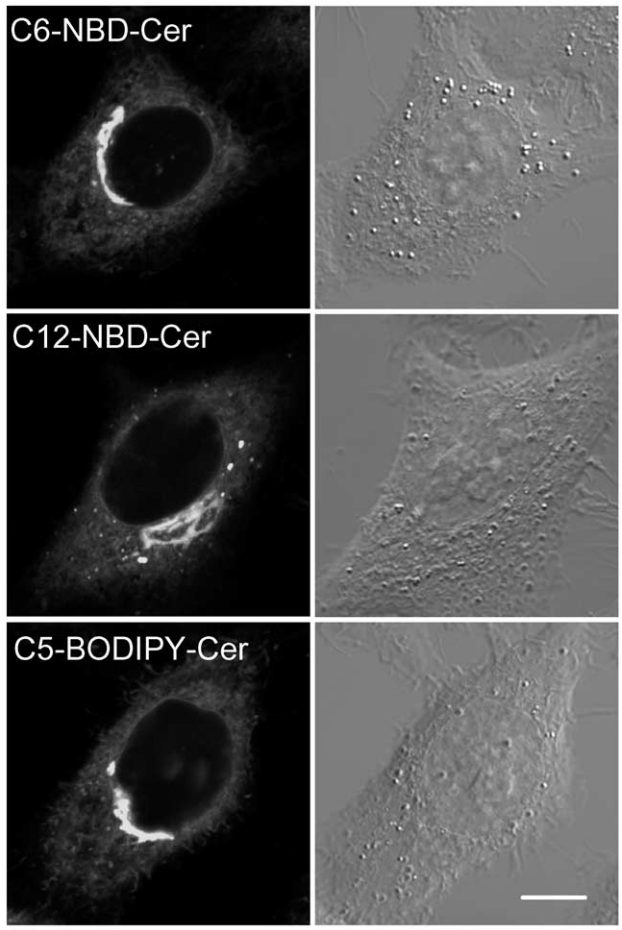

FIGURE 5 HeLa cells labeled with fluorescent ceramide analogs. Bar: 10 μm.

3. Incubate cells for 30 min at 37°C with 1 ml DMEM containing 0.5 μ*M* C6-NBD-Cer or C5-BODIPY-Cer or 5 μ*M* C12-NBD-Cer in a CO_2 incubator.
4. Wash cells twice with DMEM F-12 at room temperature.
5. Add 1 ml DMEM F-12 and observe under a microscope (Fig. 5.).

2. Alteration of Morphology of Golgi Apparatus Monitored by C5-BODIPY-Cer

Solutions

Lipid solutions are prepared as described in Section III,C,1. 5-mg/ml stock solution of brefeldin A is diluted with DMEM F-12 to give a final concentration 5 μg/ml.

Steps

1. Grow HeLa cells on 35-mm glass-bottom culture dishes for 1–2 days to reach 50–80% confluency.

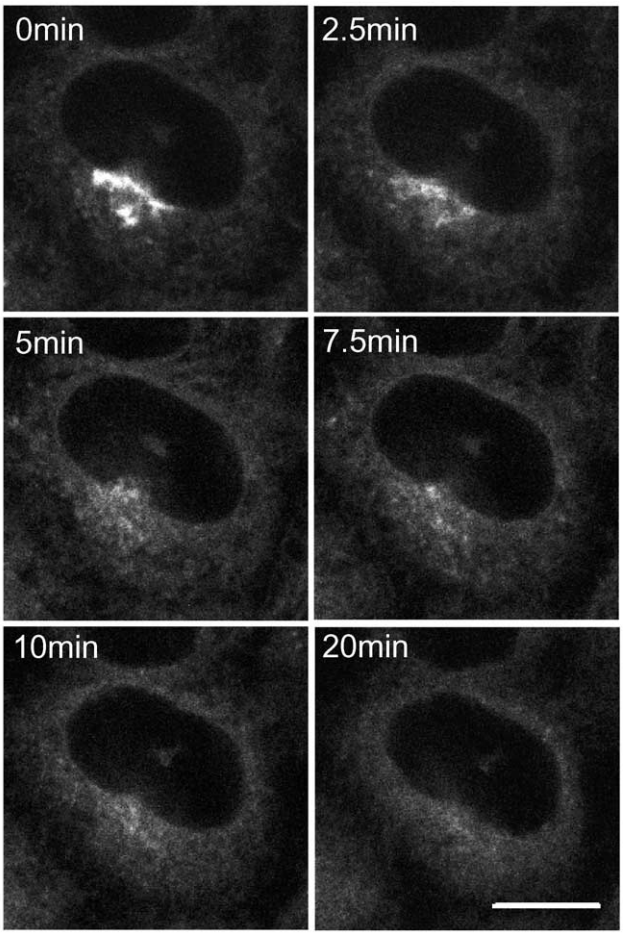

FIGURE 6 C5-BODIPY-Cer-labeled HeLa cells treated with brefeldin A for various times. Bar: 10 μm.

2. Wash cells twice with DMEM at room temperature.
3. Incubate cells for 30 min at 37°C with 1 ml DMEM containing 0.5 μ*M* C5-BODIPY-Cer in a CO_2 incubator.
4. Wash cells twice with DMEM F-12 at room temperature.
5. Add 1 ml DMEM F-12 containing 5 μg/ml brefeldin A.
6. Acquire images at appropriate intervals under a confocal microscope at room temperature (Fig. 6.).

Comments

Three different fluorescent ceramides are now available commercially. All three give similar Golgi labeling, although their working concentrations are different. Mechanisms of the accumulation of NBD-labeled ceramide and BODIPY-labeled ceramide are apparently different (Martin *et al*., 1993). Fluorescent ceramide makes it possible to follow the fate of Golgi lipids in living cells under various conditions such as brefeldin A treatment (Lippincott-Schwartz *et al*., 1991). Brefeldin A treatment induces redistribution of the Golgi apparatus into the endoplasmic reticulum (Chardin and McCormick, 1999). In Fig. 6, we adjusted the laser power of the confocal microscope to prevent bleaching of the fluorescence during observation. Spectral properties of BODIPY-labeled ceramides also allow us to differentiate membranes containing high concentrations of the fluorescent lipid and its metabolites from other regions of the cell where smaller amounts of the probe are present with a specific filter setup (Pagano *et al*., 1991).

IV. PITFALLS

1. Because of the evaporation of solvent, the stock lipid solution is gradually concentrated during storage. Concentrations of NBD- and BODIPY-lipid solution are adjusted by measuring absorbance at 475 nm and comparing the OD with that of the solution of a known concentration.
2. Degradation of lipids often occurs during storage. The purity of the lipid stock is checked periodically by thin-layer chromatography. Lipids are repurified or a new lot of fluorescent lipid is purchased when degradation compounds are detected.

Labeling of Endocytic Vesicles Using Fluorescent Probes for Fluid-Phase Endocytosis

Nobukazu Araki

I. INTRODUCTION

Endocytosis occurs by the invagination of plasma membrane to form an intracellular vesicle. Endocytic vesicles, and the intracellular organelles they communicate with, can be labeled by inclusion of fluorescent, membrane-impermeant molecules in the extracellular medium. Such probes are enclosed in the vesicles as they form and remain contained in endocytic compartments. Ultimately, these fluid-phase endocytic probes either accumulate in lysosomes, where they may be degraded, or are returned to the extracellular medium by recycling vesicles. Fluid-phase endocytosis is also called pinocytosis, which is sometimes subdivided into macropinocytosis and micropinocytosis, the formation of large and small pinosomes, respectively (Maniak, 2001; Swanson, 1989a; Swanson and Watts, 1995). Macropinocytosis is specialized for fluid-phase uptake, whereas micropinocytosis involves both receptor-mediated (membrane adsorptive) and fluid-phase uptake. Receptor-mediated endocytosis via clathrin-coated vesicles can be distinguished from fluid-phase endocytosis by using fluorescent specific ligands for the receptor, e.g., FITC-labeled transferrin for the transferrin receptor. Compared with receptor-mediated endocytosis, the biological function of macropinocytosis has been less investigated so far. However, attention has been increasingly paid to this fluid-phase endocytic pathway (Araki *et al.*, 2000, 2003; Maniak, 2001) because it has been known that macropinocytosis is utilized for antigen presentation in dendritic cells and macrophages (Norbury *et al.*, 1995; Sallusto *et al.*, 1995; Nobes and Marsh, 2000).

A variety of fluorescent probes can be used to label endocytic organelles in living cells. Vital staining techniques using such probes are useful not only for marking endocytic organelles, but also for exploring the kinetics of soluble molecules and the dynamics of endocytic organelles in the cell. This article describes methods for labeling and observing these compartments in living cells and for immunofluorescence microscopy of similarly labeled cells. In addition, it describes a method for the quantitative measurement of fluid-phase pinocytosis using fluorescent probes. These methods are optimized for the study of macrophages, which are actively endocytic cells. It should be kept in mind that most other kinds of cells exhibit lower rates of endocytosis and different kinetics of delivery from endosomes to lysosomes. One may therefore have to extend incubation times or increase probe concentrations to obtain strong fluorescent signals in the microscope or fluorometer. For any new cell type, compartment identities should be determined empirically by comparing fluorescent probe distributions in cells fixed after various pulse–chase intervals with the immunofluorescent localization of known markers for endocytic compartments (e.g., Racoosin and Swanson, 1993).

II. MATERIALS AND INSTRUMENTATION

The fluorescent fluid-phase probes, fluorescein dextran, MW 3000 (FDx3, Cat. No. D-3305), MW 10,000 (FDx10, Cat. No. D-1821), lysine fixable fluorescein

Copyright 2006, Elsevier Science (USA).
All rights reserved.

dextran, MW 10,000 (Cat. No. D-1820), and Texas red dextran, MW 10,000 (TRDx10, Cat. No. D-1828), are from Molecular Probes. Lucifer yellow CH (Cat. No. 86150-2) is from Aldrich. Fluorescein dextran, MW 150,000 (FDx150 Cat. No. FD-150), paraformaldehyde (Cat. No. P-6148), bovine serum albumin (BSA, fraction V., Cat. No. A-9647), Triton X-100 (Cat. No. T-9284), saponin (Cat. No. S-4521), HEPES (Cat. No. H-3375), and Trizma base (Cat. No. T-1503) are from Sigma Chemical. The 25% glutaraldehyde solution (EM grade, Cat. No. SP-17003-92) is from Nacalai Tesque. A primary antibody, rabbit anti-cathepsin D serum, was a gift from Dr. S. Yokota, Yamanashi Medical School. Monoclonal antibodies recognizing some marker proteins for endocytic compartments are available from the Developmental Studies Hybridoma Bank or commercial sources. Texas red-labeled anti-rabbit IgG (goat) (Cat. No. TI-1000) is from Vector Lab. Dulbecco's modified essential medium (DMEM, Cat. No. 31600-034), fetal bovine serum (FBS, Cat. No. 16000), and goat serum (Cat. No. 16210) are from GIBCO BRL. Circular glass coverslips 12 and 25 mm in diameter (No. 1 thickness, Cat. No. 12-545-102) and silicon oil (Cat. No. 5159-500) are from Fisher Scientific. Twenty-four-well (Cat. No. 430262) and 6-well (Cat. No. 430343) plates are from Corning Costar. A water aspirator with a Pasteur pipette and a digital micropipette (Nichipet EX1000) are used for quickly replacing media in cell culture wells. The Attofluor cell chamber (Cat. No. A7816) is from Molecular Probes. PermaFluor aqueous mounting medium (Cat. No. 434980) is from Lipshaw/Immunon.

An epifluorescence microscope (Axiophot, Carl Zeiss) is used for observation of both living and fixed cells. A Lucifer yellow filter set is from Omega Optical (Set No. XF-14), in addition to a conventional fluorescein filter set. For high-resolution observation, a 100× PlanApo lens, numerical aperture (NA) 1.4 or a 100× Plan-Neofluar lens, NA 1.3 is used. An inverted-type fluorescence microscope (Nikon TE300) equipped with a cooled CCD camera (Retiga EXi F-M-12-C, QImaging), light path shutter (Uniblitz VMMD1, Vincent Associates), and a thermo-controlled stage (Model TC-102, Harvard Apparatus) are used for longer observations of living cells. A personal computer (Precision 360, Dell) installed with MetaMorph version 4.6 imaging system software (Universal Imaging Co.) is used for collecting images from the CCD camera and for making time-lapse movies. For quantitation of fluorescent probes, a spectrofluorometer (Hitachi 650-40) is used.

III. PROCEDURES

A. Fluorescence Microscopy of Endocytic Compartments Labeled with Fluorescent Probes

Solutions

1. *Ringer's buffer + bovine serum albumin (BSA) (RB):* 155 m*M* NaCl, 5 m*M* KCl, 2 m*M* $CaCl_2$, 1 m*M* $MgCl_2$, 2 m*M* NaH_2PO_4, 10 m*M* HEPES, 10 m*M* D-glucose, pH 7.2, plus 0.05% BSA. To make 1 liter, add 9.1 g of NaCl, 0.37 g of KCl, 0.275 g of $NaH_2PO_4 \cdot H_2O$, 2.38 g of HEPES, 1.8 g of D-glucose, 0.22 g of $CaCl_2$, 0.2 g of $MgCl_2 \cdot 6H_2O$, and 0.5 g BSA to 950 ml distilled water, adjust to pH 7.2 with 1 *N* NaOH, and bring the volume to 1 liter. Sterilize with a 0.22-µm filter and store at 4°C.

2. *Fluorescent probe stock solutions:* Dissolve 10 mg of fluorescent probes such as Lucifer yellow, FDx3, FDx10, FDx150, and TRDx10 in 1 ml PBS. Lysine fixable dextran probes can be used to increase fluorescent signals in aldehyde-fixed cells. Divide in 200-µl aliquots in tubes and store at –20°C.

3. *Labeling medium:* Dilute fluorescent probe solutions to a final concentration at 1.0 mg/ml in RB. A volume of 0.4 ml labeling medium is required for each well of a 24-well dish. The concentrations of probes may be changed depending on cell types. One can differentially label macropinosomes and micropinosomes using different sized probes (Fig. 1). To label both macropinosomes and micropinosomes, use low molecular weight probes such as Lucifer yellow and FDx3. To label primarily macropinosomes, use larger probes, such as FDx150 (Araki *et al.*, 1996). Warm to 37°C before adding to cells.

4. *8% paraformaldehyde stock solution:* To make 50 ml, add 4 g paraformaldehyde to 30 ml distilled water and heat to 70°C while stirring. Add a few drops of 1 *N* NaOH so that the mixture becomes clear. Bring the final volume to 50 ml with distilled water and filtrate with paper filter. This solution may be kept in aliquots at –20°C. To make up a fixative, thaw an aliquot in a hot water bath (~50°C) until the solution becomes clear.

5. *80 mM HEPES stock solution, pH 7.2:* To make 100 ml, add 1.91 g of HEPES to 70 ml of distilled water. Adjust pH to 7.2 with 1 *N* NaOH while stirring. Bring the final volume to 100 ml with distilled water. Store at 4°C.

6. *Fixative*: 4% paraformaldehyde and 0.1% glutaraldehyde in 40 m*M* HEPES buffer, pH 7.2, containing 6.8% sucrose. To make 10 ml, add 5 ml of 8% paraformaldehyde solution, 40 µl of 25% glutaraldehyde solution, and 0.68 g of sucrose to 5 ml of 80 m*M* HEPES, pH 7.2.

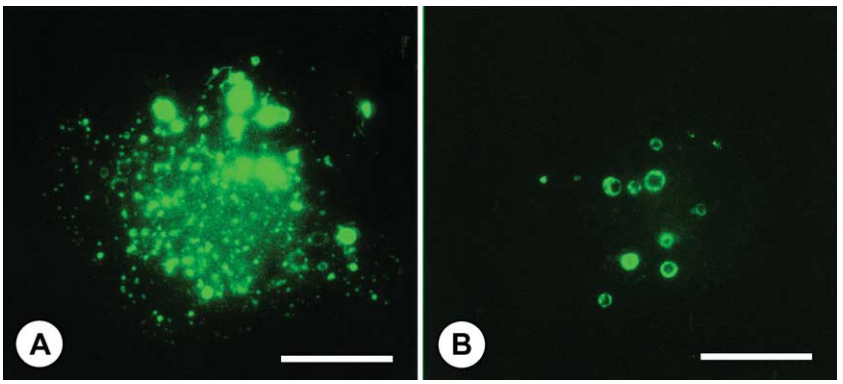

FIGURE 1 Differential labeling of macropinosomes and micropinosomes with Lucifer yellow (A) and FDx150 (B). Macrophages were incubated for 5 min in labeling medium containing Lucifer yellow or FDx150, washed briefly, and fixed immediately. A low molecular weight probe, Lucifer yellow (MW 457), labels both macropinosomes and micropinosomes (A). A larger probe, FDx150 (MW 150,000), labels predominantly macropinosomes (B). Bars: 10 µm.

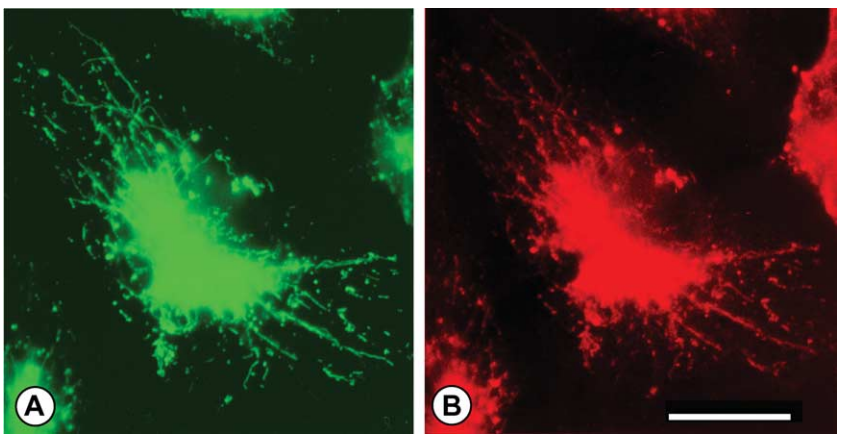

FIGURE 2 Immunofluorescence of cathepsin D in endocytic compartments labeled with endocytic probes. Macrophages were incubated for 30 min in labeling medium containing 0.5 mg/ml lysine-fixable FDx10 and were chased for 30 min. Cells were then fixed and processed for immunofluorescence using a primary antibody against cathepsin D and the Texas red-conjugated secondary antibody. (A) Fluorescein image shows that FDx10 labels tubular lysosomes. (B) Texas red image shows that tubular lysosomes, which are labeled with FDx10, are positive for cathepsin D. Bar: 10 µm.

7. *Phosphate-buffered saline (PBS):* To make 5 liters, dissolve 40 g of NaCl, 1 g of KCl, 7.1 g of Na_2HPO_4, and 1 g of KH_2PO_4 in 4 liters of distilled water. Bring the final volume to 5 liters with distilled water. The solution should be pH 7.2.

Steps

1. Culture cells on 12-mm, circular, No. 1 thickness coverslips in 24-well culture dishes in DMEM with 10% heat-inactivated FBS.

2. Aspirate the culture medium from the cell culture well and add prewarmed labeling medium. Swirl the dishes and incubate cells in labeling medium for various times at 37°C. Then rinse quickly by changing warm RB to remove fluorescent probe and chase in RB as necessary. For mouse macrophages, a 2- to 5-min labeling incubation without chase will label early endosomes, including micro- and macropinosomes (Fig. 1). A subsequent chase in the absence of the probe for 5 to 15 min should label late endosomes. A 30- to 60-min labeling incubation labels all endocytic compartments, including early and late endosomes and lysosomes, and a 30-min labeling followed by a chase longer than 60 min should label primarily lysosomes (Fig. 2).

3. Fix the cells in 4% paraformaldehyde and 0.1% glutaraldehyde in 40 m*M* HEPES, pH 7.2, containing 6.8% sucrose for 30 to 60 min at 37°C.

4. Rinse 3 × 5 min with PBS.

5. Mount the coverslip, cell side down, on a slide using mounting medium. Seal with nail polish between the coverslip and the slide.

6. Observe the slide with an epifluorescence microscope. We can observe living cells without fixation for short periods using a simple microscope culture chamber. This method has been described in detail previously (Swanson, 1989b; Raccosin and Swanson, 1994). Briefly, assemble a chamber on a slide using small coverslip fragments to support the coverslip. RB should be added to fill the space between the slide and the coverslip. Seal the coverslip to the slide using a heat-melted paraffin-based compound (Swanson, 1989b). The method for longer observations of living cells is described next.

B. Observation of Endocytic Compartments in Living Cells

Step

1. Plate cells on 25-mm No. 1 coverslips in a 6-well culture dish containing tissue culture medium.

2. Replace the culture medium with labeling medium. Incubate in labeling medium for various times at 37°C, as described earlier, to label the endocytic compartments.

3. Wash away fluorescent probe from the coverslip with RB.

4. Assemble the coverslip in an Attofluor chamber and fill with 1 ml of RB. You may slowly add a small amount of silicon oil to cover the surface of RB in the chamber. The thin layer of silicon oil protects evaporation of RB during long observations.

5. Put one drop of immersion oil on the objective lens of an inverted microscope and settle the Attofluor chamber in the Leiden chamber thermocontrolled at 37°C on the microscope stage.

6. Observe the coverslip and acquire images using a high sensitive cooled CCD camera under the lowest light exposure as possible, as intense excitation light may cause not only photobleaching, but also photochemical damage to living cells. Under optimal conditions of labeling, we can observe cells for several minutes under conditions of low-intensity illumination. This can be extended to an hour by inserting a shutter into the light path to control exposures.

7. Collect time-lapse images using MetaMorph imaging software, which controls the CCD camera and the light path shutter. These collected images can be saved as a stack file in electronic storage media such as CD-R or DVD-RAM for later processing into movies of living cells. For further information of imaging techniques, see also the sections on digital video microscopy and fluorescent microscopy of living cells in Volume 3.

C. Immunocytochemical Characterization of Endocytic Compartments Labeled with a Fluorescent Probe

Solutions

1. *Fixative:* Prepare 10 ml of 4% paraformaldehyde in 40 m*M* HEPES buffer, pH 7.2, containing 6.8% sucrose
2. *0.25% NH_4Cl in PBS (NH_4Cl/PBS):* To make 100 ml, dissolve 0.25 g of NH_4Cl in 100 ml PBS
3. *0.25% saponin or Triton X-100, 2% BSA in PBS (permeabilizing/blocking buffer):* To make 50 ml, dissolve 1 g BSA and 125 mg saponin or Triton X-100 in 50 ml of PBS
4. *Primary antibody:* Dilute serum or antibody with permeabilizing/blocking buffer. In the example shown, we diluted rabbit anti-cathepsin D serum at 1:500
5. *Secondary antibody:* Dilute Texas red-labeled anti-rabbit IgG with PBS at 1:250–500

Steps

1. Incubate the cells with labeling medium as described earlier. Lysine-fixable FDx or Lucifer yellow should be used when the other markers are to be localized by immunofluorescence. Nonfixable FDx would be lost during permeabilization of the cell.

2. Rinse in PBS to remove excess fluorescent probe, unless the cells were chased in RB without fluorescent probe.

3. Fix in 4% paraformaldehyde in 40 m*M* HEPES buffer, pH 7.2, containing 6.8% sucrose for 30–60 min at 37°C. Glutaraldehyde may be added to the fixative (0.1%), providing that antigenicity is resistant to glutaraldehyde.

4. Rinse with PBS 3 × 5 min and further immerse in NH_4Cl/PBS for 10 min to quench free aldehyde.

5. Treat cells with permeabilizing/blocking buffer for 2 × 5 min.

6. Put parafilm in a container with a moist paper. Place one 40-µl drop of primary antibody on the parafilm for each coverslip.

7. Wipe the cell-free side of the coverslip with Kimwipe paper. Place the coverslip cell side down on a drop of primary antibody. Incubate with the primary antibody for 1 h at room temperature in the moisture chamber. You may prolong the incubation time to overnight at 4°C.

8. After incubation, put the coverslip back into the well and wash three times for 5 min each with PBS.

9. Using the same method as for the primary antibody, incubate with secondary antibody, e.g., Texas red-conjugated anti-rabbit IgG diluted in PBS at a concentration 1:500, for 1 h at room temperature.

10. Wash the coverslip with PBS three times for 5 min each.

11. Mount the coverslip on a slide using the mounting medium. Seal the coverslip with nail polish. Observe the specimens with an epifluorescence microscope using fluorescein and Texas red filter sets.

D. Quantitative Fluorometric Analysis of Endocytic Compartments Labeled with Fluorescent Probes

Solutions

1. *Lysis buffer:* 0.1% Triton X-100 in 50 m*M* Tris, pH 8.5. To make 100 ml, dissolve 0.6 g of Trizma base and 0.1 g of Triton X-100 in 80 ml of distilled water. Adjust pH to 8.5 with 1 *N* NaOH. Bring the volume to 100 ml.

2. *PBS:* Make 3 liters of PBS as described earlier. Refrigerate before use.

3. *0.1% BSA/PBS:* To make 2 liters, dissolve 2 g of BSA in 2 liters of PBS.

4. *Standard solutions of fluorescent probes:* Dilute the labeling medium to concentrations of 0, 1, 5, 10, and 20 ng probe/ml in lysis buffer. Each solution should be more than 2 ml.

Steps

1. Plate the cells at a high density (e.g., 2×10^5 cells/well) in a 24-well culture dish. Triplicate experiments are desirable.

2. Replace the culture medium with labeling medium containing fluorescent probes. Dual labeling with FDx and Lucifer yellow is possible (Berthiaume *et al.*, 1995). Incubate at 37°C for various times. A 0-min incubation should be done as a control to determine the background level.

3. Discard the labeling medium and rinse the culture dish twice by dipping into a 1-liter beaker filled with ice-cold 0.1% BSA/PBS for 5 min each. Repeat with another beaker filled with cold PBS for 5 min.

4. Drain PBS and aspirate remaining PBS completely.

5. Put 0.5 ml of lysis buffer into each well and leave it at least 30 min to complete cell lysis.

6. Fill disposable 1-cm plastic cuvettes with 0.75 ml of lysis buffer. Add 0.4 ml of cell lysate into the plastic cuvette and dilute it with another 0.75 ml of lysis buffer so that the final volume is 1.9 ml.

7. Measure the fluorescence of lysate in a spectrofluorometer. Fluorescein can be measured at excitation (exc.) 495 nm and emission (em.) 514 nm. Lucifer yellow is exc. 430 nm and em. 580 nm. These wavelengths allow selective measurement of FDx and Lucifer yellow when the cells are labeled with both probes. Lucifer yellow alone is best measured at exc. 430 nm and em. 540 nm.

8. Measure the protein concentration of lysates remaining in wells using a BCA protein assay kit (Pierce Chemical Co.).

9. Prepare the standard solutions of 0, 1, 5, 10, and 20 ng probe/ml in lysis buffer and measure in a spectrofluorometer to obtain a standard curve.

10. Calculate the amount of probes from the standard curve and express the value as nanogram probe per milligram protein.

IV. PITFALLS

1. A prolonged exposure to intense excitation light may cause a release of fluorescent probes from endocytic vesicles into cytoplasm, especially in living cells. To avoid this, reduce the intensity of the excitation light or the exposure time as much as possible (Video 1 and 2 in the online version).

2. Lucifer yellow can be seen using some fluorescein filter sets with a wide band pass (e.g., Olympus BP490), but not some others (e.g., Zeiss No. 09). Choose an appropriate filter set for Lucifer yellow (e.g., Omega Optical Set No. XF-14, Zeiss No. 05).

3. Many kinds of fluorescent-conjugated probes are available commercially; however, some are not suitable for fluid-phase probes. Texas red albumin is taken up very efficiently by adsorptive endocytosis, although it is sometimes used as a fluid-phase probe. Lysine-fixable Texas red dextran may bind nonspecifically to coverslips and create a high background fluorescence.

4. In the combination of fluorescent fluid-phase probe labeling with immunocytochemistry, we are often faced with a problem that fluid-phase probes release from macropinosomes during membrane permeabilization that is necessary for antibody impregnation. In such a case, the author recommends using a mild detergent such as saponin rather than Triton X-100. The addition of 2% BSA to permeabilizing buffer considerably protects the fluid-phase probe release. The addition of 0.1% glutaraldehyde to the fixative also effectively fixes fluorescent probes in macropinosomes; however, because some antigens lose their

antigenicity, you have to examine the resistance of the antigen to glutaraldehyde.

5. For quantitative analysis using a less sensitive fluorescence plate reader, plate the cells at a higher density to increase the sensitivity for fluorescence.

For the online version

Video 1. Time-lapse video microscopy of a living macrophage labeled with Lucifer yellow. Cells were incubated with 1 mg/ml Lucifer yellow for 30 min, rinsed in RB, and observed with an inverted fluorescence microscope under the appropriate light exposure controlled by the light path shutter and ND filters. Images were acquired at 5-s intervals for 10 min and assembled into a QuickTime movie. Lucifer yellow labels macropinosomes, micropinosomes, and tubular lysosomes. A phase-contrast image was superimposed on the initial frame.

Video 2. Time-lapse video microscopy of a living macrophage exposed to intense excitation light without ND filters. Cells were labeled and observed similarly to Video 1, but ND filters were removed from the excitation light path. It is notable that an intense excitation induces rapid photobleaching and photodamage on Lucifer yellow-labeled organelles.

Protein Purification

CHAPTER

22

Preparation of Tubulin from Porcine Brain

Anthony J. Ashford and Anthony A. Hyman

INTRODUCTORY COMMENT

In the previous edition to this series (2nd Ed., Vol. 2, pp. 205–212, 1998), we described a method to purify tubulin from bovine brains. Since that time there have been concerns in many countries over the risks of handling bovine nervous tissue relating to bovine spongioform encephalitis and its possible connection with human varient Creuzfeldt–Jakob disease. As a result, abattoirs have been reluctant or have even refused to handle these tissues. Consequently we have changed the species source from which we make the tubulin and have amended the title accordingly. However the protocols described are applicable in their entirety to the bovine source. The bovine and porcine equivalents are indicated in the protocol.

I. INTRODUCTION

Recent research on microtubules has given much insight into many fundamental problems in cell biology, such as cell structure and polarity, vesicular transport, cell division, and chromosomal segregation.

Furthermore, the ability to prepare polarity marked microtubules (Howard and Hyman, (1993) has contributed much to our understanding in the behavior of microtubule motors.

Microtubules are polymers of the heterodimeric protein tubulin. Because these heterodimers have the same orientation in the microtubule lattice and the dimers themselves are not symmetric, it follows that the microtubule itself must have an inherent polarity. Polymerization can take place from either end of the growing microtubule, although at different rates, having a slow growing (–) and more rapidly growing (+) end. The tubulin heterodimer has binding sites for two GTP molecules in its unpolymerized state, only one of which (that GTP that is bound to the E site of the tubulin β subunit) is hydrolyzable. While it is not within the scope of this article to examine all the properties of microtubules and tubulin, some of these are of direct relevance to their isolation. The current model first proposed by Mitchison and Kirschner (1984a) and developed further since then (reviewed by Hyman and Karsenti [1996]) suggests that GTP-unpolymerized tubulin is incorporated at the + growing end of the microtubule and that after a delay, during which time more GTP-bound tubulin is bound at the growing end, the GTP on the β subunit is then hydrolysed to GDP, possibly destabilizing the microtubule lattice. Because GTP-bound tubulin dissociates from the microtubules slowly and the dissociation rate of exposed bound GDP tubulin is two or three orders of magnitude higher, it follows that the presence of a so-called GTP–tubulin "cap" will protect the polymerized microtubule from depolymerization. Alternatively, the GTP "cap" structure may be inherently more stable, effectively preventing the GDP (destabilized) polymerized tubulin from dissociating from the lattice. Thus the "GTP cap" hypothesis states that if the microtubule loses this GTP "cap" structure because of slow growth (e.g., due to lack of free tubulin, cold temperature, presence of Ca^{2+}), the GDP–tubulin dissociates from the lattice. Microtubules growing more slowly are more likely to have GDP–tubulin exposed and thus dissociate rapidly, causing microtubule shrinkage.

The preparation of tubulin described here utilizes these phenomena by a series of alternate depolymerizing and polymerizing steps (see Fig. 1) to obtain

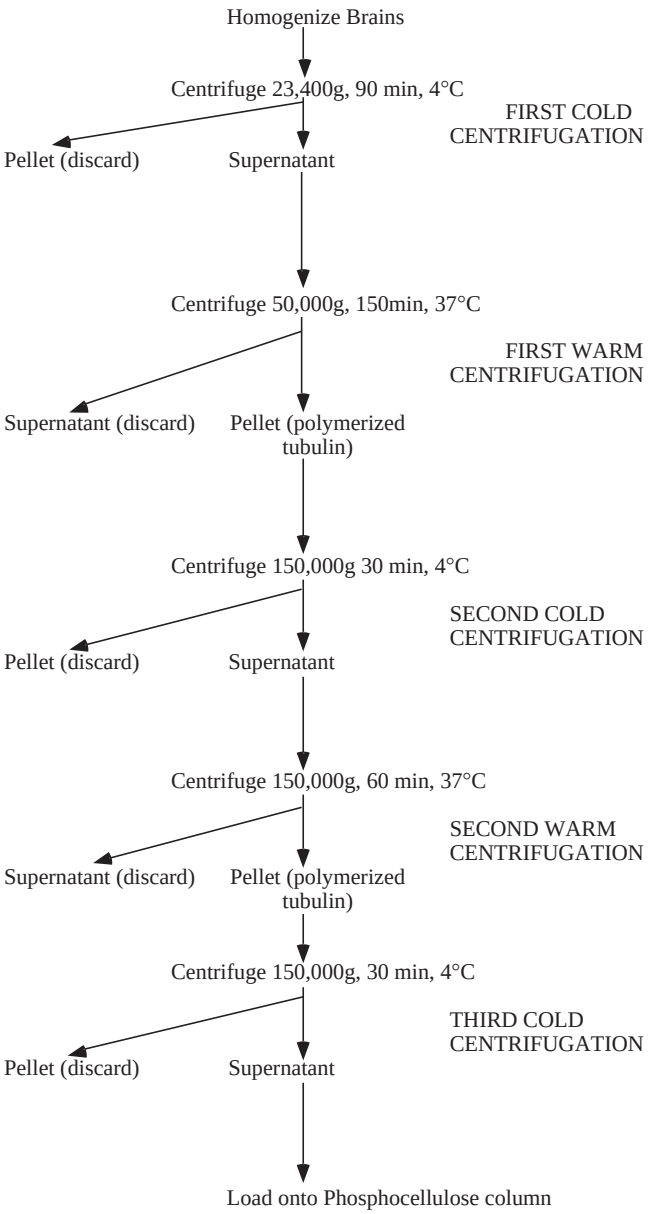

FIGURE 1 Summary of tubulin preparation.

tubulin and microtubule-associated proteins (MAPs), followed by ion-exchange chromatography to separate the tubulin from MAPs. This protocol is based on that originally described by Shelanski *et al.* (1973) and modified by Weingarten *et al.* (1974) and subsequently by Mitchison and Kirschner (1984b). Tubulin can be modified further for other uses (Hyman *et al.*, 1991).

This article describes how to make pure tubulin with emphasis on large-scale (gram quantities) purifications. This, as will be made clear in later sections, is quite an exercise in both organization and logistics. However, the method can easily be scaled downwards if large amounts of tubulin are not required.

Because the principle of tubulin preparation relies on successive rounds of polymerisation and depolymerisation steps based on temperature shifts, delays and not having the right equipment at the right temperature will reduce the yield drastically. Consequently, after one centrifuge run is completed, it is good practice to reset the temperature for the next spin and switch on the vacuum, checking the centrifuge regularly for faults. This also applies to the rotors, and it is a good idea to have some large water baths set at 37°C and some ice troughs in which to either raise or lower the rotor temperature accordingly. For the polymerization of tubulin, a good supply of hot running water is essential, as slow polymerization will reduce the overall yield.

II. MATERIALS AND INSTRUMENTATION

The protocol, as stated earlier, is suitable for preparation of large (2 to 3 gram) quantities of pure tubulin. To obtain this quantity, it will be necessary to obtain approximately 30 porcine (or 12 bovine) brains. It follows from this that the volumes involved in processing this number of brains, at least in the initial stages of preparation, will be quite large and many centrifuges will be necessary.

A. Centrifuges, Rotors, and Bottles

It is desirable, although not absolutely necessary, to have a centrifuge capable of spinning, at low speed, up to 10 litres of homogenate.

At least six Sorval RC5s, evolutions, or equivalent centrifuge series with SuperLite SLA 1500 are needed together with 36 GSA rotor bottles (250-ml capacity) and their adaptors. The Beckman equivalent to this is the Beckman Avanti using the JLA-16.250 rotor.

Four ultracentrifuges with three Beckman type 19 rotors and 24 corresponding bottles are needed along with four Beckman type 45Ti rotors and 24 (70-ml capacity) polycarbonate bottles.

As can be seen from this list, the rotors required are quite large and heavy and it is therefore important to check the vacuum and refrigeration efficiency of all the centrifuges beforehand using these rotors. Regarding the rotors themselves, these should be inspected beforehand, and any seals and "O" rings should be checked for signs of perishing, replacing where necessary. It is also important that these "O" rings are greased lightly with vacuum grease and that the screw threads for the rotor lids are smeared lightly with

Beckman "Spinkote" to ensure that the samples are sealed and that the vacuum is maintained during the run. Finally, the centrifuge rotors should be checked for the condition of the overspeed decals to prevent premature termination of the run. This is particularly true of the Beckman type 19 rotors, which seem especially sensitive on this point.

The centrifuge bottles too should be inspected for cracks and warping (particularly true of the polycarbonate Beckman type 45 bottles), and the lids and caps should be checked for condition and integrity of the "O" ring.

B. Other Equipment

A tissue blender, such as that made by Waring, along with a 4.5-litre capacity homogenizing beaker and a (motor-driven) continuous flow homogenizer, such as the Yamato LH-22 model for resuspending the tubulin pellets (or a very large Dounce hand homogenizer), as well as a 1-Litre capacity phosphocellulose (PC) column, are needed. Details of how to prepare such a column are described in detail later.

C. Chemicals

All chemicals should be of analytical grade and can be obtained from a variety of suppliers. Chemicals for the following solutions are obtained from the following suppliers.

MES (M-5057), PIPES (P-6757), EGTA (E-4378), $MgCl_2$ (104-20), GTP (G-8877), ATP (A-7699), and β-mercaptoethanol (M-6250) are from Sigma-Aldrich.

EDTA (1.08418.1000), anhydrous glycerol (1.04093. 2500), NaCl (1.06404.1000), NaOH (1.06498.1000), HCl (1.00319.2500), KH_2PO_4 (4873.1000), and K_2HPO_4 (5099. 1000) are from Merck.

III. PROCEDURES

A. Preparation of Tubulin

The buffer systems of choice for the preparation of tubulin are 2-[*N*-MES for the blending buffer (BB) and PIPES for the remainder. When making up K.PIPES buffer solutions, it is first necessary to raise the pH of the solution to about pH 6.0 using KOH in order to get the PIPES to go into solution. This initial pH adjustment must be done *without the use of a pH meter* (i.e., using pH indicator paper), as any undissolved PIPES can damage the electrode.

Approximately 6 litres of BB is needed. Blending buffer is 0.1 M MES, pH 6.5, 0.1 m*M* EDTA, 2 m*M* EGTA, and 0.5 $MgCl_2$. For 1 litre, use 21.7 g MES, 4 ml 0.5 *M* EDTA stock solution, 0.1 ml 0.5 *M* EGTA stock solution, and 0.5 ml 1 *M* $MgCl_2$ stock solution.

About six litres of polymerization buffer (PB) is needed for a large tubulin preparation; if preferred, it can be made as a 5× stock solution and then diluted with water at 4°C before use. Polymerization buffer is 0.1 *M* PIPES, pH 6.8, 0.5 m*M* $MgCl_2$, 2.0 m*M* EGTA, and 0.5 m*M* EDTA.

Approximately five litres of *Column buffer* (CB) is needed for such a preparation, which is made up as a 10× solution and diluted with water at 4°C prior to use. Column buffer is 50 m*M* PIPES, pH 6.8, 1 m*M* EGTA, and 0.2 m*M* $MgCl_2$. To make 1 litre of 10× column buffer, weigh out 151.2 g of PIPES, 3.8 g of EGTA, and 2 ms of a 1 *M* stock solution of magnesium chloride and add 45.6 g potassium hydroxide. This will adjust the pH to about pH 6.7 and further adjustments can be made using a 10 *M* solution of potassium hydroxide.

The BRB80 conversion buffer is added to the purified tubulin that has been eluted from the phosphocellulose column to convert the buffer from column buffer composition to BRB80 prior to storage of the tubulin. The BRB80 conversion buffer is added in a ratio of 1 part conversion buffer to 20 parts tubulin in column buffer.

To make up 150 mls of BRB80 conversion buffer combine 47.6 g PIPES, 4.2 ml $MgCl_2$ (1 *M*), and 1.25 ml EGTA (0.2 *M*). This should then be brought to pH 6.8 with potassium hydroxide. Having the correct pH is very important.

Nucleotides are made as stock solutions as 100 m*M* ATP and 200 m*M* GTP. It is important that the pH of these nucleotides does not become acidic, as hydrolysis will result. Consequently, they are made up in water and adjusted to pH 7.5 with sodium hydroxide. The ATP solution is made 200 m*M* with respect to $MgCl_2$. This is *not* the case with the GTP solution, as this will cause precipitation. These solutions should be stored at −80°C until needed.

Protein concentration determinations are made using the Bio-Rad version of the Bradford protein assay, reading the absorption at 595 nm using bovine serum albumin as a reference standard.

Steps

Note: All *g* forces quoted are R_{max} values.

Because brain tissue has a high density of microtubules in the dendrites and axons of its nerve cells, this is the tissue of choice for a tubulin preparation. Porcine brain is readily available from slaughterhouses. It is essential, however, to get the brains as

fresh as possible, as protein degradation will begin to take place soon after death. The brains should be warm when they are received and should be plunged immediately into a mixture of ice and saline solution for transport back to the laboratory. Do not use cold brains.

1. Preparation of Brain Tissue for the First Cold Spin

Cautionary note: As alluded to earlier, possible contact with pathogens associated with nervous tissue should be minimized by always handling the brains with gloves. Waste tissue should be disposed of by incineration.

At the laboratory cold room the brains should be stripped of brain stems, blood clots, and meninges (kitchen paper tissue is very good for this purpose). The brains are then weighed, transferred to the Waring blender, and cold BB containing 0.1% β-mercaptoethanol and 1 m*M* ATP, but without any protease inhibitors, is added in the ratio of 1 litre of buffer per kilogram of brain tissue. The brains are then homogenized twice for approximately 30 s each. Typically it can be expected to need approximately 5 litres of BB for 30 porcine (approximately 12 bovine) brains giving about 10 litres of total homogenate. If a large capacity rotor is available, this homogenate can be poured directly into the 1 litre centrifuge bottles and then centrifuged at 12,000 g for 15 min. Using this option has the advantage that any unhomogenized tissue and air (from the blending procedure) are removed rapidly. The homogenate is centrifuged further at 34,200 *g* for 60 min (SLA1500) at 4°C.

2. First Warm Centrifugation

1. Pool and pour the supernatants (approximately 5 litres for a 30 porcine brain preparation) into two 5-litre Ehrlenmeyer flasks.

2. Add a half volume of anhydrous glycerol that has been prewarmed to 37°C and then adjust the GTP, ATP, and $MgCl_2$ concentrations to 0.5, 1.5, and 3 m*M*, respectively. It is essential to bring the tubulin solution above 30°C as quickly as possible.

3. Warm the tubulin to 30°C under a continuously flowing hot tap while swirling the flask. At some point after the tubulin has reached 30°C it will be noticed that the solution becomes noticeably more viscous, indicating that polymerization is beginning to take place.

4. Incubate the tubulin for a further 60 min at 37°C in a water bath before recovery by centrifugation at 50,000 g for 150 min at 37°C in Beckman type 19 rotors.

3. Second Cold Centrifugation

1. Resuspend the pellets in approximately 700 ml of PB (with 0.1% β-mercaptoethanol) at 4°C using either a Dounce or a continuous flow homogenizer. At this point, determine the protein concentration of the resuspended pellet solution and lower the concentration to 25 mg/ml by the addition of cold PB.

2. Leave the solution on ice for 40 min to allow for complete depolymerization before centrifuging at 150,000 *g* for 30 min in Beckman type 45Ti rotors at 4°C.

4. Second Warm Centrifugation

1. Pool the supernatants from this centrifugation and adjust the concentrations of ATP, GTP, and $MgCl_2$ to 1, 0.5, and 4 m*M*, respectively.

2. As before, add a half volume of anhydrous glycerol prewarmed to 37°C and warm the entire mixture to 37°C. Allow the tubulin to polymerize at this temperature for a further 40 min prior to centrifugation at 150,000 *g* at 37°C for 1 h in Beckman type 45Ti rotors. If time is short, the polymerized tubulin pellets can be frozen in liquid nitrogen and stored at −80°C.

5. Third Cold Centrifugation

1. Collect and resuspend the polymerized tubulin pellets in a total volume of 200 ml of PB with 0.1% β-mercaptoethanol using either the continuous flow or the Dounce homogenizer.

2. Determine the protein concentration and dilute the solution with PB as necessary to a final concentration of 35 mg/ml.

3. Allow the tubulin to depolymerize on ice for a further 40 min and then centrifuge at 150,000 *g* for 30 min in the Beckman type 45Ti rotor.

4. The supernatant is now ready for loading onto the phosphocellulose column to separate the tubulin from microtubule-associated proteins.

6. Purification of Tubulin over a Phosphocellulose Column

1. Load the depolymerised tubulin onto a 1-litre-sized column (at 4°C) that has been equilibrated previously in CB. Tubulin should be loaded onto the column at a flow rate of approximately 1.5 ml/min. Once loaded, however, the flow rate can be increased to 6 ml/min or even faster if the phosphocellulose shows little sign of compressing, although some compression is inevitable.

2. The purified tubulin elutes in the flow through. Pool the protein peak and determine the protein concentration. The purified tubulin in CB can then be snap-frozen in liquid nitrogen or converted to tubulin in BRB80 using BRB80 conversion buffer prior to freez-

ing and subsequent storage at –80°C. When run on a 12% polyacrylamide gel, the purified tubulin, when stained with Coomassie, should appear as a single band free of any trace of contaminating proteins. The MAPs are retained on the column and these proteins can be eluted using CB containing 1 *M* NaCl.

B. Cycling Tubulin

It is inevitable that some tubulin will become inactivated or denatured during passage through the phosphocellulose column, as tubulin is an unstable entity. It is therefore recommended to "cycle" the tubulin after it passes through the column. To cycle tubulin means that it is polymerised at 37°C, reisolated by centrifugation through a glycerol cushion, and depolymerised at 4°C prior to freezing. This can be performed either immediately after elution from the column or after it has been stored at –80°C in CB. In both cases the tubulin buffer should be converted to BRB80 as described earlier. There are several advantages to cycling the tubulin: it enriches for active tubulin dimers, removes free nucleotides, removes denatured tubulin and other impurities, and concentrates the tubulin to approximately 10–20 mg/ml (cf. 5–10 mg/ml as it comes through the column.). The resulting cycled tubulin is suitable for use in *in vitro* assays such as video microscopy (e.g., Andersen *et al*., 1994). It is also recommended to use cycled tubulin for biochemical studies (e.g., purification of MAPs) because it is much easier to control the amount of microtubules formed when this highly active tubulin is used compared to that obtained directly from the phosphocellulose column.

Steps

To obtain a large stock of identical cycled tubulin, it is recommended to cycle approximately 30 ml of tubulin obtained directly from the phosphocellulose column.

1. Prewarm the rotor (a Beckman Ti50, TLA100, or MLA 80 rotor is suitable) in a water bath at 37°C. Fill the rotor tubes to half their volume with a glycerol cushion consisting of 60% glycerol in BRB80 (no GTP), place these in the rotor, and allow them to equilibrate to 37°C. While this is happening, proceed with polymerisation of the tubulin.
2. Thaw the tubulin rapidly using a water bath set at 37°C until the tube is half full of ice and then continue to thaw the remainder on ice. Adjust the solutes to glycerol PB using anhydrous (100%) glycerol. Allow polymerisation to occur for 40 min at 37°C.
3. Layer the polymerised tubulin onto the prewarmed cushions using tips with large openings to avoid depolymerising the microtubules. Centrifuge at 226,240 *g* (50,000 rpm in the Beckman Ti50 rotor) for 60 min or, alternatively, at 70,000 rpm for 30 min in the TLA100 rotor at 37°C.
4. Aspirate away the supernatant above the cushion. Rinse the cushion interface twice with water. Aspirate away the cushion. Resuspend the pellet in 0.25× BRB80 + 0.1% β-mercaptoethanol on ice using an homogeniser to depolymerise the microtubules. The volume of buffer used for the resuspension is chosen so that the final tubulin concentration is between 10 and 20 mg/ml (based on the assumption that approximately half the tubulin from the phosphocellulose column will polymerise). Incubate on ice for 15 min and then add 5× BRB80 to adjust the buffer to 1× BRB80. (*Note*: The volume of 5× BRB80 to add is 3/16ths of the volume of 0.25× BRB80–tubulin.)
5. Sediment the undepolymerised microtubules by centrifuging the sample at 213,483 *g* (70,000 rpm in the Beckman TLA100.2 rotor) for 15 min at 4°C.
6. Aliquots (10–200 µl) of the concentrated tubulin can be made, which should then be snap frozen in liquid nitrogen. The tubulin can then be stored either in liquid nitrogen (indefinitely) or at –80°C (for at least 12 months).

C. Preparation of Phosphocellulose Column

For large-scale preparations of tubulin (finally giving 1 g or more of purified tubulin) a phosphocellulose column of approximately 1 litre volume will be necessary. For successful preparation of PC, it has to be equilibrated *for short periods* first in base and then in acid, interspersed with water washes. This is normally achieved by suspension of the PC in either the acid or the base solution and then rapid filtration over a sintered glass funnel where the PC can be washed with large volumes of water. Large volumes of PC are, however, quite cumbersome to handle and the importance of setting up an efficient filtration system *before* commencing the PC preparation cannot be overemphasised. With volumes as large as 1 litre it may be unwise to rely on running water aspirators, as the vacuum produced may be insufficient (but for small volumes of PC these may be suitable). It is better to use a membrane-type pump and if, possible, to connect this to a wide, sintered glass funnel over which Whatmann 3 MM filter paper has been placed. Alternatively, and we have used this quite successfully, use some nylon or polypropylene meshing (available from SpectraMesh), as this allows rapid filtration rates with almost no risk of tear as there is when using Whatmann filter paper.

When considering what volume of phosphocellulose is needed, our laboratory uses 200 ml phosphocellulose to obtain 300–600 mg of purified tubulin. When equilibrated in buffer, 1 g of PC powder will give between 5 and 6 ml of PC column matrix (depending on the salt concentration), but do allow for some loss due to the removal of fines when calculating the amount of PC to prepare.

Phosphocellulose is obtained from Whatmann Scientific Ltd. and the column and adaptors can be obtained from Kontes, but any column with similar dimensions ($10 \times 30 \times 4.8$ cm) should be suitable.

Steps

Note: All stages should be performed at 4°C.

1. Having determined the amount of phosphocellulose that is needed using the information just given, slowly hydrate the dry powder by washing twice in 95% ethanol, once in 50% ethanol, and finally once in pure water.

2. Resuspend the hydrated phosphocellulose in 25 volumes (liquid volume per original dry weight of phosphocellulose) of 0.5 *M* NaOH and stir *gently* (stirring too fast produces fines, which will result in slow column flow rates if not removed later) for 5 min. Filter the phosphocellulose rapidly to remove the NaOH solution and continue to rinse with water until the pH of the washings is lower than 10 (usually at least three times the volume of the NaOH solution used).

3. As soon as the pH is sufficiently low, resuspend the phosphocellulose in 25 volumes of 0.5 *M* HCl (i.e., the same volume as the NaOH solution as used earlier) and again stir gently for 5 min and filter quickly. Continue to wash with water until no longer acid—usually around 10 times the volume of the HCl solution used.

4. If the column is not to be poured at this stage, the phosphocellulose should be resuspended and stirred for 5 min in a 2 *M* solution of potassium phosphate, pH 7.0. The PC can then be resuspended and stored in a solution of 0.5 *M* potassium phosphate, pH 7.0, containing 20 m*M* sodium azide as preservative. When the phosphocellulose is removed from storage, it should be resuspended and washed in at least 3 volumes of water.

5. At this stage, whether the column material was stored or not, the phosphocellulose should be resuspended in at least 3 volumes of water and transferred to a large measuring cylinder. The phosphocellulose should be stirred and then allowed to settle naturally. After the bulk of the phoshocellulose has settled, it will be noticed that there is a cloudy layer just above it. These are the fines and should be removed by aspiration to ensure fast column flow rates. This cycle of resuspension, stirring, and aspiration of the fines should be repeated until no more fines are visible.

6. Resuspend the phosphocellulose in column buffer solution and then degas for 30 min prior to pouring the column.

7. After use, wash the phosphocellulose column extensively and replace the buffer with a 50 m*M* potassium phosphate buffer containing 20 m*M* sodium azide.

Purification of Smooth Muscle Actin

Gerald Burgstaller and Mario Gimona

I. INTRODUCTION

Actin purified from mammalian or avian skeletal muscle is a readily available probe to study the potential interaction of a putative actin-binding protein or recombinant fragment *in vitro*. Yet, the use of a specific actin isotype for the determination of binding affinities or the tissue-specific regulatory potential of actin-associated proteins is often required.

Purification of actin from smooth muscle is much less straightforward than from skeletal muscle tissue. The major difficulty resides in the large number of actin-binding proteins, which populate the actin filaments in this tissue type. These proteins interfere with polymerization even at levels undetectable on conventional Coomassie blue-stained SDS–PAGE gels. A primary source of contamination is the copurification of tropomyosin. Moreover, because the total amount of actin present in smooth muscle is reduced compared to that in skeletal muscle, the yield is lower. However, despite the aforementioned potential pitfalls, smooth muscle actin can be purified in large quantities and high purity by the use of larger extraction volumes in the initial steps.

This article describes the method used for purifying polymerization-competent actin from mammalian or avian visceral smooth muscle (porcine stomach or turkey gizzard) and suggests some useful methods to test the functionality of the preparation prior to its use in analytical assays. The purification scheme follows the original modification of Sobieszek and Bremel (1975). The modified extraction buffer (containing 10 m*M* imidazole, 10 m*M* bis–Tris, 40 m*M* KCl, 2 m*M* $MgCl_2$, 1 m*M* cysteine, and 5 m*M* EGTA at pH 6.5) introduced by Fürst (1986) significantly improved the solubilization and removal of actin-binding/modulating proteins.

IV. PROCEDURE

The most convenient source of actin for relatively large yields is the powder remaining after the extensive drying of muscle homogenates in acetone. For this procedure, prepare the acetone powder from chicken gizzard smooth muscle according to Strzelecka-Golaszewska *et al*. (1980).

Starting with 15 g of dry acetone powder, the extraction in a final volume of 1.3 liters of G-actin buffer is let to proceed for 20–25 min at 4°C under constant agitation (using a magnetic stir bar). Centrifuge the resulting extract at 15,000 *g* for 60 min (*Sorvall GS-A rotor or equivalent*).

From the supernatant, precipitate actin by the slow addition of solid ammonium sulphate to reach 25% saturation. Let the precipitation proceed for 90 minutes at 4°C. Collect the precipitate by centrifugation at 15,000 *g* for 30 min (*Sorvall GS-A rotor or equivalent*).

Resuspend the pellet in about 50 ml G-actin buffer and dialyze against 2 liters of G-actin buffer overnight with two to three changes of buffer. Centrifuge the dialyzed actin solution to remove polymerized or aggregated actin at 32,000 *g* for 60 min (*Sorvall SS-34 rotor or equivalent*).

From this clarified solution, polymerize F-actin by the addition of 150 m*M* KCl, 2 m*M* $MgCl_2$, and 2 m*M* EGTA (final concentrations) by adding 1/10 volume of 10× polymerization solution. Allow polymerization to proceed for 90 min at 25°C.

Separate polymerized F-actin from "*dead*" (non-polymerizing) actin by centrifugating at 100,000 *g* for 30 min. Resuspend the pellets in 10–20 ml G-actin buffer and homogenize in a glass–glass homogenizer on ice.

Dialyze against 2 liters of G-actin buffer for 48 h with four to six changes of dialysis solution to thoroughly depolymerize the F-actin. Remove precipitated or polymerized material by centrifugation at 32,000 *g* as described earlier.

Apply the clarified supernatant onto a Sephadex G-150 or Sephacryl S-100 HR column, equilibrated in G-actin buffer, to remove the remaining, contaminating G-actin-binding proteins. Fractions should be analyzed by SDS–PAGE before storage.

Measure the final concentration of the G-actin solution using the absorption coefficient $A^{1\%}/_{290}$ of 6.5. Aliquots can be stored at –70°C after adding 2 mg sucrose/mg of G-actin from a 600-mg/ml stock solution.

V. TESTS

There are several possibilities to test the functionality of the actin solution before using it in *in vitro* assays.

A. General Polymerization

Polymerize the G-actin solution as described earlier (by adding 1/10 volume of the *10× polymerization stock solution*) and centrifuge the polymerized actin at 100,000 *g* for 30 min. Analyze the supernatant and pellet on a Coomassie blue-stained SDS–PAGE gel. The supernatant should essentially be devoid of actin, indicating 100% polymerization competence of the G-actin solution.

B. Cosedimentation Assays

Polymerize the G-actin solution as described earlier, but in the presence of actin-binding proteins such as α-actinin and/or tropomyosin, and analyze supernatants and pellets by SDS–PAGE. The presence of the actin-binding protein in the pellet indicates a "*functional surface*" and intact binding sites on the actin filament.

VI. COMMENTS

We found that dry acetone powder can be stored for at least 20 years at –20°C without a significant loss of quality of the purified actin. It thus may pay to stock up on acetone powder.

Initial extraction beyond the recommended 25 min results in the increased extraction of tropomyosin, which is difficult to remove at later stages. Accepting a lower yield is rewarded with higher purity!

The two tests described earlier are also recommended to evaluate the quality and functionality of fluorescently labeled actin.

The choice of buffer for the assays appears critical. F-actin reacts with structural alterations to different ionic strengths and the presence or absence of divalent or monovalent cations. The illuminating work by the Egelman group is a rewarding read.

CHAPTER

24

Purification of Nonmuscle Actin

Herwig Schüler, Roger Karlsson, and Uno Lindberg

I. INTRODUCTION

In the past decade or so, a number of new actin regulatory proteins and their functions in the motility of nonmuscle cells have been unveiled. We now understand in some detail how extracellular stimuli are transmitted to the microfilament system *via* activation of the phosphatidylinositol cycle, rho-family of GTPases, causing polymerization of actin through the recruitment of WASp, WAVE, ARP2/3, or formin proteins. The polymerization of actin requires constant supply of actin kept in an unpolymerized form by proteins such as thymosin, cofilin, and profilin. Filament-capping, cross-linking, destabilising, and sequestering proteins cooperate with monomeric (G)-actin to contribute to the dynamics of the system. Thus, complex machineries for the controlled polymerisation of actin are now being revealed (see Ridley *et al*., 2003; Innocenti *et al*., 2004).

Isoforms of actin differ in their affinities for their ligands, their functioning, and subcellular locations. Therefore, to understand the function of actin in nonmuscle cells, it is important to work with nonmuscle actin when studying actin-binding proteins (ABPs) from nonmuscle tissues. Unfortunately, this is often neglected because of the ready access to α-actin from rabbit skeletal muscle (Pardee and Spudich, 1982). A further complication is the covalent modification introduced in α-actin during the commonly used purification protocol involving acetone extraction of muscle tissue (Selden *et al*., 2000). This modification leads to the formation of stable dimers, explaining fast polymerisation kinetics and other properties thought to be characteristic for α-actin. However, i- and -actin are prepared easily from various nonmuscle tissues using the method described in this article.

Here, the isolation of β- and γ-actin isoforms from profilin:actin obtained by affinity chromatography on poly-(L-proline) Sepharose is described. It also describes the purification of yeast and recombinant β-actin using a yeast expression system and DNase I affinity chromatography, enabling the production of large amounts of mutant actins.

II. MATERIALS AND INSTRUMENTATION

All chemicals (reagent grade) are from ICN or Sigma. Hydroxyl apatite is hypatite C of *even* lot number from Clarkson Chemical Co. (Williamsport, PA). This is the only hydroxyl apatite material we have used successfully to separate actin isoforms. DNase I is from ICN (Cat. No. 100579) and poly-(L-proline) is from Sigma (Cat. No. P-2129). CNBr-activated Sepharose 4B is from Amersham Biosciences (Cat. No. 17-0430). Empty columns are XK-16/20, XK-26/20, and XK-50/20 from Amersham Biosciences. All other chromatography equipments and matrices are from Amersham Biosciences.

Yeast nitrogen base without amino acids is from Difco (Cat. No. 291940), adenine sulfate is from ICN (Cat. No. 100195), and the casamino acid vitamin assay is from Difco (Cat. No. 228820). All other media components are from Difco. Lysis of yeast cells is achieved with a purpose-designed bead mill (Innomed Konsult) using glass beads 0.25–0.5 mm in diameter (Mahlkörper MK2GX, Willy Bachofen). However, alternative procedures to break up yeast cells have been described

(Jazwinski, 1990). Low-speed centrifugations are carried out in a Beckman-Coulter Avanti J-20XP with polypropylene tubes (50 ml; Beckman Cat. No. 357007) in a Beckman JA-25.0 rotor. Large-volume centrifugations are performed with polycarbonate centrifuge bottles (500 ml; Beckman no. 335605) in a Beckman JLA-16.250 rotor. Preparative ultracentrifugations are done in a Beckman-Coulter L-series centrifuge with polycarbonate bottles (70 ml; Beckman No. 355622) in Rotor Beckman 45Ti.

III. PROCEDURES

A. Preparation of Profilin:Actin Complexes from Bovine Thymus or Spleen

This protocol is used for the purification of profilin in complex with a mixture of the cytoplasmic β- and γ-actin isoforms. The isolation procedure involves affinity binding to poly-(L-proline) and chromatography on hydroxyl apatite to separate actin isoforms, either alone or in complex with profilin (Segura and Lindberg, 1984; Lindberg, 1988). The yield of profilin:actin complex is approximately 400 mg/kg of tissue. The following section describes a preparation starting with 700 g of calf thymus. All buffer volumes and column sizes refer to that preparation size. If calf thymus cannot be obtained, calf spleen can be used instead. Actin isoform distribution is approximately 60% β-actin and 40% γ-actin in thymus, whereas spleen contains slightly more β-actin. Spleen is easier to handle, but contains more proteolytic enzymes, which are difficult to control.

1. Affinity Purification of Profilin:Actin Complexes

Solutions and Columns

1. *Homogenisation buffer (2 liters)*: 10 m*M* Tris–HCl, pH 7.6, 0.1 *M* KCl, 0.1 *M* glycine, 1% Triton X-100, and 0.5 m*M*, dithiothreitol (DTT)
2. *2× PLP buffer (3 liters)*: 20 m*M* Tris–HCl, pH 7.6, 0.2 *M* KCl, and 0.2 *M* glycine
3. *PLP elution buffer (500 ml)*: make immediately before use. Mix 250 ml of 2× PLP buffer with 150 ml of dimethyl sulfoxide (DMSO) and 100 ml distilled H_2O. Mixing DMSO with water is an exothermic reaction, thus the buffer needs to be cooled on ice before being applied to the column (no DTT).
4. *HA buffer (5 liters)*: 5 m*M* KPO_4, pH 7.6
5. *HB buffer (0.5 liter)*: 40 m*M* KPO_4 pH 7.6, 1.5 *M* glycine, and 0.5 m*M* DTT
6. *Saturated ammonium sulfate (4 liters)*: Add about 1600 g of $(NH_4)_2SO_4$ to 2 liters of water to make a saturated solution. Adjust to pH 7.6 with ammonia.
7. *Poly-L-proline (PLP) affinity matrix*: For the preparation size described here, mix 0.5 g of poly-(L-proline) to 30 g of CNBr-activated Sepharose 4B for 2 h at room temperature or overnight at 4°C according to the supplier's recommendations. Avoid extensive stirring, as this will have deleterious effects on the matrix. Monitor the coupling reaction photometrically at 234 nm in supernatants of small samples of the incubation mixture, removed at intervals. After each use, wash the matrix immediately with 1 liter of water, followed by 1 liter of 1% *N*-lauryl sarcosine, followed with 1 liter of water. Reequilibrate with PLP buffer containing 0.01% sodium azide. Stored at 4°C, this matrix should be good for 10–15 preparations and last for 1–2 years.
8. *Hydroxyl apatite column*: Degas 100 ml of settled hypatite-C in 500 ml buffer HA. Pack an XK-26/20 column with hydroxyl apatite at a flow rate of 10 ml/min. Attach a top adaptor, but allow some buffer to be present on top of the matrix and equilibrate the hydroxyl apatite column with 1 liter of buffer HA at a flow rate of 10 ml/min.

Note: Wear gloves and take extra care when working with DMSO. Do not use DTT in DMSO-containing solutions due to the formation of toxic dimethyl sulfide. All buffers should be freshly degassed when used. Add DTT only after degassing. All steps are carried out at 4°C, and all solutions should be at 4°C, unless stated otherwise. Note that Tris buffers are temperature sensitive.

Steps

1. Make 5 liters (1×) PLP buffer using the (2×) buffer stock. Degas all buffers.
2. Partially thaw 700 g thymus and remove fat and connective tissue. Cut the organ into small pieces and homogenise in a blender using approximately 2 volumes of homogenisation buffer.
3. Transfer the tissue extraxt to 500-ml polycarbonate bottles and centrifuge at 20,000 *g* (12,000 rpm with the JLA-16.250 rotor) for 30 min.
4. Filter the supernatant through glass wool, transfer to 70-ml polycarbonate bottles, and centrifuge at 100,000 *g* (30,000 rpm with the 45TI rotor) for 30 min.
5. Prepare the PLP column in a laminar flow hood: Pack an XK-50/20 column with the affinity matrix described in step 6 of the previous section and equilibrate it with PLP buffer at a flow rate of 5–10 ml/min.
6. Filter the supernatant from step 4 through glass wool and load it onto the PLP column.
7. After all the protein has been loaded, wash the matrix with PLP buffer until the color is removed from the matrix.

8. Elute bound proteins with ice-cold PLP elution buffer into a 500-ml measuring cylinder on ice. After this step the preparation already contains mainly profilin and profilin:actin complexes.

9. Dilute the PLP eluate with 2 volumes of buffer HA and load the solution onto the hydroxyl apatite column at a rate of 10 ml/min, monitoring the UV absorbance at 280 nm. The DMSO accounts for a small increase in absorbance at 280 nm. A tough layer may form on top of the matrix bed, restricting buffer flow. If necessary, stop the pump, disconnect the top adaptor, and resuspend the top centimeter of matrix bed by careful stirring with a glass pipette. Allow the matrix to resettle, replace the top adaptor, and continue loading.

10. After the protein has entered the column, wash with buffer HA to remove DMSO. Finish washing when a low baseline is reestablished. Carefully press the top adaptor onto the gel matrix.

2. *Separation of Profilin-Bound β- and γ-Actin Isoforms*

11. For separation of profilin:β-actin from profilin:γ-actin complexes, elute the hydroxyl apatite-bound material with a linear gradient of 5 m*M* potassium phosphate to 40 m*M* phosphate/1.5 *M* glycine. Employ a gradient mixer containing 350 ml HA in the start buffer compartment and 350 ml HB in the finishing buffer compartment. (If a different column dimension is used, the gradient length should be approximately 12 column volumes.) Elute the protein at a flow rate of 0.3 ml/min. Collect 10-min fractions.

12. Identify the fractions containing profilin:γ-actin and profilin:β-actin and pool the appropriate fractions (see Fig. 1). Continue as described in step 14.

3. *Elution of Total PA*

13. If isoform separation is not aspired, elute the hydroxyl apatite-adsorbed protein using HB buffer. The eluate consists of mixed actin isoforms in complex with profilin, plus a slight excess of profilin.

4. *Ammonium Sulfate Precipitation of PA*

14. Precipitate the protein by dialysis against 2 liters of saturated ammonium sulfate using dialysis tubing with a molecular mass cutoff under 12 kDa. The resulting protein is suitably stored as a precipitate in ammonium sulfate. Stored in this form at 4°C the PA is stable for 6–12 months. Estimate the concentration of protein by diluting 25–50 µl of the well-suspended solution into 1 ml of water and determine the absorbance at 280 and 310 nm (280–310 roughly corresponds to milligram per milliliter).

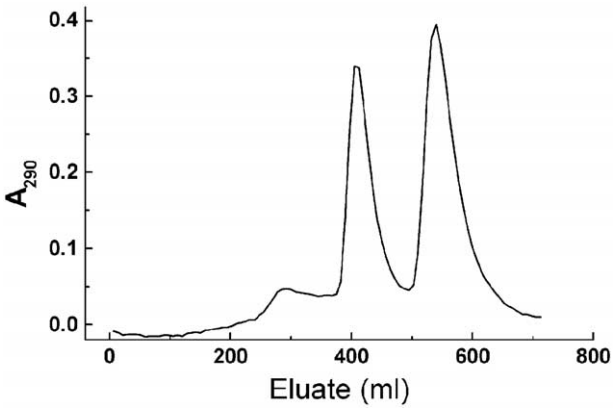

FIGURE 1 Separation of profilin, profilin:β-actin, and profilin:γ-actin using hydroxyl apatite chromatography (see Section III,A). The slightly more basic γ-actin:profilin complex elutes at lower ionic strength, followed by the β-actin:profilin complex at higher phosphate/glycine concentration. The small initial peak contains excess profilin.

The dialysis against saturated ammonium sulfate results in a reduction of the sample volume, ensuring effective protein precipitation. It is important to use enough saturated ammonium sulfate to avoid dilution of the salt below 40–50% saturation, which is the concentration precipitating the profilin:actin.

Pitfalls

For efficient extraction of the tissue, it may be helpful to pass the organ through a meat grinder before homogenisation in a blendor. The buffer over tissue ratio should not be lower than 2:1. Continue homogenisation until no chunks are visible, which should take about 2 to 3 min. Do not continue homogenisation over prolonged periods of time. Avoid excessive foaming.

5. *Isolation of Profilin and Actin from Precipitated P:A Complex*

Solutions and Columns

1. *G buffer (2 liters)*: 5 m*M* Tris–HCl, pH 7.6, 0.5 m*M* ATP, 0.1 m*M* $CaCl_2$, and 0.5 m*M* DTT
2. *Resuspension buffer (0.1 liter)*: G buffer, add DTT to 5 m*M*
3. *F buffer (0.1 liter)*: 5 m*M* Tris–HCl, pH 7.6, 0.5 m*M* ATP, 2 m*M* $MgCl_2$, 50 m*M* KCl, and 0.5 m*M* DTT
4. *2 M KPO_4 pH 7.6 (make 50 ml)*
5. *P buffer (1 liter)*: 10 m*M* KPO_4 pH 7.6, and 0.5 m*M* DTT
6. Prepare an XK-26/70 Sephacryl-300 gel filtration column equilibrated with G buffer
7. Prepare an XK-26/50 Sephadex G-25 gel filtration column equilibrated with P buffer

8. Prepare an XK-16/10 DEAE-Sephadex anion-exchange column equilibrated with P buffer

Steps

6. Purification of Actin

1. Collect 30–50 mg of ammonium sulfate-precipitated profilin:actin (either isoform; previous section, step 14) by centrifugation in a JLA-16.250 rotor at 10,000 rpm for 10 min. Discard the supernatant, leave the tubes upside down for a few minutes, and then wipe the inside of the tubes with Kleenex to remove residual ammonium sulfate.

2. Dissolve pellets in a small volume of resuspension buffer, stir, and add buffer until the solution becomes clear. Protein concentration should be 10–20 mg/ml. Centrifuge the solution again (as in step 1) to remove undissolved residues. Save the supernatant.

3. Measure the volume of the protein solution and add $MgCl_2$ to 5 m*M* and EGTA to 0.5 m*M*. Allow actin to polymerise at room temperature for 30 min.

4. Induce paracrystal formation by the addition of 1 volume of 2 *M* KPO_4. Mix carefully; avoid extensive pipetting. Leave for 1 h at room temperature or overnight at 4°C.

5. Collect the actin paracrystals by centrifugation at 10,000 *g* for 20 min at 15°C. The supernatant contains profilin and small amounts of remaining profilin:actin; save supernatant on ice for the profilin purification described later. The pellet contains actin paracrystals.

6. Resuspend the paracrystals in F buffer to dissolve the actin filaments. Mix by careful pipetting until all lumps have dissolved.

7. Sediment filaments by ultracentrifugation at 100,000 *g* for 3 h at 15°C. Remove the supernatant and add a small amount of G buffer to the F-actin pellet and leave it for 10–20 min. Seal the tip of a Pasteur pipette and use it to scrape the pellet off the walls of the tube. Carefully transfer the pieces of F-actin gel to a Dounce-type glass homogeniser and homogenise without introducing air. Measure the protein concentration using an extinction coefficient at $A_{290–310}$ of 0.63 ml/mg × cm. Dilute the F-actin to 5 mg/ml to get efficient depolymerisation.

8. Dialyze the actin sample against 10 volumes of G buffer in 12- to 14-kDa cutoff tubing with three buffer changes and homogenisations. Four to 6 h of dialysis is sufficient for every buffer change.

9. Subject the dialyzed actin to ultracentrifugation at 100,000 *g* for 3 h at 4°C in order to remove undissolved material. Load the supernatant onto the Sephacryl S-300 column. The sample volume should not exceed 4% of the column volume. Elute with G buffer at a flow rate of 30 ml/h. Collect 4- to 6-ml fractions. Measure protein concentration in the fractions and pool the protein peak. Analyze by SDS–PAGE, drop freeze (20 µl droplets) the actin in liquid N_2, and store in a nitrogen tank.

7. Purification of Profilin

10. Desalt the profilin solution from step 5 by gel filtration over Sephadex G-25. The volume of the protein solution may be up to approximately 30% of the column bed volume. Collect 2- to 3-ml fractions.

11. Determine protein concentrations across the chromatogram. Measure conductivity in the last fractions to make sure the solution will not be contaminated by salts and pool the protein-containing fractions.

12. Run the G-25 pool over the small DEAE-Sephadex column. Contaminating actin will stay on the ion exchanger. The column flow through contains pure profilin. Quick-freeze aliquots in liquid N_2 and store at –80°C.

Pitfalls

Before inducing paracrystal formation (step 4), check on the progress of the polymerisation reaction by rocking the tube carefully; the protein solution should have a gel-like consistence. If necessary, stimulate polymer formation by a few short bursts in an ultrasonicator.

Polymers of cytoplasmic actin are more cold sensitive than polymers of α-actin. Therefore, the ultracentrifugation step that aims at collecting actin filaments is carried out at 15°C.

B. Purification of Recombinant β-Actin from Baker's Yeast

This protocol is used for the large-scale preparation of recombinant actin expressed in *Saccharomyces cerevisiae* strain K923 using the temperature-inducible expression system described by Karlsson (1988). The heterologous actin cDNA is placed under the combined control of the PGK promoter and the negative transcription factor α2 and is introduced into strain K923 containing a temperature-sensitive mutation in the mating type switch (Walton and Yarranton, 1989; see also Sledziewski *et al*., 1988). This results in temperature-inducible expression of the heterologous actin. At 34°C, the cells are MATα and produce the α2 protein, which blocks transcription of the cloned cDNA. By lowering the temperature to 23°C, the cells switch mating type and cease to produce α2, leading to expression of the recombinant actin. Total actin is

isolated from yeast extracts by DNase I affinity chromatography (Zechel, 1980), and the recombinant isoform is separated from the endogenous actin by hydroxyl apatite chromatography (Karlsson, 1988). Ten liters of flask culture produces 120–150 g of yeast cells (the amount needed for a preparation as described later), yielding in the range of 10–15 mg each of yeast and recombinant actin. Usually, a fermentor culture in 10-liter fermentors is used, producing 700–800 g of yeast, which is material for five to six standard preparations of recombinant actin. The fermentation process has successfully been scaled to 50–100 liters. It should be noted that the yeast does not modify the N terminus of actin and does not methylate residue His73 (for discussion, see Nyman *et al*., 2001).

This method has been adapted for the production of human profilin (Aspenström *et al*., 1991) and should also work for other proteins.

1. Fermentor Culture of Yeast Expressing Recombinant Actin

Solutions

1. *S. cerevisiae strain K923*: HMLα, *mat::LEU2*$^+$, *hmr::TRP1*$^+$, *ura3*, *ade2*, *sir3ts*; MATa at 23°C, MATα at 34°C. This strain is grown on standard YPD medium (Sambrook and Russell, 2001) at 34°C.

2. *UYM media for transformed yeast strain K923*: Bottle 1: 8 g yeast nitrogen base without amino acids, 55 mg adenine sulfate, 55 mg L-Tyr; add H_2O to 580 ml. Bottle 2: 11 g casamino acid vitamin assay; add H_2O to 300 ml. Autoclave, allow to cool. Combine contents of bottles 1 and 2 and add 100 ml 20% glucose, 10 ml 0.5% L-Trp, and 10 ml 1% L-Leu. Grow the transformed strain on min-ura plates at 34°C.

Steps

1. Culture K923 transformed with pY-β-actin to single colonies on a min-ura plate at 34°C. Inoculate into 10 ml UYM and culture for 24 h under vigorous shaking at 34°C, transfer into 1 liter of UYM, and continue culturing for another 24 h at 34°C.

2. Transfer the inoculum into the fermenter, which has been prepared with 9 liters modified YPD [220 g peptone, 220 g yeast extract, 2.2 g adenine sulfate, 2.5 g glucose (0.25%), and PPG to avoid foaming]. Glucose is added continuously from a 50% stock, adjusting the concentration with the density of the culture (measured by OD_{640}) to keep it at approximately 0.5%. Approximately 12 h after inoculation, add 220 g of yeast extract in 500 ml water. Keep the culture at 34°C until OD_{640} is between 1 and 2 (this takes 6–8 h). At this stage, lower the temperature to 23°C to initiate the mating-type switch, which induces production of the recombinant protein. If larger scale (50–100 liters) fermenations are required, prepare the inoculum in the fermentor at a volume of 5–10 liters in UYM medium before transferring into a bigger fermentor with medium as described earlier.

3. Harvest the culture when OD_{640} no longer increases (ca. 24–26 h after inocculation). Rapidly cool the culture to below 10°C, start collecting it into ice-cold 1-liter centrifuge flasks, and centrifuge at 5000 rpm for 20 min (Sorvall RC-3 or equivalent). Collect all material into one or two flasks, centrifuge at 5000 rpm for 30 min, aliquot into suitable portions (150 g) for preparation of the protein, and store at –70°C.

2. Purification of Recombinant Actin from Yeast

Solutions and Columns

1. *2× G buffer (3 liters)*: 10 m*M* Tris–HCl, pH 7.6, 0.2 m*M* $CaCl_2$, and 1 m*M* ATP

2. *G buffer*: use 2.5 liters of the 2×G buffer to make 5 liters (5 m*M* Tris–HCl, pH 7.6, at 4°C, 0.1 m*M* $CaCl_2$, and 0.5 m*M* ATP)

3. *Na-acetate buffer (0.5 liter)*: 0.5 *M* sodium acetate, 0.5 m*M* ATP, pH 7.6, 0.1 m*M* $CaCl_2$, 10% glycerol, and 0.5 m*M* DTT

4. *DNase wash buffer Elu-I*: use the 2×G buffer to make 0.5 liter Elu-I: 5 m*M* Tris–HCl, pH 7.6, at 4°C, 0.1 m*M* $CaCl_2$, 0.5 m*M* ATP, 10% formamide, 10% glycerol, and 0.5 mM DTT

5. *DNase elution buffer Elu-II*: Use the 2×G buffer to make 0.3 liter Elu-II: 5 m*M* Tris–HCl, pH 7.6, at 4°C, 0.1 m*M* $CaCl_2$, 0.5 m*M* ATP, 40% formamide, 10% glycerol, and 0.5 m*M* DTT

6. *HA buffer (0.5 liter)*: 5 m*M* KPO_4, pH 7.6, and 0.5 m*M* DTT

7. *HB buffer (100 ml)*: 40 m*M* KPO_4, pH 7.6, 1.5 *M* glycine, and 0.5 m*M* DTT

8. *Water-diluted protease inhibitor mix (1000 × stock)*: 0.5 mg/ml each of antipain, leupeptin, pepstatin A, chymostatin, and aprotinin. Store 0.5-ml aliquots at –20°C

9. *Ethanol-diluted protease inhibitor mix (100 × stock)*: 0.1 *M* phenylmethyl-sulfonyl fluoride (PMSF) 1 m*M* benzamidine–HCl, and 0.1 mg/ml phenanthroline. Store 5-ml aliquots at –20°C

10. *RNase A (500 × stock)*: 10 mg/ml in 0.1 *M* sodium acetate, pH 5.0. Boil in a water bath for 20 min. Store 1-ml aliquots at –20°C

11. *ATP for Hypa fractions*: 10 m*M* ATP in 40 m*M* K_2HPO_4; gives a pH of approximately 7.0

12. *D buffer (1 liter)*: 10 m*M* Tris–HCl, pH 7.6, 150 m*M* NaCl, 0.5 m*M* $CaCl_2$, and 0.01% sodium azide

13. *DNase I affinity matrix*: Couple 0.3 g of DNase I to 15 g of CNBr-activated Sepharose 4B overnight at

4°C according to the supplier's recommendations. Include 1 m*M* $CaCl_2$ in all buffers. Monitor the coupling reaction photometrically at 280 nm (see step 6 of Section III,A). According to our experience, this matrix will have a capacity of approximately 40 mg actin and will allow purification of actin from up to 150 g (wet weight) of yeast coexpressing recombinant actin. Store the matrix in D buffer containing 0.01% sodium azide. If column capacity decreases after several preparations, wash off bound contaminants with 4 *M* guanidine hydrochloride, 0.5 *M* sodium acetate, and 30% glycerol. Kept at 4°C, this matrix should be good for 10–15 preparations and last for 1–2 years. Also note that long-term exposure of DNase I to reducing agents inactivates the enzyme.

14. *Hydroxyl apatite column*: Degas 20 ml of settled hypatite C. Pack an XK-16/20 column with the matrix and equilibrate with HA buffer at 120 ml/h.

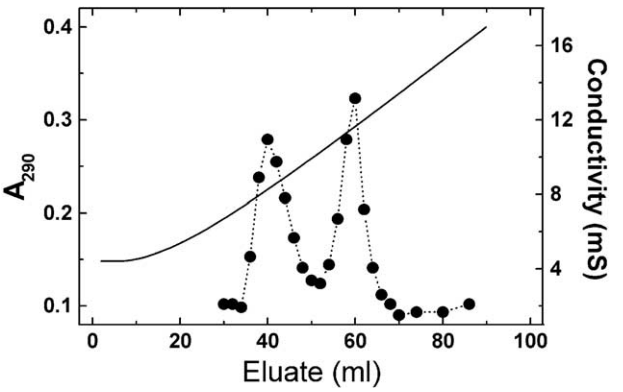

FIGURE 2 Separation of yeast actin and recombinant nonmuscle β-actin using hydroxyl apatite chromatography (Section III,B). The more acidic β-actin elutes at the higher phosphate/glycine concentration. Solid line represents the conductivity.

Steps

1. Use up to 150 g (wet weight) of yeast cells (corresponding to 10–12 liters of flask culture). Make 500 ml lysis buffer by adding water-diluted and ethanol-diluted protease inhibitors and 50 µl polypropylene glycol. Thaw the pelleted yeast in 100 ml lysis buffer. Lyse the yeast cells by passage through the bead mill and wash out the lysate using the remaining lysis buffer.

2. Add RNase A. Centrifuge the collected yeast lysate in a large-volume rotor at 12,000 rpm for 40 min at 4°C. Carefully decant the supernatant and filter it through glass wool.

3. Pour an XK-50/20 column using the DNase affinity matrix (step 13 of the previous section). Equilibrate the DNase column with G buffer. Pump the yeast lysate onto the DNase column. Wash with G buffer until a stable baseline is established as judged by OD_{290}. Wash consecutively with 5 column volumes of Na-acetate buffer, wash buffer Elu-I, and G buffer.

4. Prepare 200 ml of dilution buffer (G buffer containing 10% glycerol). Arrange a measuring cylinder with 100 ml dilution buffer on a magnetic stirrer. Blank a spectrophotometer with buffer Elu-II. Reduce the pump flow rate and start elution with buffer Elu-II. Follow the A_{290}; at 0.05–0.1, start collecting into the dilution buffer. The volume of dilution buffer should be at least 50%. Add more dilution buffer if necessary. Stop collecting when the A_{290} of the eluate is below 0.1.

5. Apply the diluted actin eluate onto the hydroxyl apatite column at a flow rate of max 100 ml/h, i.e., somewhat slower than the packing flow rate, to avoid further packing of the matrix with the more viscous actin eluate.

6. Prepare a fraction collector with 3-ml tubes containing 100-µl aliquots of buffered 10 m*M* ATP (for a final ATP concentration of 0.5 m*M*). Start collecting 2-ml fractions. Elute the actin isoforms using a gradient of 60 ml each of buffers HA and HB at a flow rate of 10 ml/h.

7. Identify actin-containing fractions by measuring the absorbance at 290 nm (Fig. 2), DNase I inhibition activity, SDS–PAGE, or dot blotting. Pool the fractions and dialyse against G buffer; alternatively, the pools may be concentrated and subjected to gel filtration.

Pitfalls

The protease inhibitor PMSF is counteracted by reducing agents. Therefore, DTT should be excluded from the lysis buffer and added to buffers only after the yeast extract has passed over the DNase column.

Failure to wash the DNase affinity column with high ionic strength (sodium acetate) buffer will result in contamination by a number of actin-binding proteins, with the most prominent one being yeast cofilin.

Prolonged exposure to 20% formamide will lead to actin denaturation. Therefore, it is important to collect the actin eluate into at least an equal volume of dilution buffer and apply it to the next column as quickly as possible. Attempts to store quick-frozen actin in this buffer have been unsuccessful.

The most probable reason for poor isoform separation is too high a flow rate during elution.

The aforementioned conditions for the separation of recombinant β-actin from yeast actin are not necessarily applicable to mutants of β-actin or other recombinant actins (e.g., Aspenström and Karlsson, 1991). Therefore, it may be necessary to alter conditions.

Purification of Skeletal Muscle Actin

Sebastian Wiesner

I. INTRODUCTION

Skeletal muscle is the most important preparative source for actin since the discovery of the protein in the 1940s. The original purification procedure developed by Feuer *et al*. (1948) is still the basis of modern protocols. In a first step, fresh skeletal muscle tissue is ground and most of the myosin is extracted by 0.5 *M* KCl. The tissue is then washed several times with distilled water and is dehydrated with acetone at –15°C to yield acetone powder, which can be stored conveniently. The second step, the actual actin preparation from this acetone powder, is based on cycles of actin extraction/depolymerization in low salt buffer, actin polymerization by the addition of salt, and sedimentation of the polymerized actin. Important methodical improvements were reached by the development of additional purification steps aimed at removing major protein contaminants. In particular, α-actinin (Ebashi and Maruyama, 1965) is eliminated by low-speed sedimentation of a thick gel formed with actin at 3 *M* KCl, and tropomyosin (Spudich and Watt, 1971) is dissociated from F-actin at high ionic strength. The procedure presented here is based on the widely used protocol of Spudich and Watt (1971; reviewed in Pardee and Spudich, 1982) followed by a gel filtration step at low ionic strength to isolate monomeric ATP-G-actin (MacLean-Fletcher and Pollard, 1980). It yields very high purity actin suitable for all common biochemical applications, such as actin binding and polymerization assays or chemical labelling. To store and handle actin efficiently, it is paramount to have an understanding of its biochemistry, especially of its interaction with Ca^{2+} and Mg^{2+} (for a review, see Carlier *et al*., 1994). At slightly alkaline pH, Ca-G-actin can be stored on ice at 2–3 mg/ml (50–75 μ*M*) without detectable self-assembly for weeks. This is not the case with Mg-actin, the prevalent species *in vivo*. The following protocol includes a procedure to convert Ca-actin to Mg-actin (Gershman *et al*., 1984).

II. MATERIALS AND INSTRUMENTATION

If not stated otherwise, chemicals are p.a. grade and are purchased from Merck. Na_2ATP is from Roche Molecular Diagnostics (0519987). Water is MilliQ grade. Acetone should be pure (99.5%). Sephadex G-200 is from Amersham Biosciences.

III. LABORATORY EQUIPMENT

Acetone powder preparation: sharp knife, large glassware (4-liter beaker, 4-liter Büchner flask), inox beaker, meat grinder, kitchen blender, gauze, and centrifuge. Actin purification: tissue grinder, thermometer, preparative ultracentrifuge, glass wool, dialysis tubes, and low-pressure chromatography system.

IV. PROCEDURES

A. Preparation of Acetone Powder from Rabbit Skeletal Muscle

Note that acetone powder is also available commercially (Sigma M-0637). To prevent protease

Copyright 2006, Elsevier Science (USA).
All rights reserved.

activity/contamination, the material should not be allowed to warm above 4°C and gloves should be worn throughout the preparation.

Solutions

1. *Extraction solution*: For 8 liters, add 298.2 g KCl and 40 g KHO_3 to 8 liters H_2O
2. *Acetone*: Chill to –20°C (acetone denatures proteins above 0°C)
3. *H_2O*: Chill to 4°C

Steps

1. **Mince preparation.** If possible, work in a group of two or three. Sacrifice two male rabbits (New Zealand white or equivalent). Skin and place in a large flat ice box. With a sharp knife, quickly excise the large muscles on both sides of the spine and from both hind legs. Chop muscles coarsely with scissors, removing as much connective tissue as possible. Grind. You should obtain about 600 g mince.

2. **Myosin extractions.** Place the mince in a large beaker and add 3 liters chilled extraction solution. Stir for 10 min and then centrifuge for 10 min at 2500 *g*. Discard supernatant and repeat this step once.

3. **Water extractions.** Discard supernatant and add pellet to 3 liters distilled water. Stir for 10 min and centrifuge as in step 3. Repeat this step three more times or until pellet begins to swell visibly; in this case, discontinue water extraction.

4. **Acetone washes.** Discard supernatant and mix washed tissue with cold acetone. Homogenize briefly with a kitchen blender. Centrifuge at 1200 *g* for 5 min. Repeat this step two more times.

5. **Drying.** After last acetone wash, pool all pellets in a large inox beaker and add 2 liters cold acetone. Stir vigorously for 20 min. Lay out a large Büchner funnel with several layers of gauze and place on a 4-liter Büchner flask. Apply suction and filter the acetone suspension. Squeeze out residual acetone by gathering the ends of the gauze and wringing. Spread the dehydrated material on filter paper and let dry overnight. Store dry acetone powder at –20°C.

B. Preparation of Ca-G-Actin from Acetone Powder

Gloves should be worn throughout the purification to avoid protease contamination.

Solutions

To prepare ATP-containing buffers, it is convenient to use a stock solution of ATP in H_2O buffered to pH 7.0. Store this stock solution at –20°C.

1. *X buffer*: 2 m*M* Tris–HCl, 0.5 m*M* ATP, 0.1 m*M* $CaCl_2$, 1 m*M* dithiothreitol (DTT), 0.01% (w/v) NaN_3, pH 7.8. Store at 4°C.
2. *Xb buffer*: 2 m*M* Tris–HCl, 1 m*M* $MgCl_2$, 1 m*M* DTT, pH 7.8. Store at 4°C.
3. *G buffer*: 5 m*M* Tris–HCl, 0.2 m*M* ATP, 0.1 m*M* $CaCl_2$, 1 m*M* DTT, 0.01% (w/v) NaN_3, pH 7.8. Store at 4°C.
4. *4 M KCl*: Store at room temperature
5. *1 M $MgCl_2$*: Store at 4°C

Steps

1. **G-actin extraction.** Add 270 ml of cold X buffer to 9 g acetone powder in a beaker on ice. Stir gently with a glass rod to completely moisten the acetone powder; excessive stirring will lead to increased α-actinin extraction. Leave on ice for 30 min, repeat stirring every 10 min.

2. **Clarification.** Centrifuge for 45 min at 25,000 *g* 4°C. Filter the supernatant through glass wool and determine the volume after filtration.

3. **Polymerization/α-actinin elimination.** Add solid KCl to a final concentration of 3.3 *M*, taking into account a volume increase of about 10%. Stir at room temperature until the solution has reached a temperature of 15°C to allow complete solubilization of the salt. Subsequently, chill the solution on ice without stirring until its temperature has fallen back to 5°C. Centrifuge for 30 min at 25,000 *g* / 4°C. Discard the F-actin/α-actinin pellet and filter the supernatant through glass wool.

4. **Dialysis.** Dialyse at 4°C overnight against 32 volumes of buffer Xb to bring $[K^+]$ to 0.1 *M*.

5. **Tropomyosin elimination.** Add 0.22 volumes of 4 *M* KCl to bring $[K^+]$ to 0.8 *M*. Stir for 90 min at 4°C. Centrifuge for 3 h 30 min at 70,000 *g*/4°C. Remove tropomyosin-containing supernatant. Collect the transparent F-actin pellets with a clean spatula and pool into a small glass tissue grinder. To collect residual actin, rinse centrifuge tubes with buffer X and add to pool. Homogenize the F-actin solution on ice, avoiding excessive foaming. Transfer to a 50-ml measuring cylinder. Add 75 µl 1 *M* $MgCl_2$ and 375 µl 4 *M* KCl and adjust volume to 38.6 ml with buffer X. (If necessary, the protocol can be interrupted at this point and the solution left to sit overnight at 4°C.) Repeat step 5 to remove tropomyosin completely, i.e., add 9 ml 4 *M* KCl, make up to 50 ml with buffer X, stir for 90 min at 4°C, centrifuge for 3 h 30 min at 85,000 g/4°C, and remove tromomyosin-containing supernatant.

6. **Depolymerization.** Resuspend and homogenize the F-actin pellets as in step 5 in a total volume of 20–30 ml buffer X. Dialyse overnight against 1 liter buffer G.

7. **Sonication.** Sonicate 2 × 10 s in the dialysis bag. Change dialysis buffer and continue dialysis for another 24 h.

8. **Clarification and gel filtration.** Centrifuge the actin for 2 h at 250,000 *g* / 4°C. Run the supernatant over a Sephadex G-200 gel filtration column equilibrated in buffer G at 15–20 ml/h. Collect 5-ml fractions. You should observe a first small and a second large peak by following the A_{290}; the second one is the actin peak. Avoid collecting the peak front because of possible CapZ contamination.

9. **Concentration determination.** Pool actin fractions and determine the concentration by spectrophotometry (ε_{290nm} = 26,600 $M^{-1}cm^{-1}$) using the G buffer as blank. Typically this will be 40–50 µ*M*. Ca-G-actin can be stored on ice for several weeks.

C. Conversion of Ca-Actin to Mg-Actin

Solutions

1. *10 mM $MgCl_2$*
2. *25 mM EGTA, pH 9.0*

Steps

1. Dilute Ca-G-actin to a concentration not higher than 10 µ*M* with G buffer.
2. Add $MgCl_2$ to a final concentration of (x + 10) µ*M*, where x is the actin concentration in µ*M*.
3. Add EGTA to a final concentration of 200 µ*M*. Mix gently by pipetting. The cation exchange will be complete in about 3 min.

V. COMMENTS

Actin can also be stored frozen or lyophilized, and lyophilized actin is available commercially (Sigma A-2522). However, these techniques lead to partial denaturation of the protein. If actin is frozen or lyophilized, sucrose should be added (2 mg/ml per mg/ml actin), and thawed or rehydrated actin should be dialysed against buffer G and recycled by a cycle of polymerization, high-speed sedimentation, and depolymerization. The protein concentration should be redetermined after this procedure.

Permeabilized Epithelial Cells to Study Exocytic Membrane Transport

Frank Lafont, Elina Ikonen, and Kai Simons

I. INTRODUCTION

Polarized exocytic transport in epithelial cells can be measured by performing *in vitro* assays on filter-grown Madin–Darby canine kidney cells (MDCK strain II cells). Techniques have been developed to establish conditions where cytosol-dependent transfer of a viral marker protein is monitored in MDCK cells permeabilized with the cholesterol-binding and pore-forming toxin *Streptococcus* streptolysin-O (SLO). The transport is assayed either early in the biosynthetic pathway, from the endoplasmic reticulum (ER) to the Golgi complex, or from the *trans*-Golgi network (TGN) to the apical or from the TGN to the basolateral plasma membrane (for a detailed characterization of the assays and their properties, see Lafont *et al*., 1998).

The assays provide the possibility to analyze the effects of exogeneous molecules added to the cytosol. Cytosolic molecules can be inactivated prior to their addition to permeabilized cells or depleted using antibodies. Membrane-impermeable molecules can gain access to lipids or membrane proteins facing the cytosol. We have successfully used fluorescent lipid analogues, chemicals, antibodies, peptides, purified proteins, and toxins. The specificity of the inhibition of transport after depleting cells for a selected cytosolic molecule may be tested by rescuing transport when the purified molecule is added back to the transport reaction. Efficiency of the transport steps can also be tested after cells have been treated with drugs affecting biosynthetic pathways, e.g., after cholesterol biosynthesis inhibition using methyl-β-cyclodextrin.

II. MATERIALS AND INSTRUMENTATION

The recombinant SLO fused to a maltose-binding protein is obtained from Dr. S. Bhakdi (University of Mainz, Mainz, Germany). PhosphorImager and ImageQuant software are purchased from Molecular Dynamics. Sonifier cell disruptor B 15 is purchased from Branson. Media and reagents for cell culture are purchased from Gibco Biocult and Biochrom.; chemicals are from Merck; ATP (Cat. No. A-6033), antipain (Cat. No. A-6271), $CaCO_3$ (Cat. No. C-5273), chymostatin (Cat. No. C-7268), cytochalasin D (Cat. No. C-5394), leupeptin (Cat. No. L-2884), pepstatin (Cat. No. P-4265), and pyruvate (Cat. No. P2256) are from Sigma; creatine kinase (Cat, No. 127566), creatine phosphate (Cat. No. 621714), dimathyl sulfoxide (DMSO) (Cat. No. D-5879), endoglycosidase H (Cat. No. 1088734), and NADH (Cat No. 107727) are from Boehringer Mannheim; trypsin and soybean trypsin inhibitor are from Worthington Biochemical Corporation; protein A–Sepharose (Cat. No. 17-0780-01) is from Pharmacia; and cell filters (0.4-μm pore size; No. 3401, 12-mm-diameter Transwell polycarbonate filters) are from Costar.

III. PROCEDURES

A. SLO Standardization

Each batch of toxin is standardized for the amount of lactate dehydrogenase (LDH) released from the filter-grown MDCK cells, and the amount of LDH released is determined according to a previously described protocol. Alternatively, it is possible to use antibody cytosol accessibility to monitor SLO permeabilization.

Solutions

1. *Growth medium (GM)*: Eagle's minimal essential medium with Earle's salts (E-MEM) supplemented with 10 m*M* HEPES, pH 7.3, 10% (v/v) fetal calf serum, 2 m*M* glutamine, 100 U/ml penicillin, and 100 µg/ml streptomycin.
2. Either purified SLO or recombinant SLO fused to a maltose-binding protein is obtained from Dr. S. Bhakdi (University of Mainz, Mainz, Germany). The recombinant SLO preparation is strored as lyophilisate at –80°C.
3. *10X KOAc transport buffer*: To prepare 1 liter, dissolve 250 m*M* HEPES (59.6 g); 1150 m*M* KOAc (112.9 g), and 50 m*M* $MgCl_2$ (25 ml from 1 *M* stock) in 800 ml water. Adjust the pH to 7.4 with ~50 ml 1 *M* KOH and make it 1 liter with water.
4. *KOAc+ buffer*: KOAC buffer containing 0.9 m*M* $CaCO_3$ (90 mg/liter) and 0.5 m*M* $MgCl_2$ (0.5 ml/liter from 1 *M* stock)
5. *Assay buffer:* KOAc plus 0.011% Triton X-100 for media and KOAc for filter
6. NADH 14 mg/ml KOAc
7. 60 m*M* pyruvate: 30 mg in 50 ml water

Steps

1. Grow MDCK cells strain II on 1.2-mm-diameter filters for 3.5 days *in vitro* and change the medium every 24 h.
2. Wash cells by dipping in KOAc.
3. Prepare a range of SLO, e.g., from 0.5 to 10 µg of recombinant SLO per filter. Activate the SLO for 30 min at 37°C in 50 µl KOAc plus 10 m*M* dithiothreitol (DTT) per filter. Place the filters on a Parafilm sheet put on a metal plate on an ice bucket.
4. Add 50 µl of activated SLO on the apical side for 15 min at 4°C.
5. Wash excess SLO by dipping the filters twice in KOAc+.
6. Transfer the filters to a 12-well dish containing 0.75 ml TM at 19.5°C. Add 0.75 ml TM to the apical side and incubate at 19.5°C for exactly 30 min in a water bath.
7. Collect apical and basolateral media, cut the filters, and shake the filters with 1 ml KOAc containing 0.1% Triton X-100.
8. Mix in a disposable cuvette:
   a. 800 µl of assay buffer (KOAc or KOAc/Triton X-100)
   b. 200 µl of sample
   c. 10 µl of NADH
   d. 10 µl of pyruvate.

   Turn the cuvette upside down twice using Parafilm to close it.
9. Read immediately the OD at 340 nm for 60 s (the OD should be around 1.5).
10. Calculate the LDH activity as the change in OD in 10 s, taking the average of the first 30 s.
11. Dissolve the recombinant SLO in KOAc buffer and store in aliquots at –80°C with the amount necessary for one set of assays per aliquot.

B. Preparation of Cytosols

Solutions

1. *Growth medium*: For HeLa cells, use Joklik's medium supplemented with 50 ml/liter newborn calf serum (heat inactivated for 30 min at 56°C), 2 m*M* glutamine, 100 U/ml penicillin, 100 µg/ml streptomycin, and 150 µl 10 *M* NaOH. For MDCK cells, use Eagle's minimal essential medium with Earle's salts (E-MEM) supplemented with 10 m*M* HEPES, pH 7.3, 10% (v/v) fetal calf serum, 2 m*M* glutamine, 100 U/ml penicillin, and 100 µg/ml streptomycin.
2. *10X KOAc transport buffer*: To prepare 1 liter, dissolve 250 m*M* HEPES (59.6 g); 1150 m*M* KOAc (112.9 g), and 50 m*M* $MgCl_2$ (25 ml from 1 *M* stock) in 800 ml water. Adjust the pH to 7.4 with ~50 ml 1 *M* KOH and make it 1 liter with water.
3. *PBS+*: PBS containing 0.9 m*M* $CaCl_2$ and 0.5 m*M* $MgCl_2$.
4. *Swelling buffer (SB)*: For 100 ml, prepare 1 m*M* EGTA 0.5 *M* (200 µl), 1 m*M* $MgCl_2$ 1 *M* (100 µl), 1 m*M* DTT 1 *M* (100 µl), and 1 µ*M* cytochalasin D 1 m*M* (100 µl).
5. *Protease inhibitor cocktail (CLAP)*: To prepare a 1000X stock, dissolve antipain, chymostatin, leupeptin, and pepstatin each at 25 µg/ml DMSO and combine.

Steps

HeLa Cytosol

1. To grow 20 liters of HeLa cells in suspension to a density of 6×10^5 cells/ml:

a. Inoculate 250 ml cell suspension (6×10^5 cells/ml) in 1 liter medium and leave stirring in a 37°C room.
b. On the third day, split 1:4 by adding 250 ml to 750 ml of fresh medium. Leave stirring in the 37°C room. This will give 4 liters of cell suspension.
c. On the fifth day, again split 1:4 by adding 1 liter of the cell suspension to 3 liters of fresh medium in a 6-liter round-bottom flask. If the cells seem overgrown, add some fresh medium. Thus, between 16 and 20 liters of cell suspension are obtained.

2. Concentrate the cell suspension to 2 liters either by centrifugation or with any cell-concentrating system.

3. Centrifuge cells at 5000 rpm in a Sorvall GS-3 rotor (400-ml buckets) at 4°C for 20 min.

4. Discard the supernatant and wash cells by resuspending the pellet with 10 ml of ice-cold PBS with a sterile 10-ml pipette (10 ml PBS/bucket). Pool the suspension in 250-ml Falcon tubes.

5. Spin at 3000 rpm for 10 min at 4°C in a minifuge. The pellet will be loose. Discard the supernatant.

6. Fill the tube with cold SB (about 35 ml). Resuspend the cells carefully with a sterile 10-ml pipette in SB. Let the pellet swell for 5 min on ice.

7. Spin in the minifuge at 2000 rpm at 4°C for 10 min. Remove as much as possible of the supernatant. The pellet should be loose.

8. Transfer the pellet to a 30-ml Dounce homogenizer (use a spatula) and, after adding SB, perform five strokes. Add 0.1 volume of 10× KOAc and homogenize further by 15–20 strokes.

9. Spin the homogenate at 4°C at 10,000 rpm for 25 min in SS-34 tubes (Sorvall). Collect the supernatant.

10. Spin at 50,000 rpm in Ti70 tubes (Beckmann) for 90 min at 4°C. Aliquot the supernatant in screw-top 1.5-ml tubes. Avoid including lipids that might be on the top of the supernatant. Freeze the aliquots in liquid N_2 and store at −70°C.

11. Measure the protein concentration; it should be around 5 mg/ml. Lower concentrations do not work.

12. When needed, thaw the aliquots quickly and keep them on ice (up to 6 h) until use. Aliquots can be refrozen at least twice.

MDCK Cytosol

1. Trypsinize thirty 24 × 24-cm dishes of confluent MDCK cells. Resuspend trypsinized cells in cold growth medium (containing 5% FCS to inactivate trypsin) and leave on ice until all dishes are trypsinized and cells are pooled. After this, all handling should be done on ice using ice-cold solutions.

2. Centrifugate at 4°C for 10 min at 2000 rpm in a RF Heraeus centrifuge. Wash medium away with PBS.

3. Wash in PBS containing 2 mg/ml STI. Wash out STI with PBS and resuspend the cell pellet in the SB (cf. see earlier discussion) and keep 10 min on ice.

4. Centrifugate at 2000 rpm for 10 min at 4°C in a RF Heraus centrifuge.

5. Sonicate the loose cell pellet (~10 ml) (power 6, 0.5-s pulse, sonifier cell disruptor B 15, Branson) until cells are broken as judged by light microscopy. Add 0.1 volume of 10X KOAc to the sample and spin it for 20 min at 3000 rpm.

6. Spin the supernatant again at 75,000 rpm for 1 h in a TLA 100.2 rotor.

The procedure routinely yields ~6 ml of cytosol at 14 mg/ml. Other cell types, e.g., NIH 3T3 fibroblasts, can also be used as starting material for cytosol preparation using the protocol just described. We have not observed significant differences between the efficiencies of the different cytosols to support transport. However, HeLa cytosol is used routinely because of the ease of preparing large quantities.

C. Transport Assays

Solutions

All solutions are sterilized and kept at 4°C unless indicated.

1. *Growth medium*: E-MEM supplemented with 10 m*M* HEPES (10 ml/liter), pH 7.3, 10% (v/v) fetal calf serum, 2 m*M* glutamine 200 m*M* (10 ml/liter), 100 U/ml penicillin 10^4 U/ml (10 ml/liter), and 100 µg/ml streptomycin 10^4 µg/ml (10 ml/liter).

2. *Infection medium (IM)*: E-MEM supplemented with 10 m*M* HEPES, pH 7.3, 0.2% (w/v) BSA, 100 U/ml penicillin, and 100 µg/ml streptomycin.

3. *Labelling medium (LM)*: Methionine-free E-MEM containing 0.35 g/liter sodium bicarbonate instead of the usual 2.2 g/liter 10 m*M* HEPES, pH 7.3, 0.2% (w/v) BSA supplemented with 16.5 µCi of [^{35}S]methionine/filter.

4. *Chase medium (CM)*: Labelling medium without [^{35}S]methionine and containing 20 µg/ml cycloheximide and 150 µg/ml cold methionine.

5. *10X KOAc transport buffer*: To prepare 1 liter, dissolve 59.6 g HEPES (250 m*M*); 112.9 g KOAc (1150 m*M*), and add 25 ml from 1 *M* stock $MgCl_2$ (50 mM) in 800 ml water. Adjust the pH to 7.4 with ~50 ml 1 *M* KOH and make it 1 liter with water.

6. *KOAc+ buffer*: KOAC buffer containing 0.9 m*M* $CaCO_3$ (90 mg/liter) and 0.5 m*M* $MgCl_2$ (0.5 ml/liter from 1 *M* stock).

7. *PBS+*: PBS containing 0.9 m*M* $CaCl_2$ (0.13 g/liter $CaCl_2 \cdot 2H_2O$) and 0.5 mM $MgCl_2$ (0.5 ml/liter from 1 *M* stock).

8. *0.5 M EGTA*: To prepare 100 ml, dissolve 19 g in 60 ml water. The solution should be turbid (pH 3.5). Add slowly ~10 ml 10 *M* KOH. When the pH of the solution starts to clear, adjust to 7.4. Make it 100 ml with water.

9. *0.1 M Ca and 0.5 M EGTA*: To prepare 100 ml, stir 1 g $CaCO_3$ and 3.8 g EGTA in ~70 ml water for at least 45 min (degas). After adding 2 ml of 10 *M* KOH, the pH is about 6. Finally, make the pH 7.4 adding few drops of 1 *M* KOH. Make it 1 liter with water.

10. *Transport medium (TM)*: To prepare 50 ml, combine 50 µl 1 *M* DTT, 200 µl 0.5 *M* EGTA, and 1 ml 0.5 *M* EGTA/0.1 *M* $CaCO_3$ in 1X KOAc.

11. *ATP-regenerating system (ARS)*: 100X stock, prepare three solutions (10 ml each):

   a. 100 m*M* ATP (disodium salt, pH 6–7, neutralized with 2 *M* NaOH; 0.605 g/10 ml)
   b. 800 m*M* creatine phosphate (disodium salt, 2.620 g/10 ml)
   c. 800 U/mg (at 37°C) creatine kinase (0.5 mg/10 ml in 50% glycerol).

   Store stocks in aliquots at –20°C. Mix solutions a–c 1:1:1 just before use.

12. *Lysis buffer (LB)*: PBS+ containing 2% NP-40 and 0.2% SDS.

13. *CLAP*: To prepare a 1000X stock, combine 25 µg/ml DMSO of antipain, chymostatin, leupeptin, and pepstatin.

Steps

The basic steps of the assays can be summarized as follows. Grow MDCK cells on a permeable filter support until a tight monolayer is formed. Grow cells on 12-mm-diameter filters and use when they display a transmonolayer electrical resistance of at least 50 Ω× cm^2. Infect cells layers with either vesicular stomatitis (VSV) or influenza virus using the G glycoprotein of VSV (VSV G) or the hemagglutinin (HA) of influenza virus N as basolateral or apical markers, respectively. After a short pulse of radioactive methionine, block the newly synthesized viral proteins either in the ER at 4°C or in the TGN after a 20°C incubation. At this stage, one cell surface is permeabilized with SLO, which allows leakage of cytosolic proteins, whereas membrane constituents, including transport vesicles, are retained inside the cells. After removal of the endogenous cytosol by washing, add cytosol and ATP and raise the temperature to 37°C. Transport of the viral proteins from the ER to the Golgi complex or from the TGN to the apical or the basolateral plasma membrane is reconstituted in a cytosol-, energy-, and temperature-dependent manner. Measure the amount of viral proteins reaching the acceptor compartment by endoglycosidase H treatment (ER to Golgi transport), trypsinization of HA on the apical surface (TGN to apical transport), or immunoprecipitation of the VSV G at the basolateral surface (TGN to basolateral transport). Obtain quantitations of viral polypeptides resolved on SDS–PAGE by PhosphorImager analysis.

Due to the handling and the various steps, the entire procedure for running one assay requires about 9 h for the apical assay and 11 h for the basolateral assay. Carry out immunoprecipitation for the basolateral assay the following day (takes 5 h). The ER-to-Golgi transport takes about 6 h before an overnight enzymatic treatment step. Samples can be frozen at –20°C before running SDS–PAGEs (routinely performed the following day). It is worth noting that for the reproducibility of the results the assays should be performed strictly, obeying the schedule indicated in the protocol.

Grow the N strain influenza virus (A/chick/Germany/49/Hav2Neq1) in 11-day embryonated chick eggs as described. Prepare a stock of phenotypically mixed VSV (Indiana strain) grown in Chinese hamster ovary C15.CF1 cells, which express HA on their plasma membrane as described. Prepare the affinity-purified antibody raised against the luminal domain of the VSV G as described.

Apical Transport Assay

1. *Cell culture*: Seed 1:72 of the MDCK cells from one confluent 75-cm^2 flask per filter (6×10^4 cells/filter) with 0.75 ml of growth medium apically and 2 ml basolaterally. Change the growth medium every 24 h and use cells 3.5 days after plating.

2. *Infection*: Prior to viral infection, wash the monolayers in warm PBS+ and then IM and infect with the influenza virus in 50 µl IM (20 pfu/cell; enough to obtain 100% infection as judged by immunofluorescence) on the apical side. After allowing adsorption of the virus to the cells for 1 h at 37°C, remove the inoculum and continue the infection for an additional 3 h after adding 0.75 ml IM on the apical side and 2 ml IM on the basolateral side of the filter.

3. *Metabolic labeling*: Rinse the cell monolayers by dipping in beakers containing warm PBS+ and LM at 37°C. Place a drop of 25 µl of the LM containing 12.5 µCi of [^{35}S]methionine on a Parafilm sheet in a wet chamber at 37°C in a water bath. Add 100 µl of only LM to the apical side of the filters and place them basal side down on the drop. Incubate for 6 min at 37°C.

4. *TGN block*: Terminate all the pulse by moving the filters to a new 12-well plate containing 1.5 ml CM already at 20°C. Add 0.75 ml of CM (20°C) on the

apical side and incubate for 75 min in a 19.5°C water bath.

5. *SLO permeabilization*: Activate the SLO in KOAc buffer containing 10 m*M* DTT at 37°C for 30 min and keep at 4°C until used for permeabilization. Use the toxin within 1 h of activation. Wash the filters twice in ice-cold KOAc+ by dipping. Carefully remove excess buffer from the apical side and blot the basolateral side with a Kleenex. Place 25-µl drops of the activated SLO (enough to release 60% LDH in 30 min, about 20 mg/ml) on a Parafilm sheet placed on a metal plate on an ice bucket. Leave the apical side without buffer. Place the filters on the drop for 15 min. Wash the basolateral surface twice by dipping in ice-cold KOAc+ buffer. Transfer the filters to a 12-well dish containing 0.75 ml TM at 19.5°C. Add 0.75 ml TM to the apical side and incubate at 19.5°C for exactly 30 min in a water bath.

6. *Transport*: Remove the filters from the water bath, rinse them once with cold TM, blot the basolateral side, and place on a 35-µl drop on either TM (control) or HeLa cytosol (±treatment or molecule to be tested) supplemented each with ARS (3 µl/100 µl TM or HeLa cytosol). Add the ARS to TM or cytosol immediately before dispensing the drops onto which the filters are placed. Layer 100 µl of TM on the apical side and incubate at 4°C for 15 min in a moist chamber. Transfer the chamber to a warm water bath for 60 min at 37°C. Terminate the transport by transferring on ice and washing the filters with cold PBS+ three times.

7. *Trypsinization*: Add to the apical surface 250 µl of 100 µg/ml trypsin freshly prepared in PBS+ and then add 2 ml of PBS+ to the basolateral chamber. Keep on ice for 30 min and stop the reaction by adding 3 µl of soybean trypsin inhibitor (STI; 10 mg/ml) to the apical side and then wash the apical surface three times with PBS+ containing 100 µg/ml STI.

8. *Cell lysis*: Solubilize the monolayers in 100 µl LB containing freshly added CLAP. Scrape the cells and spin for 5 min in a microfuge; discard the pellet. Analyze 20 µl per sample by SDS–PAGE on a 10% acrylamide gel, fix, and dry the gel.

9. *Quantitation*: Scan the gels with a PhophorImager and measure the band intensities using ImageQuant software. Calculate the amount of HA transported as the percentage of HA (68 kDa) transported to the cell surface = [2 × HA2/(HA + 2 × HA2) × 100] with HA2 (32 kDA) being the small trypsin cleavage product of HA.

Basolateral Transport Assay

1. *Cell culture*: Seed 1:72 of MDCK cells from one confluent 75-cm^2 flask per filter (6×10^4 cells/filter) with 0.75 ml of growth medium apically and 2 ml basolaterally. Change the growth medium every 24 h and use cells 3.5 days after plating.

2. *Infection*: Prior to viral infection, wash the monolayers in warm PBS+ and then in IM and infect with the vesicular stomatitis virus in 50 µl IM (20 pfu/cell; enough to obtain 100% infection as judged by immunofluorescence) on the apical side. After allowing adsorption of the virus to the cells for 1 h at 37°C, remove the inoculum and continue the infection for an additional 3 h after adding 0.75 ml IM on the apical side and 2 ml IM on the basolateral side of the filter.

3. *Metabolic labeling and chase*: Rinse the cell monolayers by dipping in beakers containing warm PBS+ and then LM at 37°C. Place a drop of 25 µl of the LM containing 12.5 µCi of [^{35}S]methionine on a Parafilm sheet in a wet chamber at 37°C in a water bath. Add 100 µl of LM to the apical side of the filter and place the filter on the drop. Incubate for 6 min at 37°C and incubate for an additional 6 min at 37°C in CM with 0.75 ml on the apical side and 2 ml on the basolateral side before the 19.5°C block.

4. *TGN block*: Terminate the pulse by moving the filters to a new 12-well plate containing 1.5 ml CM already at 20°C. Add 0.75 ml of CM (20°C) on the apical side and incubate for 60 min in a 19.5°C water bath.

5. *SLO permeabilization*: Activate the SLO in KOAc buffer containing 10 m*M* DTT at 37°C for 30 min and keep at 4°C until used for permeabilization. Use the toxin within 1 h of activation. Wash the filters twice in ice-cold KOAc+ by dipping. Carefully remove excess buffer from the apical side and blot the basolateral side with a Kleenex. Add 50-µl drops of the activated SLO (enough to release 60% LDH in 30 min, about 40 mg/ml) on a Parafilm sheet placed on a metal plate layered on an ice bucket. Leave the basolateral side without buffer. Incubate for 15 min. Wash the apical surface twice with 0.75 ml of ice-cold KOAc+ buffer. Transfer the filters to a 12-well dish containing 0.75 ml TM at 19.5°C. Add 0.75 ml TM to the apical side and incubate at 19.5°C for exactly 30 min in a water bath.

6. *Transport*: Remove the filters from the water bath, rinse them once with cold TM, blot the basolateral side, and add 100 µl of either TM (control) or HeLa cytosol (±treatment or molecule to be tested) supplemented with ARS each (3 µl/100 µl TM or HeLa cytosol) on the apical side. Add the ARS to TM or cytosol prior to dispension onto drops. Incubate at 4°C for 15 min. Put the filters on already dispensed 35-µl drops of TM supplemented with ARS on a Parafilm in a moist chamber in a water bath at 37°C. Incubate for 60 min. Terminate the transport by transferring on ice and washing the filters with cold PBS+ three times.

7. *Anti-VSV G binding*: Wash twice (2–5 min) with 2 ml of CM containing 10% FCS (CM-FCS) on the basolateral side and once with 0.75 ml on the apical side. Dilute anti-VSV-G antibodies in CM-FCS (1:18, i.e., 50 µg/ml; 300 µl) and place the filters on 25-µl drops of PBS+/ab (1.5 µl ab/filter). Add nothing on the apical side and incubate in a cold room on a metal plate placed onto an ice bucket for 90 min. Remove the filters and wash (three times) on the basolateral side with CM-FCS (2 ml with constant rocking) and once on the apical side. Shake the filters gently for efficient removal of unbound antibodies. Wash the filters once with PBS+ and place each on a 25-µl drop of PBS+ supplemented with cold virus (1:25; 300 µl). Incubate for 10 min in the cold.

8. *Cell lysis*: Solubilize the monolayers in 200 µl LB containing freshly added CLAP and cold virus (1:166). Scrape the cells, spin for 5 min, and discard the pellet. Remove a 10-µl aliquot from each sample (total).

9. *Immunoprecipitation*: Wash protein A–Sepharose powder with PBS (3×), let it swell 10 min in PBS, wash it with LB, and store as 1:1 slurry in LB at 4°C for 3 weeks maximum. Add 30 µl of the 1:1 slurry of protein A–Sepharose to the lysate. Rotate in a cold room for 60 min. Spin the resin down and wash (3×) with 500 µl LB, elute the bound sample with 35 µl 2X Laemmli buffer, and boil for 5 min at 95°C. Load 20 µl of bound material and 10 µl of total (after boiling with 10 µl of 2X Laemmli buffer) on SDS–PAGE gels (10%). Run SDS–PAGE on 10% acrylamide gels, fix, and dry the gels.

10. *Quantitation*: Scan the gels with a PhophorImager and measure band intensities using ImageQuant software. Calculate the amount of VSV G (67 kDa) transported as follows: percentage of VSV G on the cell surface = (surface immunoprecipitated VSV G / total VSV G) × 100.

ER-to-Golgi Transport Assay

In the ER-to-Golgi transport assay, influenza N- or VSV- infected MDCK monolayers can be used. An infection with the influenza virus is used here as an example.

1. *Cell culture*: Seed 1:72 of the MDCK cells from one confluent 75-cm^2 flask per filter with 0.75 ml of growth medium apically and 2 ml basolaterally. Change the growth medium every 24 h and use cells 3.5 days after plating.

2. *Infection*: Prior to viral infection, wash the monolayers in warm IM and then infect with the influenza virus in 50 µl IM (20 pfu/cell; enough to obtain 100% infection as judged by immunofluorescence) on the apical side. After allowing adsorption of the virus to the cells for 1 h at 37°C, remove the inoculum and continue the infection for an additional 3 h after adding 0.75 ml IM on the apical side and 2 ml IM on the basolateral side of the filter.

3. *Metabolic labeling*: Rinse the cell monolayers by dipping in beakers containing warm PBS+ and then LM at 37°C. Place a drop of 25 µl of the LM containing 12.5 µCi of [^{35}S]methionine on a Parafilm sheet in a wet chamber at 37°C in a water bath. Add 100 µl of LM to the apical side of the filter and place the filter on the drop. Incubate for 6 min at 37°C.

4. Terminate the pulse by moving the filters to a new 12-well plate containing 1.5 ml CM already at 4°C. Add 0.75 ml of CM (4°C) on the apical side and incubate for 30 min at 4°C.

5. *SLO permeabilization*: Activate the SLO in KOAc buffer containing 10 m*M* DTT at 37°C for 30 min and keep at 4°C until used for permeabilization. Use the toxin within 1 h of activation. Wash the filters twice in ice-cold KOAc+ by dipping. Carefully remove excess buffer from the apical side and blot the basolateral side with a Kleenex. Place 25-µl drops of the activated SLO (enough to release 60% LDH in 30 min, about 20 mg/ml) on a Parafilm sheet placed on a metal plate layered on an ice bucket. Leave the apical side without buffer. Place the filters on the drops for 15 min. Wash the basolateral surface twice by dipping in ice-cold KOAc+ buffer. Transfer the filters to a 12-well dish containing 0.75 ml TM at 4°C. Add 0.75 ml TM to the apical side and incubate at 37°C for 3 min and 1.5 ml on the basolateral side of the filter (formation of pores), followed by an incubation at 4°C for 20 min in fresh TM on both sides (cytosol depletion).

6. *Transport*: Rinse the filters once with cold TM, blot on the basolateral side, and put on a 35-µl drop of either TM (control) or HeLa cytosol (±treatment or molecule to be tested) supplemented with ARS each (3 µl/100 µl TM or HeLa cytosol). Add the ARS to TM or cytosol prior to dispension onto drops. Layer the apical side with 100 µl of TM and incubate at 4°C for 15 min in a moist chamber. Transfer the chamber to a water bath at 37°C for 45 min. Terminate the transport by transferring on ice and washing the filters with cold PBS+ three times.

7. *Cell lysis*: Solubilize the monolayers in 100 µl LB containing freshly added CLAP. Scrape the cells and spin for 5 min in microfuge; discard the pellet.

8. *Endoglycosidase H treatment*: Remove a 75-µl aliquot and add to 25 µl of 0.2 *M* sodium citrate buffer, pH of 5.0. The resulting 100 µl mixture has a pH of 5.3. Divide it in two 50-µl aliquots. One receives 5 µl of 1 U/ml endoglycosidase H and the other receives only the citrate buffer. After 20 h at 37°C, terminate the reaction by boiling in Laemmli buffer. Analyze the samples

by running SDS–PAGE on a 10% acrylamide gel, fix, and dry the gel.

9. *Quantitation*: Scan the gels with a PhophorImager and measure band intensities using ImageQuant software. Calculate the amount of HA transported as the percentage of HA acquiring endoglycosidase H resistance with the following formula: percentage of HA reaching the Golgi complex = (endo H-resistant HA / total HA) × 100.

IV. COMMENTS AND PITFALLS

In all cases the values are expressed as control cytosol-dependent transport being 100% (transport in the presence of cytosol minus transport in the absence of added cytosol). For each manipulation a matched control is used (e.g., antibody or peptide tested vs. control antibody or peptide, respectively). Assays are carried out routinely on duplicate filters and quantifications represent the mean ± SEM obtained in several experiments.

A critical parameter for the successful performance of these transport assays is the quality of SLO. MDCK cells are difficult to permeabilize compared to several other cell types (e.g., BHK, CHO, and L cells), and with the available commercial sources of SLO, the degree of permeabilization, as measured by LDH release, has not been satisfactory. The wild-type toxin purified from *Streptococci* and the recombinant toxin produced in *Escherichia coli* have both worked equally well.

The available amount of reagent often determines whether the preincubation during cytosol depletion is possible, as cytosol depletion must be carried out in an excess volume of buffer. The routinely used volume (750 µl per filter) can be, however, somewhat reduced. By using 500 µl per filter there is not yet a significant effect on transport efficiency, and by using 200 µl per filter cytosol depletion is compromised moderately, which increases the background, cytosol-independent transport, and results in a transport efficiency of about three-fourths of normal.

Because the transport is carried out in a leaky cellular microenvironment with diluted cytosolic components, the increase in transport obtained with exogenous cytosol is usually two- to threefold (three- to fourfold in the ER-to-Golgi assay). This is the window in which the differences in cytosol dependent transport are measured. In assays measuring transport in the late secretory pathway, part of the efficiency is lost due to retention of some viral marker early in the exocytic route. However, because both markers, HA and VSV G, are glycoproteins whose mobility on SDS–PAGE shifts according to the degree of glycosylation, careful examination of their mobilities will reveal, in apical and basolateral assays, if the test condition retarded significantly the processing of the marker to the terminally glycosylated form. This may therefore serve as an internal control for the specificity of inhibition. A more accurate way to test the effect of a reagent in the early secretory pathway is to assay the ER-to-Golgi transport. The real advantage of having established similar procedures for three different transport assays is the possibility of using them as internal controls for each other. This enables the identification of molecules that are specifically involved in either apical or basolateral transport routes and allows the discrimination between compounds that are needed only in the polarized routes versus those that are common to all three transport processes.

CHAPTER

27

Studying Exit and Surface Delivery of Post-Golgi Transport Intermediates Using *in vitro* and Live-Cell Microscopy-Based Approaches

Geri E. Kreitzer, Anne Muesch, Charles Yeaman, and Enrique Rodriguez-Boulan

I. INTRODUCTION

Study of the mechanisms of polarized protein sorting in epithelial cells has been facilitated greatly by the use of enveloped RNA viruses, such as vesicular stomatitis virus (VSV) and influenza virus, which bud from the basolateral and apical plasma membranes, respectively (Rodriguez-Boulan and Sabatini, 1978). Following infection, a rapid onset of viral protein synthesis occurs, leading to the vectorial transport of envelope glycoproteins to either the apical or the basolateral surface. This model continues to provide information on the mechanisms of protein sorting (Musch *et al*., 1996) and the basic protocols are included here. However, because cells cannot be coinfected efficiently with both types of viruses due to reciprocal inhibition of protein synthesis, a major drawback of this paradigm is the inability to study the segregation of apical and basolateral proteins from one another in the same cell.

Two alternative approaches have been developed that improve upon and greatly facilitate studying the molecular effectors of protein sorting in the *trans*-Golgi network (TGN) and polarized transport routes to the plasma membrane in epithelial cells. These approaches utilize either recombinant adenovirus vectors or intranuclear microinjection of cDNAs to introduce exogenous biosynthetic markers into cells. Both methodologies advance previous techniques in numerous ways: (i) they allow for high-level, simultaneous expression of two markers (Marmorstein *et al*., 2000); (ii) they are amenable to the use of temperature blocks, which allow for accumulation in and synchronous release of newly synthesized proteins from the TGN; (iii) neither method interferes with the ability of cells to synthesize and transport endogenous proteins, permitting the study of marker proteins in a normal cellular environment; (iv) adenoviral infection generally results in transduction of all cells in the culture and is thus ideal for metabolic labeling studies and biochemical analysis of biosynthetic events; (v) microinjection results in the rapid expression of cDNAs, providing a means by which to study anterograde membrane trafficking events selectively and dynamically in individual cells; and (vi) cDNAs or adenoviral particles can be introduced easily into a wide variety of cultured cells, making it relatively simple to compare secretory sorting pathways in different multiple cell types.

The most important advance provided by cDNA microinjection and adenoviral-mediated gene transfer in studying protein-sorting events is the ability to cointroduce two or more genes into cells and express simultaneously multiple secretory cargoes that follow divergent routes out of the TGN. This allows one to evaluate the role(s) of potential molecular effectors of protein sorting and targeting to different cellular domains. Furthermore, the level of expression of exogenous genes can be manipulated [by changing the amount of DNA introduced and the expression time allowed in microinjection-based assays or by varying

All rights reserved.

either the multiplicity of infection (moi) or the time in culture following adenoviral infection] to allow study of the ability to saturate the various sorting pathways available to the cell (Marmorstein *et al*., 2000). Adenoviral infection also results in high-level expression of reporter proteins in large cell populations, a factor essential in obtaining sufficient incorporation of radioactive amino acids for pulse–chase studies, as well as for immunoisolation of transport vesicles. (Once the adenovirus has been titrated and the infection conditions optimized, 100% of the cells express the desired proteins and remarkably consistent pools of cells are produced from experiment to experiment.) Procedures for adenoviral infection can be modified and adapted easily to a variety of different cell lines.

While cDNA microinjection is limited with respect to the number of cells that can be evaluated, it is exquisitely suited to live cell imaging studies aimed at evaluating highly dynamic membrane trafficking events occurring at specific points throughout the biosynthetic pathway (e.g., ER-to-Golgi events and Golgi-to-plasma membrane events, such as budding of Golgi membranes, transport of post-Golgi carriers, and exocytosis of post-Golgi carriers). Momentum in this area is due primarily to the advent of fluorescent tags, such as green fluorescent protein [GFP(Chalfie, 1994)] from the jellyfish *Aequorea* and dsRed from the coral *Discosoma* (Matz *et al*., 1999; Baird *et al*., 2000), which can be genetically appended to any DNA of choice. These tags serve as vital fluorescent indicators that facilitate direct observation and analysis of membrane-trafficking events in living cells.

This article describes an assay that monitors post-Golgi vesicle budding from semi-intact MDCK cells following infection either with enveloped RNA viruses or with recombinant adenovirus vectors. The adenoviruses we have found most useful for these applications encode receptors for neurotrophins ($p75^{NTR}$) and low-density lipoprotein (LDLR), which were shown previously to be sorted to the apical and basolateral surfaces of polarized MDCK cells, respectively (Le Bivic *et al*., 1991; Hunziker *et al*., 1991; Gridstaff *et al*., 1998). Each of these proteins, when expressed in MDCK cells, incorporates radiosulfate into carbohydrate moieties during posttranslational processing late in the secretory pathway, providing a convenient method to label markers in the sorting compartment.

In addition, this article describes methods we have developed pertaining to the use of time-lapse fluorescence imaging to study the transport of plasma membrane proteins through the biosynthetic pathway in living cells. While we only discuss this technique specifically with respect to MDCK epithelial cells, with slight modifications we have also successfully employed this approach for similar studies in several different cell lines. Additionally, we have found that these studies can be used with numerous reporter proteins of interest. Thus while we focus on reporters marking the apical or basolateral plasma membrane, the system is not limited to the study of membrane-associated proteins. Finally, this article discusses some quantitative measurements that can be made from this type of data related to protein-trafficking events occurring *in vivo*.

II. MATERIALS AND INSTRUMENTS

Dulbecco's modified Eagle's medium (DMEM, Cat. No. 10-013-CV), MEM nonessential amino acids (Cat. No. 25-025-CI), Hank's balanced salt solution (HBSS, Cat. No.21-023-CV), and L-glutamine (Cat. No. 25-005-CI) are from Cellgro. MEM SelectAmine kits (Cat. No. 19050), MEM vitamins (Cat. No. 11120), penicillin-streptomycin (Cat. No. 15140), 7.5% bovine serum albumin (BSA, Cat. No. 15260), and donor horse serum (Cat. No. 16050) can be purchased from Gibco-BRL (Grand Island, NY). Heat-inactivated fetal bovine serum (FBS, Cat. No. 100-106) is from Gemini Bioproducts. HEPES (Cat. No. H-4034), D-glucose (Cat. No. G-8270), and cycloheximide (Cat. No. C-7698) are from Sigma Chemicals. Polycarbonate filters (Transwells; 0.4 mm pore size, Cat. No. 3412 for 24-mm filters) can be purchased from Corning Costar Corp. (Cambridge, MA). Tissue culture grade plasticware is from Corning Plasticware. Tran^{35}S-label (Cat. No. 51006), [^{35}S]cysteine (Cat. No. 51002), and $H_2{}^{35}SO_4$ (Cat. No. 64040) can be purchased from ICN (Costa Mesa, CA). Reagents for the production of viruses are described elsewhere (Rodriguez-Boulan and Sabatini, 1978; see article by Hitt *et al*.) All other reagents are standard reagent grade and available from several sources. Sterile solutions are autoclaved or sterilized by ultrafiltration (0.2 mm).

There are numerous manufacturers of microscope heating and cooling chambers. We use the Harvard apparatus recording chamber (PDMI-2) and temperature controller (TC-202A). A variety of microinjection apparatuses are available from Narishige Inc. or from Eppendorf. Cooled charged-couple device (CCDs) cameras are also available from several manufacturers. For high-resolution time-lapse imaging, we recommend a camera capable of 12- to 16-bit digitization (4095–65,000 gray levels) with a 5- to 10-MHz controller for rapid acquisition rates. The Flaming Brown Micropipet puller (Model P-97) is from Sutter Instru-

ments. Glass capillaries for pulling microinjection needles are available from World Precision Instruments (Cat. No. 1B100F-6). The Sykes-Moore culture chamber, consisting of a 32 × 7-mm chamber (Cat. No. 1943-11111), silicone gaskets (Cat. No. 1943-33315), and the wrench assembly (Cat. No. 1943-44444) can be purchased from Bellco. Number 1 thickness, 25-mm glass coverslips for the chamber (Cat. No. 483800-80) are from VWR.

III. PROCEDURES

A. Adenovirus Transduction

1. Coinfection of MDCK Cells with Recombinant Adenovirus Vectors

Solutions

1. *Dulbecco's modified Eagle's medium (DMEM)*: Dissolve DMEM powder in 1 liter H_2O. Sterilize by filtering through a 0.2-μm pore filter.

2. *Complete DMEM (cDMEM)*: Add 50 ml heat-inactivated fetal bovine serum (FBS), 10 ml 0.2 *M* L-glutamine, 5 ml penicillin–streptomycin (10,000 U/ml and 10 mg/ml, respectively), and 5 ml MEM nonessential amino acids to 430 ml DMEM. Store at 4°C for up to 2 weeks.

Steps

1. For infection with replication-defective viruses, grow cells on semipermeable polycarbonate filter supports. Seed cells at confluency on day 1 and culture for 4 days with medium changed daily. MDCK strain II cells are confluent at a density of ca. 7×10^5 cells/cm^2, so approximately 3.3×10^6 cells should be seeded on each 24-mm filter.

2. Before applying adenovirus vectors, rinse cultures twice with serum-free DMEM (2 ml for the apical chamber and 2.5 ml for the basolateral chamber). Removal of serum proteins from the culture medium results in enhanced adsorption of adenovirus particles to the cell surface and improves infection efficiency. MDCK cells do not appear to be affected adversely by serum deprivation during the infection period, but this should be checked with other cell types before attempting infection.

3. Add recombinant adenoviruses, diluted in serum-free DMEM, at moi ranging from 1 to 1000 pfu/cell. Incubate at 37° for 1 h, gently tilting the plates every 15 min to mix. Two or more adenovirus vectors can be mixed together and applied simultaneously to cells. It is recommended that serial three-fold dilutions of viruses be tested in order to determine the optimal moi required for the quantitative expression of the marker proteins.

4. Vectors must be applied to the *apical* domain of epithelial cells, as infection is markedly more efficient from this surface. The reason for this is unclear, but a preference for adenovirus entry through the apical surface has been observed in every polarized epithelial cell type we have examined, including canine (MDCK), bovine (MDBK), and porcine (LLC-PK_1) kidney; rat thyroid (FRT) and retinal pigment epithelia (RPE-J); and human intestine (Caco-2). Serum-free DMEM, without virus, should be applied to the basolateral chamber. Infection should be performed in a minimum volume of DMEM required to keep the filter submerged. A recommended volume is 0.25 ml apical/0.5 ml basolateral for a 24-mm filter.

5. Following the infection period, add 2 ml cDMEM to both apical and basolateral chambers. It is not necessary to aspirate the virus because the addition of serum effectively terminates the infection. Culture the cells at 37°C for the desired incubation time. Expression of adenovirus-encoded proteins should be detectable by 4–6 h following infection, will rise gradually over the next 18 h and should reach a plateau by 24 h. This level of expression will be maintained for at least 1 week, provided the cells are fed daily. We routinely use cultures of polarized MDCK cells between 20 and 24 h postinfection.

6. Monitor infection after 24 h as follows:
   a. *Use indirect immunofluorescent staining* to determine (i) the percentage of cells in the culture expressing the transfected gene products and (ii) the intracellular distribution of the gene products. Under optimum infection conditions, at least 95% of the cells will express each adenovirus-encoded protein. If the ultimate goal of the experiment is the study of the molecular trafficking of two or more proteins in the same cell, it is essential that all of the cells that express one marker also express the second marker. Methods for fixation, permeabilization, and staining of epithelial cells grown on polycarbonate filters are described elsewhere in this manual.
   b. *Use immunoprecipitation or Western blotting* to determine (i) the molecular weight of the adenovirus-encoded proteins and (ii) the level of expression of the proteins in the culture. Ideally, both adenovirus-encoded proteins will be expressed at comparable levels.

Pitfalls

Each batch of adenovirus virus vector must be tested for optimum transduction. We find a batch-to-

batch variability in the correspondence of pfu obtained from plaque assays to the moi needed.

B. Infection of MDCK Cells with Enveloped RNA Viruses

Solutions

1. *DEAE-dextran (100X stock)*: Dissolve 100 mg DEAE-dextran (Sigma Cat. No. D1162) in 10 ml H_2O. Filter, sterilize, and store 1-ml aliquots at –20°C.

2. *Infection medium*: Add 13 ml 7.5% bovine serum albumin and 5 ml 1*M* HEPES, pH 7.4, to 482 ml DMEM. Filter, sterilize, and store at 4°C. Immediately before use, add 0.1 ml DEAE-dextran stock to 10 ml medium. DEAE-dextran is only necessary for infection with VSV.

3. *Virus stocks*: Vesicular stomatitis virus, Indiana strain (VSV), and influenza virus A (WSN strain) are grown in MDCK strain II cells, harvested, and plaque assayed as described by Rodriguez-Boulan and Sabatini (1978).

Steps

1. Set up 10-cm dishes of MDCK strain II cells, passages 6–20, and allow them to reach confluency. Cultures are infected with VSV or influenza virus 3 days after becoming confluent.

2. Before infecting cells, rinse cultures twice with infection medium. For viral infection, inoculate MDCK cells with 50 pfu/cell VSV or influenza WSN in 3.5 ml infection medium containing 0.1 mg/ml DEAE-dextran.

3. Incubate cultures for 1 h at 37°C.

4. Aspirate viral medium and rinse cultures twice with fresh infection medium.

5. Return VSV-infected cultures to 37°C and incubate a further 3.5 h before metabolic radiolabeling (see later). Incubate influenza WSN-infected cultures for 4.5 h at 37°C before labeling. Cultures should be examined hourly to monitor cytopathic effects.

C. Metabolic Radiolabeling and Accumulation of Marker Proteins in the Trans-Golgi Network

1. Radiosulfate Labeling of Glycoproteins at 20°C

Both $p75^{NTR}$ and LDLR are sulfated when expressed in MDCK cells. Sulfation occurs largely on asparagine-linked carbohydrate moieties on both proteins. Because this posttranslational modification occurs late in the secretory pathway, likely in the *trans*-Golgi or TGN, it provides a convenient method to label markers in the sorting compartment. When labeling is performed at the reduced temperature of 20°C, the labeled markers accumulate in the TGN because post-Golgi vesicular transport is inhibited.

Solutions

1. *Sulfate-free labeling medium*: Essentially, labeling medium is DMEM in which the $MgSO_4$ is replaced by $MgCl_2$. Combine 100 ml 10× DME salts (Ca^{2+}, Mg^{2+}-free), 10 ml 100× Ca^{2+}, Mg^{2+} stock, 10 ml MEM Vitamins, 10 ml of 100× stock MEM amino acid solutions (arginine, glutamine, histidine, isoleucine, leucine, lysine, phenylalanine, threonine, tryptophan, tyrosine, glycine, serine, and valine), 1 ml of 100× stock MEM solutions of methionine and cysteine, 10 ml MEM nonessential amino acid solution, 20 ml 1*M* HEPES, pH 7.4, 27 ml 7.5% BSA stock, and H_2O to a final volume of 1000 ml. Filter, sterilize, and store at 4°C.

2. *10× DME salts (Ca^{2+}, Mg^{2+}-free)*: Combine 50 ml 100 × $Fe(NO_3)_3$, 50 ml 100× NaH_2PO_4, 50 ml 100 × KCl, 22.5 g dextrose, 32 g NaCl, and 15 ml phenol red solution. Adjust volume to 500 ml with H_2O. Filter, sterilize, and store at 4°C.

3. *$Fe(NO_3)_3$ stocks*: Add 0.05 g $Fe(NO_3)_3$ to 50 ml H_2O to prepare a 100,000× stock solution. Dilute 100 µl into 100 ml H_2O to prepare 100× stock solution. Filter, sterilize, and store at 4°C.

4. *100× $Na\ H_2PO_4$*: Add 1.25 g NaH_2PO_4 to 100 ml H_2O. Filter, sterilize, and store at 4°C.

5. *100× KCl*: Add 4.0 g KCl to 100 ml H_2O. Filter, sterilize, and store at 4°C.

6. *100× Ca^{2+}, Mg^{2+}*: Add 2.96 g $CaCl_2{\cdot}2H_2O$ and 3.02 g $MgCl_2{\cdot}6H_2O$ to 100 ml H_2O. Filter, sterilize, and store at 4°C.

Steps

1. Twenty-four to 48 h following adenovirus infection, aspirate culture medium and rinse filters three times with sulfate-free labeling medium. Sulfate starve cells for 30 min at 37°C in this medium.

2. Label cells for 1 h at 20°C in sulfate-free labeling medium containing $H_2{}^{35}SO_4$. To label cells on one 75 mm Transwell filter, we use 0.5 mCi $H_2{}^{35}SO_4$ in 500 µl sulfate-free labeling medium. Place medium, preequilibrated at 20°C, on a sheet of Parafilm in a humid chamber and place the Transwell filter upon this so that label is exposed to the basolateral surface. Apply 2.5 ml sulfate-free labeling medium, without label, to the apical chamber to prevent drying.

2. Pulse–Chase Labeling with [^{35}S]Methionine/Cysteine

Solutions

1. *Methionine/cysteine-free labeling medium*: Prepare 1000 ml of medium following the product specification insert (Gibco SelectAmine kit, Cat. No. 19050), exclud-

ing the methionine and cysteine in the kit. Add 10 ml 1 *M* HEPES and 27 ml 7.5% BSA stock solution. Filter, sterilize, and store at 4°C.

For PC12 cells, replace the BSA will 20 ml dialyzed serum. To prepare the dialyzed serum, under sterile conditions, dialyze a mixture of two-thirds fetal bovine serum and one-third horse serum against PBS in 12,000 molecular weight cutoff dialysis tubing for 12–20 h. Dialyze serum to remove small molecules, which may be used to scavenge sulfate.

2. *Chase medium*: Add 5 ml of 100× MEM methionine and cysteine (left over from the Selectamine kit) solutions to 40 ml complete DMEM (or PC12 growth medium for PC12 cells). Immediately before use, add cyclohexamide to a concentration of 20 µg/ml.

Steps

1. Rinse MDCK cultures three times in methionine/cysteine-free labeling medium before incubation at 37°C for the final 30 min of incubation following viral infection. For PC12 cells, extensive rinsing may not be possible, so rinse once before the 30-min incubation.

2. Label VSV-infected MDCK cells with [^{35}S]methionine/cysteine (Tran^{35}S-label, ICN Cat. No. 51006). Label influenza WSN-infected cells with [^{35}S]cysteine (ICN Cat. No. 51002). Use 0.5 mCi, in a total volume of 3.5 ml labeling medium, to label each 10-cm plate. Pulse–label cells for 10 min at 37°C. Medium can be recycled twice if multiple dishes are to be labeled. Label LDLR- and p75-infected PC12 cells with [^{35}S]cysteine, due to the fact that these proteins are not sulfated as they are in MDCK cells. Use 0.5 mCi, in a total volume of 1 ml labeling medium, to label each 10-cm plate. Pulse–label cells for 15 min at 37°C, with gentle rocking every 5 min.

3. For MDCK cells, aspirate labeling medium and rinse plates three times with chase medium. For PC12 cultures, just aspirate medium.

4. Chase cultures at 20°C for 2 h in chase medium. During the chase at 20°C, roughly 60% of the labeled VSV G/influenza HA proteins are accumulated in the TGN (Muesch *et al*., 1996).

D. Vesicle Budding from the TGN in Semi-intact Cells

Semi-intact MDCK cells are prepared after accumulating marker proteins in the TGN (Muesch *et al*., 1996). Cells are first swollen in a low salt buffer and are subsequently scraped from the substratum, which produces large tears in the plasma membrane. Endogenous cytosol and peripheral membrane proteins are removed by washing with a high salt buffer. Addition of an exogenous source of cytosol, an energy-regenerating system, and incubation at 37°C typically result in the release of 25–65% of the total marker accumulated in the TGN into sealed vesicles. Budded vesicles are separated from the material that remains by a brief, low-speed centrifugation step.

Solutions

1. *Swelling buffer*: Add 7.5 ml 1 *M* HEPES/KOH, pH 7.2, and 7.5 ml 1 *M* KCl to 485 ml H_2O. Store at 4°C.

2. *10× transport buffer*: Add 20 ml 1 *M* HEPES/KOH, pH 7.2, 2 ml 1 *M* $Mg(OAc)_2$, and 18 ml 5 *M* KOAc to 60 ml H_2O. Store at 4°C.

3. *1× transport buffer*: Add 1 ml 10× transport buffer to 9 ml H_2O. Immediately before use, bring to 1 m*M* DTT and add protease inhibitors to 1× concentration.

4. *High salt buffer*: Add 10 ml 1 *M* HEPES/KOH, pH 7.2, 50 ml 5 *M* KOAc, and 1 ml 1 *M* $Mg(OAc)_2$ to 4391 ml H_2O. Store at 4°C. Immediately before use, bring to 1 m*M* DTT and add protease inhibitors to 1X concentration.

5. *1 M dithiothreitol stock*

6. *500× protease inhibitor stock*: Dissolve 5 mg of each of the following inhibitors individually in 330 µl dimethyl sulfoxide (DMSO) and combine the three solutions.
   a. *Pepstatin A*: (Sigma Cat. No. P-4265)
   b. *Leupeptin*: (Sigma Cat. No. L-8511)
   c. *Antipain*: (Sigma Cat. No. A-6191)

7. *100 mM PMSF stock*

8. *Energy mix*: Pipette in the following order: 3 µl ATP, 2 µl GTP, 4 µl creatine phosphate, and 3 µl creatine kinase.
   a. *0.1 M ATP* (Boehringer Mannheim Cat. No. 519 987)
   b. *0.2 M GTP* (Boehringer Mannheim Cat. No. 106 399)
   c. *0.6 M creatine phosphate* (Boehringer Mannheim Cat. No. 621 722)
   d. *8 mg/ml creatine kinase* (Boehringer Mannheim Cat. No. 127 566)

9. *Bovine brain cytosol*: Prepare gel-filtered bovine brain cytosol in batches exactly as described previously (Malhotra *et al*., 1989). The protein concentration should be 10–20 mg/ml. Snap freeze 50-µl aliquots in liquid nitrogen and store at –80°C.

Steps

All steps are performed on ice, unless otherwise specified.

1. Following the 20°C incubation, wash the monolayer twice briefly with ice-cold swelling buffer and incubate in the same for 15 min.

2. Scrape cells from the filter (or plastic dish) with a rubber policeman into 2.5 ml transport buffer. DiSPo scrapers (Baxter Scientific, McGaw Park, IL) work well for this purpose. The best way to scrape cells from the Transwell filter is to place the filter inside the lid of the dish so that the bottom lies flat against the plastic. This prevents the scraper from poking through the filter, but care must be exercised to prevent tearing the filter. Scraping does not have to be vigorous, but should be done with long, gentle strokes. Transfer cells to 1.5-ml microfuge tubes and rinse the filter (or dish) with 2.5 ml fresh transport buffer. Combine with cells from first scraping. Discard the filter as radioactive waste.

3. Pellet cells by centrifugation at 800 *g* for 5 min in a refrigerated microfuge.

4. Pool semi-intact cells into one tube and wash with 1.5 ml high salt buffer on ice for 10 min. Pellet cells by centrifugation at 800 *g* for 5 min in a refrigerated microfuge.

5. Resuspend cells in transport buffer. A volume of 250 µl is used to resuspend cells from one filter (or dish).

6. Set up vesicle budding assay.
   a. In standard assays, suspend semi-intact cells (ca. 10 µl = 20–25 µg protein) in an assay volume of 50 µl transport buffer supplemented with 50 µg gel-filtered bovine brain cytosol and an energy-regenerating system (1 m*M* ATP, 1 m*M* GTP, 5 m*M* creatine phosphate, and 0.2 IU creatine kinase). Combine components in the following order: mix 26 µl H_2O, 1 µl 100 m*M* PMSF, 4 µl 10× transport buffer, 4 µl energy mix, 5 µl cytosol (final concentration = 1 mg/ml), and 10 µl semi-intact cells.
   b. Important controls include assays in which either the cytosol or the energy mix or both components are omitted. For the complete depletion of energy from the system, cytosol and semi-intact cells must be preincubated for 10 min on ice with 0.6 U/ml apyrase before assembling the assay. In the absence of either cytosol or energy, vesicular release from semi-intact cells should be negligible. We suggest that serial dilutions of cytosol (i.e., 0.1–10 mg/ml) be tested in order to determine the optimal range of cytosol-dependent vesicle budding in the assay.

7. Incubate assays at 37°C for desired time. In standard assays, we incubate for 30–45 min. However, we suggest that a time course of vesicle budding be performed to optimize the assay for different marker proteins. As additional controls, two complete assays should be assembled and incubated at 0 and 20°C. At these reduced temperatures, vesicular release from semi-intact cells should be insignificant.

8. Pellet semi-intact cells by centrifugation at 800 *g* for 5 min in a refrigerated microfuge. Transfer supernatant fractions to clean microfuge tubes. The pellets (containing nonbudded material remaining in the TGN) and supernatants (containing the vesicles released during the 37°C incubation) can be analyzed further.
   a. To quantify the efficiency of vesicular release of each marker under different conditions, samples can be lysed in SDS–PAGE sample buffer and analyzed directly by PAGE. In cells infected with VSV or influenza WSN, the viral proteins should be the only labeled proteins in the lysates. Alternatively, following adenovirus-mediated transfer of cDNAs encoding $p75^{NTR}$ and LDLR into MDCK cells, these proteins are by far the most heavily labeled proteins when radiosulfate is used as a precursor.
   b. To confirm that markers are present inside sealed vesicles, the supernatant fraction should be treated with either proteinase K or trypsin. In the absence of Triton X-100, only the cytoplasmic domains of the proteins will be cleaved and this can be detected as a relatively small mobility increase during SDS–PAGE. In contrast, protease treatment in the presence of 1% Triton X-100 will result in complete digestion of markers. Use three 50-µl assay samples for this analysis. To tube 1, add nothing. To tube 2, add 2.5 µl protease (10 mg/ml stock → 0.5 mg/ml final). To tube 3, add 2.5 µl protease and 2.5 µl 20% Triton X-100. Incubate on ice for 30 min. Inactivate protease with 1 mM PMSF or 1 mg/ml soybean trypsin inhibitor before lysing samples in SDS–PAGE sample buffer. Analyze products by SDS–PAGE.
   c. Immunoisolation of specific classes of transport vesicles is performed using antibodies against the cytoplasmic portions of cargo proteins as well as appropriate negative controls. (i) Use 5 mg protein A-Sepharose (Pharmacia, Piscataway, NJ; Cat. No. 17-0780-01) for each immunoisolation. Swell in transport buffer for 10 min. (ii) If using a murine monoclonal primary antibody, use a bridge. Incubate 5 mg protein A–Sepharose with 50 µg rabbit anti-mouse IgG (Rockland Labs, supplied by VWR, New York, Cat. No. 610-4102) in 1 ml transport buffer for 60 min at room temperature. Wash twice with transport buffer. (iii) Block nonspecific binding sites in 1 ml trans-

port buffer containing 0.2% BSA for 60 min at room temperature. (iv) Couple primary antibody for 2 h at room temperature in transport buffer. Wash twice with transport buffer. Titrate each antibody to determine amount needed for quantitative recovery of vesicles. (v) Incubate immunoadsorbant with the supernatant fraction from the vesicle budding assay in a total volume of 1 ml transport buffer for 2–18 h at 4°C with end-over-end rotation. In some cases, vesicle coat proteins may mask epitopes on the cytoplasmic tails of cargo. Therefore, it may be necessary to wash the vesicles in high salt buffer prior to immunoisolation to strip coat proteins. Add 33 µl of 1 *M* KOAc to 50-µl vesicles. Incubate on ice for 10 min. Add 333 µl salt-free transport buffer [20 m*M* HEPES/KOH, 2 mM $Mg(OAc)_2$]. (vi) Wash immunoprecipitates six times with transport buffer. Elute bound markers by boiling 5 min in SDS–PAGE sample buffer. Analyze by SDS–PAGE.

E. Vesicle Budding from TGN-Enriched Membranes

A TGN-enriched membrane fraction is prepared from metabolically labeled PC12 cells after marker proteins have been accumulated in the TGN. Initially, a postnuclear supernatant is prepared following the method of Tooze and Huttner (1992). From the postnuclear supernatant a TGN-enriched membrane fraction is prepared (Xu *et al.*, 1995). As with semi-intact MDCK cells, addition of an exogenous source of cytosol and an energy-regenerating system leads to the release of accumulated marker protein from the TGN in sealed vesicles. All steps for the vesicle budding assay are identical to those for intact MDCK cells except that 50-µg aliquots of TGN-enriched membranes are used for each individual assay condition.

F. Expression of cDNA Using Microinjection

Solutions

1. *Preparation of cDNA stocks for microinjection*: Prepare DNA using either a midi or maxi preparation, making sure to suspend the DNA pellet (final concentration of at least 0.2 mg/ml) in sterile water rather than Tris–EDTA. DNA stocks can be stored at either 4 or –20°C.

2. *HEPEs:KCl microinjection buffer*: 10 m*M* HEPES, 140 m*M* KCl, pH 7.4

3. *cDNA for microinjection*: Dilute cDNA stock in HKCl to a final concentration of 5–20 µg/ml (see later for how to choose a concentration)

4. *MDCK cell culture medium*: DMEM prepared as per manufacturer's instructions. Add 50 ml FBS (10% FBS final concentration) and 10 ml of 1 *M* HEPES, pH 7.4 (20 m*M* final concentration), and 5 ml of MEM nonessential amino acids to 435 ml DMEM.

Steps

For microinjection, cells must be cultured on sterilized glass coverslips.

1. Sterilize coverslips using either of the following methods.
   a. ***Autoclaving:*** Place coverslips in a glass petri dish and autoclave on the dry cycle for 20 min. If cells adhere well to the glass, this method is most convenient, as many coverslips can be sterilized at once.
   b. ***Acid washing:*** Place coverslips in histology staining racks. Wash coverslips in a beaker of 2 *N* hydrochloric acid (2× 5-min washes), rinse in distilled water (2 × 5-min rinses), and wash in 100% ethanol (3 × 2 min). After the final ethanol wash, place the staining racks containing the cleaned coverslips into a dry beaker, cover with heavy-duty foil, and bake at 250°C for 1 h. Acid treatment "etches" the glass, creating a somewhat rough surface that is useful if cells are not sufficiently adherent on the coverslips.
2. Place the sterilized coverslips into a 10-cm tissue culture dish. Seven 25-mm coverslips can be placed in one 10-cm dish.
3. Trypsinize cells and seed onto coverslips placed previously in the 10-cm culture dish(es).
   a. ***For experiments in nonpolarized cells:*** Seed 5×10^5 cells onto coverslips. Use a cell stock that is actively dividing (i.e., sparse cells). Cells should be used between 36 and 48 h after they are seeded onto the coverslips. Do not use the cells prior to 36 h postplating.
   b. ***For experiments in polarized cells:*** Seed cells at confluency onto coverslips. Change the medium 24 h after plating and culture the cells another 2–4 days prior to use. Do not change the culture medium again as this can result in changes in cell morphology.
4. On the day of the experiment, transfer coverslips to 3.5-cm culture dishes. Add fresh medium and microinject the cDNA into cell nuclei. As one goal of these experiments is to achieve synchronized exogenous protein expression in a population of cells it is

important that you only inject cells on the same coverslip for ~5 min. If a sufficient number of cells was not injected in that time, take another coverslip from the incubator and repeat.

5. After injection, place cells into the incubator and wait for protein to be expressed.

6. Monitor and identify the minimum expression time.[1] We routinely find that 1 h is sufficient for the expression of many different cDNAs in both nonpolarized and polarized MDCK cells. However, we have also found that there is heterogeneity in expression time depending on the cDNA being injected, as well as on the cell types being used. Minimum expression time can be determined by merely looking at the injected cells at a series of time points (e.g., 1-h intervals) after microinjection. Fluorescently tagged reporter proteins can be visualized directly without fixation. If your reporter is not fluorescently tagged, then fix the cells at 1-h intervals after microinjection and immunostain with antibodies against the exogenous protein.

G. Synchronizing Transport through the Biosynthetic Pathway

Solutions

1. *Bicarbonate-free MDCK cell culture medium*: DMEM without bicarbonate prepared as per manufacturer instructions. Add 25 ml FBS (5% FBS final concentration), 10 ml of 1 *M* HEPES, pH 7.4 (20 m*M* final concentration), and cycloheximide (final concentration 100 µg/ml) to 475 ml DMEM.

2. *Recording medium*: Hank's balanced salt solution with calcium and magnesium (HBSS-CM). Add 5 ml FBS (1% FBS final concentration; serum does autofluoresce so it is important to keep the concentration low), 25 ml of 9% D-glucose (4.5 g/liter glucose final concentration), 5 ml HEPES, pH 7.4 (10 m*M* HEPES final concentration), and cycloheximide (final concentration 100 µg/ml) to 465 ml HBSS-CM.

Steps

Synchronization of protein trafficking can be achieved through the use of a series of temperature shifts. Cycloheximide added during the temperature shifts will effectively create a pulse of newly synthesized protein that can be chased synchronously from ER to Golgi and from the Golgi to the plasma membrane. Newly synthesized protein can be accumulated in the ER or the Golgi when cells are incubated at 15 or 20°C, respectively. These proteins will leave the Golgi when cells are shifted to the permissive temperature for secretion, (30–37°C). Because most laboratories do not maintain a tissue culture incubator set to 15 or 20°C (our laboratory uses a small refrigerator set to the desired temperature), you will need to use a bicarbonate-free medium during these incubation periods. Check that this medium remains between pH 7.2 and 7.4 during the course of the temperature blocks.

One hour after microinjection (or the minimum expression time for your protein of interest, see earlier discussion), place cells into bicarbonate-free medium with cycloheximide.

1. To study ER to Golgi events, place cells into recording medium and incubate at 15°C in the thermally regulated recording chamber mounted on a microscope for time-lapse imaging. (For a more extensive discussion on equipping an imaging work station, see Mikhailov).
   a. Monitor the total cellular fluorescence by acquiring images of your cells at 10-min intervals. When total cellular fluorescence stabilizes for ~10 min, acquire and save both transmitted light and fluorescent images of the cells you will be studying.
   b. Increase the temperature of the recording chamber to 20°C. Wait 5 min for the temperature and focus to stabilize.
   c. Acquire time-lapse images to evaluate ER to Golgi transport events. ER to Golgi transport can be studied at either low or high spatial and temporal resolution depending on the questions being addressed.

2. To study Golgi to plasma membrane events, place cells into bicarbonate-free medium and incubate at 20°C.
   a. Determine the time required to accumulate newly synthesized protein in the Golgi. We routinely find that 1–3 h is sufficient, but this time varies from protein to protein. The extent to which new protein has accumulated in the Golgi can be determined by assessing the degree of colocalization with Golgi markers at a series of time points (e.g., 30-min intervals) after shifting to 20°C.
   b. After accumulating protein in the Golgi in a 20°C incubator, place cells into recording medium and incubate at 20°C in the recording chamber mounted on a microscope for time-

[1] The minimum expression time is the time at which exogenous, newly expressed protein is present in the endoplasmic reticulum, but is not yet found at the plasma membrane. It is critical that no exogenous protein is at the cell surface for studies of Golgi to plasma membrane trafficking.

lapse imaging. Acquire and save both transmitted light and fluorescent images of the cells you will be studying.

c. Increase the temperature of the recording chamber to 32°C. Wait 5 min for the temperature and focus to stabilize.

d. Acquire time-lapse images to evaluate post-Golgi transport events. Post-Golgi transport can be studied at either low or high spatial and temporal resolution depending on the questions being addressed.

e. At the end of every time-lapse recording, save a transmitted light image of the cells from which you recorded data.

H. Kinetics of Protein Transport through the Secretory Pathway

Steps

To determine the rates at which a fluorescent protein moves from the ER to the Golgi and then to the plasma membrane using time-lapse fluorescence microscopy, it is necessary to introduce a pulse of fluorescence into individual cells. We find that microinjection of cDNA is best for this purpose, as the expression of injected cDNA is generally rapid and can be controlled temporally. The kinetics of ER-to-Golgi and Golgi-to-plasma membrane cargo transport can be determined by measuring the ratio of Golgi-associated fluorescence/total fluorescence over time. It is imperative to be able to distinguish Golgi-associated from non-Golgi-associated fluorescent signals. This can be done in two ways. First, you can coexpress a fluorescently tagged Golgi resident protein to use as a reference during time-lapse recordings. Alternatively, you can make an educated deduction as to whether your reporter is in the Golgi based on its localization and the intensity of its fluorescent signal (supplemental data in Kreitzer *et al.*, 2000). Using this differential in position and intensity, you can define a threshold above, which includes Golgi-associated fluorescence, and below, which includes all other cellular fluorescence. Given that you are trying to account for fluorescence present in the entire cell, these assays are best executed using low-magnification objectives capable of imaging an entire cell in a single focal plane.

One hour after microinjection (or the minimum expression time for your protein of interest, see earlier discussion), place cells into bicarbonate-free medium with cycloheximide and incubate at 20°C to accumulate newly synthesized protein in the Golgi.

1. To evaluate ER to Golgi transport kinetics, mount the coverslip into the precooled (20°C) recording chamber on the microscope in recording medium with cycloheximide.

   a. Acquire time-lapse images at 5- to 30-min intervals until the fluorescently tagged reporter has accumulated in the Golgi.

   b. Determine the minimum time required for maximal transport of protein from the ER to the Golgi by measuring the ratio of Golgi-associated fluorescence/total fluorescence over time.

2. To evaluate kinetics of Golgi emptying, place cells into bicarbonate-free DMEM with cycloheximide and incubate at 20°C. The duration of the 20°C temperature block depends on the time it takes to accumulate maximally your protein of interest in the Golgi (see earlier discussion).

   a. Acquire time-lapse images at 5- to 30-min intervals.

   b. Determine the rate at which fluorescently tagged cargo empties from the Golgi by measuring the ratio of Golgi-associated fluorescence/total fluorescence over time in individual cells.

I. Measuring Delivery of Post-Golgi Carriers to the Plasma Membrane

Solutions and Materials

1. Phosphate-buffered saline with calcium and magnesium (PBS-CM)

2. 2% paraformaldehyde prepared freshly in PBS-CM

3. Antibodies reactive with an extracellular epitope contained in the plasma membrane reporter protein. Surface immunolabeling is dependent on having an antibody that recognizes an extracellular epitope on the plasma membrane protein being studied. If this is not available, it may be desirable to create a cDNA probe that contains an epitope tag (e.g., HA, myc or FLAG tag) that can be immunostained.

Steps

Delivery of newly synthesized proteins to the plasma membrane can be evaluated using single cell assays or by biochemical methods. Evaluation of protein delivery to the plasma membrane in single cells can be analyzed from either fixed or living samples. Analysis in fixed samples involves cell surface selective immunolabeling of the expressed reporter protein. Analysis in living samples requires a relatively robust expression of the GFP-tagged reporter protein and acquisition of time-lapse images at relatively high frame rates using either total inter-

nal reflection fluorescence microscopy or spinning disk confocal microscopy. In TIR-FM, membrane-bound transport intermediates containing GFP-tagged fusion proteins are detected only when they move into an evanescent field, which in our experiments was within ~120 nm of the plasma membrane domain in contact with the substratum, i.e., the basal membrane. Schmoranzer and colleagues (2000) have established a quantitative method for detecting *bona fide* fusion of post-Golgi transport intermediates with the plasma membrane. Briefly, exocytic events are defined by a simultaneous rise in both the carrier's total fluorescence intensity and the area occupied by carrier fluorescence as it flattens into the plasma membrane and the cargo diffuses laterally. (For a more extensive description of TIR-FM in studying exocytosis, see Mikhailov). Exocytic events occurring in the lateral membrane of polarized epithelial cells can be identified using similar criteria when time-lapse images are acquired by high-speed confocal microscopy (for a complete description of lateral membrane fusion analysis, see Kreitzer *et al.*, 2003). Biochemical methods for studying delivery to the plasma membrane in a large population of cells, such as pulse–chase, cell surface biotinylation assays, have been described in detail previously (see article by Rodriguez–Boulan *et al.*).

1. Measuring the rate of protein delivery to the cell surface in fixed cell, "time-lapse" experiments. If cells are grown on glass (as would be the case if exogenous proteins are expressed by cDNA microinjection), this method is useful in evaluating the delivery of proteins to the apical membrane only. For surface-labeling analysis of delivery to the basolateral membrane, cells must be grown on semipermeable filter supports and exogenous proteins must be introduced by transfection or viral infection methods.
    a. Microinject GFP-tagged cDNA into the cell nuclei.
    b. Accumulate newly synthesized protein in the Golgi at 20°C.
    c. Shift to the permissive temperature for transport out of the Golgi (37°C).
    d. At 15- to 30-min intervals after releasing the Golgi block, fix cells in paraformaldehyde for 5 min at room temperature. Do not permeabilize with detergent. Fixation in a nonpermeabilizing fixative, such as paraformaldehyde, enables selective immunolabeling of surface-associated proteins.
    e. Label, by indirect immunofluorescence, the surface-associated reporter protein. Make sure to use a fluorescently conjugated secondary antibody other than fluorescein (or any dye excitable at 488 nm).
    f. Acquire images of both the surface-associated (immunostained) and the total (GFP) protein expressed at each time point after release of the Golgi block. It is imperative to use identical acquisition settings for the individual fluorophores in each time-lapse sample as this is all that allows you to quantitatively (ratiometrically) evaluate the relative amount of reporter protein delivered to the cell surface.
    g. Calculate the integrated fluorescence intensity of both surface-associated and total fluorescence in each cell expressing the reporter protein. The ratio of surface fluorescence (immunostained) to total fluorescence (GFP) of your reporter reflects the relative amount of protein that has been delivered to the plasma membrane at each time point. Over time, this ratio should increase and will directly reflect the rate of protein delivery from the Golgi to the plasma membrane.
2. Analysis of exocytosis using time-lapse total internal reflection fluorescence microscopy (TIR-FM).
    a. Microinject GFP-tagged cDNA into the cell nuclei.
    b. Accumulate newly synthesized protein in the Golgi at 20°C.
    c. Mount coverslip in the recording chamber on a microscope equipped for TIR-FM. Acquire and save both bright-field and epifluorescent images of the cells you will be studying.
    d. Shift to the permissive temperature for transport out of the Golgi and wait 5 min for the temperature and focus to stabilize.
    e. Acquire time-lapse images (aim for at least four to five frames per second) to visualize exocytic events occurring in the basal plasma membrane. The typical duration of our recordings is 1–2 min.
    f. Analyze images for exocytic events as described in Schmoranzer *et al.* (2000).
3. Analysis of exocytosis using time-lapse, spinning-disk confocal microscopy.
    a. Microinject GFP-tagged cDNA into the cell nuclei.
    b. Accumulate newly synthesized protein in the Golgi at 20°C.
    c. Mount coverslip in the recording chamber on a microscope equipped with a spinning disk confocal head. Acquire and save both bright-field and epifluorescent images of the cells you will be studying.

d. Shift to the permissive temperature for transport out of the Golgi and wait 5 min for the temperature and focus to stabilize.
e. Acquire time-lapse images (aim for four to five frames per second) to visualize exocytic events occurring along the lateral membrane. Photobleaching that occurs during confocal image acquisition typically limits the duration of time-lapse sequences to ~1–2 min.
f. To evaluate the spatial positioning of cargo delivery events, acquire time-lapse sequences as described in **step e** at multiple Z-axis positions throughout individual cells.
g. Analyze images for exocytic events as described in Kreitzer *et al.* (2003).

Assays Measuring Membrane Transport in the Endocytic Pathway

Linda J. Robinson and Jean Gruenberg

I. INTRODUCTION

Significant progress has been made in understanding mechanisms regulating endocytic membrane traffic using cell-free assays (Braell, 1987; Davey *et al*., 1985; Diaz *et al*., 1988; Gruenberg and Howell, 1986; Woodman and Warren, 1988) (see Fig. 1). Both early and late endosomes exhibit homotypic fusion properties *in vitro*, as *in vivo*, yet they do not fuse with each other (Aniento *et al*., 1993). Transport from early to late endosomes is achieved by multivesicular intermediates termed endosomal carrier vesicles (ECV/MVB), which are presumably translocated on microtubules between the two compartments (Aniento *et al*., 1996; Bomsel *et al*., 1990; Gruenberg *et al*., 1989). The vectorial or heterotypic interactions of ECV/MVBs with late endosomes have also been reconstituted *in vitro*, as has the involvement of microtubules and motor proteins in this process (Aniento *et al*., 1993; Bomsel *et al*., 1990). By reducing the components in these *in vitro* assays to a cytosol source, an ATP-regenerating system, salts, and the purified endosomal membranes, the specificity of endosomal fusion events has been addressed, and the molecules and mechanisms involved have been studied. In fact, a number of conserved molecules, as well as molecules specific for different steps of the endocytic pathway, have been identified and/or characterized using cell-free assays such as those described in this protocol (for review, see Gruenberg and Maxfield, 1995).

This assay for endocytic vesicle fusion is based on the formation of a complex resulting from a reaction between two products present in separate populations of endosomes: avidin and biotinylated horseradish peroxidase (bHRP). These reaction products can be internalized into endosomes by fluid phase or receptor-mediated endocytosis *in vivo*. Avidin and a biotinylated compound are used to provide a fusion-specific reaction because of the high binding affinity and low dissociation constant of avidin for biotin. Following internalization, cells are homogenized and purified endosomal fractions are prepared, which are combined in the assay together with cytosol and ATP. If fusion occurs, a complex is formed between avidin and bHRP. At the end of the assay, the reaction mixture is extracted in detergents in the presence of excess biotinylated insulin as a quenching agent. The avidin–bHRP complex is then detected by immunoprecipitation with antiavidin antibodies, and the enzymatic activity of the bHRP associated with the immunoprecipitate is quantified. This article describes techniques for the preparation and partial purification of three different loaded endosomal fractions from BHK cells: early endosomes, endosomal carrier vesicles, and late endosomes. In addition, this article describes the preparation of the cytosol source used, as well as the techniques for the fusion assays themselves.

II. MATERIAL AND INSTRUMENTATION

Standard laboratory rockers for washing cells and a large 37°C water bath, which can fit a metal plate of dimensions of 20 × 33 cm, are used. Large rectangular ice buckets (Cat. No. 1-6030), from NeoLab GmbH, can also accommodate metal plates of the same dimensions. Cell scrapers (flexible rubber policemen) with a silicone rubber piece of about 2 cm, cut at a sharp

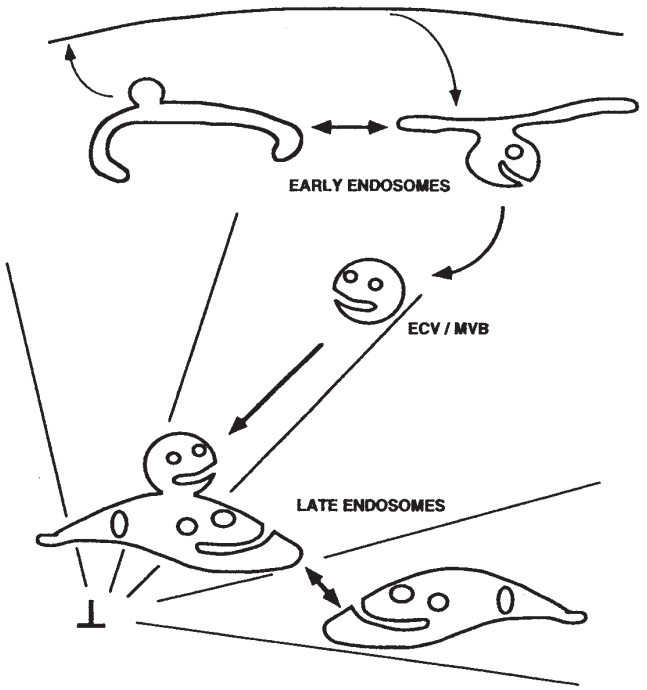

FIGURE 1 Membrane trafficking in the endocytic pathway. The reconstituted steps of the endocytic pathway described in this protocol are the (a) fusion of early endosomes with each other, (b) fusion of ECV/MVBs with late endosomes, and (c) fusion of late endosomes with each other. An *in vitro* budding assay for the formation of ECV/MVBs from early endosomes, which are competent to fuse with late endosomes, is described in Aniento *et al.* (1996). As shown, ECV/MVBs are transported along microtubules from early to late endosomes. If microtubules are depolymerized *in vivo*, prior to the loading of cells with an endocytic tracer, this tracer will accumulate in ECW/MVBs. These vesicles will then fuse with late endosomes, loaded with a different marker, *in vitro*.

angle, and attached to a metal bar, are made. A standard low-speed cell centrifuge and Beckman ultracentrifuges and rotors are used. The refractometer (Cat. No. 79729) is from Carl Zeiss Inc., and the pump for collecting sucrose gradients (peristaltic pump P-l) is from Pharmacia Fine Chemicals. A rotating wheel (such as Snijders Model 34528) with a speed of about 10 rotations per minute should be used. All tissue culture reagents, including modified Eagle's medium (MEM), are from either Sigma Chemical Company or GIBCO-BRL/Life Technologies. Peroxidase from horseradish (HRP) (Cat. No. P-8250), ATP (disodium salt, Cat. No. A-5394), and deuterium oxide (D_2O, Cat. No. D-4501) are from Sigma Chemical Company, Ltd. Biotinyl-ε-aminocaproic acid *N*-hydroxysuccinimide ester (biotin-X-NHS, Cat. No. 203188) is from Calbiochem. Avidin (egg white, Cat. No. A-887) is from Molecular Probes. Creatine phosphate (Cat. No. 621714), creatine phosphokinase (Cat. No. 127566), and hexokinase [$(NH_4)_2SO_4$ precipitate of yeast hexokinase, 1400 U/ml, Cat. No. 1426362] are from Boehringer-Mannheim GmbH. Protein A–Sepharose beads (Cat. No. CL-4B) are from Pharmacia. Antiavidin antibodies are generated by injecting purified avidin into rabbits and are affinity purified prior to use. Antiavidin antibodies are also available commercially from several companies. BCA protein assay reagents (Cat. No. 23223) are from Pierce, and Bio-Rad protein assay reagents (Cat. No. 500-0006) are from Bio-Rad Laboratories GmbH.

III. PROCEDURES

A. Internalization of Endocytic Markers into Early Endosomes (EE) from BHK Cells

Solutions

1. *Internalization media (IM)*: MEM containing 10 *mM* HEPES and 5 m*M* D-glucose, pH 7.4. Filter sterilize and store at 4°C.
2. *Phosphate-buffered saline (PBS)*: 137 m*M* NaCI, 2.7 m*M* KCL, 1.5 m*M* KH_2PO_4, and 6.5 m*M* Na_2HPO_4; should be pH 7.4. Filter sterilize and store at 4°C.
3. *Biotinylated horseradish peroxidase*: Dissolve 20 mg of HRP in 9.5 ml of 0.1 *M* NaHCO3/Na_2CO_3, pH 9.0, buffer (make fresh and check pH carefully) in a small glass Erlenmeyer flask. Dissolve 20 mg of biotin-X-NHS in 0.5 ml dirnethylformamide. Mix by adding the biotin dropwise to the HRP mixture while gently stirring or shaking the Erlenmeyer and incubate at room temperature with gentle stirring for at least 45 min (a 50:1 molar excess of biotin is important). Quench unreacted active groups with 1 ml of 0.2 *M* glycine, pH 8.0 (use KOH to pH), by adding dropwise while mixing, and mix for an additional 15 min at room temperature. Transfer to 4°C. Dialyze the mixture extensively against PBS—or IM at 4°C (at least four changes of 200 ml each time). The final dialysis should be in IM. Measure protein concentration (should be about 2 ml/ml) and HRP enzymatic activity (should be unchanged). Aliquot in sterile tubes, freeze in liquid N_2, and store at –20°C until use. Immediately before use, thaw quickly and warm to 37°C.
4. *Avidin*: Avidin powder dissolved in IM at 3 mg/ml. Make fresh immediately before use and warm to 37°C.
5. *PBS/BSA*: 5 mg/ml BSA in PBS-. Make fresh before use and cool to 4°C.

Steps

1. *Cell culture*: Maintain monolayers of baby hamster kidney (BHK-21) cells as described in Gruenberg *et al.*

(1989). For a fusion assay of 5–10 points, eight petri dishes (10 cm diameter) should be prepared 16 h before the experiment: four for preparing bHRP-labeled EEs and four for preparing avidin-labeled EEs.

2. *Fluid-phase internalization*: Wash each 10-cm dish of cells twice with 5 ml ice-cold PBS—on ice. This and other washes on ice to follow are performed most easily by placing four dishes onto a metal plate in a large ice bucket on a rocker. After the last wash, remove PBS and place the dish on a metal plate in a 37°C water bath. Add at least 3 ml/dish bHRP or avidin solution prewarmed to 37°C. Incubate for 5 min.

3. *Washes*: From now on, all work should be done at 4°C or on ice. Return the dishes to the metal plate in the ice bucket. Remove the avidin or bHRP solution and wash dishes three times for 5 min with 5 ml ice-cold PBS/BSA followed by 2 × 5 min with 5 ml ice-cold PBS.

4. *Homogenization and fractionation*: Go directly to Section IIIC.

B. Internalization of Endocytic Markers into Endosomal Carrier Vesicles (ECV) and Late Endosomes (LE)

Solutions

1. *Nocodazole stock*: 10 m*M* in dimethyl sulfoxide (DMSO), aliquoted, and stored at –20°C.
2. *IM/BSA*: IM containing 2 mg/ml BSA. Make fresh before use and warm to 37°C.
3. All solutions listed in Section III,A.

Steps

1. *Cell culture*: For a fusion assay of 5–10 points, 10 dishes (10 cm) of BHK cells should be prepared as described in Section III,A, step 1. For ECV–LE fusion assays, use 5 dishes for bHRP-labeled ECVs and 5 dishes for avidin-labeled LEs, For LE–LE fusion assays, use 5 dishes for bHRP-labeled LEs and 5 dishes for avidin-labeled LEs.

2. *Nocodazole pretreatment for ECV preparation*: Intact microtubules are required for the delivery of endocytosed markers to the LE. Therefore, markers accumulate in transport intermediates (ECVs) in the absence of microtubules. Whereas stable microtubules are cold sensitive, dynamic microtubules are depolymerized easily in the presence of nocodazole (Aniento *et al*., 1993; Bomsel *et al*., 1990). In BHK cells, microtubules can be depolymerized efficiently in the presence of nocodazole, whereas cold treatment is without effect. For ECV preparation, depolymerize the microtubules immediately before the experiment with 10 μ*M* nocodazole at 37°C for 1–2 h in media used to grow cells in a 5% CO_2 incubator. Following this step, nocodazole (10 μ*M)* should remain present in all solutions up to the homogenization step. For LE preparation, do not treat with nocodazole or include nocodazole in any solutions.

3. *Fluid-phase internalization*: Wash each 10-cm dish of cells twice with 5 ml ice-cold PBS+/– 10 μ*M* nocodazole on ice, as in Section III,A, step 2. After the last wash, remove the PBS and place the dish on a metal plate in a 37°C water bath. Add at least 3 ml bHRP or avidin solution for making LEs or bHRP + 10 μ*M* nocodazole for making ECVs. Incubate for 10 min.

4. *Chase*: Remove bHRP or avidin and wash twice quickly at 37°C with 10 ml PBS/BSA+/– 10 μM nocodazole, prewarmed to 37°C. Remove last wash, and add 8 ml IM/BSA+/– 10 μM nocodazole, prewarmed to 37°C. Incubate at 37°C (in water bath or in a 37°C incubator without CO_2) for 45 min.

5. *Washes*: Remove IM/BSA, move dishes to ice bucket, and wash 2 × 5 min with 5 ml cold PBS/BSA followed by 5 min with 5 ml cold PBS on ice.

C. Homogenization and Fractionation of Cells

Solutions

1. *PBS*: See Section IIIA.
2. *300 mM imidazole stock*: Dissolve imidazole in H_2O and adjust pH to 7.4 with NaOH, filter sterilize, and store at 4°C
3. *Homogenization buffer (HB)*: Add imidazole from 300 m*M* stock to H_2O and dissolve sucrose such that the final concentrations are 250 m*M* sucrose and 3 m*M* imidazole. Filter sterilize and store at 4°C.
4. *62% sucrose solution*: For 100 ml, add 1 ml of imidazole from 300 m*M* stock to 15 *ml* H_2O. Add 80.4 g sucrose and dissolve by stirring at 37°C. Add H_2O and mix until the refractive index is 1.4464.
5. *10 and 16% sucrose solutions in D_2O*: For 100 ml, add 1 ml imidazole from 300 m*M* stock to 50 ml D_2O. For 10% solution, add 10.4 g sucrose, and for 16% solution, add 17.0 g sucrose. Dissolve sucrose, add D_2O, and mix until the refractive index is 1.3479 for the 10% solution and 1.3573 for the 16% solution.

Steps

1. *Cell scraping*: All of the following steps should be performed on ice or at 4°C. After the last wash, remove all PBS. Add 2 ml/dish PBS and rock the dish so that cells do not dry. Using a flexible rubber policeman, scrape round 10-cm dishes by first scraping in a circular motion around the outside of the dish, followed by a downward motion in the middle of the dish. Scrape

gently in order to obtain "sheets" of cells. Using a plastic Pasteur pipette, gently transfer the scraped "sheets" of cells from four or five dishes into a 15-ml tube on ice.

2. Centrifuge at 1200 rpm for 5 min at 4°C. Gently remove supernatant.

3. Add 1 ml HB to pellet, using a plastic Pasteur pipette, gently pipette up and down one time and add an excess of HB (4–5 ml) to change buffer. Centrifuge again at 2500 rpm for 10 min at 4°C. Remove supernatant.

4. *Homogenization*: It is important that cells are homogenized under conditions where endosomes are released from cells, yet where latency is high so that the endosomes are not broken and retain their internalized marker. First add 0.5 ml HB to the cell pellet. Using a 1-ml pipetman, gently pipette up and down until the pellet is resuspended and particles can no longer be seen by eye. Do not introduce air bubbles. Using a 22-gauge needle connected to a narrow 1-ml Tubercutine syringe, prewet the needle and syringe with HB so that no air is introduced. Insert the needle into the cell homogenate, slowly pull up on the syringe until most of the cell homogenate is in the syringe, and gently expel without bubbles. Repeat this procedure until plasma membranes are broken, yet nuclear membranes are not. Monitor homogenization as follows. Take 3 µ*l* of homogenate and place in a 50-µ*l* drop of HB on a glass slide. Mix and cover with a glass coverslip. Observe by phase-contrast microscopy, using a 20× objective. Homogenize until unbroken cells are no longer observed, yet nuclei, which appear as dark round or oblong structures, are not broken. Usually between 3 and 10 up-and-down strokes through the needle are necessary. Centrifuge homogenate at 2000 rpm for 10 min at 4°C, and carefully collect the postnuclear supernatant (PNS) and nuclear pellet.

5. Save a 50-µ*l* aliquot of each PNS fraction for measuring latency and for calculating the balance sheet as described in Section III,D. Adjust the sucrose concentration of the remaining PNS to 40.6% by adding about 1.1 volume of 62% sucrose solution per volume of PNS. Mix gently but thoroughly, without bubbles. Check sucrose concentration using a refractometer.

6. Place adjusted PNS in the bottom of a SW60 centrifuge tube. On top of the PNS, layer 1.5 ml of 16% sucrose solution in D_2O, followed by 1 ml of 10% sucrose solution in D_2O, and fill tube with HB. Steps should be layered so that interfaces are clearly seen and not disturbed. See Gruenberg and Gorvel (1992) for diagram of gradients.

7. Centrifuge gradients in SW60 rotor at 35,000 rpm for 1 h at 4°C.

8. Carefully remove the interfaces from the gradients after centrifugation by first placing gradients in a test tube rack with a black backdrop. The interfaces should appear white. The layer of white lipids on top of the gradient should be removed carefully. Collect fractions at 4°C using a peristaltic pump at speed 2, with capillary tubes connected to each end. Place the outgoing end into a collection tube and collect the top interface carefully (10%/HB interface = LE + ECV fraction) first. Collect by holding the capillary tube directly in the middle of the wide interface and slowly move in a circular motion until most of the white interface is collected into the smallest possible volume. Wash the pump tubing with water and then collect the EE (16/10%) interface into another tube. Fractions can be frozen and stored in liquid N_2 until use in fusion assays if they are carefully frozen quickly in liquid N_2 and thawed quickly at 37°C immediately before use.

D. Measurement of Latency and Balance Sheet for Gradients

Solutions

1. *HRP stocks*: 1–10 ng HRP in 0.1 ml HB, for standards.

2. *HB*: See Section IIIC.

3. *HRP reagent*: 0.342 m*M* *o*-dianisidine and 0.003% H_2O_2 in 0.05 *M* Na-phosphate buffer, pH 5.0, containing 0.3% Triton X-100. To prepare, use very clean glassware or plasticware (as in for tissue culture) and mix 12 ml of 0.5 *M* Na-phosphate buffer, pH 5.0 (filter sterilized), and 6 ml of 2% Triton X-100 (filter sterilized) with 111 ml sterile H_2O. Add 13 mg *o*-dianisidine, dissolve gently, and add 1.2 ml 0.3% H_2O_2 (filter sterilized). Avoid magnetic stirring. Solution should be clear. Store at 4°C in the dark.

4. *1 mM KCN in H_2O*

5. Protein assay system (such as the BCA protein assay reagent or the Bio-Rad protein assay system)

Steps

1. Load a 20-µ*l* aliquot of bHRP PNS into an airfuge tube or a small tabletop ultracentrifuge tube of the Beckman TL-100 type and fill the tube with a known volme of HB. Mix thoroughly by pipetting without air bubbles. Centrifuge at 4°C for 20 min at 20 psi in an airfuge or at 200,000 *g* for 20 min in a tabletop ultracentrifuge rotor (such as Beckman TLA-100.1). Transfer the supernatant to another tube. Resuspend the pellet in 50 µl HB.

2. To measure the latency, adjust samples, blanks, and standards with HB so that the final volume of each is 0.1 ml. Assay both the pellet and the supernatant of

the latency measurement. If the supernatant volume is over 0.1 ml, assay only 0.1 ml. Add 0.9 ml of HRP reagent to each tube, mix quickly, and record the time with a stop clock. Allow color to develop in the dark, as this reagent is light sensitive. When a brown color has begun to develop, read the absorbance at 455 nm and record the time (results expressed as OD units/min or ng HRP/min). Stop the reaction with 10 µ*l* of 1.0 m*M* KCN if necessary.

3. Calculate latency by first adding the value (OD/min) for HRP in the pellet to that of HRP in the supernatant (OD/min after correcting for total supernatant volume). The value for the pellet divided by the total value is the percentage latency. Latency should be over 70% in order to measure endosome fusion.

4. The amount of HRP in each gradient fraction collected from the bHRP gradient can be measured by assaying an aliquot (about 50 µ*l*) of each fraction as described in step 2.

5. Measure the amount of protein in each gradient fraction using a standard protein assay system, as described in the manual.

6. Calculate percentage yield (percentage of HRP in each fraction compared to total amount of HRP in PNS), specific activity (SA) (HRP activity per unit protein), and relative specific activity (RSA) (divide specific activity of each fraction by the specific activity of the PNS). See Gruenberg and Gorvel (1992) for an example of a typical balance sheet.

E. Preparation of BHK Cell Cytosol

Solutions

1. *PBS-*: See Section IIIA.
2. *HB*: See Section IIIC.
3. *HB + protease inhibitors*: HB with the following protease inhibitors added immediately before use: 10 µ*M* leupeptin, 1 µ*M* pepstatin A, 10 ng/ml aprotinin, and, if needed, 1 µ*m* phenylmethylsulfonyl fluoride.

Steps

Two possible cytosol sources for all of the assays described are BHK and rat liver cytosol. For rat liver cytosol preparation, refer to Aniento *et al.* (1993).

1. BHK cells, maintained as described in Section IIIA, should be plated approximately 16 h before the experiment. Large (245 × 245 × 25 mm) square dishes are convenient for large cytosol preparations.

2. All steps should be performed on ice or at 4°C. Wash dishes four times with excess PBS (50 ml per dish for large square dishes).

3. Remove PBS from the last wash, add 12 ml PBS per dish, and rock the dish so that cells do not dry. Scrape cells with a rubber policeman using firm, downward motions, going from top to bottom while holding the plate at an angle, as described in Section IIIC, step 1.

4. Collect scraped cells into 15-ml tubes (one tube per dish). Centrifuge at 1200 rpm for 5 min at 4°C.

5. Remove supernatant and gently add 5 ml HB with a plastic Pasteur pipette and pipette up and down one time.

6. Centrifuge at 2500 rpm for 10 min at 4°C. Remove supernatant and resuspend pellet in 1.2 ml HB + protease inhibitors. Separate into two tubes (about 0.7 ml/tube) for homogenization and homogenize as described in step 4 of Section IIIC.

7. Centrifuge at 2500 rpm for 15 min at 4°C. Add supernatant (PNS) to a centrifuge tube for the TLS-55 rotor (for the Beckman TL-100 tabletop ultracentrifuge) and centrifuge in TLS-55 for 45 min at 55,000 rpm at 4°C. Remove fat from the top using an aspirator. Transfer supernatant (cytosol fraction) to a new tube without disturbing the pellet. Determine the protein concentration of supernatant. Cytosol should be at least 15 mg/ml to give a good signal for fusion assays. Aliquot on ice, freeze quickly, and store in liquid N_2 until use.

F. Preparation of Antiavidin Beads for the *in Vitro* Fusion Assay Described in Section IIIG

Solutions

1. *PBS/BSA*: Dissolve 5 mg/ml BSA in PBS. Filter sterilize and store at 4°C.
2. *Sterile PBS*: PBS as described in Section III,A, filter sterilize or autoclave, and store at 4°C.
3. *Antiavidin antibody*: Affinity purify and store aliquoted in 50% glycerol/PBS at –20°C.

Steps

To determine how many antiavidin beads to prepare, first determine the number of fusion assay points. From a typical gradient (see Gruenberg and Gorvel, 1992) about 150 µg of EE and 70 µg of ECV or LE are obtained. Optimal amounts of endosomes to use for fusion assays are 20 µg of each EE fraction and 10 µg of each ECV or LE fraction. Therefore, a typical experiment (one gradient each of avidin and bHRP-labeled fractions) will provide enough endosomes for about seven fusion assay points.

1. Swell 1.5 g of protein A–Sepharose beads in 10 ml sterile H_2O at room temperature overnight.

2. Wash beads three times in 10 ml sterile PBS by centrifuging beads in 15-ml tubes at 3000 rpm for 2 min, resuspending in PBS each time.

3. After the final wash, resuspend beads in an equal volume of sterile PBS per volume of packed beads. Store beads this way up to several months at 4°C.

4. One hundred microliters of this 1:1 slurry is required per fusion assay point. Therefore, for 10 assay points, block 1 ml of beads by washing 3× in 10 ml PBS/BSA, as described in step 2.

5. After final wash, resuspend beads in 10 ml PBS/BSA. For 10 assay points, add 50 µg of antiavidin antibody (5 µg per 100-µ*l* beads). Rotate tube for at least 5 h at 4°C.

6. Wash beads four times in PBS/BSA. After the last wash, for 10 assay points, resuspend beads in 10 ml PBS/BSA.

7. Aliquot 1 ml to each of 10 labeled Eppendorf tubes. Centrifuge in Eppendorf centrifuge at maximum speed for 2 min. Remove supernatant. Beads are now ready for the immunoprecipitation step of the fusion assay (Section III,G, step 10).

G. In Vitro Assay of Endocytic Vesicle Fusion

Solutions

1. *50× salts*: 0.625 *M* HEPES, 75 m*M* Mg-acetate, 50 m*M* dithiothreitol, pH 7, with KOH. Filter sterilize, aliquot, and store at –20°C.

2. *K-acetate (KOAc stock)*: 1 *M* in H_2O. Filter sterilize, aliquot, and store at –20°C. *Note:* Depending on the counterion requirement of the experiment, KOAc must be replaced by KCl (see Aniento *et al*., 1993).

3. *Biotinylated insulin*: 1 mg/ml in H_2O. Store at 4°C.

4. *AT?-regenerating system (ATP-RS)*: Mix 1:1:1 volumes of the following immediately before use.

   a. *100 mM* ATT: Dissolve in ice-cold H_2O, titrate to pH 7.0 with 1 *M* NaOH, filter sterilize, aliquot on ice, and store at –20°C.

   b. *800 mM creatine phosphate*: Dissolve in ice-cold H_2O, filter sterilize, aliquot on ice, and store at –20°C.

   c. 4 *mg/ml creatine phosphokinase*: To make 4 ml, add 80 *p*\ of 0.5 *M* $NaHPO_4$ buffer, pH 7.0, to 1.6 ml H_2O on ice. When cool, add 16 mg creatine phosphokinase. Vortex until dissolved. Add 2.3 ml ice-cold 87% glycerol. Vortex until well mixed. Aliquot on ice and store at –20°C.

5. *Hexokinase*: Vortex the suspension, pipette the desired amount (e.g., 10 µg–0.1 mg for one assay point), centrifuge for 2 min in Eppendorf at maximum speed, and aspirate supernatant. Dissolve pellet in the same volume of 0.25 *M* D-glucose. Prepare immediately before use.

6. *TxlOO stock*: 10% stock of Triton X-100 in H_2O

7. *PBS/BSA and sterile PBS*: See Section IIIF.

8. *HEP reagent*: See Section IIID.

9. *PBS/BSA/TxlOO*: PBS/BSA containing 0.2% Triton X-100, make immediately before use

Steps

1. For each fusion assay, at least three points should be included:—ATP, +ATP, and the total. To determine fusion efficiency, determine the total (maximal possible fusion value) by mixing 50 //I of each endosomal fraction in an Eppendorf tube on ice. Add 25 µ*l* Tx100 stock and vortex well. Leave on ice at least 30 min and add PBS/BSA and continue as described in step 9.

2. For all other fusion assay points, 3 µl of 50× salts, 8 µ*l* of biotinylated insulin, and 11 µ*l* of KOAc stock are needed for each point. Make a mixture of these three components by multiplying the number of assay points by 3, 8, and 11 and mix the respective amounts of each component together in one tube. Number Eppendorf tubes for the appropriate number of assay points and put them on ice. Add 22 µ*l* of the aforementioned mixture to each tube.

3. Add 50 µl (750 µ*g*–1 mg) of cytosol to each tube and mix.

4. Add either 5 µl of ATP-RS or 10 µl of hexokinase to each tube, as appropriate.

5. Add 50 µl (7–25 µg) of bHRP-labeled endosomes and 50 µ*l* (7–25 µg) of avidin-labeled endosomes to each tube. Endosomal fractions from the gradients can be diluted in HB prior to this step, if desired. Mix gently; avoid introducing air bubbles. Leave tubes on ice for 3 min.

6. Transfer tubes to 37°C for 45 min. Avoid agitation during this time.

7. Return tubes to ice. Add 5 µl of biotinylated insulin to each tube and mix.

8. Add 25 µl of Tx100 stock and vortex well. Leave tubes on ice for 30 min.

9. Add 1 ml of sterile PBS/BSA to each tube and mix well.

10. Centrifuge for 2 min at maximum speed in an Eppendorf centrifuge. Transfer supernatants to numbered tubes containing antiavidin beads, prepared as in Section IIIF.

11. Rotate beads for at least 5 h at 4°C.

12. Centrifuge in Eppendorf centrifuge at maximum speed for 2 min. Remove supernatant and wash four times with PBS/BSA/Tx100. Wash once with sterile PBS.

13. Remove final supernatant and add 900 //I of HRP reagent to each tube. Allow color to develop in

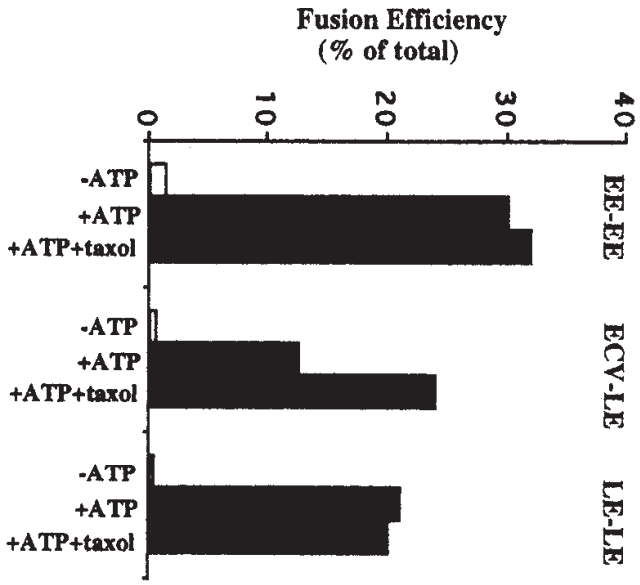

FIGURE 2 Typical fusion assay results. Fusion efficiency is expressed as a percentage of total fusion between each set of endosomal membranes. Total, or maximal, endosome fusion is measured by mixing bHRP and avidin-containing endosomal fractions together in the presence of detergent, followed by immunoprecipitation with antiavidin antibodies and HRP determination. Typical "total" values (measured as absorbance at 455 nm) are in the range of 0.6–1.0 ∧455 units for EE fusion assays and 0.3–0.7 ∧455 units for ECV and LE fusion assays. As a control for nonspecific reactions, the assay is typically carried out without ATP (—ATP). As shown, the polymerization of endogenous tubulin present in the cytosol in the presence of taxol is sufficient to facilitate interactions between ECVs and LEs (see Aniento *et al*., 1993).

the dark at room temperature. Vortex periodically for 2–3 h or put tubes on rotating wheel in the dark at room temperature while color develops.

14. Centrifuge tubes for 2 min in Eppendorf centrifuge. Measure the absorbance of the supernatants at 455 nm.

IV. COMMENTS

Refer to Gruenberg and Gorvel (1992) for an example of a typical balance sheet for the sucrose gradient fractionation step. Typical results for fusion assays are shown in Fig. 2.

Highly purified loaded endosomes can be prepared by immunoisolation as described in Howell *et al.* (1989). Immunoisolated endosomes can then be used in the fusion assays described in Section IIIG. See Gruenberg and Gorvel (1992) and Howell *et al.* (1989) for details.

ECV–LE fusion is stimulated by the addition of polymerized microtubules to the fusion assay. Endogenous microtubules can be polymerized by adding 20 μ*M* taxol to the fusion assay. The preparation of microtubules is described in the article by Ashford and Hyman. See Fig. 2 and Aniento *et al*. (1993) for more details on the effects of microtubules and MAPs on ECV–LE fusion.

V. PITFALLS

For ECV and LE preparations, cells should be homogenized until vesicles are no longer seen around the periphery of nuclei. If nuclei begin to aggregate during homogenization, however, this is a sign that some are broken as free DNA causes aggregation. Freezing and thawing of endosomes may cause a partial loss in latency. Use very clean plasticware or glassware for all fusion assay manipulations as HRP contamination can occur easily. Nocodazole, *o*-dianisidine, and KCN are very toxic.

Microsome-Based Assay for Analysis of Endoplasmic Reticulum to Golgi Transport in Mammalian Cells

Helen Plutner, Cemal Gurkan, Xiaodong Wang, Paul LaPointe, and William E. Balch

The trafficking of proteins along the first stage of the secretory pathway is mediated by small vesicles that bud from the endoplasmic reticulum (ER) and subsequently fuse with the *cis*-Golgi compartment. This article describes a biochemical assay using mammalian microsomes that can be used to measure these events independently. The microsomes are prepared from cells infected at the restrictive temperature (39.5°C) with the ts045 strain of vesicular stomatitis virus (VSV) (Lafay, 1974). As a reporter molecule the assay utilizes ts045 VSV-glycoprotein (VSV-G), which is retained in the ER during infection due to a thermoreversible folding defect; incubation *in vitro* at the permissive temperature (32°C) results in the synchronous folding and transport of VSV-G to the Golgi complex. To follow vesicle formation, a differential centrifugation procedure is employed to separate the more rapidly sedimenting ER and Golgi membranes from the slowly sedimenting vesicles. Consumption is analyzed using a two-stage assay in which vesicles isolated by differential centrifugation during stage 1 are subsequently added to stage 2 (fusion) reactions containing acceptor Golgi membranes. Transport to the Golgi is measured by following the oligosaccharide processing of VSV-G from the high mannose ER form, which is sensitive to endoglycosidase H (endo H), to the *cis/medial-Golgi* form, which is endo H resistant (Schwaninger *et al.*, 1992). The biochemical characteristics of the overall ER to Golgi transport reaction and the vesicle formation and consumption assays are described elsewhere (Aridor *et al.*, 1995, 1996b, 1998, 1999a,b, 2000, 2001; Rowe *et al.*, 1996a).

II. MATERIALS AND INSTRUMENTATION

Culture medium (α-MEM; Cat. No. 11900-099) is from Life Technologies. The medium is supplemented with penicillin/streptomycin from a 100× stock solution (Cat. No P0781; Sigma). Fetal bovine serum (FBS; Cat. No FB-01) is from Omega Scientific. D-Sorbitol (Cat. No. S-1876), leupeptin (Cat. No L-2884), chymostatin (Cat. No C-7268), pepstatin (Cat. No P-4265), phenylmethylsulfonyl fluoride (PMSF; Cat. No P-7626), actinomycin D (Cat. No A-1410), uridine 5′-diphospho-*N*-acetylglucosamine (UDP-GlcNAc; Cat. No. U-4375), and dimethyl sulfoxide (DMSO; Cat. No. D-2650), are from Sigma. The nitrocellulose membrane (Cat. No. 68260) is from Schleicher & Schuell. Horseradish peroxidase-conjugated goat anti-rabbit IgG (Cat. No. 31460) is from Pierce. Chemiluminescence reagent (Cat. No. NEL-101) and autoradiography film ("Reflection") are from NEN. Polyallomer microfuge tubes (Cat. No. 357448) are supplied by Beckman Instruments Inc. A polyclonal antibody to VSV-G is generated in rabbits immunized with the C-terminal 16 amino acids of VSV-G (Indiana serotype) coupled to KLH (Plutner *et al.*, 1991). Centrifugation at 20,000 or 100,000 *g* is performed using an Optima TL ultracentrifuge (Beckman) equipped with a TLA 100.3 rotor. A laser-scanning densitometer (personal densitometer; Molecular Dynamics) is used to quantitate data.

III. PROCEDURES

The following procedures are performed on ice unless otherwise stated.

A. Preparation of Cytosol

The following procedure for the preparation of rat liver cytosol is based on that described by Davidson *et al*. (1992).

Solutions

1. *Phosphate-buffered saline (PBS) (10× stock)*: 90 m*M* phosphate and 1.5 *M* NaCl (pH 7.4). To make 1 liter, add 80 g NaCl, 2 g KCl, 2 g KH_2PO_4, and 21.6 g $Na_2HPO_4{\cdot}7H_2O$ to distilled water. Store at room temperature.
2. *25/125*: 0.125 *M* KOAc, 25 m*M* HEPES (pH 7.4). To make 100 ml, add 3.125 ml of 4 *M* KOAc stock and 2.5 ml of 1 *M* HEPES–KOH (pH 7.4) stock to distilled water. Store at 4°C.
3. *Protease inhibitor cocktail (PIC)*: 10 µg/ml leupeptin, 10 µg/ml chymostatin, 0.5 µg/ml pepstatin A, and 1.0 m*M* PMSF. To supplement 50 ml of buffer (e.g., 25/125) with PIC, add 50 µl of 10 mg/ml leupeptin stock (in H_2O), 50 µl of 10 mg/ml chymostatin stock (in DMSO), 5 µl of 5 mg/ml pepstatin A stock (in DMSO), and 500 µl of 0.1 *M* PMSF stock (in ethanol). Use PIC buffer immediately or store at –20°C.

Steps

1. Decapitate two anesthetized adult Sprague–Dawley rats (~250 g), remove the livers, and place the tissue in a 250-ml glass beaker. Determine the weight of the tissue (typically ~20 g) and then wash two times with –50 ml of Ix PBS and once with ~50 ml of Ix PBS and once with ~50 ml of 25/125.
2. Finely mince the tissue using a pair of scissors and then homogenize in 2–3 volumes (ml/g of tissue) of 25/125 (PIC) with 20 strokes using a 40-ml Dounce (Wheaton). Use a "loose-fitting" Dounce for the first 10 strokes followed by a "tight-fitting" one for the second 10 strokes.
3. Pour the homogenate into a 38-ml polycarbonate tube (Nalgene; Cat. No. 3117-0380) and centrifuge for 10 min at 12,000 *g* (10,000 rpm) in a Beckman JA20 rotor (Beckman Instruments Inc.). Using a pipette, transfer ~13 ml of the supernatant into each of two 14 × 89-mm ultraclear centrifuge tubes (Beckman Cat. No. 344059) and centrifuge at 150,000 *g* (35,000 rpm) for 90 min in a Beckman SW41 rotor.
4. After centrifugation, remove the overlying lipid layer by aspiration and then withdraw the remaining supernatants (cytosol) from each tube using a pipette.
5. Divide the cytosol into 250-µl aliquots in 0.5-ml microfuge tubes, freeze in liquid N_2, and store at –80°C. The protein concentration of the cytosol is ~25 mg/ml.

B. Preparation of Microsomes

Solutions

1. *Actinomycin D (200× stock)*: Add 10 mg actinomycin D to 10 ml of ethanol. Store at –20°C.
2. *Homogenization buffer*: 0.375 *M* sorbitol and 20 *mM* HEPES (pH 7.4). To make 500 ml, add 34.2 g sorbitol and 10 ml of 1 *M* HEPES–KOH (pH 7.4) stock to distilled water. Store at 4°C.
3. *0.21 M KOAc buffer*: 0.21 *M* KOAc, 3 m*M* $Mg(OAc)_2$, and 20 m*M* HEPES (pH 7.4). To make 100 ml, add 5.25 ml of 4 *M* KOAc stock, 0.3 ml of 1 *M* $Mg(OAc)_2$ stock, and 2 ml of 1 *M* HEPES–KOH (pH 7.4) stock to distilled water. Store at 4°C.
4. *Transport buffer*: 0.25 *M* sorbitol, 70 *mM* KOAc, 1 *mM* $Mg(OAc)_2$, and 20 *mM* HEPES (pH 7.4). To make 100 ml, add 10 ml of 2.5 *M* sorbitol stock, 1.75 ml of 4 *M* KOAc stock, 0.1 ml of 1 *M* $Mg(OAc)_2$ stock, and 2 ml of 1 *M* HEPES–KOH (pH 7.4) stock to distilled water. Store at –20°C.

Steps

1. Prepare vesicular stomatitis virus (VSV; Indiana serotype) strain ts045 according to Schwaninger *et al.* (1992). Store the virus in 1-ml aliquots in screw-capped tubes at –80°C.
2. Grow normal rat kidney (NRK) cells on 150-mm tissue culture dishes (Cat. No. 3025; Falcon) in α-MEM medium supplemented with 5% FBS at 37°C and 5% CO_2. At confluency, infect the cells with a 5-ml cocktail (per dish) containing 0.1–0.25 ml (2–10 pfu/cell) of ts045 VSV (thawed at 32°C) and 25 µg of actinomycin D in serum-free α-MEM as described by Schwaninger *et al*. (1992). Rock the dishes for 45 min to ensure an even spread of the infection cocktail. After infection, add 20 ml of α-MEM medium supplemented with 5% FBS to each dish and incubate in the presence of 5% CO_2 for 3 h and 40 min to 4 h at the restrictive temperature (39.5°C) (see Comment 1). The method detailed later is based on a typical 12-dish microsome preparation.
3. Following incubation at 39.5°C, transfer each dish to ice, aspirate the medium immediately, and add 12 ml of ice-cold Ix PBS to cool the cells as quickly as possible.
4. Remove the PBS by aspiration, add 5 ml of homogenization buffer, and scrape the cells from the

dishes using a rubber policeman. Use a pipette to transfer the cells to 50-ml plastic tubes (Cat. No. 25325-50: Corning Inc.) and then repeat the scraping procedure to ensure that all the cells are collected. Centrifuge at 720 *g* for 3 min and remove the supernatant by aspiration.

5. Resuspend each cell pellet (from four dishes) in 0.9 ml of homogenization buffer supplemented with PIC and homogenize by three complete passes (three downward strokes with both plungers) through a 1-ml ball-bearing homogenizer (Balch and Rothman, 1985).

6. Combine the cell homogenates and dilute with an equal volume (~3 ml) of homogenization buffer + PIC. Divide the diluted homogenate into six 1.0-ml aliquots in 1.5-ml microfuge tubes and centrifuge at 720 *g* for 5 min.

7. Carefully remove the postnuclear supernatant (PNS) fractions and combine in a plastic 15-ml tube (Cat. No. 25319-15: Corning Inc.). Add 0.5 volume (~2.5 ml) of 0.21 *M* KOAc buffer to the PNS and mix. Divide the mixture into 0.8- to 1.0-ml aliquots in 1.5-ml microfuge tubes and centrifuge at 12,000 *g* (12,200 rpm) for 2 min in an Eppendorf Model 5402 refrigerated microfuge using the soft spin function.

8. Remove the supernatants by aspiration and resuspend the pellets (including any membranes on the sides of the tubes) using a P1000 Gilson tip in a total volume of 1.0 ml of transport buffer + PIC. Dispense 0.5-ml aliquots into two 1.5-ml microfuge tubes and recentrifuge the microsomes at 12,000 *g* for 2 min as described earlier.

9. Resuspend the membrane pellets by repeated trituration using a P1000 Gilson tip in 6–8 volumes (~1 ml per 75-µl membrane pellet) of transport buffer containing PIC. In a typical 12-dish preparation, 1.0–1.5 ml of resuspended microsomes (at a protein concentration of 3–4 mg/ml) is obtained depending on the starting cell density. Pool the membranes, divide into 50- or 100-µl aliquots in 0.5-ml microfuge tubes, freeze in liquid N_2, and store at –80°C. The microsomes can be stored for several months with no loss of transport activity.

C. Preparation of Acceptor Golgi Membranes

The following procedure for the preparation of Golgi membranes by flotation on a sucrose density gradient is a modification of that originally described by Balch *et al.* (1984).

Solution

57.5 mM KOAc buffer: 87.5 m*M* KOAc, 1.25 m*M* $Mg(OAc)_2$, and 20 m*M* HEPES (pH 7.4). To make 100 ml, add 2.18 ml of 4 *M* KOAc stock, 0.125 ml of 1 *M* $Mg(OAc)_2$ stock, and 2 ml of 1 *M* HEPES–KOH (pH 7.4) stock to distilled water. Store at 4°C.

Steps

1. Prepare an enriched Golgi membrane fraction from noninfected wild-type Chinese hamster ovary cells by flotation in sucrose density gradients as described by Beckers and Rothman (1992). Recover the membranes at the 29–35% sucrose interface, mix thoroughly with 4 volumes of 87.5 m*M* KOAc buffer, and divide into 0.5- to 1.0-ml aliquots in microfuge tubes. Centrifuge at 16,000 *g* (soft spin) for 10 min.

2. Remove the supernatants by aspiration, wash the pellets with 2 ml (final volume) of transport buffer, and combine the membranes into two 1.5-ml microfuge tubes. Centrifuge at 16,000 *g* (soft spin) for 10 min.

3. Resuspend the membranes using a P1000 Gilson tip in transport buffer (total volume of 1.0 ml per 1×10^6 cells). Divide the Golgi membrane fraction into 50- to 100-µl aliquots in 0.5-ml microfuge tubes, freeze in liquid N_2, and store at –80°C.

D. Reconstitution of ER to Golgi Transport

Steps

1. Set up 40-µl transport reactions containing the components indicated in Table I in 1.5-ml microfuge tubes (see Comment 2). A reaction cocktail consisting of the salts, ATP-regenerating system, and water is added first, followed by the cytosol and finally the microsomes. Mix by pipetting up and down four times using a P20 Gilson tip.

2. Transfer the reactions to a 32°C water bath and incubate for 75–90 min.

3. Terminate the reactions on ice, harvest the membranes by centrifugation at 20,000 *g* (27,000 rpm) in a Beckman TLA 100.3 rotor, and remove the supernatant by aspiration (see Comment 3).

4. Solubilize the membranes in one-third volume of 0.3% SDS in 1 *M* Na acetate, pH5.6, and freshly added 30 m*M* BME. Boil 5 min, cool, and two-third volume 1 *M* Na acetate containing 3 mU of endo H. Incubate overnight, then terminate the reactions by adding Laemmli sample buffer as described by Schwaninger *et al.* (1992).

5. Separate the endo H-sensitive and -resistant forms of VSV-G on 6.75% (w/v) SDS–polyacrylamide gels as described by Schwaninger *et al.* (1992).

6. Transfer the proteins to a nitrocellulose membrane and perform Western blotting using anti-VSV-G polyclonal primary antibody (1:10,000) and peroxidase-conjugated anti-rabbit IgG secondary antibody (1:10,000) according to Rowe *et al.* (1996).

TABLE I Reaction Cocktail for Standard ER to Golgi Transport Assay

Solution	Volume (µl)	Final concentration
Microsomes	5	~0.5 mg/ml protein [31.25 m*M* sorbitol, 8.75 m*M* KOAc, 0.125 m*M* $Mg(OAc)_2$, 2.5 m*M* HEPES (pH 7.4)]
Cytosol	8	5 mg/ml protein [25 m*M* KOAc, 5 m*M* HEPES (pH 7.4)]
20× ATP-regenerating system	2	1 m*M* ATP, 5 m*M* creatine phosphate, and 0.2 IU creatine phosphate kinase
40 m*M* UDP-GlcNAc	1	1 m*M*
10× Ca^{2+}/EGTA buffer	4	5 m*M* EGTA, 1.8 m*M* $Ca(Cl)_2$ (100 n*M* free Ca^{2+}), 2 m*M* HEPES (pH 7.4)
0.1 *M* $Mg(OAc)_2$	1	2.5 m*M*
1 *M* KOAc	1	40 m*M*
2.5 *M* sorbitol	3.5	218.75 m*M*
1 *M* HEPES (pH 7.4)	1.1	27.5 m*M*
H_2O	To 40 µl (final)	

7. Develop the blots using enhanced chemiluminescence and expose to autoradiography film. Quantitate the relative band intensities of the endo H-sensitive and -resistant forms of VSV-G in each lane by densitometry (see Comments 4 and 5).

E. Vesicle Formation Assay

Solution

Resuspension buffer: 0.25 *M* sucrose and 20 m*M* HEPES (pH 7.4). To make 100 ml, add 8.55 g of sucrose and 2 ml of 1 *M* HEPES–KOH (pH 7.4) stock to distilled water. Store at 4°C.

Steps

1. Set up 40-µl reactions as described in Section III,D, step 1, containing 5–10 µl of microsomes, 5–12 µl of cytosol, salts, and an ATP-regenerating system (see Comment 6).

2. Incubate at 32°C for 0–60 min and harvest the membranes as described in Section III,D, step 3. The membrane pellets can be stored for several hours at this stage prior to the differential centrifugation procedure described later.

3. Add 40 µl of resuspension buffer and disperse the membrane pellets by pipetting up and down 10 times using a P200 Gilson tip (see Comments 3 and 7). Incubate the membranes for 10 min on ice and repeat the trituration procedure to resuspend the membranes completely. Add 8.5 µl of a salt mix [7.3 µl of 1 *M* KOAc + 1.2 µl of 0.1 *M* $Mg(OAc)_2$] to the resupended membranes and mix by pipetting up and down 5 times with a P20 Gilson tip. Perform the differential centrifugation step at 16,000 *g* (14,000 rpm) for 3 min in an Eppendorf Model 5402 refrigerated microfuge using the soft spin function.

4. Using a P200 Gilson tip, carefully take the top 34-µ1 supernatant fraction from the side of the tube opposite the pellet. Transfer to a 1.5-ml polyallomer microfuge tube and centrifuge at 100,000 *g* (60,000 rpm) for 20 min. Carefully aspirate the remaining supernatant fraction from the 16,000-*g* (medium speed) pellet and the entire supernatant from the 100,000-*g* (high speed) pellet (see Comment 8).

5. Add 50 and 35 µl of IX Laemmli sample buffer (Laemmli, 1970) to the medium-speed pellet (MSP) and high-speed pellet (HSP) fractions, respectively, and boil at 95°C for 5 min. Determine the relative amounts of VSV-G in the MSP and HSP from each reaction by SDS–PAGE and quantitative immunoblotting as described by Rowe *et al*. (1996).

6. *A quicker alternative method to step 2 is as follows*: After incubation put the tubes on ice and spin at 16,000 *g* (14,000 rpm) for 3 min. Carefully remove the top 32 µl as described in step 4 and transfer to 1.5-ml polyallomer tubes. Spin at 100,000 *g* (60,000 rpm) for 20 min. Aspirate supernatant as in step 4 and add 40 and 32 µl 1× Laemmli sample buffer to the medium-speed pellet (MSP) and high-speed pellet (HSP) fractions, respectively. Vortex carefully and boil at 95°C for 5 min.

F. Two-Stage Fusion Assay

Solution

0.25 M sorbitol buffer: 0.25 *M* sorbitol and 20 m*M* HEPES (pH 7.4). To make 100 ml, add 10 ml of 2.5 *M* sorbitol stock and 2 ml of 1 *M* HEPES–KOH (pH 7.4) stock to distilled water. Store at 4°C.

Steps

1. For stage 1 incubations, prepare scaled-up (100 µl) vesicle formation reactions containing 25 µl of microsomes and 30 µl of cytosol as described in Section IIIE, step 1. Incubate for 10 min at 32°C.

2. Terminate the reactions by transfer to ice and sediment the membranes as described in Section IIID, step 3.

3. Resuspend the membranes in 90 µl of resuspension buffer, add 9.8 µl of salt mix [7.3 µl of 2 *M* KOAc + 2.5 µl of 0.1 *M* $Mg(OAc)_2$], and perform the differential centrifugation step as described in Section IIIE, step 3.

4. Withdraw the top 75-ml medium-speed supernatant fraction and recover the vesicles by centrifugation at high speed as described in Section IIIE, step 4.

5. Resuspend the HSPs in 25 µl of 0.25 *M* sorbitol buffer by pipetting up and down 10 times with a P200 Gilson tip and then add 1.9 µl of 1 *M* KOAc (70 m*M* KOAc final concentration) (see Comment 9).

6. Set up *40*-µl stage 2 reactions containing 10 µl of resuspended HSP fraction, 4 µl of Golgi membranes, 8 µl of cytosol, and an ATP-regenerating system and salts at the final concentrations indicated in Table I (see Comment 6).

7. Incubate for 60 min at 32°C and terminate the reactions on ice. Harvest the membranes and quantitate the conversion of VSV-G to the endo H-resistant form as described in Section IIID, steps 3–7.

IV. COMMENTS

1. To reproduce the temperature-sensitive phenotype of ts045 VSV-G transport *in vitro*, it is necessary to supplement the postinfection medium and homogenization buffer with dithiothreitol as described by Aridor *et al*. (1996).

2. Preparations of the ATP-regenerating system and Ca^{2+}/EGTA buffer are described by Schwaninger *et al*. (1992). Transport inhibitors such as antibodies are dialyzed against 25/125 prior to addition to the assay, and the volumes of the salts in the reaction cocktail are adjusted to achieve the final concentrations described in Table I. The reactions can be preincubated on ice for up to 45 min with no loss of transport activity.

3. All of the membrane-bound VSV-G is sedimented at 20,000 *g* following the 32°C incubation. In the vesicle formation assay, membranes are resuspended in sucrose buffer prior to differential centrifugation.

4. The detection system is linear over the range of VSV-G concentrations tested.

5. As an alternative to densitometry, VSV-G bands can be detected by direct fluorescence imaging (e.g., using a Bio-Rad GS-363 molecular imaging system).

6. In the vesicle formation and two-stage assays, the volumes of salts (see Table I) added to the reaction cocktail are adjusted to account for the salts present in the cytosol and membrane preparations in the assay. UDP-GlcNAc is omitted from the vesicle formation assay and from stage 1 of the two-stage assay.

7. Although in the original description of the assay (Rowe *et al*., 1996) a 0.25 *M* sorbitol buffer was used to resuspend the membranes prior to differential centrifugation, we have subsequently found that resuspension in 0.25 *M* sucrose buffer gives higher yields of vesicles at this step.

8. Because the HSP is small and translucent, care should be taken to avoid losing it during aspiration of the high-speed supernatant.

9. In a typical experiment, multiple stage 1 reactions are performed and the HSPs are resuspended successively in the desired final volume of sorbitol buffer and are then adjusted to 70 m*M* KOAc.

Cotranslational Translocation of Proteins into Microsomes Derived from the Rough Endoplasmic Reticulum of Mammalian Cells

Bruno Martoglio and Bernhard Dobberstein

I. INTRODUCTION

In mammalian cells, secretory proteins and membrane proteins of the organelles of the secretory pathway are initially transported across and integrated into the membrane of the rough endoplasmic reticulum (ER), respectively (for reviews, see Rapoport *et al*., 1996; Johnson and van Weas, 1999). This process can be studied in a cell-free translation/translocation system in which a protein of interest is synthesized and imported into microsomal membranes derived from the rough ER. Components used in such a system are rough microsomes (RM) usually prepared from dog pancreas, a cytosolic extract supporting protein synthesis, mRNA coding for a secretory or a membrane protein, and a radio-labeled amino acid, e.g., [^{35}S]methionine, for detection of the newly synthesized protein.

Upon translocation across the ER membrane, proteins become processed and modified, fold with the help of lumenal chaperones, and can assemble into oligomeric complexes (Lemberg and Martoglio, 2002; Daniels *et al*., 2003). These functions are maintained in rough microsomes and can be studied. This article describes the basic cell-free *in vitro* translocation system and provides methods to analyze the translocation of proteins across the microsomal membrane and integration into the lipid bilayer.

II. MATERIALS AND INSTRUMENTATION

Ambion: RNase inhibitor (Cat. No. 2684). Amersham Pharmacia: DEAE–Sepharose (Cat. No. 17-0709-01), [^{35}S]methionine (Cat. No. AG 1594), and Sephacryl S-200 (Cat. No. 17-0584-10). Roche Applied Science: ATP (Cat. No. 1140965), CTP (Cat. No. 1140922), GTP (Cat. No. 1140957), UTP (Cat. No. 1140949), creatin kinase (Cat. No. 736988), creatin phosphate (Cat. No. 621714), and SP6 RNA polymerase (Cat. No. 810274). Fluka: EDTA (Cat. No. 03610), octaethylene glycol monododecyl ether (Cat. No. 74680), and SDS (Cat. No. 71725). Merck: Acetic acid (Cat. No. 100063), acetone (Cat. No. 100014), calcium chloride (Cat. No. 102389), HCl (Cat. No. 100317), isopropanol (Cat. No. 109634), magnesium acetate (Cat. No. 105819), magnesium chloride (Cat. No. 105833), 2-mercaptoethanol (Cat. No. 805740), potassium acetate (Cat. No. 104820), proteinase K (Cat. No. 124568), sodium acetate (Cat. No. 106268), sodium carbonate (Cat. No. 106392), sodium citrate (Cat. No. 106448), sucrose (Cat. No. 107654), and trichloroacetic acid (Cat. No. 100810). New England Biolabs: ^{7}mG(5′)ppp(5′)G (Cat. No. 1404) and endoglycosidase H (Cat. No. 0702). Promega: Amino acid mixture minus methionine (Cat. No. L9961). Sigma: Dithiothreitol (DTT, Cat. No. D 0632), HEPES (Cat. No. H 3375), phenylmethylsulfonyl

fluoride (PMSF, Cat. No. P 7626), Sephadex G-25 (Cat. No. G-25-150), Tris base (Cat. No. T 1503), and Triton X-100 (Cat. No. T 9284). Amersham Pharmacia: ÄKTAprime chromatography system (Cat. No. 18-2237-18). Braun Biotech Int.: Potter S homogenizer. Qiagen: Plasmid Maxi Kit (Cat. No. 12162). Millipore: Amicon ultrafiltration unit 8050 (Cat. No. 5122) and YM100 ultrafiltration discs (Cat. No. 14422AM).

III. PROCEDURES

A. Preparation of Components Required for Cell-Free in Vitro Protein Translocation across ER-Derived Rough Microsomes

1. Preparation of Rough Microsomes from Dog Pancreas

RMs can be prepared from most tissues or cells in culture. Dog pancreas, however, is the most convenient source for functional RMs because this tissue is specialized in secretion and contains an extended rough ER. Most importantly, pancreas from dog, in contrast to other animals, contains very little ribonuclease that would degrade the mRNA required for the translation reaction. Dogs may be obtained from an experimental surgery department or a pharmaceutical company. Ideally, the dogs are healthy and not operated or treated with drugs, and the pancreas is excised immediately after death.

Solutions

Glass and plasticware are autoclaved, and stock solutions and distilled water are either autoclaved or filtered through 0.45-µm-pore-sized filters.

1. *Stock solutions*:

2 M sucrose: To make 500 ml of the solution, dissolve 342.25 g sucrose in water and complete to 500 ml. Sucrose stock solution may be stored in aliquots at –20°C.

1 M HEPES–KOH pH 7.6: To make 200 ml of the buffer, dissolve 47.7 g HEPES in water, adjust pH to 7.6 with KOH solution, and complete to 200 ml.

4 M KOAc: To make 200 ml of the solution, dissolve 78.5 g KOAc in water, neutralize to pH 7 with diluted acetic acid, and complete to 100 ml.

1 M $Mg(OAc)_2$: To make 100 ml of the solution, dissolve 21.5 g $Mg(OAc)_2 \cdot 4\ H_2O$ in water, neutralize to pH 7 with diluted acetic acid, and complete to 100 ml.

500 mM EDTA: To make 100 ml of the solution, dissolve 14.7 g EDTA in water, adjust to pH 8.0 with NaOH solution and complete to 100 ml.

1 M DTT: To make 10 ml of the solution, dissolve 1.54 g DTT in water and complete to 10 ml. Store in aliquots at –20°C.

20 mg/ml PMSF: To make 2 ml of the solution, dissolve 40 mg PMSF in 2 ml isopropanol. Prepare just before use.

2. *Homogenization buffer*: 250 m*M* sucrose, 50 m*M* HEPES–KOH, pH 7.6, 50 m*M* KOAc, 6 m*M* $Mg(OAc)_2$, 1 m*M* EDTA, 1 m*M* DTT, and 30 µg/ml PMSF. To make 1 liter of the buffer, add 125 ml 2 *M* sucrose, 50 ml 1 *M* HEPES–KOH, pH 7.6, 12.5 ml 4 *M* KOAc, 6 ml 1 *M* $Mg(OAc)_2$, 2 ml 500 m*M* EDTA, and complete to 1 liter with water. Add 1 ml 1 *M* DTT and 1.5 ml 20 mg/ml PMSF to the cold buffer just before use.

3. *Sucrose cushion*: 1.3 *M* sucrose, 50 m*M* HEPES–KOH, pH 7.6, 50 m*M* KOAc, 6 m*M* $Mg(OAc)_2$, 1 m*M* EDTA, 1 m*M* DTT, and 10 µg/ml PMSF. To make 200 ml of the solution, add 130 ml 2 *M* sucrose, 10 ml 1 *M* HEPES–KOH, pH 7.6, 2.5 ml 4 *M* KOAc, 1.2 ml 1 *M* $Mg(OAc)_2$, 0.4 ml 500 m*M* EDTA, and complete to 200 ml with water. Add 0.2 ml 1 *M* DTT and 0.1 ml 20 mg/ml PMSF to the cold solution just before use.

4. *RM buffer*: 250 m*M* sucrose, 50 m*M* HEPES–KOH, pH 7.6, 50 m*M* KOAc, 2 m*M* $Mg(OAc)_2$, 1 m*M* DTT, and 10 µg/ml PMSF. To make 100 ml of the buffer, add 12.5 ml 2 *M* sucrose, 5 ml 1 *M* HEPES–KOH, pH 7.6, 1.25 ml 4 *M* KOAc, 0.2 ml 1 *M* $Mg(OAc)_2$, and complete to 100 ml with water. Add 0.1 ml 1 *M* DTT and 50 µl 20 mg/ml PMSF to the cold solution just before use.

Steps

This procedure is performed in the cold room. Samples and buffers should be kept on ice.

1. Excise the pancreas (10–15 g) from a dog (e.g., beagle) and rinse in ~500 ml ice-cold homogenization buffer.
2. Remove connective tissue and fat, and cut the pancreas into small pieces. (*Optional*: Shock-freeze the pieces in liquid nitrogen and store the tissue at –80°C.)
3. Place the pieces into ~120 ml homogenization buffer and pass the tissue through a tissue press with a 1-mm mesh steel sieve.
4. Homogenize the pancreas in a 30-ml glass/Teflon potter with eight strokes at full speed (1500 rpm).
5. Transfer homogenate into 30-ml polypropylene tubes. Centrifuge at 3000 rpm (1000 *g*) for 10 min at 4°C in a Sorvall SS34 rotor.
6. Collect the supernatant, avoiding the floating lipid. Extract the pellet once more in 50 ml homogenization buffer as described in step 4 and centrifuge again (see step 5).

7. Transfer the two 1000-*g* supernatants to 30-ml polypropylene tubes. Centrifuge at 9500 rpm (10,000 *g*) for 10 min at 4°C in a Sorvall SS34 rotor.
8. Collect the supernatant, avoiding the floating lipid and repeat step 7 (centrifugation at 10,000 *g*) twice.
9. In the meantime, prepare four 70-ml polycarbonate tubes for a Ti45 rotor and add 25 ml sucrose cushion per tube.
10. After the third 10,000 *g* centrifugation (step 8), collect the supernatant and apply carefully, without mixing, onto the 25-ml sucrose cushions (see step 9).
11. Centrifuge at 35,000 rpm (142,000 *g*) for 1 h at 4°C in a Beckman Ti45 rotor.
12. Discard the supernatant and resuspend the membrane pellet, the rough microsomes (RM), in 20 ml RM buffer using a Dounce homogenizer.
13. Measure the absorption at 260 and 280 nm of a 1 : 1000 dilution of the RM suspension in 0.5% (w/v) SDS. Usually an absorption of 0.05–0.1 A_{280}/ml and a ratio A_{260}/A_{280} of ~1.7 are obtained. When the pancreas is frozen (see step 2), the A_{260}/A_{280} is 1.5–1.6.
14. Freeze 500-µl aliquots in liquid nitrogen and store at –80°C until use.

Note: RMs prepared by this procedure largely retain SRP on the membrane.

2. *Preparation of Signal Recognition Particle (SRP)*

Purification of components involved in protein translocation revealed that a cytosolic component, the signal recognition particle, is required for targeting nascent polypeptide chains to the ER membrane (Walter and Johnson, 1994). SRP is present in cytosolic extracts, but is also associated with RMs to a variable degree. In order to improve the efficiency of the translocation system, purified SRP may be added to the translation/translocation system. This is particularly useful when wheat germ extract is used for cell-free *in vitro* translation because this extract contains low amounts of functional SRP. SRP is isolated most conveniently from RMs by treatment with high salt. Released SRP is then purified by gel filtration and anion-exchange chromatography.

Solutions

Glass and plasticware are autoclaved, and stock solutions and distilled water are either autoclaved or filtered through 0.45-µm-pore-sized filters.

1. *Stock solutions* (see also preparation of RMs, Section III,A,1)

1 M Tris-OAc, pH 7.5: To make 1 liter of the buffer, dissolve 121.1 g Tris base in water, adjust to pH 7.5 with acetic acid, and complete to 1 liter.

10% (w/v) octaethylene glycol monododecyl ether: To make 10 ml of the solution, dissolve 1 g of octaethylene glycol monododecyl ether in water and complete to 10 ml.

2. *RM buffer*: As in solution 4 of Section III,A,1 (preparation of RMs).

3. *High salt solution*: 1.5 *M* KOAc and 15 m*M* $Mg(OAc)_2$. To make 50 ml of the solution, add 18.75 ml 4 *M* KOAc, 0.75 ml 1 *M* $Mg(OAc)_2$, and complete to 50 ml with water.

4. *Sucrose cushion*: 500 m*M* sucrose, 50 m*M* Tris–OAc, pH 7.5, 500 m*M* KOAc, 5 m*M* $Mg(OAc)_2$, and 1 m*M* DTT. To make 100 ml of the solution, add 25 ml 2 *M* sucrose, 5 ml 1 *M* Tris–OAc, pH 7.5, 12.5 ml 4 *M* KOAc, 0.5 ml 1 *M* $Mg(OAc)_2$, and complete to 100 ml with water. Add 0.1 ml 1 *M* DTT to the cold solution just before use.

5. *Gel filtration buffer*: 50 m*M* Tris–OAc, pH 7.5, 250 m*M* KOAc, 2.5 m*M* $Mg(OAc)_2$, 1 m*M* DTT, and 0.01% octaethylene glycol monododecyl ether. To make 1 liter of the buffer, add 50 ml 1 *M* Tris–OAc, pH 7.5, 62.5 ml 4 *M* KOAc, 2.5 ml 1 *M* $Mg(OAc)_2$, 1 ml 10% octaethylene glycol monododecyl ether, and complete to 1 liter with water. Add 1 ml 1 *M* DTT to the cold solution just before use.

6. *Washing buffer*: 50 m*M* Tris–OAc, pH 7.5, 350 m*M* KOAc, 3.5 m*M* $Mg(OAc)_2$, 1 m*M* DTT, and 0.01% octaethylene glycol monododecyl ether. To make 100 ml of the buffer, add 5 ml 1 *M* Tris–OAc, pH 7.5, 8.75 ml 4 *M* KOAc, 0.35 ml 1 *M* $Mg(OAc)_2$, 0.1 ml 10% octaethylene glycol monododecyl ether, and complete to 100 ml with water. Add 0.1 ml 1 *M* DTT to the cold solution just before use.

7. *SRP buffer*: 50 m*M* Tris–OAc, pH 7.5, 650 m*M* KOAc, 6 m*M* $Mg(OAc)_2$, 1 m*M* DTT, and 0.01% octaethylene glycol monododecyl ether. To make 100 ml of the buffer, add 5 ml 1 *M* Tris–OAc, pH 7.5, 16.25 ml 4 *M* KOAc, 0.6 ml 1 *M* $Mg(OAc)_2$, 0.1 ml 10% octaethylene glycol monododecyl ether, and complete to 100 ml with water. Add 0.1 ml 1 *M* DTT to the cold solution just before use.

Steps

This procedure is performed in the cold room and samples and buffers should be kept on ice.

1. Prepare ER-derived rough microsomes from two dog pancreas as described previously and resuspend the final RM pellet (see step 8 in Section III,A,1) in 50 ml RM buffer using a Dounce homogenizer.

2. Add 25 ml high salt solution and incubate for 15 min at 4°C on a turning wheel.

3. Distribute the membrane suspension equally to two 70-ml polycarbonate tubes for a Ti45 rotor onto 25 ml sucrose cushion per tube, avoid mixing.

4. Centrifuge at 32,000 rpm (120,000 *g*) for 1 h at 4°C in a Beckman Ti45 rotor.

5. In the meantime, prepare ten 10.4-ml polycarbonate tubes for a Ti70.1 rotor and add 1 ml sucrose cushion per tube.

6. After centrifugation (step 4), collect the supernatant and apply carefully, without mixing, onto the 1-ml sucrose cushions (see step 5).

7. Centrifuge at 65,000 rpm (388,000 *g*) for 1 h at 4°C in a Beckman Ti70.1 rotor.

8. Collect again the supernatant.

9. Concentrate the supernatant to approximately 10 ml in a 50-ml Amicon ultrafiltration unit equiped with a YM100 membrane.

10. Load concentrated sample onto a Sephacryl S-200 (2.6 × 20 cm) equilibrated with gel filtration buffer and elute with gel filtration buffer. The flow rate is 1 ml/min. Follow elution with a UV monitor (l = 280 nm) by using, e.g., the ÄKTAprime chromatography system from Amersham Pharmacia.

11. Collect flow through (20–25 ml) and load immediately onto a DEAE–Sepharose column (1 × 3 cm) equilibrated with gel filtration buffer. The flow rate is again 1 ml/min.

12. Wash column with 20 ml gel filtration buffer and 20 ml washing buffer.

13. Elute SRP with SRP buffer and collect peak fraction (2–3 ml). The SRP eluate has an absorption of 1–4 A_{260}/ml and a ratio A_{260}/A_{280} of approximately 1.4. Freeze 100-µl aliquots in liquid nitrogen and store at –80°C until use.

B. *In Vitro* Translation and Translocation Assay

Solutions

1. *Wheat germ extract*: Wheat germ extract for cell-free *in vitro* translation is prepared as described by Erickson and Blobel (1983) except that we use a gel filtration buffer with lower potassium and magnesium concentrations [40 m*M* HEPES–KOH, pH 7.6, 50 m*M* KOAc, 1 m*M* $Mg(OAc)_2$, 0.1% 2-mercaptoethanol]. Fresh wheat germ may be purchased from a local mill or from General Mills California. Store wheat germ in a desiccator over silica gel beads at 4°C. Considerable differences in translation efficiency may yield from different batches. Store wheat germ extract in 110-µl aliquots at –80°C and thaw only once.

2. *Capped mRNA*: To obtain mRNA coding for a secretory or a membrane protein, clone a cDNA encoding the protein of interest into a suitable expression vector downstream of a T7 or a SP6 promotor (e.g., pGEM from Promega Biotech). We generally prefer the SP6 promotor as the respective transcripts yield more efficient translation. Prepare plasmid DNA from *Escherichia coli* cultures using the Plasmid Maxi kit from Qiagen. For transcription, linearize the purified plasmid DNA with a suitable restriction enzyme that cuts downstream of the coding sequence. Alternatively, a template for transcription may be generated by polymerase chain reaction. Amplify the coding region of interest using *Pfu* DNA polymerase (Stratagene), an appropriate plasmid DNA as template, a forward primer containing the SP6 promotor, a Kozak sequence (Kozak, 1983) and a ATG for the initiation methionine, and a reverse primer starting with 5'-NNNNNNNNNCTA- to introduce a TAG stop codon at the desired position. Perform runoff *in vitro* transcription according to a standard protocol (e.g., in Sambrook *et al*., 1989) or by using a commercially available transcription kit (e.g., mMESSAGAmMACHINE kits from Ambion Cat. No. 1340 and 1344). Dissolve the resulting capped messenger RNA in water after extraction with phenol and chloroform and precipitation with sodium acetate and ethanol. Store mRNA at –80°C.

3. *Energy mix*: 50 m*M* HEPES–KOH, pH 7.6, 12.5 m*M* ATP, 0.25 m*M* GTP, 110 m*M* creatine phosphate, 10 mg/ml creatine kinase, and 0.25 m*M* of each amino acid *except* methionine. To make 1 ml of the solution, dissolve 41 mg creatin phosphate (disodium salt · $4H_2O$) and 10 mg creatin kinase in 590 µl water and add 50 µl 1 *M* HEPES–KOH, pH 7.6, 125 µl 100 m*M* ATP solution (Roche Applied Science), 2.5 µl 100 m*M* GTP solution (Roche Applied Science), and 250 µl 19 amino acids mix without methionine (Promega, 1 m*M* of each amino acid). Store the energy mix in 22 µl aliquots at –80°C. Do not refreeze!

4. *Salt mix*: 500 m*M* HEPES–KOH, pH 7.6, 1 *M* KOAc, and 50 m*M* $Mg(OAc)_2$. To make 1 ml of the solution, mix 500 µl 1 *M* HEPES–KOH, pH 7.6, 250 µl 4 *M* KOAc, 70 µl 1 *M* $Mg(OAc)_2$, and 180 µl water.

5. *SRP buffer*: As in solution 7 of Section III,A,2. (preparation of SRP).

6. *20% ($^w/_v$) trichloroacetic acid*: To make 100 ml of the solution, dissolve 20 g trichloroacetic acid in water and complete to 100 ml.

Steps

1. Per assay (25 µl), mix on ice 6 µl water, 1 µl salt mix, 2 µl energy mix, 10 µl wheat germ extract, 2 µl SRP buffer or SRP solution (see Section III,A,2, step 12),

2 µl RM suspension (see Section III,A,1, step 8), 1 µl [^{35}S]methionine (>1000 Ci/mmol), and 1 µl capped mRNA.
2. Incubate for 60 min at 25°C.
3. Add 25 µl (1 volume) 20% trichloroacetic acid to precipitate proteins and centrifuge at 14,000 rpm for 3 min at room temperature in an Eppendorf centrifuge.
4. Discard supernatant. Wash pellet with 150 µl cold acetone, and centrifuge as in step 3.
5. Discard supernatant and repeat step 4.
6. Discard supernatant, centrifuge tube shortly, and remove residual acetone completely with a pipette.
7. Add 20–30 µl sample buffer for SDS–polyacrylamide gel electrophoresis and heat for 10 min at 65°C.
8. Load 5–10 µl onto a SDS–polyacrylamide gel and analyze the sample by electrophoresis. Radiolabelled proteins can be visualized by autoradiography, fluorography, or on a phosphorimager.

Controls: Translation without mRNA (add water instead); translation without membranes (add RM buffer instead, see solution 4 in Section III,A,1).

Note: Translation and translocation assays have to be optimized for each mRNA with respect to magnesium and potassium concentrations as well as to the amount of mRNA, SRP, and membranes. Optimal salt concentrations vary from 1 to 3.5 m*M* magnesium and from 70 to 150 m*M* potassium and are adjusted by using adapted salt mixes. The amount of SRP and membranes may be varied by diluting SRP and RM solutions with the respective buffers.

C. Assays to Characterize the Translocation Products

1. Protease Protection Assay

Proteinase K is used to test the translocation of proteins or parts of proteins across microsomal membranes (Blobel and Dobberstein, 1975). Membranes are impermeable to the protease and therefore only proteins or protein domains exposed on the cytoplasmic side of the microsomes are digested. To demonstrate that only intact microsomal vesicles protect lumenal proteins or protein domains, nonionic detergent (e.g., Triton X-100) is added to open the membrane.

Protease treatment is also used to characterize the topology of membrane proteins. In this case, protease treatment is often followed by immunoprecipitations with antibodies directed against defined regions of the protein investigated. Successful immunoprecipitations indicate that the respective domains are exposed on the lumenal side of the microsomes and are protected from the protease.

Solutions

1. *Sucrose cushion*: 500 m*M* sucrose, 50 m*M* HEPES–KOH, pH 7.6, 50 m*M* KOAc, 2 m*M* $Mg(OAc)_2$, and 1 m*M* DTT. To make 10 ml of the buffer, add 1.25 ml 2 *M* sucrose, 0.5 ml 1 *M* HEPES–KOH, pH 7.6, 125 µl 4 *M* KOAc, 20 µl 1 *M* $Mg(OAc)_2$, 10 µl 1 *M* DTT, and complete to 10 ml with water.
2. *3 mg/ml proteinase K*: To make 1 ml of the solution, dissolve 3 mg proteinase K in 1 ml water.
3. *20 mg/ml PMSF solution*: As is solution 1 of Section III,A,1 (preparation of RMs).
4. *10% ($^{w}/_{v}$) Triton X-100*: To make 10 ml of the solution, dissolve 10 g Triton X-100 in water and complete to 10 ml.
5. *20% ($^{w}/_{v}$) trichloroacetic acid*: As in solution 6 of Section III,B.

Steps

1. Perform a translation/translocation assay (25 µl) as described in Section III,B (steps 1 and 2).
2. In the meantime, prepare a 200-µl thick-wall polycarbonate tube for a TLA100 rotor and add 100-µl sucrose cushion.
3. After translation/translocation, apply the reaction mixture carefully onto the 100-µl sucrose cushion.
4. Wash microsomes by centrifugation through the sucrose cushion at 48,000 rpm (~100,000 *g*) for 3 min at 4°C in a Beckman TLA100 rotor.
5. Remove the supernatant with a pipette.
6. Resuspend the microsome pellet in 25 µl RM buffer (see solution 4 in Section III,A,1) and split the sample in three 8-µl aliquots.

7a. To the first aliquot (mock treatment) add 2 µl water.

7b. To the second aliquot add 1 µl proteinase K solution (3 mg/ml) and 1 µl water.

7c. To the third aliquot add 1 µl proteinase K solution (3 mg/ml) and 1 µl 10% Triton X-100.

8. Incubate the samples for 10 min at 25°C.
9. Stop proteolysis by adding 1 µl 10 mg/ml PMSF per sample.
10. Add 40 µl water and 50 µl 20% trichloroacetic acid to each sample to precipitate protein.
11. Centrifuge samples, wash protein pellets with acetone, and analyze samples by SDS–polyacrylamide gel electrophoresis as described in Section III,B, steps 3–8.

2. Sodium Carbonate Extraction

By alkaline treatment with sodium carbonate at pH 11, microsomal membranes are opened and release their content and peripherally associated proteins. The

method is used to separate these proteins from proteins integrated into the lipid bilayer (Fujiki *et al*., 1982).

Solutions

1. *0.1 M Na_2CO_3*: To make 10 ml of the solution, dissolve 106 mg Na_2CO_3 in water and complete to 10 ml. Prepare just prior to use.
2. *Alkaline sucrose cushion*: 0.1 *M* Na_2CO_3 and 250 m*M* sucrose. To make 10 ml of the solution, dissolve 106 mg Na_2CO_3 in water, add 1.25 ml 2 *M* sucrose (see solutions 1 of Section III,A,1), and complete to 10 ml with water.
3. *20% ($^w/_v$) trichloroacetic acid*: As in solution 6 of Section III,B.

Steps

1. Perform a translation/translocation assay (25 µl) as described in Section III,B (steps 1 and 2).
2. Wash microsomes by centrifugation through a sucrose cushion as described in Section III,C,1, steps 2–5.
3. Resuspend microsome pellet in 25 µl carbonate solution and incubate for 15 min on ice.
4. In the meantime, prepare a 200-µl thick-wall polycarbonate tube for a TLA 100 rotor and add 100-µl alkaline sucrose cushion.
5. For centrifugation, apply the sample (step 3) carefully onto a sucrose cushion in the polycarbonate tube.
6. Centrifuge at 55,000 rpm (130,000 *g*) for 10 min at 4°C in a Beckman TLA 100 rotor.
7. Recover the supernatant and pellet.

8a. To the supernatant add 150 µl 20% trichloroacetic acid to precipitate proteins. Centrifuge the sample, wash the protein pellet with acetone, and prepare the sample for SDS–polyacrylamide gel electrophoresis as described in Section III,B, steps 3–8.

8b. To the pellet add directly 20–30 µl sample buffer for SDS–polyacrylamide gel electrophoresis (see Section III,B, steps 7 and 8).

9. Analyze samples by SDS–polyacrylamide gel electrophoresis and autoradiography or phosphorimaging.

3. Inhibition of N-Glycosylation with Glycosylation Acceptor Tripeptide

The recognition sites for N-glycosylation in the ER are Asn-X-Ser and Asn-X-Thr. In the cell-free *in vitro* translation/translocation system described herein, the tripeptide *N*-benzoyl-Asn-Leu-Thr-methylamide efficiently competes with newly synthesized proteins for N-glycosylation (Lau *et al*., 1983). The translocated protein is therefore not glycosylated in the presence of acceptor tripeptide, and the effects of oligosaccharides, e.g., on protein folding and assembly, may be investigated.

Solution

Acceptor tripeptide solution: Synthesize *N*-Benzoyl-Asn-Leu-Thr-methylamide on a peptide synthesizer. Dissolve the tripeptide in methanol at a concentration of 0.5 m*M* (0.23 mg/ml) and store the stock solution at –80°C.

Steps

1. Evaporate per translation/translocation assay (25 µl) 1.5 µl acceptor tripeptide solution in a test tube using a Speed-Vac centrifuge.
2. Add the components for the translation/translocation assay to the tripeptide, vortex gently, and perform the assay as described in Section III,B (steps 1 and 2).
3. Precipitate the sample with trichloroacetic acid and analyze by SDS–polyacrylamide gel electrophoresis and autoradiography (see Section III,B, steps 3–8).

4. Endoglycosidase H Treatment

Treatment with endoglycosidase H is used to test N-glycosylation of proteins translocated into microsomal membranes. The glycosidase cleaves oligosaccharides of the high mannose type from glycoproteins, leaving an *N*-acetylglucosamine residue attached to the polypeptide (Tarentino *et al*., 1974).

Solutions

1. *Denaturing solution*: 0.5% (w/v) SDS and 1% (v/v) 2-mercaptoethanol. To make 10 ml of the solution, dissolve 50 mg SDS in water, add 100 µl 2-mercaptoethanol, and complete to 10 ml with water.
2. *0.5 M Na-citrate, pH 5.5*: To make 10 ml of the buffer, dissolve 1.47 g Na_3-citrate · 2 H_2O in water, adjust to pH 5.5 with HCl solution, and complete to 10 ml.

Steps

1. Perform a translation/translocation assay (25 µl) as described in Section III,B (steps 1 and 2).
2. Wash microsomes by centrifugation through a sucrose cushion as described in Section III,C,1, steps 2–5.
3. Resuspend microsome pellet in 25 µl denaturing solution and incubate for 10 min at 95°C.
4. Add 2.8 µl reaction buffer and 1 µl endoglycosidase H (1000 U/µl). Incubate for 1 h at 37°C.
5. Precipitate the sample with trichloroacetic acid and analyze by SDS–polyacrylamide gel electrophoresis and autoradiography or phorphorimaging (see Section III,B, steps 3–8).

IV. COMMENTS

As an alternative to wheat germ extract, commercially available rabbit reticulocyte lysate (e.g., from Promega) may be used for cell-free *in vitro* translation. Reticulocyte lysate contains sufficient SRP and therefore no additional SRP is usually required for optimization of translocation. When reticulocyte lysate is used, however, RMs should be treated with micrococcal nuclease to digest endogenous mRNA (Garoff *et al*., 1978). The reticulocyte translation machinery will otherwise promote completion of nascent pancreatic secretory proteins.

CHAPTER

31

Use of Permeabilised Mast Cells to Analyze Regulated Exocytosis

Gerald Hammond and Anna Koffer

I. INTRODUCTION

Cell permeabilisation allows manipulation of experimental conditions that is typical for *in vitro* assays while maintaining the integrity of cellular architecture. Permeabilised mast cells, both primary and cultured cell lines, such as rat basophilic leukemia (RBL-2H3) or human mast cells (HMC-1), have been used to investigate the mechanism of exocytosis, endocytosis, phospholipid metabolism, and cytoskeletal responses. After permeabilisation with a bacterial exotoxin, streptolysin-O (SL-O), cells lose their cytosolic components but retain intact and functional secretory vesicles. These cells provide a well-controlled system, ideal for reconstitution type experiments. Permeabilisation by SL-O is usually irreversible. Reversible permeabilisation of rat peritoneal mast cells can be achieved by exposure to the tetrabasic anion of ATP (ATP^{4-}). This creates lesions (Cockcroft and Gomperts, 1979) due to interaction with a specific cell surface receptor (Tatham *et al*., 1988), the dimensions of which vary with increasing ATP^{4-} concentration (Tatham and Lindau, 1990). The pores created by ATP^{4-} are, however, always smaller than those due to SL-O. Combination of the two methods allows control of the extent of leakage of cytosolic factors (Koffer and Gomperts, 1989).

The SL-O monomer binds to membrane cholesterol and then oligomerises to form large pores, up to 30 nm in diameter (Bhakdi *et al*., 1993; Buckingham and Duncan, 1983; Palmer *et al*., 1998). The concentration of SL-O and the time of exposure needed for the permeabilisation vary for different cells. Appropriate conditions can be found using nonpermeant fluorescent dyes, such as ethidium bromide or rhodamine phalloidin. Adherent cells usually require higher concentrations of SL-O and/or longer exposure times than suspended cells.

Holt and Koffer (2000) described the use of various recombinant mutants of small Rho GTPases in permeabilised mast cells. Other reviews of permeabilisation techniques have been published previously (Gomperts and Tatham, 1992; Larbi and Gomperts, 1996; Tatham and Gomperts, 1990). This article describes a "SL-O prebind" method for permeabilising glass-attached primary rat peritoneal mast cells. This method is based on the temperature-independent binding of SL-O to the plasma membrane and the temperature-dependent polymerisation of bound SL-O molecules required to form pores (Sekiya *et al*., 1996).

Hexosaminidase, released from stimulated permeabilised cells into the supernatant, is assayed biochemically, while the remaining cells are processed for imaging. Thus, functional and morphological studies can be done in parallel. Immunostaining of mast cells poses specific problems due to the presence of highly charged secretory granules. Cell permeabilisation allows introduction of antibodies into cells before fixation. This is advantageous, as antibodies come into contact with granules still intact rather than with those permeabilised by fixatives. Staining before fixation is also recommended for membranous structures (e.g., staining with anti-PIP_2), as these are often disrupted by fixatives. Moreover, pretreatment of permeabilised cells with antibodies is useful for functional studies investigating the effects of the activity of the blocking antigen on cellular responses. We describe pretreatment of permeabilised cells before triggering, the assay of released hexosaminidase, and subsequent immunostaining either before or after fixation, with steps taken to avoid unspecific staining. The former

method is an adaptation of a previously described procedure (Guo *et al*., 1998).

II. MATERIALS AND INSTRUMENTATION

Percoll (1.13 ± 0.005 g/ml stock) is from Amersham Biosciences (1 liter, Cat. No. 17-0891-01). 10× calcium/magnesium-free phosphate-buffered saline (PBS) with defined salt densities is from Gibco RBL (500 ml, Cat. No. 14200-067). Streptolysin-O (SL-O, Cat. No. 302) and sodium dithionite (Cat. No. 303, needed for reduction of SL-O) are from iTEST plus, Ltd. (Czech Republic). Other preparations of SL-O can be obtained from Sigma (e.g., Cat. No. S 5265), and SL-O can also be obtained from VWR Scientific, US (Cat. No. DF 0482-60, manufactured by Difco), but in our hands, the just-described reagent has given the most reproducible results. Sigma provides EGTA (Cat. No. E-4378), HEPES (Cat. No. H-4034), PIPES (Cat. No. P-1851), Tris (Cat. No. T-1503), glutamic acid, monopotassium salt (Cat. No. G-1501), 4-methylumbelliferyl-*N*-acetyl-β-D-glucosaminide (Cat. No. M2133), dimethyl sulphoxide (DMSO, Cat. No. D-8779), Triton X-100 (Cat. X-100), goat serum (Cat. No. G9023), unconjugated succinyl-concanavalin A (SCA, Cat. No. L 3885), lysophosphatidylcholine (LPC, Cat. No. L-4129), paraformaldehyde (Cat. No. P-6148), and polyethylene glycol (molecular weight 3550, Cat. No. P-4338). Na_2ATP (trihydrate, Cat. No. 519979), 100 m*M* GTPγS solution (Cat. No. 1110 349), and digitonin (1 g, Cat. No. 1500 643) are from Boehringer. Citric acid (Cat. No. 100813M), glycine (Cat. No. 101196X), solutions of 1 *M* $MgCl_2$ (Cat. No. 22093 3M) and 1 *M* $CaCl_2$ (Cat. No. 190464 K), and 18-mm^2 coverslips, thickness 1 (Cat. No. 406/0187/23), are from BDH. Mowiol 4–88 is from Harco (Harlow Chemical Company Ltd.).

Pointed bottom tubes (10 ml, Cat. No. B99 783) are from Philip Harris. "Multitest" 8-well slides (Cat. No. 6040805) are from ICN Biomedicals, Inc. Ninety-six V-well clear plates (Cat. No. 651 101) and 96-well flat-bottom black plates (Cat. No. 655 076) are from Greiner Bio-One Ltd. The eight channel pipettes are Transferepettes-8, 20–100 µl, from Brand, Germany. The refrigerated centrifuge, Omnifuge 2.ORS, is from Heraeus. The plate reader, Polarstar Galaxy, is from BMG Labtechnologies.

A moisture box is a small plastic box with a well-fitting lid lined with wet tissue paper. A plastic tray that can take up to five 8-well slides is placed inside the box. Nylon mesh is from net curtain material obtained from John Lewis Department Store (London).

III. PROCEDURES

A. Preparation of Rat Peritoneal Mast Cells

This procedure has been described in detail previously (Gomperts and Tatham, 1992) and only a brief version is given here.

Solutions

1. *Percoll at a final density of 1.114 g/ml*: Prepare using the following formula:

$$\rho_{\text{Final}} \cdot V_{\text{Final}} = \rho_{\text{Percoll stock}} \cdot V_{\text{Percoll stock}} + \rho_{10\times\ \text{PBS}} \cdot \left(\frac{V_{\text{Final}}}{10}\right) + \rho_{H_2O^{\infty}} \cdot \left(V_{\text{Final}} - V_{\text{Percoll stock}} - \frac{V_{\text{Final}}}{10}\right)$$

ρ is density (g/ml) and V is volume (ml). Use 10× PBS stock with defined density and highly purified sterile water so that the density may be taken as 1.000 g/ml. Prepare 50–100 ml of Percoll solution in a sterile environment and store in 2-ml aliquots at –20°C (may be stored several years). Warm at room temperature, mix thoroughly, and transfer into a pointed bottom tube just before use.

2. *Chloride buffer (CB)*: Final concentrations 20 m*M* HEPES, 137 m*M* NaCl, 2.7 m*M* KCl, 2 m*M* $MgCl_2$, 1.8 m*M* $CaCl_2$, 5.6 m*M* glucose, and 1 mg/ml bovine serum albumin (BSA), pH 7.2. Prepare 10× concentrated stock solution without BSA. To make 500 ml of 10× CB, dissolve 40 g NaCl, 1 g KCl, 23.83 g HEPES, 5 g glucose, 10 ml of 1 *M* $MgCl_2$, and 9 ml of 1 *M* $CaCl_2$ in distilled water, adjust pH to 7.2 with NaOH, and complete to 500 ml. Store in 50-ml aliquots at –20°C. Thaw, mix, dilute, add BSA, and readjust pH to 7.2 before use.

Steps

1. Use Sprague–Dawley rats. "Retired breeders" of either sex were used but other strains of various ages are also suitable; older rats provide more cells.
2. After peritoneal lavage of rats, pellet the cells present in the washings by centrifugation (5 min at 250 *g*).
3. Resuspend cells in ~7 ml of CB and filter the suspension through a nylon mesh.
4. Overlay the filtered suspension onto a 2-ml cushion of Percoll solution placed in a 10-ml pointed bottom tube.
5. Centrifuge (10 min at 250 *g*, room temperature, slow acceleration). Dense mast cells pellet through the Percoll cushion while contaminating cells (neutrophils, macrophages, red blood cells) remain at the buffer–Percoll interface.

6. Remove the buffer, interface cells, and Percoll, resuspend the pellet in ~1 ml CB, and transfer into a clean tube (avoid touching the tube wall where some of the contaminating cells may still adhere).
7. Add further ~10 ml CB, centrifuge (5 min at 250 *g*), and resuspend pellet in 1.5 ml CB. About 1×10^6 cells (>95% purity) are obtained from one rat. This is sufficient for at least five 8-well slides.

B. Permeabilisation

SL-O binds to the cells on ice, excess SL-O (and any other additives) is removed by washing with a cold buffer, and cells are then permeabilised by the addition of warm buffer. Permeabilised cells are finally washed to remove freely soluble ions, nucleotides, and proteins before the addition of triggering solutions. A small loss of responsiveness occurs due to the "run-down" during the washing (10–20%) but the advantage is that nucleotides, ions, and proteins leaking out from cells do not come into contact with those applied exogenously. If this is of no concern (e.g., when ATP levels have been depleted by metabolic inhibition), triggers can be added at the time of permeabilisation.

Solutions

1. *Glutamate buffer (GB)*: Final concentrations 137 m*M* Kglutamate, 20 m*M* PIPES, 2 m*M* $MgCl_2$, and 1 mg/ml BSA, pH 6.8. Prepare 10× concentrated stock solution without BSA. To make 250 ml of 10× GB, dissolve 63.43 g glutamic acid, 15.12 g PIPES, and 5 ml 1 *M* $MgCl_2$ in distilled water, adjust pH to 6.8 with glacial acetic acid, and complete to 250 ml. Store 50-ml aliquots at –20°C. Thaw, mix, dilute, add BSA, and readjust pH to 6.8 before use.

2. *100 mM EGTA stock solution*: Store in 5- to 10-ml aliquots at –20°C. To make 100 ml of 100 m*M* EGTA, dissolve 3.804 g EGTA in 100 ml distilled water.

3. *Glutamate buffer–3 mM EGTA (GBE)*: Add 300 µl of 100 m*M* EGTA to 10 ml GB.

4. *Streptolysin-O (SL-O)*: Streptolysin-O from iTEST is supplied as a lyophilized powder in vials of 22 IU and must be reduced before use with sodium dithionite. To prepare a working stock at 20 IU/ml, dissolve one vial of SL-O in 550 µl PBS containing 0.1% BSA and one vial of 20 mg sodium dithionite in 550 µl PBS containing 0.1% BSA. Mix these two solutions and incubate at 37°C for 1 h. SL-O is now reduced and the solution is ready for use. For storing, divide the reduced SL-O solution into 100-µl aliquots, freeze under liquid nitrogen, and store at –80°C. Just before use, warm and mix and use on the same day. For the "prebind" method, use SL-O at the final concentration of 1.6 IU/ml: Add 1.15 ml of GBE to 100 µl of 20 IU SL-O/ml. Thus, one aliquot will provide 1.25 ml of working solution, enough for one experiment.

Steps

1. Clean 8-well slides with distilled water and then ethanol. Leave to dry. Label the slides.
2. Pipette 30 µl cell suspension in CB per well (i.e., ~20,000 cells per well). Allow 2–4 wells for each condition. Keep 150 µl of the cell suspension aside for secretion assay (see solution D3 and step D2).
3. Let cells attach for 1 h at room temperature on a plastic tray in a moisture box[1].
4. Place the slides on a metal plate on ice.
5. Wash the cells once with 30 µl ice-cold GBE.
6. Add 30 µl ice-cold SL-O (1.6 IU/ml GBE) to each well and incubate on ice for 8 min to allow SL-O to bind to the plasma membranes.
7. Wash the cells once with 30 µl ice-cold GBE to remove unbound SL-O and additives.
8. Permeabilise the cells by adding 30 µl warm (37°C) GBE and transferring to a prewarmed moisture box at 37°C for 90 s.
9. Chill the cells by placing the slide back on ice.
10. Wash once with 30 µl GB (without EGTA) to remove freely soluble components.

C. Pretreatment and Triggering

Solutions

1. *GB–30 µM EGTA*: Add 3 µl of 100 m*M* EGTA to 10 ml GB.

2. *Agent to be tested, dissolved in GB–30 µM EGTA*. These can include an antibody directed against a specific antigen whose activity is being tested. Dilution of the antibody is 10–20× less than that used for immunostaining.

3. *100 mM MgATP*: To make 16.5 ml of 100 m*M* MgATP, add 6.61 ml of 0.5 *M* Tris and 1.65 ml of 1 *M* $MgCl_2$ to 1 g Na_2ATP and add H_20 to a final volume of 16.5 ml. Store in 100-µl aliquots at –20°C.

4. *10 mM GTPγS*: Dilute the 100 m*M* stock solution with GB just before use.

5. *Ca^{2+} /EGTA buffers system*: These are obtained as described previously (Gomperts and Tatham, 1992; Tatham and Gomperts, 1990) by mixing solutions of Ca:EGTA and EGTA, both at ~100 m*M* and pH 6.8 at specified ratios. Keep 10-ml aliquots of 100 m*M* stock

[1] In some experiments, it is desirable to deplete endogenous ATP from intact cells with metabolic inhibitors. In this case, after step 2, incubate attached intact cells with CB where glucose has been omitted and 10 µ*M* antimycin A with 6 m*M* 2-deoxyglucose included. More than 90% depletion of ATP is achieved in 20 min at 30°C (Koffer and Churcher, 1993).

TABLE I Assembling 1 ml Each of the Four Typical Triggering Solutions

Stock	EA	EGA	CA	CGA
EGTA (100 m*M*)	30 µl	30 µl	0	0
ATP (100 m*M*)	30 µl	30 µl	30 µl	30 µl
GTPγS (10 m*M*)	0	5 µl	0	5 µl
Ca:EGTA (pCa5) (100 m*M*[a])	0[a]	0[a]	30 µl[a]	30 µl[a]
GB[a]	940 µl	935 µl	940 µl	935 µl

[a] Note that 100 m*M* is an ideal stock concentration of Ca:EGTA buffer, although the final concentration of stock is calculated empirically when preparing the buffers (Tatham and Gomperts, 1990). Therefore, the volume required to give the final 3 m*M* concentration of Ca:EGTA final from stock will need to be adjusted.

solutions at –20°C. Free Ca^{2+} concentration is controlled by adding the appropriate Ca^{2+}/EGTA buffer to a final concentration of 3 m*M*.

6. *Triggering solutions*: Various combinations of calcium, MgATP, and GTPγS (or GTP) in GB are used for cell stimulation. The following four conditions (final concentrations) are used most frequently: EA (basal condition, 3 m*M* EGTA–3 m*M* ATP); EGA (as EA with 50 µ*M* GTPγS); CA (3 m*M* Ca:EGTA /to maintain [Ca^{2+}] at pCa5)–3 m*M* ATP; and CGA (as CA with 50 µ*M* GTPγS). Table I gives volumes for making triggering solutions using the aforementioned stock solutions.

Steps

1. Immediately after step B9 (permeabilised cells are still on the cold plate), add 15 µl of a solution containing the protein or reagent to be tested in GB–30 µ*M* EGTA.
2. Incubate on ice (in a moisture box) for 5–30 min. The time of incubation depends on the size of the protein/reagent to be introduced into the cells. For example, small proteins such as Rho GTPases require 5–10 min but antibodies may require up to 30 min to penetrate the SL-O lesions. The time and temperature for action of the agents should be considered.
3. Add 15 µl of 2× concentrated triggering solutions containing combinations of calcium/EGTA, MgATP, and GTPγS. (If no pretreatment was required, omit steps 1 and 2 and add 30 µl of 1× triggering solutions.)
4. Stimulate by transferring to a prewarmed moisture box and incubate for 30 min at 37°C. Note that a shorter time (10–15 min) may be sufficient when GTPγS is included in the triggering solution.
5. Stop reaction by transferring slides back onto the ice-cold metal plate.

D. Secretion Assay

Solutions

1. *Fluorogenic hexosaminidase substrate*: Final concentrations 1 m*M* 4-methylumbelliferyl-*N*-acetyl-β-D-glucosaminide, 0.1% DMSO, 0.01% Triton X-100, and 200 m*M* citrate, pH 4.5. To make 500 ml, mix 189.7 mg of the reagent with 0.5 ml DMSO and then add 500 ml of 0.2 *M* citrate–0.01% Triton X-100. To make citrate solution, dissolve 21 g of citric acid and 0.5 g of Triton X-100 in H_2O, adjust pH to 4.5 using NaOH, and make volume up to 500 ml. Using Whatman filter paper No. 1, filter and store in 20- to 50-ml aliquots at –20°C. Hexosaminidase, released from mast cells, hydrolyses the substrate, producing fluorescent 4-methylumbelliferone. Triton reduces surface tension and thus artifacts.
2. *0.5 M Tris*: Dissolve 60.55 g of Tris in water, total volume 1 liter.
3. *GB*
4. *Solution for assaying total hexosaminidase content*: To 150 µl of the original cell suspension (saved at step B2), add 1 ml of 0.2% Triton X-100 in GB and mix to lyse the cells.

Steps

1. After step C5, remove 15 µl (i.e., one-half) of the triggering solutions and transfer into cold transparent 96 V-well plates (on ice).
2. Add 100 µl of cold GB to each V well using a multichannel pipette.
3. Pipette 115 µl of the solution for assaying the total hexosaminidase content into one column of V wells (i.e., 8 × 115 µl).
4. Pipette 115 µl of GB into one column of V wells (i.e., 8 × 115 µl, to be used for blanks).
5. Balance with another 96 V-well plate.
6. Centrifuge for 5 min at 250 *g* at 4°C to remove any detached cells.
7. Using a multichannel pipette, remove 50 µl of the supernatant from each V well and transfer into a black flat-bottom 96-well plate.
8. Add 50 µl of the fluorogenic hexosaminidase substrate to each well to assay for the release of hexosaminidase.
9. Cover with lid and wrap in aluminium foil.
10. Incubate 1–2 h at 37°C or overnight at room temperature.
11. Quench with 100 µl of 0.5 *M* Tris.
12. Read fluorescence using a fluorescence plate reader (excitation and emission filter at 360 and 405 nm, respectively).
13. Calculate percentage secretion as follows: % secretion = 100 × (*X*-*B*)/(*T*-*B*), where *X*, *B*, and *T* are

fluorescence values of the sample, average blank, and average total hexosaminidase, respectively.

E. Immunostaining before Fixation

Cells remaining on eight-well slides after removal of the trigger solutions for secretion assays can be stained by fluorescent phalloidin to evaluate the morphology of F-actin (Holt and Koffer, 2000) or be immunostained. Processing of the cells should be done immediately after step D1 and the secretion assay delayed until the cells are in a blocking solution or fixed.

Solutions

1. *Stock solution of succinyl-Con A, SCA, 5 mg/ml*: Dissolve 25 mg in 5 ml GB without BSA. Store 100-µl aliquots at –20°C.
2. *Glutamate buffer–3 mM EGTA (GBE)*: Add 300 µl of 100 m*M* EGTA to 10 ml GB.
3. *Blocking solution*: 32% goat serum–250 µg/ml succinyl-Con A (SCA)–GBE. To make 1 ml, add 320 µl goat serum and 50 µl SCA (5 mg/ml stock) to 630 µl GBE.
4. *Antibody solution*: 16% goat serum in GBE. To make 1 ml, add 160 µl goat serum to 840 µl GBE. Higher concentrations of antibodies are usually required if these are introduced into permeabilised cells before fixation than those used for after-fixation staining. *Note*: After dilution, centrifuge all antibodies for 1 min at ~15,000 *g* to remove any aggregates.
5. *Fixative*: 3% paraformaldehyde in GBE (without BSA)–4% polyethylene glycol (PEG, MW 3200). To make 100 ml of fixative, first prepare GB (without BSA)–3 m*M* EGTA–4% (w/v) PEG. Add 3 g of paraformaldehyde to ~80 ml of GBE-PEG and gently heat and stir in a fume cupboard, adding 10 *M* NaOH in small doses until paraformaldehyde is dissolved and colourless. Adjust pH to 6.8. Filter (in a fume cupboard) using Whatman filter paper No. 1 and store 10-ml aliquots at –20°C.
6. *Mounting solution*: Add 12 ml of water to 12 g glycerol and 4.8 g Mowiol 4-88 in a conical flask and mix for 2 h or overnight at room temperature. Add 24 ml 0.2 *M* Tris, pH 8.5, and 400 µl of 100 m*M* EGTA and stir further at 50°C (~10 min). Centrifuge for 30 min at ~5000 *g*. Discard pellets, stir the supernatants again, and store in 1-ml aliquots at –20°C.

Steps

1. After step C5 and D1 (i.e., after triggering and removal of aliquots for secretion assay), remove the remaining triggering solutions.
2. Wash once in 30 µl GBE to remove residual calcium/GTPγS.
3. Add 30 µl of blocking solution to block unspecific binding.
4. Incubate in a moisture box for 30 min at room temperature.
5. Remove blocking solution and add 30 µl of the primary antibody diluted in antibody solution.
6. Incubate in a moisture box for 30–60 min at room temperature.
7. Wash the cells 4× with 30 µl GBE.
8. Add 30 µl of secondary antibody, conjugated to a fluorescent probe and diluted in antibody solution.
9. Incubate in a moisture box for 30 min at room temperature.
10. Wash the cells 4× with 30 µl GBE
11. Fix the cells by adding 30 µl fixative for 20 min at room temperature in a moisture box.
12. Wash the cells 4× with 30 µl GBE.
13. Aspirate wells until dry and add 4 µl mounting solution and remove any bubbles.
14. Cover eight wells with 18-mm^2 coverslips.

F. Immunostaining after Fixation

To improve access of antibodies into fixed cells, permeabilisation with either lysophosphatidyl choline or digitonin is required. Blocking can be done with a lower concentration of serum when cells are fixed, but succinyl–concanavalin A should still be included because fixation exposes granule matrices that may bind antibody nonspecifically. Including a 5-min wash step with 0.4 *M* NaCl before blocking also reduces nonspecific binding of antibodies to the granule matrices without affecting cellular morphology in fixed cells.

Solutions

1. *Fixative and mounting solutions as described earlier.*
2. *GBE*: Add 300 µl of 100 m*M* EGTA to 10 ml GB.
3. *LPC-GBE, 80 µg/ml of LPC in GBE*: Used for permeabilisation of fixed cells. Stock solution is 40 mg of LPC/ml ethanol. Store at –20°C. Warm to ~40°C and mix before use. Dilute 500×, i.e., 2 µl into 1 ml of GBE to obtain the final concentration.
4. *0.2 µM digitonin–GBE*. Used as an alternative solution for permeabilisation of fixed cells. Digitonin is stored as a 1 m*M* stock solution in DMSO at room temperature. Stock is prepared by dissolving 1.23 mg digitonin/ml in DMSO. Dilute 10 µl of stock digitonin in 990 µl GBE and then add 50 µl of this 10 µ*M* solution to 950 µl GBE to prepare the 0.2 µ*M* solution.
5. *50 mM glycine–GBE*: Make 10 ml of stock 1 *M* glycine solution by adding 0.75 g glycine to 10 ml GB (without BSA). Store in 1-ml aliquots at –20°C. Add 50 µl of 1 *M* glycine stock to 950 µl GBE.

6. *Blocking solution*: 5% goat serum–250 µg/ml succinyl-Con A (SCA)–GBE. To make 1 ml, add 50 µl goat serum and 50 µl stock SCA (5 mg SCA /ml GB without BSA) to 900 µl GBE.

7. *0.4 M NaCl*: For 1 ml, add 100 µl 4 *M* NaCl to 900 µl GBE.

8. *Antibody solution*: 5% goat serum in GBE. To make 1 ml, add 50 µl goat serum to 950 µl GBE. After dilution, centrifuge all antibodies for 1 min at ~15,000 *g* to remove any aggregates.

Steps

1. After step C5 and D1 (i.e., after triggering and removal of aliquots for secretion assay), remove the remaining triggers.
2. Fix the cells by adding 30 µl fixative for 20 min at room temperature in a moisture box.
3. Wash the cells 4× with 30 µl 50 m*M* glycine–GBE.
4. Add 30 µl of LPC-GBE (or digitonin-GBE).
5. Permeabilise fixed cells for 20 min with LPC-GBE or for 5 min with digitonin–GBE, both at room temperature.
6. Wash the cells 4× with 30 µl GBE.
7. Remove GBE and add 30 µl of 0.4 *M* NaCl in GBE to each well.
8. Incubate in a moisture box for 5 min at room temperature.
9. Wash the cells 4× with 30 µl GBE.
10. Add 30 µl of blocking solution.
11. Incubate in a moisture box for 30 min at room temperature.
12. Remove blocking solution and add 30 µl of the primary antibody diluted in antibody solution.
13. Incubate in a moisture box for 30–60 min at room temperature.
14. Wash the cells 4× with 30 µl GBE.
15. Add 30 µl of secondary antibody, conjugated to a fluorescent probe, diluted in antibody solution.
16. Incubate in a moisture box for 30 min at room temperature.
17. Wash the cells 4× with 30 µl GBE.
18. Aspirate wells until dry and add 4 µl mounting solution; remove any bubbles.
19. Cover eight wells with 18-mm^2 coverslips.

IV. COMMENTS

We have described a method that allows assessment of mast cell secretory function in parallel with studies of cell morphology. An example is shown in Fig. 1. Permeabilised mast cells were stained with anti-β-actin antibody after exposure to the combinations of calcium, ATP, and GTγS described in Table I. Confocal images of equatorial slices are shown together with typical secretory responses shown in parentheses (percentage of released hexosaminidase). The method provides a large potential for investigating the significance of rearrangements of specific molecules to exocytotic function.

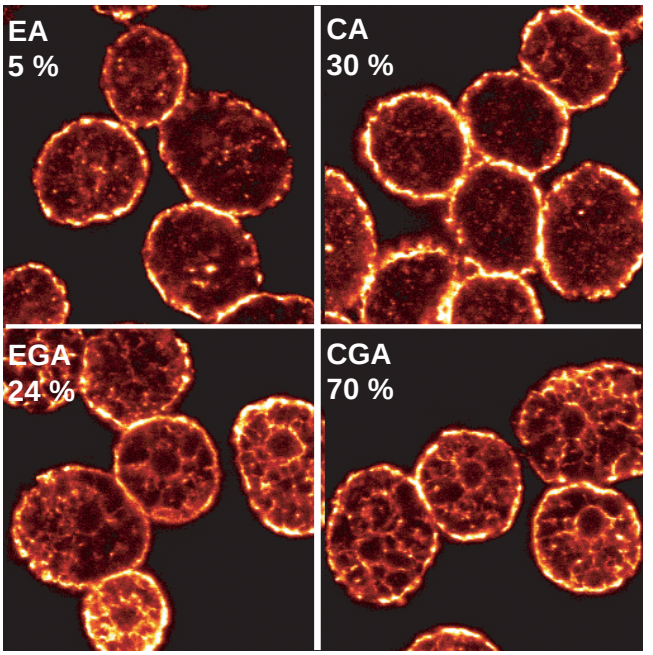

FIGURE 1 Glass-attached mast cells were permeabilised and exposed to the triggers described in Table I: EGTA/ATP (EA), calcium (pCa5)/ATP (CA), EGTA/GTP-γ-S/ATP (EGA), or calcium (pCa 5)/ GTPγS/ATP (CGA). After 20 min at 37°C, cells were fixed and stained with anti-β-actin monoclonal antibody (clone AC-15) from Sigma (used at 1/200 dilution). The secondary antibody (at 1/50 dilution in GBE) was goat antimouse IgG biotin from Sigma. Cy2 streptavidin (1/50, from Amersham Biosciences, UK) was the tertiary layer. Confocal micrographs of equatorial slices are shown. Numbers indicate the percentages of released hexosaminidase.

V. PITFALLS

Keep cells in the moisture box as much as possible to avoid evaporation. Maintain permeabilised mast cells at low (25–50 µ*M*) concentrations of EGTA before exposure to triggers to avoid spontaneous degranulation. When comparing activities of cells after various pretreatments, keep the time between permeabilisation and triggering standard; the length of the "run-down" period affects secretion. Keep 96-well plates clean, washing them with detergent and plenty of water immediately after use.

Note that when staining is performed before fixation, the nature of the endogenous antigen should be taken into account. Because Soluble proteins will leak out of the permeabilized cells, use this method for molecules known or expected to be tethered either to the membrane or to the actin cytoskeleton. Determination of the extent of leakage of the antigen under various conditions (by immunoblotting of the supernatants) is always helpful.

Syringe Loading: A Method for Assessing Plasma Membrane Function as a Reflection of Mechanically Induced Cell Loading

Mark S. F. Clarke, Jeff A. Jones, and Daniel L. Feeback

I. INTRODUCTION

In the past, we have described a method for loading large macromolecules into the cytoplasm of cultured cells via the production of transient plasma membrane wounds inflicted by defined amounts of fluid shear stress (Clarke and McNeil, 1992, 1994). This technique is referred to as "syringe loading" and has been utilized to load a variety of macromolecules (i.e., fluorescent dextrans, proteins, immunoglobulins, calcium indicator dyes, plasmid DNA, and antisense oligonucleotides) into various different cell types (i.e., endothelial cells, fibroblasts, epithelial cells, lymphocytes, and amoeba). This technique is very simple and straightforward, relying on the capacity of the plasma membrane to reseal after the infliction of a *transient* plasma membrane disruption. During the syringe loading procedure, the mechanical force applied to the cells to produce plasma membrane wounding is fluid shear stress generated as a consequence of the cell suspension being forced through a narrow orifice in the form of a 30-gauge hypodermic needle. The macromolecule to be loaded is dissolved in the suspension medium and enters the cell cytoplasm across a diffusion gradient during the time the plasma membrane wound is open. As such, this technique for macromolecular loading of cells in suspension is simple, reproducible, and inexpensive.

The series of highly coordinated, multicomponent responses that occur both within the cell cytoplasm and at the plasma membrane in response to mechanical perturbation/rupture of the external plasma membrane is known collectively as the membrane wound response (McNeil and Steinhardt, 1997). Apart from its use as a simple cell loading technique, syringe loading has also been used to investigate the underlying cellular mechanisms involved in this phenomenon (Miyake and McNeil, 1995; Clarke *et al*., 1995b). It is increasingly evident that the wound response is a fundamental, highly conserved, and normal response to mechanical loading in a wide variety of cell types (McNeil and Terasaki, 2001). In addition, inappropriate levels of membrane wounding may be important in the etiology of a number of pathological conditions, such as atherosclerosis (Reidy and Lindner, 1991; Yu and McNeil, 1992; Clarke *et al*., 1995b), unloading induced muscle atrophy (Clarke *et al*., 1998), and left ventricular hypertrophy (Clarke *et al*., 1995a). The susceptibility of the plasma membrane to mechanically induced membrane disruption and the ability of the membrane to reseal itself after disruption has occurred (*disruption followed by resealing being the definition of membrane wounding*) are both dependent on the biophysical properties of the membrane, including fluidity, elasticity, compressibility, and overall membrane order. These factors have been used to enhance macromolecular loading efficiency by the inclusion of membrane active agents, such as pluronic F68, during the syringe loading procedure in order to enhance the cell membrane resealing process (Clarke and McNeil, 1992).

To date, the mechanical properties of biological membranes have been tested by various means, including the direct measurement of membrane mechanical properties (i.e., elastic area compressibility, tensile strength, membrane toughness), using micropipette aspiration techniques (Needham and Nunn, 1990; Song and Waugh, 1993; Zhelev and Needham, 1993). In addition, indirect measurement of membrane fluidity using steady-state fluorescent anisotropic measurements, nuclear magnetic resonance, and fluorescent probe diffusion techniques have proven useful in determining changes in the physical properties of biological membranes (Tanii *et al*., 1994; Kuroda *et al*., 1996; Gimpl *et al*., 1997) associated with such physiologically relevant alterations as membrane cholesterol content (Pritchard *et al*., 1991; Clarke *et al*., 1995b; Whiting *et al*., 2000). However, all of these techniques have the disadvantage of describing the physical properties of the cell membrane in purely mechanical terms without taking into consideration the complex "biological" nature of the cell membrane system being examined.

Although complex in nature, the membrane wound response *in toto* can be quantified using direct end point measures that describe the final outcome of the process. Such measures include cell survival at a given level of mechanical perturbation, the number of wounded cells present in the surviving cell population, the amount of membrane wound marker that enters the wounded cell, and the relative size of the membrane wound created based on membrane wound marker size. If membrane wounds are produced in a defined and reproducible manner, the effects of various environmental conditions on plasma membrane function, as reflected by alterations in the membrane wound response, can be quantified by the end point measures described earlier. We have used this approach to probe the effects of different gravitational conditions on the biophysical properties of the plasma membrane in cultured ***adherent*** cells using a technique known as impact mediated loading (Clarke *et al*., 2001). This article describes the use of syringe loading as a means of investigating the effects of environmental conditions on the plasma membrane wound response in ***suspension*** cells.

Syringe loading in its simplest configuration can be carried out utilizing a manual protocol, a single 1-ml hypodermic syringe and a 30-gauge hypodermic needle (Clarke and McNeil, 1992). The second-generation approach utilized a mechanized syringe pump apparatus that produced a defined expulsion pressure for a predetermined period of time (Clarke and McNeil, 1994). This article describes the development of a third-generation syringe loader device that is capable of processing a total of 10 separate samples in an identical fashion at the same time (Fig. 1). The multisample syringe loading technology essentially performs syringe loading under the same conditions as described previously except that many replicate samples can be loaded simultaneously. This device was designed to take into consideration the effects of temperature on membrane resealing dynamics, an experimental parameter that has not been fully controlled in previous syringe loading protocols. In the new configuration, individual sample vials containing identical cell suspensions are housed in a heating block maintained at 37°C throughout the syringe loading protocol (Fig. 1). As such, the technology produces a greater total yield of loaded cells with less variability between individual samples than using either the manual or the second-generation mechanized protocol. However, it does not exhibit a significant increase in cell loading efficiency relative to earlier syringe loading protocols. Rather, the goal for this technology was to develop a simple and rapid means of testing the biophysical properties of the plasma membrane of cells (as reflected by alterations in the membrane wounding response) exposed to different environmental conditions.

With this concept in mind and utilizing the multisample syringe loader detailed in Fig. 1, this article describes a series of experiments that illustrate the utility of the syringe loading technology as an experimental tool to probe the effects of environmental conditions on membrane function. In the following example, the effects of radiation exposure on cell membrane function as it impacts the membrane wounding response are investigated. The experiment described here was designed to determine whether gamma irradiation resulted in acute (i.e., within 2 h of radiation exposure) membrane modification that resulted in an increase in susceptibility to mechanical shear force-induced membrane wounding. Membrane wounding is defined as a survivable disruption of the plasma membrane and is detected experimentally using a normally plasma membrane-impermeant fluorescent tracer such as FDx (M_r 10 kDa). Wounded cells trap the wound marker in their cytoplasm by virtue of resealing the plasma membrane disruption. However, immediately after syringe loading there are cells in the loaded sample that are positive for the wound marker but will die within a matter of hours due to irreparable membrane damage. In the case of adherent cells, these cells detach from the culture substratum and hence can be washed away after a minimum period of culture (i.e., 4 h) and are not included in any further analysis. Unfortunately, this approach cannot be employed when using suspension cells. However, if

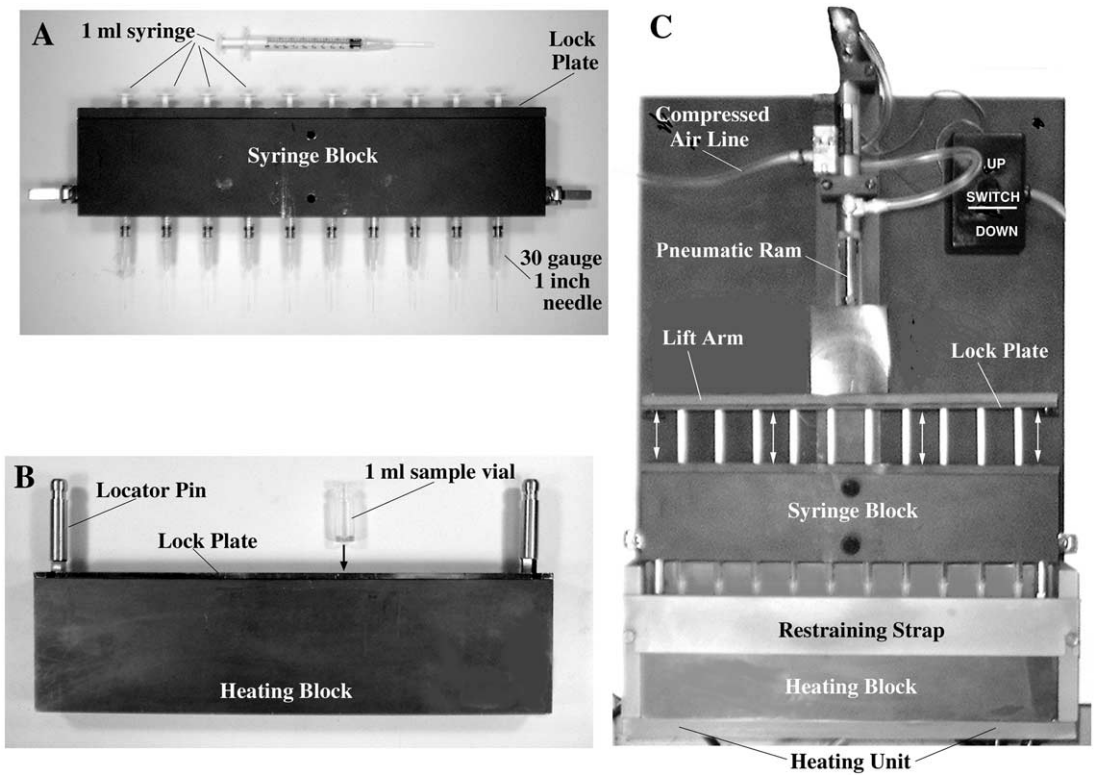

FIGURE 1 Multisample syringe loader. Ten, sterile, 1-ml disposable syringes are secured in the syringe block using a lock plate. A sterile, 30-gauge, 1-in. hypodermic needle is affixed to the tip of each syringe, making sure that the needle is seated firmly (Pl A). The syringe block is then attached to the pneumatic ram assembly of the main body of the device with the syringe plungers being secured directly to the lift arm using a lock plate (Pl C). Ten 1-ml sample vials, loaded with 0.5 ml of cells suspended in FDx loading solution, are loaded into a heating block (preequilibrated to 37°C) and secured in place using a lock plate (Pl B). The heating block containing the sample vials is then returned to its heating unit (set at 37°C) in the main body of the device and is secured in place with its restraining strap (Pl C). The pneumatic ram is placed in the "down" position so that the syringes are closed, and the whole syringe block is lowered and locked in place via the locator pins present on the top of the heating block. This arrangement ensures accurate registering of the each hypodermic needle into the center of its corresponding sample vial. The cell suspension in loading solution is pulled up into the syringe barrel by activating the pneumatic ram in the "up" direction and is expelled from the syringe by activating the pneumatic ram in the "down" direction. Expulsion pressure is controlled by a pressure valve attached to the compressed air line that feeds the ram assembly (Pl C).

the fluorescent cell viability marker, propidium iodide (PI), is introduced to the sample immediately after syringe loading, those cells that are dead or dying are positive for PI regardless if they are also positive for the membrane wound marker. As such, this approach allows rapid discrimination between those cells that are truly membrane wounded (i.e., FDx positive, PI negative) from those cells that are dead and dying (i.e., PI positive, FDx negative or positive) (Fig. 2). By utilizing our multisample syringe loading device and protocol, coupled with subsequent analysis by two-channel fluorescent flow cytometry, the experiment described here provides an example of how the syringe loading technique can be used to quantify the effects of radiation exposure on membrane function in suspension cells. We chose the lymphoblastic cell line Jurkat, as it is a widely used *in vitro* model for studying immune function, an area of specific concern with regard to radiation exposure.

II. MATERIALS AND INSTRUMENTATION

Dulbecco's modified Eagle's medium (X1 concentration) (DMEM, Cat. No. 320-1885AG), bovine calf serum (CS) (Cat. No. 200-6170AG), and penicillin–streptomycin solution (Cat. No. 600-5140AG) are obtained ready to use from Gibco BRL

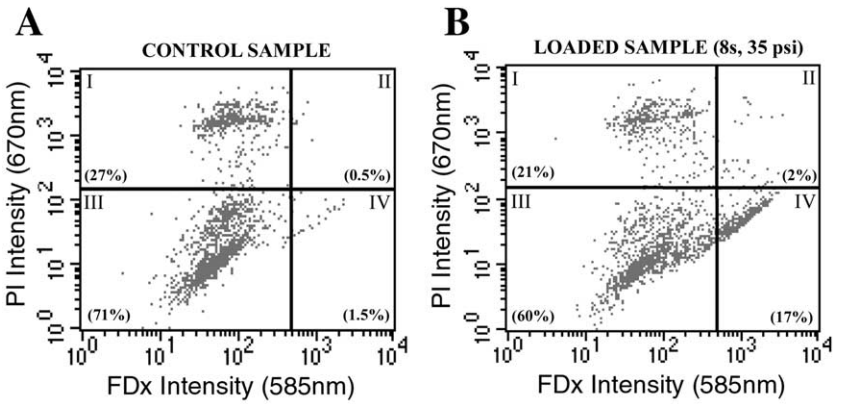

FIGURE 2 Dual-channel fluorescent flow cytometry analysis for the simultaneous determination of membrane wounding and irreparable membrane damage in suspension cells. Control samples, consisting of cell suspensions processed in an identical fashion to experimental samples other than they are not syringe loaded, are used to determine quadrant analysis parameters. Dead or dying cells, present even in the control, non-syringe loaded sample, stain positively for PI (i.e., quadrants I and II) (Pl A). After syringe loading at 35 psi expulsion for a total of eight strokes (Pl B), loaded cells stain positively for FDx (i.e., quadrants II and IV). Truly wounded cells (i.e., FDx positive and PI negative), which have completely resealed their plasma membrane disruptions before the addition of PI to the suspension, are positive only for FDx (i.e., quadrant IV). Numbers in parentheses are values (%) for the cells falling in each quadrant.

(Grand Island, NY). Fluorescein isothocyanate-labeled dextran (M_r 10 kDa) (FDx) (Cat. No. D-1821) and propidium iodide (Cat. No. P21493) are obtained from Molecular Probes (Eugene, OR). Tissue culture flasks (T75 and T25) (Cat. Nos. 10-126-41 and 10-126-26) and sterile polypropylene conical centrifuge tubes (50-ml capacity) (Cat. No. 05-538-55A) are obtained from Fisher Scientific (Pittsburgh, PA). Sterile polypropylene conical sample vials (1-ml capacity) (Cat. No. 05-538-55A) are obtained from National Scientific Company (Quakertown, PA). Disposable 1-ml syringes (Cat. No. 9602) and 30-gauge hypodermic needles (Cat. No. 305128) are from Becton-Dickinson (Rutherford, NJ). The multisample syringe loader described in Fig. 1 was built by a local machine shop to specifications provided by the authors. As such, sample vial dimensions can be varied depending on experiment requirements, including the use of sterile, septum-sealed sample vials.

III. PROCEDURES

A. Preparation of Tissue-Cultured Cells for Syringe Loading

Stock Solutions and Media Preparation

1. *Stock FDx solution*: Add 200 mg of dry FDx powder to 1 ml of serum-free DMEM and vortex periodically over a period of 30 min to achieve complete solubilization. Centrifuge this solution at 10,000 *g* for 10 min at room temperature to remove any undissolved FDx and sterilize, if desired, by ultrafiltration. Stock FDx (200 mg/ml) can be stored at 4°C in the dark for up to a month or aliquoted and frozen in the dark at –80°C for storage up to a year.

2. *Stock propidium iodide solution*: Add 100 mg of dry PI powder to 1 ml of serum-free DMEM and vortex periodically over a period of 30 min to achieve complete solubilization. Centrifuge this solution at 10,000 *g* for 10 min at room temperature to remove any undissolved PI and collect the supernatant as a stock solution. Stock PI (100 mg/ml) can be stored at 4°C in the dark for up to a month or aliquoted and frozen in the dark at –80°C for storage up to a year.

3. *FDx loading solution*: Add 250 µl of stock FDx solution to 4.75 ml of serum-free DMEM to obtain final concentrations of 10 mg/ml FDx. Use the solution immediately.

4. *5% CS.DMEM*: Add 5 ml of sterile penicillin/streptomycin solution and 50 ml of sterile CS to 445 ml of sterile (X1) DMEM solution to obtain DMEM culture medium containing 5% CS, 100 IU/ml penicillin, and 100 µg/ml streptomycin (5% CS.DMEM). Store at 4°C for up to 21 days.

Steps

1. Grow Jurkat cells to confluence in T75 (75 cm^2) culture flasks using 15 ml of 5% CS.DMEM maintained at 37°C in a 5% CO_2 humidified atmosphere with subculture every third day. Carry out subculture by

removing the cell suspension from the T75 flask and placing it in a sterile 50-ml centrifuge tube followed by centrifugation at 100 *g* (~550 rpm) for 5 min at room temperature. Decant the spent medium, resuspend the cell pellet gently in 30 ml of fresh 5% CS.DMEM, and dispense equal volumes into two fresh T75 flasks.

2. On the day of the experiment, collect cells by centrifugation as in step 1. Gently resuspend cells in 10 ml of 5% CS.DMEM and determine cell number using a hemacytometer or electronic cell counting device (i.e., a Coulter particle counter) and adjust the cell density to 2×10^6 cells/ml. Aliquot 5 ml of this cell suspension into T25 flasks in preparation for radiation exposure.

3. Expose cells to different doses of gamma irradiation using a Gammacell 1000 (Cs^{137} source). Our experiments were performed at Baylor College of Medicine (Houston, Texas).

4. Incubate cells at 37°C in a 5% CO_2 humidified atmosphere for a period of 2 h.

5. Remove cells from T25 flasks and collect each sample by centrifugation in sterile 50-ml centrifuge tubes at 100 *g* (~550 rpm) for 5 min at room temperature.

6. Carefully remove medium from the cells and filter through a 0.2-μm cellulose acetate filter to remove any remaining cell debris from the supernatant. Aliquot the medium in 1-ml aliquots and store at –80°C in the dark for subsequent biochemical testing, such as determination of lipid peroxidation marker production.

7. Resuspend each cell pellet in 2 ml of warm serum-free DMEM and determine the cell number by counting in a hemacytometer/Coulter counter.

8. Adjust the cell density of the cell suspension to 1×10^6 cells/ml by the addition of an appropriate amount of warm serum–free DMEM.

9. Dispense 0.5-ml samples of this cell suspension into a minimum of 13 sterile conical polypropylene 1-ml sample vials.

10. Add 25 μl of prewarmed stock FDx solution to all sample vials, mix by gentle vortexing, and load 10 of the 13 sample vials into the heating block (prewarmed to 37°C) of the multisample syringe loader (Fig. 1B).

11. Immediately perform syringe loading on the samples from **step 10** while the remaining three vials are incubated at 37°C in ambient air as control samples for FDx uptake by pinocytosis and cell loss due to processing.

B. Syringe Loading Protocol

1. Place heating block containing 10 sample vials containing identical aliquots of the cell suspension into the multisample syringe loader heating unit and attach the restraint strap as shown (Fig. 1C).

2. Insert the 10 separate 1-ml syringes with attached 1-in.-long, 30-gauge needles (which have been loaded previously into the syringe block, Fig. 1A) into the vials and lock in place using the guide posts (Fig. 1C).

3. Draw the cell suspension up into the barrel of the sterile syringes through the 30-gauge hypodermic needles by activating the pneumatic ram attached to the syringe plungers using the "up" switch (Fig. 1C). Set the pneumatic ram so that the syringe plungers do not move any further up than the 0.5-ml mark on the syringe barrels.

4. Once the barrels of the syringes are filled (which takes approximately 2 s), expel the cell suspensions through the 30-gauge needles back into their respective sample vials at a constant pressure of 35 psi by reversing the direction of the pneumatic ram using the "down" switch. This procedure is defined as two strokes.

5. Repeat this procedure three more times so that each cell suspension has been subjected to eight strokes under identical expulsion pressure conditions.

6. Remove the test sample vials from the multisample syringe loader.

7. Take all the samples (including the control samples, which have been incubated in FDx loading solution at 37°C but not syringe loaded), add 0.5 ml of 5% CS.DMEM to each vial, collect the cells by centrifugation at 100 *g* for 5 min at room temperature, and remove the supernatant (i.e., FDx loading solution).

8. Add 0.5 ml of warm 5% CS.DMEM to each cell pellet and resuspend the cells by gently vortexing the sample and store at 37°C in a 5% CO_2 humidified atmosphere in preparation for analysis. Analysis should be started as soon as possible.

C. Dual-Label Fluorescent Flow Cytometry Analysis

1. Immediately prior to fluorescent flow cytometry analysis, add a 10-μl aliquot of stock PI solution (final PI concentration of 1 mg/ml) to each sample and mix by gentle vortexing. Add PI to each individual sample immediately before analysis.

2. Analyze control samples first by dual-channel fluorescent flow cytometry using a Becton-Dickinson FACSCalibur system (or similar fluorescent flow cytometer) and plot a two-axis scatter plot of cell fluorescent intensity at 585 nm (FDx signal) and 670 nm (PI signal) using the associated software. These control samples are used to define "quadrant" gating

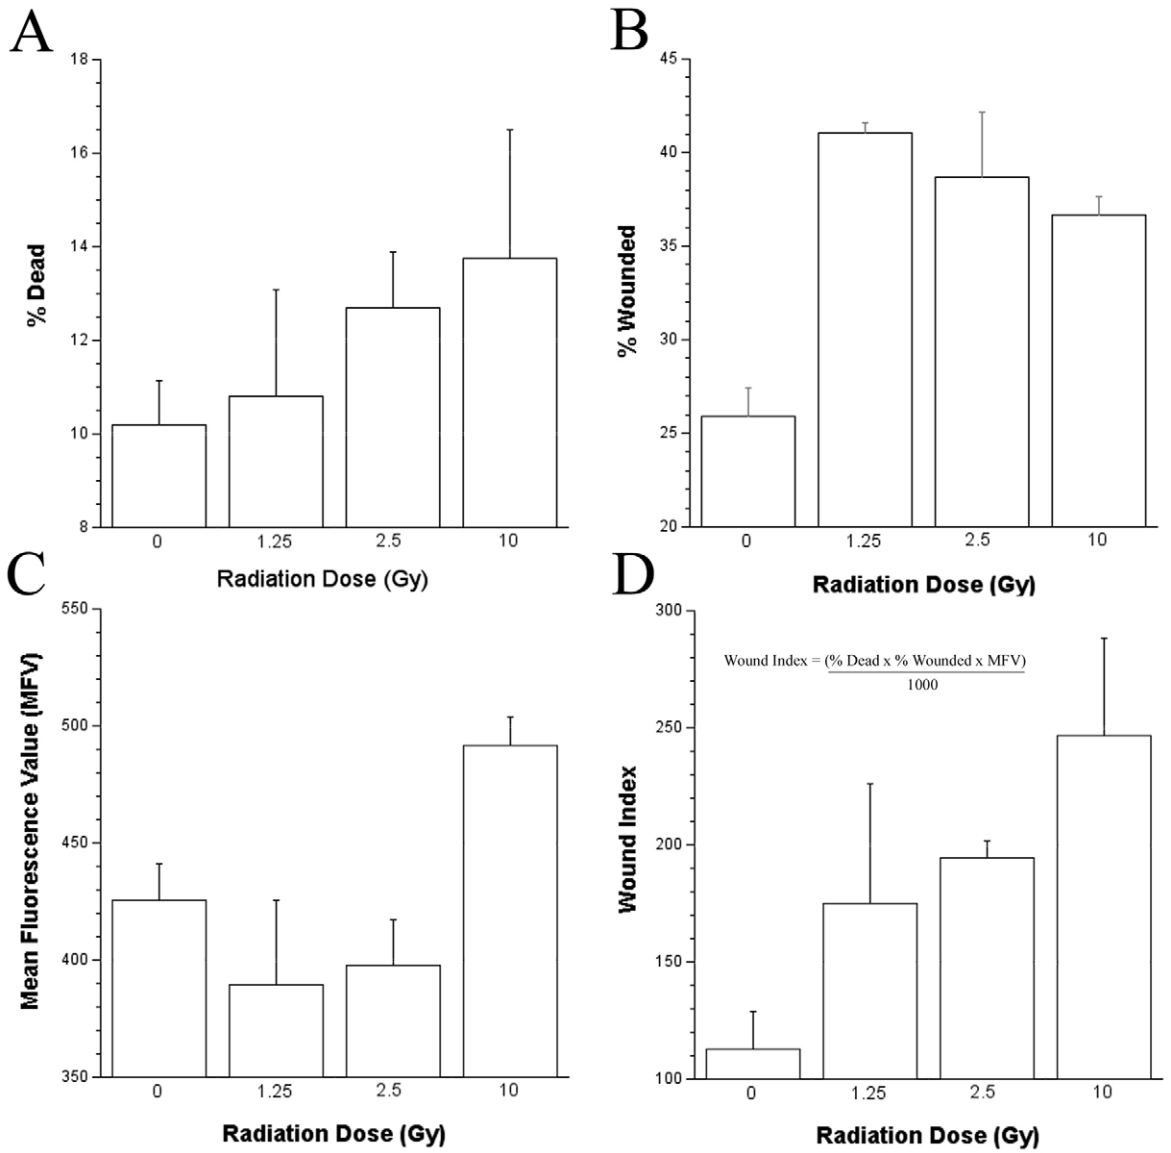

FIGURE 3 Dose-dependent effects of gamma irradiation on the syringe loading-induced membrane wounding response of the lymphoblastic cell line Jurkat.

thresholds for the control cell population with regard to FDx and PI background signals (Fig. 2). Collect a total of 10,000 events for analysis of each sample.

3. Analyze syringe loaded samples by dual-channel fluorescent flow cytometry using the quadrant gates defined earlier (Fig. 2). Collect a total of 10,000 events for analysis of each sample.

4. Calculate the number of dead or dying cells in each sample (expressed as a percentage of the total cells analyzed, Fig. 3A) by counting the number of cells in the sample that are positive for PI staining, including those cells that are also positive for FDx (i.e., Fig. 2, quadrants I and II, respectively).

5. Calculate the number of wounded cells (expressed as a percentage of the total cells analyzed, Fig. 3B) and the mean fluorescent value (MFV; Fig. 3C) of the wounded population by determining the number and staining intensity of cells that are positive for FDx staining only (i.e., Fig. 2, quadrant IV).

6. Calculate a wound index (which reflects cell survival of mechanically induced plasma membrane damage, the number, and the MFV of the wounded cells) as described previously (Clarke and McNeil, 1992) for each radiation dose (Fig. 3D), where the wound index = % dead cells × % wounded cells × mean fluorecent value/1000.

IV. COMMENTS

The technology described herein allows the effects of a wide range of environmental conditions and their potential countermeasures (e.g., radiation exposure and radio-protectants) to be assessed in a variety of cell suspension models, including peripheral blood lymphocytes from human subjects. A less refined version of this approach has been used previously to study the effects of increasing membrane cholesterol content on plasma membrane susceptibility to mechanical shear-induced membrane wounding (Clarke *et al*., 1995a). The apparatus and protocol described earlier have taken what was essentially a macromolecular loading technique and adapted it for use as a means of assessing the effects of radiation exposure on the membrane function of lymphoblastic cells in suspension. The technique also has the advantage of being able to immediately discriminate between dead and dying cells and truly wounded cells in suspension after the application of mechanical shear force using two-channel fluorescent flow cytometry (Fig. 2).

The apparent dose response in membrane wound susceptibility observed relative to radiation exposure in our model indicates that gamma irradiation induces alterations in the plasma membrane components of Jurkat cells, if not immediately, then most certainly within 2 h of exposure (Fig. 3). This time course of events suggests that these effects are not associated with genomic damage. The effects of radiation exposure on membrane wounding observed in this study are similar to that described previously after an increase in plasma membrane order. One possible reason for such an increase in membrane order after radiation exposure is the production of reactive oxygen species (ROS), such as superoxide, hydrogen peroxide, hydroxyl, peroxyl, and alkoxyl radicals, which may lead to membrane damage and consequent cross-linking of membrane components (Clarke *et al*., 2003). This concept is supported by the experimental observation that Jurkat cells exposed to gamma irradiation not only exhibit an increase in susceptibility to membrane wounding within 2 h, but also produce significant amounts of lipid peroxidation markers (data not shown).

We have observed previously that in order to obtain optimal levels of membrane wounding experimentally (i.e., maximizing cell loading while minimizing cell death caused by irreparable membrane disruption), a mechanical shear dose–response curve must be constructed. In general, most mammalian cells appear to wound best at expulsion pressures between 30 and 45 psi. However, this parameter varies with each individual cell type. Expulsion of the cell suspension under the conditions used in the example given earlier (i.e., 0.5 ml volume of cell suspension passing through a 1-in.-long, 30-gauge needle at a constant 35 psi expulsion pressure in 1.5 s) results in a theoretical average fluid shear stress of approximately 7340 dynes/cm^2. This value is derived from the equation wall shear rate $= 8 \times V_{mean}/D = 32Q/\pi D^3$, where D is the luminal diameter of the hypodermic needle (cm) and Q is the flow rate in cm^3/s, assuming that the viscosity of the loading solution is one centipoise (Clarke *et al*. 1995b). Due to the non-Newtonian fluid physics of the cell suspension, this calculated value for the shear stress inflicted on the cells syringe loading under these conditions could be artificially low. However, regardless of the actual shear stress value inflicted on the cells while passing through the needle, the multisample syringe loader induces a constant and reproducible level of mechanical shear stress from sample to sample. This translates into the infliction of well-defined and reproducible amounts of membrane wounding in cells subjected to syringe loading. The incorporation of a heating block into the device in order to maintain a constant temperature during the syringe loading procedure has also removed a potential confounding variable from the experimental protocol.

V. PITFALLS

1. Jurkat cells are relatively fragile in tissue culture. Cells should be handled gently with a minimum of agitation, being especially careful when performing manipulations that require pipetting or vortexing. This fragility is evidenced by the relatively large number of PI-positive cells (i.e., dead or dying cells) present in control samples that have not been subjected to syringe loading (see Fig. 2A).

2. Jurkat cells should be used for syringe loading experiments 1 day after subculture to ensure the optimal number of healthy cells in the culture.

3. When calculating the theoretical shear stress imposed during syringe loading, it is important to determine the flow rate through the needle experimentally. This will change primarily depending on the expulsion pressure and the number of cells in the suspension; both parameters are under the control of the investigator. These wounding parameters need to be optimized for each particular cell type.

4. It is important to prevent excessive pH changes caused by exposure of the bicarbonate-buffered

culture medium to atmospheric air during the procedure as these are potentially harmful to the cells.

Cell Surface Biotinylation and Other Techniques for Determination of Surface Polarity of Epithelial Monolayers

Ami Deora, Samit Chatterjee, Alan D. Marmorstein, Chiara Zurzolo, Andre Le Bivic, and Enrique Rodriguez-Boulan

I. INTRODUCTION

A fundamental property of epithelial cells is the polarized distribution of proteins and lipids in the apical and basolateral domains of the plasma membrane. These two domains are physically separated from each other by the tight junction. Many studies have been done over the past 20 years to understand the mechanisms that lead to the establishment and maintenance of the polarized distribution of proteins and lipids in the plasma membrane of epithelial cells (Rodriguez-Boulan *et al.*, 2005; Yeaman *et al.*, 1999; Keller and Simons, 1997).

A major advance in the study of epithelial cell polarity was achieved with the introduction of porous filter supports for the growth of epithelial cell cultures (reviewed in Rodriguez-Boulan *et al.*, 2005). This method differs from classical cell culture in that it allows direct access to the basolateral surface of cultured cells. Epithelial cells and cell lines grown on such filter supports (either nitrocellulose or polycarbonate) attain a more differentiated appearance and become polarized after relatively short times in culture. While most studies on epithelial polarity and trafficking of plasma membrane proteins have been performed using a limited number of cell lines (MDCK, FRT, Caco-2), this culture technique has been gaining in popularity and has been used now for primary cultures as well. The confluency of cells grown on permeable supports can be determined by the measurement of transepithelial electrical resistance or transepithelial [^{3}H]inulin flux (Hanzel *et al.*, 1991).

One of the biggest advantages of this culture system is the accessibility of either the apical or the basolateral surface to any reagent added to the medium and the ability to add different reagents to contact either surface. This is the basis of the biotinylation techniques that have been developed to selectively label proteins present on the apical or basolateral domains of the plasma membrane of filter-grown epithelial cells.

The proteins present on the surface of filter-grown monolayers can be selectively modified by the water-soluble cell-impermeable biotin analog sulfo-NHS-biotin. Taking advantage of the access afforded by the filter support, the addition of sulfo-NHS-biotin to only one surface of the cell results in the selective labeling of only the apical or basolateral surface proteins. The biotinylated proteins can then be detected by blotting with [^{125}I]streptavidin or streptavidin conjugated to any number of enzymatic reporters. Furthermore, the cells can be metabolically pulse labeled and the proteins of interest can then be studied using biotinylation, immunoprecipitation and subsequent streptavidin–agarose precipitation. This technique is very versatile and is applicable to the study of diverse aspects of epithelial cell polarity, such as the steady-

state distribution of specific antigens, or dynamic processes, such as targeting to the cell surface and transcytosis of membrane proteins. Several biotin analogs are available, including one that contains a disulfide bond. By differentially labeling the surfaces of epithelia *in situ* with the cleavable NHS-S-S-biotin and a noncleavable biotin, we have been able to study the polarity of a native epithelium *in situ* (Marmorstein *et al*., 1996).

The first edition of this article described a basic protocol for selective cell surface biotinylation, plus some modifications of the assay to study protein targeting and endocytosis. The second edition included a basic protocol for *in situ* domain-specific biotinylation. In this edition, we have added a protocol of surface immunolabeling as an alternative to biotin labeling for determination of polarity. This technique is critical in cell lines that may exhibit leakiness to biotin. Additionally, we have also included two sections determining the polarity of a protein by means of intranuclear microinjection of its cDNA and quantitative microscopic analysis to determine distribution of the protein relative to known polarized markers.

II. MATERIALS

Sulfo-NHS-biotin (sulfosuccinimidobiotin, Cat. No. 21217); NHS-LC-biotin (sulfosuccinimidyl-6-(biotinamido)-hexanoate, Cat. No. 21335); NHS-SS-biotin (sulfosuccinimidyl-2-(biotinamido)-ethyl-1,3-dithioproprionate, Cat. No. 21331); and immunopure-immobilized streptavidin (Cat. No. 20347) are from Pierce (Rockville, IL). Protein A–Sepharose Cl-4B (Cat. No. 17-0780-01) is from Pharmacia/LKB (Piscataway, NJ). Glutathione (Cat. No. G-6529) and cycloheximide (Cat. No. C-7698) are from Sigma Chemical Co. (St. Louis, MO). *Staphylococcus aureus* cells (Pansorbin, Cat. No. 507858) are from Calbiochem (La Jolla, CA). Cells are grown on polycarbonate filters (Transwell, 12 mm diameter, Cat. No. 3401; 24 mm diameter, Cat. No. 3412) from Corning-Costar (Cambridge, MA); MEM-Select-Amine kits (Cat. No. 19050-012) are from GIBCO BRL Life Technologies (Grand Island, NY); [^{35}S]EXPRE^{35}S ^{35}S (methionine/cysteine) and [^{35}S]cysteine are from Dupont NEN (Boston, MA) (Cat. No. NEG 072 for Express and Cat. No. NEG 022T for [^{35}S]cysteine); [^{125}I]streptavidin can be obtained from Amersham (Arlington Heights, IL) (Cat. No. IM236); streptavidin conjugated to horseradish peroxidase can be obtained from Sigma (Cat. No. S-5512).

III. PROCEDURES

A. Cell Surface Biotinylation

This procedure is used to determine the relative percentage of a plasma membrane protein(s) in the apical versus basolateral plasma membrane of epithelial cells grown on permeable filter supports (modified from Sargiacomo *et al*., 1989).

Solutions

1. *PBS-CM*: Phosphate-buffered saline containing 1.0 m*M* $MgCl_2$, and 1.3 m*M* $CaCl_2$
2. *Sulfo-NHS-biotin or sulfo-NHS-LC-biotin*: Stock solution is 200 mg/ml in dimethyl sulfoxide (DMSO), which can be stored for up to 2 months at –20°C. Thaw just prior to use and dilute to a final concentration of 0.5 mg/ml in PBS-CM. Use immediately.
3. *50 mM NH_4Cl in PBS-CM or Dulbecco's modified Eagle's medium (DMEM)*: Use to quench the excess biotin at the end of the labeling reaction

Steps

All steps are carried out on ice and with ice-cold reagents.

1. For all experiments, use confluent monolayers of cells plated at confluency (for most cell lines, $2.5–3.5 \times 10^5$ cells/cm^2 of filter) 4–5 days prior to biotinylation. Measure transepithelial electrical resistance (TER) and discard monolayers that do not exhibit acceptable resistances (different cell lines exhibit different TER values ranging from tens to thousands of $\Omega \cdot cm^2$; monolayers should be used that exhibit TER values in the normal range for your cell line. We have successfully performed this assay on cells with TERs as low as $50\,\Omega \cdot cm^2$).
2. Wash filters on both sides three times with ice-cold PBS-CM.
3. Add a fresh solution of sulfo-NHS-biotin (0.5 mg/ml in PBS-CM) to the apical or basolateral chamber. Add PBS-CM to the other chamber. We use 0.7 ml apical and 1.4 ml basolateral for 24-mm-diameter filters and 0.4 and 0.8 ml for 12-mm-diameter filters. Incubate with gentle shaking for 20 min at 4°C and then repeat this step.
4. Quench the reaction by removing the solutions from both chambers and replacing with 1 ml of 50 m*M* NH_4Cl in PBS-CM. Incubate with gentle shaking for 10 min at 4°C.
5. Rinse twice with PBS-CM.
6. Excise filters and either freeze at –80°C (the freeze thaw involved with storage at –80°C appears to

inactivate some proteases) or immediately proceed with the extraction of biotinylated proteins as outlined in Section III,F.

Analysis of Results

The amount of protein present on the apical or basolateral surface is determined by a densitometric analysis of the autoradiographs. Multiple exposures are necessary if using the film to ensure that the values obtained are in the linear range of the film. Polarity is expressed as the percentage of total surface protein present on one surface of the monolayer.

B. Biotin Targeting Assay

This procedure is used to determine if proteins are delivered directly, indirectly (transcytotically), or nonpolarly to the apical and/or basolateral surface of an epithelial cell (modified from Le Bivic *et al*., 1990).

Solutions

1. *Starvation medium*: DMEM without methionine or cysteine. This solution is prepared using a MEM Select-Amine kit by not adding the methionine and cysteine.

2. *[^{35}S]EXPRESS (methionine/cysteine:) or [^{35}S]cysteine*: 1 mCi per multiwell plate (12 × 1.2-cm or 6 × 2.4-cm-diameter filters). In some cases, proteins are effectively labeled with [^{35}S]SO_4, an advantage for studies of post-Golgi sorting, because the addition of sulfate occurs in the *trans*-Golgi network (see chapter by Kreitzer *et al*.).

3. *Chase medium*: DMEM containing a 10× concentration of methionine and cysteine (made by addition of methionine and cysteine to starving medium) or the normal medium in which the cells grow.

4. *HCO_3-free DMEM containing 20 mM HEPES and 0.2% bovine serum albumin (BSA)*

5. *Sulfo-NHS-biotin (NHS-LC-biotin or NHS-SS-biotin)*: 0.5 mg/ml in PBS-CM + all of the reagents used in the cell surface biotinylation protocol.

6. *Lysis buffer*: 1% Triton X-100 in 20 m*M* Tris, 150 m*M* NaCl, 5 m*M* EDTA, 0.2% BSA, pH 8.0, and protease inhibitors

7. *Immunopure-immobilized streptavidin on agarose beads*

8. *10% SDS*: sodium dodecyl sulfate

Steps

1. Wash cells on filters three times with starvation medium and incubate for 20–40 min in starvation medium. The starving period will depend on your cell type. MDCK cells work well with a 20-min starvation; RPE-J require longer times.

2. Pulse for 20–30 min (again depends on cell line) in starving medium containing [^{35}S]EXPRESS of [^{35}S]cysteine at 37°C. The pulse solution is starving medium plus the ^{35}S label. Minimal volumes are recommended. For MDCK cells we pulse with 20–40 µl from the basolateral surface. A drop of pulse medium is placed on a strip of Parafilm in a humidified chamber (we use a plastic box lined with wet towels), and the insert containing the filter and MDCK monolayer is removed from the multiwell and dropped on top of the pulse medium. Some cell lines (i.e., RPE-J) are better labeled from the apical surface. For apical pulse, starvation medium is removed from both chambers and pulse medium is applied only to the apical chamber. For 1.2-cm-diameter filters we use a 100-µl volume; for 2.4-cm-diameter filters we use a 350-µl volume of pulse medium.

3. The pulse is terminated by washing with chase medium three times.

4. At different chase times, aspirate chase medium and replace with ice-cold $NaHCO_3$-free DMEM containing 20 m*M* HEPES and 0.2% BSA and store on ice until all chase points have been collected.

5. Proceed to apical or basolateral biotinylation following the protocol described earlier for cell surface biotinylation.

6. Excise filters and either freeze at –80°C or immediately lyse cells and immunoprecipitate specific proteins as described in the section extraction of biotinylated proteins.

7. Remove immunoprecipitated proteins from beads by adding 40 µl of 10% SDS and heating for 5 min at 95°C. Immediately dilute with 460 µl of lysis buffer and pellet for 1 min in a microfuge. Remove 450 µl and place in a new tube. Dilute the remaining 50 µl with 50 µl of 2× Laemmli sample buffer. This sample is used to normalize for differential incorporation of radiolabel from filter to filter. The remaining 450 µl is diluted with a further 1 ml of lysis buffer to which is added an additional 50 µl of streptavidin agarose that has been preblocked for 1–12 h with lysis buffer.

8. Streptavidin precipitation is allowed to proceed for 1 h to overnight at 4°C. Then the beads are washed successively in TPII, TPIII, and TPIV as described in Section III,F. After the final wash the beads are resuspended in Laemmli sample buffer and heated to 95°C for 5 min.

9. Both the sample representing total and surface protein are resolved on SDS–PAGE gels. The gels are dried and exposed for autoradiography.

C. Targeting Assay by Surface Immunolabeling

Epithelial cells such as LLC-PK1 may not form a tight monolayer and hence could be leaky to biotin analogs (MW~ 400–600). To overcome this problem, we have used antibody labeling against the protein of interest (Gan *et al*., 2002). Antibodies are less likely to traverse through leaky monolayers. Leakiness of antibodies should be directly determined before using this method.

Solutions

1. *PBS-CM*: See Section III,A
2. *DMEM containing 0.2% BSA*

Steps

1. The initial steps are similar to Section III,B (steps 1–4). Label the ice-cold filters from different chase time points with antibody added to either apical or basolateral domains for 1 h on ice in a cold room kept at 4°C. Dilute the antibody in DMEM containing 0.2% BSA at an approximate concentration of 1 µg/ml. After 1 h, wash filters four times in ice-cold PBS-CM containing 0.2% BSA.
2. Excise filters and either freeze at –80°C or immediately lyse cells in lysis buffer.
3. Pull down the antigen–antibody complex with protein A or G beads from nine-tenths of the postnuclear supernatants. Subject one-tenth of the supernatant again to immunoprecipitation to measure total labeled protein.
4. Wash immunoprecipitates on the beads successively in TPII, TPIII, and TPIV as described in Section III,F.
5. After the final wash, resuspend the beads in Laemmli sample buffer and heat to 95°C for 5 min.
6. Resolve both the sample representing total and surface proteins on SDS–PAGE gels. Dry and expose the gels for autoradiography.

Analysis of Results

The polarity of the protein is determined at each time point by densitometric analysis of the autoradiographic data. The values obtained for the surface protein should be normalized against the values obtained form the totals (including precursor forms). This controls for differences in the incorporation of label (specific activity) between monolayers. If the protein is highly polarized from the first time point at which it is detected on the cell surface, then it is delivered directly to that surface. If it is polarized on one surface early in the chase and then switches polarity later in the chase, then it is delivered indirectly. If the protein is nonpolar early in the chase and acquires polarity only after longer chase times, then it is not sorted in the TGN, but its final polarity is acquired by differential stability on the apical and basolateral surfaces.

D. Biotin Assay for Endocytosis

This assay examines the internalization of plasma membrane proteins (from Graeve *et al*., 1989)

Solutions

1. *PBS-CM*
2. *Cleavable biotin reagent*: NHS-SS-biotin
3. *DMEM containing 0.2% BSA*
4. *Reducing solution*: 310 mg glutathione (free acid) dissolved in 17 ml H_2O (50 m*M*). Add 1 ml of 1.5 *M* NaCl, 0.12 ml of 50% NaOH, and 2 ml of serum just before use.
5. *Quenching solution*: 5 mg/ml iodoacetamide in PBS-CM containing 1% BSA

Steps

1. Wash cells on filters four times, 15 min each time with ice-cold PBS-CM.
2. Add 1 ml of NHS-SS-biotin (0.5 mg/ml in ice-cold PBS-CM) to the chamber being labeled and PBS-CM to the other chamber. Incubate for 20 min at 4°C and repeat with fresh solutions.
3. Wash filters twice with DMEM/0.2% BSA. Keep two filters on ice (one of these will represent the total amount of proteins at the surface before internalization and the other will be treated with the reducing solution and represents your control of efficiency of reduction) and transfer the other filters to 37°C for various times to allow the biotinylated proteins to be internalized.
4. Stop incubation by transferring filters back to 4°C.
5. Wash twice in PBS-CM + 10% serum.
6. Incubate filters for 20 min in reducing solution. Repeat. (Mock treat one filter.)
7. After washing, quench free SH groups in 5 mg/ml iodoacetamide in PBS-CM + 1% BSA for 15 min.
8. Lyse cells and immunoprecipitate as described in the section extraction of biotinylated proteins.
9. Run the samples on SDS–PAGE gels, transfer to nitrocellulose or PVDF, blot with [^{125}I]streptavidin, and expose for autoradiography.

Analysis of Results

Endocytosis of the protein of interest is indicated by protection of the NHS-SS-biotin-labeled surface

protein from reduction by glutathione. By chasing the cells for various lengths of time, a rate of endocytosis can be calculated by comparing the percentage of protein protected at each time point. Obviously if none of the protein is protected from reduction, it is 100% at the surface; conversely, if all of the protein is protected, 100% has been internalized.

E. *In Situ* Domain Selective Biotinylation of Retinal Pigment Epithelial Cells

The retinal pigment epithelium is uniquely suited for biochemical studies of polarity *in situ*. The RPE exists as a natural monolayer with a broad apical surface that is easily exposed after gentle enzymatic treatment to remove the adjacent neural retina. The apical surface of the tissue is labeled with a noncleavable biotin analog such as NHS-LC-biotin for the identification of apical proteins. For identification of basolateral proteins the biotinylatable sites on the apical surface are labeled with the cleavable NHS-SS-biotin. After isolation of RPE cells, the nonlabeled basolateral proteins are labeled in suspension with the noncleavable form. Removal of the cleavable NHS-SS-biotin by reduction with 2-mercaptoethanol results in the presence of biotin only in the population of proteins present on the basolateral surface of the RPE (Marmorstein *et al*., 1996)

Solutions

1. *Sulfo-NHS-biotin, or NHS-LC-biotin, and NHS-SS-biotin stock solutions in DMSO*
2. *HBSS*: 10 m*M* HEPES buffered Hank's balanced salt solution
3. *PBS-CM*
4. *DMEM containing 10 mM HEPES*
5. *Bovine testicular hyaluronidase*
6. *CMF-PBS*: PBS calcium and magnesium free
7. *PBS-EDTA*: CMF-PBS + 1 m*M* EDTA

Steps

All steps are carried out on ice unless otherwise indicated.

1. Rats are euthanized by CO_2 asphyxiation, and the eyes are enucleated and stored for 3 h to overnight in the dark on ice in HBSS.
2. A circumferential incision is made above the ora serrata, and the cornea, iris, lens, and vitreous are removed.
3. The eyecups are incubated for 10–30 min at 37°C in HBSS containing 290 units/ml bovine testicular hyaluronidase.
4. The ora serrata is removed, and the neural retina is peeled carefully away from the RPE. The optic nerve head is severed and the neural retina is removed. The RPE is inspected under the dissecting microscope. Black spots on the outer surface of the retina or tracts of smooth reflective surface in the eyecup indicate damage. Damaged eyecups are discarded.
5. Soluble components of the interphotoreceptor matrix are removed by incubation in 2-ml microcentrifuge tubes (one eye per tube) on a rotator in ice-cold HBSS for 20 min. This is repeated three times.
6. The apical surface of the RPE in one eyecup is biotinylated with 1 ml of PBS-CM containing 2 mg of sulfo-NHS-biotin. The other eyecup is biotinylated with 1 ml of PBS-CM containing 2 mg of NHS-SS-biotin. This procedure is repeated three times.
7. The reaction is quenched with 1 ml of 10 m*M* HEPES buffered DMEM for 10 min at 4°C.
8. The eyecups are rinsed once in ice-cold CMF-PBS and are then incubated in PBS-EDTA on ice for 30 min.
9. The RPE is gently teased from the inner surface of the eyecup using a 22-gauge needle. The RPE layer is collected in a 1.5-ml microcentrifuge tube and pelleted for 10 s in a microfuge. Cells labeled apically with noncleavable sulfo-NHS-biotin or NHS-LC-biotin at this stage are held on ice until the basolateral samples are ready.
10. For cells labeled with cleavable NHS-SS-biotin, the pellet is resuspended in 1 ml of PBS-CM containing 2 mg/ml sulfo-NHS-biotin or NHS-LC biotin and incubated on a rotator at 4°C. After 20 min the cells are pelleted for 10 s in a microfuge and this step is repeated.
11. The reaction is quenched with 50 m*M* NH_4Cl in PBS-CM for 10 min. The cells are then pelleted in the microfuge for 10 s.
12. At this point, both apical and basolaterally labeled pellets are frozen dry at –80°C or immediately lysed and specific proteins immunoprecipitated as described in the section extraction of biotinylated proteins.
13. Immunoprecipitated proteins are resuspended in Laemmli sample buffer containing 5% 2-mercaptoethanol or 50 m*M* dithiothreitol to release the NHS-SS-biotin from the apical proteins in basolateral samples. After heating to 95°C for 5 min, samples are resolved by SDS–PAGE, transferred to nitrocellulose or PVDF membranes, and blotted with streptavidin.

Analysis of Results

Analysis of the results proceeds as in the section on cell surface biotinylation.

F. Extraction and Immunoprecipitation of Biotinylated Proteins

Solutions

1. *TPI*: 1% Triton X-100, 20 m*M* Tris, 150 m*M* NaCl, 5 m*M* EDTA, pH 8.0, containing 0.2% BSA, and protease inhibitors
2. *TPII*: 0.1% SDS, 20 m*M* Tris, 150 m*M* NaCl, 5 m*M* EDTA, pH 8.0, containing 0.2% BSA
3. *TPIII*: 20 m*M* Tris, 500 m*M* NaCl, 5 m*M* EDTA, pH 8.0, containing 0.2% BSA
4. *TPIV*: 50 m*M* Tris, pH 8.0
5. *Laemmli sample buffer*
6. *Protein A–Sepharose*
7. *Staphlycoccus A cells*: Pansorbin

Steps

1. Excise filters from inserts using a #11 scalpel blade or razor blade. Lyse in 1 ml of TPI at 4°C. In some cases it may be necessary to use more stringent conditions for lysis (i.e., RIPA buffer, which contains 0.5% deoxycholate and 0.1% SDS in addition to 1% Triton X-100).
2. Wash 100 µl/sample of Pansorbin three times with TPI. *Do not omit protease inhibitors.*
3. Centrifuge lysate in a microfuge at 4°C at 13,000 *g* for 10 min. Collect the supernatant and discard the pellet.
4. Add 100 µl of washed Pansorbin to each supernatant. Preclear for 1 h at 4°C.
5. Resuspend 5–10 mg of protein A-Sepharose/lysate in 1 ml TPI /lysate. If you are immunoprecipitating with a mouse IgG, after 10 min, when the Sepharose beads are swollen, add 2 mg of rabbit anti-mouse IgG. After 1 h wash the beads three times with TPI. On the last wash, pellet the beads in microcentrifuge tubes.
6. Pellet the Pansorbin by centrifugation at 13,000 *g* for 10 min. Collect the supernatant, add an appropriate volume of antibody, and incubate at 4°C for 1 h to overnight.
7. Transfer the immunoprecipitates to the tubes containing the protein A–Sepharose and incubate for 1 h at 4°C.
8. Centrifuge the immunoprecipitates in a microfuge at 13,000 *g* for 30 s. Remove the supernatant and resuspend the beads in 1 ml of TPI. Repeat this step three times with TPII, three times with TPIII, and once with TPIV.
9. Resuspend with an appropriate volume of Laemmli sample buffer, heat to 95°C for 5 min, and resolve by SDS–PAGE. For streptavidin blotting, transfer the gel to nitrocellulose or PVDF.

G. Streptavidin Blotting

Solutions

1. *Blocking buffer*: 5% Carnation instant milk, 0.3% BSA, in PBS-CM
2. *Rinse buffer*: 1% BSA, 0.2% Triton X-100 in PBS-CM
3. *[^{125}I]Streptavidin or streptavidin conjugated to horseradish peroxidase or alkaline phosphatase (streptavidin-HRP)*
4. A phosphorimager, Kodak X-OMAT AR film and a cassette with an intensifying screen, or an enhanced chemiluminescence reagent kit (such as those supplied by Amersham) and appropriate film.

Steps

1. After transfer to nitrocellulose or PVDF (PVDF is superior for chemiluminescent detection systems and is used in our laboratory for most streptavidin blots), block the blot for 1 h in blocking buffer.
2. Rinse once with rinse buffer.
3. Incubate for 1 h in 40 ml rinse buffer containing 1–2 × 10^6 cpm/ml of [^{125}I] streptavidin or 0.5–1.0 mg/ml streptavidin-HRP.
4. Wash three to five times for 5–10 min each with rinse buffer.
5. Dry the blot and expose to a phosphorimager screen, autoradiograph it with Kodak X-OMAT AR film, or use any of the many enhanced chemiluminescent kits that are available.

H. Quantitation of Polarized Distribution by Confocal Microscopy Imaging Technique

Modern quantitative optical microscopy offers an alternative method to quantify the relative polarity of fluorescently labeled cell surface proteins in cells developing polarity in settings such as the calcium switch assay (Rajasekaran *et al*., 1996). This quantitation is based on the relative fluorescent pixel intensities in serial horizontal confocal sections of the target protein to a known polarized marker.

Requirements

1. Confocal laser-scanning microscope
2. Software to measure fluorescence intensity, e.g., Metamorph, Image Space Software.

Steps

1. Samples subjected to immunofluorescence technique (not discussed here) are imaged on a laser confocal microscopic system. Samples are subjected to

optical sectioning (*xy*) of the entire thickness (*z*) of the monolayer. We select an interval between sections for optimized collection of fluorescence from a given plane without contribution from the neighboring *z* planes. Choice of interval depends on pinhole dimension, which in turn depends on characteristics of the excitation wavelength. [Refer to a handbook on confocal microscopy, e.g., Pawley (1995), or a confocal microscope manufacturer's manual for optimizing microscopic parameters.]

2. For each optical section, quantify the average per-pixel fluorescence intensity of the labeled proteins using the imaging software. Determine the ratio of intensity obtained for the protein of interest to that of a known marker.

Analysis of Results

The ratio of fluorescent intensity obtained represents the relative distribution of the target protein and is interpreted as follows.

a. A constant pixel intensity ratio for all optical sections of a given monolayer suggests overlapping distribution of the target protein with the known marker.

b. Decreasing pixel intensity ratio in from basolateral to apical domain of the target protein and the apical or tight junction marker would mean that the protein is localized in the basolateral domain.

c. Increasing intensity ratio with a basolateral marker would mean that the target protein is apically targeted (see Rajasekaran *et al*., 1996).

I. Determination of Plasma Membrane Protein Polarity after Intranuclear Microinjection of Its cDNA

This procedure is used for rapid qualitative determination of the steady-state polarity of a newly synthesized protein in polarized cells. Analysis is performed using either a fluorescence wide-field or a confocal microscope. We have utilized this technique to study the regulation of polarity of basolateral and apical membrane markers by GTPases and their downstream effectors. Normal polarization of the monolayer needs to be confirmed by studying the localization of known apical or basolateral markers.

Solutions

1. *Microinjection buffer*: H-KCl buffer containing 10 m*M* HEPES, pH 7.4, 140 m*M* KCl. Dissolve 1.04 g of KCl in 99 ml deionized H_2O and then add 1.0 ml HEPES from a 1 *M* stock (pH 7.4). Sterilize the buffer by passing through a 0.22-µm filter and store at 4°C (Müsch *et al*., 2001).

2. *PBS/CM*: See Section III,A

3. *H-DMEM*: DMEM containing HEPES. Dissolve bicarbonate-free powdered DMEM in 900 ml deionized H_2O. Add 20 ml HEPES from a 1 *M* stock and adjust the pH to 7.4. Sterilize the medium through a 0.22-µm filter and store at 4°C.

4. *B–DMEM*: DMEM containing sodium bicarbonate

Steps

1. Plate MDCK II cells on sterile glass coverslips at a concentration of 1.6×10^6 cells/ml or at an approximate plating density of 2×10^5 cells per cm^2 in B-DMEM and 10% fetal bovine serum (FBS). Allow the cells to polarize for 4–5 days and change the medium only once on day 2 postplating. Growth conditions required to attain polarity for different cell lines vary and require optimization.

2. Dilute the stock of cDNA (stock prepared in deionized H_2O at a concentration of 0.5 mg/ml) in microinjection buffer to a concentration of around 10 µg/ml. It is highly recommended that cDNA constructs also contain a tag sequence, such as Myc, HA, GFP, and its variants, in-frame with the gene of interest so as to distinguish the newly synthesized proteins from endogenous proteins. For experiments involving more than one cDNA construct, cDNAs can be coinjected. However, the efficiency of expression of a construct may vary in the presence of another. Therefore, proper conditions should be established for good expression of each coinjected construct. A range of concentrations between 1 and 20 µg/ml of DNA should be tested to optimize their expression levels.

3. Prepare microinjection needles by pulling 1-mm-diameter and 6-in.-long borosilicate glass capillaries (1B100F-6, World Precision Instruments, Inc, Sarasota, FL) using a micropipette puller (e.g., Flaming/Brown Micropipette Puller Model P-97, Sutter Instrument Co., Novato, CA).

4. Load the cDNA diluted in microinjection buffer through the blunt end of the needle into the needle holder of the micromanipulator (Narishige Company, Ltd., SE-TAGAYA-KU, Tokyo, Japan) attached to the inverted microscope (Zeiss-Axiovert 25, Germany).

5. Transfer coverslip into 35-mm-diameter tissue culture dishes. Add 4 ml of H-DMEM containing 5% FBS to each dish and place the dish on the dish holder of the micromanipulator-microscope described earlier. Microinject the nucleus of cells. Avoid microinjecting cells that are right next to each other. This simplifies

the analysis of distribution of apical and basolateral markers. In order to avoid unsynchronized protein synthesis, preferably microinject within 10–15 min of transferring the dish to the microscope stage.

6. Incubate the microinjected cells with B-DMEM–10% FBS medium at 37°C. Most of the proteins accumulate in the ER within 60 × 90 min at 37°C post-microinjection. Different levels of expression should be tested to ensure that the sorting pathways are not saturated. For coinjections, it is necessary to standardize the conditions for sufficient expression of each protein. Adjustment of DNA concentrations (as described in step 2) and time of incubation at 37°C postmicroinjection are two steps that need to be tuned for expression of multiple constructs.

7. After appropriate incubation at 37°C, replace medium with B-DMEM–10% FBS containing 100 µg/ml cycloheximide (concentration may be lowered down to 20 µg/ml if cells detach from coverslip) to inhibit new protein synthesis. the chase time for plasma membrane delivery of protein is initiated at 37°C for 3–4 h.

8. After an appropriate chase period, fix cells with either –20°C chilled methanol for 10 min or 2% paraformaldehyde at room temperature for 15 min. Methanol fixation should be followed by a blocking step at room temperature with 1% BSA prepared in PBS-CM for 30 min. Paraformaldehyde fixation of cells is followed by permeabilization at room temperature for 30 min with either 0.2% Triton-X 100 or 0.075% saponin prepared in PBS-CM containing 1% BSA. Cells can now be processed for immunofluorescence with the appropriate primary and secondary antibodies.

Analysis of Results

Cells processed for immunofluorescence are imaged on either a confocal or a wide-field microscope. The correct orientation of the cells is determined by analyzing the staining of known polarized markers. In case of a wide-field microscope, the entire monolayer is subjected to *z* sectioning at least at 0.5-µm intervals with a 60× 1.4 NA objective, and standard deconvolution software is used to enhance the resolution. Alternatively, we use a confocal microscope in frame-scan mode and collect *xyz* stacks of the entire monolayer and display the *xyz* stack in the orthogonal plane. The cells can be displayed directly as a *xz* cross section by doing a line scan, i.e., scanning in the *xzy* mode. Localization of the protein is determined depending on the staining pattern, e.g., relative to a tight junctional marker such as ZO-1.

IV. COMMENTS

The methods described here represent examples of applications of the biotinylation technique; other examples of possible applications are (1) a transcytotic assay using a combination of the targeting and endocytosis protocols (Le Bivic *et al*., 1989; Zurzolo *et al*., 1992) and (2) detection of GPI-anchored proteins at the cell surface using Triton X-114 phase separation and PI-PLC digestion in place of the standard lysis procedure (Lisanti and Rodriguez-Boulan, 1990). Another analog of biotin, biotin hydrazide, can be used to label oligosaccharides of surface glycoproteins following periodate oxidation (Lisanti *et al*., 1989).

V. PITFALLS/RECOMMENDATIONS

1. It has been suggested that the use of pH 9.0 buffer to dilute sulfo-NHS-biotin would enhance the efficiency of labeling of surface proteins (Gottardi and Caplan, 1993). In our experience this is not always true and depends on different proteins and cell lines.

2. Always cut the filters out of the plastic holder before lysis. We have found that the cells can grow along the inside of the plastic ring supporting the filter. Lysis of these cells can result in erroneous results (Zurzolo and Rodriguez-Boulan, 1993).

3. Occasionally, in targeting experiments, intracellular nonbiotinylated forms are recovered on streptavidin beads. Using NHS-LC-biotin and keeping the SDS concentration at 0.4% helps reduce this. Another approach is to use NHS-SS-biotin and remove it from the streptavidin beads by incubation in 50 m*M* dithiothreitol of 5–10% 2-mercaptoethanol in 62.5 m*M* Tris, pH 8.0. Then spin the beads out and dilute the supernatant 1:1 with 2× Laemmli sample buffer.

4. The *in situ* biotinylation assay works best for proteins that are restricted to the RPE cell (i.e., RET-PE2 antigen). Quantification of proteins present in adjacent tissues (particularly the choroid) can contaminate the basolaterally labeled material and yield an incorrectly high level of basolateral labeling.

5. Determination of polarity by confocal microscopy can provide visual validation of the biochemical assay. It is useful for measuring the polarity of steady-state protein and dynamic changes involved in tight junction assembly in the Ca^{2+} switch assay. A thorough analysis with known markers of different domains is recommended before determining polarity of the target protein.

6. For determination of polarity by means of intranuclear microinjection of cDNA, thorough optimization regarding the protein expression level and the incubation time is necessary. Moreover, it is critical to avoid saturating the sorting pathway. Hence, coinjecting and monitoring a known apical or basolateral marker are critical for final evaluation. Because the basolateral domain of the polarized monolayer on the coverslip is not accessible to the antibody without permeabilization, it is difficult to distinguish the pool of basolateral protein that is associated with submembrane structures closely juxtaposed to the cytoplasmic side of plasma membrane and the pool present in the external leaflet of the plasma membrane.

Mitochondria

CHAPTER

34

Protein Translocation into Mitochondria

Sabine Rospert and Hendrik Otto

I. INTRODUCTION

Mitochondria from different sources such as rat liver, rabbit brain, or yeast can be isolated as intact organelles. Isolated mitochondria are able to respire, maintain a membrane potential across their inner membrane, possess an active ATP synthase, and shuttle nucleotides across their membranes. In addition, even a process as complicated as import of mitochondrial precursor proteins can be studied outside the living cell. For this purpose, radiolabeled precursor proteins, synthesized in an *in vitro* transcription/translation system, are mixed with isolated mitochondria (Glick, 1991; Melton *et al*., 1984). In the presence of ATP, precursor proteins will cross the mitochondrial membranes, become processed to their mature form, and fold to their native state. Building on this basic "import assay," sophisticated experiments have been developed and the results of these experiments provide most of what we know about mitochondrial import today (Neupert, 1997; Pfanner and Geissler, 2001).

This article describes a standard protocol for the *in vitro* synthesis of a radiolabeled precursor protein and the subsequent import of this precursor into isolated yeast mitochondria. As an example, we have selected the precursor protein yeast malate dehydrogenase (Dubaquié *et al*., 1998). The N-terminal presequence of the yeast malate dehydrogenase precursor, as is of most mitochondrial precursor proteins, is removed by a protease localized in the mitochondrial matrix (Jensen and Yaffe, 1988). The mRNA of the precursor protein is transcribed with SP6 RNA polymerase (Melton *et al*., 1984).

II. MATERIALS AND INSTRUMENTATION

SP6 RNA polymerase (Cat. No. 810 274); RNase inhibitor from human placenta (Cat. No. 799 017); set of ATP, CTP, GTP, UTP, lithium salts, 100 m*M* solutions (Cat. No. 1 277 057); creatine kinase from rabbit muscle (Cat. No. 127 566); creatine phosphate, disodium salt (Cat. No. 127 574); and proteinase K (Cat. No. 1092766) are from Roche. Tris (Cat. No. 108382); KCl (Cat. No. 104936); KOH (Cat. No. 105021); $MgCl_2$ (Cat. No. 105833); NaN_3 (Cat. No. 822335); 25% NH_3 solution (Cat. No. 105432); ethanol (Cat. No. 100983); and sodium salicylate (Cat. No. 106602) are from Merck. Spermidine (Cat. No. S 0266); bovine serum albumin, essentially fatty acid free (BSA) (Cat. No. A-7511); dithiothreitol (DTT) (Cat. No. D 5545); HEPES (Cat. No. H 7523); trypsin (Cat. No. T 1426); trypsin inhibitor, from soybean (Cat. No. T 9003); α-nicotinamide adenine dinucleotide disodium salt, reduced form (NADH) (Cat. No. N 6879); EDTA (Cat. No. E 9884); $(NH_4)_2SO_4$ (Cat. No. A 2939); $CaCl_2$, dihydrate (Cat. No. C 5080); magnesium acetate tetrahydrate (Cat. No. M 2545); valinomycin (Cat. No. V 0627); ATP, disodium salt (Cat. No. A 7699); glycerol (Cat. No. G 6279); potassium acetate (Cat. No. P 5708); KH_2PO_4 (Cat. No. P 5379); L-methionine (Cat. No. M 9625); urea (Cat. No. U 5128); phenylmethylsulfonyl fluoride (PMSF) (Cat. No. P 7626); tRNA, from bovine liver (Cat. No. R 4752); and Triton X-100 (Cat. No. T 9284) are from Sigma. Rabbit reticulocyte lysate (Cat. No. L 4960) and amino acid mixture, minus methionine (Cat. No. L 4960), are from Promega. NaCl (Cat. No. 9265.1) and trichloroacetic acid (TCA) (Cat. No. 8789.1) are

from Roth. Sorbitol (Cat. No. 2039) is from Baker. L-[^{35}S]methionine, >1000 Ci/mmol (Cat. No. SJ 235), m^{7}G(5Ç)ppp(5Ç)G (G-cap) (Cat. No. 27 4635 02), and Kodak X-OMAT X-ray film (Cat. No. V1651496) are from Amersham Biosciences. Sorvall centrifuge RC M120 GX, Kendro. Sorvall Rotor S100 AT3-204, Kendro. Eppendorf centrifuge 5417 R, "microfuge" Eppendorf. Greiner PP-tubes 15 ml (Cat. No. 188261), Greiner. X-ray cassettes (Cat. No Rö 13), GLW. Plasmid is pSP65mdh1 (Dubaquié *et al*., 1998). Highly purified mitochondria (25 mg/ml) are prepared after Glick and Pon (1995).

III. PROCEDURES

Solutions used directly as obtained from the supplier are only listed in Section II. Protocols for the preparation of solutions used throughout the procedure are only given once.

A. Transcription Using SP6 Polymerase

Solutions

1. *1 M Tris–HCl stock solution, pH 7.5*: Dissolve 12.1 g Tris in 80 ml H_2O and adjust pH to 7.5 with 5 *M* HCl. Add H_2O to 100 ml. Autoclave and store at room temperature.
2. *1 M HEPES–KOH, pH 7.4*: Dissolve 23.8 g HEPES in 80 ml H_2O and adjust pH to 7.4 using 4 *M* KOH. Add H_2O to 100 ml. Autoclave and store at room temperature.
3. *1 M spermidine*: Dissolve 145 mg spermidine in 1 ml H_2O. Store at –20°C.
4. *100 mg/ml BSA*: Dissolve 500 mg BSA in 5 ml H_2O. Store at –20°C.
5. *2.5 M $MgCl_2$*: Dissolve 50.8 g $MgCl_2$ in 100 ml H_2O. Autoclave and store at 4°C.
6. *2.5 M KCl*: Dissolve 18.6 g KCl in 100 ml H_2O. Autoclave and store at 4°C.
7. *100 mM DTT*: Dissolve 15.4 mg DTT in 1 ml H_2O. Store at –20°C. Make a fresh solution about every 4 weeks.
8. *5× SP6 reaction buffer*: 200 m*M* Tris–HCl, pH 7.5, 30 m*M* $MgCl_2$, 10 mM spermidine, and 0.5 mg/ml BSA. To obtain 10 ml of a 5x reaction buffer, mix 2 ml 1 *M* Tris–HCl, pH 7.5, 120 µl 2.5 *M* $MgCl_2$, 100 µl 1 *M* spermidine and 50 µl 100 mg/ml BSA. If necessary, readjust the pH to 7.5. Store in 1-ml aliquots at –20°C.
9. *G-cap (m^{7}G(5′)ppp(5′)G)*: Dissolve 25 A_{250} units in 242 µl H_2O. Freeze 10-µl aliquots in liquid nitrogen. Store at –70°C.
10. *5 mM* NTP–GTP: To make a 500 µl stock, add 25 µl 100 m*M* ATP, 25 µl 100 m*M* UTP, and 25 µl 100 m*M* CTP to 425 µl 20 m*M* HEPES–KOH, pH 7.4. Store in 100-µl aliquots at –70°C.
11. *5 mM GTP*: Mix 475 µl 20 m*M* HEPES–KOH, pH 7.4, with 25 µl 100 m*M* GTP solution.
12. *RNase inhibitor buffer*: 20 m*M* HEPES–KOH, pH 7.4, 50 m*M* KCl, 10 m*M* DTT, and 50% glycerol. Make 10 ml of the buffer by mixing 200 µl 1 *M* HEPES–KOH, pH 7.4, 200 µl 2.5 *M* KCl, 1 ml 100 m*M* DTT, and 5 ml glycerol. Add H_2O to 10 ml and store at –20°C.
13. *4 units/µl RNase inhibitor*: Add 500 µl RNase inhibitor buffer to 2000 units of RNase inhibitor. Store at –20°C for up to 6 months.
14. *1 µg/µl linearized plasmid DNA*: Prepare the linearized plasmid (pSP65mdh1) according to standard molecular biology procedures.

Steps

1. Mix the following solutions carefully, avoiding the formation of air bubbles. Follow the indicated order of addition because the DNA might precipitate in 5× SP6 buffer. Precipitation of DNA can also occur if the mixture is placed on ice. Incubate the mixture at 40°C for 15 min.

H_2O	12 µl
4 units/µl RNase inhibitor	1 µl
1 µg/µl linear plasmid (pSP65mdh1)	5 µl
5 m*M* rNTPs minus GTP	5 µl
5 m*M* G-cap	5 µl
100 m*M* DTT	5 µl
5× SP6 buffer	10 µl
SP6 polymerase	2 µl

2. Start transcription by adding 5 µl 5 m*M* GTP solution and incubate for 90 min at 40°C.
3. Extract the mRNA with phenol/chloroform and then with chloroform/isoamylalcohol, precipitate with 100% ethanol, and wash with 70% ethanol. Resuspend the dried pellet in 125 µl H_2O.
4. The mRNA obtained by this procedure is used directly in the translation protocol. mRNA can be stored in 10-µl aliquots at –70°C. If frozen mRNA is used for translation, thaw rapidly and keep at room temperature before adding the mRNA to the translation reaction.

B. Translation Using Reticulocyte Lysate

Solutions

1. *1 M DTT*: Dissolve 154 mg DTT in 1 ml H_2O. Store at –20°C. Make a fresh solution about every 4 weeks.

2. *8 mg/ml creatine kinase*: Dissolve 8 mg creatine kinase in 475 µl H_2O. Add 20 µl 1 *M* HEPES–KOH, pH 7.4, 5 µl 1 *M* DTT, and 500 µl glycerol. Freeze in 10-µl aliquots in liquid nitrogen and store at –70°C.
3. *5 mg/ml tRNA*: Dissolve 10 mg tRNA from bovine liver in 2 ml H_2O. Store in 100-µl aliquots at –20°C.
4. *400 mM HEPES–KOH, pH 7.4*: Mix 6 ml H_2O with 4 ml 1 *M* HEPES–KOH, pH 7.4. If necessary, readjust pH.
5. *10 mM GTP*: Mix 450 µl 20 m*M* HEPES–KOH, pH 7.4, with 50 µl 100 m*M* GTP. Store at –20°C.
6. *100 mM ATP*: Dissolve 55.1 mg ATP in 900 µl H_2O. Adjust to pH ~7 using 4 *M* NaOH and pH indicator paper. Adjust volume to 1 ml and store at –20°C.
7. *600 mM creatine phosphate*: Dissolve 153.06 mg creatine phosphate in 1 ml H_2O. Store at –20°C.
8. *4 M potassium acetate*: Dissolve 3.92 g potassium acetate in 10 ml H_2O. Do not adjust the pH. Store at –20°C.
9. *50 mM magnesium acetate*: Dissolve 10.7 mg magnesium acetate tetrahydrate in 1 ml H_2O. Store at –20°C.

Steps

1. Prepare the reticulocyte lysate mix and the tRNA mix fresh. To obtain a 100-µl translation reaction, mix the following solutions.

Reticulocyte lysate mix		tRNA mix	
0.4 *M* HEPES–KOH	5 µl	5 mg/ml tRNA	6 µl
10 m*M* GTP	0.6 µl	4 units/µl RNase inhibitor	6 µl
100 m*M* ATP	0.5 µl	4 *M* potassium acetate	3 µl
1 m*M* amino acid mix	3.75 µl		
0.6 *M* creatine phosphate	2 µl		
reticulocyte lysate	50 µl		
8 mg/ml creatine kinase	2 µl		

2. Use the mRNA obtained in Section III,A. It is possible to use mRNA produced in a different transcription system, e.g., with T7 RNA polymerase. Mix 60 µl reticulocyte lysate mix, 10 µl tRNA mix, 2 µl 50 m*M* magnesium acetate, 18 µl mRNA, 10 µl [^{35}S]methionine, and 2 µl 1 *M* DTT.

3. Incubate this mixture for 60 min at 30°C. Shield it from light to prevent heme-induced photooxidation of the precursor proteins. Remove ribosomes after the translation reaction by centrifugation for 15 min at 150,000 *g* (65,000 rpm with S100 AT3-204 rotor in Sorvall centrifuge). Remove the supernatants, being careful not to disturb the ribosomal pellet.

C. Denaturation of Radiolabeled Precursor Protein

Solutions

1. *Saturated $(NH_4)_2SO_4$ solution*: Weigh 100 g $(NH_4)_2SO_4$ and add H_2O to a final volume of 100 ml. Stir for 30 min at room temperature. The $(NH_4)_2SO_4$ will not dissolve entirely. Remove the supernatant and keep at room temperature.
2. *8 M urea*: Dissolve 4.85 g urea in a final volume of 10 ml 25 m*M* Tris–HCl, pH 7.5, containing 25 m*M* DTT.

Steps

1. Proteins synthesized in reticulocyte lysate are either folded or bound to chaperone proteins present in the lysate (Wachter *et al*., 1994). In order to unfold the protein prior to import, it can be precipitated by high concentrations of ammonium sulfate and subsequently denatured in 8 *M* urea.

2. Add 200 µl of the $(NH_4)_2SO_4$ solution to the 100-µl translation reaction. Mix well and allow precipitation of the protein for 30 min on ice. Collect precipitate by centrifugation in an Eppendorf centrifuge at 20,000 *g* for 10 min.

3. Discard the supernatant and dissolve the pellet in 100 µl of 8 *M* urea solution. Keep the denatured precursor at room temperature for 10–30 min. This precursor solution is used for the import reaction (Section III,D) and preparation of the precursor standard (Section III,G).

D. Import of Denatured Radiolabeled Precursor Proteins

Solutions

For additional solutions required, see Sections III,A and III,B.

1. *2.4 M sorbitol*: Dissolve 43.7 g of sorbitol in a final volume of 100 ml H_2O. Autoclave and store at 4°C.
2. *1 M KH_2PO_4*: Dissolve 1.36 g KH_2PO_4 in 10 ml H_2O. Filter sterilize and keep at room temperature.
3. *1 M HEPES–KOH, pH 7.0*: Dissolve 23.8 g HEPES in 80 ml H_2O and adjust pH to 7.0 with 4 *M* KOH. Add H_2O to a final volume of 100 ml. Filter sterilize and store at room temperature.
4. *250 mM EDTA, pH 7.0*: Resuspend 7.3 g of EDTA in 70 ml H_2O. Adjust pH to 7.0 using 5 *M* NaOH. Add H_2O to a final volume of 100 ml. Filter sterilize and keep at room temperature.
5. 2× *import buffer*: 1.2 *M* sorbitol, 100 m*M* HEPES–KOH, pH 7.0, 100 m*M* KCl, 20 m*M* $MgCl_2$,

5 m*M* EDTA, pH 7.0, 4 m*M* KH_2PO_4, 2 mg/ml BSA, and 1.5 mg/ml methionine. To make 100 ml of 2× import buffer, mix 50 ml 2.4 *M* sorbitol, 400 µl 1 *M* KH_2PO_4 solution, 4 ml 2.5 *M* KCl, 10 ml 1 *M* HEPES–KOH, pH 7.0, 0.8 ml 2.5 *M* $MgCl_2$, 2 ml 250 m*M* EDTA, pH 7.0, 150 mg methionine, and 200 mg BSA. Adjust pH to 7.0 and add H_2O to 100 ml. Store at –20°C.

6. *1× import buffer minus BSA*: Prepare 2× import buffer, but without BSA. To obtain 1× import buffer minus BSA, mix 2 ml 2× import buffer with 2 ml H_2O.

7. *500 mM NADH*: Dissolve 35.5 mg of NADH in a final volume of 100 µl 20 mM HEPES–KOH, pH 7.0. Store at –20°C.

8. *1 mg/ml valinomycin*: Dissolve 2 mg valinomycin in 2 ml ethanol. Store at –20°C.

9. *Purified yeast mitochondria*: 25 mg mitochondrial protein/ml. Store at –70°C in 0.6 *M* sorbitol, 20 m*M* HEPES–KOH, pH 7.4, and 10 mg/ml BSA. Thaw rapidly at 25°C immediately before the experiment. Do not refreeze. A detailed protocol of the purification procedure is given in Glick and Pon, (1995).

Steps

1. Import into the matrix of mitochondria requires a membrane potential across the inner mitochondrial membrane. Therefore, the most thorough control for the specificity of an import reaction is to determine its dependence on a membrane potential. Adding ATP and the respiratory substrate NADH generates this potential. (Note that mammalian mitochondria cannot oxidize added NADH.)

2. Perform two import reactions, one in the absence and one in the presence of valinomycin. Preincubate the import reaction in a 15-ml Greiner tube at 25°C for 1–2 min.

Reaction 1 (+ membrane potential)		**Reaction 2 (no membrane potential)**	
2× import buffer	500 µl	2× import buffer	500 µl
100 m*M* ATP	20 µl	100 m*M* ATP	20 µl
500 m*M* NADH	4 µl	500 m*M* NADH	4 µl
Yeast mitochondria	20 µl	Yeast mitochondria	20 µl
H_2O	406 µl	H_2O	405 µl
		1 mg/ml valinomycin	1 µl

3. Add 50 µl of the denatured precursor protein solution (see Section III,C) containing denatured malate dehydrogenase to each reaction (reactions 1 and 2). Intact mitochondria should be handled gently. However, it is essential to mix the denatured precursor protein into the import reaction rapidly. Agitate the import reaction gently on a vortex mixer while adding the denatured precursor mixture dropwise. If mixing is performed only after addition, the precursor protein tends to aggregate and becomes import incompetent.

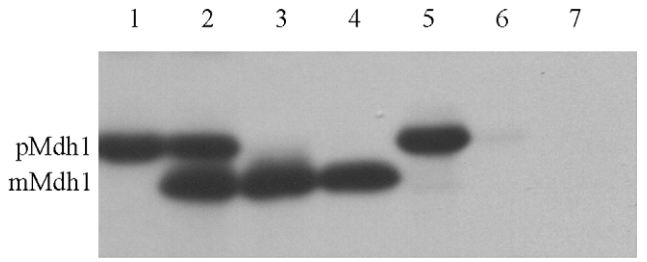

FIGURE 1 Import of radiolabeled yeast malate dehydrogenase into isolated yeast mitochondria. Lane 1, 10% of the material added to each import reaction; lanes 2–4, import in the presence of ATP and a membrane potential across the inner mitochondrial membrane; and lanes 5–7, import in the absence of ATP and a membrane potential across the inner mitochondrial membrane. Lanes 2 and 5: total; material isolated together with the mitochondrial pellet. Lanes 3 and 6: import; material protease protected in intact mitochondria. Lanes 4 and 7: folded; material protease resistant even after solubilization of the mitochondria with Triton X-100. pMdh1, precursor form of Mdh1; mMdh1, mature form of Mdh1. For experimental details, see text.

4. Incubate at 25°C for 10 min. Agitate gently every other minute to facilitate gas exchange. Stop the import reaction by transferring the tubes onto ice. Add 1 µl of 1 mg/ml valinomycin to reaction 1.

5. Remove 200 µl each from reactions 1 and 2 and put the samples on ice. Spin down mitochondria in an Eppendorf centrifuge and remove the supernatant (be careful, the pellet will be very small). Resuspend the mitochondrial pellets of reactions 1 and 2 in each 200 µl of 1× import buffer. These samples represent the **total** of the two import reactions (Fig. 1, lanes 2 and 5). Add 22 µl 50% TCA to each. Keep on ice and process further after all samples have been acid denatured (for the method of TCA precipitation, see Section III,G).

E. Protease Treatment of Intact Mitochondria

Solutions

1. *10 mg/ml trypsin*: Dissolve 3 mg of trypsin in 300 µl H_2O. Make fresh.
2. *20 mg/ml trypsin inhibitor*: Dissolve 6 mg of trypsin inhibitor in 300 µl H_2O. Make fresh.

Steps

Perform the following steps in parallel with both import reactions.

1. To digest precursor proteins that stick to the surface of the mitochondria, add 8 µl 10 mg/ml trypsin (final concentration 100 µg/ml). Incubate for 30 min on ice.

2. Add 8 µl 20 mg/ml trypsin inhibitor (final concentration 200 µg/ml) and incubate on ice for 5 min.
3. Transfer the sample into a new Eppendorf tube.
4. Spin for 3 min in an Eppendorf microfuge at 10,000 *g*. Remove the supernatant carefully by aspiration.
5. Carefully resuspend the mitochondrial pellet in 800 µl 1× import buffer minus BSA. As it is extremely important to resuspend the pellet completely, it should be done as follows. First add 100 µl of 1× import buffer minus BSA and resuspend mitochondria by pipetting up and down. Then add another 700 µl of 1× import buffer minus BSA to yield 800 µl final volume.
6. Remove 200 µl of each sample and add 22 µl 50% TCA. Keep on ice. These samples represent the material that has crossed the outer membrane completely (**import**, Fig. 1, lanes 3 and 6).

F. Inherent Protease Resistance of the Imported Protein

Solutions

1. *1 M Tris–HCl stock solution, pH 8.0*: Dissolve 12.1 g Tris in 80 ml H_2O and adjust pH to 8.0 using 5 *M* HCl. Add H_2O to a final volume of 100 ml. Autoclave and store at room temperature.
2. *2 M $CaCl_2$*: Dissolve 14.7 g $CaCl_2$ in 50 ml H_2O. Autoclave and store at room temperature.
3. *10% Triton X-100 (w/v)*: Dissolve 10 g of Triton X-100 in a final volume of 100 ml H_2O. Store at room temperature in the dark.
4. *10% NaN_3*: Dissolve 1 g NaN_3 in a final volume of 10 ml H_2O. Store at room temperature.
5. *Proteinase K buffer*: 50 m*M* Tris–HCl, pH 8.0, 1 m*M* $CaCl_2$, and 0.02 % NaN_3. To make 10 ml of proteinase K buffer, mix 500 µl 1 *M* Tris–HCl, pH 8.0, 5 µl 2 *M* $CaCl_2$, and 20 µl 10% NaN_3. Add H_2O to a final volume of 10 ml. Store at room temperature.
6. *10 mg/ml proteinase K stock*: Dissolve 5 mg of proteinase K in 500 µl proteinase K buffer. Store at 4°C for up to 1 week without loss of activity.
7. *200 µg/ml proteinase K solution*: Mix 10 µl of 10 mg/ml proteinase K stock with 390 µl H_2O. Add 100 µl 10% Triton X-100. Make fresh.
8. *200 mM PMSF*: Make a fresh solution of PMSF by dissolving 34.85 mg of PMSF in 1 ml of ethanol.

Steps

1. Transfer 200 µl from the remainder of the import reaction into a fresh Eppendorf tube. Add 200 µl of the 200-µg/ml proteinase K solution and mix rapidly. Leave the tube on ice for 15 min.

2. Add 2 µl 200 mM PMSF while agitating on a vortex mixer. Keep on ice for 5 min. Add 44 µl 50% TCA. Add 300 µl of acetone to dissolve the Triton X-100 that precipitates in the presence of TCA. These samples measure the fraction of the precursor protein that has completely crossed the outer membrane and has reached the folded state (**folded**, Fig. 1, lanes 4 and 7).

G. Final Processing of Samples and Preparation of a Precursor Standard

Steps

1. To inactivate proteases, incubate the TCA-precipitated samples (total, import, folded) at 65°C for 5 min. Place on ice for 5 min and subsequently collect the TCA precipitate by spinning for 10 min at 20,000 *g*.
2. Remove supernatant by aspiration and dissolve the pellets in 30 µl 1× sample buffer. If the sample buffer turns yellow, overlay the sample with NH_3 gas taken from above a 25% NH_3 solution. Agitate to mix the gaseous NH_3 gas into the sample buffer until the color turns blue again.
3. Incubate the samples for 5 min at 95°C.
4. To estimate the efficiency of the import reaction, the amount of precursor protein added to the import reaction has to be determined. The efficiency of import for most precursor proteins is between 5 and 30%. Here we use a 10% standard (Fig. 1, lane 1).
5. To obtain a 10% standard, mix 4µl of purified yeast mitochondria (see Section III,D) with 30 µl 1× sample buffer. Incubate at 95°C for 3 min.
6. Add 1 µl of the precursor protein solution (Section III,C) and incubate for 5 min at 95°C.

H. SDS–Gel Electrophoresis and Processing of the Gel

Solutions

1. *5% TCA*: To make 5 liter, add 250 g of TCA to 5 liter H_2O.
2. *1 M Tris base*: Dissolve 121 g of Tris in 1 liter H_2O.
3. *1 M sodium salicylate*: Dissolve 160 g of sodium salicylate in 1 liter H_2O.

Steps

1. Run samples on a 10% Tris–tricine gel (Schägger and von Jagow, 1987) stabilized by the addition of 0.26% linear polyacrylamide prior to polymerization.
2. To reduce radioactive background, boil 5% TCA in a beaker under the hood. Add the gel to the boiling TCA and incubate for 5 min.

3. Recover the gel and place it into a tray. Wash briefly with water. Neutralize by incubation in 1 *M* Tris-base for 5 min on a shaker.
4. Wash briefly with water. Add 1 *M* sodium salicylate and incubate for 20 min on a shaker.
5. Dry gel on a Whatman filter paper and expose to a Kodak X-OMAT X-ray film for the desired time. Exposure time for the experiment shown in Fig. 1 was 12 h.

IV. COMMENTS

The method describes a standard experiment to test a precursor protein that has not been used in mitochondrial import before. Most importantly, as demonstrated here for malate dehydrogenase, the protocol will reveal if import is dependent on a membrane potential (compare Fig. 1 lanes 3 and 6). This is essential, as sometimes protease-resistant precursor proteins tend to stick to the outside of mitochondria, thereby "mimicking" import.

The efficiency of import can be deduced by a comparison of the amount of imported material with a precursor standard (compare Fig. 1 lanes 1 and 3). In addition, the experiment reveals if a precursor protein folds to a protease-resistant conformation after its import into the mitochondrial matrix. Under the conditions chosen here, complete protease resistance was obtained for malate dehydrogenase (Fig. 1, lanes 3 and 4).

V. Pitfalls

The quality of the DNA used for transcription is essential for efficiency. Use a clean, RNA- and RNase-free plasmid preparation (e.g., purified with a Qiagen plasmid kit, Qiagen). Linearize plasmid by cutting with a restriction enzyme behind the coding region of the gene of interest. Extract with phenol/chloroform and then with chloroform/isoamylalcohol, precipitate with 100% ethanol, and wash with 70% ethanol. Resuspend the dried pellet in H_2O at a concentration of 1 µg/µl and store at 4°C. Never freeze DNA templates used for transcription.

To avoid RNase contamination, solutions used for transcription and translation have to be prepared with special caution. Always wear gloves even when loading pipette tips into boxes. If initiation at downstream AUG codons is a problem, try diluting the reticulocyte lysate up to fourfold.

It is important to establish that import is linear with time. To establish those conditions it is necessary to perform time course experiments of the import reaction and to try import at different temperatures.

Methods for determining the intramitochondrial localization of an imported precursor protein (Glick, 1991), investigating the energy requirements of mitochondrial import (Glick, 1995), and detecting interaction between imported precursor proteins and matrix chaperones (Rospert and Hallberg, 1995) have been published elsewhere.

Polarographic Assays of Mitochondrial Functions

Ye Xiong, Patti L. Peterson, and Chuan-pu Lee

I. INTRODUCTION

Mitochondrial metabolic functions are primarily concerned with the conservation of energy liberated by the aerobic oxidation of respiring substrates. Energy is conserved in the form that can subsequently be used to drive various cell functions. In recent years, it has been found that mitochondria also play critical roles in various cellular functions, including electrolyte balance, signal transduction, calcium homeostasis, oxidative stress, immunologic defense, and natural aging and/or apoptosis (cf. Lee, 1994).

Application of the oxygen electrode technique to study mitochondrial respiration and oxidative phosphorylation was first introduced by Chance and Williams in 1955. The kinetic dependence of mitochondrial respiration on the availability of inorganic phosphate and ADP had been earlier reported by Lardy and Wellman (1952). Together, these studies provided the basis of the concept of respiratory control. The polarographic technique for measuring rapid changes in the rate of oxygen utilization by cellular and subcellular systems is now widely used by many laboratories because of its simplicity and ease of performance. Concurrent monitoring of the metabolic changes induced kinetically by various substrates and reagent(s) can provide invaluable information.

This article describes a typical protocol employed in the authors' laboratory for the measurement of respiratory rates and its accompanied oxidative phosphorylation, which are catalyzed by isolated mitochondria. As an example, isolated intact mitochondria were chosen for presentation and discussion. The technique for preparation of isolated intact mitochondria has been described previously (Lee *et al.*, 1993a, b).

II. INSTRUMENTATION AND MATERIALS

The polarographic technique for measuring mitochondrial oxidative changes requires the following four basic components: an oxygen electrode, a closed reaction vessel, a constant voltage source, and a recorder. The Clark-type oxygen electrode is used most commonly (Yellow Springs Instrument Co., Yellow Springs, Ohio, 45387) and consists of a platinum cathode and a Ag/AgCl anode, which is bathed in a half-saturated KCl solution. The tip of the electrode is covered by a polyethylene membrane, which is held firmly over the end of the electrode by a rubber "O" ring. The reaction vessel can be constructed of glass, Plexiglas, or polycarbonate, and the design and the size of the vessel vary, depending on the requirements of the system under investigation. A number of vessels are available commercially. The reaction vessel used routinely in the authors' laboratory was made of polycarbonate and is composed of two parts: a cylindrical open top reaction chamber and a plug that fits in the top of the chamber. The temperature of the reaction chamber is constantly maintained with a water jacket. Constant stirring of the contents of the reaction chamber is accomplished by a disk-shaped, plastic-encased magnet located at the bottom of the reaction chamber. The polycarbonate plug, which is secured with a screw, fits tightly in the top of the reaction chamber. The plug has two vertical openings: the

larger is fitted with a screw that holds the Clark electrode securely and the smaller one is used for the delivery of substrate(s) and reagent(s) into the reaction mixture. The physical arrangement of the reaction chamber and the oxygen electrode in the assembled form are shown in Fig. 1A. The disassembled form, which shows the details of each individual component, is shown in Fig. 1B.

It is imperative that closed reaction vessels are utilized so that air bubbles are not trapped and back diffusion of oxygen is reduced to a minimum. To facilitate this, the bottom of the plug is uneven to ensure that no air bubbles are trapped (cf. Fig. 1B). This aids the exit of air bubbles (if any) from the chamber and allows the mixing of added reagents without introducing air bubbles into the reaction mixture. Use of the magnetic stirrer permits continued steady mixing, at a constant temperature, of the reaction mixture. This facilitates the establishment of equilibrium between the oxygen dissolved in solution and the gas diffusing through the polyethylene membrane of the oxygen electrode. The electrode equilibrates with the air-saturated reaction mixture. Reactants and substrates are added through the small narrow opening at the top of the reaction chamber.

At the conclusion of each experiment the reaction chamber is cleaned by first disassembling the plug from the reaction chamber, aspirating the reaction mixture, and washing the plug, oxygen electrode, and the interior of the reaction chamber thoroughly with water. When a water-insoluble reagent is used, initial cleaning is accomplished with ethanol and is then followed with water rinsing. It is essential that no traces of ethanol are left behind as adverse effects may be induced. The reaction vessel is then reassembled and is ready for the next experiment.

When a voltage is imposed across the two electrodes immersed in an oxygen-containing solution, with the platinum electrode negative relative to the reference electrode, oxygen undergoes an electrolytic reduction. When current is plotted as a function of polarizing voltage, a plateau region is observed

between 0.5 and 0.8 V. With a polarization voltage of –0.6 V, the current is directly proportional to the oxygen concentration of the solution (Davies and Brink, 1942). The current is generally measured with a suitable amplifier and recorder combination. An oxygen meter (SOM-1, University of Pennsylvania Biomedical Instrumentation Group) and a Varian XY recorder (Model 9176) are used in our laboratory.

Reagents

From Sigma Chemicals Co.: Sucrose (Cat. No. S-978), bovine serum albumin (BSA, Cat. No. A-4378), EGTA (Cat. No. E-4378), EDTA (Cat. No. ED2SS), adenosine 5'-diphosphate (ADP, Cat. No. A-6646), L-malic acid (Cat. No. M-1000), pyruvic acid (Cat. No. P-2256), β-NADH (Cat. No. 340-110), HEPES (Cat. No. H-3375), carbonyl cyanide 4-trifluoromethoxyphenyl-hyddrazone (FCCP, Cat. No. C22920), antimycin A (Cat. No. A 8674), oligomycin (Cat. No. O-4876), Tris (Cat. No. T-1503), crystalline *Bacillus subtilis* protease (Nagarse) from Teikoku Chemical Company, Osaka, Japan, or Sigma P-4789, protease type XXVII (7.6 units/mg solid), phospho(enol)pyruvic acid (PEP, Cat. No. P-0564), pyruvate kinase (Cat. No. P-9136), β-hydroxybutyric acid (Cat. No. H 6501), and lactic dehydrogenase (LDH, Cat. No. L-2375).

From other sources: $MgCl_2 \cdot 6H_2O$ (M-33, Fisher Scientific), KH_2PO_4 (P-285, Fisher Scientific), HCl [UN1789, 36.5% (w/w), Fisher Scientific], K_2HPO_4 (3252-2, T. J. Baker), and KCl (No-3040, T. J. Baker), KOH (UN1813, Fisher Scientific), KCN (Lot 6878KBPH, Mallinckrodt, Inc., KT 40361).

III. PROCEDURES

A. Preparation of Solutions

1. *0.25 M sucrose*: Dissolve 171.15 g of sucrose in 1000 ml distilled water, filter through a layer of glass wool, add distilled water to 2 liters in a volumetric flask, mix well, and store at 4°C.

2. *0.5 M Tris–HCl, pH 7.4*: Dissolve 30.28 g Tris into 400 ml distilled water, adjust pH to 7.4 with 4 *N* HCl, add distilled water to 500 ml in a volumetric flask, mix well, adjust the pH if necessary, and store at 4°C.

3. *0. 5 M* $MgCl_2$: Dissolve 10.17 g of $MgCl_2 \cdot 6H_2O$ in 100 ml distilled water.

4. *0.1 M phosphate buffer, pH 7.4*: To 800 ml distilled water, dissolve 11.83 g of Na_2HPO4 and 2.245 g of KH_2PO4 with the aid of magnetic stirrer. Check the pH and adjust with 0.1 *M* HCl or 0.1 *M* NaOH if necessary. Add distilled water to 1000 ml in a volumetric flask, mix well, and store at 4°C.

5. *0.2 M EDTA, pH 7.4*: Dissolve 3.72 g EDTA in 35 ml of 1 *N* NaOH. Stir until it dissolves completely; adjust pH to 7.4 with 1 *N* HCl. Add distilled water to 50 ml. Divide into 10 × 5.0 ml and store at –20°C.

6. *0.1 M HEPES, pH 7.4*: Dissolve 23.83 g HEPES in 800 ml distilled water. Adjust with 1 *M* NaOH to pH 7.4. Add distilled water to 1000 ml in a volumetric flask. Mix well and store at 4°C.

7. *Sucrose/Tris–Cl (S/T) reaction medium*: 60 ml 0.25 *M* sucrose, 5 ml 0.5 *M* Tris–HCl (pH 7.4), and 35 ml distilled water to a final volume of 100 ml. Make the S/T medium fresh every day.

8. *1.0 M pyruvate, pH 7.4*: Dissolve 5.5 g pyruvic acid in 20 ml of 1 *N* NaOH; adjust with 5 *N* NaOH to pH 7.4. Add distilled water to 50 ml in a volumetric flask. Mix well, transfer into 10 test tubes with each containing 5 ml, and store at –20°C.

9. *0.5 M malate, pH 7.4*: Dissolve 3.35 g of DL-malic acid in 20 ml of 1 *N* NaOH; adjust with 5 *N* NaOH to pH 7.4. Add distilled water to 50 ml in a volumetric flask. Mix well and transfer into 10 test tubes and store at –20°C.

10. *0.1 M ADP, pH 6.8–7.4*: Dissolve 0.48 g ADP in 5 ml distilled water, adjust with 1 *N* NaOH to pH to 6.8–7.4, and add distilled water to 10 ml in a volumetric flask. Mix well, transfer into five test tubes (≈ 2 ml/tube), and store at –20°C. The concentration of ADP will be determined spectrophotometrically with the pyruvate kinase coupled with lactate dehydrogenase system (see later).

11. *0.1 M phosphoenolpyruvate (PEP), pH. 7.4*: Dissolve 20.8 mg PEP into 0.6 ml 1 *N* KOH, adjust pH to 7.4 with 5 *N* KOH, and add distilled water to 1.0 ml. Mix well, transfer into five vials (0.2 ml/vial), and store at –20°C.

12. *1.0 mg/ml oligomycin*: Dissolve 10 mg oligomycin in 10 ml absolute ethanol. Store at –20°C.

13. *FCCP 1 mM*: Dissolve 5.03 mg FCCP into 20 ml absolute ethanol in a glass tube (either dark glass or covered with aluminum foil to protect against light) and store at –20°C.

B. Enzymatic Assay of ADP Concentration (Jaworek et al., 1974)

This assay is based on a pair of coupled reactions. ADP in the presence of an excess amount of (PEP) and pyruvate kinase will be completely converted into ATP and an equal concentration of pyruvate. The pyruvate will then be converted to lactate in the presence of

lactate dehydrogenase and an excess amount of NADH. The NAD^+ formed is equal to the concentration of lactate. The stoichiometry of ADP to NADH bears a 1:1 relationship. The concentration of ADP is therefore equal to that of NADH oxidized. See the following reaction mixture: 2.8 ml S/T medium, 50 µl pyruvate kinase (3 IU), 10 µl lactic dehydrogenase (1 IU), 15 µl NADH (30 m*M*), 20 µl PEP (0.1 *M*), 80 µl $MgCl_2$ (0.25 *M*), and 20 µl KCl (1.0 *M*). The total volume equals 3.0 ml.

Calibrate the spectrophotometer and the settings of the recorder according to the instruction manuals of the instrument and set the wavelength at 340 nm.

1. Place the sample cuvette in the sample chamber with 150 µ*M* NADH (15 µl, 30 m*M*) present; an absorbance in the vicinity of 0.9 is indicated on the instrument and the recorder.
2. Turn on the recorder, let it proceed to a constant reading (a minute or two), add 3 µl of 0.1 *M* ADP, and stir the solution well with a glass or plastic stirrer; the absorbance at 340 nm will decline quickly (when sufficient pyruvate kinase and lactate dehydrogenase are present) followed by a sharp transition to a constant level where there are no more changes in 340 nm absorbance. The decline of 340 nm absorbance reflects the oxidation of NADH. The extent of absorbance change (i.e., $\Delta A = 0.63$) is dependent on the amount of ADP added into the cuvette.
3. The concentration of ADP can therefore be calculated from the absorbance changes at 340 nm. The millimolar absorbance coefficient for NADH is 6.22 $mM^{-1}\,cm^{-1}$. The ADP concentration = [0.63 / 6.22] × [3.0 / 0.003] = 101 m*M*.

C. Calibration of Oxygen Concentration

A simple and rapid method of determining the oxygen content of the reaction medium accurately is by using submitochondrial particles (SMP) with a limiting amount of NADH. The high affinity of SMP for NADH permits a stoichiometric titration of oxygen content. NADH concentration can be determined accurately spectrophotometrically (as shown in the previous section). When limiting concentrations of NADH are added, the change in current, which occurs with complete oxidation of the NADH, can be determined directly. A direct calibration can therefore be obtained. For example, add 0.98 ml of air-saturated S/T medium first followed by 10 µl SMP (0.2 mg protein) to the reaction chamber. Allow the reaction mixture to thermo equilibrate; no air bubbles should be trapped in the reaction vessel. Add 5 µl NADH (150 µ*M*) to the chamber. Immediately initiated oxygen uptake with a linear kinetics, followed by a sharp transition to a straight line (i.e., oxygen uptake ceases) when all the added NADH is oxidized. This assay can also be used to estimate of back diffusion of oxygen into the reaction mixture. For instance, if there is a back diffusion of oxygen, an increase in oxygen concentration in the reaction mixture will be noted on the left deflection (a negative slop) of the recorder tracing.

D. Determination of Rate of Oxygen Consumption and ADP/O Ratio of Intact Mitochondria

Figure 2A shows a recording tracing from a typical experiment utilizing the oxygen electrode apparatus of the type shown in Fig. 1 to determine the respiratory control index (RCI) and P/O ratio of a tightly coupled mitochondrial preparation. Suspend freshly prepared mouse skeletal muscle mitochondria (30–50 µl) in an air-saturated P_i-containing isotonic sucrose medium (0.9 ml); the addition of substrates [5 µl pyruvate (1 *M*) + 5 µl malate (0.5 *M*)] causes a slow rate of oxygen uptake (state 4). Subsequent addition of 3 µl ADP (100 m*M*) increases the rate (state 3) by 11-fold. Upon the expenditure of the added ADP, as indicated by the sharp transition in the polarographic tracing, the rate of oxygen uptake declines to that observed before the addition of ADP. The duration of the increased rate of oxygen uptake is proportional to the amount of ADP added to the reaction mixture. The concentration of oxygen consumed is proportional to the amount of ADP phosphorylated to ATP. These cycles of

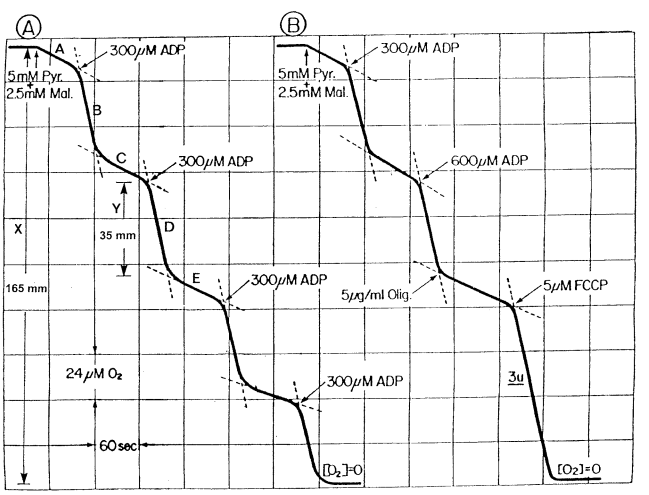

FIGURE 2 Polarographic tracing of mouse skeletal muscle mitochondria oxidizing pyruvate plus malate. The reaction mixture consists of 150 m*M* sucrose, 25 m*M* Tri–HCl, and 10 m*M* phosphate, pH 7.5. Additions are as indicated. Volume, 1.0 ml; temperature, 30°C.

stimulation of respiration by the addition of ADP could be repeated several times in a single experiment until all the oxygen in the reaction mixture is consumed (Fig. 2A). The ADP/O [P/O] ratio and RCI can be calculated directly from the oxygen electrode tracing. The dependence of substrate oxidation on the presence of ADP indicates that electron transfer of the respiratory chain and ATP synthesis are coupled to each other. Unless the energy generated during electron transfer is utilized for ATP synthesis or other energy-requiring processes, the oxidation of respiring substrate is restrained.

The recorder deflection "*X*" (165 mm) represents the total oxygen content of the reaction medium (e.g., 240 μ*M* O_2 at 30°C). Distance "*Y*" is determined by extending the slops of lines A, B, and C and measuring the length of the tracing from the intersects of lines A and B and lines B and C. "*Y*" (34 mm) represents the amount of O_2 utilized by the externally added ADP (300 μ*M*). The ADP/O ratio can therefore be calculated by dividing the amount of ADP by the amount of oxygen utilized. The amount of oxygen utilized can be calculated as follows: Total oxygen content {[240 μ*M*] ÷ "*X*" [165 mm]} × "*Y*" [34 mm] × volume of the reaction mixture [1.0 ml] × 2 = 99 mμatoms oxygen utilized. The amount of ADP was added at the point indicated, e.g., 300 μ*M* ADP or 300 mμmol ADP. The ADP/O ratio is therefore = 300 / 99 = 3.01.

The respiratory control index is defined as the ratio of respiratory rate in the presence of added ADP (state 3) to the rate either before ADP addition or the rate following ADP expenditure (state 4). State 3 and state 4 respiratory rates are 79 and 7 mm/min, respectively. Therefore, the RCI is 79/7 = 11.4. For tightly coupled intact mitochondria as shown in Fig. 2A, the respiratory rates before the addition of ADP and then following the expenditure of ADP are virtually identical. However, if mitochondria are loosely coupled and/or contaminated with ATPase, the respiratory rate following the expenditure of ADP is considerable faster than that with substrate alone before the addition of ADP. The quality of the mitochondrial preparation is readily reflected from the polarographic tracing.

Tightly coupled intact mitochondria exhibit a very low (if any) ATPase activity (basal ATPase) that can be stimulated by Mg^{2+} and/or uncouplers. Figure 2B illustrates the effects of energy transfer inhibitors and uncoupler on the respiratory rates of intact mitochondria. The best-known energy transfer inhibitors are oligomycin and aurovertin, which primarily inhibit the phosphorylation reaction (e.g., synthesis and hydrolysis of ATP). Electron transfer is inhibited secondarily because of the tight link between oxidation and phosphorylation. Uncoupling agents also prevent the synthesis of ATP, but differ from energy transfer inhibitors in that they do not inhibit phosphorylation directly but rather uncouple phosphorylation from respiration by dissipating the energy generated by substrate oxidation as waste. Thus no energy is available for the synthesis of ATP from ADP and P_i, or any other energy utilizing processes. Uncouplers do not inhibit ATP hydrolysis. In the presence of an uncoupler, respiration proceeds at its maximal rate even in the absence of ADP and P_i. The most commonly used uncouplers are dinitrophenol (DNP) and carbonyl cyanide *p*-trifluoromethoxyphenylhydrazone (FCCP).

As shown in Fig. 2B, The ADP-induced state 3 respiratory rate declined to the level comparable to state 4 upon the addition of oligomycin. The oligomycin-induced inhibition was released by the addition of FCCP. The FCCP-induced rate (usually referred to as state 3U) is virtually identical to that at state 3.

IV. COMMENTS, PITFALL, AND RECOMMENDATIONS

1. It is imperative that glass redistilled water be used throughout all the experiments.
2. A closed reaction vessel free of air bubbles and back diffusion of oxygen are essential for the success of polarographic assay of mitochondrial function.
3. It is imperative that the excessive part of the polyethylene membrane, which covers the electrode after secured by a rubber O ring, be removed with a sharp blade, as the presence of excessive polyethylene membrane may trap materials and make cleaning difficult.
4. All aqueous solutions of medium and reagent should be at neutral pH (i.e., 7.2–7.4). During the assays the temperature of the reaction mixture has to be maintained constant.
5. When water-insoluble reagents are used, at the completion of the experiment, the reaction chamber needs to be cleaned thoroughly first with ethanol followed by distilled water. Contamination of either reagent and/or ethanol of the chamber will result in obscure data, which cannot be interpreted.
6. Tarnish of the Ag/AgCl electrode can be removed by cleaning with a cotton-tipped swab dipped in 4*N* NH_4OH aqueous solution followed by rinsing thoroughly with distilled water.
7. The polarographic oxygen electrode technique is a convenient method for the determination of P/O ratio and RCI. However, its suitability is dependent on the quality of the mitochondrial preparations. Meaningful results can only be derived from tightly coupled

mitochondrial preparations that are free from contamination by other cellular constituents. Consideration of the tissue constituents, i.e., lipid content, and properties will aid in the design of isolation and purification procedures. For instance, as compared to liver and heart, only a small portion of the total mass of skeletal muscle consists of mitochondria, with the bulk of the tissue being myofibrils. Additionally, skeletal muscle contains a relatively high content of Ca^{2+}, which is capable of damaging mitochondria during the isolation process. Because of the high content of myofibril, the separation of mitochondria from other components is very difficult in nonelectrolyte medium (e.g., the isotonic sucrose used to isolate mitochondria from liver and heart). A similar difficulty results when attempts are made to isolate mitochondria from brain. Because of its high lipid content and high rate of aerobic metabolism, improper isolation may result in data fraught with artifact. In recent years, the polarographic technique has been widely used to evaluate the lesions of mitochondrial functions of skeletal muscle derived from patients suffering from mitochondrial myopathy. A reproducible technique that isolates tightly coupled, intact mitochondria is essential before statements regarding etiology can be made. Impairments in mitochondrial function may actually result from an artifact generated during the isolation procedure rather than a genuine impairment of mitochondrial function caused by the disease.

After many years of experience in our laboratory we have designed a simple method for the isolation and purification of intact skeletal muscle mitochondria (Lee *et al*., 1993a). This method allows preparation of isolated, intact mitochondria from a small amount (1–3 g, wet weight) of muscle biopsy specimens. Additionally, we have designed a simple and fast procedure to isolate intact brain mitochondria from one hemisphere of rat brain (approximately 0.6 g wet weight) (Lee *et al*., 1993b; Xiong *et al*., 1997a) with excellent yield and stability. This technique has been applied successfully on studies of the impairment of mitochondrial functions induced by head trauma (Xiong *et al*., 1997a,b, 1998, 1999) and ischemia (Sciamanna *et al*., 1992; Sciamanna and Lee, 1993).

Analysis of Nuclear Protein Import and Export in Digitonin-Permeabilized Cells

Ralph H. Kehlenbach and Bryce M. Paschal

I. INTRODUCTION

Transport between the nucleus and the cytoplasm is mediated by nuclear pore complexes (NPCs), specialized channels that are embedded in the nuclear envelope membrane. Proteins that undergo nuclear import or nuclear export usually encode a nuclear localization signal (NLS) or a nuclear export signal (NES). These signals are recognized by import or export receptors that, in turn, facilitate targeting of the protein to the NPC and translocation through the central channel of the NPC. Both import and export pathways are regulated by the Ras-related GTPase Ran. Nuclear Ran in its GTP-bound form promotes the release of NLS-proteins from import receptors after the NLS-protein/import receptor has reached the nuclear side of the NPC. In contrast, nuclear Ran in its GTP-bound form promotes the assembly of NES-containing proteins with export receptors by forming an NES-protein/export receptor/RanGTP. Export complexes are then disassembled on the cytoplasmic side of the NPC through the action of a Ran GTPase-activating protein that stimulates GTP hydrolysis by Ran. More specific information regarding import and export complex assembly, models for translocation, and additional aspects of nuclear transport regulation are described elsewhere (Steggerda and Paschal, 2002; Weis, 2003 and references therein).

Digitonin-permeabilized cells have become one of the most widely used experimental systems for studying nuclear transport (Adam *et al*., 1990). They have been used to analyze nuclear import and export signals (Pollard *et al*., 1996), to purify nuclear transport factors from cell extracts (Görlich, 1994; Paschal and Gerace, 1995; Kehlenbach *et al*., 1998), and to measure nuclear transport kinetics (Görlich and Ribbeck, 2003). In all of these applications, the principle is that treating mammalian cells with a defined concentration of digitonin results in selective perforation of the plasma membrane, leaving the nuclear membrane intact. Thus, soluble transport factors are released from the cytoplasmic compartment and low molecular weight transport factors such as Ran (24 kDa) and NTF2 (28 kDa) are released from the nuclear compartment by diffusion through the NPC. Nuclear import and export can subsequently be reconstituted in digitonin-permeabilized cells by the addition of transport factors, an energy-regenerating system, and inclusion of a fluorescent NLS or NES reporter protein to monitor transport (Adam *et al*., 1990). Transport factors can be supplied as unfractionated cytosol from HeLa cells or as commercially available rabbit reticulocyte lysate. The level of import is then measured by following the accumulation of an NLS reporter in the nucleus or, in the case of export, by the loss of an NES reporter from the nucleus.

This article describes assays for both nuclear import and export (Fig. 1). The nuclear import assay can be performed with various cell lines and analyzed by fluorescence microscopy. The nuclear export assay is described for HeLa cells expressing a GFP-tagged reporter protein, the nuclear factor of activated T cells (GFP-NFAT). NFAT is a transcription factor that contains defined nuclear localization and nuclear export signals and that shuttles between the cytoplasm and the nucleus in a phosphorylation-dependent manner (for review, see Crabtree and Olsen, 2002). We take advantage of the tight regulation of nucleocytoplasmic transport of GFP-NFAT to induce nuclear import in intact cells, followed by export under controlled conditions from nuclei of permeabilized cells (Kehlenbach

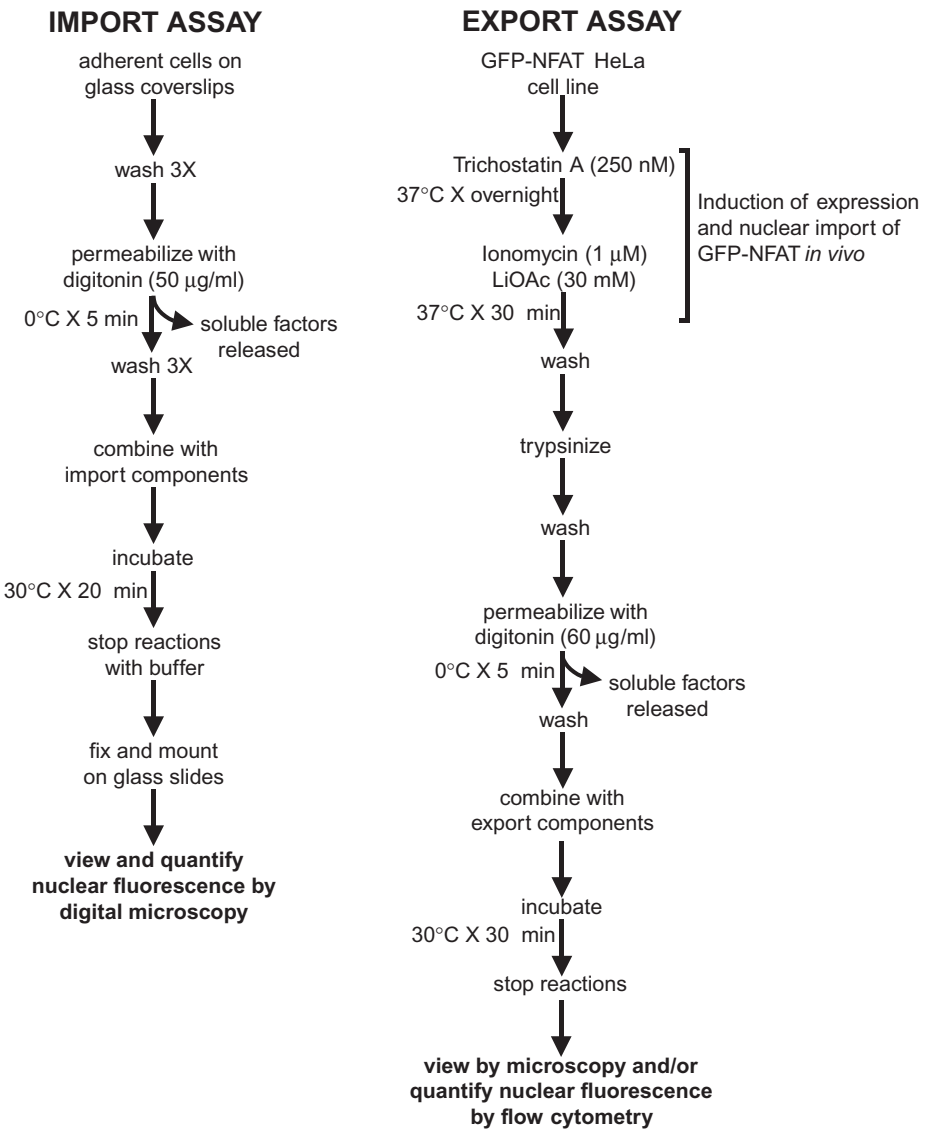

FIGURE 1 Overview of assays for measuring nuclear import and export in digitonin-permeabilized cells. See text for details.

et al., 1998). The efficiency of nuclear export can be analyzed either qualitatively by fluorescence microscopy (see Fig. 3) or quantitatively by flow cytometry (see Fig. 4). In the latter case, nuclear import of a fluorescently labeled reporter protein can be analyzed in parallel.

II. MATERIALS AND INSTRUMENTATION

Rabbit recticulocyte lysate (L4151) is from Promega. HeLa S3 cells (CCL-2.2) and NIH 3T3 cells are from the American Type Culture Collection. Joklik's modified minimum essential medium for suspension cell culture (JMEM; Cat. No. M0518) is from Sigma. Newborn calf serum (Cat. No. 16010-159), penicillin–streptomycin (Cat. No. 15140-122), and trypsin EDTA (Cat. No. 25200-056) are from GIBCO/Invitrogen. ATP (Cat. No. A-2383), creatine phosphate (Cat. No. P-7936), creatine phosphokinase (Cat. No. C-7886), sodium bicarbonate (Cat. No. S-4019), HEPES (Cat. No. H-7523), potassium acetate (Cat. No. P-5708), magnesium acetate (Cat. No. M-2545), EGTA (Cat. No. E-4378), dithiothreitol (DTT, Cat. No. D-5545), NaCl (Cat. No. S-9763), potassium phosphate, monobasic (Cat. No. P-0662), phenyl-

methylsulfonyl fluoride (PMSF, Cat. No. P-7626), dimethyl sulfoxide (DMSO, Cat. No. D-8779), sodium carbonate (Cat. No. S-7795), trypan blue (Cat. No. T-8154), ionomycin (Cat. No. I-0634), LiOAc (Cat. No. L-4158), Hoechst 33258 (Cat. No. B-2883), 4',6-diamidino-2-phenyindole, dilactate (DAPI; Cat. No. 9564), and trichostatin A (Cat. No. T-8552) are from Sigma. High-purity bovine serum albumin (BSA, Cat. No. 238031), aprotinin (Cat. No. 236624), leupeptin (Cat. No. 1017101), and pepstatin (Cat. No. 253286) are from Roche. The FITC isomer I (Cat. No. F-1906) and sulfo-SMCC (Cat. No. 22322) are from Molecular Probes and Pierce, respectively. PD-10 columns (Cat. No. 17-0851-01), Cy2 (Cat. No. PA-22000), and Cy5 (Cat. No. PA-25001) are from Amersham Pharmacia Biosciences. Centricon filters (30-kDa cutoff, Cat. No. 4208) are from Amicon. High-purity digitonin (Cat. No. 300410) is from Calbiochem. Vectashield mounting medium (Cat. No. H-1000) is from Vector Laboratories. Six-well dishes (Cat. No. 3516) are from Corning. Glass coverslips (#1 thickness; Cat. No. 12-548A) and the polystyrene tubes used for the transport assays (Cat. No. 2058) are from Fisher. The microscope used for measuring nuclear import in adherent cells is a Nikon E800 equipped with a charge-coupled device camera. The system is linked to a MacIntosh computer running OpenLab software for image acquisition. An Olympus IX70 inverted fluorescence microscope is used for analysis of nuclear export. Images from import and export assays are processed using Adobe Photoshop. The flow cytometric analysis system is the FACScan unit from Beckton-Dickinson.

The following equipment required for growing and harvesting HeLa cells is from Bellco Glass. The 250-ml spinner flask (Cat. No. 1965-00250) and stir plate (Cat. No. 7760-0600) are used for the continuous culture of HeLa cells. Additional spinner flasks are required to scale up the preparation to 15 liters. These include 100 ml (Cat. No. 1965-01000), 3000 ml (Cat. No. 1965-03000), and 15 liter (Cat. No. 7764-00110), cap assembly (Cat. No. 7764-10100), and Teflon paddle assembly (Cat. No. 1964-30015).

Equipment for centrifugation includes the JS5.2 swinging bucket rotor and J6B centrifuge, the JA-20 fixed angle rotor and J2 centrifuge, and the type 60Ti fixed angle rotor and L7 centrifuge, all from Beckman. Cytosol dialysis is carried out using the collodion vacuum dialysis apparatus (Cat. No. 253310), and 10,000-Da cutoff membranes (Cat. No. 27110) are from Schleicher and Schuell. The homogenizer used for cell disruption is a 0.02-mm-clearance stainless-steel unit (Cat. No. 885310-0015) from Kontes.

III. PROCEDURES

A. Preparation of Cytosol

The rabbit reticulocyte lysate contains all the soluble factors necessary to reconstitute import and export in digitonin-permeabilized cells (Adam *et al*., 1990). The only preparation involved is dialysis against 1× transport buffer containing 2 m*M* DTT and 1 µg/ml each of aprotinin, leupeptin, and pepstatin (two buffer changes). Reticulocyte lysate is used at 50% (by volume) of transport reactions. This results in a relatively high total protein concentration (~25–40 mg/ml) in transport assays because the reticulocyte lysate contains a high concentration of hemoglobin. A more economical approach, especially if larger quantities of cytosol are needed for protein purification, is to prepare cytosol from suspension culture HeLa cells. In this case, only 1–2 mg/ml (final assay concentration) of HeLa cell cytosol is required to obtain a maximum level of protein import or protein export in digitonin-permeabilized cells.

Solutions

1. *10× transport buffer*: 200 m*M* HEPES, pH 7.4, 1.1 *M* potassium acetate, 20 m*M* magnesium acetate, and 5 m*M* EGTA. To make 1 liter, dissolve 47.6 g HEPES, 107.9 g potassium acetate, 4.3 g magnesium acetate, and 1.9 g EGTA in 800 ml distilled water. Adjust the pH to 7.4 with 10 *N* NaOH and bring the final volume to 1 liter. Sterile filter and store at 4°C.
2. *1× transport buffer*: 20 m*M* HEPES, pH 7.4, 110 *M* potassium acetate, 2 m*M* magnesium acetate, and 0.5 m*M* EGTA. To make 1 liter, add 100 ml of 10× transport buffer to 900 ml distilled water.
3. *1 M HEPES stock, pH 7.4*: To make 500 ml, dissolve 119.1 g HEPES (free acid) in 400 ml distilled water. Adjust the pH to 7.4 with 10 *N* NaOH and bring the final volume to 500 ml. Sterile filter and store at 4°C.
4. *1 M potassium acetate stock*: To make 500 ml, dissolve 49 g potassium acetate in 400 ml distilled water. Bring the final volume to 500 ml, sterile filter, and store at 4°C.
5. *1 M magnesium acetate stock:* To make 500 ml, dissolve 107.2 g magnesium acetate (tetrahydrate) in 400 ml distilled water. Bring the final volume to 500 ml, sterile filter, and store at 4°C.
6. *0.2 M EGTA stock*: To make 500 ml, dissolve 38 g EGTA (free acid) in 400 ml distilled water. Adjust the pH to ~7.0 with 10 *N* NaOH and bring the final volume to 500 ml. Store at 4°C.
7. *Cell lysis buffer*: 5 m*M* HEPES, pH 7.4, 10 m*M* potassium acetate, 2 m*M* magnesium acetate, and

1 m*M* EGTA. To make 500 ml, combine 2.5 ml 1 *M* HEPES, pH 7.4, 5 ml 1 *M* potassium acetate, 1 ml 1 *M* magnesium acetate, 2.5 ml 0.2 *M* EGTA, and 489 ml distilled water. Store at 4°C.

8. *Phosphate-buffered saline (PBS)*: To make 1 liter, dissolve 8 g sodium chloride, 0.2 g potassium chloride, 1.44 g sodium phosphate (dibasic), and 0.24 g potassium phosphate (monobasic) in 900 ml distilled water. Adjust the pH to 7.4 and bring the final volume to 1 liter. Store at 4°C.

Steps

1. Grow HeLa cells at a density of 2–7 × 10^5 cells per milliliter in a spinner flask (30–50 rpm) in a 37°C incubator (CO_2 is not required). The medium is JMEM containing 2.0 g sodium bicarbonate and 2.38 g HEPES per liter. Adjust the pH to 7.3, sterile filter, and store at 4°C. Before use, supplement the medium with 10% newborn calf serum and 1% penicillin–streptomycin. The cells should have a doubling time of approximately 18 h, making it necessary to dilute the culture with fresh, prewarmed medium every 1–2 days.

2. HeLa cells from a 250-ml culture provide the starting point for scaling up the preparation to 15 liters. This is carried out by sequential dilution of the culture into larger spinner flasks. The culture should not be diluted to a density below 2 × 10^5 cells/ml. The spinner flasks used for scaling up preparation are 250 ml (1 each), 1 liter (1 each), 3 liters (2 each), and 15 liters (1 each). This process generally takes 5 days.

3. Perform the cell harvest and subsequent steps at 0–4°C. Collect the cells by centrifugation (300 *g* for 15 min) in 780-ml conical glass bottles in a Beckman J6B refrigerated centrifuge equipped with a JS5.2 swinging bucket rotor. The cell harvest takes about 1 h.

4. Wash the cells by sequential resuspension and centrifugation. Two washes are carried out in ice-cold PBS (1 liter each) and one wash is carried out in 1× transport buffer containing 2 m*M* DTT. The yield from a 15-liter culture should be approximately 40 ml of packed cells.

5. Resuspend the cell pellet using 1.5 volume of lysis buffer, supplemented with 3 µg/ml each aprotinin, leupeptin, pepstatin, 0.5 m*M* PMSF, and 5 m*M* DTT. Allow the cells to swell on ice for 10 min.

6. Disrupt the cells by two to three passes in a stainless-steel homogenizer. Monitor the progress of homogenization by trypan blue staining and phase-contrast microscopy. The goal is to obtain ~95% cell disruption. Excessive homogenization should be avoided because it results in nuclear fragmentation and the release of nuclear contents into the soluble fraction of the preparation.

7. Dilute the homogenate with 0.1 volume of 10× transport buffer and centrifuge in a fixed angle rotor such as the Beckman JA-20 (40,000 *g* for 30 min).

8. Filter the resulting low-speed supernatant fraction through four layers of cheesecloth. Subject the filtered low-speed supernatant to ultracentrifugation using a fixed angle rotor such as the Beckman type 60 Ti (150,000 *g* for 60 min).

9. Dispense the resulting high-speed supernatant fraction (~50 ml, protein concentration ~5 mg/ml) into 1- and 4-ml aliquots, flash freeze in liquid N_2, and store at –80°C indefinitely.

10. HeLa cell cytosol is generally subjected to a rapid dialysis step before use in transport reactions. Thaw a 4-ml aliquot of cytosol at 0–4°C and dialyze for 3 h in 1× transport buffer containing 2 m*M* DTT and 1 µg/ml each of aprotinin, leupeptin, and pepstatin (two buffer changes). We use a vacuum apparatus and a collodion membrane to achieve a twofold concentration of the sample (10 mg/ml). Dispense the dialyzed, concentrated cytosol into 100-µl aliquots, flash freeze in liquid N_2, and store at –80°C.

B. Preparation of FITC-BSA-NLS Import Substrate

Synthetic peptides containing an NLS can be used to direct the nuclear import of a variety of fluorescent reporter proteins. FITC- or Cy2-BSA-NLS and Cy5-BSA-NLS are all suitable for measuring import in the fluorescence microscope or in the flow cytometer. Because excitation and emission spectra of Cy5 are distinct from GFP, Cy5-BSA-NLS is ideal for measuring import and GFP-NFAT export in the same cells. Importantly, the average size of the protein conjugate (>70 kDa) is too large to allow diffusion through the NPC and it displays low nonspecific binding to the permeabilized cell. Preparation of fluorescent import ligands is carried out in three steps: fluorescent labeling of BSA, modification of the fluorescent BSA with the heterobifunctional cross-linker sulfo-SMCC, and attachment of NLS peptides. Sulfo-SMCC provides a covalent linkage between primary amines on BSA and cysteine present on the N terminus of the NLS peptide.

Solutions

1. *PBS*: To make 1 liter, dissolve 8 g sodium chloride, 0.2 g potassium chloride, 1.44 g sodium phosphate (dibasic), and 0.24 g potassium phosphate (monobasic) in 900 ml distilled water. Adjust the pH to 7.4 and bring the final volume to 1 liter. Store at 4°C.

2. *0.1 M* sodium carbonate: To prepare 250 ml, dissolve 3.1 g sodium carbonate in 200 ml distilled water, adjust the pH to 9.0, and bring the final volume to 250 ml. Store at 4°C.

3. *1.5 M* hydroxylamine: To prepare 100 ml, dissolve 10.4 g in a total volume of 100 ml distilled water. Store at room temperature.

4. *10 mg/ml FITC*: Add 1 ml DMSO to 10 mg FITC in an amber vial and vortex to dissolve.

5. *20 mM sulfo-SMCC*: Prepare a 20 m*M* stock of sulfo-SMCC in the following manner. Preweigh a microfuge tube on a fine balance and use a small spatula to add approximately 1–2 mg of sulfo-SMCC to the microfuge tube. Reweigh the tube containing the sulfo-SMCC and add DMSO for a final concentration of 8.7 mg/ml.

Steps

1. Dissolve 10 mg high-purity BSA in 1 ml sodium carbonate buffer, pH 9.0.
2. Stir the BSA solution in a glass test tube with a microstir bar and add 0.1 ml of 10 mg/ml FITC. Cover with foil and stir for 60 min at room temperature.
3. Stop the reaction by adding 0.1 ml 1.5 *M* hydroxylamine.
4. Separate FITC-labeled BSA from unincorporated FITC by desalting on a PD-10 column equilibrated in PBS, collecting 0.5-ml fractions. The bright yellow FITC-BSA will elute in the void volume of this column.
5. Pool the four or five most concentrated fractions, dispense into 1-mg aliquots, and freeze in foil-wrapped microfuge tubes at –20°C.
6. Combine 1 mg of FITC-BSA with 50 µl of freshly prepared 20 m*M* sulfo-SMCC and mix end over end for 45 min at room temperature.
7. Separate the sulfo-SMCC-activated FITC–BSA from unincorporated sulfo-SMCC by desalting on a PD-10 column equilibrated in PBS. After loading the sample, fill the buffer reservoir of the column with PBS and collect 0.5-ml fractions. The bright yellow FITC–BSA will elute in the void volume as before.
8. Pool the three most concentrated fractions of sulfo-SMCC-activated FITC–BSA and combine with 0.3 mg of NLS peptide (CGGGPKKKRKVED). Mix end over end in a foil-wrapped microfuge tube overnight at 4°C.
9. Remove unincorporated NLS peptide by subjecting the sample to four cycles of centrifugation and resuspension in 1× transport buffer using a 2-ml 30-kDa cutoff Centricon filter. Follow the manufacturer's recommendations for centrifugation conditions.
10. Adjust the FITC–BSA–NLS conjugate to a final concentration of 2 mg/ml, dispense into 50-µl aliquots, flash freeze in liquid N_2, and store at –80°C.

C. Preparation of Cy2- or Cy5-BSA-NLS Import Substrate

The preparation of Cy2- and Cy5-labeled import substrate is very similar to the method described earlier for the FITC-labeled substrate.

Steps

1. Dissolve 2.5 mg BSA in 1 ml 0.1 *M* sodium carbonate. Use one vial-activated Cy2 or Cy5 for coupling. Incubate for 40 min at room temperature.
2. Separate the CyDye-BSA conjugate from the free dye by chromatography on a PD-10 column equilibrated with PBS.
3. To activate CyDye-BSA, add sulfo-SMCC to a final concentration of 2 m*M*. Incubate for 30 min at room temperature. Remove free cross-linker using a PD-10 column as described earlier.
4. Dissolve 1 mg of NLS-peptide (CGGGP-KKKRKVED) with activated CyDye-BSA and incubate the solution overnight at 4°C. Remove free peptide and adjust protein concentration as described previously.
5. Freeze aliquots in liquid nitrogen and store at –80°C. After thawing, the import substrate can be kept at 4°C in the dark for a few weeks.

D. Nuclear Protein Import Assay

Solutions

1. *10× and 1× transport buffer*: See Section III,A.
2. *Complete transport buffer*: 1× transport buffer containing 1 µg/ml each aprotinin, leupeptin, pepstatin, and 2 m*M* DTT.
3. *10% digitonin*: To make 2 ml, add 0.2 g high-purity digitonin to 1.7 ml DMSO and dissolve by vigorous vortexing, Dispense into 20-µl aliquots and freeze at –20°C.
4. *100 mM MgATP*: To make 5 ml, add 0.5 ml 1 *M* magnesium acetate and 0.1 ml 1 *M* HEPES, pH 7.4, to 4 ml distilled water. Add 275.1 mg ATP, dissolve by vortexing, and bring the final volume to 5 ml. Dispense into 20-µl aliquots and freeze at –80°C.
5. *250 mM creatine phosphate*: To make 5 ml, add 0.32 g creatine phosphate to 4 ml distilled water, dissolve by vortexing, and bring the final volume to 5 ml. Dispense into 20-µl aliquots and freeze at –20°C.

6. *2000 U/ml creatine phosphokinase*: To make 5 ml, dissolve 10,000 U creatine phosphokinase in 20 m*M* HEPES, pH 7.4, containing 50% glycerol. Dispense into 1-ml aliquots and store at –20°C.

Steps

1. Plate NIH 3T3 cells onto glass coverslips in six-well dishes at a density of ~5×10^4 cells/well and grow overnight.
2. Place the six-well dishes on ice. Aspirate media and gently replace with 2 ml ice-cold, complete transport buffer. Aspirate the transport buffer and replace with fresh transport buffer twice, taking care not to disturb the cells. Complete transport buffer in this and subsequent steps refers to ice-cold, 1× transport buffer supplemented with DTT and protease inhibitors.
3. To permeabilize the cells, aspirate the transport buffer from each well and immediately add 0.05% digitonin diluted into complete transport buffer. Incubate for 5 min on ice.
4. Stop the permeabilization reaction by aspirating the digitonin solution and replacing with complete transport buffer. Wash the cells twice by alternate steps of aspiration and buffer addition.
5. Assemble the import reactions in 0.6-ml microfuge tubes on ice. Each reaction contains (final concentration given) unlabeled BSA (5 mg/ml), FITC-BSA-NLS (25 µg/ml), MgATP (1 m*M*), MgGTP (1 m*M*), creatine phosphate (5 m*M*), creatine phosphpkinase (20 U/ml), rabbit reticulocyte lysate (25 µl), and complete transport buffer in a total volume of 50 µl.
6. Create an incubation chamber by lining a flat-bottomed, air-tight box with parafilm and include a moistened paper towel in the chamber as a source of humidity. Place the chamber on ice.
7. Using fine forceps, remove each coverslip, wick excess buffer using filter paper, and place cells side up on the parafilm. Pipette the import reaction onto the coverslip surface without introducing bubbles.
8. Float the incubation chamber on a 30°C water bath for 20 min.
9. Using fine forceps, remove each coverslip, wick most of the import reaction using filter paper, and immediately place back into the wells of the six-well dish.
10. Wash the coverslips twice by alternate steps of aspiration and complete transport buffer addition.
11. Fix the coverslips by aspirating the complete transport buffer, adding formaldehyde (3.7%) diluted into PBS, and incubating for 15 min at room temperature.
12. Remove each coverslip, submerge in distilled water briefly, wick excess water, and mount on glass slides using Vectashield. Seal the edges with clear nail polish.
13. View the cells by fluorescence microscopy, and quantify the nuclear fluorescence in 50–100 cells per condition using image analysis software such as OpenLab.

E. Nuclear Protein Export Assay

Solutions and Reagents

1. The HeLa cell line stably expressing GFP-NFAT, which is used for the export assay, has been described in detail (Kehlenbach *et al*., 1998) and is available upon request.
2. *1 mM trichostatin A*: Dissolve 1 mg trichostatin A in 3.3 ml ethanol. Store in aliquots at –20°C. Trichostatin A is an inhibitor of histone deacetylases and promotes the expression of GFP-NFAT.
3. *1 mM ionomycin*: Dissolve 1 mg ionomycin in 1.34 ml DMSO. Store in aliquots at –20°C. Nuclear accumulation of the reporter protein is induced by the calcium ionophore ionomycin.
4. *Double-stranded oligonucleotides*: Dissolve oligonucleotides (5'AGAGGAAAATTTGTTTCATA and 5'TATGAAACAAATTTTCCTCT), each at 200 µ*M*, in 40 m*M* Tris, pH 7.4, 20 m*M* $MgCl_2$, and 50 m*M* NaCl. Anneal by heating to 65°C for 5 min and slow cooling to room temperature. Freeze in aliquots and store at –20°C. The oligonucleotide sequence corresponds to a DNA-binding site of NFAT. It stimulates export of GFP-NFAT about twofold, probably by releasing the protein from chromatin.
5. *1× transport buffer with LiOAc*: 20 m*M* HEPES, pH 7.4, 80 m*M* potassium acetate, 2 m*M* magnesium acetate, and 0.5 m*M* EGTA. To make 1 liter, dissolve 4.76 g HEPES, 7.85 g potassium acetate, 3.06 g lithium acetate dihydrate, 0.43 g magnesium acetate tetrahydrate, and 0.19 g EGTA in 800 ml distilled water. Adjust the pH to 7.4 with 1 *N* KOH and bring the final volume to 1 liter. Before use, add 1 µg/ml each of aprotinin, leupeptin, pepstatin, and 2 m*M* DTT.
6. *Complete transport buffer*: See Section III,D.

Steps

1. To stimulate expression of GFP-NFAT, add 250 n*M* trichostatin A to stably transfected HeLa cells and incubate overnight. One 15-cm dish containing ~10^6 cells is sufficient for 30 reactions.
2. Induce nuclear import of GFP-NFAT by adding 1 µ*M* ionomycin and 30 m*M* LiOAc directly to the culture media and return the cells to the 37°C incubator for 30 min. Lithium inhibits one of the kinases

involved in nuclear phosphorylation of NFAT, a step that is required for efficient export *in vivo*.

3. Rinse cells with PBS and remove from dish by adding trypsin EDTA containing 1 μ*M* ionomycin and 30 m*M* LiOAc. Transfer the cells to 50 ml of cold transport buffer with 5% newborn calf serum. Centrifuge for 5 min at 300 *g* at 4°C and wash once in 50 ml transport buffer.

4. Resuspend cells in complete transport buffer at 10^7/ml. Add digitonin to 100 μg/ml (1 μl of a 10% stock per 10^7 cells). Leave on ice for 3 min and check permeabilization with trypan blue. Dilute the cells to 50 ml with transport buffer to release soluble transport factors and collect by centrifugation as described previously.

5. Preincubation (optional): Resuspend cells in transport buffer containing 30 m*M* LiOAc at 10^7/ml and add MgATP (1 m*M*), creatine phosphate (5 m*M*) and creatine phosphokinase (20 U/ml). Incubate for 15 min in a 30°C water bath. Wash cells with transport buffer. This step results in the depletion of additional transport factors such as CRM1, rendering them rate limiting in the subsequent reaction. The reporter protein largely remains in the nucleus under these conditions.

6. Resuspend cells in transport buffer at 3×10^7/ml. Assemble 40-μl transport reactions in FACS tubes: 300,000 permeabilized cells (10 μl), ATP-regenerating system (1 m*M* MgATP, 5 m*M* creatine phosphate, 20 U/ml creatine phosphokinase), Cy5-BSA-NLS (25–50 μg/ml), 1 μ*M* annealed oligonucleotide, and HeLa cytosol (2 mg/ml).

7. Incubate tubes in a 30°C water bath for 30 min. Control reactions contain the same components but are kept on ice, as nuclear import and export are temperature dependent.

8. Stop the reaction by adding 4 ml of cold transport buffer. Centrifuge for 5 min at 400 *g* and 4°C. Remove most of supernatant by aspiration and resuspend cells in residual buffer. Proceed to step 9 or fix cells for microscopic analysis by the addition of 2 ml of formaldehyde (3.7% in PBS). Incubate cells for 15 min at room temperature, add 1 μl Hoechst 33258 (10 mg/ml in H_2O), and incubate for 5 more minutes. Collect cells by centrifugation (300 *g* for 5 min), wash twice with 1 ml PBS, and resuspend the final cell pellet in 15 μl PBS. Apply the cell suspension to a glass slide, cover with a coverslip, and seal with nail polish.

9. Measure the fluorescence of 10,000 cells by flow cytometry. In Becton-Dickinson instruments, GFP-NFAT (or BSA-NLS, labeled with FITC or Cy2, if only import is analyzed) is detected in FL1 and Cy5-BSA-NLS in FL4.

10. Normalize the mean fluorescence values with respect to a reaction kept on ice.

IV. COMMENTS

Several of the basic controls for assaying nuclear import in digitonin-permeabilized cells are shown (Fig. 2). Nuclear import in digitonin-permeabilized

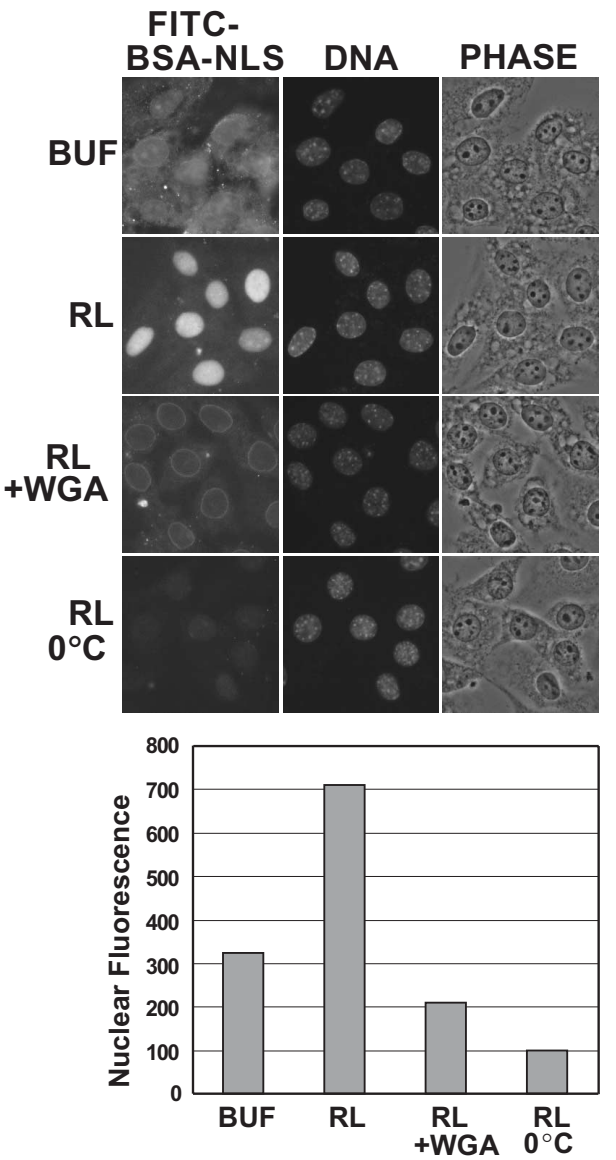

FIGURE 2 Nuclear import of FITC-BSA-NLS analyzed by fluorescence microscopy. (Top) NIH 3T3 cells were digitonin permeabilized and incubated with the indicated components (BUF, buffer; RL, reticulocyte lysate; WGA, wheat germ agglutinin). DAPI staining of DNA and phase-contrast (PHASE) images are also shown. Note that FITC-BSA-NLS binds nonspecifically to cells in the absence of cytosol. The rim fluorescence in the presence of WGA reflects the arrest of FITC-BSA-NLS in import complexes at the NPC. (Bottom) The level of nuclear import observed under each condition was quantified from 12-bit images. Values reflect the average fluorescence intensity per pixel from at least 100 nuclei per condition. Data courtesy of Leonard Shank (University of Virginia).

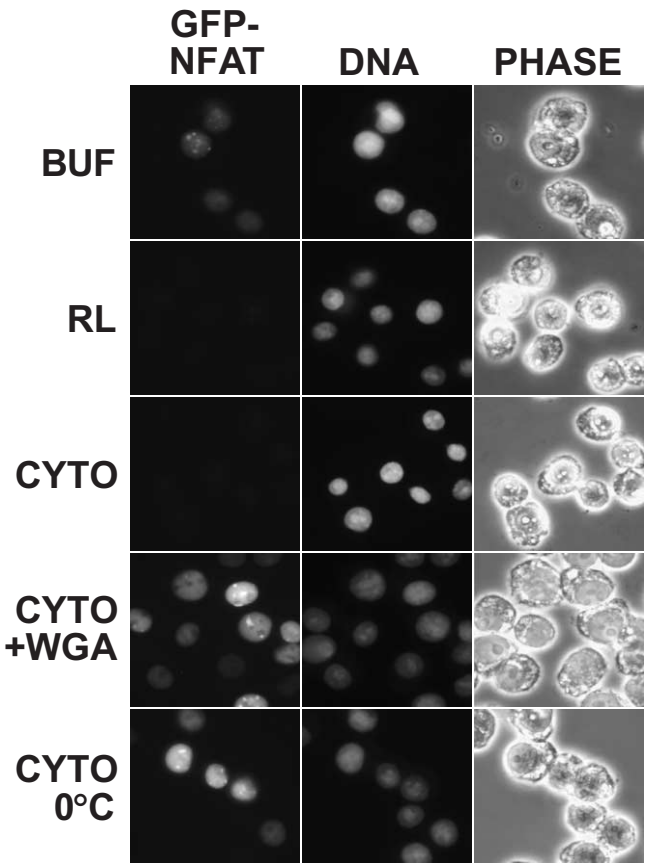

FIGURE 3 Nuclear export of GFP-NFAT was analyzed by fluorescence microscopy. GFP-NFAT cells were treated with trichostatin A and ionomycin to induce expression and nuclear import of GFP-NFAT. After digitonin permeabilization, the cells were incubated with the indicated components (BUF, buffer; RL, reticulocyte lysate; CYTO, HeLa cytosol; WGA, wheat germ agglutinin). Hoechst staining of DNA and phase-contrast (PHASE) images are also shown.

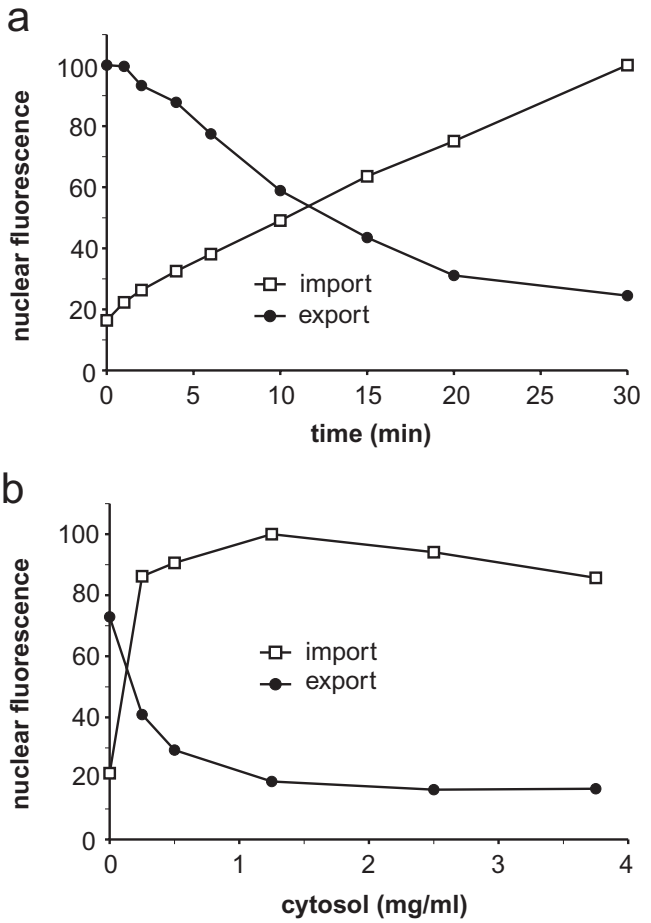

FIGURE 4 Nuclear export of GFP-NFAT and nuclear import of Cy5-BSA-NLS were analyzed in parallel by flow cytometry. (a) Time course of nuclear transport. All reactions contained 2 mg/ml of cytosol and 25 µg/ml of recombinant Ran. (b) Cytosol dependence of nuclear transport. Reactions contained 50 µg/ml of recombinant Ran and the indicated amounts of cytosol. All reactions were performed using preincubated cells (see step 5 in Section III,E) to enhance the cytosol dependence of transport. Portions of this figure were reprinted by permission from the *J. Cell Biol.*, Rockefeller University Press.

cells is stimulated by the addition of HeLa cytosol or reticulocyte lysate, which provides a source of factors, including import receptors and Ran. A low level of cytosol-independent import is usually observed because digitonin permeabilization does not result in the quantitative release of transport factors. Nuclear import is inhibited at low temperature or by incubation with wheat germ agglutinin (0.2–0.5 mg/ml), a lectin that binds to NPC proteins and blocks translocation through the pore. The level of nuclear import is quantified by measuring the nuclear fluorescence in 50–100 cells per condition using a commercially available program such as OpenLab or using a public domain program such as ImageJ (http://rsb.info.nih.gov/ij/).

The same controls that apply to nuclear import are also used to validate nuclear export reactions (Fig. 3). Export of GFP-NFAT is stimulated by the addition of cytosol or reticulocyte lysate and is inhibited at low temperature or by the addition of wheat germ agglutinin. Note that the preexport level of GFP-NFAT fluorescence, measured in cells that have been kept on ice, will vary depending on the cellular expression level. Therefore, a reliable quantification of nuclear export requires analysis of a large number of cells in order to obtain statistically meaningful results. To this end, we use flow cytometry to measure the residual fluorescence in 10,000 cells (Fig. 4). This approach allows rapid analysis of a large number of samples, e.g., for determination of the transport kinetics (Fig. 4a) or the cytosol dependence of transport (Fig. 4b). Nuclear import of a fluorescently labeled import substrate can

be analyzed simultaneously, allowing a direct comparison between different transport pathways. Nuclear import and nuclear export can be reconstituted using recombinant factors instead of cytosol, an approach that allows the contributions of individual transport factors to be analyzed (Görlich *et al*., 1996; Black *et al*., 2001; Kehlenbach and Gerace, 2002).

V. PITFALLS

Any compromise in the integrity of the nuclear envelope renders permeabilized cell assays uninterpretable. This could occur if cells are overpermeabilized with digitonin. Under such a condition, NLS-containing reporters can appear to undergo nuclear import when they are, in fact, simply binding to DNA after leakage through a permeabilized nuclear envelope. Likewise, NES-containing reporters can appear to undergo export due to simple leakage from the nucleus. The easiest way to establish that nuclear import or export is mediated by the NPC is to test for inhibition by WGA. Alternatively, the intactness of the nuclear envelope can be demonstrated by showing that a fluorescently labeled dextran (≥70 kDa) is excluded from the nucleus. Thus, it is helpful to test a range of digitonin concentrations (25–100 μg/ml) and stain with trypan blue to optimize permeabilization of the plasma membrane.

The assays described in this article feature NIH 3T3 and HeLa cells; however, these methods should be applicable to virtually any mammalian cell line. Digitonin permeabilization on adherent cells works best when the cells are 40–70% confluent and poorly if the cells are approaching confluence. Cells that are not well adhered may detach during the permeabilization and wash steps, a problem that usually can be overcome by coating coverslips with poly-D-lysine or by plating the cells 2 days before permeabilization. Also, because cells near the edge of the coverslip may be subject to evaporation artifacts even in a humid chamber, it is best to restrict analysis to the central region of the coverslip.

Heterokaryons: An Assay for Nucleocytoplasmic Shuttling

Margarida Gama-Carvalho and Maria Carmo-Fonseca

I. INTRODUCTION

Interspecies heterokaryon assays are used to analyse the shuttling properties of proteins that localise predominantly in the nucleus at steady state. Conventional localisation methods do not allow the detection of small amounts of protein transiently present in a cellular compartment. Thus, demonstration of a predominantly nuclear (or cytoplasmic) localisation for a given protein frequently obscures the existence of a constant shuttling activity between the two major cell compartments. Indeed, the number of proteins shown to possess nucleocytoplasmic shuttling activity has increased enormously in the past few years, highlighting the importance of shuttling in the regulation of many cellular processes (reviewed by Gama-Carvalho and Carmo-Fonseca, 2001).

Identification of shuttling cytoplasmic proteins can be achieved through analysis of the localisation pattern of deletion mutants affecting export signals or by analysing the effect of inhibition of the major protein export pathway by the drug leptomycin B. In either case, the observation of a shift in the steady-state localisation of the protein from the cytoplasm to the nucleus suggests that the protein under study shuttles continuously between both compartments and that the mutation or drug treatment has interfered with its export pathway.

Identification of nuclear shuttling proteins can be achieved by a number of assays. Using yeast cells, identification of nuclear proteins that shuttle to the cytoplasm can be performed with temperature-sensitive nuclear import mutant strains. In this case, cytoplasmic accumulation of the protein of interest at the restrictive temperature indicates shuttling activity (Lee *et al.*, 1996). In higher eukaryotes, the original demonstration that nuclear proteins shuttle between the nucleus and the cytoplasm was based on nuclear transfer experiments whereby the nucleus from a [^{35}S] methionine-labelled cell was transferred to an unlabelled cell and the appearance of radioactivity in the unlabelled nucleus was monitored (Goldstein, 1958). However, the identification of specific shuttling proteins had to await the development of antibody microinjection or interspecies heterokaryon assays (Borer *et al.*, 1989).

In the microinjection assay, antibodies against the protein of interest are introduced in the cytoplasm of the cell and their appearance in the nucleus is monitored in the presence of protein synthesis inhibitors. As immunoglobulins do not cross the nuclear envelope unless they are bound to a protein that is targeted to the nucleus via a receptor-mediated import pathway, the detection of the antibody in the nucleus in the absence of protein synthesis indicates that the target protein has the ability to shuttle between the nucleus and the cytoplasm. Although virtually any cultured cell type may be used, microinjection assays are often performed in *Xenopus laevis* oocytes, a widely used model system to study transport across the nuclear envelope. A major advantage of this model, in addition to the ease of microinjection, is the possibility to dissect and analyse the contents of the cytoplasm and germinal vesicle (i.e., the nucleus) of a single oocyte, allowing for quantitative biochemical assays. However, it is noteworthy that shuttling assays using *X. laevis* oocytes have provided contradictory results to microinjection or heterokaryon assays performed with human HeLa cells (e.g., Bellini and Gall, 1999; Almeida *et al.*, 1998; Calado *et al.*, 2000). One possibility is that the same protein may have different shuttling proper-

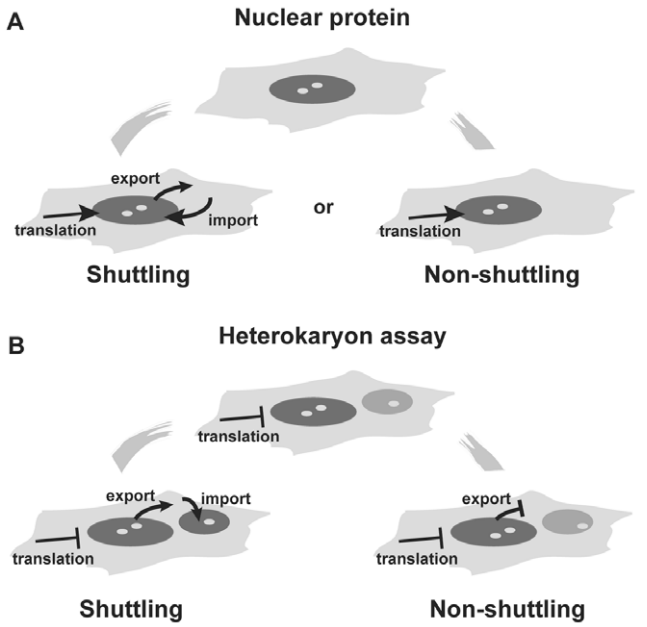

FIGURE 1 **The heterokaryon assay.** (**A**) Proteins may accumulate in the nucleus as the result of a unidirectional import pathway (nonshuttling nuclear proteins). Alternatively, proteins may be targeted simultaneously by import and export pathways, resulting in a dynamic cycling (shuttling) between the nucleus and the cytoplasm. (**B**) Heterokaryon assays distinguish between shuttling and nonshuttling nuclear proteins. If a protein originally present in the donor (large) nucleus shuttles, then it will appear in the receptor (small) nucleus. Nonshuttling proteins are not exported from the donor nucleus and are never detected in the receptor nucleus. Assays have to be performed in the presence of protein synthesis inhibitors in order to prevent the import of newly synthesised protein into the receptor nucleus.

ties in *X. laevis* oocytes and human somatic cells. Alternatively, oocytes may contain a surplus of nuclear proteins stored in the cytoplasm that are not normally present in somatic cells.

Interspecies heterokaryons, which constitute the most widely used shuttling assay, involve the formation of hybrid cells containing at least two nuclei from different species. In an interspecies heterokaryon, a cell line containing the protein of interest—donor cell—is fused with a cell line from a distinct species that does not contain the same protein—receptor cell. The appearance in the "receptor" nucleus of the protein of interest that was originally found exclusively in the "donor" nucleus is monitored by fluorescence microscopy. The assay is performed in the presence of translation inhibitors to ensure that the imported protein has not been newly synthesised in the cytoplasm but rather has been exported from the donor cell nucleus (Fig. 1).

Two different approaches may be taken to label the protein of interest present in donor nuclei. If a species-specific antibody is available, the endogenous protein can be identified by immunostaining of the heterokaryons. For example, when a monoclonal antibody directed against a human protein does not recognise its homologue in *Drosophila melanogaster*, heterokaryons can be made by fusion of human HeLa and *D. melanogaster* SL2 cell lines. These heterokaryons have the advantage that human and fly nuclei are easily distinguished by their different sizes. However, the small size of SL2 nuclei may limit the use of a *D. melanogaster*-specific antibody in a reverse assay, where the larger mammalian nuclei serve as receptors. In this case, the concentration of the target protein in the receptor nucleus may be below the detection limit of the fluorescence microscope. Depending on the specificity of the antibody available, other donor/receptor nuclei combinations are possible, namely human × mouse heterokaryons. An alternative approach to identify the protein of interest involves transfection of a vector encoding a tagged form of the protein into the donor cell line, followed by fusion with a nontransfected receptor cell line. Both green fluorescent protein or amino acid epitope tags have proven to work successfully in these assays. In this case, heterokaryon assays are usually performed with human HeLa and murine NIH 3T3 cell lines. Murine nuclei are easily distinguished by their typical heterochromatin staining pattern.

When a shuttling protein is identified, heterokaryon assays may be further employed to dissect the signals and pathways involved in the transport. More recently, heterokaryon assays have been used to characterise the intranuclear pathway of newly imported proteins (Leung and Lamond, 2002). In this case, a donor cell line transfected with a nucleolar shuttling protein was used as a source of labelled protein, whose entry into the receptor nuclei could be followed in a time course assay from the moment of cell fusion. As receptor nuclei do not contain this protein, the intranuclear pathway followed after import until it accumulated in the nucleolus could be determined.

To perform heterokaryons assays, knowledge of basic tissue culture, transient transfection, and immunofluorescence microscopy techniques is required and will not be addressed here.

II. MATERIALS AND INSTRUMENTATION

Human HeLa cells
Murine NIH 3T3 and/or *D. melanogaster* SL2 cells
Minimum essential medium (MEM) with Glutamax-I

(Cat. No. 41090-028) and MEM nonessential amino acids (Cat. No. 11140-035) (Gibco BRL)
Dulbeco's modified Eagle Medium (D-MEM) (Cat. No. 41966-029) or *D. melanogaster* Schneiders medium (Cat. No. 21720-024) and 200 m*M* L-glutamine (Cat. No. 25030-032) (Gibco BRL)
Fetal bovine serum (FBS, Cat. No. 10270-1064, Gibco BRL)
Basic tissue culture facility with a 37°C, 5% CO_2 incubator and a 29°C, 5% CO_2 incubator (required only for HeLa × SL2 heterokaryons)
35 × 10-mm (P35) tissue culture dishes and general tissue culture material required for cell line maintenance
10 × 10-mm glass coverslips
Curved tweezer
Transfection reagents: Lipofectin (Cat. No. 18292-037, Invitrogen) or Fugene (Cat. No. 1814443, Roche Applied Science)
Protein synthesis inhibitors: anisomycin (Cat. No. A9789), cycloheximide (Cat. No. L9535) or emetine dihydrochloride hydrate (Cat. No. E 2375) (all from Sigma-Aldrich)
Polyethylene glycol (PEG) 1500 (Cat. No. 783 641, Roche Applied Science)
Primary antibody specific for the human–target protein or protein–fusion construct in eukaryotic expression vector with GFP or amino acid epitope tags (e.g., Ha, FLAG, His) and anti-tag primary antibody
Anti-hnRNP C mAb 4F4 (Choi and Dreyfuss, 1984) and anti-hnRNP A1 9H10 mAb (Pinol-Roma *et al*., 1988)
DAPI, dilactate (Cat. No. D 9564, Sigma-Aldrich)
Fluorochrome-conjugated secondary antibodies (Jackson Laboratories)
Fluorescence microscope

III. PROCEDURES

A. HeLa × SL2 Heterokaryons

Cell Culture

1. Maintain HeLa cells routinely in MEM supplemented with nonessential amino acids and 10% FBS and grow in a 37°C, 5% CO_2 incubator. Cells should be split the day before the heterokaryon assay is performed.

2. Grow SL2 *D. melanogaster* cells in Schneider's medium supplemented with 12% FBS and 2 m*M* glutamine at 25°C without CO_2 (a clean laboratory drawer will provide a convenient "incubator"). This is a suspension cell line that can be induced to adhere to the coverslips in the absence of serum.

3. Heterokaryon medium: HeLa × SL2 heterokaryons should be maintained in MEM supplemented with nonessential amino acids and 12% FBS in a 29°C, 5% CO_2 incubator.

Solutions

1. *Protein synthesis inhibitors*: Prepare a stock solution at 10 mg/ml in 50% ethanol and store at –20°C. Final use concentrations should be established for the cell lines used; most widely used concentrations range between 20 and 100 µg/ml for cicloheximide or anisomycin and 0.5 and 20 µg/ml for emetine.

2. *Phosphate-buffered saline PBS*: 137 m*M* NaCl, 2.68 m*M* KCl, 8.06 m*M* Na_2HPO_4, and 1.47 m*M* KH_2PO_4. Prepare by weighing 8 g NaCl, 0.2 g KCl, 1.14 g Na_2HPO_4, and 0.2 g KH_2PO_4 for 1 liter of solution. Sterilise by autoclaving.

Steps

1. All the steps of the procedure should be performed in a laminar flow hood using sterile cell culture material and solutions. The procedure is adapted for cells grown on 10 × 10-mm coverslips placed in P35 dishes.

2. HeLa cells should be grown to subconfluent density on 10 × 10-mm coverslips. A 35 × 10-mm tissue culture petri dish can accommodate four of these coverslips.

3. Resuspend exponentially growing *D. melanogaster* SL2 cells in serum-free HeLa culture medium to a concentration of 3–4 × 10^7 cells/ml.

4. Remove the medium from the HeLa cell culture and overlay coverslips with 500 µl of the SL2 suspension. Incubate for 20 min in a 29°C, 5% CO_2 incubator to induce adherence of SL2 cells.

5. Replace medium with 1.5 ml heterokaryon medium and add the protein synthesis inhibitor. Place cells in the 29°C, 5% CO_2 incubator for at least 3 h to inhibit protein synthesis. A control experiment replacing the protein synthesis inhibitor with a similar volume of 50% ethanol should be performed.

6. For the fusion procedure, place a 50-µl drop of PEG 1500 prewarmed to 29°C in a sterile petri dish.

7. Remove the HeLa/SL2 coculture from the incubator and wash twice with PBS prewarmed to 29°C.

8. With a sterile forceps, remove a coverslip and invert it over the PEG drop for 2 min (cell side down). Then, place the coverslip (cell side up) in a new P35 dish and rinse twice with PBS prewarmed to 29°C. Replace the PBS with 1.5 ml of prewarmed heterokaryon medium with a protein synthesis inhibitor and place the heterokaryons in the incubator for the

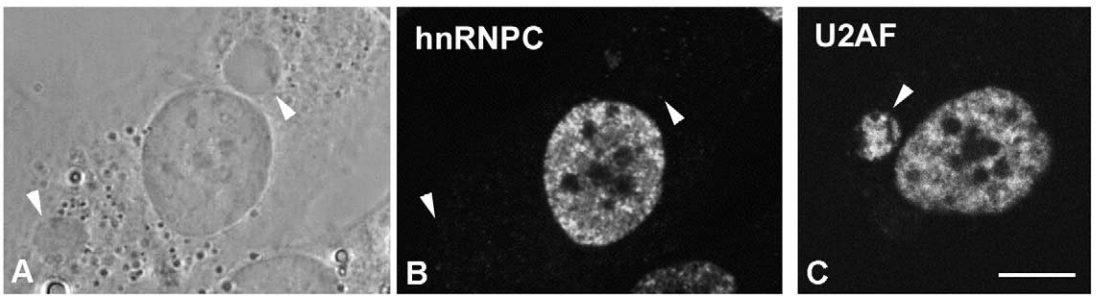

FIGURE 2 HeLa × SL2 heterokaryons. Monoclonal antibodies directed against a human protein often do not cross-react with its *Drosophila melanogaster* homologue. In this case, shuttling of the endogenous human protein can be analysed in a HeLa × SL2 heterokaryon. (**A**) Phase-contrast image of a HeLa × SL2 heterokaryon. Arrowheads label small SL2 nuclei from cells that have fused with the HeLa cytoplasm. (**B**) The heterokaryon shown in A has been immunostained with a monoclonal antibody specific for the human non-shuttling protein hnRNPC (mAb 4F4; Choi and Dreyfuss, 1989), showing it to be restricted to the HeLa nucleus in the presence of protein synthesis inhibitors (20 µg/ml emetine). Arrowheads point to the position of SL2 nuclei. (**C**) Immunostaining of a HeLa × SL2 heterokaryon with a monoclonal antibody specific for human $U2AF^{65}$ (mAb MC3; Gama-Carvalho *et al.*, 1997) shows that the human protein is present in the SL2 nucleus (arrowhead) in the presence of protein synthesis inhibitors, demonstrating the shuttling activity of this protein (Gama-Carvalho *et al.*, 2001).

duration of the shuttling assay (usually 6 h or more).

9. Fix and immunostain cells using standard procedures, following a time course with 1-h intervals. Positive and negative control experiments should be performed using monoclonal antibodies directed against human hnRNPA 1 (a protein that shuttles between the nucleus and the cytoplasm; Pinol-Roma *et al.*, 1988) and human hnRNPC (a protein that does not shuttle; Choi and Dreyfuss, 1984) (Fig. 2).

B. HeLa × 3T3 Heterokaryons

Cell Culture

1. Maintain HeLa cells routinely in MEM supplemented with nonessential amino acids and 10% FBS and grow in a 37°C, 5% CO_2 incubator. Cells should be split to petri dishes 2 days before the heterokaryon assay is performed and transfected on the following day.

2. Grow mouse 3T3 cells in D-MEM supplemented with 10% FBS at 37°C, 5% CO_2.

3. Heterokaryon medium: HeLa × 3T3 heterokaryons should be maintained as 3T3 cells.

Solutions

1. *PBS*: 137 m*M* NaCl, 2.68 m*M* KCl, 8.06 m*M* Na_2HPO_4, and 1.47 m*M* KH_2PO_4. Prepare by weighing 8 g NaCl, 0.2 g KCl, 1.14 g Na_2HPO_4, and 0.2 g KH_2PO_4 for 1 liter of solution. Sterilise by autoclaving.

2. *DAPI*: Prepare a stock solution at 1 mg/ml and store at –20°C protected from light; staining solution: dilute stock to 1 µg/ml in PBS and store at +4°C protected from light for several weeks.

3. *Protein synthesis inhibitors*: Prepare a stock solution at 10 mg/ml in 50% ethanol and store at –20°C. Final use concentrations should be established for the cell lines used; most widely used concentrations range between 20 and 100 µg/ml for cicloheximide or anisomycin and 0.5 and 20 µg/ml for emetine.

Steps

1. All the steps of the procedure should be performed in a laminar flow hood using sterile cell culture material and solutions. The procedure is adapted for cells grown on 10 × 10 mm coverslips placed in P35 dishes.

2. The evening before the assay, HeLa cells should be transfected with the desired construct and left to grow to subconfluent density on 10 × 10-mm coverslips. A 35 × 10-mm tissue culture petri dish can accommodate four of these coverslips. Common transfection reagents such as Lipofectin or Fugene work well with this procedure and can be used according to the instructions of the manufacturer. The number of hours between transfection and the heterokaryon assay should be determined for each construct to avoid overexpression of the exogenous protein.

3. Tripsinise and count 3T3 cells. For each P35 HeLa culture, prepare 1.5 ml of a 3T3 suspension with 1×10^6 cells/ml in DMEM with 10% FBS and protein synthesis inhibitor.

4. Remove the medium from the HeLa cell culture and overlay coverslips with the 3T3 suspension.

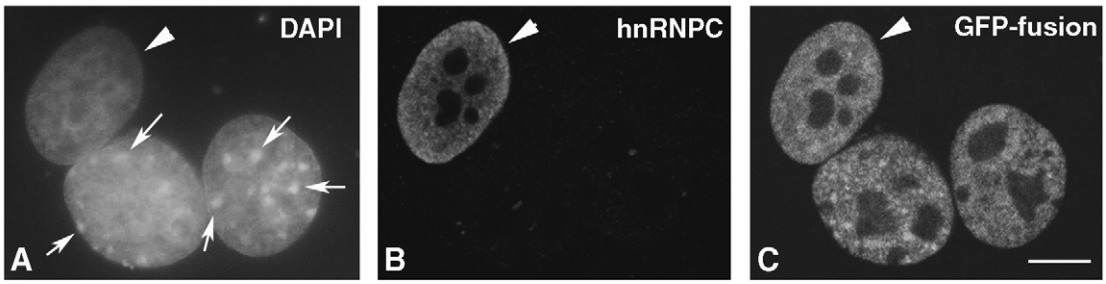

FIGURE 3 HeLa × 3T3 heterokaryons. HeLa cells were transiently transfected with a vector encoding GFP-U2AF^{65} (Gama-Carvalho *et al.*, 2001) and fused with murine NIH 3T3 cells in the presence of 20 µg/ml emetine. A single heterokaryon labelled with DAPI (A), anti-hnRNPC mAb (B), and GFP (C) is shown. (**A**) DAPI staining of the HeLa × 3T3 heterokaryon. Murine cells are easily distinguished by the presence of brightly stained blocks or pericentric heterochromatin (arrows). (**B**) The heterokaryon shown in A was stained with an antibody specific for the nonshuttling human hnRNP C protein (mAb 4F4; Choi and Dreyfuss, 1989). hnRNP C is restricted to the HeLa cell nucleus (arrowhead), confirming that there is an efficient inhibition of protein synthesis. (**C**) Detection of GFP in the HeLa × 3T3 heterokaryon reveals that the fusion protein originally present in HeLa cells shuttles between the nucleus and the cytoplasm. Bar: 10 µm.

Incubate for 3 h in a 37°C, 5% CO_2 incubator to allow 3T3 cells to adhere and inhibit protein synthesis.

5. For the fusion procedure, place a 50-µl drop of prewarmed PEG 2000 in a sterile petri dish per coverslip.

6. Remove the HeLa/3T3 coculture from the incubator and wash twice with prewarmed PBS.

7. With a sterile forceps, remove a coverslip and invert it over the PEG drop for 2 min. Then place the coverslip (cell side up) in a new P35 dish and rinse twice with prewarmed PBS. Replace the PBS with 1.5 ml of prewarmed heterokaryon medium with protein synthesis inhibitor and place the heterokaryons in the incubator for the duration of the shuttling assay (usually from 1 to 5 h).

8. Fix and stain cells using standard procedures, following a time course with 1-h intervals. In addition to the procedure (if any) necessary for detection of the exogenous protein, cells should be stained with DAPI to allow identification of heyterokaryon nuclei. Positive and negative control experiments should be performed using monoclonal antibodies directed against human hnRNPA 1 (a protein that shuttles between the nucleus and the cytoplasm; Pinol-Roma *et al.*, 1988) and human hnRNPC (a protein that does not shuttle; Choi and Dreyfuss, 1984) (Fig. 3).

IV. COMMENTS

Shuttling rates vary significantly from protein to protein, with some being extremely slow (e.g., nucleolin takes up to 16 h to be detected in the receptor nuclei) and others very fast (e.g., transport receptors are detected in receptor nuclei within minutes after the fusion). The ideal time period for a shuttling assay should thus be determined for each case by performing a time course analysis. As a general rule, detection of the protein in receptor nuclei in HeLa × 3T3 heterokaryon assays involving transient expression of exogenous protein is significantly faster than HeLa × SL2 assays with the endogenous protein. For example, for the same protein, equilibrium between donor and receptor nuclei may be achieved in 90 min in the first case and take up to 7 h in the second.

Proper interpretation of results from a heterokaryon assay requires the use of adequate controls. Whenever possible, shuttling activity should be demonstrated for both endogenous and exogenously expressed proteins, as amino acid tags and protein overexpression may modify the results. When assaying for shuttling of the endogenous protein, the specificity of the antibody has to be demonstrated carefully. The efficiency of protein synthesis inhibition must be controlled properly as different cell strains may show a wide variation in the sensitivity to protein synthesis inhibitors. Demonstration of efficient translation inhibition can be performed by staining the heterokaryons with a monoclonal antibody specific for a human nuclear nonshuttling protein, such as the hnRNP C protein (mAb 4F4, Choi and Dreyfuss, 1984). If cytoplasmic protein synthesis is going on, this protein will be detected in the nucleus of the receptor cell. Whenever possible, heterokaryons should be double stained for the protein of interest and hnRNPC. Alternatively, when the protein of interest is also detected with a mAb, a parallel assay should be performed in which the heterokaryons are labelled with the anti-hnRNP C antibody.

If a shuttling protein is identified, it is convenient to determine whether it is diffusing through the nuclear pores passively or being exported from the nucleus through a receptor-mediated pathway. For this purpose, donor cells should be placed at 4°C for the same period of time as used for the heterokaryon assay in culture medium supplemented with the protein synthesis inhibitor and 20 m*M* HEPES. Immunostaining for the protein of interest should then be performed. At low temperature, receptor-mediated nuclear import and export processes do not occur. Thus, if the protein is exported via a receptor-mediated pathway, it should be retained in the nucleus. In contrast, if the protein can leak through the nuclear pores passively, it will accumulate in the cytoplasm. If translation is not inhibited, newly synthesised proteins will also accumulate in the cytoplasm, invalidating the assay. When performing shuttling analysis based on transient transfection, it is important to note that accumulation of exogenous protein in the cytoplasm and passive leakage from the nucleus are common events in cells expressing the protein at high levels. Thus, analysis of exogenous proteins should always be centred on cells with low expression levels. A control experiment to determine the degree of exogenous protein leakage to the cytoplasm should also be performed (e.g., a low temperature shift experiment).

The use of interspecies heterokaryons in association with transient transfection opens the possibility to analyse the protein domains involved in the export pathway by the use of mutant forms of the protein. However, this analysis can only be performed with mutants that retain full nuclear localisation. Moreover, leakage of small deletion mutants to the cytoplasm should be monitored carefully.

V. PITFALLS

The confluence of HeLa cells is critical for the procedure. If the density of the culture is too low, few heterokaryons will form. If cells have reached confluence, there will be no space left for the SL2 or 3T3 cells to adhere and often their nuclei will be above HeLa nuclei, making analysis of the results impossible. HeLa coverslips should be checked one by one to choose those with an appropriate subconfluent density.

Often during the fusion procedure there is a significant loss of cells. This may result from the mechanical stress generated when the coverslips that were turned over the PEG droplet are picked. To avoid this, simply pipette PBS beneath the coverslip to make it float and then pick it up with a forceps. In addition, it is possible that the protein synthesis inhibitor is inducing apoptosis of a high percentage of cells in culture. Indeed, some cell strains are highly sensitive to these inhibitors at concentrations that have no negative effects for other cells. Thus, the choice of inhibitor and concentration should be assayed carefully for the particular cell strain used in the assay. Cycloheximide is the most widely used inhibitor, although some cell lines may be more sensitive to emetine. In some cases, efficient protein synthesis inhibition may be hard to achieve, with a significant proportion of cells in the culture showing significant levels of newly translated protein. To prevent this from influencing the interpretation of the assay, perform double labelling of heterokaryons with the anti-hnRNP C 4F4 mAb whenever possible and consider only heterokaryons in which this protein is restricted to the human nuclei.

Finding HeLa × 3T3 heterokaryons in the preparation may present some difficulty, as the observation in phase contrast does not always allow a clear visualisation of the cytoplasm. The best approach is to look for two nuclei that are very close together, which is done most easily when visualising DAPI staining. The identification of murine nuclei by staining with DAPI also requires some training. Staining with the 4F4 mAb can serve as an aid, as it will only label human cells when translation is inhibited.

As discussed earlier, when analysing the shuttling ability of transiently transfected proteins, it is crucial to consider only low expressing cells. A good fluorescence microscope is essential for detecting low levels of expression. Often, multinucleated heterokaryons form. These should not be considered in the shuttling assay, as it is hard to identify the donor nucleus and access the original expression level of the protein (as it has spread out to many nuclei).

Chromatin Assembly

CHAPTER

38

DNA Replication-Dependent Chromatin Assembly System

Jessica K. Tyler

I. INTRODUCTION

Chromatin is a periodic structure made up of repeating, regularly spaced subunits, the nucleosomes. Each nucleosome includes a core octamer of two molecules each of histone proteins H3, H4, H2A, and H2B, around which the DNA is wrapped almost twice. The assembly and structure of chromatin modulate the accessibility of proteins to the genome and hence regulate all processes that utilize the DNA. Analyses of transcription, DNA replication, and repair from *in vitro*-assembled chromatin templates reveal a wealth of information not provided by studies on naked DNA templates, as the chromatinized template more accurately reflects the state of the genome in the cell. This article outlines and compares systems for the assembly of recombinant DNA templates into arrays of nucleosomes *in vitro* to enable the reader to select the appropriate chromatin assembly system for their experimental question and resources. In addition, this article describes the DNA replication-coupled chromatin assembly system used in our laboratory and directs the reader to recent method chapters providing excellent descriptions of the other chromatin assembly systems. Chromatin assembly systems fall into two classes: "defined" systems where all the components are purified or recombinant and "cell-free" systems where the components required for assembly are supplied by a crude extract. The cell-free chromatin assembly systems can be further subcategorized into replication-independent systems and DNA synthesis-coupled systems. Defined chromatin assembly systems should be used if the experiment requires that any component of the chromatin assembly reaction or the resulting chromatin be manipulated, such as the nature of the histone proteins. Defined chromatin assembly systems fall into two classes: histone transfer systems and ATP-dependent chromatin assembly systems.

A. Defined Chromatin Assembly Systems for Histone Transfer

The core of the chromatin assembly reaction is the transfer of histone proteins to DNA, as mediated by a histone transfer vehicle or histone chaperone. If DNA and histones are combined in the absence of a histone transfer vehicle at physiological salt conditions, an undefined insoluble aggregate is obtained due to the intrinsic electrostatic attraction between the DNA and the highly basic histone proteins. A histone transfer vehicle binds to the histones and facilitates the ordered formation of nucleosomes from histones and DNA by reducing their inherent affinity for each other.

A variety of histone transfer vehicles can be used *in vitro* to assemble chromatin, including polyanions such as polyglutamate and counterions such as sodium chloride. The observation that high salt concentrations (>1.2 *M* NaCl) dissociate nucleosomes led to the discovery that this process was reversible by the progressive dialysis of mixtures of DNA and histones from high to low salt (Fig. 1A) (Lee and Narlikar, 2002). Chromatin assembly by salt dialysis is the simplest and cleanest way to form nucleosomes and has been invaluable for structural analyses of single nucleosomes (mononucleosomes; Luger *et al.*, 1999). However, arrays of nucleosomes made by salt dialysis are very close packed, with a nucleosome repeat length of around 150–160 bp as compared to that of 180–190 bp for nucleosomes *in vivo* (nucleosome repeat

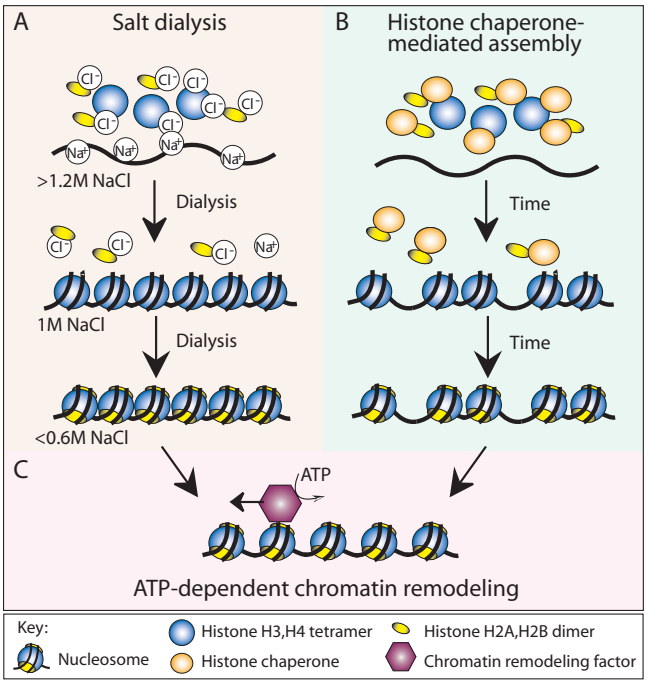

FIGURE 1 Overview of chromatin assembly systems. Histones can be deposited onto DNA to form nucleosomes *in vitro* via (A) the sequential reduction in the salt (NaCl) concentration via dialysis, resulting in regular, but close packed arrays of nucleosomes, or (B) histone chaperone-mediated histone deposition onto DNA, resulting in irregular arrays of nucleosomes. (C) The presence of an ATP-dependent chromatin remodeling activity, either during or after histone deposition, will result in regular, physiological spacing of the nucleosomes.

length is the center-to-center distance between adjacent nucleosomes; Fig. 1). This unphysiological close-packed characteristic of the salt dialysed chromatin can be overcome by incubation with an ATP-dependent chromatin remodeling factor (see later; Fig. 1C). Salt dialysis can yield nucleosomal arrays with more physiological spacing when DNA templates that comprise tandem arrays of nucleosome positioning sequences derived from the sea urchin 5S RNA gene are used (Carruthers *et al.*, 1999). However, the use of nucleosome positioning sequences places a sequence limitation on the DNA template and does not reflect the situation *in vivo* where nucleosomes are generally not positioned by the underlying DNA sequence.

Histone transfer *in vitro* can also be achieved by physiologically relevant histone chaperones, such as nucleosome assembly protein 1 (NAP-1), chromatin assembly factor 1 (CAF-1), and antisilencing function 1 (ASF1) or by histone storage proteins such as nucleoplasmin and N1/N2. Histone chaperone-mediated chromatin assembly (in the absence of an ATP-dependent chromatin remodeling factor) generally results in the unphysiological random spacing of nucleosomes along the DNA (Fig. 1B). The major applications for nucleosomal arrays assembled by histone transfer are for protein interaction analyses and for testing the ability of chromatin remodeling factors to convert irregularly spaced or close-packed nucleosomes into physiologically spaced, regular nucleosomal arrays.

B. Defined ATP-Dependent Chromatin Assembly Systems

In order to generate regularly spaced arrays of nucleosomes that resemble chromatin *in vivo*, an ATP-dependent chromatin remodeling factor is required in addition to a histone chaperone (Fig. 1C). Chromatin remodeling factors, e.g., ATP-utilizing chromatin assembly and remodeling factor (ACF) and chromatin accessibility complex (CHRAC), are multisubunit protein complexes that use the energy from ATP hydrolysis to space nucleosomes along the DNA template (Fig. 1C). These ATP-dependent chromatin assembly factors were identified by fractionation of *Drosophila* embryo chromatin assembly extracts and function together with histone chaperones, such as NAP-1 or CAF-1 (Fyodorov and Levenstein, 2002). A human ATP-dependent chromatin assembly factor, termed remodeling and spacing factor (RSF), appears to act as both the histone chaperone and the ATP-dependent chromatin remodeling factor during chromatin assembly *in vitro* (Loyola *et al.*, 2001). These defined ATP-dependent chromatin assembly systems provide powerful approaches to generate regular nucleosomal arrays with physiological nucleosomal spacing, albeit at the expense of time-consuming purification of the chromatin assembly factors and histones.

C. Generation of Reagents for Defined Chromatin Assembly Systems

In order to use defined chromatin assembly systems, it is necessary to use purified or recombinant chromatin assembly factors and histones. Recombinant histone chaperones and ATP-dependent chromatin remodeling factors are generated by affinity purification following baculovirus-mediated expression in Sf9 cells (Fyodorov and Levenstein, 2002). Core histones (H3, H4, H2A, and H2B) can be purified from a range of organisms using established protocols (Schnitzler, 2002). In addition, recombinant *Xenopus*, *Drosophila*, and yeast core histones can be expressed and purified from *Escherichia coli*, allowing assembly of chromatin lacking posttranslational modifications

or with specific histone mutations (Lee and Narlikar, 2002; Levenstein and Kadonaga, 2002; Luger *et al*., 1999; White *et al*., 2001). For those with time constraints, individual recombinant *Xenopus* core histones can be purchased from Upstate Biologicals and individual purified core histones from calf thymus can be purchased from Roche Applied Science. Due to the highly conserved nature of chromatin assembly factors and nucleosome structure across eukaryotes, it is not generally necessary to adhere to species specificity within the chromatin assembly machinery, histones, and the subsequent application of the chromatin templates. For example, there is no gross functional or structural difference in the chromatin assembled from yeast, human, or *Drosophila* core histones using human, *Drosophila*, or yeast chromatin assembly factors.

D. Cell-Free Replication-Independent Chromatin Assembly Systems

Cell-free chromatin assembly systems were developed prior to the defined ATP-dependent chromatin assembly systems, but are still the system of choice for many researchers. Technically, chromatin assembly in cell-free systems requires less empirical optimization than defined ATP-dependent chromatin assembly systems, while still generating high-quality regular arrays of nucleosomes with physiological spacing in an ATP-dependent manner. Extracts remain a requirement for the analysis of processes coupled to chromatin assembly, such as the assembly of chromatin during ongoing DNA synthesis *in vitro*. Limitations of cell-free chromatin assembly systems include the inability to fully control the nature of histones and nonhistone proteins incorporated into the chromatin or the chromatin assembly factors used for assembly, as these are contained within the cell-free extract. Conversely, the crude nature of these extracts can be an advantage if, for example, unknown factors are required to facilitate subsequent transcriptional activation from the chromatin template.

Cell-free extracts for generating physiologically spaced, regular arrays of nucleosomes have been derived from *Xenopus laevis* eggs and oocytes, *Drosophila melanogaster* embryos, and human tissue culture cells by high-speed (HS) centrifugation (Table I) (Bonte and Becker, 1999; Fyodorov and Levenstein, 2002; Gruss, 1999; Tremethick, 1999). The realization that the early developmental stages of *Xenopus* and *Drosophila* contain stockpiles of the components necessary to assemble the rapidly dividing DNA into chromatin was key to the development of highly active chromatin assembly extracts. For transcription analy-

TABLE I Comparison of Chromatin Assembly Systems

Organism/method	ATP dependent	Nucleosomal spacing[a]	Histone source[b]	Replication or repair-coupled chromatin assembly possible?[c]
Defined chromatin assembly systems				
Salt dialysis mediated	No	Close packed	Added	No
Histone chaperone mediated	No	Irregular	Added	No
NAP-1 + CHRAC/ACF mediated	Yes	Regular	Added	No
RSF mediated	Yes	Regular	Added	No
Cell-free chromatin assembly systems				
Budding yeast mitotic extract	Yes	Irregular	Endogenous	No
Drosophila embryo extract	Yes	Regular	Supplement[d]	SSS,[e] NER[f]
Xenopus egg extract	Yes	Regular	Endogenous	SSS,[e] NER[f]
Xenopus oocyte extract	Yes	Regular	Endogenous	No
Human HeLa cell extract	Yes	Regular	Supplement	SV40 DNA replication, SSS[e], NER[f]
Human 293 cell extract[g]	ND[h]	Irregular	Endogenous	SV40 DNA replication, NER[f]

[a] Nucleosomal spacing is interpreted as irregular if limited ladders were obtained from micrococcal digestion analyses.
[b] This column indicates whether histones are supplied by the extract "endogenous" or are only partially supplied by the extract and have to be supplemented ("supplement") or whether all the histones have to be added ("added").
[c] Refers to whether it is possible to perform replication or repair-coupled chromatin assembly in each system upon addition of single strand, damaged, or SV40-origin bearing templates (together with SV40 large T-antigen).
[d] The Kadonaga S190 extract requires supplementation with histones, whereas the Becker/Wu S150 extract does not.
[e] Refers to second-strand synthesis of M13 templates.
[f] Refers to nucleotide excision repair of damaged templates.
[g] Note that this extract requires supplementation with a source of CAF-1 to obtain replication-dependent chromatin assembly.
[h] Not determined.

ses, the DNA template is usually assembled into chromatin using these extracts, followed by the addition of transcription factors or a transcription extract. Chromatin templates generated from the *Xenopus* egg HS extract are inherently flawed for subsequent transcriptional analyses due to the abundance of variant linker histone B4 and transcription factors in the extract. In fact, assembly of transcription complexes competes with chromatin assembly in the *Xenopus* egg HS extract. In general, the *Xenopus* egg HS extract is used for DNA synthesis-coupled chromatin assembly, whereas the *Xenopus* oocyte extract (S150; where S refers to the sedimentation coefficient) is used for assembling templates into chromatin for their subsequent transcriptional analyses (Gaillard *et al*., 1999; Tremethick, 1999). The *Drosophila* S150 and S190 embryo extracts (Bonte and Becker, 1999; Fyodorov and Levenstein, 2002) have been widely used to assemble chromatin templates for subsequent analyses of transcriptional regulation, recreating many of the features of transcriptional regulation *in vivo* (Robinson and Kadonaga, 1998). These extracts also contain factors that can modify subsequent transcription reactions, such as chromatin remodeling activities, and therefore it may be desirable to purify the chromatin templates by sedimentation centrifugation or size exclusion prior to transcription analysis. Removal of nonhistone proteins from the chromatin may be achieved by treatment with Sarkosyl prior to purification of the chromatin template (Mizuguchi and Wu, 1999). However, defined chromatin assembly systems are the ideal method for complete control of the subsequent transcription reaction on chromatin templates.

A chromatin assembly extract has been developed from *Saccharomyces cerevisiae* that enables the powerful combination of genetics and biochemistry (Table I). This yeast extract also supports transcriptional activation and can be isolated from any yeast strain that has been altered by genetic manipulations. This enables investigation of the effect of specific mutations on chromatin assembly and transcriptional regulation of the *in vitro*-assembled chromatin templates (Schultz, 1999). However, this extract is limited by its inability to generate extensive regular arrays of nucleosomes (Table I).

E. DNA Synthesis-Coupled Chromatin Assembly Systems

In the cell, the majority of chromatin assembly is coupled to ongoing DNA replication and repair. The process of chromatin assembly coupled to double-strand DNA replication has been recreated *in vitro* using extracts from human tissue culture cells (Table I). In addition, *Drosophila*, human cell, and *Xenopus* egg HS extracts can mediate nucleotide excision repair-coupled chromatin assembly on damaged templates and second-strand synthesis-coupled chromatin assembly on M13 templates (Bonte and Becker, 1999; Gaillard *et al*., 1999). The human 293 cell extract has been widely used to study the process of DNA replication coupled-chromatin assembly using an SV40 origin to initiate replication via the method described in this article (Fig. 2). In this system, DNA replication occurs on only a portion of the total DNA templates, allowing comparison of chromatin assembly on the newly replicated DNA (labelled with a radioactive nucleotide) to chromatin assembly on the total DNA (Fig. 2). As such, this system has led to the identification and characterization of histone chaperones that mediate chromatin assembly onto newly synthesized DNA, such as CAF-1 and ASF1 (Smith and Stillman, 1989; Tyler *et al*., 1999). Furthermore, the SV40 DNA template can be preassembled into chromatin using *Drosophila* and *Xenopus* chromatin assembly extracts and then replicated using human DNA replication extracts (Gruss, 1999). Refinement of this approach may recreate epigenetic inheritance of chromatin structures *in vitro*.

F. Evaluation of *in Vitro*-Assembled Chromatin

Once assembled, it is important to check the extent of nucleosome assembly and the regularity of nucleosomal spacing. The extent of chromatin assembly can be measured by DNA supercoiling analysis, as the formation of each nucleosome introduces one negative supercoil into covalently closed circular DNA. The number of negative supercoils therefore corresponds to the number of nucleosomes assembled and is measured after deproteinization by agarose gel electrophoresis. Plasmid supercoiling by an extract cannot always be attributed to chromatin assembly, as these extracts potentially contain unrelated DNA supercoiling activities. Therefore, it is necessary to confirm that the supercoiling is due to chromatin assembly, usually by the micrococcal nuclease digestion assay. In this assay, the chromatin is partially digested by micrococcal nuclease, which cleaves both strands of DNA between the nucleosomal cores. The resulting chromatin fragments are deproteinized and the DNA is resolved by agarose gel electrophoresis. A DNA ladder derived from the chromatin fragments is observed if the assembly was efficient and the nucleosomes were regularly spaced, and the size of the DNA

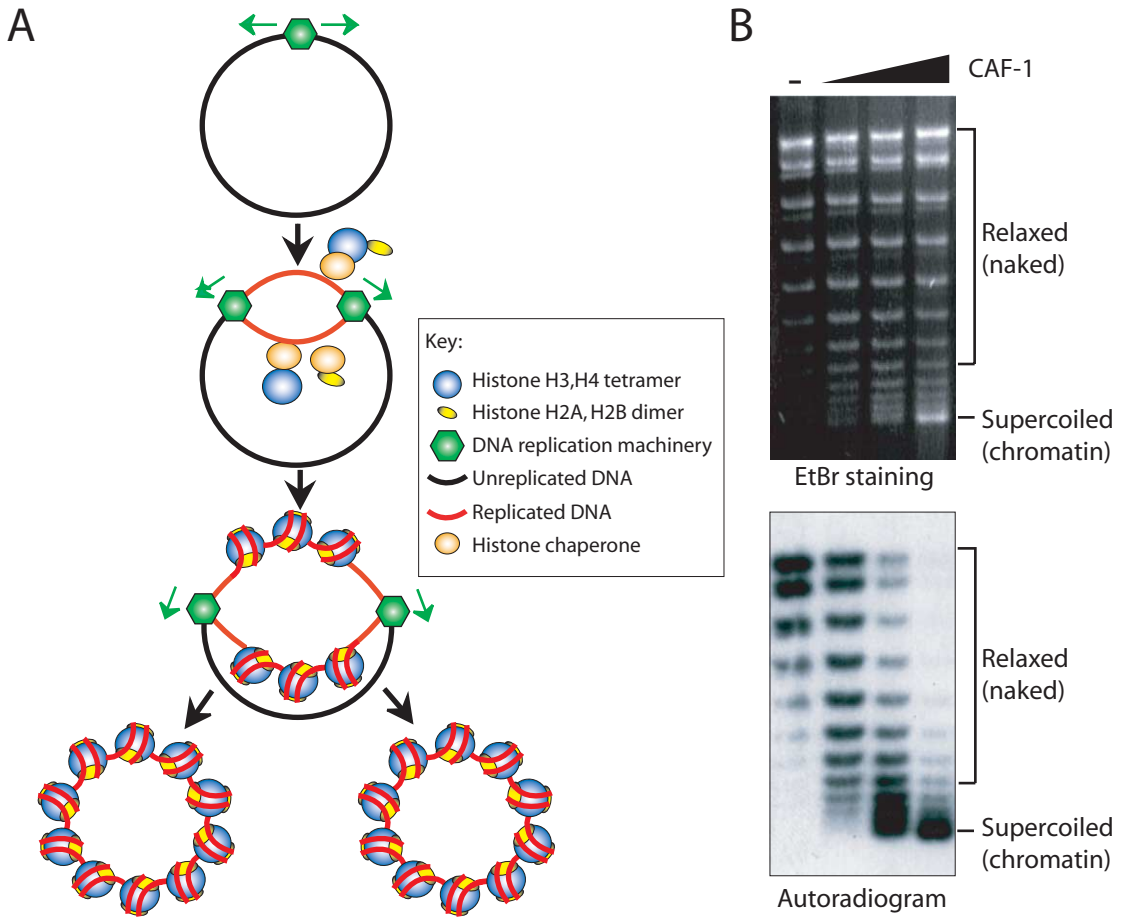

FIGURE 2 DNA replication-coupled chromatin assembly. (A) Overview of the SV40 T-antigen-driven replication assay in a human cell-free extract coupled to chromatin assembly. The newly replicated DNA (red) becomes labelled by the incorporation of a radioactive nucleotide. (B) Example of supercoiling analysis of the products of DNA replication-coupled chromatin assembly. By comparison of EtBr staining and autoradiogram of the same agarose gel, preferential assembly (supercoiling) of the replicated DNA into chromatin is apparent upon addition of CAF-1.

fragments allows the nucleosome repeat length to be estimated.

II. MATERIALS AND INSTRUMENTATION

Plasmid template carrying SV40 origin of DNA replication [we use pSV011 (Stillman, 1986)]. SV40-T antigen, affinity purified (Simanis and Lane, 1985) or purchased (Cat. No. 5800-01) from CHIMERx. Spinner-adapted version of HEK293 cells (Cat. No. CRL1573) is from ATTC. Joklik's modification of MEM (Cat. No. 1032324) and sodium butyrate (Cat. No. 218453) are from ICN. Fetal bovine serum (Cat. No. 16000-044) is from Life Technologies Inc. Ribonucleotides (ATP, CTP, GTP, UTP, Cat. Nos. E6011, E6021, E6031, E6041) and deoxyribonucleotides (dATP, dCTP, dGTP, dTTP, Cat. No. U1330) are from Promega. Filters (0.22 µm) (Cat. No. GSWP04700) are from Millipore. A 40-ml Wheaton dounce homogenizer with B pestle (Cat. No. 06-435-C), Corex 8445 tubes (Cat. No. 05-566-55), agarose (Cat. No. BP1356), chloroform (Cat. No. C298), EDTA (Cat. No. S311), dithiothreitol (DTT, Cat. No. BP172-25), glycerol (Cat. No. G3320), HEPES (Cat. No. BP310), magnesium chloride ($MgCl_2$, Cat. No. M33), phenol:chloroform:isoamylalcohol 25:24:1 (Cat. No. BP17521), potassium chloride (KCl, Cat. No. P217), potassium hydroxide pellets (KOH, Cat. No. P250), potassium phospate monobasic (KH_2PO_4 Cat. No. P285), proteinase K (Cat. No. BP1700), sodium acetate trihydrate (NaOAc, Cat. No. S209), sodium chloride (NaCl, Cat. No. S271), sodium phosphate dibasic ($Na_2HPO_4{\cdot}7H_2O$ Cat. No. S373), sodium phosphate monobasic (NaH_2PO_4 Cat. No. S369), Tris base

(Cat. No. BP152), xylene cyanol FF (XC, Cat. No. BP565), and X-ray film (Cat. No. 05-728-24) are from Fisher. Boric acid (Cat. No. B0252), bromphenol blue (BPB, Cat. No. B-6131), creatine phosphate (Cat. No. P7936), creatine phosphokinase (CPK, Cat. No. C3755), ethidium bromide (EtBr, Cat. No. E-8751), glycogen (Cat. No. G0885), IGEPAL (NP40, Cat. No. I3021), RNase A (Cat. No. R6513), and sodium hydroxide pellets (NaOH, Cat. No. S-0899) are from Sigma. Sodium dodecyl sulphate (SDS, Cat. No. 161-0302) is from Bio-Rad. [α-^{32}P]dATP 3000 Ci/mmol, 10 µCi/µl (Cat. No. BLU512H) is from Dupont NEN. Complete protease inhibitor cocktail (Cat. No. 1836153) is from Roche.

A 37°C tissue culture incubator (CO_2 not required) and a magnetic stir plate for spinner flasks (Thermodyne Cat. No. 45700) are from Fisher. The 6-liter spinner flask (Cat. No. 1965-06000) is from Bellco. Refrigerated centrifuge Sorvall RC-5B with SS34, HB6, and GSA rotors (or equivalent). Beckman ultracentrifuge with Ti70 rotor. Rotary Speed-Vac, gel dryer, and –80°C freezer are from Thermo Savant (or similar). Agarose gel electrophoresis equipment, Gibco H5 system (or similar). Liquid nitrogen tank. Eppendorf Model 5415D microcentrifuge (or similar).

III. PROCEDURES

A. Preparation of DNA Replication-Dependent Chromatin Assembly Extract

These procedures are modified from those of Stillman (1986).

Solutions

1. *Phosphate-buffered saline (PBS)*: 136 m*M* NaCl, 2.7 m*M* KCl, 3.4 m*M* Na_2HPO_4, and 1.47 m*M* KH_2PO_4. For 100 ml of 1X PBS, combine 90 ml MilliQ or double-distilled water (ddH_2O) and 10 ml 10X PBS, use within days. For 1 liter of 10X PBS, to 900 ml ddH_2O add 80 g NaCl, 2 g KCl, 9.2 g $Na_2HPO_4{\cdot}7H_2O$, and 2 g KH_2PO_4. Stir until dissolved and then add ddH_2O to 1-liter final volume. Autoclave and store 10X PBS at 4°C.

2. *1 M HEPES–KOH, pH 8.0*: For 1 liter, to 600 ml ddH_2O add 238.3 g HEPES. Once dissolved, adjust pH to 8.0 using KOH pellets and add ddH_2O to 1-liter final volume. Pass through 0.22-µm filters. Store in a sterile bottle at 4°C.

3. *3 M KCl*: For 1 liter, to 700 ml ddH_2O add 223.68 g KCl. Once dissolved, add ddH_2O to 1-liter final volume. Autoclave and store at room temperature.

4. *1 M $MgCl_2$*: For 1 liter, to 700 ml ddH_2O add 203.3 g $MgCl_2$. Once dissolved, add ddH_2O to 1-liter volume. Autoclave and store at room temperature.

5. *0.5 M DTT*: For 50 ml, dissolve 3.85 g DTT in 50 ml ddH_2O and store at –20°C.

6. *1 M sodium phosphate, pH 7.2*: Dissolve 26.807 g NaH_2PO_4 in 70 ml ddH_2O and adjust volume to 100 ml once dissolved. Dissolve 13.8 g $Na_2HPO_4{\cdot}7H_2O$ in 80 ml ddH_2O and adjust volume to 100 ml once dissolved. Combine the two solutions together (approximately 68 ml : 31 ml, respectively) until pH 7.2 is reached. Store at room temperature.

7. *1 M Na butyrate*: 1 *M* Na butyrate and 20 m*M* sodium phosphate, pH 7.2. For 100 ml, dissolve 11 g butyric acid (sodium salt) in 80 ml ddH_2O and then pH to 7.2 with NaOH. Next, add 2 ml 1 *M* sodium phosphate, pH 7.2. Add ddH_2O to 100-ml final volume. Store at 4°C. This solution has an unpleasant odour.

8. *Hypotonic buffer*: 20 m*M* HEPES–KOH, pH 8.0, 5 m*M* KCl, 1.5 m*M* $MgCl_2$, and 0.1 m*M* DTT. For 100 ml, add 2 ml 1 *M* HEPES–KOH stock, 0.16 ml 3 *M* KCl, 150 µl 1 *M* $MgCl_2$, and 20 µl 0.5 *M* DTT (stored at –20°C). Bring to volume with ddH_2O. Prepare fresh and chill on ice.

9. *5 M NaCl*: For 1 liter, to 700 ml ddH_2O add 292.2 g NaCl. Once dissolved, add ddH_2O to 1-liter final volume. Autoclave and store at room temperature.

Steps

1. Grow 4 liters of 293 cells in Joklik's modification of MEM plus 5% bovine calf serum in a 6-liter spinner flask to 6×10^5 cells/ml at 37°C. Note that because this medium is not buffered by sodium bicarbonate, you can use a sealed spinner in a 37°C room if necessary.
2. Spin down 293 cells in six GSA bottles at 2500 rpm at 4°C for 10 min with brakes off. Pour off and discard the supernatant.
3. Repeat step 2 using the same GSA bottles until all cells are pelleted. Keep the bottles on ice whenever possible. Perform all the following procedures in a 4°C room.
4. Resuspend cells in the liquid remaining in the GSA bottles and transfer to an SS34 tube on ice. Wash the remaining cells out of the GSA bottles with chilled PBS and pool into the SS34 tube.
5. Centrifuge at 2500 rpm at 4°C for 3 min and then slowly pour off and discard the supernatant.
6. Add 20 ml of chilled PBS to the cell pellet and resuspend by gentle pipetting with a plastic 25-ml pipette.
7. Centrifuge cells again for 3 min and slowly pour off and discard the supernatant.

8. Estimate the volume of packed cells in each tube in order to determine the volume of hypotonic buffer to be added later (by pipetting water into another SS34 tube and estimating the pellet volume by comparison, usually approximately 7–8 ml).
9. To 100 ml hypotonic buffer, add 0.5 ml of 1 *M* Na butyrate (to 5 m*M* final) and protease inhibitor cocktail tablets.
10. Add 20 ml of hypotonic buffer (with additives) to cells and resuspend by gentle pipetting.
11. Centrifuge at 2500 rpm at 4°C for 5 min and remove and discard the supernatant using a pipette.
12. Resuspend cells in 1 ml of hypotonic buffer for each milliliter of packed cell volume estimated in step 8. Resuspend cells by gentle pipetting. Incubate cells on ice for 10 min.
13. Transfer cell suspension to a 40-ml dounce homogenizer. Rinse SS34 tube with a small amount of hypotonic buffer and pour the rinse into the dounce homogenizer. Remove 10 µl of cell suspension for step 14.
14. Dounce cells on ice for 25–30 passages with a "B" pestle. Remove 10 µl of cell suspension, and compare cells before and after douncing using an optical microscope to estimate extent of lysis. If there are significant numbers of intact cells after douncing, dounce for a few more passages.
15. Pour lysed cells into two prechilled 30-ml Corex tubes. Incubate on ice for 30 min.
16. Centrifuge in an HB6 rotor at 10,000 rpm at 4°C for 10 min. Pour the supernatant into a 15-ml conical tube to estimate volume. Add NaCl to 0.1 *M* final concentration (a 1/50 dilution of 5 *M* NaCl) into the supernatant and mix gently.
17. Divide solution between two ultracentrifuge tubes (Beckman Ti70) and centrifuge in a prechilled Ti70 rotor at 31,000 rpm at 4°C for 60 min.
18. Transfer the supernatant to a new tube (it is okay if some lipids transfer over). Divide into 0.5-ml aliquots, freeze in liquid N_2, and store at –80°C.

B. DNA Replication-Dependent Chromatin Assembly and Supercoiling Assay

Solutions

1. *1 M creatine phosphate*: Add 1 g of creatine phosphate to 80 µl 1 *M* HEPES–KOH, pH 8.0, and 3.92 ml ddH_2O. Store at –80°C.

2. *5X RM*: 200 m*M* HEPES–KOH, pH 8.0, 15 m*M* ATP, 1 m*M* CTP, 1 m*M* GTP, 1 m*M* UTP, 0.125 m*M* dATP, 0.5 m*M* dCTP, 0.5 m*M* dGTP, 0.5 m*M* dTTP, 200 m*M* creatine phosphate, 40 m*M* $MgCl_2$, and 2.5 m*M* DTT. To make 1.2 ml 5X RM, combine, in order, 426.5 µl ddH_2O, 240 µl 1 *M* HEPES–KOH, pH 8.0, 180 µl 100 m*M* ATP, 12 µl 100 m*M* CTP, 12 µl 100 m*M* GTP, 12 µl 100 m*M* UTP, 1.5 µl 100 m*M* dATP, 6 µl 100 m*M* dCTP, 6 µl 100 m*M* dGTP, 6 µl 100 m*M* of dTTP, 240 µl 1 *M* creatine phosphate, 28 µl 1 *M* Mg_2Cl, and 6 µl 0.5 *M* DTT. Freeze in liquid N_2 and store at –80°C.

3. *2 M Tris–HCl, pH 7.5*: to make 2 liters, add 484.4 g Tris base to 1.5 liters of ddH_2O. Adjust pH to 7.5 with HCl. Pass through a 0.22-µm filter and store in in sterile bottle at room temperature.

4. *CPK*: 5 mg/ml CPK, 50% glycerol, 25 m*M* Tris–HCl, pH 7.5, 1 m*M* EDTA, 25 m*M* NaCl, and 1 m*M* DTT. To make 10 ml CPK, add 50 mg creatine phosphokinase to 4.785 ml ddH_2O, 5 ml glycerol, 125 µl 2 *M* Tris–HCl, pH 7.5, 20 µl 0.5 *M* EDTA, 50 µl 5 *M* NaCl, and 20 µl 0.5 *M* DTT. Make 10-µl aliquots, freeze in liquid N_2, and store at –80°C.

5. *Master mix*: For each of x reactions ($x = n + 1$, where n is the number of reactions being performed), combine on ice in the following order: 5 µl 5X RM, 0.1 µl CPK, 1 µl template DNA (at 50 ng/µl), 1 µl SV40 T-antigen, and 0.1 µl [α-^{32}P]dATP. Use immediately.

6. *0.5 M EDTA, pH 8.0*: For 1 liter, to 700 ml ddH_2O add 186.12 g EDTA. Add NaOH pellets until white emulsion begins to clear. Adjust pH to 8.0 with NaOH pellets. Add ddH_2O to 1-liter final volume. Autoclave and store at room temperature.

7. *25 mM buffer A*: 18.75 m*M* Tris–HCl, pH 7.5, 2.5% glycerol, 1 m*M* EDTA, and 0.125% NP-40. For 4 ml, combine 3.45 ml ddH_2O, 37.5 µl 2 *M* Tris–HCl, pH 7.5, 500 µl glycerol, 10 µl 0.5 *M* EDTA, and 4 µl NP-40. Store at 4°C.

8. *10 mg/ml RNase A*: Dissolve 1 g RNase A in 100 ml ddH_2O. Make aliquots and store at –20°C.

9. *EDTA/RNase buffer*: For 1 ml, combine 935 µl ddH_2O, 50 µl 0.5 *M* EDTA, pH 8.0, and 15 µl 10 mg/ml RNase A. Use immediately.

10. *Glycogen stop buffer*: 20 m*M* EDTA, 1% (w/v) SDS, 0.2 *M* NaCl, and 250 µg/ml glycogen. For 50 ml, combine 45.5 ml ddH_2O, 2 ml 0.5 *M* EDTA, 500 mg SDS, 2 ml 5 *M* NaCl, and 12.5 mg glycogen. Store at room temperature.

11. *Proteinase K*: 2.5 mg/ml proteinase K, 10 m*M* Tris–HCl, pH 7.5, and 1 m*M* EDTA. To make 10 ml, dissolve 25 mg proteinase K in 9.9 ml ddH_2O, 50 µl 2 *M* Tris–HCl, pH 7.5, and 20 µl 0.5 *M* EDTA. Make aliquots and store at –20°C.

12. *3 M NaOAc*: For 1 liter, to 500 ml ddH_2O add 408.24 g sodium acetate trihydrate. Once dissolved, add ddH_2O to 1-liter final volume. Autoclave and store at room temperature.

13. *1X TBE*: 89 m*M* Tris, 89 m*M* boric acid, and 2.5 m*M* EDTA. For 1 liter of 1X TBE, combine 900 ml

ddH_2O and 100 ml of 10X TBE, For 1 liter 10X TBE, to 600 ml ddH_2O add 108 g Tris base, 55 g boric acid, and 7.49 g EDTA. Stir until dissolved and then add ddH_2O to 1-liter final volume. Store at room temperature. Discard solution when white particles appear.

14. *1X TBE gel-loading buffer*: 89 m*M* Tris, 89 m*M* boric acid, 2.5 m*M* EDTA, 6% glycerol, 0.05% BPB, and 0.05% XC. For 50 ml of 1X TBE gel loading buffer, combine 15 ml ddH_2O, 15 ml glycerol, 25 ml 10X TBE, 0.125 g BPB, and 0.125 g XC. Store at 4°C.

15. *10 mg/ml EtBr*: Add 0.5 g EtBr (weighed in a fume hood) to 50 ml ddH_2O. Store in the dark at 4°C.

Steps

1. Thaw T-antigen, CPK, 293 extract, and samples being tested in a room temperature water bath and place on ice once thawed. Assemble master mix on ice. Set up replication reactions on ice by adding in order 7.8 µl 25 m*M* buffer A, 7.2 µl master mix, and 10 µl 293 replication extract. Mix by pipetting up and down. If samples are being tested for their effect on DNA replication and/or chromatin assembly, add the samples first and adjust the volume of 25 m*M* buffer A so that the reaction has a final volume of 25 µl. Discard remainder of CPK aliquot and master mix. Freeze all unused reaction components in liquid N_2 and store at –80°C.
2. Incubate replication reactions at 30°C for 90 min.
3. Stop reactions by the addition of 6.25 µl EDTA/RNase buffer. Incubate at room temperature for 15 min.
4. Add 95 µl glycogen stop buffer and 5 µl proteinase K. Incubate at 37°C for 15 min.
5. Extract samples with 1 volume of phenol:chloroform:isoamyl alcohol (25:24:1) and then with 1 volume of chloroform:isoamyl alcohol (24:1).
6. Precipitate DNA by addition of 1/10 volume of 3 *M* NaOAc and 3 volumes of 100% EtOH. Invert to mix and microcentrifuge at full speed for 15 min.
7. Remove and discard supernatant and wash pellets with 75% EtOH. Dry pellets in a Speed-Vac.
8. Resuspend pellets in 8 µl of 1X TBE gel loading buffer. Load into wells of 1% agarose gel in 1X TBE and run until BPB runs off the gel (35 V for 14 h).
9. Stain gel in 500 ml ddH_2O + 30 µl 10 mg/ml EtBr for 30 min. Destain in ddH_2O for 30–60 min and photograph.
10. Dry gel on two layers of Whatman 3 MM paper overlaid with Saran wrap on a gel drier for 2 h with heater set to 65°C. Expose gel to film.

Figure 2B shows the products of the DNA replication-coupled chromatin assembly reactions, where the top shows total DNA and the bottom shows the newly replicated DNA.

IV. COMMENTS

1. For each batch of T-antigen, the optimal amount needs to be determined empirically by determining the lowest amount that gives the maximum amount of replication. Occasionally, the volume of each extract for chromatin assembly may need to be determined in a similar manner.
2. The amount of sample to use in a typical reaction needs to be determined empirically, as addition of too much chromatin assembly factor (i.e., CAF-1, ASF1) will inhibit DNA replication. Because too much salt in the samples can interfere with replication efficiency, in general it is advisable to dialyze samples into 25 m*M* buffer A before replication analysis.
3. Controls for replication dependence, as opposed to nucleotide excision repair of the nicked plasmid, include omission of T-antigen or use of a plasmid lacking the SV40 origin of DNA replication.

V. PITFALLS

In our hands, there is significant variation between different 293 extracts in terms of the amount of active CAF-1 and ASF1 that they contain, for unknown reasons. For example, we have generated extracts that do not require the addition of CAF-1 for chromatin assembly, only require the addition of CAF-1, or require the addition of both CAF-1 and ASF1, and we have even generated extracts that fail to replicate DNA! Therefore, each extract needs to be assessed by performing the replication reaction and supercoiling analysis with and without complementation by CAF-1, ASF1, or crude extracts. This extract variability is not an issue if a crude extract (such as the cell-free chromatin assembly extracts described in Section I,C) are being used to supply chromatin assembly factors. In fact, the variability in the extracts has allowed the original biochemical identification of CAF-1 and ASF1 by complementation of the 293 extracts (Smith and Stillman, 1989; Tyler *et al*., 1999).

Cygnets: Intracellular Guanosine 3′,5′-Cyclic Monophosphate Sensing in Primary Cells Using Fluorescence Energy Transfer

Carolyn L. Sawyer, Akira Honda, and Wolfgang R.G. Dostmann

I. INTRODUCTION

Guanosine 3′,5′-cyclic monophosphate (cGMP) is a key player in the regulation of various physiological processes, including smooth muscle tone, neuronal excitability, epithelial electrolyte transport, phototransduction in the retina, and cell adhesion (Eigenthaler *et al*., 1999; Kaupp and Seifert, 2002; Lincoln *et al*., 2001; Schlossmann *et al*., 2003). Although the cGMP second messenger pathway has been steadily gaining recognition for its role in intracellular signaling, cGMP remains the least well understood member of the cyclic nucleotide family due to the following peculiarities of the cGMP signal transduction system. (1) The control of cGMP levels is complex, with formation of cGMP occurring through two different forms of guanylyl cyclases (Russwurm and Koesling, 2002; Wedel and Garbers, 2001) and degradation by a number of cGMP-specific phosphodiesterases (PDEs) (Rybalkin *et al*., 2003). (2) The intracellular actions of cGMP are mediated by cGMP-dependent protein kinases (PKGs) (Hofmann *et al*., 2000) and by several types of cyclic nucleotide-activated ion channels (Kaupp and Seifert, 2002). (3) The enzymes modulating cGMP levels are expressed differentially throughout mammalian tissues. Furthermore, a tightly controlled equilibrium of synthesis and breakdown generates highly flexible intracellular cGMP transients, contributing to the experimental and conceptual obstacles posed by the multiplicity in mechanisms of cGMP signaling and the difficulty of studying cGMP in broken cell preparations.

Genetically encoded indicators based on the insertion of conformationally sensitive domains between two mutants of green fluorescent protein (GFP) that participate in fluorescence resonance energy transfer (FRET) have proved to be powerful tools for observing the dynamics of intracellular signaling molecules noninvasively. Examples of such indicators include those that detect the second messengers Ca^{2+} (Miyawaki *et al*., 1997) and cAMP (Zaccolo and Pozzan, 2002). For the construction of our cGMP indicators, which we have named cygnets (cyclic GMP indicators using energy transfer), we chose PKG as the central cGMP sensor because it binds cGMP with high affinity, undergoes a conformational change in response to cGMP, and is not restricted to membranes (Pfeifer *et al*., 1999; Ruth *et al*., 1991; Zhao *et al*., 1997). We have demonstrated the validity of this intramolecular FRET approach and could show that cygnets (i) are exclusively selective for cGMP, (ii) allow detection of intracellular cGMP in single living cells, (iii) are fully reversible to monitor fast spatial and temporal cGMP changes, and (iv) are minimally invasive when analyzing intracellular cGMP signaling events (Honda *et al*., 2001; Sawyer *et al*., 2003). This article provides a detailed methodology for the use of our latest cGMP indicator version, Cygnet-2.1, in primary cell culture.

II. MATERIALS AND INSTRUMENTATION

The RFL-6 (CCL-192) established cell line is from American Type Culture Collection. The FuGENE 6 transfection reagent is from Roche (1814443). Cygnet-2.1 DNA (pcDNA3.1(-)-Cygnet-2.1) is constructed as described previously (Honda *et al*., 2001).

Dulbecco's modification of Eagle's medium (DMEM, with 4.5 g/liter glucose and L-glutamine, with sodium pyruvate; MT 10-013-CM), Ham's F-12 medium (MT 10-080-CM), fetal bovine serum (FBS, MT 35-010-CV), trypsin EDTA (MT 25-052-CI), amphotericin B (MT 30-003-CI), and gentamycin sulfate (30-005-CR) are from cellgro by Mediatech, Inc. Bovine serum albumin (BSA, A7638) and potassium phosphate [dibasic (K_2HPO_4, P-3786) and monobasic (KH_2PO_4, P-0662)] are from Sigma-Aldrich. Elastase (100617) is from ICN Biomedicals. Collagenase (199152) is from Worthington Biochemical Corporation. Penicillin/streptomycin/neomycin (15640-055) is from Gibco-BRL/Invitrogen. Collagen (354231), BD Falcon polystyrene 35 × 10-mm (353001) and 60 × 15-mm (353004) cell culture dishes are from BD Biosciences. Benzamidine hydrochloride (105240250) and EDTA (118430010) are from Fisher Scientific. The extracellular solution used for microscopic imaging consists of Hank's balanced salt solution (HBSS; cellgro by Mediatech, MT 21-020-CV) with 20 m*M* HEPES (cellgro by Mediatech, MT 25-060-CI) and 2 g/liter glucose (Sigma-Aldrich, G-7021).

cGMP (40732-48-7; reconstituted in distilled H_2O) and fluorescence grade 8-(4-chlorophenylthio)guanosine-3′, 5′-cyclic monophosphate [8-pCPT-cGMP; 51239-26-0; reconstituted in dimethyl sulfoxide (DMSO)] are from BIOLOG Life Science Institute.

The following chemicals have been used to modulate intracellular cGMP levels: Nitric oxide donors *S*-nitrosoglutathione (GSNO; Calbiochem 487920, protect from light and reconstitute in cold distilled H_2O free of divalent cations other than Ca^{2+}; stock solution is stable for 2 h at 4°C), *N*-(2-aminoethyl)-*N*-(2-hydroxy-2-nitrosohydrazino)-1,2-ethylenediamine [NOC-22, spermine NONOate; Calbiochem 567703; reconstitute in 0.1 *N* NaOH, ≥pH 10; $t_{1/2}$ of NO release = 230 min in phosphate-buffered saline (PBS), pH 7.4, 22°C] diethylamine NONOate (DEA NONOate; Calbiochem 292500, reconstitute in distilled H_2O; $t_{1/2}$ of NO release = 16 min in PBS, pH 7.4, 22°C), and (±)-*S*-nitroso-*N*-acetylpenicillamine (SNAP; Calbiochem 487910; protect from light and reconstitute in DMSO; $t_{1/2}$ of NO release = 10 h) are reconstituted to 100× the final concentration of 100 μ*M* prior to use and stored on ice until needed.

Atrial [ANP (3-28), rat; 14-5-44A] and brain [BNP (1-32), Rat; 14-5-11A] natriuretic peptides are from American Peptide Company. The C-type natriuretic peptide [CNP (6-22), human and porcine; 05-23-0310] is from Calbiochem. Peptides are reconstituted in distilled H_2O to 100 μ*M* stock solutions and stored at –20°C for several months until their use at a final concentration of 0.1–1 μ*M*.

The phosphodiesterase inhibitors 3-isobutyl-1-methylxanthine (IBMX; 410957; nonspecific inhibitor of cAMP and cGMP phosphodiesterases, final concentration 0.6 m*M*), vinpocetine (677500; PDE I inhibitor; final concentration 0.2 m*M*), 8-methoxymethyl-3-isobutyl-1-methylxanthine (MM-IBMX; 454202; PDE I inhibitor; final concentration 40 μ*M*), erythro-9-(2-hydroxy-3-nonyl)adenine, HCl (EHNA; 324630; PDE II inhibitor; final concentration 8 μ*M*; reconstitute in distilled H_2O), 1,6-dihydro-2-methyl-6-oxo-(3,4′-bipyridine)-5-carbonitrile (Milrinone; 475840; PDE III inhibitor; final concentration 3 μ*M*), 4-[3-(cyclopentyloxy)-4-methoxyphenyl]-2-pyrrolidinone (Rolipram; 557330; PDE IV inhibitor; final concentration 8 μ*M*), and 1,4-dihydro-5-(2-propoxyphenyl)-7H-1,2,3-triazolo[4,5-d]pyrimidine-7-one (Zaprinast; 684500; PDE V inhibitor; final concentration 4.5 μ*M*) are from Calbiochem. After reconstitution in DMSO (unless otherwise noted), stock solutions are stored at –20°C and used within 2 months. Sildenafil is a generous gift from Pfizer.

The fluorescence spectrometer F-4500 is from Hitachi. Quartz fluorescence cells (14-385-918A) for spectrophotometers and Dithiothreitol (DTT, 16568-0050) are from Fisher Scientific. Dithiothreitol (DTT, 16568-0050),

A light-duty portable punch size XX (130010001) outfitted with a 0.5-in. round dye (Type O) is from Roper Whitney of Rockford, Inc. A Sylgard 184 silicone elastomer kit is from Dow Corning Corporation. Coverslips (22 × 22 mm, 1 thickness; 12-544-10) are acquired from Fisher Scientific.

An inverted Nikon Diaphot 200 microscope equipped with a Nikon Fluor 40/1.30 oil Ph4DL objective (Part 140010) is outfitted with an ORCA ER cooled charge-coupled device camera (Hamamatsu). Three filter wheels, one each for excitation, emission, and neutral density filters, and a shutter at the excitation filter wheel are controlled by Lambda 10-2 optical filter changers from Sutter Instruments. A lambda LS xenon arc lamp and power supply are also obtained from Sutter Instruments. The Cameleons 2 filter set (71007a) purchased from Chroma Technologies for dual emis-

sion consists of a D440/20x excitation filter, a 455DCLP dichroic, and two emission filters (D485/40m and D535/30m). Neutral density filters (0.1, 0.3, 0.5, 1, 2, 3) are also obtained from Chroma. Image acquisition is controlled by a computer loaded with Metamorph and Metafluor 4.64 software from Universal Imaging (Media, PA). A stage adaptor to hold 35-mm imaging dishes was constructed at the Instrumentation and Model Facility at the University of Vermont.

III. PROCEDURES

A. Cygnet Expression and Purification

Express recombinant Cygnet-2.1 protein in *Spodoptera frugiperda* (Sf9) cells using the Bac-to-Bac baculovirus system (GIBCO/BRL) and purify using cAMP-agarose as described earlier (Honda *et al*., 2001).

B. *In Vitro* cGMP Titration

Perform cGMP titrations of Cygnet-2.1 by adding 50 n*M* of protein to a quartz fluorescence cell with buffer (50 m*M* KPO_4, pH 6.8, 10 m*M* DTT, 10 m*M* benzamidine, and 5 m*M* EDTA) for a final volume of 500 µl. Excite samples in a fluorescence spectrometer at 432 nm and monitor emission intensities from 450 to 550 nm. Plat the ratios of the 475 to 525 emission intensities against the concentration of cGMP added to the sample to generate a titration curve.

C. Cell Culture

The following cell types have been used successfully to express cygnets and monitor intracellular cGMP levels. Details on their preparation and handling are as follow.

1. Rat Fetal Lung Fibroblast Cells (RFL-6)

Cells should be cultured according to the supplier. Briefly, grow RFL-6 cells in Ham's F12 medium supplemented with 20% fetal bovine serum at 37°C, 5% CO_2. Subculture every 5–6 days with 0.25% trypsin at a ratio of 1:4 and plate on glass-bottom dishes for imaging. RFL-6 cells should not used beyond passage number eight. Routinely verify cGMP responses with cygnet-transfected RFL-6 cells, an established cell line known to respond with high cGMP levels upon stimulation (Ishii *et al*., 1991).

2. Rat Aortic Smooth Muscle Cells (RASMC)

Preparation and Culture of RASMC

1. Euthanize mature female or male Sprague–Dawley rat (250–350 g) by a lethal dose of pentobarbital sodium and exsanguination and remove thoracic aorta.
2. Clean aorta of fat and connective tissue and slice into 1- to 2-mm rings with a sterile scalpel.
3. With a scalpel, score a 60-mm cell culture dish to create a grid of three horizontal and three vertical lines, and embed each ring where two grooves intersect.
4. To prevent rings from detaching from the bottom of the dish, carefully add DMEM containing 10% FBS, 50 µg/ml gentamicin, and 2.5 µg/ml amphoteracin B and incubate at 37°C in humidified 5% CO_2. Replenish media every 2–3 days and smooth muscle cells will proliferate from the aortic explants within 1 week.
5. When cells reach confluency between gridlines, remove artery sections and rinse plate with trypsin. Add 1 ml fresh trypsin and aspirate off, leaving only a small amount in the dish. Incubate at 37°C until cells have detached, less than 5 min.
6. Resuspend cells in 2–3 ml supplemented media and transfer approximately 300 µl of cell suspension to glass portion only of glass-bottom imaging dishes.
7. When cells have adhered to the coverslip, aspirate media and replace with 2 ml fresh media in entire dish. These cells are henceforth referred to as passage one (P1) cells. Use only P1 cells in imaging experiments.

Alternatively, RASMC can be dissociated from the aorta using an isolation protocol adapted from Cornwell and Lincoln (1989) and Smith and Brock (1983).

1. After extracting aorta, place in isolation media consisting of DMEM, 20 m*M* HEPES, 1 mg/ml BSA, 5 µg/ml amphoteracin B, and 50 µg/ml gentamicin.
2. Clean aorta of fat and connective tissue and incubate in isolation media supplemented with 1 mg/ml elastase and 130 units/ml collagenase for 8 min at 37°C.
3. Rinse aorta to remove endothelial and other nonadherent cells, and remove tunicae adventitia as an everted tube.
4. Mince the medial layer of the aorta and digest pieces in isolation media supplemented with 200 units/ml collagenase for 1 to 2 h or until single cells are attained.
5. Wash cells twice in isolation media and culture in DMEM, 10% FCS, and 50 µg/ml gentamicin.

D. Preparation of Imaging Dishes

1. Prepare glass-bottomed dishes for fluorescence imaging by punching 0.5-in. holes in the bottoms of 35-mm cell culture dishes with an industrial punch.
2. Mix 1 part Sylgard 184 curing agent with 10 parts Sylgard 184 silicone elastomer (w/w) carefully to avoid introducing air bubbles.
3. Pipette a thin line of Sylgard around the hole on the bottom of the dish. Place a coverslip over the ring of Sylgard and tamp down with a cotton-tipped applicator to seal.
4. Allow Sylgard to cure overnight.
5. Sterilize dishes in a sterile hood under ultraviolet light for at least 30 min.
6. Dishes may be treated with 0.1 mg/ml collagen to promote cell adherence to coverslips.

E. Transfection of Cygnet-2.1

1. Grow primary RASMC to 50–60% confluency on 35-mm glass-bottomed dishes.
2. For each 35-mm dish, pipette 3 µl FuGENE 6 directly into 200 µL serum-free DMEM in a plastic 1.5-ml microfuge tube, minimizing the contact that FuGENE 6 has with the wall of the tube.
3. Add 1 µg highly purified pcDNA3.1(-)-Cygnet-2.1 to the DMEM–FuGENE 6. Close the tube and mix by inversion.
4. Allow DNA/lipid complexes to form at room temperature for 15 min.
5. Without removing media from 35-mm dishes, add transfection mixture dropwise using a pipette. Distribute transfection mixture around dish by gently shaking dish side to side.
6. Incubate RASMC at 37°C for 24 h and RFL-6 cells 48 h before imaging. Culture media may be replaced after 6 h of transfection, if desired. However, leaving cells in FuGENE until the time of imaging does not cause toxicity.

F. Data Acquisition and Analysis

Dual-Emission Imaging Protocol Using Metafluor

1. Open Metafluor software from Universal Imaging Corporation and select "New" on the toolbar to begin a new experiment.

2. Select configure/configure acquisition and define wavelengths 1 and 2 as ECFP and EYFP, respectively, and the excitation wavelength for both as 440 nm. The emission wavelengths for ECFP and EYFP must be defined as 480 and 535 nm, respectively. Chose file/save protocol file to save these parameters. When starting Metafluor from now on, begin by selecting "Protocol" and then open a new experiment.

3. Check the "Save Images" box in the control panel. As long as the box remains checked, every image acquired from now on will be saved as part of the file you are now prompted to name. *Note*: Each experiment is saved as an .inf file, which is composed of a .tif file of every image acquired during the experiment.

4. To locate transfected cells, manually select the 440-nm excitation filter and open the shutter (if applicable) in the illumination control box found in the configure menu.

5. Focus the transfected cell(s) of interest through the camera by selecting "Focus" on the control panel and the focusing screen will appear. Choose "Start Focusing" and your image will appear. Bring the image displayed on the monitor into focus and then click on "Stop Focusing." Selecting "Close" will bring you back to the experimental menu.

6. Select "Acquire One" on the toolbar to get an idea of what your image will look like. Cygnet-transfected cells should be visible in both 475 and 535 emission channels (Figs. 1A and 1B). Cells can be pseudocolored during at a later period during data analysis to correlate color hue with 475/535 emission ratio (Figs. 1C and 1D). If the cell is too bright (saturated pixels appear black) or too dim, the exposure time may need to be altered in the configure acquisition menu.

7. To start the experiment, press "Acquire" on the control panel menu and images will be captured at intervals until "Pause" is pressed.

8. To set the time lapse between image acquisitions to 10 s, select "Timelapse" on the control panel menu and enter the desired time.

9. Define regions on your image in which to monitor intensity values by selecting "Regions" on the toolbar. Select the circle tool and place a circle on a dark area of the image for background measurements. Then trace several regions (shape and number depending on cell) on the cell(s) of which you would like to monitor the fluorescence. Select "Close" to return to the experimental menu.

Note: The defined regions appear on one of the images, but fluorescence intensity data are collected from both wavelength channels in the same exact position defined on the cell. Graph 1 and Graph 2 plot the wavelength intensity value and ratio of (wavelength 1)/(wavelength 2) intensity values, respectively, against time.

10. As the program acquires images and plots data collected from the regions that you have defined, monitor the trace in Graph 2, the plot of the ECFP/EYFP ratio. Once you have established a stable baseline, pharmacological agents can be added and the

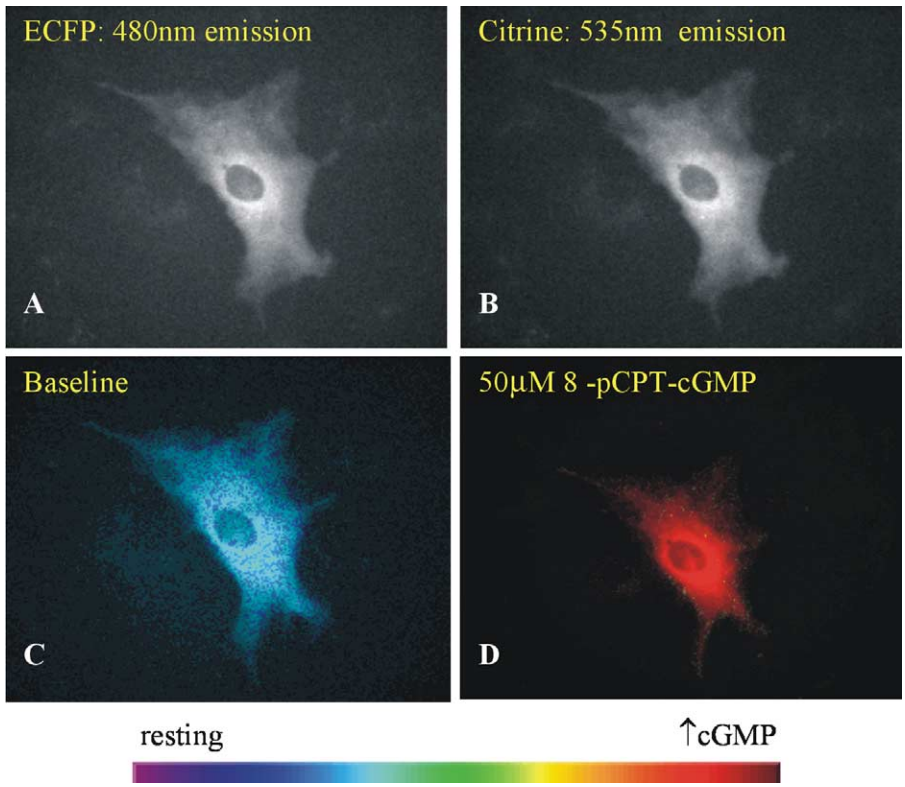

FIGURE 1 Cygnet-2.1 expression indicates cytosolic localization and nuclear exclusion in cultured rat aortic smooth muscle cells (top) as shown by the fluorescence images of (A) ECFP (480 nm emission) and (B) EYFPcitrine (535 nm emission). Pseudocolor representations of the 480- to 535-nm FRET ratio at resting (C) and elevated (D) cGMP levels were elicited with 50 µ*M* 8-pCPT-cGMP.

event markers used to note when things were added (select "Events" on the toolbar to define and mark events). At the end of an experiment, a cell-permeable cGMP analog can be applied to verify indicator fidelity (Fig. 2A).

11. To end the experiment, select "Close" on the control panel.

Data Collection

1. To collect data, select "Open" from the toolbar and select an experiment.
2. Define regions for background and on the cell(s) as before.
3. To subtract the background (i.e., make the intensity of background equal to zero), select run experiment/reference images. In the pull-down menu, choose to subtract the average intensity of a region and indicate which number refers to the region defining the background. Check the box on the lower left-hand corner to "Subtract Background" and close the menu.
4. Check "Log Data" on the control panel to save the intensity and ratio values of the wavelengths associated with each region.
5. Press "Forward" on the control panel to run through the experiment. As each image appears, the intensity and ratio values for each region on each wavelength channel (ECFP and EYFP) are saved. To make certain that the regions stay in the approximate same place on the cell, their placement may need adjustment. The log file that has been generated can be opened in a spreadsheet program and time plotted against the ECFP/EYFP intensity ratio.
6. To save individual images, select the desired image by playing through the experiment using the "Forward" button or the slider bar and then click on the image so that the window is highlighted. Under utilities/save as an 8-bit image, select to save the image as a .TIF file.

Making a Movie of a Pseudocolored Cell

1. To create a movie of a pseudocolored cell, define regions on the background and cell(s) and subtract background as described previously.
2. Play through the experiment and determine the minimum and maximum ratio values the cell displays by referencing Graph 2.

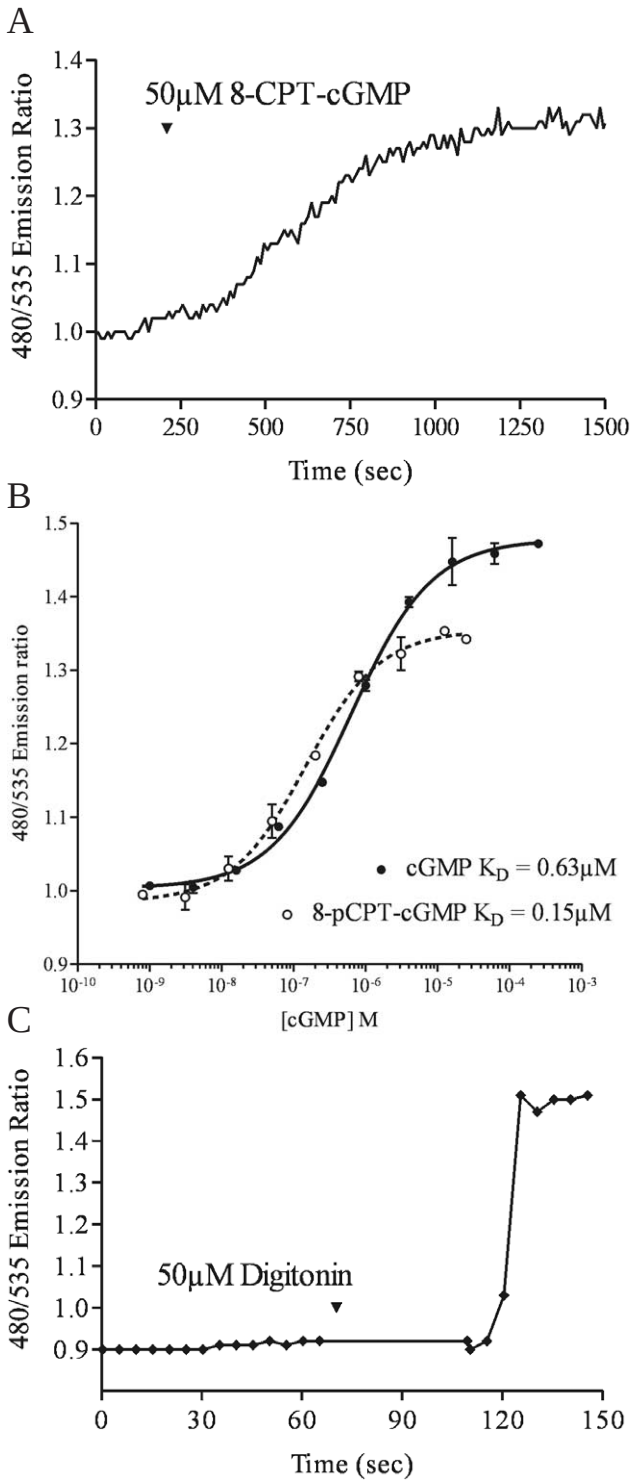

FIGURE 2 (A) Cygnet-2.1 expressed in an individual RASM cell exhibits a 30% EYFP/citrine ratio change in response to a saturating dose of the membrane-permeable cGMP analog 8-CPT-cGMP. (B) *In vitro* Cygnet-2.1 titration with cGMP reveals a maximum FRET ratio change of 45%. Saturating concentrations of the analog 8-CPT-cGMP can only generate a 30% change. (C) A RASM cell expressing Cygnet-2.1 was permeabilized with 50 μ*M* digitonin in an extracellular solution containing 8 μ*M* cGMP. The indicator responded to the cGMP influx with a FRET ratio change of 47%.

3. Select configure/image display control and choose Ratio 1 (ECFP/EYFP) from the top pull-down menu. From the lower pull-down menus choose intensity modulated display (IMD). In the "Minimum" and "Maximum" boxes, enter the approximate minimum and maximum ratio values determined from Graph 2. Setting the ratio values slightly inside the actual minimum and maximum values often enhances the visual effect as seen in the Ratio 1 box.

4. After optimizing the color changes the cell undergoes throughout the experiment, check the "Save Ratio" box on the control panel and forward through the entire experiment. The images displayed in the Ratio 1 box have now been saved as .TIF files.

5. Exit Metafluor and open Metamorph.

6. Select file/build stack/numbered names and select the first image. When prompted, select the last image. A "stack" of .TIF files has now been created.

7. Select stack/make movie, and a movie is generated from the compiled stack, which can be saved as an .AVI file under the stack menu.

8. A representative movie corresponding to the trace shown in Fig. 3 is published as supplemental data on the *Cell Biology* website.

Note: .AVI files generated with Metamorph are very large (40–100 MB) but can be compressed down to a few megabytes (50× or more) using a program such as VideoFramer.

G. Example of cGMP Sensing in Primary Rat Aortic Smooth Muscle Cells

At approximately 50–60% confluency, passage one cells were transfected with FuGENE 6 using a 3:1 ratio of FuGENE reagent to pcDNA3.1–Cygnet-2.1 DNA. Cells were imaged 24 h posttransfection at 25°C using Hank's balanced salt solution with 20 m*M* HEPES (pH 7.35) and glucose (2 g/liter) as the extracellular solution and 500-ms exposures at 10-s intervals.

Cygnet-2.1 expressed in both rat aortic smooth muscle cells (Figs. 1A and 1B) and RFL-6 cells (Honda *et al.*, 2001) demonstrated cytosolic localization and nuclear exclusion when ECFP and citrine emissions were viewed individually. Pseudocoloring of the cell (Figs. 2C and 2D) correlates the ratio of the ECFP/citrine emissions to a color scale, with lower and higher ratios and cGMP levels represented by blue and red, respectively. A saturating dose of the cell membrane-permeable cGMP analog 8-pCPT-cGMP changed the pseudocoloring from blue to red (Fig. 1D) and correlates to a 30% increase in FRET ratio (Fig. 2A). However, *in vitro* results with purified Cygnet-2.1 showed that cGMP consistently causes a 40–50% ratio

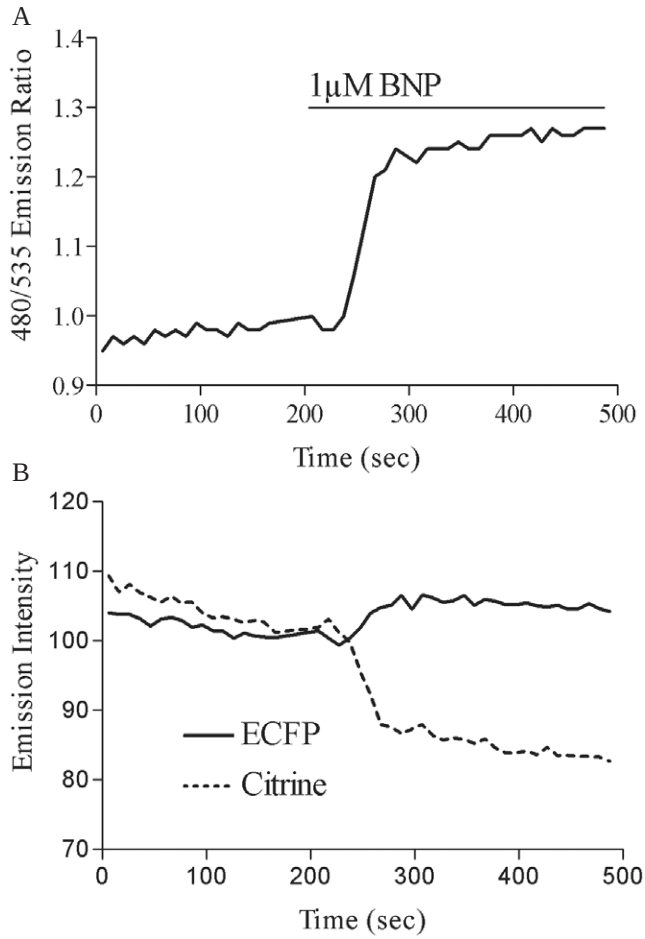

FIGURE 3 (A) Stimulation of the particulate guanylate cyclase (pGC) NPR-A with the natriuretic peptide BNP produces a FRET ratio change of approximately 28%. (B) Analysis of the individual emission intensities of ECFP and citrine during pGC activation demonstrates an increase in ECFP and a decrease in citrine emissions.

change. To analyze this apparent discrepancy, Cygnet-2.1 purified from Sf9 cells was titrated with cGMP and 8-CPT-cGMP (Fig. 2B). The purified indicator's maximum ratio change attained with cGMP was approximately 45%, while the analog still only elicited a maximal ratio change of 30%. In fact, in cells permeabilized with 50 μ*M* digitonin in the presence of saturating concentrations of cGMP, cygnets demonstrated a 47% FRET ratio change as expected from the *in vitro* results (Fig. 2C).

Activating the particulate guanylate cyclase with 1 μ*M* brain natriuretic peptide produced a FRET ratio change of 28% (Fig. 3A). Atrial natriuretic peptide produced a similar response, and both ANP- and BNP-induced cGMP accumulation could be washed out to near baseline (data not shown). Analysis of the individual emission intensities of ECFP and citrine demonstrates the mechanism of our cGMP indicator: cGMP generated in response to the activation of guanylate cyclase binds to the indicator and triggers a conformational change in the receptor. Subsequent alterations in the relative spatial arrangement of the two fluorophores result in a loss of energy transfer from ECFP to citrine and an increase in ECFP emission and a decrease in that of citrine (Fig. 3B).

IV. COMMENTS

Experiments acquiring images at 10-s intervals can run for greater than 30 min. We have accumulated as many as 200 exposures before applying a stimulus and have observed no significant loss in indicator sensitivity. It should be noted that cells have the tendency to react quite differently to the same stimulus.

V. PITFALLS

1. Transfection efficiency and cygnet expression may be low in some cells, particularly in primary cultures. Optimal expression may require alternative transfection reagents and optimization of transfection conditions, depending on the cell type.
2. Because intracellular cGMP fluctuations can potentially be buffered by the expression of the indicator, it is important to compare the total cGMP-binding capacity of untransfected and cygnet-transfected cells. This can be accomplished by the use of antibodies to PKG to determine if total PKG immunoreactivity, and therefore cGMP-binding capacity, is elevated by the expression of cygnets.
3. Because excessive illumination of cygnets may result in photobleaching of GFP mutants, fluorophore excitation should occur at the minimum intensity, frequency, and duration possible. The emission profiles of ECFP and citrine should be monitored to ascertain that changes in FRET are not due to aberrant behavior of the individual fluorophores due to photobleaching or other phenomena such as pH-induced alterations.

Ca^{2+} as a Second Messenger: New Reporters for Calcium (Cameleons and Camgaroos)

Klaus P. Hoeflich, Kevin Truong, and Mitsuhiko Ikura

I. INTRODUCTION

The intracellular Ca^{2+} ion concentration has been found to be associated with a wide variety of cellular processes (Carafoli, 2003). These include diverse events such as secretion, fertilization, cleavage, nuclear envelope breakdown, and apoptosis. Several diseases, including types of muscular dystrophy, diabetes, and leukemia, involve proteins that directly respond to or control Ca^{2+}. Indeed, it may be more difficult to find cellular processes that do not involve Ca^{2+} than ones that do. From decades of research we have learned that the process of Ca^{2+} signaling consists, in general terms, of molecules for Ca^{2+} signal production, spatial and temporal shaping, sensors, and targets that elicit changes in biological function. Hence, this has prompted the development of sensitive signaling techniques to measure and image submicromolar levels of $[Ca^{2+}]$ and decode the dynamic Ca^{2+} messages throughout the propagation of the signal.

Ca^{2+} transients have traditionally been measured using synthetic fluorescent chelators (such as Fura-2 and Quin2) or recombinant aequorin (Grynkiewicz *et al.*, 1985: Montero *et al.*, 1995). Synthetic molecules provide a bright fluorescent signal, but these dyes are not easy to load and gradually leak out of cells at physiological temperatures. Cellular targeting is also not specific and some chemical indicators have been shown not to accumulate well in certain organelles. Aequorin is targeted easily but it requires incorporation of the cofactor coelenterazine, is irreversibly consumed by Ca^{2+}, and is very difficult to image due to low bioluminescence. By comparison, green fluorescent protein (GFP) and calmodulin (CaM)-based "cameleon" probes have been developed and retain several of the benefits of the aforementioned indicators, yet also provide significant improvements for *in vivo* imaging (Miyawaki, 2003; Zhang *et al.*, 2002; Truong and Ikura, 2001).

The use of cameleon indicators is gradually becoming more common within the Ca^{2+} signaling community and the literature is rich with examples of various applications. For instance, fusion of cameleons to specific signal sequences has successfully sorted them to nuclei, endoplasmic reticulum, caveolae, and secretory granule membranes (Isshiki *et al.*, 2002; Demaurex and Frieden, 2003; Emmanouilidou *et al.*, 1999). In addition to their use in detecting rapid stimulus-induced $[Ca^{2+}]$ transients, genetic studies in which cameleons were stably expressed in *Arabidopsis* stomatal guard cells (Allen *et al.*, 1999), nematode pharyngeal muscle (Kerr *et al.*, 2000), or larval thermoresponsive neurons of *Drosophila* (Liu *et al.*, 2003) show that the sensors are also applicable to long-term monitoring of Ca^{2+} concentration. This has been demonstrated further for murine cells where the circadian rhythm of cytosolic but not nuclear Ca^{2+} in hypothalmic suprachiasmatic neurons was demonstrated (Ikeda *et al.*, 2003).

It is hoped that this article provides some explicit and practical information relevant to the laboratory use of cameleon fluorescence resonance energy transfer (FRET) indicators. Our aim is that it will benefit and be of interest to colleagues both unfamiliar or experienced in using fluorescent Ca^{2+} indicators.

II. MATERIALS AND INSTRUMENTATION

A. Expression and Purification of Cameleons

Enhanced cyan fluorescent protein (ECFP) and enhanced yellow fluorescent protein (EYFP) expression constructus (Clontech Cat. No. 6075-1 and 6004-1, respectively); calmodulin cDNA (M. Ikura); pRSETB prokaryotic expression vector (Invitrogen Cat. No. V351-20); Luria broth (LB) media; isopropyl-β-D-thiogalactopyranoside (IPTG, Fermentas Cat. No. R0391); complete protease inhibitor cocktail tablets (Roche Cat. No. 1697498); Ni-NTA agarose (Qiagen Cat. No. 1018240); *Escherichia coli* BL21 (DE3) strain (Stratagene Cat. No. 200133); sonicator; EGTA buffer: 100 m*M* KCl, 50 m*M* HEPES (pH 7.4), and 10 m*M* EGTA; $CaC1_2$ buffer: 100 m*M* KCl, 50 m*M* HEPES (pH 7.4), 10 m*M* EGTA, and 10 m*M* $CaCl_2$.

B. *In Vitro* Fluorescence Quantitation

Shimadzu spectrofluorometer RF5301; 10-mm pathlength quartz cuvette.

C. *In Vitro* Imaging of Cameleons

pcDNA3 eukaryotic transient expression vector (Invitrogen Cat. No. V790-20); uncoated; γ-irradiated, 35-mm tissue culture dishes with glass bottom No. 0 (MatTek Cat. No. P35G-0-10-C); Dulbecco's modified Eagle medium (DMEM) supplemented with 10% dialyzed fetal bovine serum (FBS, Invitrogen Cat. No. 26400044), Hanks' balanced salts solution (HBSS) with Ca^{2+} (Invitrogen Cat. No. 14170120); 37°C CO_2 incubator; HeLa cells or appropriate eukaryotic strain; Lipofectamine (Invitrogen Cat. No. 18324012) and PLUS (Invitrogen Cat. No. 11514015) reagents; histamine, ionomycin, ethylene glycol-bis(2-aminoethylether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA) and 1,2-bis(2-aminophenoxy)ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid tetrakis(acetoxymethyl ester) (BAPTA-AM) (Sigma Cat. No. H7125, I0634, E0396, and A1076, respectively); Olympus IX70 inverted epifluorescence microscope; Olympus Xenon lamp; MicroMax 1300YHS CCD camera and Sutter Lambda 10-2 filter changers controlled by Metafluor 4.5r2 software (Universal Imaging); ECFP-EYFP FRET filter set (Omega Optical); 440AF21 excitation filter (ECFP excitation), 455DRLP dichroic mirror, 480AF30 emission filter (ECFP emission), and 535AF26 emission filter (EYFP emission); neutral density (ND) filter set (Omega Optical); UApo 40xOil Iris/340 objective (Olympus); U-MNIBA bandpass mirror cube unit (Olympus).

III. PROCEDURES

A. Engineering Cameleon Constructs

The history of cameleon engineering is reflected in its nomenclature (Table I). Optimization of Ca^{2+} affinities, pH dependency, maturation time, and other parameters is by no means complete. However, we present construction of a general cameleon designed in our laboratory, YC6.1, to serve as a reference point for future work (Truong *et al*., 2001). Molecular biology techniques for manipulating recombinant DNA are not given as they can be obtained from common reference books.

In these constructs, ECFP and EYFP function as a donor–acceptor pair for nonradiative, intramolecular FRET. During FRET, excitation of the donor (cyan) leads to emission from the acceptor (yellow), provided that the molecules are close enough (within 80 Å) and in a parallel orientation. In this way, on binding Ca^{2+} the CaM wraps around its adjacent CKKp target peptide and ECFP and EYFP are brought closer to each other and FRET increases (Fig. 1).

TABLE I Properties of Commonly Used Cameleon Indicators

Name	pK_a	[Ca^{2+}] range (μM)	Comments	Reference
Cameleon-1	6.9	0.1–10	BFP/GFP hybrid with CaM-M13 tandem	Miyawaki *et al*. (1997)
YC2	6.9	0.1–10	Use of ECFP/EYFP for donor/acceptor	Miyawaki *et al*. (1997)
YC2.1	6.1	0.1–10	V68L/Q69K for increased pH resistance	Miyawaki *et al*. (1999)
YC2.12	6.0	0.1–10	"Venus" quick-maturation derivative	Nagai *et al*. (2002)
YC3	6.9	0.5–1000	E104Q low-affinity indicator	Miyawaki *et al*. (1997)
YC3.3	5.7	0.5–1000	Q69M "citrine" for added pH resistance	Griesbeck *et al*. (2001)
YC4	6.9	10–1000	E31Q low-affinity indicator	Miyawaki *et al*. (1997)
YC6.1	6.1	0.1–1	Internal CKKp CaM recognition peptide	Truong *et al*. (2001)
SapRC2	5.5	0.2–0.4	Sapphire/DsRed cameleon	Mizuno *et al*. (2001)

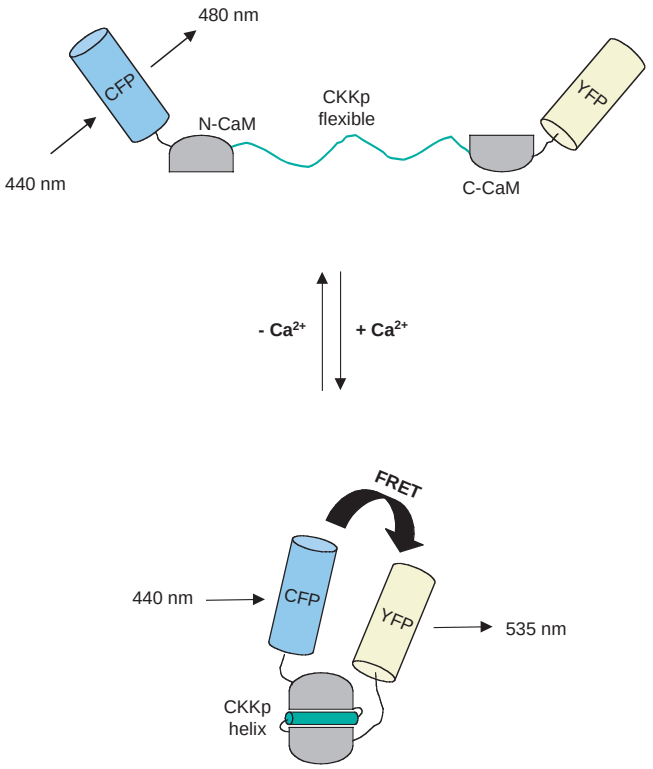

FIGURE 1 Schematic depiction of YC6.1 FRET in response to [Ca^{2+}]. See text for details.

1. A successful construction of GFP-fused protein indicators is facilitated greatly by careful inspection of available three-dimensional structure information of the protein or protein domain used for sensing functions. Typically, such structural analysis can be done using SwissPDBviewer (Windows) and MODELLER (Unix), which allow the measurement of atomic distances and the molecular modeling of fusion proteins, respectively. This was also the case for designing YC6.1. We found that by virtue of the hairpin-like complex structure of CKKp, the peptide can be inserted into the domain linker region (residues 78–81) of CaM.

2. Insert a CaM-binding peptide derived from CaM-dependent protein kinase kinase (CKKp; residues 438–463) between the terminal EF hand Ca^{2+}-binding domains (N-CaM and C-CaM) within the CaM linker domain (between CaM residues 79 and 80) and connect via two Gly-Gly linkers.

3. Add ECFP- and EYFP-encoding open reading frames to termini of the (N-CaM)-GG-CKKp-GG-(C-CaM) module by recombinant DNA methods. Expression vectors for many GFP family members are available through Clontech. Cameleon constructs can benefit from truncation of the last 11 C-terminal amino acids of ECFP (the minimal region to form GFP) to reduce the relative tumbling of the fluorophores. Additionally, linkers introduced between CaM domains and the target peptide can be optimized for complex formation.

4. Sequence construct to ensure polymerase chain reaction errors are not present. Note that oligonucleotides designed to the 5′ or 3′ end of ECFP open reading frames will also recognize the counterpart sequences in EYFP due to high sequence identity.

5. Subclone this cameleon domain into either pRSETB plasmid, for prokaryotic protein expression sufficient for biochemical and biophysical characterization, or pcDNA3.1 for mammalian expression and *in vivo* Ca^{2+}-imaging experiments. If optimal expression is not crucial, we also found that the pTriEx3 (Novagen) vector is convenient for expression in both prokaryotic and eukaryotic systems.

6. In addition to this cytoplasmic version of cameleon YC6.1, nucleus- and endoplasmic reticulum-targeted versions (YC6.1nu and YC6.2er, respectively) can be constructed by the addition of appropriate signal sequences to termini.

B. Overexpression and Purification of Cameleons

1. From a single colony of newly transformed *E. coli* strain BL21(DE3), grow liquid cultures at 37°C in LB medium containing 100 µg/ml ampicillin.
2. At OD_{600}, induce cultures with 0.5 m*M* IPTG at 15°C overnight.
3. Harvest cells by centrifugation at 6500 rpm for 20 min at 4°C.
4. Resuspend cell pellets in 1/20 culture volume of lysis buffer [50 m*M* HEPES (pH 7.4), 10% glycerol, 100 m*M* KCl, 1 m*M* $CaCl_2$, and 1 m*M* phenylmethyl sulfonyl fluoride (PMSF)], sonicate, and centrifuge at 15,000 rpm for 30 min to remove debris.
5. Incubate the supernatant with nickel chelate agarose for 1 h at 4°C and wash with of 50 m*M* HEPES (pH 7.4), 100 m*M* KCl, and 5 m*M* imidazole.
6. Elute YC6.1 with 300 m*M* imidazole in the aforementioned buffer. Proteolytic cleavage to remove the $(His)_6$ tag is not necessary as it does not interfere with YC6.1 fluorescent properties.
7. *Optional*: The eluant can be then purified further on a Superdex 75 HR 10/30 FPLC column using 20 m*M* HEPES, pH 7.5, 150 m*M* KCl, 5% glycerol, 5 m*M* dithiothreitol, and 1 m*M* PMSF.
8. Use the fraction that has the highest FRET ratio for fluorescence experiments.
9. Dialyze the sample against 2 liter of 50 m*M* HEPES (pH 7.4), 100 m*M* KCl at 4°C.

10. *Optional*: Glycerol can be added to the sample at a final concentration of 20%, and aliquot, flash freeze in liquid N_2, and store the YC6.1 at –70°C.

If necessary, it is possible to perform the characterization using a mammalian cell lysate. For harvesting, cells should be transfected in several 100-mm-diameter culture dishes, washed thoroughly to remove traces of phenol red and serum, and lysed in a hypotonic lysis buffer [50 m*M* HEPES (pH 7.4) 100 m*M* KCl, 5 m*M* $MgCl_2$, and 0.5% Triton X-100]. Following removal of cellular debris by centrifugation, dialyze the supernatant in 2 liter of buffer [50 m*M* HEPES (pH 7.4) and 100 m*M* KCl]. Finally, the sample can be used for characterization as described.

C. *In Vitro* Cameleon Fluorescence Spectroscopy

1. Record fluorescence spectra on a Shimadzu spectrofluorometer RF5301 using a 10-mm path-length quartz cuvette at room temperature.
2. Dilute cameleon chimeric proteins in 50 m*M* HEPES (pH 7.4), 100 m*M* KCl, and 20 μ*M* EGTA to a final concentration of 60 nM. Although many dilution factors are acceptable, intermolecular ECFP-EYFP FRET will occur at higher concentrations, thereby inflating the emission signal falsely.
3. Excitate at 433 nm and monitor the fluorescence emission between 450 and 570 nm with excitation and emission slit widths of 5 nm (Table II).
4. Record the fluorescence emission spectra of buffer (background) and cameleon protein solutions.
5. Subtract the background spectrum for buffer alone from the cameleon sample to find spectra of the cameleon in the absence of Ca^{2+}.
6. Determine the fluorescence emission ratio (R) by dividing the integration of fluorescence intensities of the FRET acceptor (for EYFP, between 520 and 536 nm) by that of the FRET donor (for ECP, between 470 and 485 nm).

TABLE II Fluorescent Properties of Fluorescent Protein Pairs Used for FRET Studies

Donor	Acceptor	Donor excitation wavelength (nm)	Donor emission wavelength (nm)	Acceptor emission wavelength (nm)
EBFP	EGFP	370	440	510
ECFP	EYFP	440	480	535
EYFP	mRFP1	510	535	607
Sapphire	DsRed	400	510	580

7. Determine R_{min} from this spectrum. A key parameter for a Ca^{2+} indicator is its dynamic range in response to $[Ca^{2+}]$. The dynamic range of a cameleon is defined as the division of the maximum ratio, R_{max}, by the minimum ratio, R_{min}.
8. In the presence of 1 m*M* $CaCl_2$, repeat to find spectra of the cameleon in the presence of saturating amounts of Ca^{2+}. Determine R_{max} from this spectrum.

The Ca^{2+}-binding curve is used to assess the effective range of $[Ca^{2+}]$ measurement. Ca^{2+}/EDTA and Ca^{2+}/EGTA buffers are used as standards because even trace Ca^{2+} contaminants can significantly distort $[Ca^{2+}]_{free}$ values at low $[Ca^{2+}]$ (Bers *et al*., 1994; Miyawaki *et al*., 1997).

1. Prepare EGTA buffer [100 m*M* KCl, 50 m*M* HEPES (pH 7.4), 10 m*M* EGTA] and $CaC1_2$ buffer [100 m*M* KCl, 50 m*M* HEPES (pH 7.4), 10 m*M* EGTA, 10 m*M* $CaCl_2$]. pH should be held constant.
2. Use a 1-ml cuvette and dilute the sample in the EGTA buffer. Record the fluorescence emission spectrum from 450 to 570 nm at 433-nm excitation. Determine the emission ratio.
3. To obtain the Ca^{2+}-binding curve, add successive fractions of the $CaC1_2$ solution to the sample and determine the emission ratio. Given that the experiment is performed in 20°C with these EGTA and $CaCl_2$ buffers, the free calcium can be calculated by solving the quadratic equation: $[Ca^{2+}]_{free}^2 + (10{,}000{,}060.5 - [Ca^{2+}]_{total}) * [Ca^{2+}]_{free} - 60.5 * [Ca^{2+}]_{total} = 0$.
4. To produce the Ca^{2+}-binding curve, plot the $[Ca^{2+}]_{free}$ versus emission ratio change (percentage of maximum). Initial cameleons show biphasic Ca^{2+} dependency, whereas YC6.1 has a monophasic response.
5. Extract the apparent dissociation constant (K'_d) and Hill coefficient (n) from the fitted curves.
6. The emission ratio can then be transformed to $[Ca^{2+}]$ according to

$$[Ca^{2+}] = K'_d[(R - R_{min})/(R_{max} - R)]^{1/n}$$

D. Live Cell Cameleon Fluorescence Imaging

This section describes a Ca^{2+}-imaging experiment using HeLa cells; however, with minor modifications the method can be applied to other cellular and physiological contexts.

1. Plate HeLa cells on 35-mm-diameter glass-bottom dishes with DMEM–10% FBS media.
2. Incubate the cells at 37°C (5% CO_2) until cells are 50–80% confluent.
3. Transfect cells with the mammalian expression plasmid containing your cameleon using Lipofecta-

mine and PLUS reagents (Invitrogen) according to the manufacturer's instructions.

4. Remove the transfection mixture after 5–18 h and replace with fresh 1.5 ml of DMEM–10% FBS media.

5. Incubate the cells at 37°C (5% CO_2) for 24 h. The cells are ready to perform the Ca^{2+}-imaging experiment.

6. All data acquisition should be performed in a dark room to reduce background light.

7. Wash with 1 ml of HBSS (+$CaCl_2$) and add 1 ml of fresh HBSS (+$CaCl_2$).

8. Put the cells on the stage of the microscope. Cells are viable and healthy for at least 60 minutes at ambient conditions. A CO_2 box and temperature controller are required for long-term/extended time course experiments.

9. The MetaFluor software controls the shutters, filter exchangers, and camera during data acquisition.

10. Screen for EYFP fluorescence (which is brighter and distinguished more easily than ECFP fluorescence) using the eyepiece to find transfected cells expressing the cameleon construct. Turn the filter turret to the U-WNIBA band-pass mirror cube and use ND filter in the range of 0.1–10% to reduce photobleaching depending on the intensity of fluorescence emission (Table III).

11. Using the 40× oil objective, center the microscope viewing area on a cell that has a healthy morphology and displays a strong cytosolic fluorescence.

12. Acquire single images on the computer screen using MetaFluor while adjusting the focus until you have the sharpest screen image. Focus through the eyepiece and the CCD usually vary slightly.

13. Turn the filter turret to the cube with the 455DRLP dichroic mirror. This allows visible light shorter and longer than ~455 nm to be reflected as excitation to the sample and collected as emission from the sample, respectively. Consult spectra from Omega Optical for relatively wavelength transmission efficiencies.

14. To monitor the peak emissions of ECFP and EYFP as a result of ECFP peak excitation over time, set the data acquisition conditions as follows: time interval to every 10 s and exposure time to 200 ms for ECFP and EYFP. Longer exposures improve resolution at the expense of bleaching the fluorescent signal. MetaFluor will display the emission ratio over time.

15. Draw a region of interest on the field of view of the CCD. Usually, this region will outline the whole cell, but one can specify only a portion of a cell if desired (e.g., the nucleus). It is important that the stage or the cell does not move during the observation period as the region initially drawn may drift from the region of interest. Additionally, the intensity in the region (the signal) should be at least five times the intensity of the background.

16. The emission intensities of both ECFP and EYFP will decrease over the course of the experiment due to some unavoidable photobleaching; however, the effect on the emission ratio should be negligible. To reduce photobleaching, decrease exposure time and excitation light intensity. Also, binning can sum the signal from multiple pixels on the CCD camera so that less light is required while keeping a good signal-to-noise ratio.

17. MetaFluor will record the fluorescence emission intensities of the ECFP and EYFP, together with their emission ratios in the regions over time.

18. When the emission ratio reaches a steady state, add 50 µl of 2 m*M* histamine to the culture dish for a final concentration of 100 µ*M*. Be careful not to move the culture dish in this process. The histamine binds to cell receptors on the plasma membrane that set off a signaling cascade, resulting in the release of Ca^{2+} from the endoplasmic reticulum through the inositol-1,4,5-triphosphate receptor. This should cause a conformational change in the cameleon that can be observed by

TABLE III Recommended Optical Components[a]

	FRET system			
	BFP/GFP	**ECFP/EYFP**	**ECFP/EYFP/RFP**	**Sap/DsRed**
Excitation filter	365WB50	440AF21	440DF21 (ECFP) 510DF23 (EYFP)	400DF15
Dichroic mirror	400DCLP	455DRLP	450-520-590TBDR	455DRLP
Emission filter, donor	450DF65	480AF30	480AF30 (ECFP) 535AF26 (EYFP)	480DF30
Emission filter, acceptor	535AF45	535AF26	535AF26 (EYFP) 600ALP (RFP)	535DF25

[a] The components are from Omega Optical but can be substituted with several equivalent products from other companies.

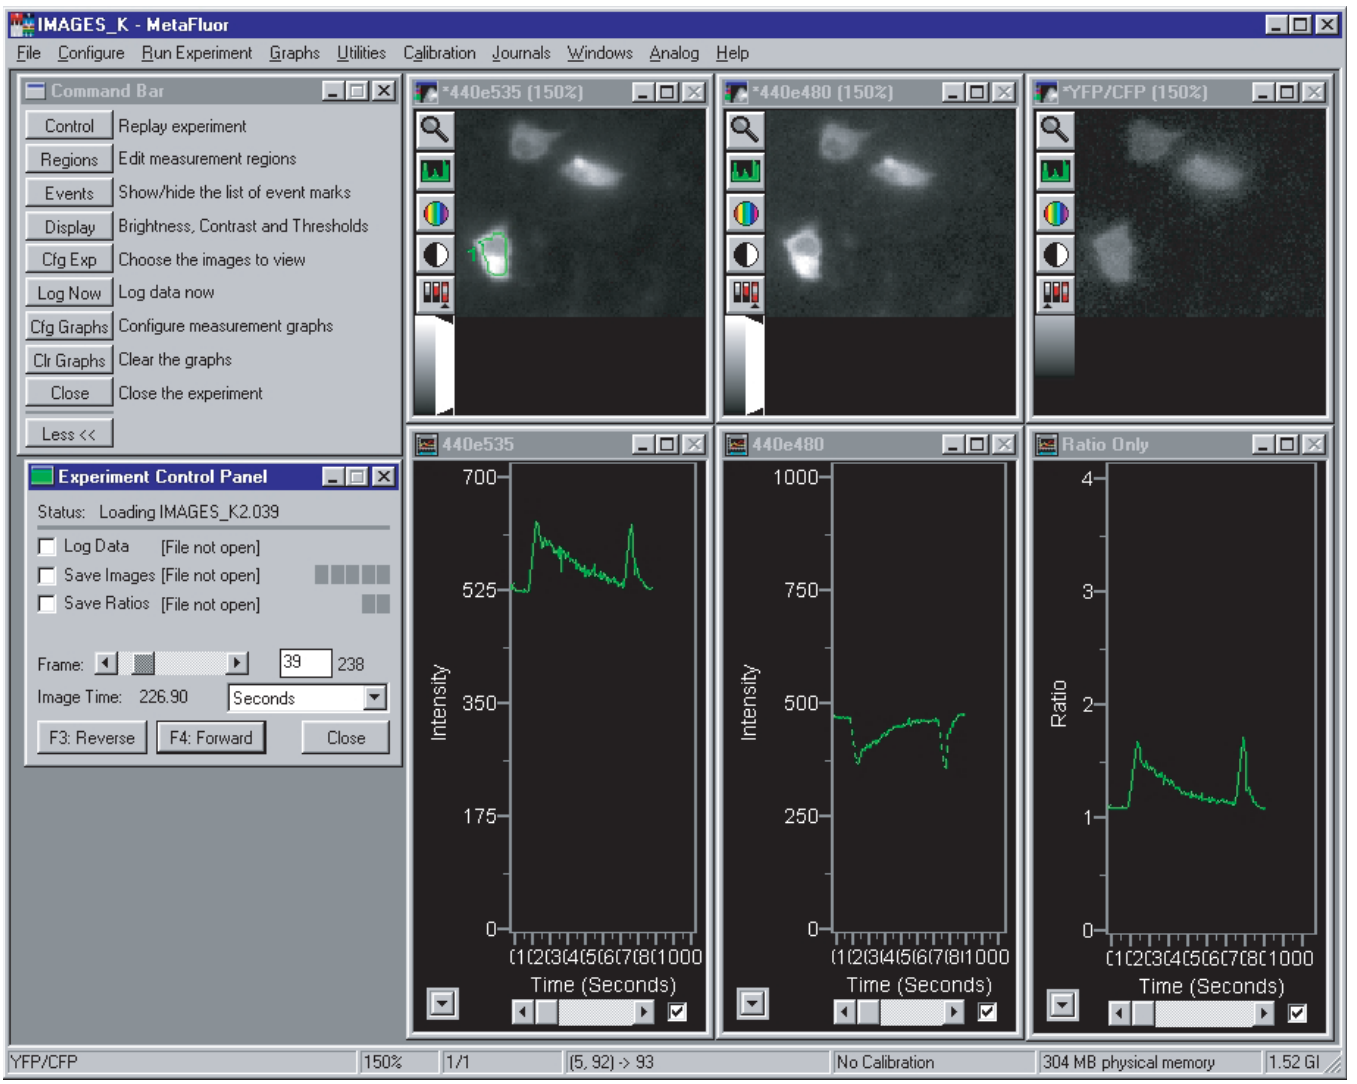

FIGURE 2 Example of Ca^{2+} imaging experiment using MetaFluor software. The region of observation is highlighted green in the 440e535 panel. The 440e535 panel and graph plot the change in EYFP fluorescence as a result of ECFP excitation; the 440e480 panel and graph plot the change in ECFP fluorescence as a result of ECFP excitation; the EYFP/ECFP panel and graph are the ratio of 440e535 and 440e480 panels and graphs. In this experiment, the graphs display a sharp rise in $[Ca^{2+}]_c$ from the initial stimulation with histamine followed by a slow decline in $[Ca^{2+}]_c$ to baseline levels. The second stimulation with histamine causes a significantly more rapid return to baseline levels.

a rise in emission intensity of EYFP and a decline in ECFP intensity. Therefore, the emission ratio should increase. The EYFP/ECFP emission ratio should return to steady-state levels when the effect of the histamine wanes. Figure 2 shows a representative example of MetaFluor software as it is collecting data.

19. In order to correlate the emission ratio to $[Ca^{2+}]_{cytosolic}$, it is necessary to determine R_{min} and R_{max} so that emission ratios can be mapped to the Ca^{2+}-binding curve. Add 50 µl of 20 µ*M* ionomycin for a final concentration of 1 µ*M*. Ionomycin open pores on the plasma membrane to allow permeability to Ca^{2+} ions. Because the medium is saturated with $CaCl_2$, the ratio will rise to R_{max}. To determine R_{min}, add 50 µl of 100 m*M* EGTA and 600 µ*M* BAPTA-AM for a final concentration of 5 m*M* and 30 µ*M*, respectively. The emission ratio should drop to R_{min}.

IV. OTHER APPROACHES

Several other Ca^{2+} probes are also being developed, including the so-called "camgaroos" and "pericams."

Camgaroos take an alternative approach to designing fluorescent Ca^{2+} sensors based on CaM and GFP family members (Baird *et al*., 1999). While ECFP and EYFP in cameleons are appended to the amino and carboxyl termini of CaM and Ca^{2+} binding is detected by FRET, camgaroo indicator proteins take advantage of the robust structure and profound fluorescence sensitivity of GFP to altered pK_a values and chromophore orientation. Circular permutations and insertion of whole CaM in place of Tyr-145 within EEYFP thereby render this indicator responsive to Ca^{2+} binding. As a result, both excitation and emission spectra of camgaroo simply increase in amplitude by up to seven-fold upon saturation with Ca^{2+}, without any significant shift in peak wavelength. This Ca^{2+}-dependent fluorescence enhancement is substantially larger than other published genetically encoded fluorescent indicators. However, camgaroos are limited by pH sensitivity inherent in the current mechanism of modulating fluorescence via changes in pK_a of the chromophore and have to date only been preliminarily subjected to systematic mutational improvement.

Pericams, in which EYFP is circularly fused to CaM and the M13 myosin light chain kinase peptide, improve approximately 10-fold upon the low affinity of camgaroo for Ca^{2+} ($K_d = 7\,\mu M$) and are thereby better capable of sensing low physiological changes in intracellular [Ca^{2+}] (Nagai *et al*., 2001). Taken together, these strategies offer alternatives complementary to cameleons for creating genetically encoded, physiological Ca^{2+} indicators.

V. OTHER CONSIDERATIONS AND PITFALLS

A. Ca^{2+} Ion Sensitivity

Although cameleon probes vary in their Ca^{2+} affinities, most are suitable for monitoring [Ca^{2+}] between 0.5 and 100 μM. This poses a problem for examining the relatively high [Ca^{2+}] found in the endoplasmic reticulum of resting cells (approximately 500 μM). However, CaM mutagenesis studies have shown that substitution of a conserved glutamic acid residue at the 12th position of each Ca^{2+}-binding loop abolishes its Ca^{2+}-binding ability (Zhu *et al*., 1998). The effect of combinations of these mutations on cameleon Ca^{2+} range is currently being examined further in our laboratory.

B. Maturation

GFP variants have been developed in which chromophore oxidative maturation (and thereby become fluorescent) occurs more quickly and efficiently at 37°C. It would be advantageous to utilize efficiently folding versions, such as the recently developed "Venus" form of EYFP (F46L/F64L/M153T/V163A/S175G). These EYFP mutations confer an eight-fold increase of fluorescence intensity when expressed in mammalian cells (Nagai *et al*., 2002; Rekas *et al*., 2002). This will enable assay of cells 24 h postrecovery transfection, if so desired.

C. pH Sensitivity

The hydrogen bond network within the β barrel of the chromophore is sensitive to external pH. Hence, in order to analyze Ca^{2+} levels in acidic organelles (such as secretory vesicles), the FRET donor/acceptor pair must be engineered so that it is pH resistant. Two mutations within EEYFP (V68L and Q69K) have been shown to decrease its pK_a to 6.1 (Miyawaki *et al*., 1999). The pH sensitivity was improved further via a Q69M or "citrine" mutation (pK_a 5.7; Griesbeck *et al*., 2001). Another approach would be to change the donor/acceptor pair to the pH-insensitive sapphire-red cameleon probe (SapRC2). Although this construct has a tendency to aggregate and form homotetramers, the recent engineering of a monomeric mRFP1 offers an interesting alternative (Campbell *et al*., 2002).

D. Oligomerization

GFP family proteins have been observed to form obligate dimers and may thereby generate false-positive FRET signals. However, this aggregation problem need not preclude their use in biological systems, even when present in higher local concentrations. Nonoligomerizing mutants of EYFP have been suggested from its crystal structure (Wachter *et al*., 1998; Rekas *et al*., 2002), but these have yet to be validated experimentally. Alternatively, using a monomeric version of the evolutionary distinct RFP (mRFP1) in tandem with a EYFP donor would also serve to eliminate this issue (Campbell *et al*., 2002).

E. Influences on Biological Systems

It is very important to consider potential competition of the FRET indicator for native CaM or CaM-dependent enzymes. Previous comparisons of the effect of recombinant CaM and cameleon chimeras on prototypical CaM-dependent enzymes have revealed that the primary effect of cameleons is on buffering [Ca^{2+}] and not interfering with CaM-mediated signaling (Miyawaki *et al*., 1999). This could be due to the CaM component of the cameleon being inhibited by

the adjoining CKKp efficiently occupying its substrate-binding site. Also, as the YC6.1 CKKp is embedded within the cameleon polypeptide, it is not likely to interact with endogenous CaM proteins.

F. Interpretation of Live Cell FRET Data

There are two commonly used simple and practical approaches. The first, measurement of donor emission quenching and acceptor emission enhancement by using three filter sets and then mathematical processing to determine emission/FRET ratios, is described in Section III. The alternative approach is by detection of donor dequenching following acceptor bleaching. We find bleaching with a minimum of 200 ms, compared to 1 ms for control excitation, is sufficient.

G. Additional Ways to Do Ratio Imaging

FRET requires rapid intensity measurements at different wavelengths. Switching time (in the millisecond range) may be an important parameter for some applications. New imaging systems have become available in the marketplace, notably TILLvisION (T.I.L.L. Photonics) and AquaCosmos (Hamamatsu), which allow for excellent time resolution for fluorescence–intensity ratio imaging.

H. FRET Using Red Fluorescence Protein

For YC6.1 applications, the ECFP-EYFP FRET filter set is sufficient. However, if you are using RFP for FRET, the following dichoric mirrors and filters from Omega Optical (or equivalents) will be needed: 450-520-590TBDR for the dichoric mirror; 440DF21 for ECFP excitation; 510DF23 for EYFP excitation; 575DF26 for RFP excitation; 480AF30 for ECFP emission; 535AF26 for EYFP emission; and 600ALP for RFP emission. This filter set allows you to excite or acquire emission from ECFP, EYFP, and RFP individually, albeit with a tradeoff in efficiency.

I. Imaging Systems

Using a confocal microscope is the best way to increase spatial resolution for FRET experiments. Confocal YC6.1 measurements can be performed with single-photon excitation using the 458-nm line of an argon laser, but much more efficient excitation of ECFP is attained with the 442-nm line of a HeCd laser. Two-photon excitation microscopy, in addition to providing optical sections of a specimen as with confocal microscopy, offers certain advantages. Its applicability to cameleons has been demonstrated using video-rate scanning instrumentation (Fan *et al*., 1999). This latter imaging approach may not be readily available to most laboratories, however.

J. Preparation of Ca^{2+}/EGTA Buffers

The accuracy of the Ca^{2+}-binding curve depends on accurate preparation of the Ca^{2+}/EGTA and Ca^{2+}/HEEDTA systems below 10^{-5} M free Ca^{2+} and unbuffered Ca^{2+} above (Bers *et al*., 1994). The purity of EGTA, temperature, and pH are all practical issues.

Acknowledgments

We are grateful to Atsushi Miyawaki for his help in setting up a FRET microscope system in our laboratory, as well as for much advice on the use of GFP variants. This work was supported by grants from the Cancer Research Society Inc. and the Institute for Cancer Research of the Canadian Institutes of Health Research (CIHR). K.P.H. is a recipient of a NCIC Research Fellowship, K.T. holds a CIHR scholarship, and M.I. is a CIHR senior investigator.

Ratiometric Pericam

Atsushi Miyawaki

I. INTRODUCTION

Our understanding of the structure–photochemistry relationships of green fluorescent protein (GFP) (Tsien, 1998) has enabled the development of genetic calcium probes based on a circularly permuted GFP (cpGFP) in which the amino and carboxyl portions have been interchanged and reconnected by a short spacer between the original termini (Baird *et al*., 1999). The resulting new amino and carboxyl termini of the cpGFP have been fused to calmodulin and its target peptide M13, generating a chimeric protein named pericam (Nagai *et al*., 2001). This new protein was fluorescent, and its spectral properties changed reversibly with Ca^{2+} concentration, probably due to the interaction between calmodulin and M13, which alters the environment surrounding the chromophore. Three types of pericam have been obtained by mutating several amino acids adjacent to the chromophore. Of these, "flash pericam" becomes fluorescent with increasing Ca^{2+}, whereas "inverse pericam" dims. However, "ratiometric pericam" has an excitation wavelength that changes in a Ca^{2+}-dependent manner, thereby enabling dual-excitation ratiometric Ca^{2+} imaging. Ratiometric dyes permit quantitative Ca^{2+} measurements by minimizing the effects of several artifacts that are unrelated to changes in the concentration of free Ca^{2+} ($[Ca^{2+}]$), such as uneven loading or partitioning of dye within the cell or varying cell thickness. This article presents an outline of an imaging experiment using HeLa cells expressing ratiometric pericam to measure receptor-stimulated changes in intracellular $[Ca^{2+}]$ ($[Ca^{2+}]_i$) (Protocol 1).

In contrast to cameleons (Miyawaki *et al*., 1997), which are fluorescence resonance energy transfer-based Ca^{2+} indicators, pericams can be easily targeted into the mitochondria matrix using an upstream targeting sequence encoding subunit IV of cytochrome *c* oxidase. Ratiometric pericam has been used successfully to monitor changes in $[Ca^{2+}]$ in mitochondria ($[Ca^{2+}]_m$) (Nagai *et al*., 2001). In most dual-excitation imaging experiments, the excitation wavelength is alternated using a rotating wheel containing two bandpass filters. However, it is also possible to use a high-speed grating monochromator to increase the rate at which the ratio measurement is conducted to approximately 10 Hz. The latter instrumentation enables the measurement in spontaneously contracting cardiac myocytes of beat-to-beat changes in $[Ca^{2+}]_m$, contributing to the demonstration that $[Ca^{2+}]_m$ oscillates synchronously with cytosolic $[Ca^{2+}]$ during beating (Robert *et al*., 2001). This article discusses factors to be considered when using such a monochromator with ratiometric pericam.

Although the aforementioned measurements are typically performed using conventional microscopy, the monitoring of changes in $[Ca^{2+}]$ is often severely limited by the poor spatiotemporal resolution of such wide-field techniques. To obtain a more reliable representation of changes in subcellular $[Ca^{2+}]$, it is necessary to increase the *z*-axis resolution and the speed of production and collection of the ratios of the excitation peaks. This article provides a detailed protocol describing a modified laser-scanning confocal microscopic (LSCM) system for ratiometric pericam (Protocol 2). In our experiment (Shimozono *et al*., 2002), fast exchange between two laser beams was achieved

using acousto-optic tunable filters (AOTFs). Samples were scanned on each line sequentially by a violet laser diode (408 nm) and a diode-pumped solid-state laser (488 nm). In this way, the ratios of the excitation peaks can be obtained at a frequency of up to 200 Hz.

II. MATERIALS

HeLa cells (ATCC # CCL-2.2)
Culture medium: Add fetal bovine serum (Gibco BRL, Life Technologies) to Dulbecco's modified Eagle's medium (DMEM) (Sigma Aldrich) to a final concentration of 10% (v/v)
Hank's balanced salt solution (HBSS): Dissolve $CaCl_2$ (0.14 g), KCl (0.40 g), KH_2PO_4 (0.06 g), $MgCl_2{\cdot}6H_2O$ (0.10 g), $MgSO_2{\cdot}7H_2O$ (0.10 g), NaCl (8.00 g), $NaHCO_3$ (0.35 g), Na_2HPO_4 (0.048 g), and D-glucose (1.00 g) in 800 ml of distilled H_2O, adjust the pH to 7.4, and then adjust the volume to 1 liter.
Histamine solution: Dissolve 1.841 mg of histamine dihydrochloride (Sigma Aldrich, H7125) in 1 ml of HBSS to make a 10 m*M* stock solution.

III. INSTRUMENTATION

A. Conventional Microscopy for Time-Lapse $[Ca^{2+}]_i$ Imaging

Dual-excitation imaging with ratiometric pericam uses two excitation filters (485DF15 and 400DF15), which are alternated by a filter changer (Lambda 10-2, Sutter Instruments, Novato, CA), a 505DRLP-XR dichroic mirror, and a 535AF45 emission filter. The excitation and emission spectra of ratiometric pericam

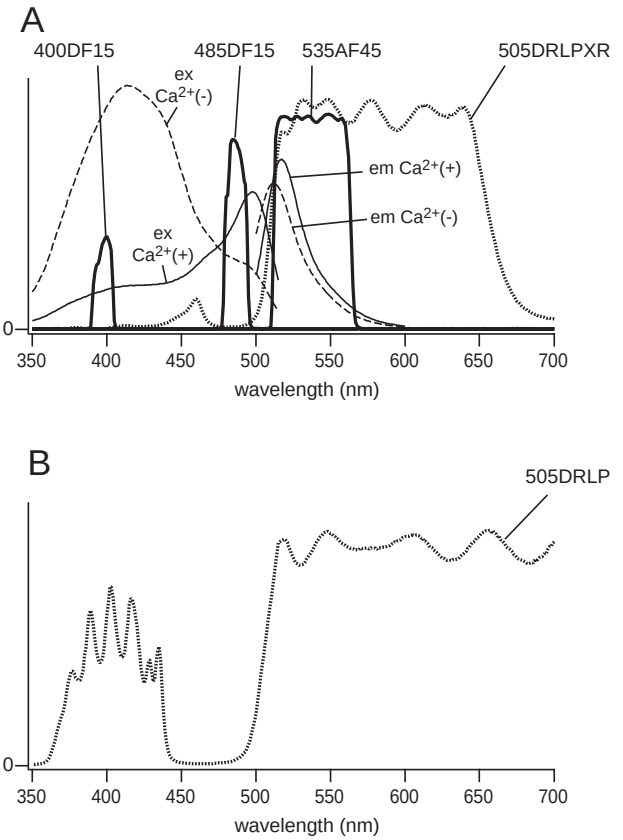

FIGURE 1 (A) Fluorescence excitation and emission spectra of ratiometric pericam in the presence (solid line) and absence (broken line) of Ca^{2+}. Transmittance spectra for filters (400DF15, 485DF15, and 535AF45) and the dichroic mirror (505DRLPXR) are shown with solid and dotted lines, respectively. (B) The transmittance spectrum for a 505DRLP dichroic mirror.

in the presence and absence of Ca^{2+} with passbands of the emission filter and two excitation filters are shown in Fig. 1A. Also, the transmittance of the dichroic mirror (505DRLP-XR) is superimposed. The dichroic mirror has an eXtended Reflection region below 505 nm; it was designed originally for the measurement of Ca^{2+} (fura-2) and pH (BCECF). In this situation, the broad reflection of a dichroic mirror is imperative. A more common long-pass dichroic mirror (505DRLP) cannot be used; superimposition of its transmission spectrum (Fig. 1B) makes one notice a complex transmission band at short wavelengths, which prevents reflection of the 400-nm light. The author strongly recommends that researchers make graphs of spectra plotted as percentage transmittance for the interference filters (excitation filters, emission filters, and dichroic mirrors) that are actually used, together with excitation and emission spectra of the relevant fluorescent dyes. The transmittance curves for the filters (normal incidence) and dichroic mirrors (45°

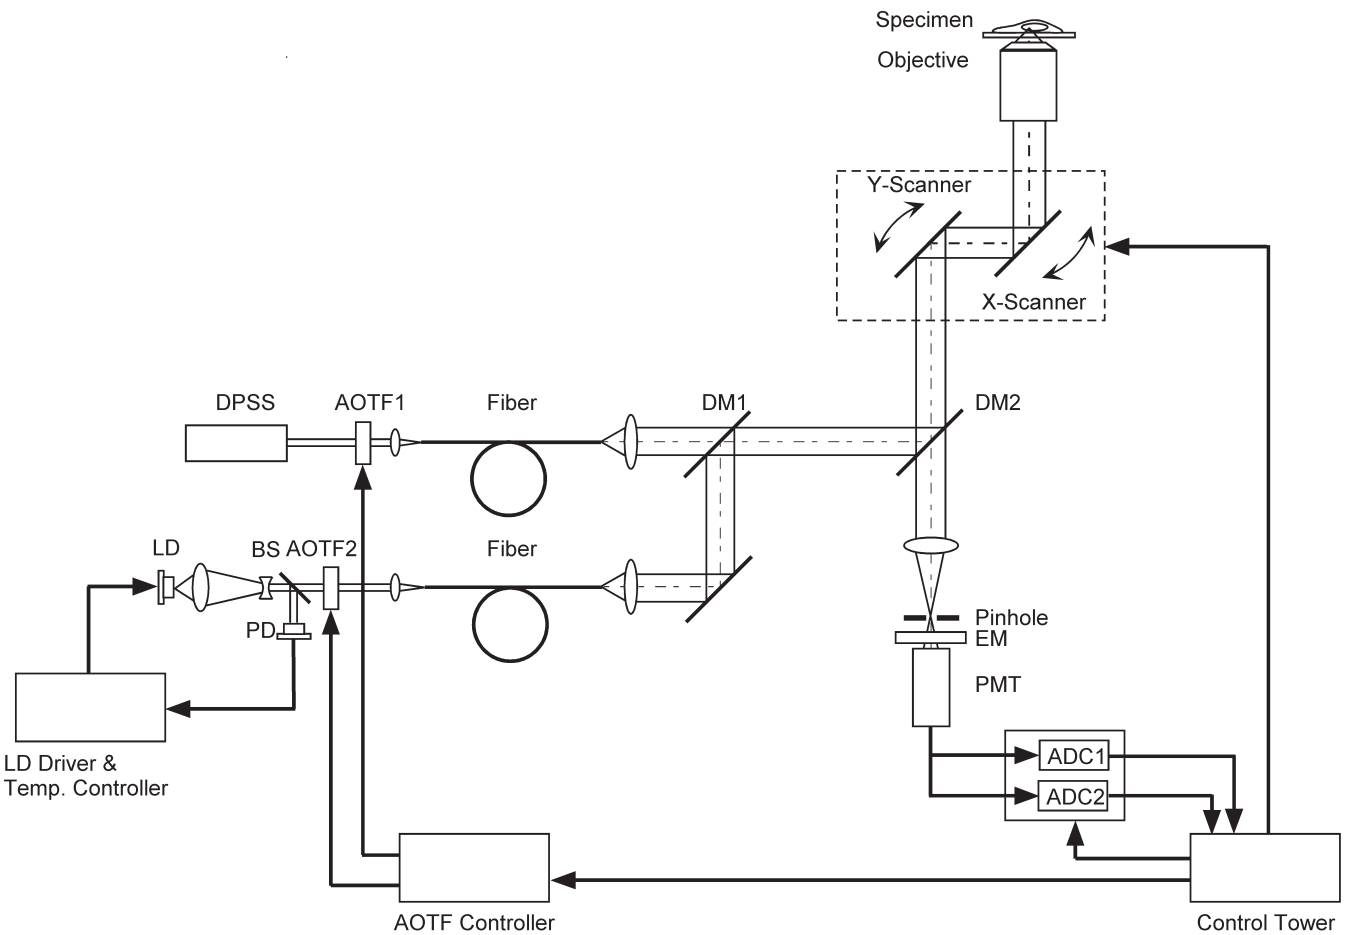

FIGURE 2 Schematic diagram of the laser-scanning confocal microscopy system for fast dual-excitation ratiometric imaging. DPSS, diode pumped solid-state laser; LD, laser diode; PD, photodiode; BS, beam splitter; DM, dichroic mirror; EM, emission filter; PMT, photomultiplier tube; ADC, analog-to-digital converter.

incidence) can be measured easily using a conventional spectrophotometer. This measurement also provides a chance for researchers to check the quality of their interference filters, which may deteriorate with time.

B. A Modified LSCM System for Ratiometric Pericam

Although the following procedure assumes familiarity with LSCM, and with the Olympus LSCM in particular, the procedure can be adapted easily to other LSCM types. The microscope and lasers we use are described in Fig. 2. The beam from a diode-pumped solid-state laser (Sapphire 488-20, COHERENT) directly enters an AOTF (AOTF1; AOTF.8C, AA Opto-Electronic). The light is relayed through an optical fiber (FV5-FUR, Olympus) to a confocal microscope scan head and passes through a dichroic mirror (DM1; DM420SP, Olympus). A laser diode (NLHV3000E, NICHIA) is mounted on a heat sink with temperature control, which consists of an LD mount and heat sink [F125-4A (Suruga Seiki)], LD current driver [LDX-3525 (ILX Lightwave)], and LD temperature controller [LDT5525 (ILX Lightwave)]. The output of the laser diode is collimated (made parallel) using multiple lenses, and its power is stabilized by a feedback-regulated device. The beam is directed into another AOTF (AOTF2; AOTF.4C UV, AA Opto-Electronic). The diffracted light is sent through another fiber-optic line (FV5-FUR-UV, Olympus) to the scan head and is then reflected on DM1. The two AOTFs are controlled electronically, allowing the reciprocal choice of one of the two laser lines. The chosen laser beam is reflected on a second dichroic mirror (DM2; FV5-DM442, Olympus). The scan head is coupled to an inverted microscope (IX70, Olympus) through its right-side port. The objective lens used is a PlanApo 60× N.A.

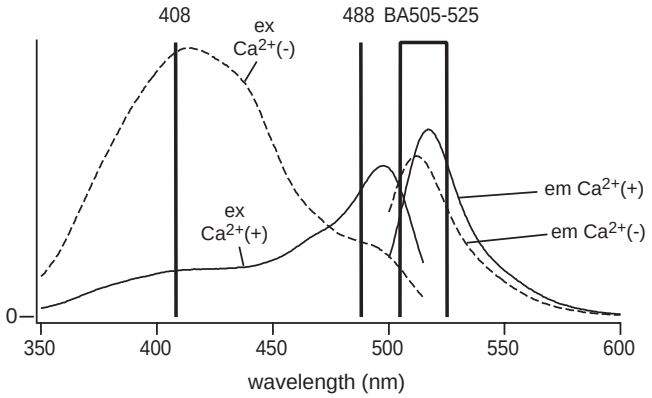

FIGURE 3 Fluorescence excitation and emission spectra of ratiometric pericam in the presence (solid line) and absence (broken line) of Ca^{2+}. The wavelengths of the two laser lines, 408 nm (laser diode) and 488 nm (diode-pumped solid state), are indicated by vertical lines. The wavelengths that pass through the emission filter BA505–525 are shown by a box. Modified with permission from T. Nagai, A. Sawano, E. S. Park, and A. Miyawaki, Proc. Natl. Acad. Sci. U.S.A. 98, 3197 (2001). Copyright (2001) National Academy of Sciences, U.S.A.

1.00 WLSM (Olympus). The fluorescent light is descanned, passed through DM2, a pinhole, and an emission filter (BA505-525 (Omega)), and detected by a photomultiplier. Fluorescence signals with excitation wavelengths of 408 and 488 nm are distributed into two channels during analog-to-digital conversion. The pair of galvanometer mirrors, the digitized detector output, and the AOTF controller are orchestrated. The excitation and emission spectra of ratiometric pericam in the presence and absence of Ca^{2+} , together with the passband of the emission filter (BA505-525) and the two laser lines, are shown in Fig. 3.

IV. PROCEDURES

Protocol 1

The procedure for time-lapse $[Ca^{2+}]_i$ imaging in HeLa cells is as follows.

1. Plate HeLa cells or cells of interest onto a 35-mm glass-bottom dish with culture medium.
2. Transfect the cells with 1 µg per dish of cDNA encoding ratiometric pericam mitochondria using Lipofectin according to the manufacturer's instructions.
3. Between 2 and 10 days after cDNA transfection, image HeLa cells on an inverted microscope (IX7) with a cooled CCD camera (MicroMax or Cool Snap HQ, Roper Scientific, Tucson, AZ). Expose cells to reagents in HBSS containing 1.26 m*M* $CaCl_2$. Image acquisition and processing are controlled by a personal computer connected to a camera and a filter wheel (Lambda 10-2, Sutter Instruments, San Rafael, CA) using the program MetaFluor (Universal Imaging, West Chester, PA). The excitation filter wheel in front of the xenon lamp (Lambda 10-2, Sutter Instruments, San Rafael, CA) is also under computer control. Excitation light from a 75-W xenon lamp is passed through a 400DF15 (400 ± 7.5) or 485DF15 (485 ± 7.5) excitation filter. The light is reflected onto the sample using a 505-nm long-pass (505DRLP-XR) dichroic mirror with an extended reflection. The emitted light is collected with a 40X (numerical aperture: 1.35) objective and passed through a 535 ± 22.5-nm band-pass filter (535AF45). Interference filters are from Omega Optical or Chroma Technologies (Brattleboro, VT).
4. Define several factors for image acquisition, including (i) excitation power, which depends on the type of light source and neutral density filter, (ii) numerical aperture of the objective, (iii) time of exposure to the light, (iv) image acquisition interval, and (v) binning. The last three factors should be considered in terms of whether temporal or spatial resolution is pursued.
5. Choose moderately bright cells. Select regions of interest so that pixel intensities are averaged spatially.
6. At the end of an experiment, convert fluorescence signals into values of $[Ca^{2+}]$. R_{max} and R_{min} can be obtained as follows. To saturate the intracellular indicator with Ca^{2+}, increase the extracellular $[Ca^{2+}]$ to 10–20 m*M* in the presence of 1–5 µ*M* ionomycin. Wait until the fluorescence intensity reaches a plateau. Then, to deplete the Ca^{2+} indicator, wash the cells with Ca^{2+}-free medium (1 µ*M* ionomycin, 1 m*M* EGTA, and 5 m*M* $MgCl_2$ in nominally Ca^{2+}-free HBSS). The *in situ* calibration for $[Ca^{2+}]$ uses the equation $[Ca^{2+}] = K'_d[(R - R_{min})/(R_{max} - R)]^{(1/n)}$, where K'_d is the apparent dissociation constant corresponding to the Ca^{2+} concentration at which R is midway between R_{max} and R_{min} and n is the Hill coefficient. The Ca^{2+} titration

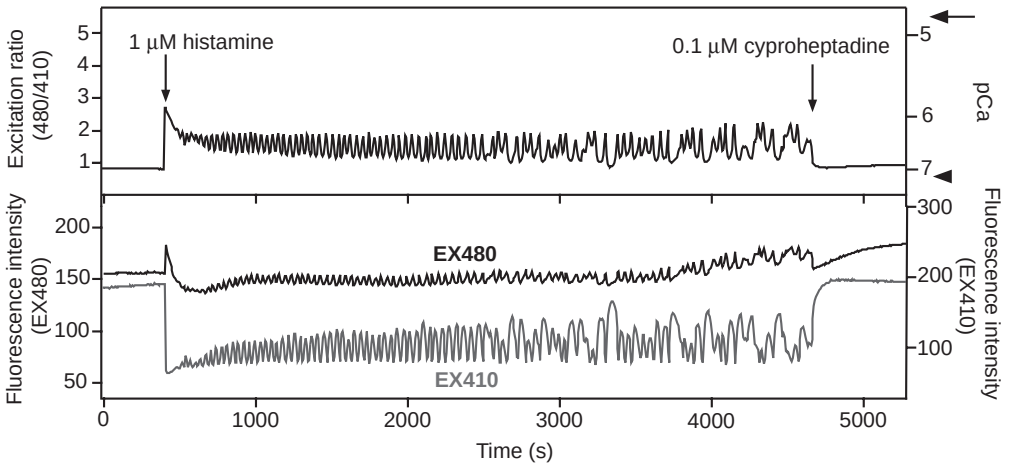

FIGURE 5 Typical $[Ca^{2+}]_i$ transients and oscillations induced by receptor stimulation in HeLa cells expressing ratiometric pericam. The sampling interval was 3–5 s. (Top) Excitation ratios of 480 and 410 nm. The right-hand ordinate indicates $[Ca^{2+}]_i$ in μM with R_{max} and R_{min} indicated by an arrow and arrowhead, respectively. (Bottom) Excitations of 480 nm (black line, left-hand scale) and 410 nm (gray line, right-hand scale). Modified with permission from T. Nagai, A. Sawano, E. S. Park, and A. Miyawaki, Proc. Natl. Acad. Sci. U.S.A. 98, 3197 (2001). Copyright (2001) National Academy of Sciences, U.S.A.

curve of ratiometric pericam can be fitted using a single K'_d of 1.7 μM and a single Hill coefficient of 1.1 (Fig. 4). A typical time course of $[Ca^{2+}]_i$ reported by ratiometric pericam is shown in Fig. 5.

Protocol 2

The following is a procedure for confocal imaging of $[Ca^{2+}]_m$ in HeLa cells using the modified LSCM system.

1. Plate HeLa cells or cells of interest onto a 35-mm glass-bottom dish with culture medium.
2. Transfect the cells with 1 μg per dish of cDNA encoding ratiometric pericam mitochondria using Lipofectin according to the manufacturer's instructions.
3. Incubate the cells in a humidified atmosphere at 37°C under 5% CO_2 for 1 to 3 days.
4. Replace the culture medium with HBSS.
5. Observe the cells on an inverted microscope (IX70, Olympus) for green fluorescence of the indicator (ratiometric pericam-mt) using a 490-nm excitation light generated using 490DF10.
6. Choose moderately bright cells in which the fluorescence is well distributed in the mitochondria.
7. Switch on the lasers, AOTF controller, scanning head, and the computer. The lasers need 30 min to warm up and stabilize.
8. Start the scanning process with only excitation from the 408-nm laser diode. Set the scan mode to "Normal (unidirectional)" and scan speed to "Fast." While looking at the acquired fluorescence images, adjust the laser intensity to the minimum level that allows easy identification of individual cells, adjust the sensitivity of the photomultiplier tube (PMT) for an optimal signal-to-noise ratio, and adjust the size of the pinhole for acceptable depth of the image. There is a trade-off between the scan speed and the pixel size: faster scanning speeds decrease resolution because fewer pixels of information are collected.
9. Adjust the intensity of the 488-nm laser by setting the microscope to "Normal (unidirectional)" scan mode and "Fast" scan speed. While looking at the acquired fluorescence images, adjust the laser intensity to a minimum level that allows easy identification of individual cells and adjust the sensitivity of the PMT for an optimal signal-to-noise ratio and the size of the pinhole for acceptable depth of the image. Establishing the microscope settings described in steps 8 and 9 is a process that must be iterated to produce adequate ratio images.
10. Start the control software for line-sequential dual-excitation ratio analysis. The "Normal" scan mode and "Fast" scan speed, with adequate pixel size, enable rapid exchange between the two lasers on a line every 5 to 20 ms.
11. Determine the desired scanning field (image size) and reduce the height of the image so that 5 to 10 frames can be obtained per second.
12. Start to acquire images every 100 to 200 ms for 1 to 5 min.
13. During image acquisition, add histamine solution to a final concentration of 10 μM for receptor stimulation.
14. Determine the image ratio by dividing the images acquired with excitation at 488 nm by those acquired at 408 nm.

(*Inset*) The crossing of the two curves for 490-nm light and 500SP on an expanded scale.

V. COMMENTS

A. pH and Photochromism as Practical Considerations

Ratiometric pericam is sensitive to changes in pH in both the presence and the absence of Ca^{2+} (Fig. 6). pH-related artifacts were not an issue in experiments that used HeLa cells because agonist-induced $[Ca^{2+}]_c$ mobilization did not induce any intracellular pH changes detectable by the pH indicator, BCECF (data not shown). However, ratiometric pericam expressed in dissociated hippocampal neurons was perturbed by acidification following depolarization or glutamate stimulation (data not shown).

Pericams are derived from yellow fluorescent protein (YFP). If YFP is excited too strongly, its fluorescence will be reduced. This apparent bleaching is actually photochromism because the fluorescence recovers to some extent spontaneously and can be restored further by UV illumination (Dickson *et al.*, 1997). Intense excitation of ratiometric pericam also causes photochromism, which results in a decrease in the 490/410-nm excitation ratio independent of Ca^{2+} change. The extent of photochromism is dependent on excitation power, numerical aperture of the objective, and exposure time. Therefore, it is necessary to optimize these factors for each cell sample in order to minimize photochromism while preserving a high signal-to-noise ratio. A good solution is to bin pixels at the cost of spatial resolution. The increased signal-to-noise ratio permits a decrease in intensity of the excitation light with a neutral-density filter and the observation of $[Ca^{2+}]_i$ oscillations without significant photochromism of the indicators.

B. Use of a High-Speed Grating Monochromator

Instead of a filter wheel containing 400DF15 and 485DF15 excitation filters, a fast wavelength exchanger based on a grating monochromator (U7773-XX and U7794-16, Hamamatsu Photonics) can be used with a fast-acquisition CCD camera (HiSCA, C6790-81, Hamamatsu Photonics). The spectrum of the excitation light when the wavelength was set at 410 or 490 nm is shown in Fig. 7. Because light acquired with the setting at 490 nm spills over into the observing optical path, it is preferable to eliminate the unwanted light by putting a short-pass filter like 500SP (Fig. 7, broken line) in front of the microscope.

C. Calcium Transients in Motile Mitochondria

When changes in $[Ca^{2+}]_m$ are monitored by alternating the excitation wavelength automatically with wide-field conventional microscopy, the rate of acquisition of the excitation ratio is about 10 Hz, which is identical to the frame rate. Despite this rapid rate of data collection, the $[Ca^{2+}]_m$ measurements are often affected adversely by the active motion of mitochondria, especially at warmer temperatures. Using our LSCM technique, we attempted to increase the speed of the alternation of excitation wavelengths so that it was faster than the movement of mitochondria. With this method, the frame rate was 5 Hz and the rate of ratio acquisition was 200 Hz. Although the frame rate did not allow us to fully follow the rapid movement

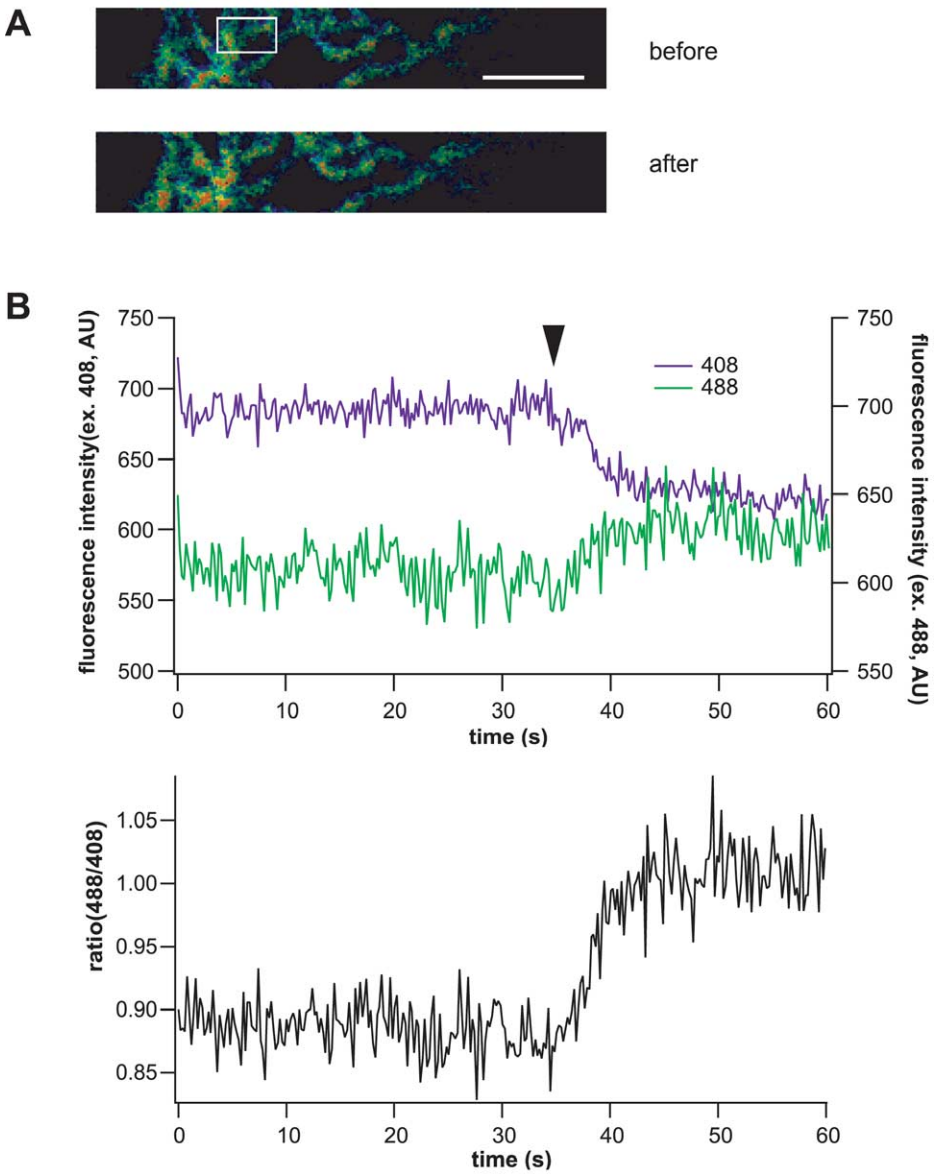

FIGURE 8 Confocal and dual-excitation imaging of $[Ca^{2+}]_m$ using ratiometric pericam mitochondia. (A) Ratio images before and after application of 10 μM histamine. Scale bar: 5 μm. (B) Time course of averaged fluorescence signals from the white box in A with excitation at 488 (green) and 408 nm (violet) (top) and their ratio (bottom). The arrowhead indicates the time when histamine was applied.

of mitochondria, the fast rate of ratio acquisition minimized the time lag between the two measurements used to calculate the ratiometric signal. We feel that this method of imaging $[Ca^{2+}]_m$ effectively corrects for mitochondrial movement in all three possible both laterally and into and out of the optical section. After the application of histamine, spots of $[Ca^{2+}]_m$ increase within a single mitochondrion were identifiable (Fig. 8A) and the global increase in $[Ca^{2+}]_m$ was found to occur relatively slowly (Fig. 8B).

Fluorescent Indicators for Imaging Protein Phosphorylation in Single Living Cells

Moritoshi Sato and Yoshio Umezawa

I. INTRODUCTION

To study protein phosphorylation, investigators have used electrophoresis, immunocytochemistry, and *in vitro* kinase assays. However, these methods do not provide enough information about spatial and temporal dynamics of protein phosphorylation in each living cell. To overcome this limitation, we have developed genetically encoded novel fluorescent indicators and visualized signal transduction based on protein phosphorylation in living cells (Sato *et al*., 2002) (Fig. 1). Within the fluorescent indicator, a substrate domain for a protein kinase of interest is fused with a phosphorylation recognition domain via a flexible linker sequence. The tandem fusion unit consisting of the substrate domain, linker sequence, and phosphorylation recognition domain is sandwiched with two different color fluorescent proteins, cyan fluorescent protein (CFP) and yellow fluorescent protein (YFP), which serve as the donor and acceptor fluorophores for fluorescence resonance energy transfer (FRET). As a result of phosphorylation of the substrate domain and subsequent binding of the phosphorylated substrate domain with the adjacent phosphorylation recognition domain, FRET is induced from CFP to YFP when CFP is excited at 440 ± 10 nm. Upon activation of phosphatases, the phosphorylated substrate domain is dephosphorylated and the FRET signal is decreased. This FRET change is represented by the change in the fluorescence emission ratio of CFP at 480 ± 15 nm and YFP at 535 ± 12.5 nm, both of which were monitored continuously by a dual-emission fluorescence microscope. We named this indicator "phocus" (a fluorescent indicator for protein phosphorylation that can be custom-made). Until now, by using suitable substrates and phosphorylation recognition domains, we have developed a large number of phocus variants for several key protein kinases, such as a receptor tyrosine kinase, insulin receptor, and a serine/threonine protein kinase, Akt/PKB (Table I). In addition, these phocus variants were further tailored to visualize subcellular local activity of the respective protein kinases in living cells (Table I). For example, the phocus variant for Akt protein kinase was tethered to the cytoplasmic surface of mitochondria or Golgi membranes by connecting each appropriate sequence/domain. This membrane tethering prevented the free diffusion of the indicator and avoided the resulting loss of spatial information as to phosphorylation by the activated Akt. We thus found that the activated Akt is not in the cytosol but is localized at subcellular membranes, including Golgi and mitochondria membranes, when the cells were stimulated.

II. MATERIALS AND INSTRUMENTATION

ECFP (Cat. No. 6900-1) and EYFP (Cat. No. 6006-1) expression vectors are from Clonthech. Ham's F-12 medium (Cat. No. 21700), fetal bovine serum (Cat. No. 10099-141), and LipofectAMINE 2000 (Cat. No. 11668-019) reagent are from Invitrogen. Other chemicals used are all of analytical reagent grade. Glass-bottom dishes are from Asahi Techno Glass (Cat. No. 3911-035).

Cells are observed with a 40× oil-immersion objective (Carl Zeiss) on a Axiovert 135 microscope (Carl Zeiss) with a cooled CCD camera MicroMAX (Roper Scientific Inc.) controlled by MetaFluor (Universal Imaging). An excitation filter (440AF21), a dichroic mirror (455DRLP), and emission filters for CFP (480AF30) and YFP (535AF26) are from Omega Optical.

III. PROCEDURES

Solutions

1. *Culture medium*: Add fetal bovine serum to Ham's F-12 medium to give a final concentration of 10%.
2. *Serum starvation medium*: Add bovine serum albumin to Ham's F-12 medium to give a final concentration of 0.2%.
3. *Hank's balanced salt solution (HBSS)*: Dissolve 0.35 g of $NaHCO_3$, 0.06 g of KH_2PO_4, 0.048 g of Na_2HPO_4, 0.14 g of $CaCl_2$, 0.40 g of KCl, 0.10 g of $MgCl_2{\cdot}6H_2O$, 0.10 g of $MgSO_4{\cdot}7H_2O$, 8.00 g of NaCl, and 1.00 g of D-glucose in 800 ml of Milli-Q water, adjust the pH to 7.4, and then adjust the volume to 1 liter.

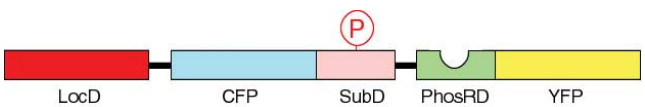

FIGURE 1 Schematic representation of the present fluorescence indicator for protein phosphorylation, which was named phocus. Upon phosphorylation of the substrate domain within phocus by the protein kinase, the adjacent phosphorylation recognition domain binds with the phosphorylated substrate domain, which changes the efficiency of FRET between the GFP mutants within phocus. By tethering a localization domain with phocus, the phocus can be localized in the specific intracellular locus of interest to visualize the local phosphorylation event there. LocD, localization domain; CFP, cyan fluorescent protein; SubD, substrate domain; PhosRD, phosphorylation recognition domain; YFP, yellow fluorescent protein; P in an open circle, the phosphorylated residue.

Steps

1. Plate CHO-IR cells that express human insulin receptor onto a glass-bottom dish with culture medium and incubate the cells at 37°C under 5% CO_2 for 1 day.
2. Transfect the cells with 0.8 μg of cDNA (phocus-2 or phocus-2pp) using Lippofecetamine 2000 reagent according to the manufacturer's instructions.
3. Incubate the cells at 37°C under 5% CO_2 for 1 to 2 days.
4. Replace the culture medium with serum starvation medium and incubate the cells at 37°C under 5% CO_2 for 2 to 4 h.
5. Replace the serum starvation medium with HBSS.
6. Set the glass-bottom dish onto the 40× oil immersion objective equipped on the fluorescence microscope.
7. Observe the cells with a 440-nm excitation filter (440AF21), 455-nm dichroic mirror (455DRLP), and 535-nm emission filter (535AF26).
8. By browsing the cells on the dish, choose moderately bright cells in which the fluorescence is well distributed in the cytosol.
9. Determine the desired observation field in which only the cells of interest are covered.
10. Select several regions of interest within the cells to examine time courses of CFP/YFP emission ratio during the following image acquisition.
11. Start to acquire images every 5 to 10 s for 10 to 30 min with the 440-nm excitation filter (CFP), 455-nm dichroic mirror, 480-nm emission filter (CFP), and 535-nm emission filter (YFP).

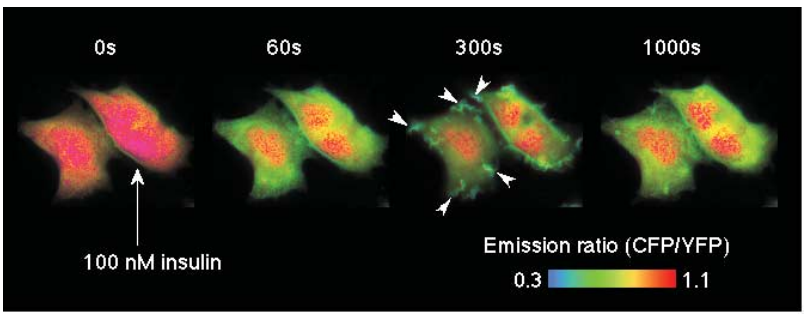

FIGURE 2 Fluorescence imaging with phocus-2pp upon insulin stimulation. Pseudocolor images of the CFP/YFP emission ratio are shown before (time 0 s) and 60, 300, and 1000 s after the addition of 100 n*M* insulin at 25°C, obtained from CHO-IR cells expressing phocus-2pp. Insulin-induced accumulation of phocus-2pp at the membrane ruffles is indicated by white arrows in the image at 300 s.

12. During image acquisition, add insulin to give a final concentration of 100 n*M*.
13. After finishing all the experiments, wipe the residual immersion oil out of the objective.

IV. EXAMPLES

Substrates for protein kinases and phosphatases often exhibit each unique localization, including mitochondria, Golgi, nucleus, and plasma membrane in living cells, which is thought to be critical for specific signal transduction in the respective intracellular loci (Hunter, 2000). Thus, we further tailored our phocuses to analyze the phosphorylation events in such particular locations in single living cells. Here we exemplify phocus for insulin receptor and that for Akt/PKB; the latter was named Aktus.

A. Phocus for Imaging Phosphorylation by Insulin Receptor

IRS-1 is one of the major substrates of insulin receptor. It contains a peckstrin-homology (PH) domain and a phosphotyrosine-binding (PTB) domain in its N-terminal end. The PH and PTB domains bind, respectively, with the phosphoinositides at the plasma membrane and with the juxtamembrane domain of insulin receptor, which is immediately tyrosine phosphorylated by insulin stimulation (Paganon *et al.*, 1999). Thus, the concentration of IRS-1 is thought to be increased around the insulin receptor at the plasma membrane upon insulin stimulation. These PH and PTB domains were fused with phocus, named phocus-2pp, to locate the phocus around the insulin receptor like the IRS-1 and to measure the local phosphorylation event there. When phocus-2pp was expressed in CHO-IR cells, fluorescence was observed throughout the cells (Fig. 2, time 0 s). Upon insulin stimulation, the CFP/YFP emission ratio, which is expressed with pseudocolor, was decreased in the cytosol due to phosphorylation-induced FRET from CFP to YFP within phocus-2pp. Three hundred seconds after insulin stimulation, membrane ruffles, in which a large extent of phocus-2pp were accumulated, appeared around the plasma and disappeared in 1000 s (Fig. 2). In these membrane ruffles, phocus-2pp has been found to colocalize with the insulin receptor accumulated there by insulin stimulation. Interestingly, in these membrane ruffles, the extent of phocus-2pp phosphorylation was visualized to be ~2-fold greater than that in the cytosol. This difference in phosphorylation levels between intracellular loci could be due to a different balance of kinase and phosphatase activities between intracellular loci. Phocus-2pp should contribute to reveal the biological significance of such a characteristic domain for tyrosine kinase signaling in the membrane ruffles, which were formed upon insulin stimulation, with high spatial and temporal resolution.

B. Aktus for Imaging Phosphorylation by Akt/PKB

Akt/PKB is a serine/threonine kinase that regulates a variety of cellular responses, such as cell proliferation, cell survival, and angiogenesis (Marte and Downward, 1997). To provide information on the spatial and temporal dynamics of the Akt activity in single living cells, we have developed a genetically encoded fluorescent indicator for Akt, named Aktus (Sasaki *et al.*, 2003). Almost all Akt substrates are localized to subcellular regions. For example, eNOS (Fulton *et al.*, 2001), which mediates a vasodilatory effect by nitric oxide production, is localized predominantly to

TABLE II Differential Subsellular Localization of Activated Akt between Cellular Stimuli

	Cytosol[a]	Golgi[b]	Mitochondria[c]
Insulin	–	+	–
17β-Estradiol	–	+	+

[b] Measured with eNOS-Aktus.
[c] Measured with Bad-Aktus.

the Golgi apparatus, whereas Bad (Chao and Korsmeyer, 1998), which is related to apoptosis promotion, is present in mitochondrial outer membranes. By fusing the Aktus with the respectively subcellular localization domains within the eNOS and Bad, eNOS-Aktus and Bad-Aktus, which are respectively localized to the Golgi apparatus and mitochondrial outer membrane, were developed as shown in Table I and compared with the cytosolic diffusible indicator Aktus. We have shown that in vascular endothelial cells, the Golgi-localized indicator, eNOS-Aktus, was phosphorylated upon stimulation with insulin and with 17β-estradiol, whereas the mitochondria-localized Bad-Aktus was phosphorylated by 17β-estradiol but not by insulin (Table II). However, the diffusible indicator Aktus was not phosphorylated efficiently upon both insulin or 17β-estradiol stimulation (Table II). From these results, it is suggested that the activated Akt is localized to subcellular compartments, including the Golgi apparatus and/or mitochondria, rather than diffusing in the cytosol, thereby efficiently phosphorylating its substrate proteins. Different observation with the mitochondria-localized indicator indicates that localization of the activated Akt to mitochondria is directed differently between insulin and 17β-estradiol via distinct mechanisms. The present indicators and their applications are thus expected to contribute to the studies of a whole range of dynamics of the activated Akt in living cells.

V. PITFALLS

1. Avoid too bright cells to reproducibly obtain quantitative FRET signals. Also avoid too dim cells because they often exhibit noisy images.
2. Our measurement conditions do not significantly affect the stability of phocus, but if photobleaching of fluorescent proteins, particularly YFP, is still observed, we recommend using ND filters and/or to irradiate the cells less. We usually irradiate the cell for 50 to 100 ms.

CHAPTER

43

In Situ Electroporation of Radioactive Nucleotides: Assessment of Ras Activity or ^{32}P Labeling of Cellular Proteins

Leda Raptis, Adina Vultur, Evi Tomai, Heather L. Brownell, and Kevin L. Firth

I. INTRODUCTION

Binding to nucleotide(s) can determine a state of activation of a protein; a number of GTP-binding proteins such as Ras exist in two distinct, guanine nucleotide-bound conformations, the active Ras.GTP state and the inactive Ras.GDP form, so that the fraction of Ras bound to GTP (percentage Ras.GTP/GTP + GDP) can determine its state of activation (Lowy and Willumsen, 1993). Several indirect assays are in existence for measurement of Ras activity (Scheele *et al*., 1995; Taylor *et al*., 2001). However, in a number of instances, a direct measurement of Ras.GTP binding is necessary (Egawa *et al*., 1999) and is commonly performed through the addition of [^{32}P]orthophosphate to the growth medium followed by Ras immunoprecipitation and guanine nucleotide elution (Downward, 1995). This approach is relatively inefficient due to the fact that the isotope is incorporated into all phosphate-containing cellular components. To circumvent this problem, [α^{32}P]GTP has been introduced into the cell and its breakdown into [α^{32}P]GDP after Ras binding monitored as described earlier (Downward, 1995). Because, contrary to free bases or nucleosides, most nucleotides do not cross the cell membrane, [α^{32}P]GTP has to be introduced into intact cells after cell membrane permeabilization.

Protein phosphorylation is a ubiquitous regulator of a large variety of cellular functions. The *in vivo* radiolabelling and detection of phosphoproteins is usually conducted through the addition of [^{32}P]orthophosphate to the culture medium, followed by immunoprecipitation and electrophoretic separation of precipitated proteins. Just as in the case of Ras activity measurement, this method is relatively inefficient, hence ATP, the common immediate phosphate donor nucleotide, may be used for *in vivo* protein labelling, which must be introduced into intact cells through membrane permeabilization.

This article describes a technique where the introduction of nucleotides into adherent cells is performed through *in situ* electroporation. Cells are grown on a glass surface coated with electrically conductive, optically transparent indium-tin oxide at the time of pulse delivery, a coating that promotes excellent cell adhesion and growth. Unlike other techniques of cell membrane permeabilization, such as streptolysin-O (SLO) treatment, *in situ* electroporation does not detectably affect cellular metabolism, presumably because the pores reseal rapidly so that the cellular interior is restored to its original state; under the appropriate conditions there is no increase in the activity of the extracellular signal-regulated kinase (Erk1/2) or two stress-activated kinases, JNK/SAPK or p38^{hog} (Brownell *et al*., 1998). Results show that Ras activity measurement through electroporation of [α^{32}P]GTP could be performed using approximately 50–100 times lower amounts of radioactivity; although the ^{32}P is in the form of [α^{32}P]GTP exclusively, this technique offers higher specificity compared to labelling through the addition of [^{32}P]orthophosphate to the culture medium. In addition, labelling of two viral phosphoproteins, the large tumor antigen of simian virus 40 and adenovirus E1A, by *in situ* electroporation of [γ^{32}P]ATP requires a fraction of the amount of radioactive phosphorus, while offering enhanced specificity.

II. MATERIALS AND INSTRUMENTATION

Dulbecco's modification of Eagle's medium (DMEM) is from ICN (Cat. No. 10-331-22). Phosphate-free DMEM (Cat. No. D-3916) is from Sigma. Fetal calf serum (Cat. No. 2406000AJ) is from Life Technologies Inc. Calf serum is from ICN (Cat. No. 29-131-54). The following reagents are from Sigma: insulin (Cat. No. I-6643), NaCl (Cat. No. S-7653), HEPES (Cat. No. H-9136), Lucifer yellow CH dilithium salt (Cat. No. L-0259), trypsin (Cat. No. T-0646), $MgCl_2$ (Cat. No. M-8266), Triton X-100 (Cat. No. T-6878), deoxycholate (Cat. No. D-5760), EDTA (Cat. No. E-5134), EGTA (Cat. No. E-3889), phenylmethylsulfonyl fluoride (PMSF, P-7626), aprotinin (Cat. No. A-6279), leupeptin (Cat. No. L-2023), benzamidine (Cat. No. B-6506), dithiothreitol (DTT, Cat. No. D-9779), $CaCl_2$ (Cat. No. C-4901), Tris-base (Cat. No. T-6791), sodium orthovanadate (S-6508), and LiCl (Cat. No. L-4408). The following reagents are from BDH: Extran-300 detergent (Cat. No. S6036 39), SDS (Cat. No. 44244), TLC silica gel plates containing a fluorescence indicator (Cat. No. M05735-01), isopropanol (Cat. No. ACS720), concentrated ammonia solution (Cat. No. ACS033-74), Nonidet P-40 (Cat. No. 56009), and glycerol (Cat. No. B10118). GTP (Cat. No. 106 372) and GDP (Cat. No. 106 208) are from Boehringer Mannheim. The monoclonal anti-Ras antibody is from Oncogene Science (Pan-Ras Ab2, Cat. No. OP22), the monoclonal antibody to simian virus 40 large tumor antigen is from Pharmingen (p108, Cat. No. 14121A), and the monoclonal antibody to adenovirus E1A is from Calbiochem (M73, Cat. No. DP11). Staph. A Sepharose beads (17-0780-03) for immunoprecipitation are from Pharmacia. X-ray film is from Kodak (X-OMAT AR, Cat. No. 165 1454). CelTak™ (Cat. No. 354240) is from BD Biosciences. Tissue culture petri dishes (6 cm diameter) are from Corning or Sarstedt.

The purity of the material to be electroporated is of paramount importance. [α^{32}P]GTP (Cat. No. NEG 006H) and [γ^{32}P]ATP (Cat. No. NEG 002A) are from Dupont NEN Research Products (HPLC purified).

The apparatus for electroporation *in situ* (Epizap model EZ-16) is available from Ask Science Products Inc. (487 Victoria St. Kingston, Ontario Canada). The inverted, phase-contrast and fluorescence microscope, equipped with a filter for Lucifer yellow (excitation: 435, emission: 530), is from Olympus (Model IX70).

The technique can be applied to a large variety of adherent cell types. We have used a number of lines, such as the Fisher rat fibroblast F111 and its polyoma or simian virus 40 virus-transformed derivatives, mouse fibroblast NIH 3T3, mouse Balb/c 3T3, mouse NIH 3T6, mouse C3H10T½ fibroblast derivatives expressing a *ras*-antimessage [e.g., lines R14 and 25B8 (Raptis *et al*., 1997)], Ras^{leu61}-transformed 10T½, and rat liver epithelial T51B, as well as a variety of differentiated adipocytes (Brownell *et al*., 1996). All cells can be grown in plastic petri dishes in DMEM supplemented with 5% calf serum in a humidified 5% CO_2 incubator with the exception of R14 and 25B8, which are grown in DMEM supplemented with 10% fetal calf serum. Cells that do not adhere can be grown and electroporated on the same conductive slides coated with CelTak™, poly-L-lysine or collagen.

III. PROCEDURE

The apparatus for *in situ* electroporation is described in Fig. 1. Cells are grown on conductive and transparent glass slides, which are placed in a petri dish to maintain sterility. The cell growth area is defined by a "window" formed with an electrically insulating frame made of Teflon. The pulse is transmitted through a stainless-steel negative electrode, which is slightly larger than the cell growth area and is placed on top of the cells, resting on the Teflon frame. Another stainless-steel block is used as a positive contact bar. A complete circuit is formed by placing the electrode set on top of the slide as shown in Figs. 1A and 1B. The frame creates a gap between the conductive coating and the negative electrode so that current can only flow through the electroporation fluid and cells growing in the window. In order to obtain a uniform electric field strength over the entire area below the negative electrode, despite the fact that the conductive coating exhibits a significant amount of electrical resistance, the bottom surface of the negative electrode must be inclined relative to the glass surface, rising in the direction of the positive contact bar, in a manner proportional to the resistance of the coating (Raptis and Firth, 1990); glass with a surface resistivity of 2 Ω/sq requires an angle of 1.5°, whereas glass of 20 Ω/sq requires an angle of 4.4°. The procedure described is for glass with a surface resistivity of 20 Ω/sq, which is readily available and relatively inexpensive, hence it can be discarded after use to limit exposure to radioactivity (see *Comment* 1). Similarly, the electrode can be made out of inexpensive aluminum for a single use.

Upscaling

A large number of signal transducers are present in small amounts in the cell so that a large number of cells

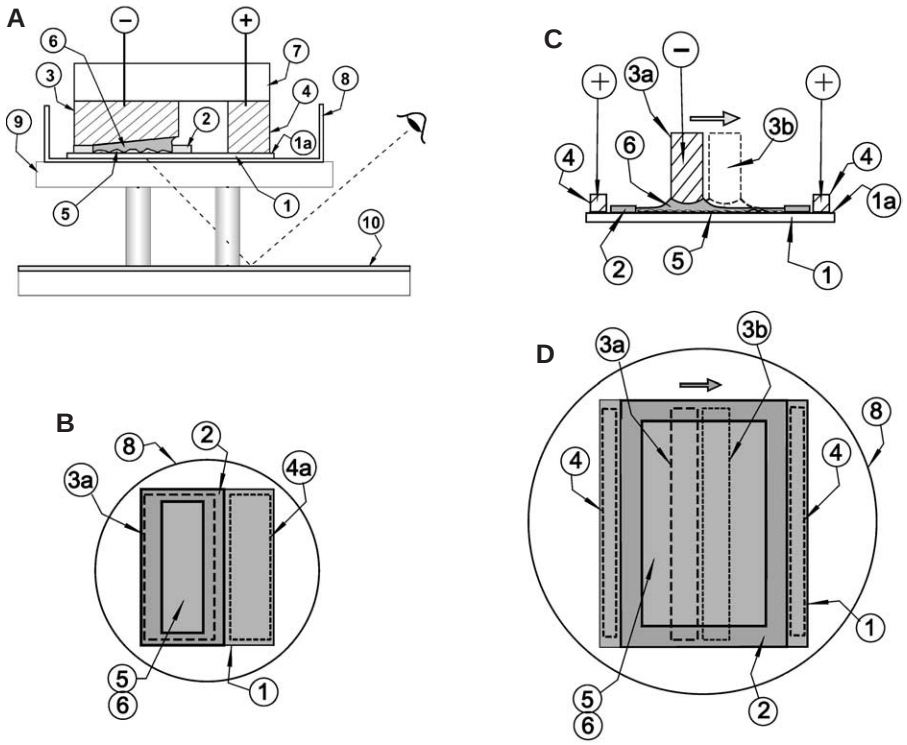

FIGURE 1 **Electroporation electrode assembly. (A) Side view.** A Delrin carrier (7) holds the negative electrode (3) and the positive contact bar (4) so that they form one unit, which can be placed on top of the slide (1) with its frame (2) and cells (5) in place. Negative (–) and positive (+) signs indicate the electrical connecting points via which the pulse of electricity is delivered to the electrodes from the pulse generator. The underside of the negative electrode (3) is machined to a slight angle, which compensates for the surface resistivity of the conductive slide to provide uniform electroporation of the whole cell growth area. The negative electrode rests on a Teflon frame (2), which insulates it from the conductive surface. The fluid containing the material to be electroporated just fills the cavity below the negative electrode. When a capacitor is discharged, current passes through the electroporation fluid (6) and cells (5) attached to the conductive glass slide (1) to the positive contact bar (4) and back to the pulse source. Note that the angle of the negative electrode has been exaggerated to better illustrate the meniscus of the radioactive electroporation solution (6). The slide and electrode fit in a 6 cm petri dish (8) that is locked in place on a stand (9). The top plate supports the petri dish and is made of transparent acrylic so that the operator can look in the mirror (10) to ensure that the liquid (6) is properly filling the cavity without air bubbles. **(B) Top view.** The outline of the conductive slide (1) with a Teflon frame (2) in place to define the area of cell growth and electroporation are indicated [from Brownell *et al*. (1997), reprinted with permission]. **Upscaling. (C) Side view.** Cells to be electroporated (5) are grown on a glass slide (1), coated with ITO (1a). The negative electrode (3a and 3b) is a narrow steel bar mounted across the width of the slide, resting on the Teflon frame (2), which is moved across the surface of the slide as shown by the arrow, by an insulated carrier. The underside of the negative electrode is curved in both directions, such as to optimise the uniformity of electrical field. Note that only the area of cells immediately below the electrode is electroporated by a given pulse. The curvature of the negative electrode has been exaggerated to better illustrate its contour. Note that due to the narrow shape of the electrode, air bubbles do not get trapped easily under it, hence a stand with a mirror may not be necessary. **(D) Top view.** The outline of the conductive slide with a Teflon frame (2) in place to define the area of cell growth and electroporation and the counterelectrodes (4) are indicated. The assembly is placed in a 10 cm petri dish (8) [from Raptis *et al*. (2003) and Tomai *et al*. (2003), reprinted with permission].

may be required to obtain a strong signal. Uniform electroporation of a cell growth area of 32 × 10 mm using 20 Ω/sq glass (i.e., an angle of 4.4°) and a Teflon frame with a thickness of 0.279 mm using the assembly in Figs. 1A and 1B requires a volume of ~280 µl. Simple scale-up of this assembly, e.g., to a cell growth area of 50 × 30 mm, which can be accommodated in a standard, 10 cm petri dish, is faced with the problem of burning the ITO coating that occurs at the higher voltage and capacitance settings required to electroporate this larger area because of the resistance generated by the greater distance the current has to travel. In addition, the volume required, ~1.7 ml, cannot be held in place by surface tension, while the cost of purchase and disposal of the

isotope can be prohibitive for certain experiments. These problems can be solved by using an assembly with a narrow, moveable electrode that electroporates a "strip" of cells at a time (Figs. 1C and 1D); in this configuration, only cells immediately below the negative electrode are electroporated by a given pulse of electricity. After electroporation of the first strip of cells, the electrode is translocated laterally, dragging the solution under it by surface tension so that a new strip of cells is electroporated using mostly the same solution (Figs. 1C and 1D). The electric circuit formed during pulse delivery starts at the negative electrode, passes through the electroporation fluid, the cells and the conductive slide surface, to the two positive contact bars, one on each side of the slide. The two positive contact bars form parallel circuit paths, both carrying current from the conductive surface. To compensate for the resistance of the coating, the bottom surface of the negative electrode must be inclined toward each of the positive contact bars; a 25 mm radius on the bottom of the electrode produces successive strips of even electroporation over the entire cell growth area. Using this assembly, an area of 32 × 10 mm can be electroporated using less than 50 µl of solution with a 2.5 mm-wide electrode, whereas an area of 50 × 30 mm can be electroporated effectively in four, 8 mm-wide strips, with a total of 200 µl of solution.

A. Electroporation of [α^{32}P]GTP for Measurement of Ras Activity

Solutions

1. ***Lucifer yellow solution, 5 mg/ml***: To make 1 ml, add 5 mg Lucifer yellow to 1 ml phosphate-free DMEM.

3. ***[α^{32}P]GTP***: Prepare a solution of 500–2000 µCi/ml in phosphate-free DMEM (*see Comment* 2).

4. ***Ras extraction buffer***: 50 m*M* HEPES, pH 7.4, 150 m*M* NaCl, 5 m*M* $MgCl_2$, 1% Triton, 0.5% deoxycholate, 0.05% SDS, 1 m*M* EGTA, 1 m*M* PMSF, 10 µg/ml aprotinin, 10 µg/ml leupeptin, 10 m*M* benzamidine, and 1 m*M* vanadate. The stock solutions can be made ahead of time. To make 50 ml, add 2.5 ml of HEPES stock, 1.5 ml of NaCl stock, 0.25 ml of $MgCl_2$ stock, 0.5 ml Triton, 0.05 g deoxycholate, 0.25 ml of SDS stock, and 0.5 ml of EGTA stock and then the protease inhibitors, 0.5 ml of PMSF stock solution, 0.05 ml of aprotinin stock, 0.05 ml of leupeptin stock, 0.5 ml of benzamidine stock, and 0.05 ml of vanadate stock and bring the volume to 50 ml with distilled H_2O on the day of the experiment.

10% sodium dodecyl sulfate stock solution: Dissolve 100 g in 1 liter H_2O. Store at room temperature. Stable for more than a year.

5 M NaCl stock solution: Dissolve 292.2 g NaCl in 1 liter distilled H_2O. Autoclave and store at room temperature. Stable for more than a year.

1 M $MgCl_2$ stock solution: Dissolve 203.3 g $MgCl_2 \cdot 6H_2O$ in 1 liter H_2O. Autoclave and store at room temperature. Stable for more than a year.

100 mM EGTA stock solution: Dissolve 38.04 g in 800 ml distilled H_2O. Adjust pH to 8.0 with NaOH and complete volume to 1 liter with distilled H_2O. Stable for more than a year at room temperature.

100 mM PMSF stock solution: Dissolve 17.4 mg PMSF in 10 ml isopropanol and store in aliquots at –20°C. Stable for several months.

10 mg/ml aprotinin stock solution: Dissolve 100 mg in 10 ml of 0.01 *M* HEPES, pH 8.0. Aliquot and store at –20°C. Stable for several months.

10 mg/ml leupeptin stock solution: Dissolve 100 mg in 10 ml distilled H_2O. Aliquot and store at –20°C. Stable for several months.

1 M benzamidine stock solution: Dissolve 1.56 g in 10 ml distilled H_2O. Aliquot and store at –20°C. Stable for several months.

1 M vanadate stock solution: Dissolve 1.84 g in 10 ml distilled H_2O. Aliquot and store at –20°C. Stable for several months.

5. ***Guanine nucleotide elution buffer***: 2 m*M* EDTA, 2 m*M* DTT, 0.2% SDS, 0.5 m*M* GTP, and 0.5 m*M* GDP.

1 M dithiothreitol stock solution: Dissolve 3.09 g DTT in 20 ml of 0.01 sodium acetate (pH 5.2). Store in 1 ml aliquots at –20°C. Stable for more than a year.

0.5 M EDTA, pH 8.0 stock solution: Add 186.1 g disodium ethylenediaminetetraacetate · $2H_2O$ to 800 ml distilled H_2O. To dissolve, adjust the pH to 8.0 with NaOH pellets while stirring. Bring volume to 1 liter. Stable for more than a year at room temperature.

10 mM GTP stock solution: Dissolve 52.3 mg in 10 ml distilled H_2O and store at –20°C. Stable for a month.

10 mM GDP stock solution: Dissolve 44.3 mg in 10 ml distilled H_2O and store at –20°C. Stable for a month.

See earlier list for other required stock solutions: To make 500 µl of elution buffer, add 10 µl of 10% SDS stock solution, 2 µl of EDTA stock solution, 1 µl of DTT stock solution, 25 µl each of GTP and GDP stock solutions, and bring volume up to 500 µl with H_2O.

6. ***Thin-layer chromatography (TLC) running buffer***: 66% isopropanol and 1% concentrated ammonia. To make 100 ml, mix 66 ml isopropanol, 1 ml concentrated ammonia solution, and 33 ml distilled H_2O in a fume hood. Make fresh the day of the experiment. Depending on the size of the chromatography tank, this volume may need to be increased.

Steps

The appropriate institutional regulations for isotope use must be followed for all experiments.

1. **Choice of slides.** Cell growth areas of 32 × 12 mm are sufficient for most cases. However, for some lines with low Ras levels, a larger number of cells may be required to obtain an adequate signal. In this case, the assembly in Figs. 1C and 1D (cell growth area, 50 × 30 mm) may be used. Make sure the glass is clean and free of fingerprints (see *Comment* 5).

2. **Plate the cells.** Uniform spreading of the cells is very important, as the optimal voltage depends in part on the degree of cell contact with the conductive surface (*see Comment* 3). Place the sterile glass slide inside a 6 cm (for 32 × 10 mm) or 10 cm (for 50 × 30 mm) petri dish. Add a sufficient amount of medium to cover the slide (approximately 9 ml for a 6 cm dish). Pipette the cell suspension in the window (Fig. 1) and place the petris in a tissue-culture incubator.

3. **Starve the cells from phosphates** by placing them in phosphate-free DMEM and the required amounts of dialysed serum for 2–3 h or overnight, depending on the experiment.

4. Prior to pulse application, **remove the growth medium** and wash the cells gently with phosphate-free DMEM.

5. Carefully **wipe** the Teflon frame with a folded Kleenex tissue to create a dry area on which a meniscus can form (see *Pitfall* 1).

6. **Add the [α^{32}P]GTP solution.** The volume of the solution under the electrode varies with the electroporation assembly and cell growth area. For the setup in Fig. 1A and a cell growth area of 32 × 10 mm, the volume is ~280 µl, whereas the assembly in Fig. 1C requires ~200 µl for a cell growth area of 50 × 30 mm. Depending on the exact concentration, this volume will contain ~200 µCi [α^{32}P]GTP in phosphate-free DMEM.

7. Carefully **place the electrode** on top of the cells. Make sure there is a sufficient amount of electroporation buffer under the positive contact bar to ensure electrical contact. Make sure there are no air bubbles between the negative electrode and the cells by looking in the mirror. If necessary, the electrode can be sterilized with 70% ethanol before the pulse, and the procedure carried out in a laminar-flow hood, using sterile solutions.

8. Apply three to six **pulses** of the appropriate strength (40–200 V, see *Comment* 3) from a 10- or 20-µF capacitor, depending on the apparatus used (Fig. 1A vs Fig. 1C).

9. **Remove the electrode set.** Because usually only a small fraction of the material penetrates into the cells, the [α^{32}P]GTP solution can be carefully aspirated and used again.

10. **Add phosphate-free medium** containing dialysed serum if permitted by the experimental protocol and incubate the cells for the desired length of time (see *Comment* 4).

11. **Remove the unincorporated material**: wash the cells twice with phosphate-free medium lacking serum.

12. **Extract the proteins.** Add 1 ml of extraction buffer to the window area of the slide. Scrape the cells using a rubber policeman into a 15 ml tube and rock the tubes on ice for 20 min. Centrifuge for 30 min at 1,000 rpm in a Beckman J-6 centrifuge to clarify. Preclear the lysates by adding 100 µl packed Staph. A–Sepharose beads, incubating on ice for 1 h, and centrifuging for 5 min at 1,000 rpm in a Beckman J-6 centrifuge.

13. **Immunoprecipitate Ras.** Incubate the precleared supernatant overnight with pan ras Ab2 antibody bound to Staph. A Sepharose beads while rocking on ice.

14. **Wash the immunoprecipitate** four times with 1 ml of extraction buffer lacking the inhibitors. Use a Hamilton syringe to completely remove all traces of wash solution.

16. **Elute** GTP and GDP off the beads by adding 10–20 µl elution buffer to the beads and incubating at 68°C for 20 min.

17. **Spot** the eluate containing the labelled nucleotides on a silica gel TLC plate containing a fluorescence indicator. Spot 1 µl each of the stock GTP and GDP solutions to serve as cold standards, easily visible under UV light. Develop the plate using a solution of 1% ammonia–66% isopropanol for about 3–4 h.

18. Dry the TLC plate, **expose** to Kodak X-OMAT AR film, and excise the spots for liquid scintillation counting or submit to phosphorimager analysis (see Fig. 2).

B. Electroporation of [γ^{32}P]ATP for Labeling of Cellular Proteins: Labeling of the Simian Virus 40 Large Tumor Antigen or Adenovirus E1A

Solutions

1. ***[γ^{32}P]ATP***: 600–1000 µCi/ml in phosphate-free DMEM.

2. ***Simian virus large tumor antigen (SVLT) or adenovirus E1A extraction buffer***: 122 m*M* NaCl, 18 m*M* Tris-base, pH 9.0, 0.8 m*M* $CaCl_2$, 0.43 m*M* $MgCl_2$, 10% glycerol, 1% NP-40, 10 µg/ml aprotinin, 10 µg/ml leupeptin, 1 m*M* PMSF, and 1 m*M* vanadate. Add 8.0 g

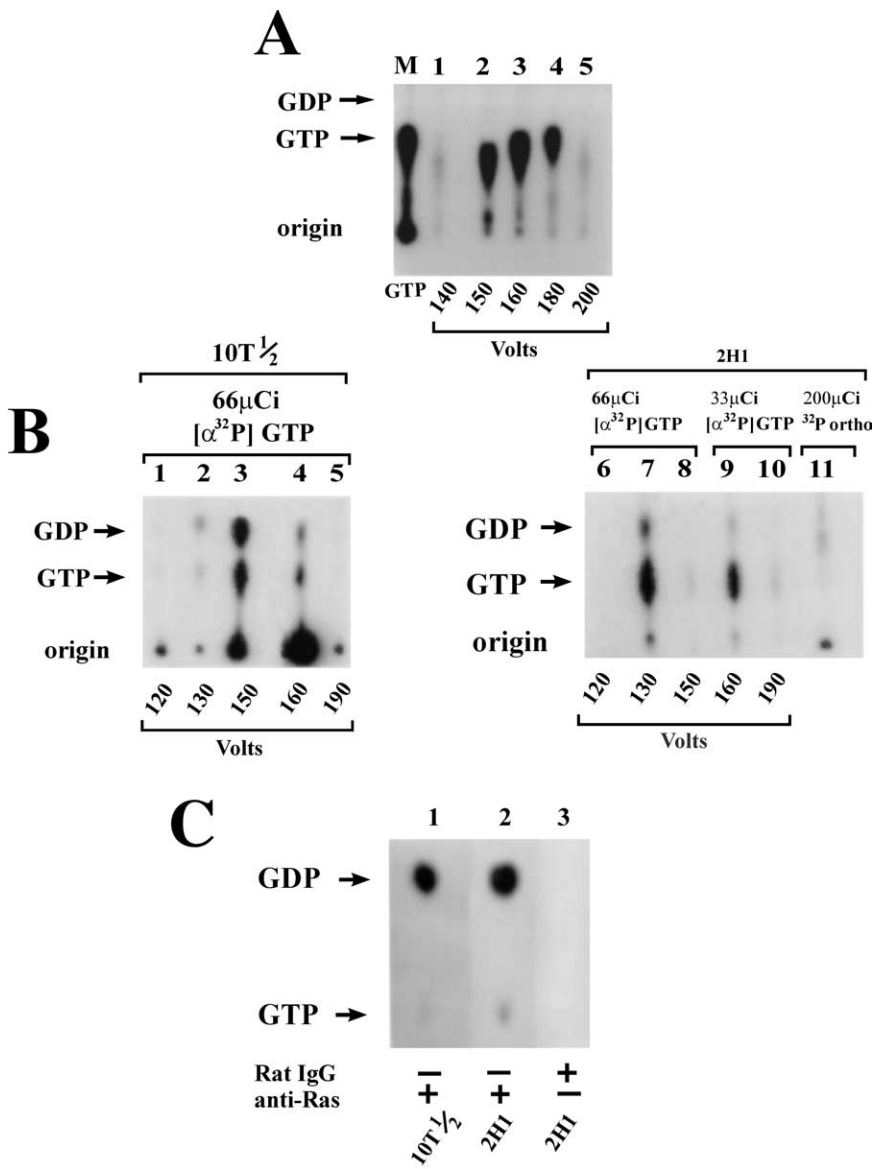

FIGURE 2 **Assessment of Ras activity through electroporation of [α[32]P]GTP.** Cells were grown on conductive glass (cell growth area, 32 × 10 mm, Figs. 1A and 1B) and starved from serum and phosphates. A solution containing [α[32]P]GTP was added to the cells and introduced with three pulses delivered from a 20 μF capacitor at different voltages as indicated. Cells were subsequently placed in a humidified 37°C, CO_2 incubator for 3 h. Ras was extracted and precipitated with the pan-ras Ab2 monoclonal antibody, the bound GTP and GDP eluted and separated by thin-layer chromatography (see text). The plate was exposed for 15 h to Kodak XAR-5 film with an intensifying screen. In all panels, arrows point to the positions of cold GTP and GDP standards, respectively. **(A) Electroporation does not induce a rapid breakdown of intracellular GTP.** Lanes 1–5: Mouse 10T½ fibroblasts were electroporated using voltages of 140–200 V as indicated in the presence of 5 μCi [α[32]P]GTP. Three hours later, nucleotides in a 2 μl aliquot of each clarified lysate were separated as described earlier without Ras immunoprecipitation. Lane M: As a marker, an aliquot of the [α[32]P]GTP used in this experiment was run in parallel. **(B) Assessment of Ras activity through electroporation of [α[32]P]GTP in normal 10T½ and their *ras*-transformed counterparts.** Lanes 1–10: 10T½ cells (lanes 1–5) or their *ras*^{val12}-transformed counterparts, 2H1 (lanes 6–10), were electroporated using voltages of 120–190 V as indicated in the presence of 66 or 33 μCi [α[32]P]GTP, respectively. Proteins were extracted, and the Ras-bound GTP and GDP were separated as described earlier. As a control (lane 11), 2H1 cells growing in a 3 cm petri to were metabolically labelled with 200 μCi [α[32]P]orthophosphate and processed as described previously. **(C) Assessment of Ras activity in normal 10T½ fibroblasts and their *ras*-transformed counterparts, 2H1, using the standard SLO permeabilization assay.** This assay was performed as described (Brownell *et al.*, 1997) and is shown here as a comparison. Lane 1, 10T½; lane 2, *ras*^{val12}-transformed, 10T½-derived line 2H1; and lane 3, 2H1 precipitated with control rat IgG instead of anti-Ras antibodies.

NaCl, 2.42 g Tris-base, 0.1 g $CaCl_2$, 0.04 g $MgCl_2$, 10 ml NP-40, and 100 ml glycerol to 800 ml H_2O. Adjust pH to 9.0 and store at –20°C. On the day of the experiment, add 0.1 ml aprotinin stock, 0.1 ml leupeptin stock, 1 ml PMSF stock, and 0.1 ml vanadate stock solutions to 100 ml of this solution.

3. ***Tris–LiCl solution for washing immunoprecipitates***: 0.1 *M* Tris-base and 0.5 *M* LiCl. Make a stock solution of 10X (4 litres). Add 484 g of Tris-base and 848 g of LiCl in 4 litres of H_2O. Adjust pH to 7.0 using concentrated HCl.

4. ***SDS gel-loading buffer***: 15 ml 10% SDS, 1.5 ml mercaptoethanol, 6 ml glycerol, 3 ml 1.25 *M* Tris, pH 6.8, 0.75 ml 0.3% bromphenol blue, and water to 30 ml.

5. *10% SDS stock solution*

6. *1.25 M Tris–HCl (pH 6.8) stock solution*: Add 151.3 g Tris-base to 800 ml distilled water. Adjust the pH to 6.8 using concentrated HCl and the volume to 1 liter with distilled water.

Steps

1. **Plate, starve from phosphates, and wash** the cells with phosphate-free DMEM as in Section III,A.

2. **Add the [γ^{32}P]ATP solution.**

3. Apply three to six **pulses** of the appropriate strength (40–200 V, see *Comment* 3) from a 10- or 20-μF capacitor, depending on the apparatus used (Fig. 1A vs Fig. 1C). If the setup in Fig. 1 A is employed, then the solution can be carefully aspirated and reused once more after the pulse.

4. **Add phosphate-free medium** and incubate the cells for 2–3 h in a tissue-culture incubator.

5. **Extract** the proteins by adding 1 ml SVLT extraction buffer to the window, scraping into a 15 ml tube, and rocking on ice. Clarify by spinning for 30 min at 1,000 rpm in a Beckman J-6 centrifuge (2,000 *g*).

6. **Precipitate** with the pAb108 (SVLT) or M73 (E1A) monoclonal antibody and wash three times with PBS, twice with the Tris–LiCl solution, and once with H_2O. Elute labelled proteins from the beads with SDS gel-loading buffer and resolve by acrylamide gel electrophoresis (Fig. 3).

IV. COMMENTS

The technique of *in situ* electroporation is very versatile. A large variety of molecules, such as peptides (Boccaccio *et al*., 1998; Raptis *et al*., 2000), nucleotides (Brownell *et al*., 1997), antibodies (Raptis and Firth, 1990), or drugs (Marais *et al*., 1997), can be introduced, alone or in combination, at the same or different times, in continuously growing or growth arrested cells or cells at different stages of thefir division cycle (see chapter 44 by Raptis *et al*.).

1. The slides can normally be washed with Extran-300 and reused a number of times. However, in the case of introduction of radioactive material, exposure of personnel to irradiation is an important consideration. The removal of ^{32}P-labelled nucleotides from the ITO-coated glass is difficult because the phosphate group is attracted to this coating (Tomai *et al*., 2000), hence the use of inexpensive slides and electrodes that can be discarded after use is highly desirable. Slides with a conductivity of 20 Ω/sq are sufficiently inexpensive that they can be discarded after use or stored for the ^{32}P to decay before washing. The use of less conductive ITO-coated glass (100 Ω/sq) would reduce the cost of the slides further. However, in our experience, the conductivity of this grade of glass is not sufficiently consistent for electroporation experiments due to problems related to uniformity of thickness encountered with the thinner coating of the less conductive, commercially available surface. On the other hand, the use of more conductive glass (2 Ω/sq) requires a smaller electrode angle, which reduces the cost of the material substantially. However, this glass is not a regular production item, hence it is more expensive.

2. The [α^{32}P]GTP must be of the highest purity. Because a number of lots were found to contain varying amounts of [α^{32}P]GDP, it is wise to test the preparation by thin-layer chromatography before use.

3. **Determination of the optimal voltage and capacitance.** Electrical field strength has been shown to be a critical parameter for cell permeation, as well as viability (Chang *et al*., 1992). It is generally easier to select a discrete capacitance value and then control the voltage precisely. The optimal voltage depends on the strain and metabolic state of the cells, as well as the degree of cell contact with the conductive surface, possibly due to the larger amounts of current passing through an extended cell (Yang *et al*., 1995; Raptis and Firth, 1990). Densely growing, transformed cells or cells in a clump require higher voltages for optimum permeation than sparse, subconfluent cells. Similarly, cells that have been detached from their growth surface by vigorous pipetting prior to electroporation require substantially higher voltages. In addition, cells growing and electroporated on collagen, poly-L-lysine, or CelTak™-coated slides require substantially higher voltages than cells growing directly on the slide.

The margins of voltage tolerance depend on the size and electrical charge of the molecules to be introduced. For the introduction of small, uncharged molecules such as Lucifer yellow or nucleotides, a wider range of field strengths permits effective permeation with

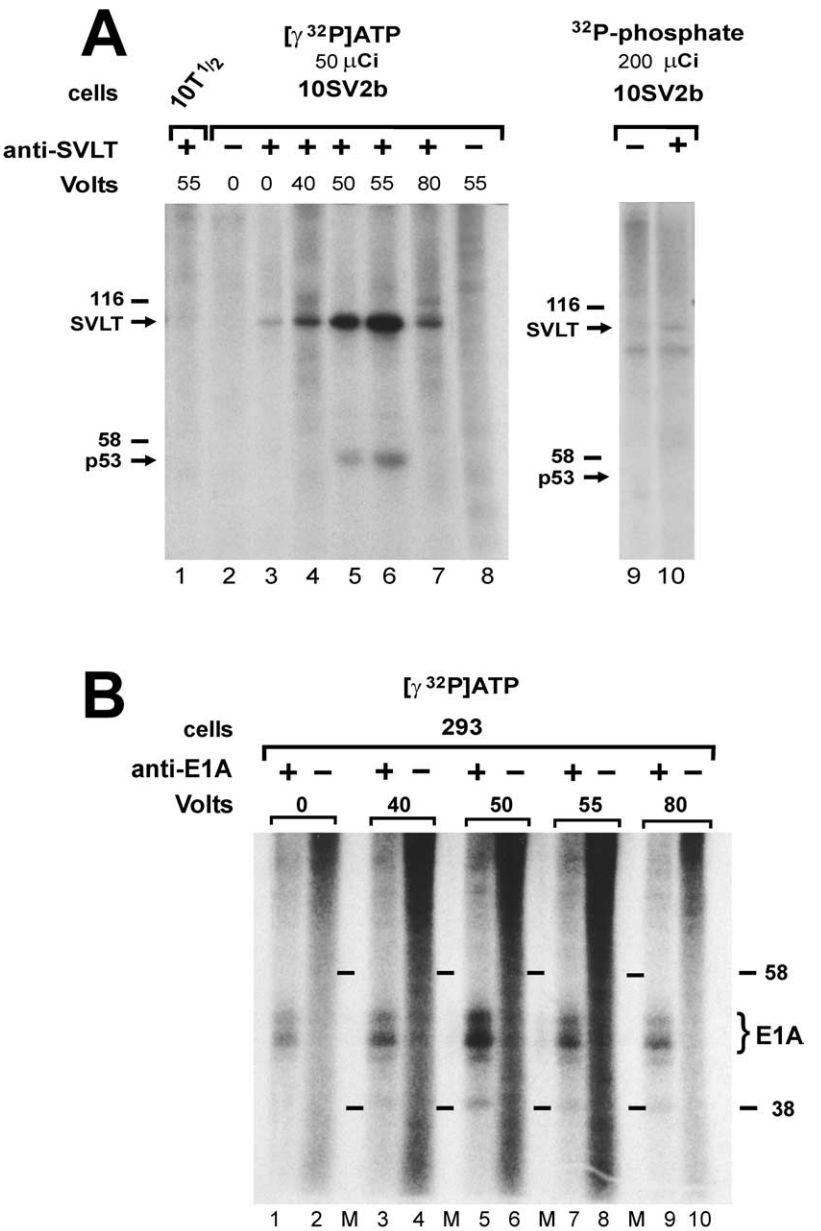

FIGURE 3 Labeling of the simian virus 40 large tumor antigen or adenovirus E1A through *in situ* electroporation of [γ^{32}P]ATP. (A) Mouse 10T½ cells (lane 1) or their SVLT-transformed derivatives (line 10SV2b, lanes 2–8) were grown on 50 × 30 mm conductive areas (Figs. 1C and 1D). A solution containing 50 μCi [γ^{32}P]ATP in phosphate-free DMEM was added to the cells, and six capacitor-discharge pulses of 10 μF, 40–80 V were applied as indicated. Cells were placed in a humidified incubator for 30 min. For a comparison (lanes 9 and 10), the same SVLT-transformed cells were labeled *in vivo* with the indicated amounts of [^{32}P]orthophosphate. SVLT was precipitated from detergent extracts with the pAb108, anti-SVLT antibody (lanes 1, 3–7, and 10), or normal mouse IgG (lanes 2, 8, and 9) and labeled proteins were resolved by acrylamide gel electrophoresis. Dried gels were exposed for 1 h to Kodak XAR-5 film with an intensifying screen. Note the intense and specific labeling of SVLT and the associated phosphoprotein, p53, by *in situ* electroporation (lanes 5 and 6) compared to cells labeled *in vivo* with 200 μCi [^{32}P]orthophosphate (lanes 9 and 10). **(B)** Human 293 cells transformed with adenovirus DNA were labeled as described earlier and extracts were preadsorbed with normal mouse IgG (lanes 2, 4, 6, 8, and 10) or immunoprecipitated using the M73, anti-E1A antibody (lanes 1, 3, 5, 7, and 9). Bracket points to the position of the phosphorylated E1A bands. M, molecular weight marker lanes.

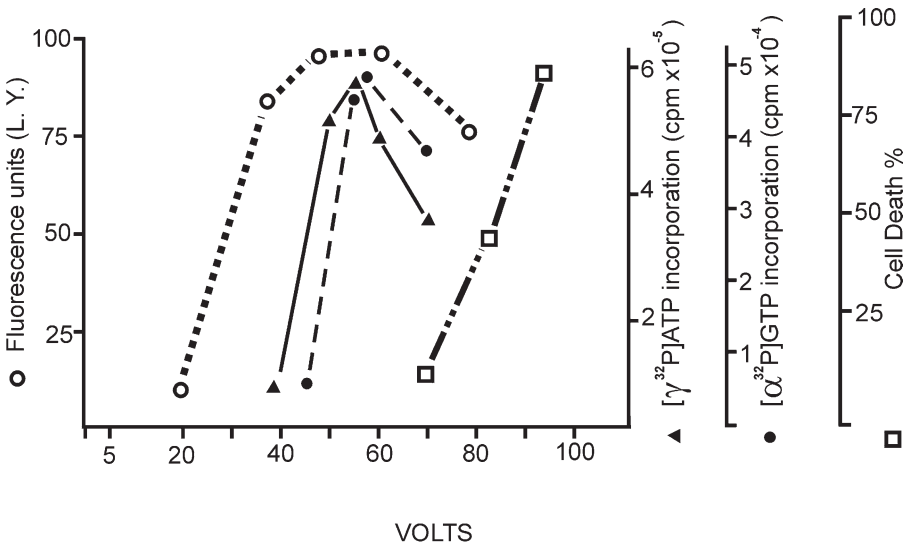

FIGURE 4 Effect of field strength on the introduction of nucleotides. Six pulses of increasing voltage were applied from a 10 µF capacitor to serum-starved $10T^{1}/_{2}$ cells growing on a conductive surface of 50 × 30 mm in the presence of 10 µCi [α^{32}P]GTP (●) or 10 µCi [γ^{32}P]ATP (▲). Total protein labelling was quantitated using a nitrocellulose filter-binding assay (Buday and Downward, 1993). Numbers refer to cpm per 100 µg of protein in clarified extracts. As a control, cells were electroporated with 5 mg/ml Lucifer yellow (○), and its introduction was assessed by fluorescence measurement of cell lysates using a Perkin–Elmer Model 204A fluorescence spectrophotometer. Cell killing (□) was calculated from the plating efficiency of the cells 2 h after the pulse [from Raptis *et al*. (2003) and Tomai *et al*. (2003), reprinted with permission].

minimal damage to the cells than the introduction of antibodies or DNA (Raptis and Firth, 1990; Brownell *et al*., 1997). For all cells tested, the application of multiple pulses at a lower voltage can achieve a better permeation and is better tolerated than a single pulse. This is especially important for the electroporation of serum-starved cells where the margins of voltage tolerance were found to be substantially narrower compared to their counterparts growing in 10% calf serum (Brownell *et al*., 1997). Results of a typical experiment are shown in Fig. 4. Rat F111 cells were grown on slides with a 50 × 30 mm cell growth area (Figs. 1C and 1D) and six pulses were delivered from a 10 µF capacitor. Following electroporation of the first strip of cells, the negative electrode was translocated laterally (Fig. 1C, arrow) so that the whole area was electroporated in four strips. The application of six exponentially decaying pulses of an initial strength of ~40–55 V resulted in essentially 100% of the cells containing the introduced dye, Lucifer yellow, whereas [α^{32}P]GTP required ~50 V for a maximum signal.

Cell damage is microscopically manifested by the appearance of dark nuclei under phase-contrast illumination. For most lines, this is most prominent 5–10 min after the pulse. Such cells do not retain Lucifer yellow and fluoresce very weakly, if at all (Fig. 5). It was also noted that the current flow along the corners of the window is slightly greater than the rest of the conductive area. For this reason, as the voltage is progressively increasing, damaged cells will appear on this area first. This slight irregularity has to be taken into account when determining the optimal voltage.

Example of determination of the optimal voltage. Prepare a series of slides with cells plated uniformly in a 32 × 10 mm window (Figs. 1A and 1B). Set the apparatus at 20 µF capacitance. Prepare a solution of 5 mg/ml Lucifer yellow in phosphate-free DMEM and a solution of [α^{32}P]GTP or [γ^{32}P]ATP containing 5 mg/ml Lucifer yellow in phosphate-free DMEM. Electroporate the Lucifer yellow solution at different voltages, 20 µF, three pulses, to determine the upper limits where a small fraction of the cells at the corners of the window (usually the more extended ones) are killed by the pulse, as determined by visual examination under phase-contrast and fluorescence illumination 5–10 min after the pulse (Fig. 5). Depending on the cells and growth conditions, this voltage can vary from 130 to 190 V. Repeat the electroporation using the radioactive nucleotide solution at different voltages starting at 20 V below the upper limit and at 5 V increments. The Lucifer yellow offers a convenient marker for cell permeation and it was found not to affect the results.

4. Serum was shown to facilitate pore closure (Bahnson and Boggs, 1990).

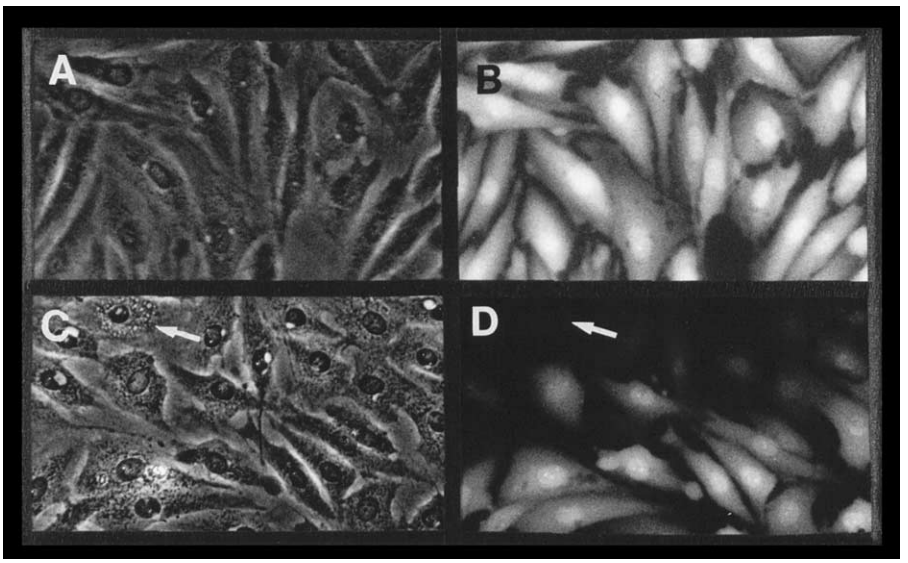

FIGURE 5 Determination of optimal voltage. Rat F111 fibroblasts growing on conductive slides (Figs. 1A and 1B, cell growth area, 32 × 10 mm) were electroporated in the presence of 5 mg/ml Lucifer yellow using three pulses of 155 (A and B) or 190 (C and D) volts delivered from a 20 μF capacitor. After washing of the unincorporated dye, cells were photographed under phase-contrast (A and C) or fluorescence (B and D) illumination. Arrows in C and D point to a cell that has been killed by the pulse. Note the dark, pycnotic and prominent nucleus under phase contrast and the flat, nonrefractile appearance. Such cells do not retain any electroporated material, as shown by the absence of fluorescence (C). It is especially striking that cells at the top of frames C and D, situated at the edge of the electroporated area, received a larger amount of current and have been killed by the pulse. Magnification: 240 times.

5. The slides come with the apparatus and are sterile. If sterility is compromised or if the slides have been washed to reuse, then place in petris and sterilize by adding 80% ethanol for 20 min and then removing the ethanol by rinsing with sterile distilled water.

Other characteristics of the technique. Under the appropriate conditions, *in situ* electroporation does not affect cell morphology or the length of the G1 phase of serum-stimulated cells and does not induce c-*fos* (Raptis and Firth, 1990; Brownell *et al*., 1997). In addition, it does not affect activity of the extracellular signal-regulated kinase (Erk1/2) or two kinases commonly activated by a number of stress-related stimuli, JNK/SAPK and $p38^{hog}$ (Robinson and Cobb, 1997), presumably because the pores reseal rapidly so that the cell interior is restored to its original state (Brownell *et al*., 1998).

Measurement of steady-state Ras activity is possible using this method because, contrary to other methods of cell permeabilization, such as streptolysin-O (Buday and Downward, 1993), the cells are not detectably affected by the procedure so that they can be incubated for long periods of time before extraction. In addition, electroporation does not appear to induce a rapid breakdown of intracellular GTP in any of the lines tested, even under conditions where a substantial fraction of the cells are killed by the pulse (Fig. 2). As a result, determination of the Ras-bound, GTP/GTP + GDP ratio is made easier by the fact that although the optimal voltage must be determined empirically as in all electroporation experiments, excessively high voltages, despite the fact that they may kill a substantial proportion of the cells, do not alter the ratios obtained (Fig. 2B), presumably because such cells rapidly lyse, without affecting the results.

V. PITFALLS

1. Care must be taken so that cells do not dry during the procedure, especially during wiping of the frame with a tightly folded Kleenex. It was found that serum-starved cells were especially susceptible. The morphology of cells that have been killed by drying is very similar to cells that have been killed by the pulse (Fig. 5).

2. Accurate determination of the optimal voltage is very important. For most nucleotide introduction applications, optimal labelling was observed in the range of 140–160 V, whereas these margins were found to be narrower for serum-starved cells. Nevertheless,

the Ras-bound GTP/GTP + GDP ratios or the profile of SVLT or E1A labelling obtained was found to be the same even when a substantial proportion of the cells were killed by the pulse, in which case merely ^{32}P incorporation is reduced.

Dissecting Pathways; *in Situ* Electroporation for the Study of Signal Transduction and Gap Junctional Communication

Leda Raptis, Adina Vultur, Heather L. Brownell, and Kevin L. Firth

I. INTRODUCTION

Electroporation has been used for the introduction of DNA and proteins, as well as various nonpermeant drugs and metabolites into cultured mammalian cells (reviewed in Neumann *et al*., 2000; Chang *et al*., 1992). Most electroporation techniques for adherent cells involve the delivery of the electrical pulse while the cells are in suspension. However, the detachment of these cells from their substratum by trypsin or EDTA can cause significant metabolic alterations (Matsumura *et al*., 1982), while the efficient incorporation of proteins, peptides, or drugs without cellular damage is an especially crucial requirement, since contrary to DNA, no convenient large-scale method exists for the selection of viable from damaged cells or cells where no introduction took place after electroporation, for most proteins or drugs of interest. For these reasons, a number of approaches have been taken to bypass this problem (Kwee *et al*., 1990; Yang *et al*., 1995).

This article describes a technique where cells are grown on a glass surface coated with electrically conductive, optically transparent indium-tin oxide (ITO) at the time of pulse delivery. This coating promotes excellent cell adhesion and growth, allows direct visualization of the electroporated cells, and offers the possibility of ready examination due to their extended morphology. The procedures described are applicable to a wide variety of nonpermeant molecules, such as peptides (Giorgetti-Peraldi *et al*., 1997; Boccaccio *et al*., 1998; Bardelli *et al*., 1998), oligonucleotides (Boccaccio *et al*., 1998; Gambarotta *et al*., 1996), radioactive nucleotides (Boussiotis *et al*., 1997), proteins (Nakashima *et al*., 1999), DNA (Raptis and Firth, 1990), or drugs (Marais *et al*., 1997). These compounds can be introduced alone or in combination, at the same or different times, in growth-arrested cells or cells at different stages of their division cycle. After introduction of the material, cells can be either extracted and biochemically analysed or their morphology and biochemical properties examined *in situ*. In a modified version, this assembly can be used for the study of intercellular, junctional communication. The instant introduction of the molecules into essentially 100% of the cells makes this technique especially suitable for kinetic studies of effector activation. Unlike other techniques of cell permeabilization, under the appropriate conditions, *in situ* electroporation does not affect cell morphology, the length of the G1 phase of serum-stimulated cells (Raptis and Firth, 1990), the activity of the extracellular signal regulated kinase (Erk1/2 or Erk), or two kinases commonly activated by a number of stress-related stimuli, JNK/SAPK and $p38^{hog}$ (Robinson and Cobb, 1997), presumably because the pores reseal rapidly so that the cell interior is restored to its original state (Brownell *et al*., 1998).

II. MATERIALS AND INSTRUMENTATION

The purity of the material to be electroporated is of paramount importance. Substances such as detergents,

Copyright 2006, Elsevier Science (USA).
All rights reserved.

preservatives, or antibiotics could kill the cells into which they are electroporated, even if they have no deleterious effects if added to the culture medium of nonelectroporated cells.

Dulbecco's modification of Eagle's medium (DMEM) is from ICN (Cat. No. 10-331-22). Fetal calf serum (Cat. No. 2406000AJ) and phosphate-buffered saline (PBS, Cat. No. 20012-027) are from Gibco Life Technologies. Calf serum is from ICN (Cat. No. 29-131-54). EGF is from Intergen (Cat. No. 4110-80). HEPES (Cat. No. H-9136), Lucifer yellow CH dilithium salt (Cat. No. L-0259), trypsin (Cat. No. T-0646), $MgCl_2$ (Cat. No. M-8266), Triton (Cat. No. T-6878), deoxycholate (Cat. No. D-5760), EDTA (Cat. No. E-5134), EGTA (Cat. No. E-3889), phenylmethylsulfonyl fluoride (PMSF, P-7626), aprotinin (Cat. No. A-6279), leupeptin (Cat. No. L-2023), benzamidine (Cat. No. B-6506), dithiothreitol (DTT, Cat. No. D-9779), $CaCl_2$ (Cat. No. C-4901), Tris (Cat. No. T-6791), paraformaldehyde (Cat. No. P-6148), bovine serum albumin (BSA, Cat. No. A-4503), SigmaFast DAB kit (Cat. No. D-9167 and Cat. No. U-5005), and sodium orthovanadate (Cat. No. S-6508) are from Sigma. Extran-300 detergent (Cat. No. B80002), SDS (Cat. No. 44244), NP-40 (Cat. No. 56009), glycerol (Cat. No. B10118), and peroxide (B 80017) are from BDH. CelTak™ is from BD Biosciences (Cat. No. 354240). The cell staining kit, including goat serum, secondary antibody, and avidin–biotin complex, was from Vector Labs (Vectastain kit Cat. No. PK-6101). Rabbit antipeptide antibodies against the double threonine and tyrosine phosphorylated (activated) Erk1/2 kinase are from Biosource International (Cat. No. 44-680). When stored frozen in aliquots, they are stable for more than 5 years. They are used at 1:500 for immunostaining and 1:10,000 for Western blotting. Three- and 6-cm tissue culture dishes are from Corning or Sarstedt. Please note that only these brands of plates fit the electroporation stand.

The Grb2-SH2 binding peptide is based on the sequence flanking the Y^{1068} of the EGF receptor (PVPE-Pmp-INQS, MW 1123). To enhance stability of the phosphate group, the phosphotyrosine analog, phosphono-methylphenylalanine (Pmp), which cannot be cleaved by phosphotyrosine phosphatases yet binds to SH2 domains with high affinity and specificity (Otaka *et al*., 1994), is incorporated at the position of phosphotyrosine. The Pmp monomer is custom synthesized by *Color your enzyme Inc*., (Kingston, Ontario, Canada). As control, we used the same peptide containing phenylalanine at the position of Pmp. Peptides are synthesized by the Queen's University Core Facility using standard Fmoc chemistry.

The system for electroporation *in situ* (Epizap Model EZ-16) can be purchased from Ask Science Products Inc. (Kingston, Ontario, Canada, phone: 613 545-3794). The inverted, phase-contrast and fluorescence microscope, equipped with filters for Lucifer yellow and fluorescein, was from Olympus (Model IX70).

III. PROCEDURES

The technique of *in situ* electroporation can be used equally effectively for large-scale biochemical experiments (Giorgetti-Peraldi *et al*., 1997; Boccaccio *et al*., 1998; Bardelli *et al*., 1998) or for the detection of biochemical or morphological changes *in situ* (Raptis *et al*., 2000a). Cells are grown on glass slides coated with conductive and transparent indium-tin oxide (ITO). The cell growth area is defined by a "window" formed with an electrically insulating frame made of Teflon as shown. A stainless-steel electrode is placed on top of the cells resting on the frame and an electrical pulse of the appropriate strength is applied, as illustrated in Fig. 1 (see also chapter 43 by Raptis *et al*.). The technique can be applied to a large variety of adherent cell types (Brownell *et al*., 1996). Cells that do not adhere well can be grown and electroporated on the same conductive slides coated with CelTak™ or poly-L-lysine used according to the manufacturer's instructions.

A. Electroporation of Peptides into Large Numbers of Cells for Large-Scale Biochemical Experiments. Use of Fully Conductive Slides

To study the effect of protein interactions *in vivo* on cellular functions, such complexes can be disrupted through the introduction of peptides corresponding to the proteins' point(s) of contact. An example of this approach is described here.

Growth factors such as the epidermal growth factor (EGF) stimulate cell proliferation by binding to, and activating, membrane receptors with cytoplasmic tyrosine kinase domains. *In vitro* binding and receptor mutagenesis studies have shown that ligand engagement induces receptor autophosphorylation at distinct tyrosine residues, which constitute docking sites for a number of effector molecules, such as the growth factor receptor-binding protein 2 (Grb2), which are recruited to specific receptors through modules termed Src-homology 2 (SH2) domains (reviewed in *Schlessinger*, 2000). Grb2 binds to the receptors for PDGF and EGF at a number of sites, an event activating the Sos/Ras/Raf/Erk pathway, which is central to the mitogenic response stimulated by many growth factors. Previous results indicated that a synthetic

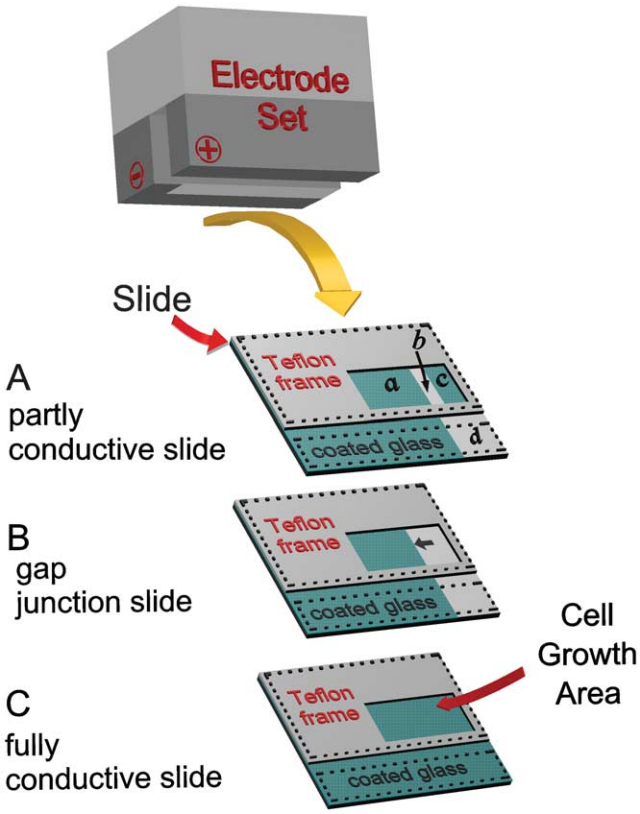

FIGURE 1 Electroporation electrode and slide assembly. Cells are grown on glass slides coated with conductive and transparent ITO within a "window" cut into a Teflon frame as shown. The window can be different sizes, depending on the cell growth area required. The peptide solution is added to the cells and introduced by an electrical pulse delivered through the electrode set, which is placed directly on the frame. Dotted lines point to the positions of negative and positive electrodes during the pulse. Three slide configurations are described. (A) Partly conductive slide assembly, with electroporated (*a*) and non-electroporated (*c*) cells growing on the same type of ITO-coated surface. (*b*) area where the conductive coating has been stripped, exposing the non-conductive glass underneath. Cells growing in areas *b* and *c* are not electroporated (Fig. 3). (B) Partly conductive slide assembly for use in the examination of gap junctional, intercellular communication. Arrow points to the transition line between conductive and non-conductive areas (Fig. 4). (C) Fully conductive slide assembly for use in biochemical experiments. In the setup shown, cell growth area can be up to 7 × 15 mm, but larger slides and electrodes offer larger areas, up to 32 × 10 mm (Fig. 2).

phosphopeptide corresponding to the Grb2-binding site of the EGF receptor (EGFR, flanking the EGFR tyr[1068], PVPE-pY-INQS), when made in tandem with peptides that allow for translocation across the cell membrane, could inhibit EGF-mediated mitogenesis and Erk activation in newt myoblasts induced by 1 ng/ml EGF, but was less effective at 10 ng/ml (Williams *et al.*, 1997). To better determine the functional consequences of disrupting the association of Grb2 *per se* with different receptors *in vivo* in mammalian cells, we delivered large quantities of this peptide into intact, living NIH3T3 fibroblasts by *in situ* electroporation.

Solutions

Spent medium: Grow cells to confluence in DMEM with 10% calf serum. Seven days postconfluence, collect the culture supernatant and dilute 1:1 with fresh DMEM. Growth-arrest cells by incubating in spent medium prepared from the same line.

Lucifer yellow solution, 5 mg/ml: To make 10 ml, dissolve 50 mg Lucifer yellow in 10 ml calcium-free DMEM. Stable at 4°C for at least a month.

Peptides: The peptide concentration required varies with the strength of the signal to be inhibited. For the inhibition of the EGF-mediated Erk activation, prepare a solution of 5–10 mg/ml (~5–10 m*M*) of the Grb2-SH2-blocking peptide (PVPE-pmp-INQS, MW 1123 Da) in calcium-free DMEM (see *Comment* 1).

Epidermal growth factor: To make a 10,000× stock solution, dissolve 100 µg of lyophilised EGF in 100 µl sterile water and freeze in 5 µl aliquots. Just prior to the experiment, add 1 µl stock solution to 10 ml calcium-free DMEM (final concentration, 100 ng/ml). The stock solution is stable at –20° or –70°C for up to 2 months.

Lysis buffer: 50 m*M* HEPES, pH 7.4, 150 m*M* NaCl, 10 m*M* EDTA, 10 m*M* $Na_4P_2O_7$, 100 m*M* NaF, 2 m*M* vanadate, 0.5 m*M* PMSF, 10 µg/ml aprotinin, 10 µg/ml leupeptin, 1% Triton X-100.

Steps

1. **Choice of slides**. For Western blotting experiments on cell extracts following electroporation, use fully conductive slides (Fig. 1C). Since the custom-made peptide is usually the most expensive reagent in this application, to avoid waste, choose the smallest possible cell growth area which provides a sufficient number of cells. Cell growth areas of 32 × 10 mm are generally sufficient to detect Erk1/2 activity inhibition by the Grb2-SH2 blocking peptide in EGF-stimulated, mouse NIH3T3 fibroblasts. In this case, the volume of the solution under the electrode is ~140 µl and will contain approximately 700–1,400 µg peptide in calcium-free DMEM. If fewer cells suffice, then slides with a cell growth area of 7 × 15 mm can be used, requiring ~40 µl of peptide solution. However, for the determination of [^{3}H]thymidine uptake, cell growth areas of 7 × 4 mm are preferred and they require only ~14 µl of solution (see *Comment* 2).

2. **Plate the cells**. Uniform spreading of the cells is very important, as the optimal voltage depends in part

on the degree of cell contact with the conductive surface (see *Comment* 3). Add a sufficient amount of medium (DMEM containing 10% calf serum) to cover the slide (approximately 9 ml for a 6 cm dish). Pipette the cell suspension in the window cut in the Teflon frame (Fig. 1) and place the petris in a tissue-culture incubator until confluent.

3. Prior to the experiment, **starve** the cells overnight in DMEM without serum. Alternatively, cells can be incubated in spent medium for 48 h; this treatment offers wider margins of voltage tolerance (see *Comment* 3).

4. Prior to pulse application, **remove the growth medium** and wash the cells gently once with calcium-free DMEM.

5. Carefully **wipe** the Teflon frame with a folded Kleenex tissue to create a dry area on which a meniscus can form (see *Pitfall* 1).

6. **Add the peptide** solution to the cells with a micropipettor in calcium-free DMEM.

7. Carefully **place the electrode** on top of the cells and clamp it in place. To ensure electrical contact, a sufficient amount of growth medium or PBS should be present under the positive contact bar. Make sure there are no air bubbles under the negative electrode. If necessary, the electrode can be sterilized with 80% ethanol before the pulse and the procedure carried out in a laminar flow hood, using sterile solutions.

8. Apply three to six **pulses** of the appropriate voltage and capacitance (see *Comment* 3).

9. **Remove the electrode set**. Since usually only a small fraction of the material enters the cells, the peptide solution may be carefully aspirated and used again. However, care must be exercised so that the cells do not dry (see *Pitfall* 1).

10. **Add serum-free growth medium** and incubate the cells for 2–5 min at 37°C to recover.

11. **Add EGF** to the medium to a final concentration of 100 ng/ml for 5 min. Controls receive the same volume of calcium-free DMEM.

12. **Extract** the cells with 50 µl extraction buffer for a cell growth area of 32 × 10 mm. For smaller cell growth areas, the voltage can be adjusted accordingly.

13. To **detect activated Erk1/2**, load 100 µg of total cell extract protein on an acrylamide–SDS gel and analyse by Western immunoblotting using the antibody directed against the dually phosphorylated, i.e., activated, form of Erk1/2.

14. For examination of the effect of the peptide upon [^{3}H]thymidine incorporation into DNA, serum-starve 50% confluent, NIH3T3 cells as described earlier and electroporate in the presence or absence of peptide. Incubate in medium with or without EGF for 12 h at 37°C, followed by a 2 h incubation with 50 µCi/ml [^{3}H]thymidine. Wash the cells with PBS and measure acid-precipitable counts. Growth areas of 4 × 7 mm are sufficient for this experiment, and [^{3}H]thymidine can be added to the window only, in a volume of ~50 µl which is held in place by surface tension.

As shown in Fig. 2A, electroporation of the Grb2-SH2 blocking peptide caused a dramatic reduction in EGF-mediated Erk activation in mouse NIH3T3 cells at growth factor concentrations permitting full receptor stimulation (compare lanes 2 and 3 with lane 4). In addition, electroporation of this peptide reduced EGF-mediated [^{3}H]thymidine uptake (Fig. 2B). In contrast, the same peptide had only limited or no effect on Erk activation triggered by HGF, although it could inhibit PDGF signalling (Raptis *et al.*, 2000a). These findings demonstrate that the *in situ* electroporation approach described can very effectively inhibit growth factor-stimulated mitogenesis and thereby detect the differential specificity in the coupling of activated receptor tyrosine kinases to the Erk cascade.

B. Electroporation for the Study of Morphological Effects or Biochemical Changes *in Situ*: Use of Partly Conductive Slides

Assessment of Erk activity by Western blotting following electroporation of the Grb2-SH2 blocking peptide can reveal the involvement of this domain in growth factor-mediated Erk activation. However, to ensure that the treatment itself does not cause cell stress, examination of cellular morphology, in conjunction with measurement of gene product activity by immunocytochemistry, offers a distinct advantage. This approach can demonstrate the specificity of action of the Grb2-SH2 binding peptide, as well as examine the distribution of signal inhibition across the cell layer. An added advantage is that it requires a small number of cells, hence a substantially smaller volume of the peptides (~14 µl in the setup shown in Fig. 1A), compared to Western blotting (~140 µl for a cell growth area of 32 × 10 mm), which could be a significant consideration given their production costs. To precisely assess small background changes in morphology or gene expression levels, the presence of non-electroporated cells side by side with electroporated ones can offer a valuable control and this can be achieved by growing the cells on a conductive slide where part of the coating has been stripped by etching with acids, thus exposing the non-conductive glass underneath. However, as shown in Fig. 3, area *a* vs *b*, the slight tinge of the glass combined with the more effective staining of cells growing on ITO (possibly due to a chemical attraction of different reagents to the coating) can

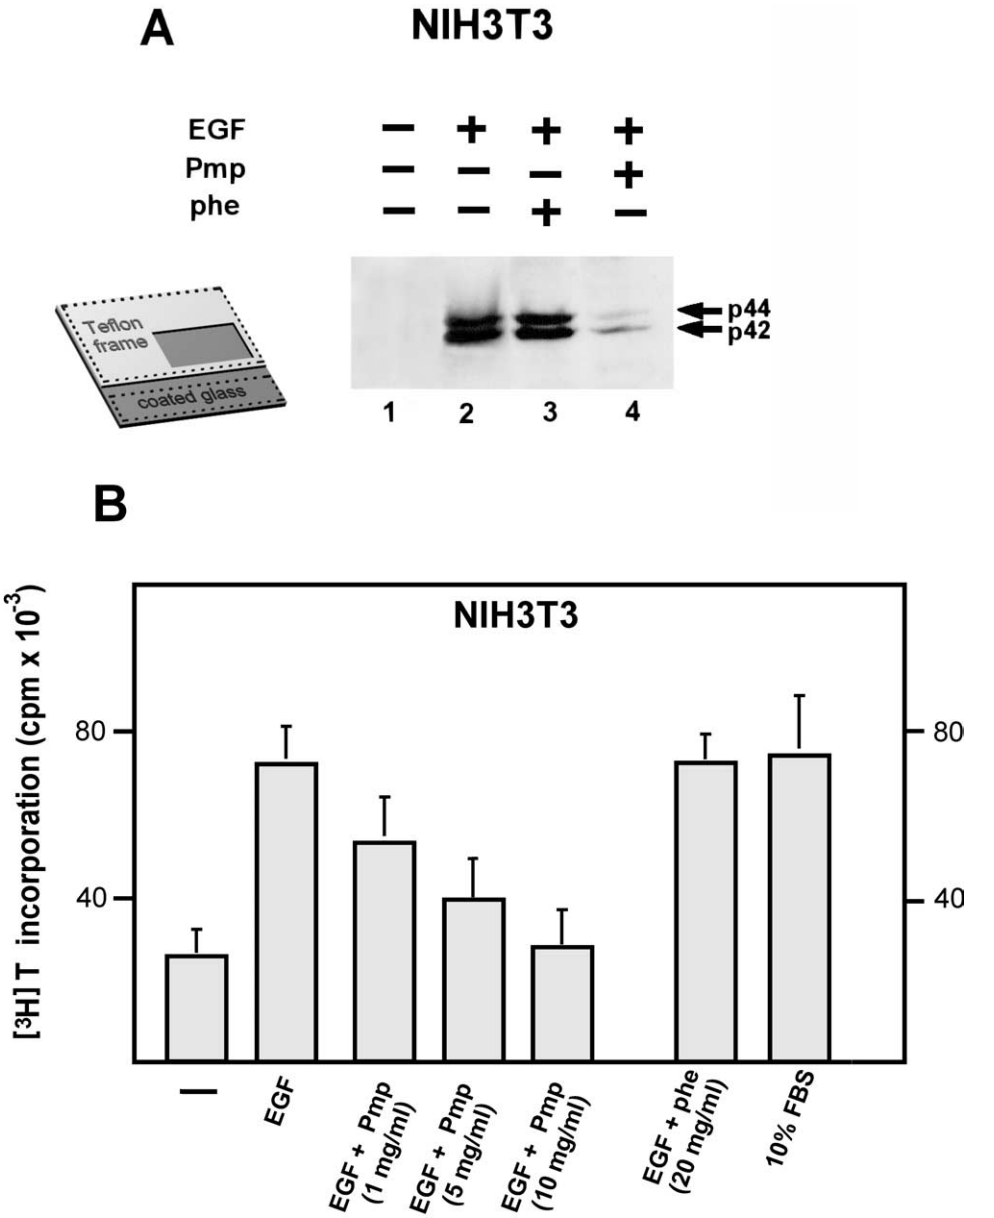

FIGURE 2 **(A) The Grb2-SH2 blocking peptide inhibits EGF-mediated Erk activation in living cells; detection by Western blotting.** The Grb2-SH2 blocking peptide was electroporated into NIH3T3 cells growing on fully conductive slides (inset, Fig. 1C, cell growth area 32 × 10 mm) and growth-arrested by serum starvation. After a 5 min incubation in DMEM, cells were stimulated with 100 ng/ml EGF (lanes 2–4) for 5 min. Proteins in detergent cell lysates were resolved by polyacrylamide gel electrophoresis and analysed by Western blotting using the antibody against the dually phosphorylated, active Erk enzymes. Lane 1, control, unstimulated cells; lane 2, control non-electroporated, EGF-treated cells; lane 3, cells electroporated with the control, phenylalanine-containing peptide and EGF stimulated; and lane 4, cells electroporated with the Grb2-SH2-binding peptide and EGF stimulated. From Raptis *et al.* (2000), reprinted with permission. **(B) The Grb2-SH2 blocking peptide inhibits EGF-mediated DNA synthesis.** The Grb2-SH2 blocking peptide (Pmp) or its phenylalaline-containing counterpart (phe) were electroporated at the indicated concentrations into NIH3T3 cells growing on fully conductive slides (Fig. 1C, cell growth area, 4 × 7 mm) and growth-arrested by serum starvation. Following incubation at 37°C and stimulation with EGF or 10% calf serum for 12 h, cells were labelled for 2 h with 50 μCi/ml [^{3}H]thymidine and acid-precipitable radioactivity was determined. Numbers represent the mean ± SE from three experiments. From Raptis *et al.*, (2000), reprinted with permission.

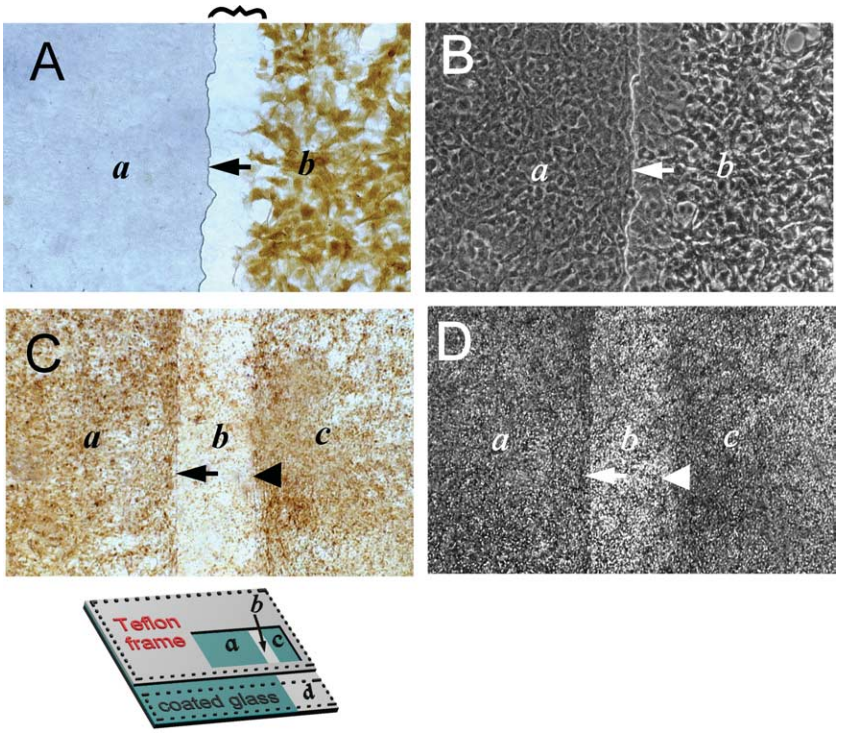

FIGURE 3 The Grb2-SH2 blocking peptide inhibits EGF-mediated Erk activation in living cells; detection by immunocytochemistry. The Grb2-SH2 blocking peptide (A and B) or its control, phenylalanine-containing counterpart (C and D) were introduced by *in situ* electroporation into NIH3T3 cells growing on partly conductive slides (inset, Fig. 1A) and growth arrested in spent medium. Five minutes after pulse application, cells were stimulated with EGF for 5 min, fixed, and probed for activated Erk1/2, and cells from the same field were photographed under bright-field (A and C) or phase-contrast (B and D) illumination. Magnification: A and B, 240×, C and D, 40×. Arrow points to the transition line between stripped (*b*) and electroporated (*a*) areas, while arrowhead points to the line between control ITO-coated (*c*) and stripped (*b*) areas (Fig. 1A). Cells growing on the left side (*a*) are electroporated, whereas cells on the stripped zone (*b*) or right side (*c*) of the slide do not receive any pulse. Note that the Grb2-SH2 blocking peptide dramatically reduced the EGF signal (A, *a*), whereas the degree of Erk activation is the same on both sides of the slide (*a* or *c*) for cells electroporated with the control, phenylalanine-containing peptide (C). In A, inhibition of the signal extends into approximatily three to four rows of adjacent cells in the non-electroporated area (squiggly bracket in *b*), probably due to movement of the peptide through gap junctions (Raptis *et al*., 1994). At the same time, there is no detectable effect on cell morphology as shown by phase contrast (B and D). From Raptis *et al*. (2000), reprinted with permission.

create problems in the interpretation of results. In addition, it was found that a number of cell lines grow slightly better on the conductive, ITO-coated glass than the nonconductive area, possibly due to the fact that the ITO-coated surface is not as smooth as glass, thus providing a better anchorage for the growth of adherent cells (Folkman and Moscona, 1978). As a result, cell density may be higher on the conductive than the etched side, which could have important implications if cell growth effects are being studied. It follows that, to assess the effect of the peptide, it is important to compare the staining and morphology of electroporated cells with non-electroporated ones while both are growing on the same type of surface. This was achieved by plating the cells on a slide where the conductive coating was removed in the pattern shown in Fig. 1A (Firth *et al*., 1997). A thin line of plain glass separates the electroporated and control areas while etching extends to area Fig. 1A,d so that there is no electrical contact between the positive contact bar and area Fig. 1A,c. Application of the pulse results in electroporation of the cells growing in area Fig. 1A,a exclusively, while cells growing in area Fig. 1A,b or c do not receive any pulse. In this configuration, electroporated cells are being compared to nonelectroporated ones, while both are growing on ITO-coated glass. Because the coating is only ~1,600 Å thick, this transition zone does not alter the growth of cells across it and is clearly visible microscopically, even under a cell monolayer (Figs. 3 and 4).

Solutions

Peptide solution: 5–10 mg/ml in calcium-free DMEM. See Section III,A and *Comment* 1

Lucifer yellow solution: 5 mg/ml in calcium-free DMEM. See Section III,A

Epidermal growth factor: 100 ng/ml in calcium-free DMEM. See Section III,A.

Steps

1. Choice of slides. Use partly conductive slides where the coating has been removed in a line as shown in Fig. 1A.
2. Plate the cells as described earlier and starve them from serum.
3. Aspirate the medium and wash the cells once with calcium-free DMEM.
4. Add the peptide solution as described previously.
5. Apply a pulse of the appropriate strength (see *Comment* 3).
6. Add serum-free growth medium and place the cells in a 37°C incubator for the pores to close (2–5 min).
7. Treat the cells with EGF for 5 min as in Section III,A.
8. Fix the cells with 4% paraformaldehyde and probe with the anti-active Erk antibody according to the manufacturer's instructions.

As shown in Fig. 3, electroporation of the Grb2-SH2 blocking peptide totally inhibited EGF-induced Erk activation (panel A, area "*a*"), while the control, phenylalanine-containing peptide had no effect (panel C, area "*a*"). This inhibition was uniform across the cell layer, in agreement with previous results indicating that *in situ* electroporation can introduce the material into essentially 100% of the treated cells. It is especially noteworthy that this inhibition ***extends into three to four rows of the adjacent, nonelectroporated cells*** growing on the nonconductive part of the slide (panel A, area "*b*", squiggly bracket), probably due to movement of the 1123 Da peptide through gap junctions (Raptis *et al*., 1994). This finding constitutes compelling evidence that the observed inhibition must be due to the peptide rather than an artifact of electroporation. At the same time, as shown by phase-contrast microscopy (panel B), there was no alteration in the morphology of the electroporated cells under these conditions, suggesting that the observed effect is a result of a specific inhibition rather than toxic action. EGF stimulation for up to 30 min after peptide electroporation did not result in lower levels of Erk signal inhibition, indicating that the binding of the peptide to Grb2 is stable during this period of time. As expected, the phenylalanine-containing, control peptide (panels C and D) had no effect on Erk activation. In contrast, the Grb2-SH2 binding peptide had little effect in inhibiting Erk activity triggered by the hepatocyte growth factor (HGF) in NIH3T3 cells expressing the HGF receptor through transfection or in human A549 cells that naturally express this receptor (Raptis *et al*., 2000a).

The introduction of peptides to interrupt signaling pathways using the modification of *in situ* electroporation described is a powerful approach for the *in vivo* assessment of the relevance of *in vitro* interactions. Results presented in Fig. 2 and 3 clearly demonstrate that an essentially complete and specific inhibition of EGF-dependent Erk activation can be achieved through peptide electroporation. The stepwise dissection of signaling cascades is essential for the understanding of normal proliferative pathways, which could lead to the development of drugs for the rational treatment of neoplasia.

C. Electroporation on a Partly Conductive Slide for the Assessment of Gap Junctional, Intercellular Communication

One of the targets of a variety of signals stemming from growth factors or oncogenes may be membrane channels, which serve as conduits for the passage of small molecules between the interiors of cells. Oncogene expression and neoplasia invariably result in a decrease in gap junctional, intercellular communication (GJIC) (Goodenough *et al*., 1996). The investigation of junctional permeability is often conducted through microinjection of a fluorescent dye such as Lucifer yellow, followed by observation of its migration into neighboring cells. This is a time-consuming approach, requiring expensive equipment, while the mechanical manipulation of the cells may disturb cell-to-cell contact areas, interrupt gap junctions, and cause artefactual uncoupling. These problems can be overcome using a setup where cells are grown on a glass slide, half of which is coated with electrically conductive, optically transparent, indium-tin oxide. An electric pulse is applied in the presence of Lucifer yellow, causing its penetration into cells growing on the conductive part of the slide, and migration of the dye to non-electroporated cells growing on the nonconductive area is observed microscopically under fluorescence illumination.

The technique can be applied to a large variety of adherent cell types, including primary human lung carcinoma cells (Tomai *et al*., 1998; Raptis *et al*., 1994; Brownell *et al*., 1996; Vultur *et al*., 2003).

Solutions

Lucifer yellow solution: 5 mg/ml in calcium-free DMEM or other growth medium. See Section III.A

Calcium-free growth medium with or without 5% dialysed serum

Steps

1. Plate the cells on partly conductive slides in 3 cm petris. Electroporated areas can be 4 × 4 mm and non-electroporated ones 4 × 3 mm (Fig. 1B). Other slide configurations are also available (Raptis *et al*., 2000b).
2. Aspirate the medium. Wash the cells with calcium-free DMEM.
3. Add the Lucifer yellow solution.
4. Apply a pulse of the appropriate strength so that cells growing on the conductive coating at the border with the non-conductive area are electroporated without being damaged. As described in *Comment* 3, this area receives slightly larger amounts of current than the rest of the conductive growth surface.
5. Add calcium-free DMEM containing 5% dialysed serum, remove the electrode, and incubate the cells for 3–5 min in a 37°C, CO_2 incubator. The inclusion of dialysed serum at this point helps pore closure.
6. Wash the unincorporated dye with calcium-free growth medium.
7. Microscopically examine under fluorescence and phase-contrast illumination (Fig. 4).
8. **Quantitate intercellular communication**. Photograph the cells with a 20× objective under fluorescence and phase contrast illumination (Figs. 4A and 4B). Identify and mark electroporated cells at the border with the non-conductive area (black stars) and fluo-

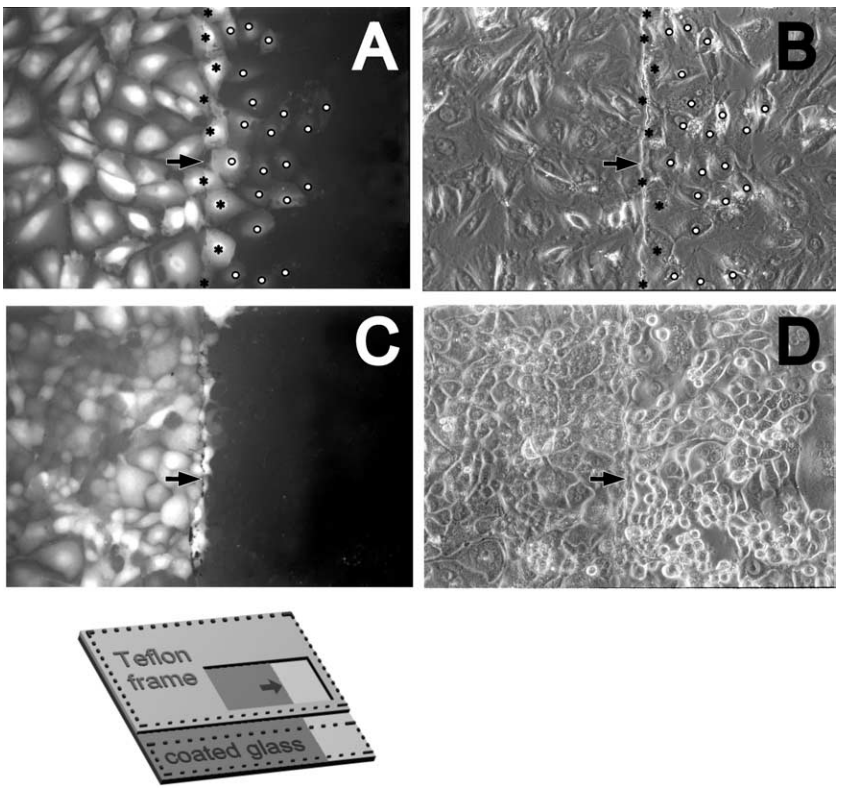

FIGURE 4 ***In situ*** **electroporation on a partly conductive slide for the measurement of intercellular, junctional communication.** (**A and B**) An established, mouse lung epithelial type II line (E10) was plated on partly conductive slides (inset, Fig. 1B) and at confluence was electroporated in the presence of 5 mg/ml Lucifer yellow. After washing away any unincorporated dye, cells from the same field were photographed under fluorescence (A) or phase-contrast (B) illumination (Raptis *et al*., 1994). Note the gradient of fluorescence indicating dye transfer through gap junctions. To quantitate intercellular communication, the number of cells into which the dye transferred through gap junctions per electroporated border cell was calculated by dividing the total number of fluorescing cells on the non-conductive side (white circles) by the number of cells growing at the border with the conductive coating (black stars). (**C and D**) A spontaneous transformant of the E10 line (line E9), was plated on partly conductive slides, electroporated, washed, and photographed as described earlier. Fluorescence (C) and phase-contrast (D) illumination photograph of the same field. Note the absence of dye transfer through gap junctions. In all photographs, the left side is conductive. Arrows on the conductive side point to the interphase between conductive and non-conductive areas. Magnification: 200×. From Vultur *et al*. (2003), reprinted with permission.

rescing cells on the nonconductive side (white circles) where the dye has transferred through gap junctions. Divide the total number of fluorescing cells on the non-conductive area by the number of electroporated cells along the border with the etched side. The transfer from at least 200 contiguous electroporated border cells is calculated for each experiment (Raptis *et al*., 1994). A careful kinetic analysis of dye transfer from 30 s to 2 h showed that the observed transfer is essentially complete by 5 min for all lines tested, while fluorescence is eliminated from the cells within approximately 60 min. After the transfer is complete, cells can be fixed with formaldehyde, in which case fluorescence is retained for approximately 2 h.

IV. COMMENTS

1. Peptides

The concentration of peptide required varies with the strength of the signal to be inhibited. For example, for the inhibition of the HGF-mediated Stat3 activation in MDCK cells, a concentration of 1 μg/ml of a peptide blocking the SH2 domain of Stat3 (^{P}YVNV) is sufficient (Boccaccio *et al*., 1998), whereas for the inhibition of the EGF-mediated Erk activation in a variety of fibroblasts or epithelial cells, a concentration of 5–10 mg/ml (~5–10 m*M*) of the Grb2-SH2 blocking peptide is necessary (Raptis *et al*., 2000a). The purity of the material is of utmost importance. Peptides must be HPLC-purified because impurities can cause cell death or give unexpected results. The pH of the peptide solution must be neutral, as indicated by the color of the DMEM medium where the peptide is dissolved. If it is too acidic, then it must be carefully neutralised with NaOH. In this case, the salt concentration of the no-peptide controls (DMEM without calcium) must be adjusted to the same level with NaCl because a change in conductivity may affect the optimal voltage required (see *Comment* 3).

Any peptide which is soluble in DMEM or other aqueous buffer can be very effectively electroporated. Good solubility is especially important because the concentration needed for effective signal inhibition can be as high as 10 mg/ml. It was nevertheless found that, at least for certain applications, the inclusion of DMSO in the electroporation solution at a concentration of up to 5%, which might aid peptide solubility, did not affect results significantly. However, a number of peptides, e.g., peptides made as fusions with the homeobox domain or other membrane translocation sequences, are usually not sufficiently soluble for this application.

2. Slides

As described in detail in Chapter 43 by Raptis *et al*., to obtain a uniform electrical field intensity over the entire area below the negative electrode, despite the fact that the conductive coating exhibits a significant amount of electrical resistance, the bottom surface of the negative electrode must be inclined relative to the glass surface in a manner proportional to the resistance of the coating. For electroporation of peptides, to minimise the volume of custom-made peptide used, slides with a conductivity of 2 Ω/sq, the most conductive commercial grade available, are used. The slides and electrodes come in different sizes, with the biggest cell growth area in this configuration being 32 × 10 mm. Depending on the experiment, if larger numbers of cells are required, extracts from two to three slides may be pooled. In this case, the peptide solution can be aspirated and used again. Alternatively, an electrode configuration with two positive contact bars can be employed, as described in Chapter 43 by Raptis *et al*.

The slides come with the apparatus, individually wrapped and sterile. However, they can be reused many times after washing with Extran-300 detergent while scrubbing with a toothbrush. In this case they must be sterilized with 80% ethanol for 20 min and the ethanol rinsed with sterile distilled water prior to plating the cells. Alternatively, the slides can be gas-sterilized. Do not autoclave. The glass can withstand high temperatures, but autoclaving would damage the Teflon frames.

3. Determination of the Optimal Voltage and Capacitance

Electrical field strength has been shown to be a critical parameter for cell permeation, as well as viability (Chang *et al*., 1992). It is generally easier to select a discrete capacitance value for a given electroporated area and space between the conductive coating and the negative electrode and then precisely control the voltage. Both parameters depend upon the size of the electroporated area; larger conductive growth areas necessitate higher voltages and/or higher capacitances for optimal permeation. For the 32 × 10 mm cell growth area, some damage to the coating may be noted at the higher voltages necessary if a single pulse is employed. However, using higher capacitance values and multiple pulses with lower voltage settings can yield efficient cell permeation with no damage to

the coating, and this treatment is also better tolerated by the cells. For greater growth areas, the dual positive contact bar design described in Chapter 43 by Raptis *et al.* can be employed.

The optimal pulse strength depends on the strain and metabolic state of the cells, as well as on the degree of cell contact with the conductive surface. Densely growing, transformed cells or cells in a clump require higher voltages for optimum permeation than sparse, subconfluent cells, possibly due to the larger amounts of current passing through an extended cell. Similarly, cells that have been detached from their growth surface by vigorous pipetting prior to electroporation require substantially higher voltages. It is especially striking that cells in mitosis remain intact under conditions where most cells in other phases of the cycle are permeated (Raptis and Firth, 1990). In addition, cells growing and electroporated on CelTak™-coated slides require substantially higher voltages than cells growing directly on the slide.

The margins of voltage tolerance depend on the size and electrical charge of the molecules to be introduced (Fig. 5). For the introduction of small, uncharged molecules such as Lucifer yellow or peptides, a wider range of field strengths permits effective permeation

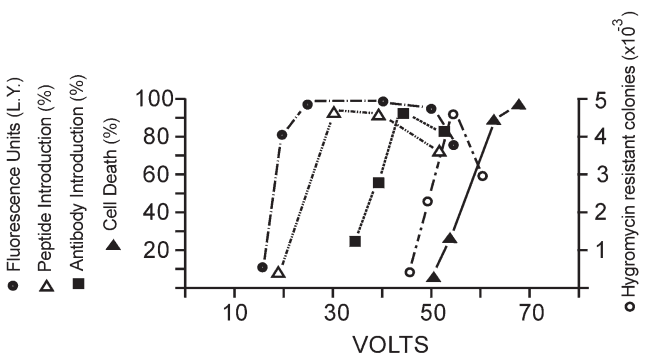

FIGURE 5 Effect of field strength on the introduction of different molecules. Three pulses of increasing voltage were applied to confluent rat F111 fibroblasts growing on a conductive surface of 32 × 10 mm from a 32 µF capacitor in the presence of 5 mg/ml Lucifer yellow (●), 5 mg/ml of the Grb2-SH2 blocking peptide (□), 5 mg/ml chicken IgG (■), or 100 µg/ml pY3 plasmid DNA, coding for resistance to hygromycin (Raptis and Firth, 1990) (○). Cells were lysed and Lucifer yellow fluorescence was measured using a Model 204A fluorescence spectrophotometer (●), probed with the anti-active Erk antibody (□), probed for incorporated IgG (■), or selected for hygromycin resistance (○) (Raptis and Firth, 1990). Introduction of chicken IgG was quantitated from the percentage of cells staining positive with their respective antibodies. Cell killing (▲) was assessed by calculating the plating efficiency of the cells after the pulse. Note that a wider range of voltages (20–50 V) permits efficient introduction of Lucifer yellow with no detectable loss in cell viability than the introduction of IgG or DNA. Points represent averages of at least three separate experiments. L.Y., Lucifer yellow.

with minimal damage to the cells than the introduction of antibodies or DNA (Raptis and Firth, 1990; Brownell *et al.*, 1997). For a number of experiments involving cell growth, it may be necessary to electroporate serum-arrested cells. Voltages required are lower, and especially the margins of voltage tolerance were found to be substantially narrower for serum-starved cells compared to their counterparts growing in 10% calf serum (Brownell *et al.*, 1997). Also, it is important to keep all solutions at 37°C, which facilitates pore closure and efficient electroporation. If the material is applied in a medium with a lower salt concentration than DMEM, then the voltages required are lower, presumably due to the hypotonic shock to the cells and to the longer duration of the pulse because of the lower conductivity of the medium. Conversely, electroporation in a hypertonic solution requires higher voltages for optimum permeation.

Cell damage is manifested microscopically by the appearance of dark nuclei under phase-contrast illumination. For most lines this is most pronounced 5–10 min after the pulse. Such cells do not retain Lucifer yellow and fluoresce very weakly, if at all (Fig. 6). Despite the fact that every effort is made to make the electric field uniform over the whole cell growth area, the current flow along the border with the etched side is greater than the rest of the conductive surface. For this reason, as the voltage is progressively increasing, damaged cells will appear on this edge first (Fig. 6). Another area receiving a slightly higher current is corners of the window. This slight irregularity has to be taken into account when determining the optimal voltage.

4. Example of the Determination of Optimal Voltage for the Introduction of Peptides

Prepare a series of slides with cells plated uniformly in a 4 × 7 mm window on a partly conductive slide (Figs. 1A or 1B). Set the apparatus at 0.5 µF capacitance. Prepare a solution of 5 mg/ml Lucifer yellow and electroporate at different voltages (0.5 µF, three pulses) to determine the upper limits where a small fraction of the cells at the border with the etched side (probably the more extended ones) are killed by the pulse, as determined by visual examination under phase-contrast and fluorescence illumination (Fig. 6). Depending on the cells, this voltage can vary from 20 to 40 V. Repeat the electroporation using the peptide solution at different voltages starting at 10 V below the upper limit and at 2 V increments. The Lucifer yellow dye offers an easy way to test for cell permeation.

Results of a typical experiment of electroporation of cells growing on a 32 × 10 mm surface are shown in

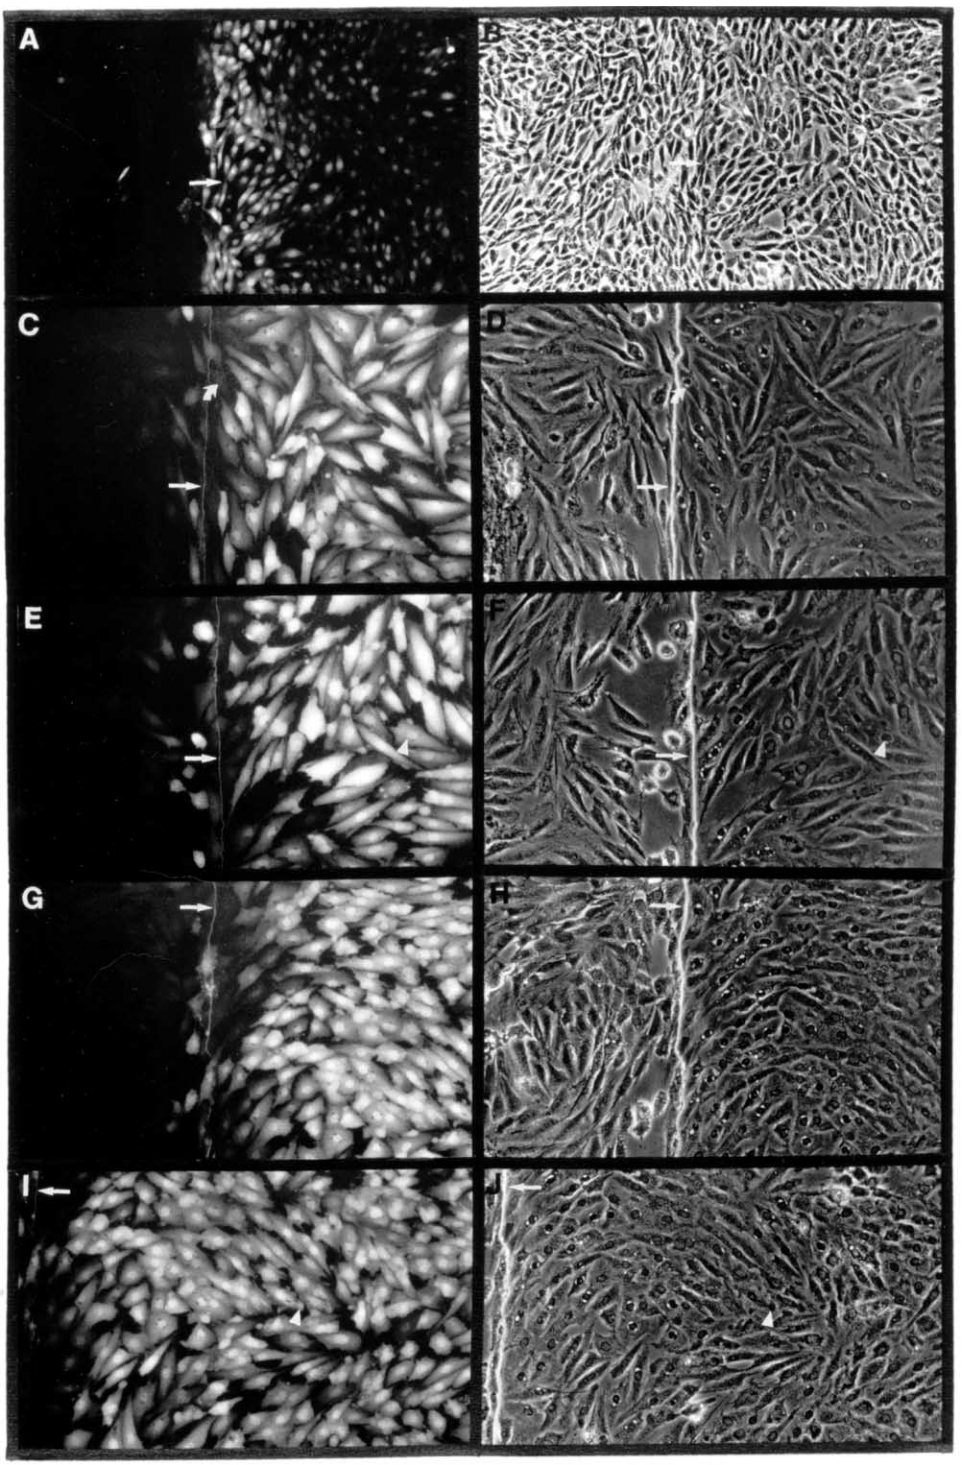

FIGURE 6 **Determination of the optimal voltage.** Rat F111 fibroblasts growing on partly conductive slides (Fig. 1B, conductive area, 4×4 mm) were electroporated in the presence of 5 mg/ml Lucifer yellow using three pulses of increasing voltage delivered from a 0.2 μF capacitor. (A and B) 18 V, (C and D) 26 V, (E and F) 28 V, (G and H) 32 V, and (I and J) 40 V. After washing of the unincorporated dye, cells were photographed under fluorescence (A, C, E, G, I) or phase-contrast (B, D, F, H and J) illumination. Straight arrow points to the interphase between conductive (right) and non-conductive (left) areas. Curved arrows in C and D point to a cell which has been killed by the pulse. Note the dark, pycnotic and prominent nucleus under phase contrast and the flat, nonrefractile appearance. Such cells do not retain any electroporated material as shown by the absence of fluorescence (C). Note that the number of such cells along the border with the non-conductive area increases with voltage. Arrowheads in E and F point to a cell that has a prominent nucleus under phase contrast (F) but has retained the dye (E). Such cells rapidly recover their normal morphology, indistinguishable from their non-electroporated counterparts. White arrowheads in I and J point to membrane blebs which tend to enclose Lucifer yellow and fluoresce strongly. Such membrane blebbing tends to be more prominent under higher voltages. Note that if the determination of intercellular communication is desired, then the voltage must be such that cells at the border with the non-conductive area are electroporated without being damaged (e.g., 18 V, A and B), whereas for all other applications, voltages of approximately 26–32 V would be preferred (C to H). Magnification: A and B, 120X; C–J, 240×.

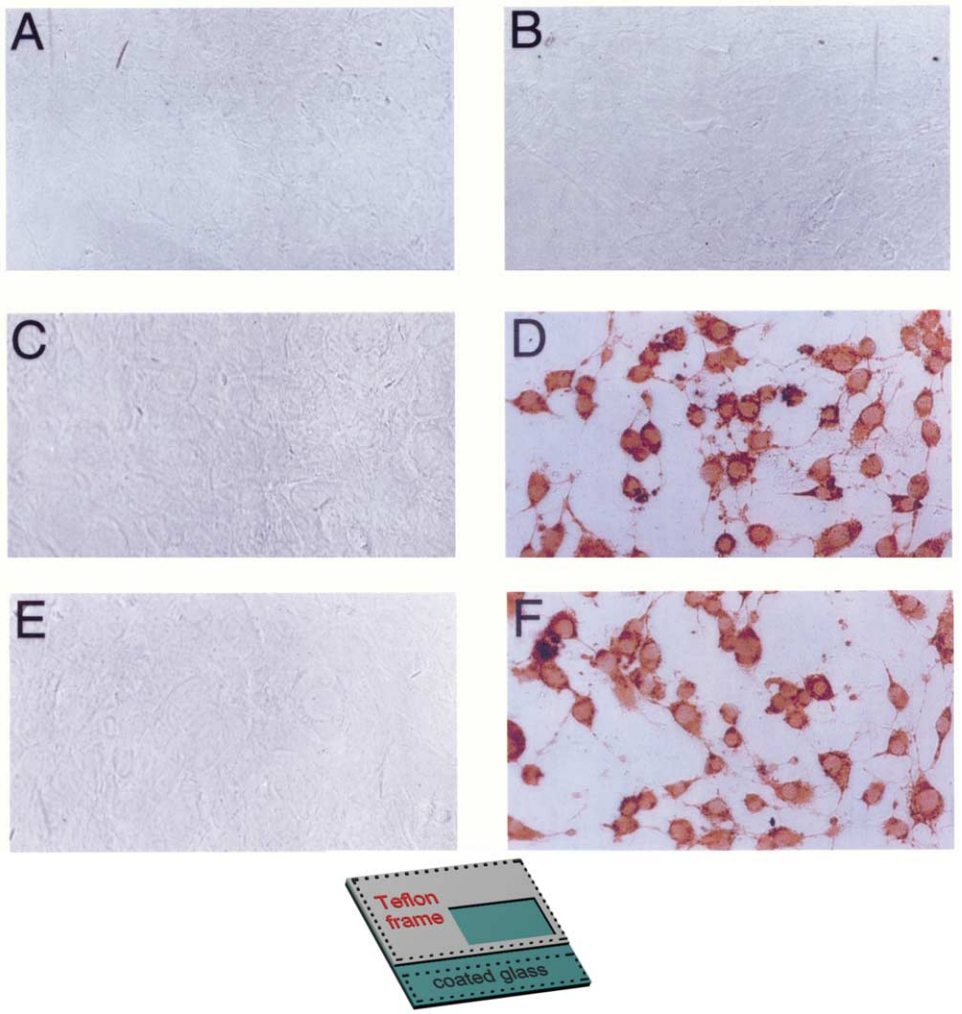

FIGURE 7 ***In situ*** **electroporation does not affect ERK activity or the stress pathway.** (**A, C, and E**) NIH3T3 cells were plated on fully conductive slides (inset, Fig. 1C, conductive growth area 4 × 8 mm), growth arrested in 50% spent medium, and electroporated in the presence of PBS containing 0.025% DMSO (0.2 µF, 70 V, four pulses). Ten minutes after the pulse, cells were fixed and stained for activated ERK (A), activated JNK/SAPK (C), or activated $p38^{hog}$ (E), respectively. Electroporated cells were photographed under bright-field illumination. (**B, D, and F**) NIH3T3 cells were plated on conductive slides, treated with UV light for 10 min, fixed, and stained for activated ERK (B), activated JNK/SAPK (D), or activated $p38^{hog}$ (F), respectively. From Brownell *et al.* (1998), reprinted with permission. Magnification: 240×.

Fig. 5. The Application of three exponentially decaying pulses of an initial strength of 25 V from a 32 µF capacitor to rat F111 cells growing on a conductive growth area of 32 × 10 mm, resulted in essentially 100% of the cells containing the introduced Lucifer yellow, whereas introduction of a nine amino acid peptide required 30 V and the stable expression of DNA 45 V, respectively, for maximum signal. If a 20 µF capacitor is used, the corresponding voltages are ~80–180. Electroporation on 7 × 15 mm slides requires a 2 µF capacitor and voltages of 25–50. For etched slides with a conductive area of 4 × 4 mm, if a 0.5 µF capacitor and three pulses are used, the voltages are 20–40. However, if a 0.1 µF capacitor and six pulses are used, the voltages will be ~30–50.

Under the appropriate conditions, electroporation was shown not to affect the activity of Erk1/2 or the stress-activated kinases JNK/SAPK and $p38^{hog}$. This was shown by probing with antibodies specific for the activated forms of these kinases (Fig. 7); no activation of JNK/SAPK or $p38^{hog}$ was found under conditions of up to 70 V (Figs. 7C and 7E). These kinases were,

however, slightly activated at voltages higher than 85 V, when more than 60% of the cells were killed by the pulse (not shown).

V. PITFALLS

1. Care must be taken so that cells do not dry during the procedure, especially during wiping of the frame with a tightly folded Kleenex. It was found that serum-starved cells were more susceptible than their counterparts grown in medium containing serum. The morphology of cells that have been killed by drying is very similar to cells that have been killed by the pulse (Fig. 6). Slightly dried cells may incorporate Lucifer yellow and appear almost normal under phase contrast, whereas cells that have dried to a great extent display dark nuclei and may not retain Lucifer yellow. It was also found that the combination of even slight drying with electroporation may have undesirable effects on gene expression (e.g., induction of *fos* by serum; unpublished observations). In the case of electroporation on a partly conductive slide (Figs. 1A or 1B), drying of the cells is immediately suspected if cells growing on the non-electroporated area exhibit Lucifer yellow fluorescence.

2. Accurate determination of the optimal voltage is very important. The limits of voltage tolerance are narrower for serum-starved cells (Brownell *et al*., 1997) or if the introduction of larger molecules is attempted.

3. For the determination of GJIC, it is important to wash the dye using a calcium-free solution (growth medium or PBS). If calcium-containing growth medium is used instead, the values obtained may be reduced, presumably because of the calcium influx, which was shown to interrupt junctional communication.

Acknowledgments

The financial assistance of the Canadian Institutes of Health Research, the Canadian Breast Cancer Research Initiative, the Natural Sciences and Engineering Research Council of Canada (NSERC), and the Cancer Research Society Inc. is gratefully acknowledged. AV is the recipient of NSERC and Ontario Graduate studentships, a Queen's University graduate award, and a Queen's University travel grant. HB was the recipient of a studentship from the Medical Research Council of Canada and a Microbix Inc. travel award. We are grateful to Dr. Erik Schaefer of Biosource Int. for numerous suggestions and valuable discussions.

Detection of Protein–Protein Interactions *in vivo* Using Cyan and Yellow Fluorescent Proteins

Francis Ka-Ming Chan

I. INTRODUCTION

The phenomenon of fluorescence resonance energy transfer (FRET) describes the transfer of energy from one fluorophore to another through dipole–dipole interaction (Forster, 1946, 1948). It is a sensitive "molecular ruler" that can detect molecular associations within a range of 100 Å (Stryer, 1978). Early work using FRET to measure biological associations relied on either fluorescent analogs of biomolecules or fluorescent antibodies as donors and acceptors. However, the utility of this technique in detecting biological associations was limited by the availability of monoclonal antibodies that recognize epitopes of the receptor where maximum energy transfer can occur without disrupting the interactions under examination. This limitation was overcome with the use of spectral variants of the green fluorescent protein (GFP) (Tsien, 1998). The use of GFP variants such as CFP (cyan) and YFP (yellow) in FRET analysis has the additional advantage of allowing detection of intracellular associations in living cells. While most of the applications of FRET have employed fluorescence microscopic imaging methods, it has recently become feasible to perform FRET analysis using flow cytometry. For example, it has been used successfully to determine the ligand-independent association between different Fas receptors (Siegel *et al*., 2000). More recently, flow cytometric FRET analysis has been used to study the interaction between histone acetylase PCAF and histone deacetylase HDAC1 and other chromatin-binding proteins (Kanno *et al*., 2004; Yamagoe *et al*., 2003), to detect the presence of *Bacillus anthracis* spores in a test biological sample (Zahavy *et al*., 2003) and to detect caspase activation during apoptosis induction (He *et al*., 2003). Flow cytometry-based FRET analysis permits the screening of a large number of interactions within a short time and will be a useful technique in the screening of molecular associations in the proteomics era. We will focus our discussion to flow cytometry-based FRET analysis. For a more detailed description of fluorescence microscopic FRET analysis, readers are referred to the following link: http://www.stke.org/cgi/content/full/OC_sitrans;2000/38/pl1.

II. MATERIALS AND INSTRUMENTATION

The FACS Vantage SE flow cytometer is from BD Bioscience (San Jose, CA). RPMI 1640 without phenol red (Cat. No. 11835055), penicillin and streptomycin (Cat. No. 10378016), L-glutamine (Cat. No. 25030081), phosphate-bultered saline (PBS, Cat. No. 14190250), and trypsin versene (Cat. No. 15040066) are from Invitrogen (Carlsbad, CA). Fetal calf serum (FCS) is from Biofluids (Cat. No. 200P-500). HEK 293T cells are from ATCC (Cat. No. CRL-11268). Fugene 6 (Cat. No. 1814443) and propidium iodide (Cat. No. 1348639) are from Roche. The CFP (Cat. No. 6900-1) and YFP (Cat. No. 6006-1) parental plasmids are from BD Clontech (CA). Flowjo software is from Treestar Inc. (San Carlos, CA). β-Mercaptoethanol (Cat. No. M-6250) and bovine serum albumin (BSA, Cat. No. A-7906) are from Sigma (MO).

III. PROCEDURES

A. Transfection of FRET Constructs

1. Split HEK 293T cells by washing the cell monolayer with 10 ml PBS and incubating cells at 37°C for 5–10 min in 1× trypsin versene (2–5 ml). Seed cells at 2.5×10^5 cells per well in 1 ml volume of phenol red-free RPMI 1640 (supplemented with 10% FCS, 100 units/ml of penicillin and streptomycin, 2 *mM* of L-glutamine, and 54 μ*M* β-mercaptoethanol) in a 12-well culture plate.

2. Incubate cells in a CO_2 incubator for 16–20 h. Cells should be 70–90% confluent at the time of transfection.

3. Prepare the DNA mixture by mixing an equal molar ratio of CFP to YFP plasmids in an Eppendorf tube. The optimal molar ratio of CFP to YFP plasmids may be different for different FRET pairs and should be determined empirically. The total amount of DNA should be 1 μg per 3 μl of Fugene 6 for transfection in 12-well plate.

4. Add 100 μl of serum-free Dulbecco's Modified Eagles Medium to an Eppendorf tube. Add 3 μl of Fugene 6 to the serum-free medium. Gently tap the tube to mix it. Incubate at room temperature for 5 min.

5. Add the diluted Fugene 6 solution from step 4 to the DNA mixture in step 3. Gently tap the tube to mix well. Incubate the mixture at room temperature for 15 min.

6. Add the DNA/Fugene 6 mixture from step 5 to the cells dropwise. Gently swirl the plate to distribute the mixture evenly.

7. Incubate the cells in a 37°C CO_2 incubator for 24–48 h. It is not necessary to change the medium after transfection.

8. After 24–48 h, aspirate the medium from the wells. Resuspend the cells in 1 ml PBS supplemented with 2% BSA. Spin the cells down at 1500 rpm in a Beckman tabletop centrifuge for 5 min at 4°C.

9. Decant the supernatant. Resuspend cells in 1 ml of PBS supplemented with 2% BSA. Keep cells on ice until they are ready for analysis. Alternatively, cells can be fixed in 4% paraformaldehyde until they are ready for analysis.

B. Collection of Data on FACS Vantage SE

1. Setup of Flow Cytometer

Analyze cells on a FACS Vantage SE flow cytometer (equipped with an ILT air-cooled argon laser and a Spectra Physics Model 2060 krypton laser). Tune the argon to 514 nm for direct excitation of YFP and the krypton laser to 413 nm for excitation of CFP. Replace the forward and side scatter filters with the 513/10 bandpass filter. Use a filter with 470/20-nm bandpass for CFP detection in the P6 channel and filters with 546/10-nm bandpass for YFP and FRET detection in P3 and P5 channels, respectively. Direct YFP fluorescence for detection in the P7 channel for interlaser compensation (see step 2). Use a 505LP dichroic mirror to separate the CFP and FRET signals in P5 and P6 channels. Adjust the fluidics pressure to 29–30 psi.

2. Compensations

Perform electronic compensation to remove CFP emission from the FRET channel (P5–P6). Perform interlaser compensation between CFP and YFP using Omnicomp circuitry to remove YFP excitation from the 413-nm laser. Alternatively, compensations can be performed "off-line" using softwares such as Flowjo during data analysis.

3. Run and Collect Samples

Collect 50,000 live events per sample. To facilitate distinction of live and dead cells, 1 μg/ml of propidium iodide can be added to cells prior to collection of events on the flow cytometer.

4. Analysis of Data

Analyze collected data using Flowjo software. Control samples transfected with noninteracting FRET pairs should be used as negative controls to determine the baseline FRET signal. An example of step-by-step analysis of the homotypic interaction of the ectodomain of p60 TNFR-1 using flow cytometric FRET analysis is given in Fig. 1. TNFR-1 forms ligand-independent complexes through a domain at the N terminus of the receptor called the preligand assembly domain (PLAD) (Chan *et al*., 2000). The cytoplasmic tail of TNFR-1 is replaced by CFP or YFP. The resulting fusions are expressed in HEK 293T cells. A positive interaction between the differentially tagged TNFR-1 ectodomains is observed as the FRET signal increases over cells expressing only the CFP-tagged receptor (Fig. 1a). Moreover, when TNF is added to the cells, a ligand-dependent rearrangement of the complex results in further increase of the FRET signal (Fig. 1a). The interaction between different TNFR-1 chains is specific, as replacing the fluorescence donor or acceptor with another TNFR-like receptor DR4 abolishes the FRET signal (Figs. 1b and 1d). However, cells expressing DR4-CFP and DR4-YFP exhibit a positive FRET signal (Fig. 1c), demonstrating that flow cytometric FRET analysis can accurately recapitulate the known biochemical interactions of these receptors (Chan *et al*., 2000).

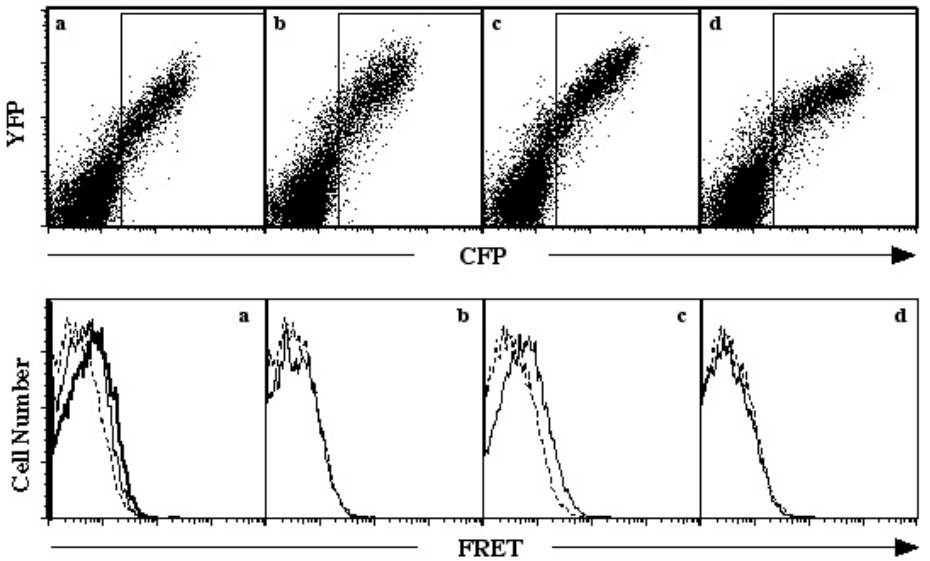

FIGURE 1 HEK 293T cells were transfected using Fugene 6 with (a) p60-CFP and p60-YFP, (b) p60-CFP and DR4-YFP, (c) DR4-CFP and DR-YFP, or (d) DR4-CFP and p60-YFP. (Top) Live cells were analyzed for their expression of CFP and YFP. Cells that express both CFP and YFP were gated (rectangular box) and analyzed for FRET. (Bottom) Histogram overlays of control cells expressing only CFP (dotted lines) or cells expressing CFP and YFP (solid lines) show that only (a) p60-CFP and p60-YFP or (c) DR4-CFP and DR4-YFP exhibited FRET. (a) The heavy line shows the increased FRET when the ligand TNF was added to the cells.

IV. COMMENTS

In addition to the FACS Vantage SE flow cytometer, other models of flow cytometers can be used for flow cytometric FRET analysis if the proper lasers are installed. For example, the LSRII flow cytometer from BD Bioscience can be adapted for FRET analysis if equipped with a violet laser for excitation at 405 nm. Other methods of detecting molecular interactions using the concept of FRET include fluorescence lifetime imaging microscopy and microscopic photobleaching (Bastiaens and Squire, 1999; Miyawaki and Tsien, 2000).

IV. PITFALLS

1. FRET is sensitive to the distance and orientation of the fluorescence donor and acceptor (Miyawaki and Tsien, 2000; Pollok and Heim, 1999; Truong and Ikura, 2001). Moreover, the spacer length between the CFP or YFP moieties and the protein of interest can also affect the efficiency of FRET (Chan *et al*., 2001). Therefore, it is sometimes necessary to test multiple fusion constructs to find the optimal fusions for FRET analysis.

2. Low transfection efficiency is detrimental in FRET analysis. For 293T cells, Fugene 6 is the transfection reagent of choice because of its consistency in yielding high protein expression. Cell culture conditions can also be significant in the success of transfections. Typically, seeding 2.5×10^5 cells on 12-well plates will yield a 70–80% confluent culture after a 16- to 20-h incubation, which is ideal for high transfection efficiency.

3. To optimize the FRET signal, it is necessary to have the fluorescence acceptor molecule in slight excess relative to the fluorescence donor molecule. Therefore, different ratios of CFP to YFP plasmids should be tested to determine the optimal ratio that will yield maximal FRET signals.

Tracking Individual Chromosomes with Integrated Arrays of *lac*^{op} Sites and GFP-*lac*^{i} Repressor: Analyzing Position and Dynamics of Chromosomal Loci in *Saccharomyces cerevisiae*

Frank R. Neumann, Florence Hediger, Angela Taddei, and Susan M. Gasser

I. INTRODUCTION

The visualisation of specific DNA sequences in living cells, achieved through the integration of *lac* operator arrays (*lac*^{op}) and expression of a GFP-lac repressor fusion, has provided new tools to examine how the nucleus is organised and how basic events such as sister chromatid separation occur (Straight *et al*., 1996; Belmont, 2001). In contrast to other methods, such as fluorescence *in situ* hybridisation, the *lac*^{op}/GFP-*lac* repressor (GFP-*lac*^{i}) technique is noninvasive and therefore interferes minimally with nuclear structure and function. In addition, it facilitates analysis of the rapid dynamics of specific DNA loci (Gasser, 2002). Although this technique has been adapted to organisms from bacteria to humans, the ease with which GFP fusions can be targeted to specific chromosomal sites depends on the ability of the organism to carry out homologous recombination. This process is very efficient in budding yeast, allowing pairs of chromosomal loci to be analysed at the same time through the use of two bacterial repressors (*lac*^{i} and *tetR*) fused to different GFP variants. Given the relatively advanced state of the art in budding yeast, this article presents protocols optimised for this organism. These provide a starting point for adapting multilocus tagging to other species. Moreover, the techniques described here for the quantitative analyses of locus dynamics are universally applicable.

II. MATERIALS AND INSTRUMENTATION

Yeast minimal and rich media (SD, YPD) are described in Guthrie *et al*. (1991). Cells can be mounted on a depression slide (Milian SA, Cat. No. CAV-1, Fig. 2A) upon 1.4% agarose (Eurobio Cat. No. 018645) containing SD medium with 4% glucose (Fluka). Aliquots of this can be kept at 4°C for several months. Alternatively, cells can be immobilised on a 18-mm coverslip treated with concanavalin A (Con A, Sigma, Cat. No. C-0412) in a cell observation chamber (Ludin chamber, Life Imaging Services, Fig. 2B). Con A dissolved to 1 mg/ml in H_2O is stable at –20°C for months. Widefield microscopy is performed on a Metamorph-driven Olympus IX 70 inverted microscope with Olympus Planapo 60×/NA = 1.4 or Zeiss Planapo 100×/NA = 1.4 objectives on a **piezoelectric translator** (**PIFOC;** Physik Instrumente), illuminating with a PolychromeII monochromator (T.I.L.L. Photonics). Also needed is a CoolSNAP-HQ digital camera (Roper Scientific) or equivalent, and both the FITC filter set for detecting

Copyright 2006, Elsevier Science (USA).
All rights reserved.

GFP (Chroma, Ref. 41001) and the CFP/YFP filter set (e.g., Chroma, Ref. 51017). Confocal microscopy can be performed on a Zeiss LSM510 Axiovert 200M, equipped with a Zeiss Plan-Apochromat 100×/NA = 1.4 oil immersion or a Plan-Fluar 100×/NA = 1.45 oil immersion objective. The stage is equipped with a hyperfine motor HRZ 200. Temperature is stabilised using a temperature-regulated box surrounding the microscope (The Box, Life Imaging Services). Software used for analysis is (a) Excel (Microsoft), (b) ImageJ public domain software (Rasband), (c) Imaris v 3.3 (Bitplane), (d) Mathematica 4.1 (Wolfram Research), and (e) Metamorph v 4.6r6 **(Universal Imaging Corp.)**.

III. PROCEDURES

A. Preparations

1. Plasmids and Strains

Yeast transformation and growth are as described (Guthrie *et al*., 1991). The *lac*^{op}/GFP-*lac*^{i} system for site recognition exploits the high affinity and specificity of the bacterial *lac* repressor for its recognition sequence (*lac*^{op}). All procedures are performed analogously for the *tetR*/*tet*^{op} system (Michaelis *et al*., 1997).

1. Plasmids or integrations of repetitive arrays are difficult to propagate in both bacteria and yeast due to recombination induced excision events. To avoid this, bacteria should be grown at 30°C in a recombination-deficient strain [STBL2 (Invitrogen Life Technologies) or SURE (Stratagene)].

2. Integrate a copy of *lac* repressor fused in frame to sequences encoding the S65T V163A, S175G derivative of GFP and a nuclear localisation signal, e.g., pAFS144 into the yeast strain. This red-shifted GFP derivative has a higher emission intensity and longer fluorescence time than natural GFP (Straight *et al*., 1998). The *lac*^{i} later helps to stabilise the *lac*^{op} array in yeast.

3. Insert a multimerised *lac*^{op} array (usually 256 copies or ~10kb) into the chromosome by standard transformation using a linearised construct that integrates by homologous recombination. Integration is directed to a genomic locus by a unique cleavage within a polymerase chain reaction (PCR)-generated genomic sequence >200bp inserted into the host plasmid (e.g., pAFS52 integration is selected by growth on SD-trp; Straight *et al*., 1996; Heun *et al*., 2001a; Hediger *et al*., 2002). In yeast as few as 24 contiguous *lac*^{op} sites can be detected readily.

4. Check the proper insertion by standard colony PCR and/or Southern blotting (Guthrie *et al*., 1991). Binding of *lac*^{i}-GFP to the *lac*^{op} array results in a bright focal spot, detected readily by fluorescence microscopy within the nucleoplasm. Confirmed transformants with bright signals should be frozen and stored immediately as individual colony isolates. When strains are recovered from frozen stocks, they should be grown on selective medium to avoid further excision events.

Note: Other GFP fusions, optimised forms of CFP or YFP (or ECFP and EYFP), have also been used successfully in yeast (Lisby *et al*., 2003). The lac repressor used is also modified to prevent tetramerisation, thus minimising artefactual higher order interactions between *lac*^{op} sites (Straight *et al*., 1996).

5. Double tagging. If the position or mobility of two genomic loci is to be compared, one should avoid tagging both with the same repeats. It has been shown that identical arrays can undergo a pairing event that, at least in the case of the *tet* system, depends on the expression of the repressor (*tetR;* Fuchs *et al*., 2002). By using *tet*^{op} for one site, and *lac*^{op} for the second, the risk of spurious pairing is eliminated. Useful pairs of GFP derivatives are CFP and YFP, or GFP and the new monomeric mRFP (Campbell *et al*., 2002).

6. In contrast to the *lac*^{i}–GFP fusion (Figs. 1A and 1B), the *tetR*–GFP gives a high and generally diffuse nucleoplasmic background in yeast, both in the presence and in the absence of *tet*^{op} repeats (Figs. 1C and 1D).

7. Dynamics. If movement analysis is to be pursued, it is important to differentiate the movement of the nucleus itself or that induced by mechanical vibrations from the dynamics of the chromosome. Nuclear movement must be determined and then subtracted from that of a specifically tagged site, using any of the following methods.

a. Visualisation of the nuclear envelope with Nup49–GFP (Belgareh *et al*., 1997; Heun *et al*., 2001a). In this case the nuclear centre can be interpolated from the oval or circular pore signal in an automated fashion by software such as ImageJ or Metamorph (Figs. 1A and 1B). The DNA locus position is then determined relative to the nuclear centre for each frame.
b. Diffuse nucleoplasmic signal of *tetR*–GFP (Figs. 1C and 1D). The centre of the nucleus is defined by interpolation frame by frame and locus movement is calculated relative to this.
c. By comparing the motion of two tagged loci, one can calculate average movement without concern for nuclear drift. The fact that both

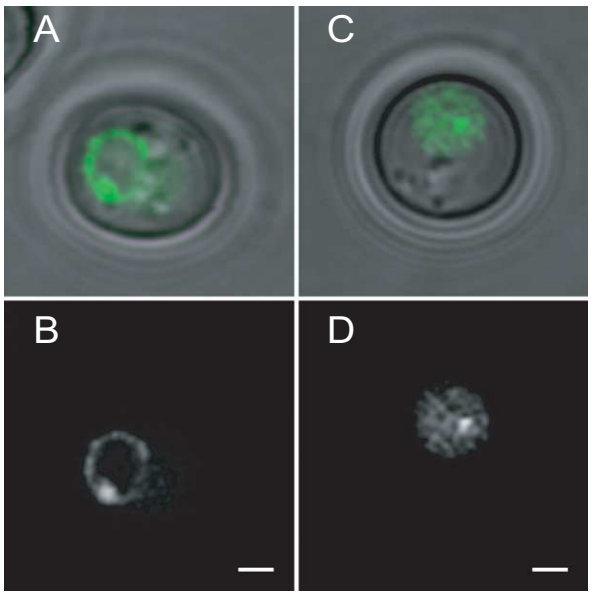

FIGURE 1 (**A** and **C**) An overlay of the phase image and the fluorescence image of a GFP-tagged yeast cell in G1 phase. (**B** and **D**) The corresponding fluorescence image. The *lac*^{op} array is integrated at the *LYS2* locus; the nucleus is visualised by the tagged nuclear pore component Nup49-GFP (**A,B**) or by using the diffuse staining of nucleoplasm by *tetR*-GFP (**C,D**). Bar: 1 µm.

loci are moving has to be taken into account for movement quantitation (see later).

2. *Growth and Cell Preparation*

1. All yeast strains to be analysed should be cultured identically and preferably to an early exponential phase of growth (<0.5×10^7 cells/ml) in synthetic or YPD medium, starting from a fresh overnight culture. Depletion of glucose or growth on alternative carbon sources can alter chronetin dynamics. Wash cells once before observation to avoid YPD autofluorescence. We recommend two mounting techniques for living cell visualisation.

2a. *SD–agarose-filled slides* (Fig. 2A): Immobilised cells between an agarose patch on a depression slide and a coverslip to avoid flattening or distortion of the yeast by coverslip pressure on a normal glass slide. Cells sealed in this way are in a closed environment in which the depletion of O_2 and production of CO_2 bubbles can influence growth and impair visualization. Optimally this technique is used for imaging periods limited to <60 min.

i. Melt an aliquot of SD/agarose at 95°C until the agarose has completely melted, but not longer.
ii. Vortex briefly and transfer 150 µl into the well of a depression slide that is preheated either by a heating block or by passage through the flame of a Bunsen burner.

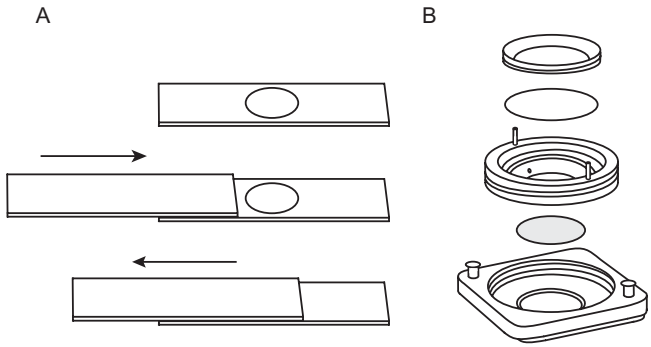

FIGURE 2 Yeast cells can be immobilised for imaging either using an agarose patch on a depression slide (**A**) or using a cell observation chamber (e.g., Ludin chamber; **B**).

iii. Immediately pass a normal microscope slide over the depression to remove excess agarose as depicted in Fig. 2A.
iv. While the agarose solidifies, recover the cells from 1 ml of culture by centrifugation for 1 min at <10,000 g.
v. Resuspend the cells in ~20 µl of appropriate medium.
vi. Once the agarose has solidified, remove the upper slide by sliding along the depression slide surface and place ~5 µl of concentrated cells on the agarose patch.
vii. Close with a coverslip, eliminate eventual air bubbles, and seal with nail polish.

Note: Monitor bud emergence and cell division carefully, as some brands of nail polish contain solvents that influence yeast cell physiology negatively.

2b. *Cell observation chamber* (Ludin chamber, Fig. 2B): The second technique uses a Ludin chamber in which cells are attached noncovalently to a coverslip by a lectin. The medium-filled chamber is assembled as shown in Fig. 2B. A flow of fresh medium can be applied.

i. Coat 18-mm coverslips with 10 µl Con A (1 mg/ml in H_2O) and let them air dry for >20 min. Coated slides can be kept for weeks at room temperature.
ii. Adhere cells to the Con A-coated coverslip by sedimenting 1 ml of the culture at 1 *g* for 3 min at room temperature.
iii. Remove excess culture and add ~1 ml fresh preheated medium before closing the chamber.

3. *Temperature Control*

In order to have a stable condition for microscopic observation, the temperature of the microscope and

room should be controlled carefully (±2°C). Two mechanisms are used standardly. The first is to enclose the entire imaging part of the microscope in a commercially available temperature-regulated box (e.g., Life Imaging Services or Zeiss). A second, less precise method is to regulate the temperature of the slide through a heated stage.

B. Image Acquisition

1. General

The choice of imaging technique depends on the question being asked. To derive quantitative information on the position of a given locus relative to a fixed structure (e.g., the spindle pole body, nucleolus, or nuclear envelope), three-dimensional (3D) stacks and detection of different wavelengths may be necessary. An analysis of fine movement and chromatin dynamics, however, requires the rapid and extended capture of one or more fluorochromes. Bleaching of the signal is often a major limiting factor in time-lapse imaging. One should note that chromatin movement is very fast [movements >0.5 µm in less than 10 s (Heun *et al.*, 2001a)], making it necessary to have rapid image acquisition with a minimal interval between sequential images. To optimise acquisition, parameters such as image resolution, the number of *z* frames, intervals between frames, light intensity, and exposure time can be varied. In all cases, it is of utmost importance to minimise and monitor laser- or light-induced damage to the organism during imaging, in part by comparing the time required for one division cycle in imaged and nonimaged cells.

Cell Cycle Determination

As position and mobility of a chromosomal locus can vary with stages of the cell cycle, it is crucial to determine precisely what stage each imaged cell is in. This is done by monitoring bud presence and bud size, as well as the shape and position of the nucleus, as visualised by the Nup49-GFP fusion and a transmission or phase image. Figure 3 summarises the morphologies that characterise each stage of the cell cycle.

2. Wide-Field Microscopy and Deconvolution

For the imaging of large fields of cells, best results are obtained with a wide-field microscope equipped with **a PIFOC**, Xenon light source, and monochromator that allows a broad and continuous range of incident light wavelengths, as well as rapid switching between these values. Images are acquired by a high-speed monochrome CCD camera run by a rapid imaging software, such as Metamorph. The limiting step is often the speed of signal transfer from the CCD chip to the RAM and/or hard disk of your computer.

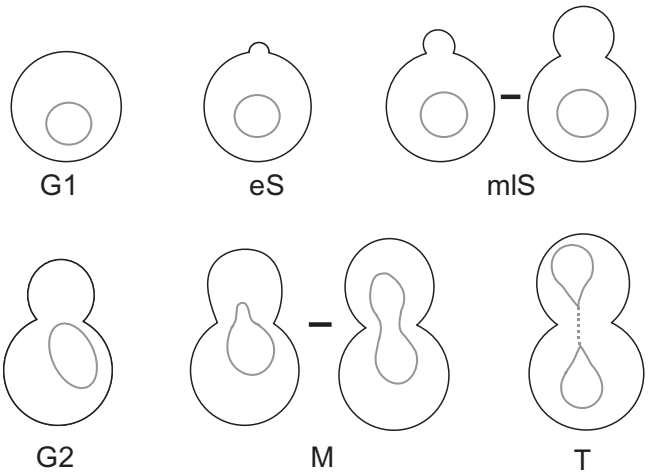

FIGURE 3 Diagrams of a budding yeast cell at different characteristic points in the cell division cycle. The following criteria are used to identify the indicated stage. *G1 phase*, unbudded cells with round nuclei or attached pairs of posttelophase cells that have two round, clearly separated nuclei; *early S*, with initial bud emergence, cells are in early S; *mid-to-late S*, cells with a bud big enough to form a ring at the bud neck, in which nuclei are still round and centred in the mother cell; *G2 phase*, large budded cells (bud ≥ two-thirds of mother) with the nucleus at the bud neck; *mitosis (M)*, large budded cells in which the nucleus extends into the daughter cell due to spindle extension; *telophase (T)*, two globular cells with two distinct nuclei that remain connected by residual NE structures.

z-Stacks

Wide-field microscopy is well adapted to experiments in which a large number of cells (200–300) need to be scored, e.g., when determining the subnuclear position of a given locus relative to the nuclear envelope or another tagged locus or landmark (e.g., spindle pole body or nucleolus). The reference point should optimally be tagged with a different fluorescent protein. If two loci bind the same fluorescent fusion proteins, then their intensities should be significantly different. Rapid through-focus stacks of images using the full chip capacity of the camera are taken of cells growing on agar or in a Ludin chamber (such that 20–30 individual cells are resolved per field). Optimal parameters for GFP are as follows: exposure time, 100–200 ms; *z* spacing of 200 nm for 18 focal planes, excitation wavelength 475 nm. For dual-wavelength capture, images of both wavelengths (CFP: 432 nm, ~300 ms; YFP: 514 nm, ~150 ms) must be acquired before the focal plane changes. A phase image is taken after every stack of fluorescence images. Wide-field images have out-of-focus haze and deconvolution of the *z* stack is often necessary to reassign blurred intensities back to their

original source. Use Metamorph software or other available deconvolution packages.

Three-Dimensional Time Lapse

The conditions for capturing 3D time-lapse series are as follows: 5–11 optical *z* slices taken every 1 to 4 min, *z* sections are 200 to 400 nm in depth, and the exposure time is ~50 ms. Using these settings, up to 300 stacks of five sections each (1500 frames) at 1-min intervals can be captured without affecting cell cycle progression. More rapid sampling with this system, however, leads to bleaching and potential cellular damage. Until this can be remedied by more rapid and more sensitive CCD cameras, wide-field microscopy is recommended for less rapid time-lapse imaging (intervals ≥60 s) on larger fields and confocal microscopy (see later) for very rapid time-lapse imaging (intervals ≤2 s) on small regions of interest (typically one yeast nucleus).

For very long imaging times (>1 h), stray light should be suppressed by inserting an additional shutter. Deconvolution is performed using the Metamorph fast algorithm with five iterations, a sigma parameter of 0.7, and a frequency of 4.

3. Confocal Microscopy

To follow chromatin dynamics in individual cells with rapid time-lapse microscopy, the Zeiss LSM510 scanning confocal microscope is particularly well adapted, although the laser and acousto-optic tuneable filter (AOTF) system is limited in activation wavelengths. Its positive attributes are an ability to limit scanhead motion to a minimal region of interest (ROI), rapid and well-regulated scanning speeds, and the possibility to adjust pinhole aperture and laser intensities to very low levels, while maintaining maximal sensitivity.

General Settings

To reduce the risk of damage by illumination, the laser transmission is kept as low as possible, and the cells are imaged as rapidly as possible within a minimal ROI. Useful settings for the Zeiss LSM510 are as follows.

Laser: argon/2 458, 488, or 514 nm tube current 4,7 amp. Output 25%.

Filters: Channel 1: Lp 505 for GFP alone; channel 1 Lp 530, channel 3 Bp 470–500 for YFP/CFP single track acquisition.

Channel setting: Pinhole 1–1.2 airy unit (corresponding to optical slice of 700 to 900 nm); detector gain: 930 to 999; amplifier gain: 1–1.5; amplifier offset: 0.2–0.1 V; laser transmission AOTF = 0.1–1% for GFP alone, 1–15% for YFP, and 10–50% for CFP in single track acquisition. In order to use minimal laser transmission the pinhole must be aligned regularly.

Scan setting: Speed 10 (0.88 µs/pixel); 8 bits one scan direction; 4 average/mean/line; zoom 1.8 (pixel size: 100 × 100 nm)

Imaging intervals: 1.5 s

Note: If CFP and YFP signals are very weak, images can be acquired sequentially using the more sensitive LSM 510 channel 1 in multitrack mode. This allows the use of broader filters: long-pass filter Lp 475 for CFP and Lp 530 for YFP. Alternatively, and to avoid any cross talk, recover the YFP signal as before and use Bp 470–500 on channel 3 for CFP. These latter parameters will slow the imaging process.

Two- or Three-Dimensional Time Lapse

If maximal capture speed is desired, only one image per time point can be taken, as long as the GFP spot stays in the imaged plane of focus (called 2D time lapse). Often the plane of focus has to be changed manually to follow the spot. Image acquisition in 3D has two main advantages. (1) The GFP spot does not have to be followed manually as it is always present in one of the focal planes. A subsequent maximal projection along the *z* axis produces a complete 2D time sequence without loss of focus on the GFP spot. (2) After image reconstruction, one can visualise the nucleus and calculate distances in 3D. Such measurements are nonetheless compromised by the reduced optical resolution in *z* (≥0.5 µm for 488-nm light).

Specific 3D time-lapse settings are as follows: six to eight optical slices in *z*, 300- to 450-nm spacing in *z* with Hyperfine HRZ 200 motor using a ROI of 3 × 3 to 4 × 4 µm and time intervals of 1.5 s. A 12-min time-lapse series at 0.2% laser transmission did not influence cell cycle progression.

C. Image Analysis

1. z Stacks

Determination of the subnuclear position of a GFP-tagged locus is monitored relative to the centre of the Nup49-GFP ring. Nuclei in which the tagged locus is at the very top or bottom of the nucleus are not scored because the pore signal no longer forms a ring but a surface and a peripheral spot will appear internal.

1. Measure the distance from the centre of intensity of the GFP spot to the nearest pore signal along the nuclear diameter, as well as the nuclear diameter itself, using the middle of the GFP-Nup49 ring as the periphery (Fig. 4). Several programs can export coordinates

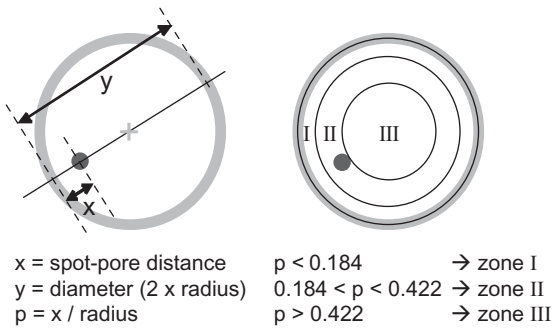

FIGURE 4 Analysis of DNA locus position. Relative locus position is calculated by normalising measured distance × by the radius (0.5 × measured distance *y*). The relative radial distances can then be classified and attributed to three groups of equal surface. The peripheral zone (zone I) is a ring of width = 0.184 × the nuclear radius (*r*). Zone II lies between 0.184 and 0.422*r*, and zone III is the centre of the nucleus with radius = 0.578*r*. In a predicted random distribution every group would contain one-third of the cells.

of points of interest, and the publicly available point picker plug in for ImageJ (Rasband) is useful.

2. Calculate the distances/diameter ratio, e.g., using Excel. Determine the precise relative radial position by dividing the distance between pore and the spot by half of the calculated diameter, thus normalising distances.

3. Classify the position of each spot with respect to three concentric zones of equal surface (Fig. 4). The peripheral zone (zone I) is a ring of width = 0.184 × the nuclear radius (*r*). Zone II lies between 0.184 and 0.422*r* and zone III is the core of the nucleus with radius = 0.578*r*. The three zones are of equal surface no matter where the nuclear cross section is taken.

4. Compare the measured distribution to another (e.g., other cell cycle phase, another condition or a random distribution) with a χ^2 analysis. If only percentages of one zone (e.g., the outermost zone) are compared for different conditions (or to a random distribution), a proportional test should be applied. Statistical significance is determined using a 95% confidence interval.

2. *Three-Dimensional Time Lapse Locus Tracking*

A prerequisite for the precise description of chromatin movement is the knowledge of the coordinates of the locus and of the nuclear centre for each frame of a time-lapse movie. In collaboration with D. Sage and M. Unser (Swiss Federal Institute of Technology, Lausanne), a best-fit algorithm has been developed that reliably tracks a moving spot in 2D time-lapse movies or in maximal projections of *z* stacks in 3D time lapse using nuclei carrying Nup49-GFP or expressing *tetR*-GFP to detect the nucleoplasmic signal. This system is complete and dramatically improves reproducibility and the speed of analysis, while allowing user intervention at several stages. The algorithm has been implemented as a Java plug in for the public domain ImageJ software (Rasband; Sage *et al*., 2003). The spatiotemporal trajectory is exported as *x*,*y* coordinates for each time point in a spreadsheet. An implementation for 3D image stacks over time is also available (Sage et al, 2005). Automated image analysis requires three steps.

a. Alignment phase. The first step is an alignment module that compensates for the translational movement of the nucleus, cell, or microscope stage. This is achieved by a modifiable threshold on the image. The extracted points are then fitted within an ellipse using the least-squares method. Finally, each image is realigned automatically with respect to the centre of the ellipse.

b. Preprocessing phase. To facilitate the detection of the tagged locus, the images are convolved with a Mexican-hat filter. This preprocessing compensates for background variations and enhances small spot-like structures.

c. Tracking phase. The final step is the tracking algorithm. Using dynamic programming, which takes advantage of the strong dependency of the spot position in one frame on its position in the next, the optimal trajectory over the entire period of the movie is determined. The following three criteria influence spot recognition: (1) maximum intensity (i.e., the tagged DNA is usually brighter than the pore signal), (2) smoothness of trajectory, and (3) position relative to the nuclear centre. This latter criterion is necessary because Nup49-GFP staining can be confused with a weak perinuclear locus. All three parameters can be modulated individually in order to optimise the tracking for different situations (loci that are more mobile, more peripheral, of variable intensity, etc). Most importantly, the program has the option of further constraining the optimisation by forcing the trajectory to pass through a manually defined pixel. In that way mistracked spots can again be added manually to the correct trajectory, which is recalculated quasi-instantaneously. This tracking method proves to be extremely robust and reproducible due to its global approach.

Note: Some commercially available software are also able to track objects [e.g., Imaris (Bitplane), Volocity (Improvision)], although tracking efficiency is variable and usually requires uniformly high-quality images. The algorithms are mostly based on threshold principles, which are rarely modifiable or interactive, and which are ill-suited for noisy images.

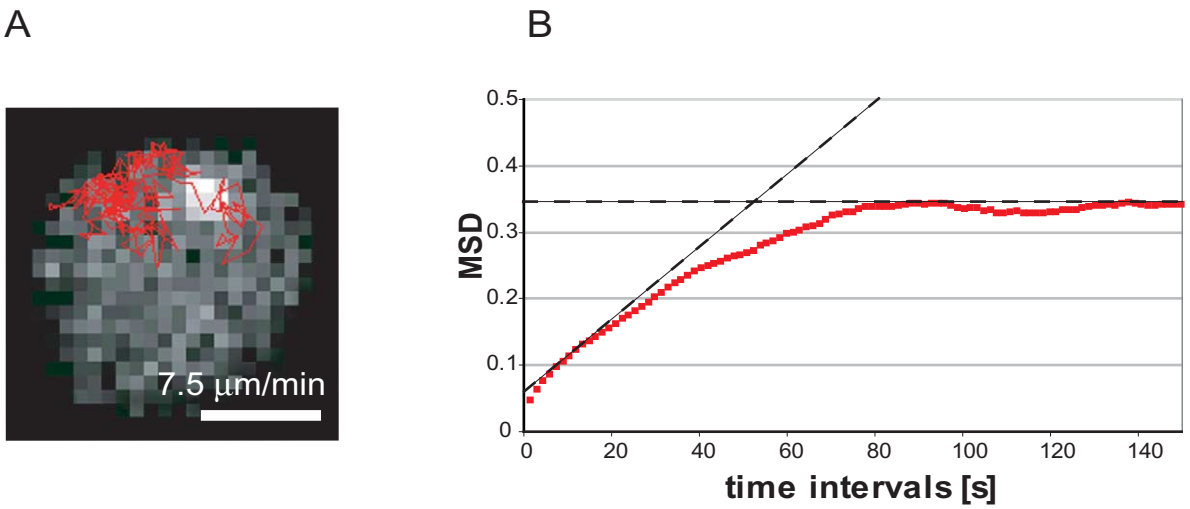

FIGURE 5 Analysis of DNA locus dynamics. (**A**) The projected trace of 300 images of a movie of the *LYS2* locus. The average track length in 5 min is 37.4 µm. Bar: 1 µm. (**B**) A mean square displacement (MSD, $\langle \Delta d^2 \rangle$ in [µm^2]) analysis on an average of 8 movies of the *LYS2* locus. All cells were observed in G1 phase.

Characterisation of Movement

Because each time-lapse series represents a single cell, it is indispensable to average 8–10 movies over a total time >40 min for a given strain or condition. Subtle differences require a larger data source. Useful parameters for quantitative analysis include the following.

a. Track length. The projected track of the tagged locus can be visualised using LSM software, ImageJ, Excel, or other programs (Fig. 5A). The sum of all 1.5-s step lengths within a time-lapse series yields the total track length of that movie. From this, average track length and velocity (µm/min) can be calculated, but often this parameter is not very revealing.

b. Step size. A histogram of step size distribution describes the nature of the movement more precisely. Statistical parameters such as mean, median, and standard deviation of individual and groups of movies can be calculated and compared with statistical tests (e.g., ANOVA). Even small but reproducible significant differences can be documented due to the large number of measurements.

c. Large movements. Often differences in mobility are not obvious by comparing average speed, yet the frequency of large steps >500 nm will vary significantly. These indicate transient high velocity movements. We generally score for steps larger than 500 nm during seven frames (10.5 s), an interval that has proven useful for distinguishing patterns of mobility between different physiological states and stages of the cell cycle (Heun *et al.*, 2001b). These are reported as the number of large steps per 10 min, averaged over at least 50 min of time-lapse imaging. Although a 500 nm is a meaningful cutoff, any threshold over 300 nm can be used.

d. Mean square displacement (MSD). Observing the movement of a DNA locus over time not only gives information about its velocity, but also about the subvolume of the nucleus that it occupies during a given period of time. It has been shown for several chromosomal loci that chromosomal domains are able to move apparently randomly in a given subvolume (Gasser, 2002). This constraint can be quantified by MSD analysis, assuming that the movement of the spot follows a random walk. Ideally it describes a linear relationship between different time intervals and the square of the distance travelled by a particle during this period of time (MSD or $\langle \Delta d^2 \rangle$, where $\Delta d^2 = \{d(t) - d(t + \Delta t)\}^2$ (Berg, 1993; Marshall *et al.*, 1997; Vazquez *et al.*, 2001). In order to get the numbers, one must calculate the distances travelled by the spot for each time interval (1.5, 3, 4.5 s . . .) and plot the square of the mean against increasing time intervals. These calculations and the corresponding graphs can be performed easily in Excel (Microsoft) or Mathematica (Wolfram Research). A representative MSD graph is shown in Fig. 5B. In these curves, the slope reflects the diffusion coefficient of the particle, and the linearity of the curve is usually lost at larger time intervals due to spatial constraint on the freedom of movement of the locus, i.e., the random walk of the particle is obstructed by the nuclear envelope or other subnuclear constraints, leading to a plateau (horizontal dashed line in Fig. 5B). The height of this plateau is related to the volume in which the particle is restricted. The slope of the MSD relation is directly correlated with diffusion coefficient. As

explained earlier, in enclosed systems, the diffusion coefficient decreases with increasing Δt due to space constraints exerted on the particle dynamics. Nevertheless, the maximal diffusion coefficient can be calculated for very short time intervals and reflects the intrinsic mobility of particles (see sloping dashed line in Fig. 5B). For chromosomal loci in yeast, we observed a maximal diffusion coefficient in the range of 1×10^{-4} to $1 \times 10^{-3} \mu m^2/s$ based on short time intervals. If distances are measured between two separate moving loci, $\langle \Delta d^2 \rangle$ reflects two times the MSD of an individual spot or locus moving relative to a fixed point (Vazquez *et al*., 2001). A more theoretical discussion of these parameters is found in Berg (1993).

IV. COMMENTS

It is very difficult to accurately quantify the intensity of a small, mobile GFP-lac^i focus. Even in deconvolved images it can differ by twofold in sequential images.

This protocol shows the optimal method for the described microscope setups. For different microscopes, the values and methods of this protocol are simply a starting point for further optimisation. As improvements in technology (e.g., more sensitive and rapid CCD cameras) and reagents (e.g., more stable or more intense GFP variants) evolve, future adjustments of this protocol will be indispensable.

The method described here can also be applied to *Schizosaccharomyces pombe* with a few changes, one being immobilisation on a coverslip with isolectin B (1 mg/ml) (Williams *et al*., 2002) or lectin from *Bandeiraea simplicifolia* (lyophilized powder, Sigma Cat. No. L2380).

V. PITFALLS

1. To ensure that DNA movements are not the result of nuclear rotation, fluorescence recovery after photobleaching on GFP nuclear pore components should be performed over the same time intervals used to monitor DNA movement.

2. To increase oxygen concentration and to prevent massive production of CO_2 under the cover slide, vortex the agarose/medium before making the patch.

3. Growth conditions must be standardised thoroughly, because both choice of carbon source and its concentration significantly influence subnuclear position and dynamics of tagged loci.

4. Cells grown in minimal medium may not pellet as well as cells grown in YPD. Concentrate cells by centrifuging 2 volumes of culture in the same 1.5-ml tube.

5. In the Ludin chamber yeast cells often bud upwards into the medium (i.e., parallel to the optical axis). Thus it is important to scan the entire cell in transmission mode not to miss the presence of a bud.

6. Observations made on individual cells are often not representative of entire populations. It is crucial to verify observed differences with the appropriate statistical tests.

Assays and Models of *in vitro* and *in vivo* Motility

CHAPTER

47

Microtubule Motility Assays

N. J. Carter and Robert A. Cross

I. INTRODUCTION

As the pivotal role of microtubule (MT) motors in the cell cycle becomes more widely recognized, so the demand for motility assays will increase. This article presents a robust and straightforward set of protocols based on experience gained in our laboratory. Readers seeking to set up more specialised assays should refer to one of the excellent methodological compendia that are available (Inoue and Spring, 1997; Cross and Kendrick Jones, 1991; Scholey, 1993).

II. MATERIALS AND INSTRUMENTATION

A. Hardware

1. Microscope

Unstained MTs are visualized most conveniently by video microscopy using computer-enhanced differential interference contrast (DIC). MTs assembled from fluorescently labeled tubulin can be visualized using epifluorescence. This article concentrates on these two contrast modes. It is also possible to visualise microtubules by dark field, which gives a high contrast image of unstained microtubules, or by phase contrast, but both modes are susceptible to dirt in the solutions and so may be inconvenient for routine work. Interference reflection produces higher contrast than DIC and gives information in the *Z* direction, but again is susceptible to dirt.

For all modes of contrast the main requirement of the microscope is that it should be as simple as possible. It should also be big and heavy to give it some vibration resistance. Uprights are less expensive, optically straightforward, and more convenient if the bathing solution is to be exchanged during observation (which is often the case). Inverted scopes are more stable and provide much better access to the specimen if other inputs (micromanipulators, flash-photolytic lasers, evanescence prisms) are envisioned.

Human eyes work in colour and have a higher dynamic range, better spatial resolution, and a bigger view field than a video camera. It is very useful to be able to use them to find focus. To do this the microscope needs to incorporate some sort of device to switch the light between the eyepieces and the camera.

2. Illumination

One hundred Watt Hg lamps generate large amounts of heat and it is necessary to remove this heat from the illuminating light. Glass heat filters may be used, but the best way to filter out heat is to use a hot mirror, a mirror that transmits infrared but reflects visible light (technical video).

DIC optics are optimised for visible wavelengths, and it is conventional to use a green interference filter to give narrow band illumination. In practice the improvement this brings is often too slight to be obvious by eye, and removing the green filter can be a convenient way to brighter illumination. The UV emitted by Hg lamps is removed substantially removed by optical (lead) glass, but for DIC an in-line UV filter is nonetheless a sensible precaution.

A useful improvement in both fluorescence and DIC image quality can be achieved by sending the illuminating light through a fibre-optic light scrambler (Technical Video). Light from the lamp is focussed into one end of the fibre (Fig. 1), and the other end emits a

uniform disc of light (of Gaussian intensity profile), which is used to illuminate the microscope.

3. Optical Train

For maximum image quality in all contrast modes, it is advisable to reduce the number of optical components between the objective and the camera to a minimum. The most critical component is the objective. The light intensity transmitted by a lens is proportional to the square of its numerical aperture (NA), whilst resolution rises linearly with the NA. It is important therefore to use a 1.4 NA (therefore oil immersion) 60 or 100× planapo objective in order to maximise light-gathering power and resolution, particularly so in epifluorescence, where the objective doubles as the condensor.

We use a novel configuration that replaces the condensor on a Zeiss Axiovert with a home-built fitting that improves light collection from the Zeiss tungsten lamp and mounts a second objective in place of the condensor. This arrangement (Fig. 1) gives good MT DIC with a field about 40 µm and brings the considerable advantages of the tungsten lamp, which is much more stable than the Hg lamp. For smaller view fields, the higher radiant intensity of the Hg lamp is necessary.

4. Antivibration Hardware

Vibration will degrade the highly magnified image. Low frequencies (people walking across the floor) will cause the image to bounce around, whilst high frequencies will be averaged out by the video framing rate and cause the image to blur. The extent of this problem is, however, often overemphasized. Before purchasing an expensive and awkward vibration-damping equipment, try placing a few layers of bubble wrap under the microscope baseplate.

5. Temperature Control Hardware

Motility rates for several motors are extremely temperature sensitive in the range of room temperature, and temperature control is consequently important if

measurements taken at different times are to be compared. The best way is to temperature clamp the entire microscope. If you have air conditioning this will already be happening. To warm specimens above ambient temperature, we use a homemade plexiglass box with a warm-air blower coupled to the side. Another option is to use water jackets for the objective and stage. These are readily fashioned by wrapping flexible, narrow-bore copper tubing around several times and connecting the ends to a water bath with a circulator (e.g., Techne) using silicon tubing. If cooling is necessary, we find it useful to wrap the microscope in a tent made of cling film, reducing condensation.

6. Camera

For fluorescence of moving objects, two types of low-light level / high-contrast / high-framing rate cameras are suitable: intensified charge-coupled device (ICCD) and intensified silicon-intensified tube (ISIT) cameras. ICCD cameras are better for current purposes because ISIT cameras, although more sensitive, introduce spatial and intensity distortions across the view field that are tedious to correct for. All the aforementioned produce an analogue video signal, e.g., ISIT Hamamatsu C2400-08 and ICCD Hamamatsu C2400-97E. An alternative approach that is becoming feasible uses a digital camera to record direct to computer hard disc in time lapse. A cooled CCD camera coupled to a generation 4 intensifier gives excellent sensitivity for fluorescence work, but is limited by the quantum efficiency of the intensifier (about 30%) and is currently very expensive and the digital data can be awkward to archive. If considering this route, be sure to test the software, which in our experience can place more severe limits on performance than the specifications of the hardware.

For DIC, a nonintensified scientific grade CCD is fine, e.g., grey-scale CCD camera Hamamatsu C2400 77e.

7. Camera Coupling/Magnification

The ideal magnification sets four or more camera pixels across the width of the MT. For a 512×512 pixels (2/3 in.) CCD, this corresponds to a square field with sides of 20–25 μm. Zoom couplings are wonderfully convenient but are not always a good idea because they absorb a lot of light. Magnification must be calibrated using a stage micrometer.

8. Image Processor

CCD cameras are often offered with a hardware box providing real time analogue enhancement of the video signal (any or all of gain, back-off and shading correction). A digital video processor is better, which is able to digitise incoming video frames, perform frame averaging, contrast enhancement, background subtraction, and caption overlay and then re-encode the image as an analogue video signal, all in real time. The Hamamatsu Argus 20 is so well thought out that it is virtually standard equipment for video microscopy laboratories. The best and most flexible arrangement is to adjust the gain and backoff on an Argus 20 or similar processor controls such that there are no areas in the image that are completely saturated and then apply further digital enhancement. The resulting signal is displayed on a monitor and is fed to the PC for direct grabbing of video clips and to the VCR for archiving.

9. Monitor

It is worth investing in a high-quality 14-in. multiformat monitor. Larger monitors look impressive but are only helpful if they have to be placed a long distance from the operator.

10. Video Recording

At the time of writing, the most convenient and practical way to store large amounts of video is still to use video tape. Recording to VCRs inevitably involves some degradation of the image (loss of spatial resolution, noise, contrast effects). For practical purposes the resolution loss is potentially the most serious problem. The effective resolution following recording can be visualised by recording and replaying a test card image having black and white lines at various spatial frequencies. Currently the best option is digital recording to video tape. Digital video tape recorders input and output an analogue signal, but encode data digitally to tape. The digitization involves some compression of the incoming video signal, but most of the compression is on the chrominance rather than the luminance, with the result that spatial information is relatively well preserved, particularly for grey-scale signals. Unlike other compression schemes such as DVD, there is no compression along the temporal axis. There are currently two sizes of tape: digital video (DV) and mini-DV. There are also two different formats: DVCAM (Sony) and DVCPRO (Panasonic). These two formats use the same compression scheme but DVCPRO spaces the tracks further apart on the tape, giving (arguably) better reliability and accuracy for editing, but with correspondingly less recording time on the tapes. Digital video recorders tend to be built for the pro market and are more robustly engineered than consumer machines, but are also more expensive.

We have evolved a video-recording strategy that offers maximum flexibility: Time-lapse digital

recording of grabbed video frames to computer hard disc (with no resolution loss) and simultaneous real-time recording to digital VCR. The VCR runs uninterrupted in the background and generates an archive. The operator is free to go back to this archive at a later date and transfer interesting sequences to the computer for analysis. Captured digital sequences can be archived to external hard discs. We now have a fast digital capture and analysis application RETRAC II, which allows batch digitisation of video clips from tape for subsequent analysis. RETRAC II can be downloaded from our website (http://mc11.mcri.ac.uk/Retrac/index.html).

Analogue video recording is still in widespread use. Different video formats unfortunately operate in different countries. In the United States and Japan, NTSC format applies (525 lines per frame; 30 frames/s, typically captured at 640 × 480 pixels). European countries use PAL, which has higher spatial resolution but lower time resolution (625 lines per frame, 25 frames per sec, typically captured at 768 × 576 pixels).

11. Computing

The most convenient way to analyse motility is to capture a sequence of frames into computer memory and to track objects using a mouse-driven cursor. It helps to have a hard disc big enough to hold 2 day's work (more is dangerous because of the temptation not to back up) and enough hard memory to hold the stack of captured frames. A typical 20 frame stack uses about 8 Mb of application memory; if you want to use larger stacks then you need more memory. Processed stacks can conveniently be archived to removable discs. We use 100-Mb zip discs or 230-Mb magneto-optical discs. CD writers are getting less expensive and are worth considering if a permanent archive is required. Video compression protocols (JPEG, MPEG) are best avoided, as all involve some data loss. That said, Quicktime has become a standard for digital video and can use a variety of compressors, some of which are lossless.

12. Frame Grabber Card

Large numbers of video grabbing cards are available. Only a few are supported by Retrac and NIH Image, the freeware software packages that are recommend later. Because the situation is fluid, please check the software documentation for a list of supported cards.

13. Software

On the Mac, the best route for analysis is NIH Image, which can be customised using macros to track objects and output data in spreadsheet-compatible format. Macros for basic tracking through NIH Image stacks are available for download from our web page http://mc11.mcri.ac.uk/retrac.html. NIH Image runs on system 9 macs, with support for the Scion LG3 frame capture board, or in classic in OSX but without the Scion support. Wayne Rasband is continuing development of ImageJ, an NIH image—inspired java programme that runs in OSX and currently has partial support for the LG3 board (http://rsb.info.nih.gov/ij/). NIH Image and ImageJ are both available for the PC.

RETRAC 2 for Windows is purpose-written for the analysis of motility assay data. The latest version supports time-lapse frame grabbing from either VCR or live video, autofocus, autocontrast, tracking (including drift correction) spatial filtration, and magnification. The programme now incorporates a powerful file manager. Figure 2 shows a screenshot during tracking.

14. Glassware

The type of slide used does not matter. The type of coverslip does. The thickness of the coverslip should be matched to the objective. The objective will be marked appropriately [e.g., 60/planapo DIC 1.4 0.17/160 means a 60× objective selected as strain free for DIC, aplanatic (flat field); apochromatic (low chromatic aberration for blue yellow and green); optimised for cover glasses 0.17 mm thick and with a 160-mm focal length]. We use Chance 22 × 22-mm No.1.5 coverslips. In the past we have used these without any special cleaning treatment and rejected "bad" batches of coverslips that show poor binding of motor and/or a poor image because of surface contamination. This is still a workable approach, but we have begun to use a cleaning procedure that appears effective in removing contamination and making the coverslip reproducibly hydrophilic, as evidenced by the spreading of a drop of buffer placed on the surface so that it wets the entire surface. This coverslip cleaning procedure is based heavily on that given on the Technical Video website (http://www.technicalvideo.com/Products/CCP.html). Our localized variant is on our website (http://mc11.mcri.ac.uk/protocols.html).

III. PROCEDURES

A. Taxol-Stabilised Microtubules

Solutions

1. *1 M K–PIPES:* PIPES dissolves around its isoelectric point of about pH 6.5. Take 500 ml water, add 65 g solid KOH, and then, after cooling if necessary, slowly add 302 g PIPES buffer (Sigma P-6757). Once everything is dissolved, monitor pH and roughly adjust by

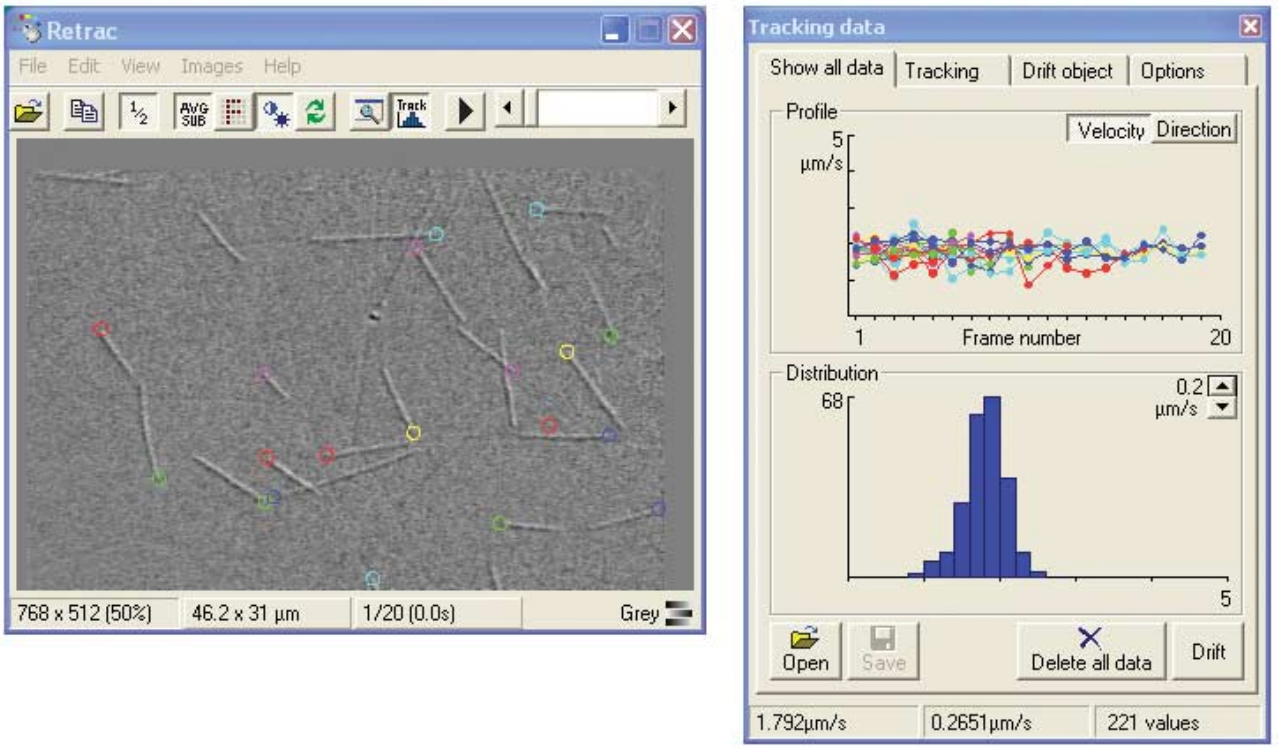

FIGURE 2 A screenshot from RETRAC 2.

adding more KOH pellets as necessary. Allow the warm solution to cool and then fine-adjust pH using 5 *M* KOH. Be careful not to overshoot, as there is no way back.

2. *100 mM NaGTP stock solution:* Because nucleoside triphosphates such as GTP and ATP undergo rapid hydrolysis at acidic pH, efforts should be made to control pH when dissolving and storing them. Dissolve 1 g NaGTP (Sigma G8877) in 15 ml 10 m*M* Na-PIPES, pH 6.9, monitoring pH. Rapidly reneutralise pH by titrating in 5 *M* KOH. Fine adjust pH and then make volume up to 19.11 ml. Store frozen at –20°C in aliquots of 5–2000 µl. Do not add $MgCl_2$ to the stock solution (it precipitates).

3. *100 mM MgATP stock solution:* Dissolve 5.87 g NaATP (Sigma A7699 ATP ultra or Boehringer 519 987) in 60 ml 10 m*M* K-PIPES, pH 6.9, monitoring pH continuously and holding as close as possible to neutral using concentrated KOH. Once the ATP is dissolved, add 10 ml of 1 *M* $MgCl_2$ and readjust pH to 6.9. Adjust volume to 100.0 ml and freeze in aliquots of 5–5000 µl.

4. *Taxol stock solution:* Wear gloves and work in the fume hood. Inject 2.93 ml anhydrous dimethyl sulfoxide (DMSO, Aldrich 27685-5) into a 25-mg bottle of taxol (Sigma T 7402). Dissolve by vortexing and store as 2- to 20-µl aliquots at –20°C. Taxol is stable in DMSO but unstable in water. It is insoluble in aqueous buffers above about 18 µ*M*. DMSO is explosive if it gets wet. Store small volumes at room temperature over beds of Sephadex G-50.

5. *0.2 M NaEGTA:* Dissolve 15.2 g EGTA (Sigma E 4378) in 190 ml water. Adjust pH to neutral by adding concentrated NaOH and then make volume to 200.0 ml. Store at room temperature.

6. *1 M* $MgCl_2$: 20.33 g $MgCl_2 \cdot 6H_2O$ to 100 ml water. Sterile filter and store at room temperature.

7. *BRB 80 (Brinkley reassembly buffer):* 80 m*M* K-PIPES, 1 m*M* $MgCl_2$, 1 m*M* EGTA, pH 6.9. Make up as a 10× stock, store at 4°C, and dilute freshly for use.

Purified tubulin at about 100 µ*M* (protocol for tubulin preparation on our web page) in BRB80 should be flash frozen in 10- to 25-µl aliquots in the presence of 30% glycerol by immersion in liquid nitrogen and stored either at –70°C or preferably in liquid nitrogen.

Steps

1. Thaw an aliquot of tubulin (typically 200 µ*M*) and add stock 100 m*M* NaGTP to 1 m*M* and $MgCl_2$ to 2 m*M*. Warm to 37°C and incubate for 20 min.
2. After 20 min, add taxol from a 10 m*M* stock in DMSO to 20 µ*M* final. Dilute microtubules 1000-fold for use using BRB80 buffer supplemented with 20 µ*M* taxol.

B. Preparation of Flow Cells

Steps

1. Apply single-sided Scotch tape to the long edges of a microscope slide such that the strip of glass surface between the two pieces of tape is 8–10 mm wide. Trim away overhangs with a razor blade.

2. Extrude two parallel stripes of Apiezon M grease from a syringe with a squared-off wide-bore needle along the inner edges of the tape strips.

3. Press a clean coverslip onto the grease. The volume of the flow cell can be adjusted by spacing the grease strips apart and/or by placing spacers between the coverslip and the slide. Single-sided Scotch magic tape is about 50 µm thick, giving a flow cell of about 10 mm × 5 mm × 50 µm, or 25 µl. Thinner metal or cellophane foils can be used to make a shallower flow cell and conserve sample. It is helpful to make the flow cell shallow because the microtubules below the top surface scatter light and reduce contrast. For inverted scopes, it is convenient to arrange flow crosswise. The inset to Fig. 1 illustrates flow cells for inverted (A) and upright (B) microscopes.

C. Surface Adsorption of Motor

Solutions

1. *Motility buffer:* BRB 80 plus 1 m*M* MgATP. For fluorescence work only, degas and add 1% of 100× antibleach mix (GOC), which is 100 mg/ml glucose oxidase (Sigma G7016), 18 mg/ml catalase (Sigma C100), and 300 mg/ml glucose (Sigma G7528) in BRB80 plus 50% glycerol. When aliquoting, fill tubes to exclude oxygen, cap, and store at –20°C.

2. *100× diluted MTs:* either motility buffer or motility buffer plus GOC.

Steps

1. Place the flow cell flat. Using a Gilson, inject into the cell 1 chamber volume of motor solution. The solution is drawn into the cell by capillarity. Incubate the slide in a moisture chamber for 2–5 min at 20°C to allow the motor to adsorb to the glass.

2. Wash the cell with 2 chamber volumes of assay buffer, applying the solution to one side of the chamber using a micropipette and drawing the solution gently through the cell using the capillary action of the torn edge of a strip of Whatman 3 MM, placed at the exit of the chamber.

3. Flow in 1 volume of MTs in motility buffer + taxol and mount the slide on the microscope stage, oiling the condensor to the bottom of the slide (it may be possible to use a dry condensor for quick-and-dirty assays).

4. Extra for fluorescence work 1. Degas some BRB80. To 10 ml, add 100 µl of 100× GOC. Take another 3 ml and add MgATP to 2 m*M*. Fill and cap tubes to exclude oxygen and hold buffers on ice. Add taxol to 20 µ*M* freshly before use.

D. Microscope Setup

1. DIC

Before the day's work, align the microscope roughly using a test specimen (a slide made using a suspension of plastic beads provides a stable and realistic test specimen). Switch on the lamp and allow a few minutes for the arc to stabilise. Rack down the objective and oil it to the slide. Insert some neutral density filtration to protect your eyes from the intensely bright light, focus roughly on the top surface of the grease at the edge of the chamber, and then drive the stage to centre the sample below the objective. Find some beads attached to the undersurface of the coverslip. Open the condensor aperture and close the field aperture. Obtain Koehler illumination by focussing and centring the condensor so that a sharp image of the field diaphragm appears in the view field. Open the field diaphragm again and adjust DIC sliders close to extinction.

Focussing on MTs in the experimental flow cell is also best done using the grease surface as a guide. Focus as described earlier and then remove neutral density filters and switch in the video system. Adjust fine focus to image the surface. Adjust light intensity to almost saturate the camera (this is the point where signal to noise is maximal). With the contrast on the Argus set to maximum, microtubules should be visible without background subtraction. Defocus slightly, collect a background image, and subtract. Microtubules should now be clearly visible.

2. Epifluorescence

A test sample of multispectral fluorescent beads is very useful (Molecular Probes multispeck M-7900). Switch on the arc lamp and allow a few minutes for the arc to stabilise. Once the lamp is stable, align the microscope for epifluorescence: Remove an objective and place a piece of paper on the stage. Inset some neutral density filtration. Close the field diaphragm slightly and focus and centre the image of the lamp filament that appears on the paper. Replace the objective.

Focussing on microtubules in the experimental cell is much easier with dark-adapted eyes. Using the full intensity of the mercury lamp, rack the objective down until MTs are visible, first as a dim red glow, and then as sharply defined bright red lines on a black back-

ground. Immediately reduce the illumination intensity to protect against photobleaching, switch in the intensified camera, and start recording.

E. Recording Data

The most flexible arrangement for data recording is to set up time-lapse digital recording of video frames to a computer hard disc (with no resolution loss) and simultaneous recording to VCR. The VCR runs uninterupted in the background for 3 h per tape and generates an archive. The operator is free to go back to this archive at a later date and recapture interesting sequences for analysis.

F. Analysing Data Calibration

Image a stage graticule, a slide with etched lines at 1- or 10-μm intervals (from microscope manufacturers). It is important to calibrate both in X and Y; simply rotate the camera 90°. Most systems will give a different number of pixels per micrometer in X and Y. Tracking software compensates for this effect.

The best way to track is to follow the tip of a moving microtubule: tracking the centroids, as common in cell tracking, for example, will give you the wrong answer as soon as the microtubule bends. For maximum accuracy, the time lapse between frames should be adjusted to minimise the effects of operator error when tracking using the mouse. In practice we try to collect 20 frames and adjust the time lapse so that the microtubules move across the full field (22 μm) during this time.

IV. COMMENTS

A. Archiving Data

It is very important to have a formal system for identifying every video frame on every tape. In this way there is no possibility of confusing data sets. The simplest way to do this is to time and date stamp the frames as they are generated, using the overlay feature of the Argus. As ever, keeping careful written notes also helps a lot. For complex experiments it can be useful to speak notes onto the audio track of the tape. Digital clips are archived most conveniently on external.

B. Imminent Technology

As computers get quicker, it is realistic to start recalculating images in real time. Autocontrast is one interesting possibility, whereby the pixels of each incoming frame are parsed and the look-up table is stretched to optimise contrast. It will be some time before we can dispense with the VCR. Real-time recording of uncompressed grey-scale video to disc is pushing the limits at present, but sufficiently fast sustained data transfer rates will soon be available. This is not the real problem, however. One frame of PAL video is 768 × 512 pixels, which, with 8 bit (256 greys) data, means that each frame is 384 kb. Real-time recording to hard disc fills the disc up at about 0.5 Gb per minute, and it soon becomes necessary to archive data to video tape.

C. Workstation Ergonomics

It is worth paying some attention to the ergonomics of your microscope workstation. Microscope focus, mouse, keyboard video, and contrast-adjustment electronics all need to be within easy reach of a seated operator. Screens should be visible with only a slight turn of the head. It is very helpful to have a foot switch to dim the room lights and blinds on windows.

D. Best Practice

Because of inherent uncertainties about the way a particular protein attaches to a particular glass, motility assays are at their strongest when used to measure the relative motility in different treatments of samples. It is commonly assumed that motility assays measure motor-driven microtubule sliding under zero load. It is probably more correct to assume that an unspecified, variable, (but low) load applies.

V. PITFALLS

A. Computerphilia

The most common fault in video microscopy is to overprocess an indifferent optical image. Too much processing can seriously degrade the amount of information in the image. A good primary image has high spatial resolution (sharpness), high contrast, and low background noise. Obtaining one is partly a function of specimen preparation and partly of microscope setup.

B. Lamp Intensity Fluctuates

In DIC, a troublesome problem is sudden variations in light intensity caused by the arc of the mercury lamp wandering. These are not noticeable in normal modes

of microscopy, but with electronic amplification of contrast they become annoying. The only solution is to change the lamp. Cooling the lamp using a fan may help. Mercury lamps typically need changing after 100 h, because after that their intensity drops fairly rapidly.

C. Microtubules Fishtail or Do Not Move At All

Some motor proteins bind better to the glass surface than others. Erratic motility may be due to your protein denaturing on the glass or binding in such a way that its force-generating conformational change is inhibited. Areas of uncoated glass can also bind microtubules and inhibit sliding. Increase motor concentration if possible or try infusing the motor twice over and/or reducing or eliminating the wash step prior to infusing microtubules. Including casein at 0.1–1 mg ml in the assay buffer efficiently protein coats glass. Because motor activity can also be sensitive to thiol oxidation, try including 5 m*M* DTT in your motility buffer.

CHAPTER

48

In vitro Assays for Mitotic Spindle Assembly and Function

Celia Antonio, Rebecca Heald, and Isabelle Vernos

I. INTRODUCTION

During the past two decades, cell biology has entered a phase in which technology is so powerful that fundamental questions concerning the morphogenesis and function of cellular organelles can be addressed. One essential and beautiful structure is the mitotic spindle. The work of Lohka and Maller (1985), followed by that of a few other laboratories (Murray and Kirschner, 1989; Sawin and Mitchison, 1991; Shamu and Murray, 1992), opened up a novel approach to studying such a complex and dynamic structure. The idea is not to purify individual spindle components and put them back together hoping that a spindle will assemble, it is rather to open up the cell and prepare a cytoplasmic extract as crude and concentrated as possible to keep the conditions close to the *in vivo* situation. At first sight, this approach seems uninformative: one merely mimics *in vitro* what happens *in vivo*. However, several methods have been developed to manipulate the system, such as the addition of reagents and depletion of proteins. Also the microscopy techniques have evolved and now allow the study of different aspects of spindle formation and function (Desai *et al*., 1998; Kalab *et al*., 2002). Thus, this system can be used both to analyze the mechanism of spindle assembly and function and to evaluate the role of individual molecules in the process. More methods are still being developed or improved that will increase the usage and the utility of these extracts even more.

II. MATERIALS AND INSTRUMENTATION

A. Preparation of *Xenopus laevis* Egg Extracts

Incubator at 16°C, clinical centrifuge, DuPont Sorvall RC-5 centrifuge, HB-4 or HB-6 rotor with rubber adaptors (Sorvall Cat. No. 00363), Beckman ultraclear SW50 tubes (Cat. No. 344057), Sarstedt 13-ml adaptor tubes (Cat. No. 55.518), 1-ml syringes, 18- and 27-gauge needles, glass pasteur pipettes.

Mature female frogs are from African Reptile Park. Pregnant mare serum gonadotropin (Intergonan) is from Intervet. Human chorionic gonadotropin (HCG, Cat. No. CG-10), cytochalasin D (Cat. No. C-8273), EGTA (Cat. No. E-4378), 4.9 *M* $MgCl_2$ (Cat. No. 104.20), and ATP (Cat. No. A-2383) are from Sigma. $CaCl_2$ (Cat. No. 2383), KCl (Cat. No. 1.04936.1000), NaCl (Cat. No. 1.06404.1000), and L-cysteine (Cat. No. 1.02838.1000) are from Merck. Leupeptin (Cat. No. E18) and pepstatin (Cat. No. E19) are from Chemicon. Aprotinin (Cat. No. 981532) and creatine phosphate (Cat. No. 0621714) are from Roche. HEPES is from Biomol. Sucrose is from USB (Cat. No. 21938).

B. Preparation of DNA Beads

Biotin-21-dUTP (Cat. No. 5201-1) is from Clontech. Biotin-14-dATP (Cat. No. 19524-016) is from Invitrogen. Thio-dCTP (Cat. No. 27-7360-02), thio-dGTP (27-7370-04), and G-50 gel-filtration (NICK) columns

Copyright 2006, Elsevier Science (USA).
All rights reserved.

(17-0855-01) are from Amersham Pharmacia Biotech. Restriction enzymes and Klenow (Cat. No. M02125) are from New England Biolabs. The magnetic particle concentrator (MPC) and Kilobase BINDER kit containing Dynabeads M-280 Streptavidin, washing, and binding solutions can be obtained from Dynal. Trizma base (Cat. No. T-1503) is purchased from Sigma, and EDTA (Cat. No. 1.08418.1000) is from Merck.

C. Spindle and Aster Assays

Freshly prepared CSF extract, sperm nuclei (3000/µl)(Murray, 1991), rhodamine-labelled tubulin (2–3 mg/ml) (Hyman *et al*., 1991), 76 × 26-mm microscope slides, 22 × 22-mm coverslips, fluorescence microscope. PIPES (Cat. No. P-6757), Triton X-100 (Cat. No. T-8787), glutaraldehyde (Cat. No. G-5882), $NaHB_4$ (Cat. No. S-9125), GTP (Cat. No. G-8877), and Hoechst dye (bisbenzimide, Cat. No. H33342) are from Sigma. Glycerol (Cat. No. 1.04093.2500) and formaldehyde (Cat. No. 1.04003) are from Merck. Protein A dynabeads (Cat. No. 100.02) are from Dynal. Dimethyl sulfoxide (DMSO, Cat. No. 27,685-5) is from Sigma-Aldrich, and Paclitaxel (taxol equivalent) (Cat. No. P-3456) is from Molecular Probes. For sedimentation and immunofluorescence experiments, corex tubes (15 ml) are equipped with plastic adaptors (home-made, see Evans *et al*., 1985) to support 12-mm round coverslips. The tubes are centrifuged in an HB-4 rotor containing rubber adaptors. pGEX expression vectors are from Amersham Pharmacia Biotech.

III. PROCEDURES

A. Preparation of *X. laevis* CSF Egg Extracts

Good protocols detailing the preparation of Xenopus egg extracts and sperm nuclei have already been published (Murray, 1991). We describe here only the preparation of metaphase cytostatic factor-arrested "CSF" extracts as optimized in our laboratory for spindle assembly reactions.

Solutions

1. *Pregnant mare serum gonadotropin (PMSG)*: Dissolve in sterile water to a final concentration of 200 units/ml. Store at 4°C
2. *Human chorionic gonadotropin (HCG)*: Dissolve in sterile water to a final concentration of 2000 units/ml. Store at 4°C.
3. *MMR*: 100 m*M* NaCl, 2 m*M* KCl, 1 m*M* $MgCl_2$, 2 m*M* $CaCl_2$, 0.1 m*M* EDTA, 5 m*M* HEPES, pH 7.8. Prepare a 20X MMR stock solution. Adjust pH with NaOH, autoclave, and store at room temperature. Before use make 1X MMR from the 20X stock solution and adjust pH again if necessary.
4. *Dejellying solution*: 2% L-cysteine, pH 7.8. Prepare in water and adjust pH with NaOH. Make fresh just before use.
5. *LP*: dissolve leupeptin and pepstatin in DMSO to a final concentration of 10 mg/ml. Store in 50-µl aliquots at –20°C.
6. *Aprotinin*: Dissolve in sterile water to a final concentration of 10 mg/ml. Store in 50-µl aliquots at –20°C.
7. *Cytochalasin D*: Dissolve in DMSO to a final concentration of 10 mg/ml. Store in 50-µl aliquots at –20°C.
8. *20X XB salts*: 2 *M* KCl, 20 m*M* $MgCl_2$, 2 m*M* $CaCl_2$. Filter sterilize and store at 4°C.
9. *XB*: 1X XB salts containing 50 m*M* sucrose and 10 m*M* HEPES. Adjust pH to 7.7 with KOH. Prepare fresh before use.
10. *CSF-XB*: Prepare from XB buffer by adjusting $MgCl_2$ to 2 m*M* and adding 5 m*M* EGTA. To prepare CSF-XB with protease inhibitors (CSF-XB with PI), add LP stock solutions and aprotinin to a final concentration of 10 µg/ml.
11. *Energy Mix*: 20X stock contains 150 m*M* creatine phosphate, 20 m*M* ATP, 2 m*M* EGTA, 20 m*M* $MgCl_2$. Store in 100-µl aliquots at –20°C.

Steps

1. Inject four to six frogs subcutaneously with 0.5 ml (1000 units) PMSG each using 1-ml syringes and a 27-gauge needle at least 4 days before planning to make an extract. They should be used within 2 weeks after the priming injection. The number of frogs required depends on the quantity and quality of eggs. Five milliliters of eggs (one SW50 tube) gives approximately 1 ml of extract.

2. Sixteen to 18 h before use, inject frogs subcutaneously with 0.25–0.5 ml (500–1000 units) HCG. Place the frogs in individual boxes containing 500 ml MMR at 16°C.

3. Prepare all solutions before starting collecting the eggs: 2 liters MMR, 500 ml XB, 400 ml CSF-XB, 100 ml CSF-XB with PI, and 500 ml of dejellying solution. Rinse all glassware with distilled water (eggs stick to plastic dishes). Cut off the end of a glass pasteur pipette and fire polish it to make a wide-mouth pipette.

4. Collect laid eggs in MMR. Frogs can also be squeezed, which often gives the highest quality eggs. Keep eggs from different frogs in separate batches. Discard batches of eggs containing more than 5% of lysed, ugly, or stringy eggs.

5. Wash a few times with MMR to take away skin and other detritus and remove bad eggs. Pour off MMR and add 250 ml dejellying solution. When laid, eggs are enveloped in a transparent jelly coat and do not pack closely together. Swirl the beaker frequently and change the dejellying solution. After removal of the jelly coat, eggs pack together. This takes about 5 min. Eggs left for too long in cysteine will lyse.

6. Pour off the dejellying solution and add 500 ml MMR. Repeat the rinse one more time. After removal of the jelly coat, the eggs become fragile. They lyse easily and can activate if in contact with air. They must always remain immersed in buffer. Remove all bad-looking eggs: white and puffy, flattened, or activated ones (darker pole retracted), and those with mottled pigmentation.

7. Wash three times with 100–200 ml XB.

8. Remove as much buffer as possible, keeping all eggs immersed. Wash three times with 100–200 ml CSF-XB and finally keep eggs in CSF-XB with PI.

9. Transfer eggs using the cut glass Pasteur pipette to SW50 tubes containing 1 ml CSF-XB with PI plus 3 µl cytochalasin D (30 µg/ml). Always immerse the pipette tip in solution before expelling eggs to prevent contact with air. Transfer the SW50 tubes to 13-ml Sarstedt adaptor tubes, which contain 0.5 ml of water to prevent the tubes from collapsing.

10. Centrifuge in a clinical centrifuge at 16°C at 600 *g* for 1 minute and then immediately increase the speed to 1200 *g* for an additional 30 s. After centrifugation, remove all excess buffer from the top of the packed eggs. Removal of buffer is critical to obtain a concentrated cytoplasm.

11. Place the tubes in an HB-4 or HB-6 rotor containing rubber adaptors. Centrifuge at 10,500 rpm for 15 min at 16°C to crush the eggs.

12. Place the tubes on ice. A yellow lipid layer is at the top of the tube. Underneath is the cytoplasmic layer, then heavy membranes, and yolk particles at the bottom of the tube. Wipe the sides of the tubes with a tissue before piercing with a 18-gauge needle at the bottom of the cytoplasmic layer. Slowly and carefully aspirate the cytoplasm using a 1-ml syringe with the needle opening facing upward. Remove needle from syringe and carefully expel the cytoplasm into a 1.5-ml tube. Place on ice.

13. Add LP and aprotinin to 10 µg/ml (1:1000 dilution of stocks) and cytochalasin D to 20 µg/ml (1:500 dilution of stock). Add energy mix (1:20 dilution of stock) and mix gently.

Comments on Sperm Nucleus Preparation

Based on Gurdon (1976) and modified by Murray (1991), our only modification is to mash fragments of testes between two frosted (rough) slides before filtering through a cheesecloth mesh.

B. Preparation of DNA Beads

For preparation of DNA beads, linearized couple plasmid DNA and fill in with nucleotides so that one end contains biotinylated bases and the other thio-nucleotides to inhibit exonuclease activity and the formation of large aggregates of beads. Couple the DNA to 2.8 µm magnetic beads. Incubation in the extract will allow the association of chromatin proteins and the consequent formation of chromatin (Heald *et al*., 1996).

Solutions

1. *TE*: 10 m*M* Tris, 1 m*M* EDTA, pH 8. Adjust pH with HCl, autoclave, and store at room temperature.
2. *Washing and binding solutions*: Included with Kilobase BINDER kit.
3. *Bead buffer*: 2 *M* NaCl, 10 m*M* Tris, 1 m*M* EDTA, pH 7.6. Adjust pH with HCl and store at room temperature.
4. *Hoechst dye solution*: Dissolve bisbenzimide in water to a final concentration of 10 mg/ml. Store in the dark at 4°C.

Steps

1. Prepare plasmid DNA by Qiagen column purification. While the sequence of the DNA is not important, the plasmid should be more than 5 kb to effectively induce chromatin assembly. Cut 50 µg of the DNA with two restriction enzymes that have unique sites in the polylinker to produce one short and one long DNA fragment. One end of the long fragment should terminate in an overhang containing Gs and Cs and the other should contain only As and Ts (e.g., *Not*1, *Bam*H1). See Fig. 1.

2. Ethanol precipitate the DNA and resuspend in 25 µl TE. Quantify recovery by OD_{260} measurement.

3. Prepare fill-in reaction in 70 µl containing 1X Klenow buffer, 30 µg DNA, 50 µ*M* nucleotides (biotin-dATP, biotin-dUTP, thio-dCTP, and thio-dGTP) and 20 units Klenow. Incubate for 2 h at 37°C.

4. Remove unincorporated nucleotides, following instructions supplied with the Sephadex G-50 gel filtration column (NICK column). The DNA is eluted in a large volume (400 µl), but the recovery is better than with spin columns. Quantify recovery by OD_{260} measurement.

5. Prepare coupling mix by combining 400 µl biotinylated DNA and 400 µl binding solution. Set aside 25 µl of the coupling mix for later evaluation of coupling efficiency.

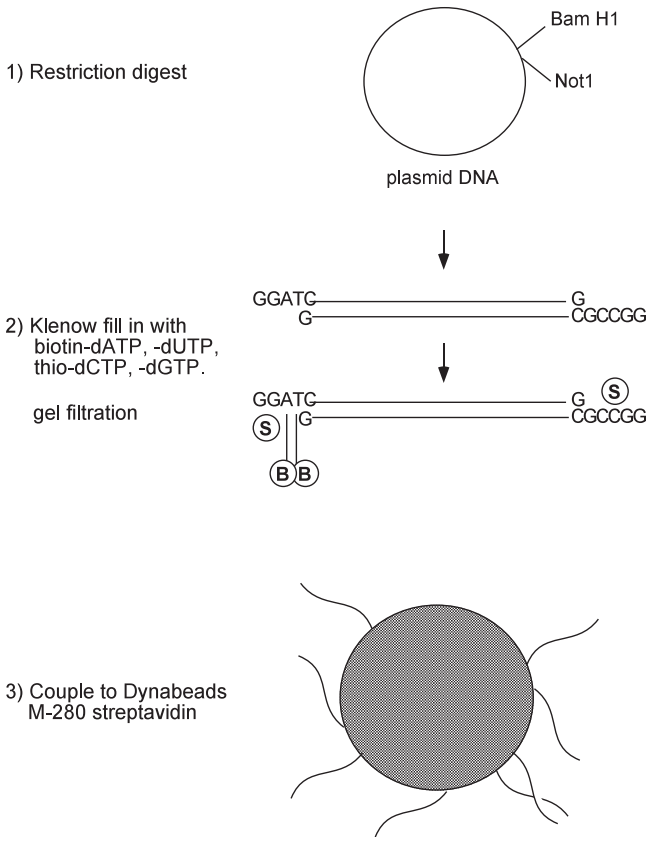

FIGURE 1 Steps in preparation of DNA beads.

6. Prepare 3µl of streptavidin-conjugated dynabeads for each microgram of DNA recovered, so 120µl for 30µg. Retrieve beads using the MPC (magnet) and wash once with 5 volumes of binding solution (600µl for 120-µl beads). Retrieve the beads and resuspend them in coupling mix containing DNA.

7. Incubate bead/coupling mixture for several hours (or overnight) on a rotating wheel at 4°C.

8. Retrieve the beads and save the supernatant. Compare the OD_{260} of the supernatant to the sample taken before coupling to determine the amount of DNA immobilized. Typically two-thirds of the DNA is coupled. Stain 1µl of beads with 5µg/ml Hoechst dye and observe them by fluorescence microcopy. The beads should appear as very bright dots with no dark patches. If the amount of DNA coupled in the first round does not seem sufficient, incubate the beads a second time with biotinylated DNA.

9. Wash beads twice with washing solution and then twice with bead buffer. After the last wash, resuspend the beads in bead buffer so that the final concentration of immobilized DNA is 1µg/5µl of beads. Store at 4°C.

C. Spindle and Aster Assembly *in vitro*

Chromatin triggers spindle assembly in CSF Xenopus egg extract. Experimentally there are two ways to induce formation of the spindle: by the addition of sperm nuclei (Desai *et al.*, 1999) or DNA beads to the extract (Heald *et al.*, 1996). To decide on which method to use it is important to understand the characteristics of the two systems. Each sperm nucleus is tightly associated to a centriole. In a very simple process, half spindles can assemble around sperm nuclei just by incubation of the sperm nuclei in extract. Over time these half spindles fuse to form bipolar spindles. If the extract is cycled through interphase the DNA replicates and each centrosome duplicates. The addition of fresh CSF extract sends the extract back into mitosis, chromosomes with their paired kinetochores condense, the duplicated centrosomes move apart, and a bipolar spindle assembles. Anaphase can be induced at this point by the addition of calcium to the system.

DNA beads are made from any kind of plasmid DNA that is long enough to induce chromatin assembly. They are unlikely to assemble kinetochores, as centromere sequences are not present. Spindle assembly around DNA beads is achieved by first assembling chromatin on the beads in an extract that is cycled through interphase. The beads are then retrieved and resuspended in fresh CSF extract. Using this method, spindles assemble in the absence of kinetochores and centrosomes. It is then ideal to study certain processes of spindle assembly that are independent of these structures.

A simplified method to study microtubule dynamics and focusing of microtubule minus ends is the assembly of asters in CSF extract. Asters can be assembled by the addition of human centrosomes purified from KE37 lymphoid cells (Bornens *et al.*, 1987), DMSO, or taxol to the extract (Wittmann *et al.*, 1998).

Solutions

1. *10X calcium solution*: 4 m*M* $CaCl_2$, 100 m*M* KCl, 1 m*M* $MgCl_2$. Store in aliquots at –20°C.
2. *4.9 M $MgCl_2$ stock solution (Sigma)*
3. *10X MMR*: See Section III,A.
4. *Hoechst dye solution*: See Section III,B.
5. *Spindle fix*: 48% glycerol, 11.1% formaldehyde, 5µg/ml Hoechst dye in 1X MMR. Always prepare fresh on day of use.
6. *BRB80*: 80 m*M* PIPES, 1 m*M* $MgCl_2$, 1 m*M* EGTA, pH 6.8. Prepare a 5X BRB80 solution. Dissolve components in sterile water and, while stirring, add KOH pellets until the PIPES dissolves. Adjust to pH 6.8 with KOH solution. Sterilize by filtration and store at 4°C.

7. *Dilution buffer*: 1X BRB80 containing 30% glycerol and 1% Triton X-100. Store at room temperature. Better preservation of the spindles can be achieved by adding 0.25% glutaraldehyde to the dilution buffer. Use a full vial of glutaraldehyde and store in aliquots at –20°C.

8. *Aster dilution buffer*: BRB80 containing 10% glycerol, 0.25% glutaraldehyde, 1 m*M* GTP, 0.1% Triton X-100. Use a fresh vial of glutaraldehyde to prepare buffer and store in aliquots at –20°C.

9. *Cushion*: 40% glycerol, BRB80. Store at 4°C.

10. *Aster cushion*: 25% glycerol, BRB80. Store at 4°C.

11. *PBS*: 137 m*M* NaCl, 2.7 m*M* KCl, 4.3 m*M* Na_2HPO_4, 1.4 KH_2PO_4 m*M*, pH 7.4. Sterilize by autoclaving and store at room temperature.

12. *Immunofluorescence buffer (IF buffer)*: PBS containing 2% BSA and 0.1% Triton X-100. Add azide and store at 4°C.

13. *Mowiol*: 10% Mowiol 4–88, 25% glycerol, and 0.1 *M* Tris, pH 8.5. To prepare, mix 6 g Mowiol with 6 g glycerol. Add 6 ml sterile water and stir for several hours at room temperature. Add 12 ml 0.2 *M* Tris, pH 8.5, and place the mixture in a heating plate at 50°C for 10 min with continues stirring. After the Mowiol dissolves, centrifuge at 5000 *g* for 15 min. Store in aliquots at –20°C.

Steps for Spindle Assembly around Sperm Nuclei (see Fig. 2)

1. Before using an extract to assemble spindles, its quality should be tested by setting up a "half spindle" reaction. Combine 20 µl CSF extract, 0.2 µl rhodamine-labelled tubulin and 0.8 µl sperm nuclei (about 75 nuclei/µl extract) in a 1.5-ml tube and mix. The extract can be mixed by gently moving the pipette in circles

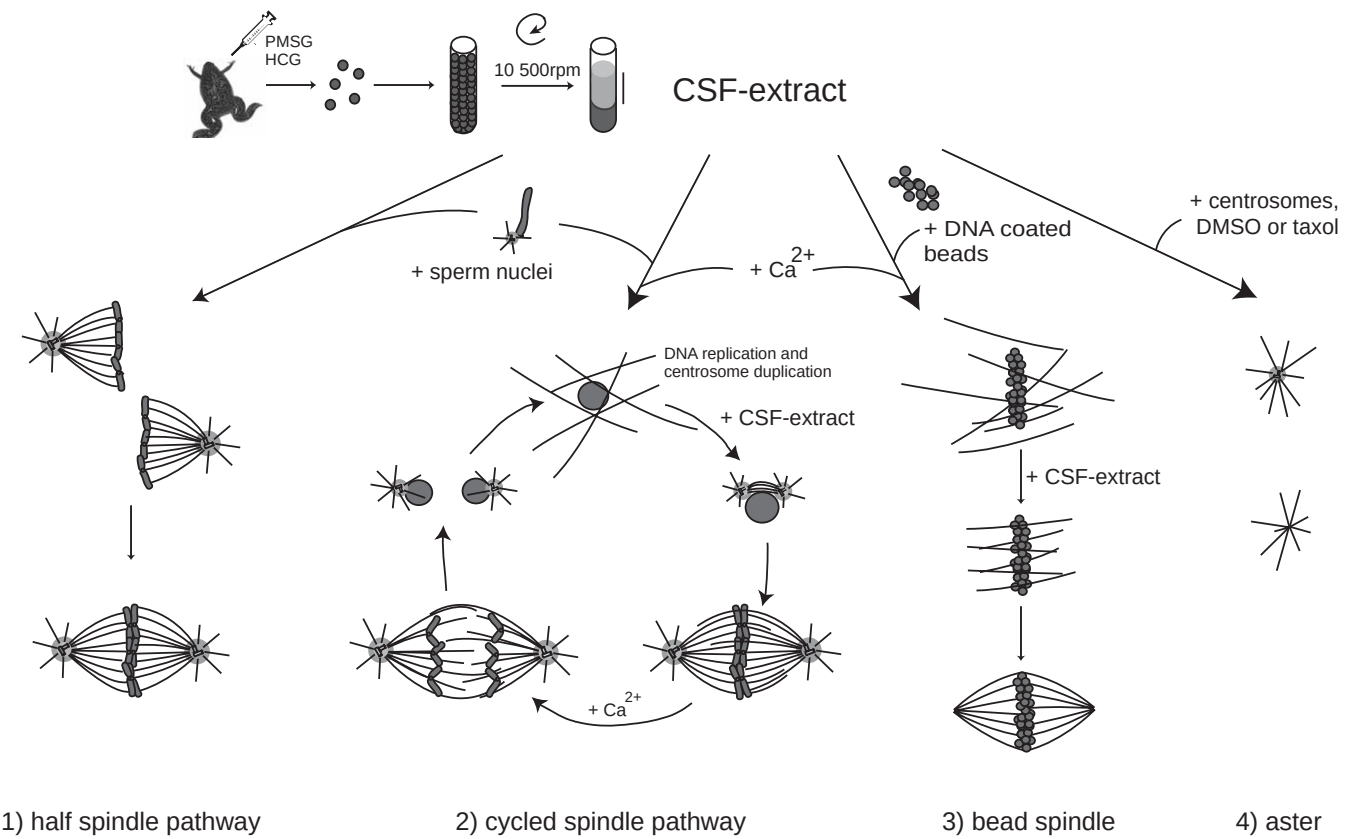

FIGURE 2 Preparation of CSF Xenopus egg extract and structures that assemble after addition of different components. (1) Addition of sperm nuclei to the CSF extract leads to the formation of half spindles that can fuse to form bipolar spindles. (2) Addition of calcium together with sperm nuclei sends the system into interphase, allowing DNA replication and centrosome duplication to occur. Addition of fresh CSF extract sends the system back to mitosis and bipolar spindles form. Calcium addition at this point induces chromosome segregation and entry into interphase. (3) Bead spindle: addition of DNA-coated beads and calcium to an extract leads to the formation of chromatin and nuclei around beads. Addition of CSF extract followed by incubation in fresh CSF extract allows the formation of bipolar spindle. (4) Asters: Addition of purified centrosomes or DMSO or taxol leads to the formation of microtubule asters with microtubule minus ends focused at the centrosome or at the center of the aster.

or by pipetting up and down, always avoiding making bubbles. Incubate the reaction mixture at 20°C and take a squash at 30–40 min. To make a squash, using a cut-off tip, transfer 1 µl of reaction mixture to a microscope slide, carefully place 5 µl of spindle fix solution on top, and gently place a 18 × 18-mm coverslip on top. Analysis of the squash by fluorescence microscopy should reveal half spindles with condensed chromosomes and occasionally also spindles. There should be no free microtubule nucleation.

2. If the extract is good, proceed with the spindle assembly protocol. For each reaction add on ice 0.2 µl rhodamine-labelled tubulin and 0.8 µl sperm nuclei to 20 µl CSF extract in a 1.5-ml tube and mix. Incubate for 10 min at 20°C and then release extract into interphase by the addition of 2 µl 10X calcium solution. Mix gently.

3. Incubate for 80 min at 20°C. Check that the extract is in interphase by taking a squash as described in step 1. If the sample is to be saved, seal the coverslip to the slide with nail polish. At this stage, nuclei should appear large, round, and uniform, and microtubules should be long and abundant.

4. At 90 min postcalcium addition, add 20 µl of fresh CSF extract containing 0.2 µl rhodamine-labelled tubulin to the reaction.

5. Incubate further at 20°C. Take squashes (step 1) at different time points to assess the stage of spindle formation. During the incubation, prepare 15 ml Corex tubes with plastic adapters, a round 12-mm coverslip, and 5 ml of cushion.

6. Forty-five to 60 min after mitosis reentry (step 4), quickly add 1 ml dilution buffer and mix by gently inverting the tube a couple of times. Carefully layer the mixture over the cushion using a cut pipette tip. Centrifuge at 16°C for 12 min at 12,000 rpm in an HB-4 or HB-6 rotor. Aspirate supernatant and cushion before removing the coverslip. Fix coverslips in –20°C methanol for 5 minutes. Rehydrate samples by placing the coverslips in PBS. If dilution buffer contains glutaraldehyde, incubate the coverslips twice for 10 min in 0.1% $NaHB_4$ in PBS and wash with PBS.

7. To perform immunofluorescence, place the coverslip face up on a surface covered with parafilm. Incubate the coverslips with primary antibodies diluted in IF buffer for 20–30 min. Wash the coverslips two times for 5 min with PBS and incubate with IF buffer containing the secondary antibody and 5 µg/ml Hoechst for 20–30 min. Wash three times for 5 min with PBS and carefully place the coverslips upside down on a 3- to 4-µl drop of Mowiol on a microscope slide, avoiding air bubbles. Prior to observation, allow the Mowiol to set for 15 min at 37°C or at room temperature for several hours.

8. To visualize the early steps of anaphase, add 4 µl 10X calcium solution to the metaphase spindles before step 6. Take samples before calcium addition and every 5 min after calcium addition for 20–30 min and process them as described earlier. It is not always possible to visualize separation of the sister chromatids and only high-quality extracts can be used successfully to study anaphase.

Steps for Spindle Assembly around Chromatin Beads (see Fig. 2)

1. Transfer 3 µl of DNA beads (about 0.5 µg DNA) to a 0.5-ml Eppendorf tube and place on a magnet. Remove supernatant, and wash beads by resuspending them in 20 µl of extract.

2. Retrieve beads and resuspend in 100 µl CSF extract. Transfer to a 1.5-ml Eppendorf tube and incubate at 20°C.

3. After 10 min, release the CSF extract into interphase by adding 10 µl of calcium solution. Incubate for 2 h at 20°C.

4. Return the extract containing the beads to mitosis by adding 50 µl of fresh CSF extract. Incubate for 30 more min at 20°C. The procedure can be continued or stopped at this point by freezing the beads in the extract using liquid ethane and storing them in liquid nitrogen.

5. Incubate the bead mixture on ice for several minutes. Retrieve the beads on ice over 10–15 minutes. Due to the viscosity of the extract, bead retrieval is slow. Pipette the mixture every several minutes, keeping the tube on the magnet.

6. Remove the supernatant and resuspend the beads in 150 µl of fresh CSF extract containing 1.5 µl rhodamine-labelled tubulin.

7. Incubate at 20°C. Monitor the spindle assembly by taking 1-µl samples and squashing with fixative as described earlier. Spindle assembly requires between 30 and 90 min, depending on the extract. For immunofluorescence studies, spin the bead spindles through a cushion onto a coverslip and perform immunofluorescence as described previously for spindle assembled around sperm nuclei.

Steps for Aster Formation (see Fig. 2)

1. For each reaction, add on ice 0.2 µl rhodamine-labelled tubulin to 20 µl CSF extract in a 1.5-ml tube. To assemble asters, add either purified human centrosomes (Bornens *et al.*, 1987) or 5% DMSO or 1 µ*M* taxol.

2. Incubate the reaction for 30–60 min in a 20°C water bath. During this incubation, prepare as before 15-ml Corex tubes with plastic adapters, round 12-mm coverslip, and 5 ml aster cushion.

3. At the end of the incubation time, dilute the reactions with aster dilution buffer and carefully layer them on top of the cushion using a pipette with a cut tip and subsequently centrifuge onto the coverslips in a HB4 or HB6 rotor at 12,000 rpm for 12 min at 16°C.

4. As before, remove the cushion with a vacuum pump and postfix the coverslips in –20°C methanol for 5 min. To quench the glutaraldehyde, incubate twice for 10 min in 0.1% $NaHB_4$ in PBS and process for immunofluorescence.

D. Functional Studies of Proteins Involved in Spindle Assembly

The Xenopus egg extract system is a powerful tool to assess the involvement of individual proteins in the process of spindle assembly. Different methods have been developed to address specific questions.

Localization studies can be performed by classical immunofluorescence methods or by direct visualization of GFP-tagged proteins added to the reaction mixture or by a combination of both by adding GST-tagged proteins followed by immunofluorescence with anti-GST antibodies.

Functional studies can be performed by adding dominant-negative constructs to the reaction mixture or by depleting the protein or antibodies under study from the extracts before use (Antonio *et al.*, 200••; Boleti *et al.*, 1996). Depletion experiments should be complemented by "add back" or rescue experiments in which a recombinant protein is added to the depleted extracts (Fig. 3). In all tree cases, a careful quantification of the structures found in control or treated samples has to be performed.

Solutions

1. *CSF-XB with PI*: See Section III,A.
2. *PBS-TX*: PBS containing 0.1% Triton X-100. Store at 4°C.

Steps for Immunodepletion

1. Usually around 10 µg of specific antibody is needed to deplete 150 µl of extract. The amount of antibody has to be adjusted for each case depending on the antibody itself and on the abundance of the protein in the extract. Prepare a control mock-depleted extract using the same amount of unspecific purified IgG.

2. Transfer 40 µl of Dynal beads coupled to protein A to a 1.5-ml tube and retrieve them using a magnet. Wash them twice by resuspending the beads in 500 µl PBS-TX and retrieving them with the magnet.

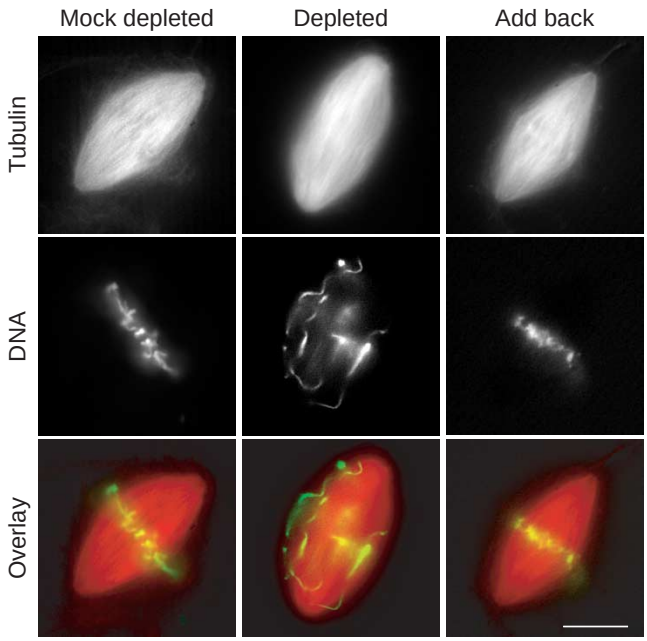

FIGURE 3 Spindles assembled in CSF Xenopus egg extract following the cycled spindle pathway. The extract was mock depleted, Xkid depleted, or Xkid depleted supplemented with recombinant Xkid protein (add back). When Xkid was depleted, mitotic chromosomes failed to align at the metaphase plate. Alignment of chromosomes was rescued by the addition of recombinant protein to the extract. Scale bar: 10 µm.

3. Incubate the beads with 10 µg of antibody diluted in 200 µl of PBS-TX for 1 h on a rotating wheel at 4°C

4. Wash twice as just described with PBS-TX and once with CSF-XB containing PI. Remove as much wash buffer as possible and carefully resuspend the beads in 150 µl of extract by pipetting up and down. Keep the extract (containing the beads) on ice for 90 min with occasional mixing by pipetting up and down.

5. Retrieve the beads by placing the tube on the magnet for 5 min on ice. Collect the extract into a new tube and keep it on ice. To remove the beads more efficiently, repeat this procedure once more. Check the efficiency of depletion by Western blot analysis of mock and protein-depleted extracts. To visualize the immunoprecipitated protein, wash the beads once with CSF-XB containing PI and three times with PBS-TX. Resuspend the beads in Laemmli sample buffer and incubate at room temperature for 5 min. Retrieve the beads on a magnet and boil the supernatant before loading on SDS–PAGE.

6. An important control to include in depletion experiments is the add back of the purified recombinant protein to the depleted extract in a range of concentrations close to that of the endogenous protein. In case the protein is degraded during interphase, the

recombinant protein should be added only at mitosis reentry.

7. The depleted, the control mock depleted, and add-back extracts can now be used in parallel to assemble asters and spindles following the methods described in Section III,C.

6. Compare the spindles or asters formed in each reaction either by taking samples and squashing them in a slide with fixative solution or by centrifuging them onto coverslips and performing immunofluorescence.

Steps for Specific Antibodies or Dominant-Negative Protein Addition

1. In the case of addition of specific antibodies, prepare a concentrated solution (at least 2 mg/ml) of an affinity-purified polyclonal or monoclonal antibody in PBS or CSF-XB. It is a good idea to try different concentrations of antibody (ranging from 200 to 400 µg/ml). For dominant-negative addition, prepare constructs expressing different fragments of the protein under study fused to GFP or GST. Purify the fusion proteins and dialyze them extensively against CSF-XB.

2. Add the antibodies or dominant-negative protein to the extract in a volume corresponding to one-tenth of the total volume and follow the protocol for spindle assembly or aster formation as described in Section III,C. The antibodies or dominant negative can be added at the beginning of the spindle assembly procedure or at mitosis reentry.

3. When adding antibodies, two control samples should be run in parallel: one containing a similar amount of a control antibody and another containing the same volume of buffer. In the case of dominant-negative addition, include also the same volume of buffer as control and a sample containing GST or GFP protein.

4. Samples taken at different time points are fixed and analyzed as before. To examine the localization of the antibody, process the samples by immunofluorescence using a fluorochrome-conjugated secondary antibody. Localization of the dominant negative can be observed directly if the tag is GFP or by using an anti-GST antibody.

IV. PITFALLS

The biggest pitfall in studying spindle assembly with this system is the problem of reproducibility in Xenopus egg extracts. To obtain good eggs, the frog colony must be healthy and well cared for. This requires a substantial commitment on the part of the laboratory. Even with healthy frogs, there is seasonal variation in the quality of eggs, with summer being the off season. Furthermore, even experienced extract makers do not manage to prepare functional extracts every time, which can be frustrating. Therefore, experiments must be repeated several times to ensure a valid interpretation.

In vitro Motility Assays with Actin

James R. Sellers

I. INTRODUCTION

The interaction between actin and myosin has been studied for years using a variety of techniques, including ultracentrifugation, light scattering, chemical cross-linking, fluorescence, and measurement of the effect of actin on the MgATPase activity of myosin. The sliding actin *in vitro* motility assay constitutes a relatively recent technique for studying actin–myosin interaction. This assay, developed by Kron and Spudich (1986), takes advantage of the ability to image rhodamine–phalloidin-labeled actin filaments by fluorescence microscopy as they interact with and are translocated by myosin bound to a coverslip surface. The sliding actin *in vitro* motility assay is among the most elegant biochemical assays, reproducing the most fundamental property of a muscle, the ability of myosin to translocate actin using only the two highly purified proteins. It is a close *in vitro* correlate of the maximum unloaded shortening velocity of muscle fibers (Homsher *et al.*, 1992). As shown here, it is simple to set up, reproducible, quantitative, and utilizes as little as 1 µg of myosin per assay. The assay is now used routinely in a large number of laboratories studying myosin and actin biochemistry. Although originally developed for studying the conventional class II myosin, it can be adapted to study unconventional myosins also.

This article discusses the design of the assay, describes the equipment required for its setup, and deals with methods for quantification and presentation of the results. Because different myosins exhibit a range of actin translocation speeds from 0.02 to 60 µm/s (Sellers, 1999), it will be necessary to discuss modification of the experimental setup for fast and slow myosins. Also, differences between low- and high-duty cycle myosins are discussed. We will describe the instrumentation that we use in our system and elaborate on other options where applicable.

II. MATERIALS AND INSTRUMENTATION

The following reagents are from Sigma Chemical Company (www.sigmaaldrich.com): MOPS (Cat. No. M-5162), EGTA (Cat. No. E-4378), ATP (Cat. No. A-5394), glucose (Cat. No. G-7528), glucose oxidase (Cat. No. G-6891), catalase (Cat. No. C-3155), and methylcellulose (Cat. No. M-0512). Rhodamine–phalloidin (Cat. No. R415) is from Molecular Probes, Inc. (www.probes.com). Nitrocellulose (superclean grade, Cat. No. 11180) is from Ernest F. Fullam, Inc. (www.fullam.com). Bovine serum albumin (BSA, Cat. No. 160069) and dithiothreitol (DTT, Cat. No. 856126) are from ICN (www.icnbiomed.com). The following items are from Thomas Scientific (www.thomassci.com): microscope slides (Cat. No. 6684-H30) and microscope 18-mm^2 No. 1 thickness coverslips (Cat. No. 6667-F24). Double sticky cellophane tape (Scotch Brand) and Sony sVHS videotapes (ST120) are from local suppliers.

The following instrumentation is used in our laboratory for the following procedures. Zeiss Axioplan microscope and objectives (www.zeiss.com), Air Therm Heater (www.wpiinc.com), intensified CCD camera from Videoscope, International (www.videoscopeintl.com), TR black-and-white videomonitor and sVHS videotape recorder (Model AG7350) from Panasonic (www.panasonic.com), Argus 10 image

All rights reserved.

processor from Hamamatsu Photonics (www.hamamatsu.com), and VP110 digitizer from Motion Analysis (www.motionanalysis.com).

III. PROCEDURES

A. Construction of Flow Cells

Steps

1. Prepare nitrocellulose-coated coverslips by first placing 3 µl of a 1% solution of nitrocellulose in isoamylacetate directly on a No. 1 thickness 18-mm^2 coverslip and spreading with the broad side of the micropipette tip. Dry the coverslip to create the film and use within 1 day. Some investigators use silicon coating of the coverslips (Fraser and Marston, 1995)
2. Place two 5 × 25-mm strips of double sticky Scotch cellophane tape about 10 mm apart on a 25 × 75-mm glass microscope slide. Place a nitrocellulose-coated coverslip with the coated side down onto the tracks. Press gently to create a tight seal.

B. Preparation of Rhodamine–Phalloidin-Labeled Actin

1. Place 60 µl of 3.3 µ*M* rhodamine–phalloidin (in methanol) into an Eppendorf tube and dry using a Speed-Vac concentrator.
2. Redissolve the rhodamine–phalloidin powder in 3–5 µl of methanol.
3. Add 85 µl of 20 m*M* KCl, 20 m*M* MOPS (pH 7.4), 5 m*M* $MgCl_2$, 0.1 m*M* EGTA, and 10 m*M* DTT (buffer A). To make 100 ml of buffer A, add 1 ml of 2 *M* KCl, 1 ml of 2 *M* MOPS (pH 7.4), 0.5 ml of 1 *M* $MgCl_2$, 0.02 ml of 0.5 *M* EGTA, and 154 mg DTT. Bring to 100 ml with H_2O and adjust pH to 7.4.
4. Add 10 µl of a freshly diluted 20 µ*M* F-actin solution (in buffer A) and incubate for an hour on ice. The rhodamine–phalloidin actin can routinely be used as is at this stage.
5. If a lower background fluoresence is desired, centrifuge for 15 min at 435,000 *g* in a TL-100 ultracentrifuge (Beckman Instruments), remove the supernatant, and gently resuspend the pink rhodamine–phalloidin-labeled actin pellet in buffer A using a pipettor tip that has been cut to widen the bore size.
6. The rhodamine–phalloidin-labeled actin solution is stable for several weeks.

C. Preparation of Sample for Motility Assay

Solutions

1. *Wash solution:* 50 m*M* KCl, 20 m*M* MOPS (pH 7.4), 5 m*M* $MgCl_2$, 0.1 m*M* EGTA, and 5 m*M* DTT; to make 100 ml, add 2.5 ml of 2 *M* KCl, 1 ml of 2 *M* MOPS, (pH 7.4), 0.5 ml of 1 *M* $MgCl_2$, 0.02 ml of 0.5 *M* EGTA, and 77 mg of DTT. Bring volume to 100 ml with H_2O and pH to 7.4.
2. *Blocking solution:* 1 mg/ml BSA in 0.5 *M* NaCl, 20 m*M* MOPS (pH 7.0), 0.1 m*M* EGTA, and 1 m*M* DTT solution. To make 100 ml of blocking solution, add 10 ml of 5 *M* NaCl, 1 ml of 2 *M* MOPS (pH 7.4), 0.02 ml of 0.5 *M* EGTA, 15.4 mg of DTT, and 100 mg of BSA. Bring to 100 ml with H_2O and pH to 7.0.
3. *Rhodamine–phalloidin-labeled actin solution:* 20 n*M* rhodamine–phalloidin-labeled actin. To make 1 ml, take 10 µl of 2 µ*M* rhodamine–phalloidin-labeled actin, 10 µl of 500 m*M* DTT, and 980 µl of wash solution.
4. *ATP–actin wash:* 1 m*M* ATP and 5 µ*M* F-actin (unlabeled) in wash solution. To make 1 ml, add 10 µl of 0.1 *M* ATP and 50 µl of 100 µ*M* F-actin to 940 µl of wash solution.
5. *4X stock solution:* 80 m*M* MOPS (pH 7.4), 20 m*M* $MgCl_2$, and 0.4 m*M* EGTA. To make 100 ml, add 4 ml of 2 *M* MOPS (pH 7.4), 2 ml of 1 *M* $MgCl_2$, and 0.08 ml of 0.5 *M* EGTA. Bring volume to 100 ml with H_2O and pH to 7.4.
6. *1.4% methycellulose solution:* Dissolve 1.4 g of methylcellulose in a final volume of 100 ml of H_2O by stirring overnight. Occasionally it is necessary to homogenize the solution with a glass–Teflon homogenizer to aid in solubilization. Dialyze the dissoved methylcellulose against 4 liters of H_2O overnight. Divide into 10-ml aliquots and freeze at –20°C.
7. *Motility buffer:* 50 m*M* KCl, 20 m*M* MOPS (pH 7.4), 5 m*M* MgCl2, 0.1 m*M* EGTA, 1 m*M* ATP, 50 m*M* DTT, 2.5 mg/ml glucose, 0.1 mg/ml glucose oxidase, and 0.02 mg/ml catalase. To make 1 ml, add 250 µl of 4X stock solution, 10 µl of 0.1 *M* ATP, 25 µl of 2 *M* KCl, 100 µl of 0.5 *M* DTT (prepare fresh each day by adding 77 mg DTT to 1 ml of H_2O), 20 µl of 125 mg/ml glucose, 20 µl of 5 mg/mol glucose oxidase, 1 µl of 20 mg/ml catalase, and 573 µl of H_2O. If methylcellulose is to be used in the motility buffer (see later), then add 500 µl of 1.4% methylcellulose and 73 µl of H_20.

Steps

1. Apply 0.2 mg/ml myosin in 0.5 *M* NaCl, 20 m*M* MOPS (pH 7.0), 0.1 m*M* EGTA, and 1 m*M* DTT to fill the flow chamber. Wait 1 min.
2. Wash with 75 µl of blocking buffer. Wait 1 min.

3. Wash with 75 µl of wash solution, followed by 75 µl of ATP–actin wash solution. Wait 1 min. This step is optional.
4. Wash with 75 µl of wash solution, followed by 75 µl of rhodamine–phalloidin-labeled actin solution. Wait 1 min.
5. Initiate reaction by the addition of 75 µl of motility buffer.
6. Place slide on microscope stage and image.

Comments

In the protocol just described, myosin is bound to the surface as monomers. If myosin is to be bound as filaments, it is necessary to block with BSA that is in a low ionic strength solution, such as the wash solution. Alternatively, heavy meromyosin or a soluble unconventional myosin can be applied to the flow chamber at either low or high ionic strength. In some cases, myosin or HMM can be attached to the surface via specific antibodies against their carboxyl-terminal sequence (Winkelmann *et al*., 1995; Cuda *et al*., 1993; Reck-Peterson *et al*., 2001), which may also serve the purpose of further purifying the desired isoform of myosin. If actin filaments are binding poorly to the surface, the motility buffer can be augmented with 0.7% methylcellulose (modify motility buffer preparation to add 0.5 ml of 1.4% methylcellulose and add less water to bring the final volume to 1 ml. Note that this solution is very viscous and must be mixed well).

Although each myosin has its own characteristic velocity, the velocity of a given myosin can vary with ionic and assay conditions. In general the velocity tends to increase as the ionic strength is raised from 20 to 100 m*M* and increases with temperature. At higher ionic strengths the actin filaments typically begin to become weakly associated with the myosin-coated surface and move erratically. The velocity of actin filament translocation by some myosins, such as vertebrate smooth muscle myosin and *Limulus*-striated muscle myosin, is increased markedly (two to four times) by the inclusion of 200 n*M* tropomyosin in the motility buffer (Wang *et al*., 1993; Umemoto and Sellers, 1990). However, tropomyosin inhibits the movement of brush border myosin I (Collins *et al*., 1990).

Step 3 is optional. It is often included to improve the "quality" of movement by binding unlabeled actin to noncycling myosin heads that would otherwise bind and tether the labeled actin added subsequently. This step can be omitted if the myosin is capable of moving actin filaments smoothly. For myosin V, better quality movement can be obtained by first blocking the surface with 0.1–1.0 mg/ml of BSA before adding the myosin.

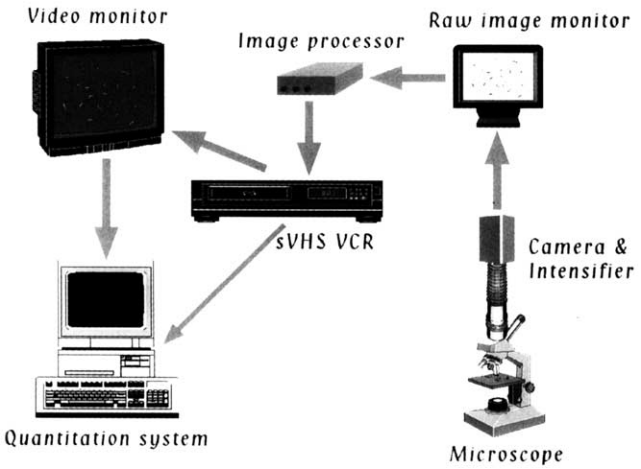

FIGURE 1 Schematic diagram of equipment setup.

D. Recording and Quantifying Data Steps and Equipment

A schematic diagram of the equipment setup is shown in Fig. 1. The following describes the equipment used in our laboratory. There is a wide selection of video microscopy equipment represented by many manufacturers.

1. Place the microscope slide under a 100X, 1.4 NA Plan-Neofluor objective in an Axioplan microscope (both from Carl Zeiss, Germany) equipped for epifluorescence. Other microscopes, including ones with an inverted format, are also suitable and a variety of objectives can be used, but note that high numerical apertures are required for maximal brightness. Illumination is via a 100-W mercury lamp. An IR filter should be placed between the source and the sample to attenuate heat; neutral density filters are useful to attenuate light intensity if needed. A filter set designed for rhodamine fluorescence measurements should be utilized in the filter cube. For quantitative work it is necessary to control the temperature of the assay. This can be accomplished in several ways. The most inexpensive way is to create an air curtain using a hair dryer. Other methods include fabricating a water jacket for the objective and to use a circulating water bath to regulate temperature or creating an environmental box heated with an Airtherm heater (World Precision Instruments). In our experience, commercial stage heaters are not sufficient as oil immersion objectives act as large heat sinks.

2. Image actin filaments using an ICCD 350F intensified CDD camera (Videoscope International). Other low-light systems are possible, such as an SIT camera or intensified SIT camera. Several

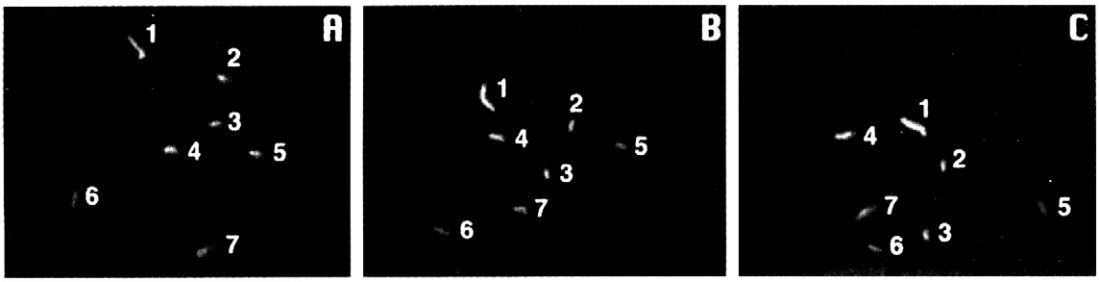

FIGURE 2 One-second intervals of actin filaments moving over a myosin-coated surface.

manufacturers sell this equipment. These camera systems produce an analog output that can be viewed on a standard black-and-white video monitor (TR Panasonic) and recorded on an AG7350 sVHS recorder (Panasonic). It is also possible to collect data digitally using a cooled CCD camera linked to a computer.

3. It is useful to process the raw image using an image processor such as the Argus 10 or Argus 20 (Hamamatsu Photonics) to perform frame averaging and/or background subtraction. There are several commercial software packages that can do this also. Display the processed image on another video monitor.

4. Determine the movement of individual actin filaments using an automated tracking system equipped with a VP110 digitizer from Motion Analysis. Many investigators have created there own software routines to track actin filaments in a semiautomated manner.

Comments

Given the range of motility rates of different myosins, there is no standard number of frames to average in order to get a good image. If the myosin is moving at 5 μm/s, a 2 or 4 frame average is used along with high illumination levels that can be tolerated because of the short exposure time needed to define a filament path. With slow myosins that may move at rates of less than 0.1 μm/s, it is possible to average 64 frames and to reduce the light intensity so that longer recording periods are possible.

The quantification of the rate of actin filament sliding is perhaps the most difficult part of the motility assay. The method just described requires a fairly expensive apparatus that is accurate, very fast, and can give unbiased results (for an extensive discussion of quantification of data, see Homsher *et al.*, 1992). The user inputs the desired sampling rate and sampling time to collect data from either the live image or a prerecorded image. The computer determines the centroid position of each actin filament in each frame, connects the centroids to form paths, calculates the incremental velocity between each successive data point in a path, and, finally, calculates a mean ± SD for each filament path. This process takes only seconds for a field of 25–30 actin filaments. Several investigators use commercial frame grabbers and write their own software for semiautomated tracking of actin filaments (Work and Warshaw, 1992; Marston *et al.*, 1996). There is at least one free downloadable source of semiautomatic tracking software available (http://mc11.mcri.ac.uk/retrac/).

E. Presentation of Data

Figure 2 shows three frames taken at 1-s intervals of actin filaments moving over a myosin-coated surface as it would appear on the video monitor. Data from such an experiment are presented most commonly as the mean ± SD of the velocity of the population of actin filaments. In general, the SD is typically 10–20% of the mean. There are two cases where merely reporting this number does not always accurately describe what is occurring in the assay. One such case is when something (perhaps a regulatory protein) is affecting the number of filaments that are moving. If, in the absence of the regulatory protein, >95% of the actin filaments are moving at 1 μm/s whereas only 5% of the filaments move at any velocity in the presence of the regulatory protein, reporting only the mean value for the velocity in each case does not reflect the difference that is observed in the assay between the two conditions. A better method for data display for this example is to display all data in the form of a histogram so that one can see that most of the actin filaments are not moving in the presence of the regulatory protein. This display also allows the reader to see whether the regulatory protein affects the speed of movement of the few actin filaments that remain moving. The other case where more complex data display is necessary is if the filaments are moving erratically. Here the mean velocity will underestimate the "instantaneous" velocity and will have a considerably larger standard deviation than that of smoothly moving filaments. One way to display these data graphically is to show a path plot

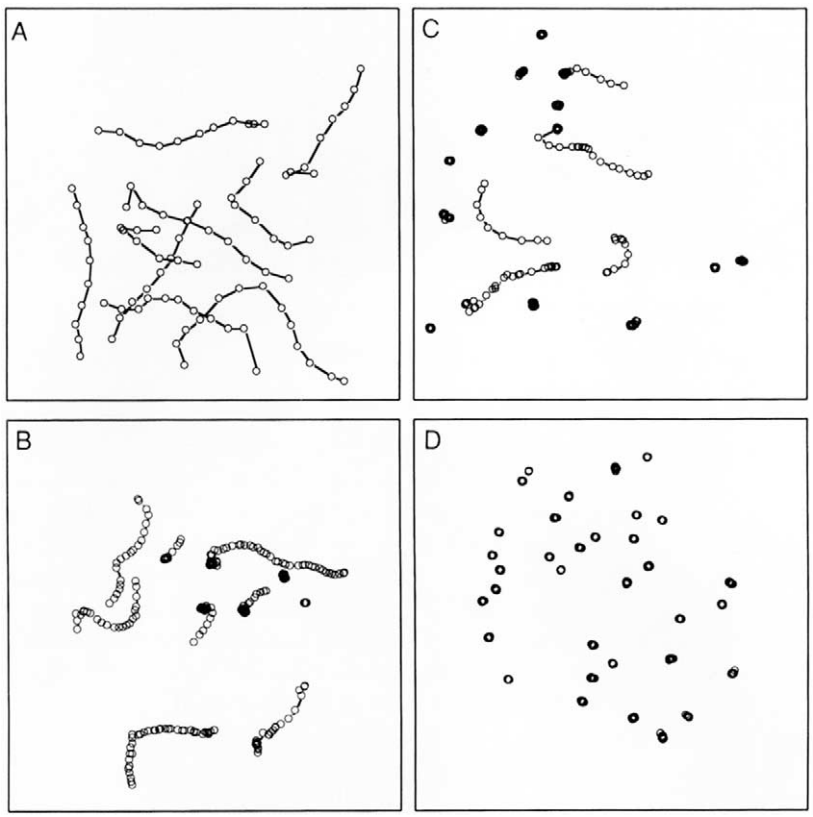

FIGURE 3 Actin filaments plotted in two-dimensional space as a function of time. A) smoothly moving actin filaments; B) actin filaments moving more erratically; C) a mixture of moving and nonmoving actin filaments; D) nonmoving actin filaments.

in which the centroid position of the moving actin filaments is plotted in two-dimensional space as a function of time (Fig. 3).

IV. PITFALLS

1. Actin filaments are moving erratically or only a fraction of the actin filaments are moving. The cause of this phenomena is usually noncycling heads in the preparation. Using the actin–ATP wash solution described in Section III,C,3 usually helps or eliminates the problem, but if erratic motility persists, do the following. Bring the myosin solution to 0.5 *M* in NaCl and add actin to a final concentration of 10 μM, ATP to 2 m*M*, and $MgCl_2$ to 5 m*M*. Immediately sediment at 435,000 *g* for 15 mn in a Beckman TL-100 ultracentrifuge. Remove the supernatant and use it for the motility assay.

2. Actin filaments shear quickly into small dots. Several things can contribute to this phenomenon. Poor-quality myosin containing a significant number of noncycling heads might be a problem. See Pitfall 1 for advice on how to remove these. Decreasing the density of myosin heads on the surface and/or increasing the ionic strength of the assay solution also sometimes helps, as does decreasing the light intensity. In general, myosin bound to the surface as monomers tend to shear less than myosin bound as filaments.

3. Actin filaments appear wobbly when they move or are moving in a back and forward type manner. If the assay does not contain methylcellulose, any portion of the actin filament that is not bound along its length by myosin will experience Brownian motion and appear very wobbly. Even though these filaments may be moving, their movement will be erratic and difficult to quantify. Increasing the density of myosin on the surface, decreasing the ionic strength of the assay, or using methylcellulose in the assay buffer usually helps. The back and forward motion of the actin filaments seen in the presence of methylcellulose is merely Brownian motion in the presence of the viscous solution where the actin filament is restricted to move mostly along its long axis. If the actin filament is not bound it will move back and forward. Increasing the density of myosin or decreasing the ionic strength of the solution should help.

4. Actin filaments photobleach rapidly. Decrease the light intensity if possible and use image processing

to do frame averaging to improve the signal-to-noise ratio. Degas the solutions. Make sure the glucose, glucose oxidase, and catalase components of the motility buffer are good. The presence of 50 m*M* DTT also aids in preventing photobleaching.

5. Actin filaments leave comet tail-like images as they move. If you are frame averaging, merely decrease the number of frames averaged. If not, the problem is likely to be encountered when the actin filaments are moving fast and a non-CCD type camera is used. The streaking or persistence in this case is related to the fact that the tube cameras effectively average about four frames in producing their image. The persistence can be attenuated by increasing the light level or by switching to a lower magnification objective.

Acknowledgments

CHAPTER

50

Use of Brain Cytosolic Extracts for Studying Actin-Based Motility of *Listeria monocytogenes*

Antonio S. Sechi

I. INTRODUCTION

Cell motility is essential for numerous biological events. Unicellular organisms, for instance, use directed movement to find and ingest food. In multicellular organisms, cell motility is required for the morphogenetic movements that accompany embryogenesis, fibroblast migration during wound healing, and the chemotactic movement of immune cells during an immune response. Cell motility is characterised by the formation of cellular extensions that, depending on their morphology and cellular context, are called lamellipodia, ruffles, or filopodia. In recent decades many cell biological, biochemical, and biophysical studies have established that the formation of these structures depends on the activity of the actin cytoskeleton and its associated proteins. More specifically, the assembly of a network of actin filaments at the leading edge of motile cells provides the propulsive force for the extension of these structures (see Small *et al*., 2002). Despite much effort, however, the complexity of cell motility has precluded the detailed analysis of the molecular mechanisms and components that govern this process.

Since the mid-1980s, much work focused on the intracellular actin-based motility of the gram-positive bacterium *Listeria monocytogenes*. *Listeria* can induce its own uptake by phagocytic and nonphagocytic cells and, once free in the cytoplasm, recruits host cell cytoskeletal components, which are then rearranged into phase-dense actin tails. The assembly of actin monomers at the actin filament (+) ends abutting the bacterial surface provides the propulsive force that allows *Listeria* to move within the infected cells and spread to adjacent cells while avoiding exposure to the host's humoral immune system. As these bacteria imitate the protrusive behaviour of lamellipodial edges, *Listeria* motility is considered a simplified model system for actin filament dynamics during cell motility (Cossart and Bierne, 2001; Frischknecht and Way, 2001). As one approach towards defining the molecular basis of bacterial motility, we and others have developed simple *in vitro* systems that support actin-based *Listeria* motility based on *Xenopus*, platelets, and mouse brain extracts (Theriot *et al*., 1994; Marchand *et al*., 1995; Laurent and Carlier, 1998; Laurent *et al*., 1999; May *et al*., 1999). These cell-free systems in combination with bacterial genetics and cell biological studies have been essential for the characterisation of two key regulators of actin cytoskeleton dynamics: Ena/VASP proteins and the Arp2/3 complex (Pistor *et al*., 1995, 2000; Smith *et al*., 1996; Niebuhr *et al*., 1997; May *et al*., 1999; Skoble *et al*., 2000, 2001; Geese *et al*., 2002). They also provided the basis for further development of *in vitro* motility systems that culminated in the reconstruction of bacterial motility using a limited set of purified proteins (Loisel *et al*., 1999). This article describes procedures for the preparation and use of mouse brain extracts for studying *Listeria* motility.

II. MATERIALS AND INSTRUMENTATION

Calcium chloride (Cat. No. 102378), magnesium chloride hexahydrate (Cat. No. 105832), potassium chloride (Cat. No. 4936), HEPES (Cat. No. 10110), sucrose (Cat. No. 1.07654), sodium chloride (Cat. No. 1.06404), disodium hydrogen phosphate dihydrate (Cat. No. 1.06580), sodium dihydrogen phosphate hydrate (Cat. No. 6346), and paraffin (Cat. No. 1.07160) are from Merck. EGTA (Cat. No. E-3889), methylcellulose (Cat. No. M-0555), ATP (Cat. No. A-2383), erythromycin (Cat. No. E-6376), and lanoline (Cat. No. L-7387) are from Sigma. Chymostatin (Cat. No. 17158), leupeptin (Cat. No. 51867), pepstatin (Cat. No. 52682), PEFABLOCK (Cat. No. 31682), aprotinin (Cat. No. 13178), and creatine kinase (Cat. No. 127566) are from Boehringer-Ingelheim. Dithiothreitol (DTT, Cat. No. 43815), Tris–HCl (Cat. No. 93363), and glycerol (Cat. No. 49770) are from Fluka. Cell-Tak (Cat. No. 354241) is from BD Biosciences. Creatine phosphate (Cat. No. 621714) is from Roche. Vaseline (Cat. No. 16415) is from Riedel-de Haen. Brain heart infusion (BHI) culture medium and Bacto agar are from Difco Laboratories. Rhodamine-labelled actin (Cat. No. AR05) is from Cytoskeleton. A glass homogeniser equipped with a Teflon piston, glass slides (76 × 26 mm), glass coverslips (22 × 22 mm), forceps, scissors, and razor blades are from local suppliers. Bacterial motility is observed using an Axiovert 135TV microscope (Zeiss) equipped with a Plan-Apochromat 100×/1.4 NA oil immersion objective. Images can be acquired with a cooled, back-illuminated CCD camera (TE/CCD-1000 TKB; Roper Scientific) driven by IPLab Spectrum software (Scanalitics).

III. PROCEDURES

A. Explantation of Mouse Brains

Solution

Phosphate-buffered saline (PBS): 130 m*M* NaCl, 1.5 m*M* $NaH_2PO_4 \cdot H_2O$, and 4 m*M* $Na_2HPO_4 \cdot 2H_2O$, pH 7.4. For 1 litre, weigh out 7.65 g NaCl, 0.21 g $NaH_2PO_4 \cdot H_2O$, and 0.72 g $Na_2HPO_4 \cdot 2H_2O$. Dissolve in 900 ml H_2O, adjust pH to 7.4 with 1 *N* NaOH, and bring volume to 1 litre. Store at 4°C.

Steps

1. Kill mice using CO_2 or by cervical dislocation.
2. Remove skin and fur from the head using thin-tipped scissors and discard.
3. Cut the skull bone by sliding the scissors along the sagittal suture (Fig. 1a, dashed red line).
4. Cut the frontal, parietal, and interparietal bones along their sutures and remove them (Fig. 1a, dashed green line).
5. Gently pinch the surface of the brain to lift the meninges up and gently ease the brain out of the skull.
6. Put explanted brains in ice-cold PBS.
7. Wash brains three times in ice-cold PBS to remove tissue debris and blood residues.

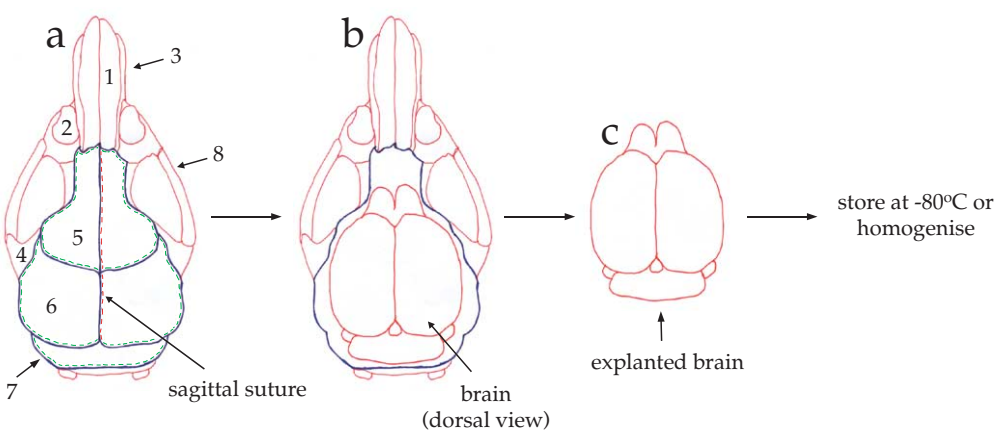

FIGURE 1 Diagram of the explantation of mouse brains. (a) Dorsal view of mouse skull showing the nasal bone (1), eye socket (2), nasal process of incisive bone (3), zygomatic process (4), frontal bone (5), parietal bone (6), interparietal bone (7), and zygomatic bone (8). (b) Dorsal view of skull after cutting (along the dashed green and red lines) and removing the frontal, parietal, and interparietal bones. (c) Dorsal view of explanted brain.

8. Proceed to Section III,B or flash freeze the brains in liquid nitrogen. Store frozen brains at –80°C.

B. Preparation of Cytosolic Extracts

Solutions

1. *Homogenisation buffer (HB)*: 20 m*M* HEPES, pH 7.5, 100 m*M* KCl, 1 m*M* $MgCl_2 \cdot H_2O$, 1 m*M* EGTA, and 0.2 m*M* $CaCl_2$. For 1 litre, weigh out 4.76 g HEPES, 7.45 g KCl, 0.2 g $MgCl_2 \cdot H_2O$, 0.38 g EGTA, and 0.02 g $MgCl_2$. Dissolve in 900 ml H_2O, adjust pH to 7.5 with 1 *N* NaOH, and bring volume to 1 litre. Store at 4°C.

2. *Protease inhibitors*: 20 mg/ml chymostatin, 1 mg/ml leupeptin, 1 mg/ml pepstatin, 167 m*M* Pefabloc, and 10 mg/ml aprotinin. To prepare stock solutions, dissolve 1 mg chymostatin in 50 µl dimethyl sulfoxide, 0.5 mg leupeptin in 500 µl H_2O, 0.5 mg pepstatin in 500 µl methanol, 20 mg Pefabloc in 500 µl H_2O, and 0.5 mg aprotinin in 50 µl H_2O. Aliquot and store at –20°C.

3. *0.1 M ATP*: For 50 ml, weigh out 2.75 g ATP. Dissolve in H_2O, aliquot, and store at –20°C.

4. *0.1 M DTT*: For 50 ml, weigh out 0.77 g DTT. Dissolve in H_2O, aliquot, and store at –20°C.

5. *2 M sucrose*: For 20 ml, weigh out 13.69 g sucrose. Dissolve in H_2O, aliquot, and store at –20°C.

6. *Homogenisation buffer supplemented with protease inhibitors (HBI)*: HB containing 60 µg/ml chymostatin, 5 µg/ml leupeptin, 10 µg/ml pepstatin, 4 m*M* Pefabloc, 2 µg/ml aprotinin, 0.5 m*M* ATP, and 1 m*M* DTT. Shortly before use add to 20 ml of HB 60 µl of 20 mg/ml chymostatin, 100 µl of 1 mg/ml leupeptin, 200 µl of 1 mg/ml pepstatin, 476 µl of 167 m*M* Pefabloc, 4 µl of 10 mg/ml aprotinin, 200 µl of 0.1 *M* DTT, and 50 µl of 0.1 *M* ATP.

Steps

1. After the last wash in PBS (see Section III,A, step 7) remove PBS and weigh the brains.
2. Cut the brains into small pieces using a razor blade (keep brains on ice).
3. Add 0.75 ml of HBI per gram of wet tissue (keep brain suspension on ice).
4. Transfer brain suspension into a glass homogeniser on ice.
5. Grind brain tissue for 20 passages of the pestle on ice.
6. Centrifuge crude extract at 15,000 *g* for 1 h at 4°C.
7. Recover clarified supernatant (cytosolic brain extract) and supplement it with 150 m*M* sucrose, 50 mg/ml creatine kinase, 30 m*M* creatine phosphate, and 0.5 m*M* ATP.
8. Aliquot and flash freeze in liquid nitrogen. Store frozen aliquots at –80°C.

C. Preparation of Bacteria

Solutions

1. *Brain heart infusion (BHI) broth*: Prepare liquid medium according to the manufacturer's instruction, autoclave, filter, and store at 4°C. For agar plates, add Bacto-agar (15 g/liter of BHI broth), autoclave, and pour 30 ml in a 10-cm petri dish. Store plates at 4°C.
2. *Erythromycin stock solution*: Dissolve 50 mg of erythromycin in 10 ml of pure ethanol. Store at 4°C.

Bacterial Culture

1. Streak the bacteria onto BHI agar plates. Incubate at 37°C for 24 h.

2. Put 5 ml of BHI (supplemented with 50 µg/ml erythromycin) in a 15-ml sterile Falcon tube. Scrape a few colonies off the BHI plate using a sterile pipette tip or a flamed bacteriological loop. Inoculate the broth and grow bacteria overnight at 37°C with vigorous shaking.

3. Transfer bacterial culture to a centrifuge tube and pellet the bacteria at 10,000 *g* for 3 min.

4. Wash bacterial pellet three times in homogenisation buffer. After the final washing step, resuspend pellet in a final volume of homogenisation buffer corresponding to the initial volume of bacterial culture.

5. Alternatively, supplement the overnight culture with 20% glycerol, aliquot, and store at –80°C.

D. Listeria Motility Assay

Solutions

1. *2% methycellulose in homogenisation buffer (stock solution)*: Heat 100 ml of HB to 60°C and then add 2 g of methylcellulose. Stir vigorously until the methycellulose dissolves. Cool down and store at room temperature.

2. *0.5% methycellulose in homogenisation buffer (working solution)*: To make 10 ml, mix 7.5 ml of HB with 2.5 ml of 2% methycellulose. Store at 4°C.

3. *VALAP*: Mix vaseline, lanoline, and paraffin in a 1:1:1 ratio (w/w/w) and homogenise at 75°C. Store at room temperature.

4. *G buffer*: 5 m*M* Tris–HCl, pH 7.6, 0.5 m*M* ATP, 0.1 m*M* $CaCl_2$, and 0.5 m*M* DTT. For 1 litre, weigh out 0.8 g Tris–HCl, 0.01 g $CaCl_2$, and then add 5 µl of 0.1 *M* ATP and 5 µl of 0.1 *M* DTT. Dissolve in 900 ml H_2O,

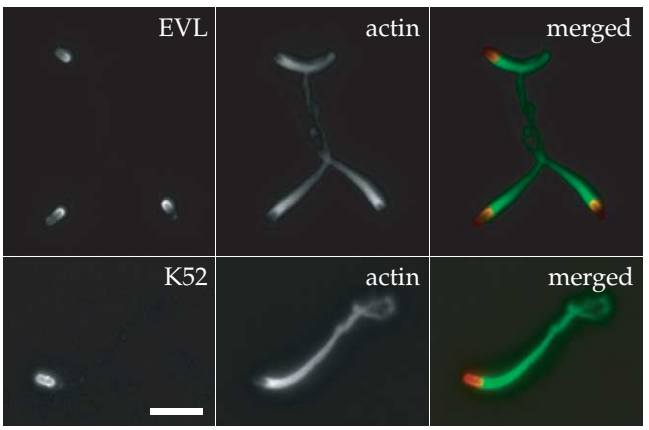

FIGURE 2 Immunofluorescence microscopy showing *Listeria* actin tails formed in mouse brain extracts. Bacteria were incubated in mouse brain extract for 30 min at room temperature and then 5 µl of motility mixture was applied onto Cell Tak-coated cover slips (the coating procedure was done according to the manufacturer's instructions) and incubated for 5 min on ice. Afterwards, bacteria were fixed with 4% PFA for 20 min at room temperature. Immunolabelling was done according to Geese *et al*. (2002) using the affinity-purified polyclonal antibody K52 to label bacterial surface, the monoclonal antibody 84H1 to label EVL, and Texas red-labelled phalloidin to label the actin tails. Primary antibodies were detected using Alexa 488-conjugated secondary antibodies. Scale bar: 5 µm.

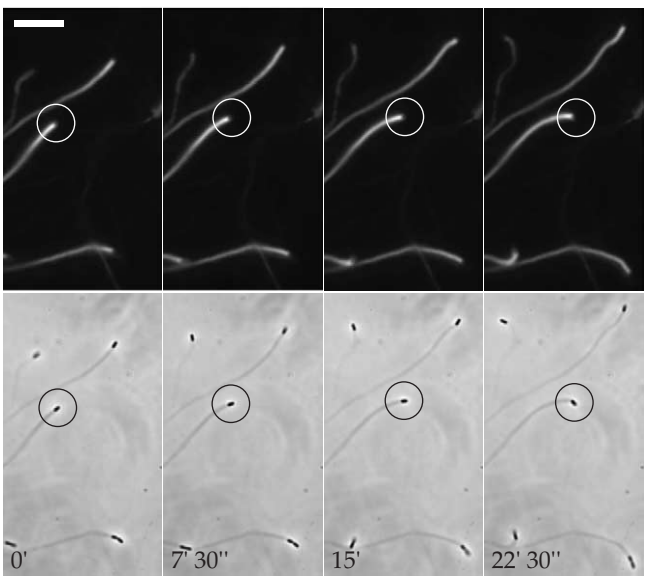

FIGURE 3 Dynamics of *Listeria* motility in mouse brain extracts. Bacteria were mixed with 4 µl brain extract, 4 µl of 0.5% methycellulose, and 0.2 µl rhodamine-labelled actin and were incubated at room temperature for 10 min. Thereafter, 1.7 µl of motility mixture was spotted onto a glass slide and a 22 × 22-mm glass coverslip overlaid on it. Bacterial motility was observed using a Axiovert 135 TV inverted microscopy equipped with phase-contrast and epifluorescence optics using a Plan-Apochromat 100×/1.4 NA oil immersion objective. Images were acquired using a cooled, back-illuminated CCD camera (TE/CCD-1000 TKB; Roper Scientific) driven by IPLab Spectrum software (Scanalitics). (Top) Rhodamine-labelled actin and (bottom) the corresponding phase-contrast images. Scale bar: 10 µm.

adjust pH to 7.6 with 1 *N* NaOH, and bring volume to 1 litre. Store at 4°C.

5. *Rhodamine-labelled actin*: Add 6 µl of G buffer to one aliquot of rhodamine-labelled actin. Mix gently and store on ice.

Steps

1. Wash bacteria three times in homogenisation buffer. Resuspend pellet in 20 µl homogenisation buffer.

2. In a small Eppendorf tube, mix 4 µl brain extract, 4 µl of 0.5% methycellulose, 0.5 µl bacteria suspension, and 0.2 µl rhodamine-labelled actin. Mix by pipetting up and down gently. Do not vortex. Incubate mixture at room temperature for 10 min.

3. Remove 1.7 µl of motility mixture and spot it onto a glass slide. Gently place a 22 × 22-mm glass coverslip over the drop and press down until the drop spreads to the edges. Seal the coverslip edges with VALAP.

4. Observe slide with an upright or inverted microscope. Actin comet tails can be observed easily by phase contrast or epifluorescence using a Plan-Apochromat 100×/1.4 NA oil immersion objective (Figs 2 and 3).

IV. COMMENTS AND PITFALLS

Although cell-free systems based on egg extracts of *Xenopus laevis* or human platelet extracts provide excellent *in vitro* systems for supporting actin-based bacterial motility, their ability to do so can be affected negatively by various factors, such as health of eggs or quality and age of platelet preparations. In this context, mouse brain extracts offer a more "robust" *in vitro* system that does not seem to be influenced by external factors such as mouse strain and age.

The reconstitution of *Listeria* motility using mouse brain extracts can have a variety of uses. For instance, it can be used to study the role of actin cytoskeletal components involved in *Listeria* motility by interfering with their function using specific inhibitors or antibodies, as described in May *et al*. (1999). Moreover, the procedure described here may be further developed and adapted to obtain cell-free extracts from normal cultured cells or cells that lack or express mutated ver-

sions of the actin cytoskeletal proteins of interest, thus widening the spectrum of *in vitro* systems available for studying bacterial motility.

Three main parameters have to be considered to achieve optimal *Listeria* motility with mouse brain extracts. First, the protein ActA must be expressed at high levels on the bacterial surface. As most wild-type strains express low levels of this protein under standard culture conditions, a *Listeria* strain (see Lingnau *et al*., 1996) that constitutively expresses high levels of this protein must be used in this assay. The second critical parameter is the total protein concentration of the brain extract, which must be at least 10 mg/ml. The total protein concentration can be increased by reducing the amount of homogenisation buffer per gram of wet tissue. Moreover, mouse brain extracts should not be diluted more than fourfold as further dilution leads to loss of activity in the motility assay. Finally, the high amount of actin present in these extracts induces its spontaneous polymerisation, characterised by the formation of short actin bundles. As this actin network may affect bacterial motility, mouse brain extracts must be kept on ice to reduce the tendency of actin to polymerise.

Pedestal Formation by Pathogenic *Escherichia coli*: A Model System for Studying Signal Transduction to the Actin Cytoskeleton

Silvia Lommel, Stefanie Benesch, Manfred Rohde, and Jürgen Wehland

I. INTRODUCTION

Dynamic rearrangement of the actin cytoskeleton in response to signal transduction plays a fundamental role in the regulation of cellular functions. Understanding actin dynamics therefore represents one of the challenges of modern cell biology. Several pathogens have evolved diverse strategies to trigger rearrangement of the host actin cytoskeleton to facilitate and enhance their infection processes. By manipulating the actin assembly machinery or signalling routes leading to its activation, pathogens can either block or induce phagocytosis, drive intracellular motility, and exploit their host cells in other ways. Analyses of host pathogen interactions have not only broadened our knowledge of how these pathogens cause disease, but have also emerged as model systems in the study of cellular actin dynamics (for examples, see Frischknecht and Way, 2001). The focus of this article is on the formation of cytoskeletal rearrangements called actin pedestals induced by the diarrhoeagenic extracellular bacterial pathogens enteropathogenic *Escherichia coli* (EPEC) and enterohaemorrhagic *E. coli* (EHEC) as systems to study signalling and actin assembly at the plasma membrane.

During infection of the intestinal mucosa, EPEC and EHEC induce specific, so-called attaching and effacing (A/E) lesions on intestinal epithelial cells (for review, see Nataro and Kaper, 1998). A/E lesions are characterized by a localized loss of microvilli and intimate adherence of bacteria to the cell surface followed by recruitment of the cellular actin assembly machinery to sites of bacterial attachment, resulting in the formation of actin-rich pseudopod-like structures termed pedestals to which the bacteria intimately adhere.

Importantly, the histopathological changes associated with the A/E phenotype *in vivo* can be mimicked in cell culture [(Knutton *et al.*, 1987), see Fig. 1], which allows to define the molecular mechanisms employed by EPEC and EHEC to induce cytoskeletal rearrangements. The ability to form actin pedestals on cultured cells furthermore correlates with the ability of EPEC and EHEC to colonize the intestine and cause disease in human and other animal hosts (e.g., Donnenberg *et al.*, 1993).

The genes necessary for A/E lesion formation in EPEC map to an about 35-kb chromosomal pathogenicity island, designated the locus of enterocyte effacement (LEE), which is highly conserved in EHEC. Although EPEC and EHEC produce highly similar lesions, EPEC in the small intestine and EHEC in the large intestine, the molecular mechanisms of pedestal formation employed by EPEC versus EHEC differ (for review, see Campellone and Leong, 2003).

Both pathogens translocate their own receptor, the translocated intimin receptor (Tir, EspE), which binds to the bacterial surface protein intimin, via a type III secretion system into the underlying host cell. EPEC Tir becomes tyrosine phosphorylated upon insertion

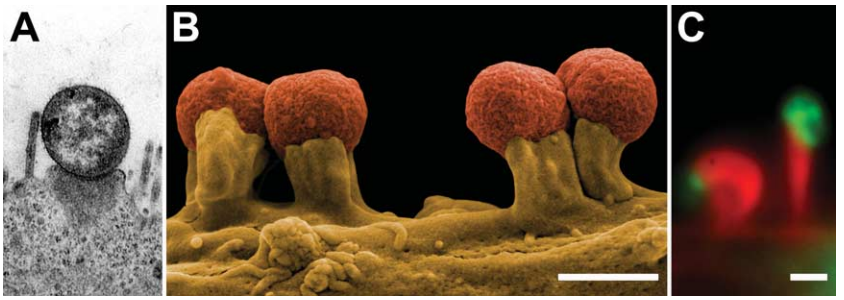

FIGURE 1 Actin pedestal formation induced by EHEC and EPEC *in vivo* and on the surface of cultured cells. (A) Transmission electron micrograph showing the characteristic attaching and effacing (A/E) lesion formation of the enterohaemorrhagic *Escherichia coli* (EHEC) O157:H7 strain 86/24 observed in piglet colon. Note the intimate attachment, localized loss of microvilli, and formation of a raised, pedestal-like structure beneath the bacterium that characterizes this lesion (courtesy of Florian Gunzer, Institute of Medical Microbiology, Hannover Medical School, Germany). **(B)** Scanning electron micrograph of enteropathogenic *E. coli* (EPEC) O127:H6 strain E2348/69 (pseudocoloured in red) sitting on top of pedestals induced on the surface of cultured murine embryonic fibroblast cells upon infection that resemble A/E lesions formed by EPEC *in vivo*. **(C)** EHEC O157:H7 strain 86/24-induced actin pedestal formation as visualized by fluorescence actin staining using AlexaFluor 594 phalloidin to specifically label F-actin (shown in red). EHEC bacteria shown in green were detected with monoclonal antibodies against EspE (Deibel *et al*., 1998) and AlexaFluor 488-conjugated goat antimouse secondary antibodies. Bars: 1 µm.

into the host cell membrane and binding to intimin. This phosphorylation is critical for actin pedestal formation by EPEC (Kenny, 1999), as it allows recruitment of the cellular signalling adaptor protein Nck to bacterial attachment sites. Nck, in turn, triggers by a so far unknown mechanism recruitment and activation of N-WASP. Both Nck and N-WASP are essential host proteins for pedestal formation induced by EPEC, as cells lacking either Nck or N-WASP are resistant to actin pedestal formation by EPEC (Gruenheid *et al*., 2001; Lommel *et al*., 2001) (for N-WASP, see Fig. 2). N-WASP is a member of the WASP/Scar family of cellular nucleation-promoting factors and has emerged as a central node protein that regulates actin polymerisation by activating the Arp2/3 complex, a main factor for nucleation of actin filaments in response to multiple upstream signals.

In contrast, EHEC Tir is not tyrosine phosphorylated and pedestals are formed independently of Nck. Despite that, EHEC-induced pedestal formation still depends on N-WASP function (Lommel *et al*., 2004) to promote Arp2/3 complex-mediated actin polymerisation. Thus, EPEC and EHEC have evolved different strategies to trigger cellular signalling routes leading to actin assembly, which converge in recruitment and activation of N-WASP to promote Arp2/3-mediated actin polymerisation.

The aim of this article is to outline a methodology for the analysis of actin pedestal formation by EPEC and EHEC using cultured cells as model systems to study regulatory mechanisms controlling actin assembly at the plasma membrane. This article describes

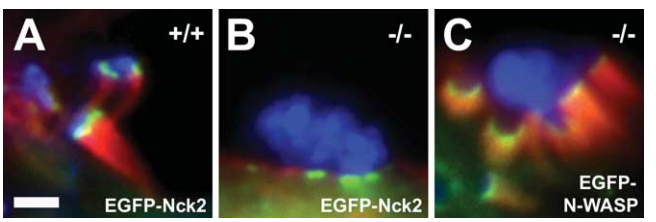

FIGURE 2 EGFP-tagging and knockout cell lines as tools for analysis of the molecular mechanism of actin pedestal formation induced by EPEC. Cultured murine embryonic fibroblasts expressing (+/+, **A**) or lacking N-WASP (–/–, **B** and **C**) were infected with EPEC and examined by immunofluorescence microscopy. F-actin is shown in red as detected by fluorescence actin staining with AlexaFluor 594 phalloidin, bacteria are shown in blue as detected with anti-EspE monoclonal antibodies in combination with AlexaFluor 350-conjugated goat antimouse secondary antibodies, and the host proteins Nck2 **(A** and **B)** and N-WASP **(C)** expressed ectopically with an EGFP tag are shown in green. Whereas EPEC induced the formation of prominent pedestals in N-WASP-expressing cells (+/+, **A**), they were unable to trigger actin accumulation on N-WASP-defective cells (–/–, **B**). The bacterial ability to direct actin reorganisation in N-WASP-defective fibroblasts was restored by providing EGFP-tagged N-WASP by transient transfection (**C**). Together, this clearly demonstrates that N-WASP is a host cell protein essential for pedestal formation induced by EPEC. Recruitment of the host cell signalling adaptor protein Nck2 is triggered by EPEC independently of actin accumulation, as was revealed by ectopic expression of EGFP-tagged Nck2 in either N-WASP-expressing (+/+, **A**) or N-WASP-defective cells (–/–, **B**). Bar: 2 µm, (valid for A–C).

protocols for the coculture of bacteria with cell lines and for basic immunofluorescence microscopy techniques that are used to examine bacterial–host cell interactions in terms of bacterial attachment and

effects on the actin cytoskeleton. These may be combined with ectopical expression of host cell proteins tagged with green fluorescent protein (GFP) for analysis of subcellular localisation and dynamic reorganisation of a protein during the infection process using digital fluorescence microscopy (for examples, see Fig. 2). A further advance to unravel the molecular mechanism of pedestal formation is the use of cell lines derived from knockout mice. Cell lines derived from such mice can be reconstituted by expressing wild-type or mutated proteins tagged with GFP, which facilitates the analysis of the contribution of specific protein domains to actin pedestal formation (for examples, see Fig. 2).

II. MATERIALS AND INSTRUMENTATION

A Cell Lines, Bacterial Pathogen Strains, and Culture Media Reagents

1. Cells

Epithelial cell lines used commonly for EPEC and EHEC infection experiments are HeLa and HEp-2 cells, as well as the intestinal epithelial cell lines T84 or Caco-2 (available from American Type Culture Collection). EPEC and EHEC will also adhere and induce the formation of actin pedestals on mouse embryonic fibroblast cell lines (MEFs), which are used routinely in our laboratory. Embryonic fibroblast cell lines offer the advantage that such cell lines can be established quite easily from conditional or conventional knockout mice, thus allowing the analysis of specific host proteins in actin pedestal formation induced by EPEC and EHEC.

2. Bacterial Pathogen Strains

Prototype enteropathogenic and enterohaemorrhagic *E. coli* strains used in analyses of the molecular mechanism of actin pedestal formation are enteropathogenic *E. coli* strain E2348/69 (O127:H6) (Levine *et al*., 1978), enterohaemorrhagic *E. coli* strain 86/24 (O157:H7) [isolated from an outbreak in Walla Walla, WA., U.S.A. (Griffin *et al*., 1988)], and enterohaemorrhagic *E. coli* strain EDL933 (O157:H7) (American Type Culture Collection #700927; for genome sequence information, see Perna *et al*., 2001).

3. Cell and Bacterial Culture Reagents

Dulbecco's modified eagle medium (DMEM), low glucose (Invitrogen Corp., GIBCO #31885-023), fetal bovine serum (Sigma-Aldrich #F 7524), L-glutamine (Invitrogen Corp., GIBCO #25030-024), penicillin/streptomycin (Invitrogen Corp., GIBCO #15070-063), Luria-Bertani (LB) broth agar (e.g., BD #244520), LB broth (e.g., BD #244620), and HEPES (Sigma-Aldrich #H 3375), fibronectin (pure) (Roche #1051407).

B. Constructs and Reagents for Expression of GFP-Tagged Host Proteins

1. *Transfection reagent*, e.g., FuGENE 6 (Roche #1 814 443)
2. A set of vectors for construction of EGFP fusions is available from Clontech (BD Biosciences).
3. *EGFP-N-WASP*: as described (Lommel *et al*., 2001)
4. *EGFP-Nck2*: as described (Scaplehorn *et al*., 2002)

C. Additionally Needed Reagents and Plasticware

1. Basics

General equipment and plasticware for molecular biology and cell culture techniques.

2. Cell Culture and Immunofluorescence Microscopy

Twenty-four-well cell culture plates (e.g., Corning Inc. #3524), 12-mm round glass coverslips (e.g., Assistent #1001, thickness 0.17 mm), absolute ethanol (Sigma-Aldrich #E 7023), HCl (37%) (Sigma-Aldrich #H 7020), lint-free absorptive paper [e.g., GB002, Schleicher&Schuell #10427736 (58 × 68 cm) and #10485285 (22.2 × 22.2 cm)], large square plastic dish (e.g., 24.5 × 24.5-cm polystyrene dish with lid, Sigma-Aldrich #Z37,165-3), Parafilm M (e.g., Fisher Scientific #917 00 02), forceps with curved fine tips (e.g., coverslip forceps Dumont #11251-33), NaCl (Sigma-Aldrich #S 7653), KCl (Sigma-Aldrich #P 1338), Na_2HPO_4 (Sigma-Aldrich #S 7907), KH_2PO_4 (Sigma-Aldrich #P 0662), paraformaldehyde (PFA), (Sigma-Aldrich #P 6148), NaOH (Merck/VWR International #109913), Triton X-100 (Sigma-Aldrich #T 8532), normal goat serum (Invitrogen Inc.: GIBCO #16210-064), bovine serum albumin (BSA, Sigma-Aldrich #A 2153), goat anti-mouse Alexa Fluor 350- or Alexa Fluor 488-conjugated secondary antibodies (Molecular Probes #A-11045 and #A-11001), DAPI (e.g., Molecular Probes, #D-1306), fluorophore-coupled phalloidin [e.g., Alexa Fluor 594 phalloidin (red fluorescence, Molecular Probes #A-12381)], glycerol (87%, analytical grade) (e.g., Merck/VWR International #104094), Mowiol 4-88 (Calbiochem #475904), Tris base (e.g., Trizma base, Sigma-Aldrich #T 1503), *n*-propyl gallate (Sigma-

Aldrich #P 3130), and SuperFrost microscope glass slides (Fisher Scientific #9161161).

D. Instrumentation and Laboratory Equipment

1. Centrifuges

Tabletop centrifuge (e.g., centrifuge 5414D, Eppendorf #5425 000.219), centrifuge equipped with rotor suitable for microtiter plates, and 15- and 50-ml polypropylene tubes (e.g., centrifuge 5810, Eppendorf #5810 000.017 with rotor A-4-81 and A-4-81-MTP).

2. Clean Benches and Cell Incubators

Clean bench and cell culture incubator suitable for work with EPEC and EHEC pathogens in accordance with respective national safety regulations.

3. Microscope

Inverted microscope (e.g., Axiovert 135TV, Carl Zeiss Jena GmbH) equipped for epifluorescence microscopy with 40×/1.3 NA and 100×/1.3 NA Plan-NEOFLUAR oil immersion objectives, 1.6 and 2.5 optovar magnification, electronic shutters (e.g., Uniblitz Electronic 35-mm shutter including driver Model VMMD-1, BFI Optilas) to allow for computer-controlled opening of the light paths, excitation and emission filters (Omega Optical Inc. or Chroma Technology Corp.) to enable three-colour epifluorescence, and mercury short arc lamp (Osram, HBO103W/2) for fluorescence light path.

4. Data Acquisition

Preferably a back-illuminated, cooled charge-coupled device (CCD) camera (e.g., Princeton Research Instruments TKB 1000×800, SN J019820; Controller SN J0198609) driven, for instance, by IPLab (Scanalytics Inc.) or Metamorph software (Universal Imaging Corporation).

III. PROCEDURES

Solutions

1. *Cell culture growth media*: Cell culture growth medium suitable for the propagation of the cell line chosen. We use DMEM, low glucose supplemented with 10% heat-inactivated fetal bovine serum, 2 m*M* L-glutamine, and 50 U/ml each of penicillin and streptomycin for propagation of our embryonic fibroblast cell lines.

2. *Cell culture growth media for bacterial infection experiments*: For bacterial infection experiments, omit penicillin and streptomycin from growth media starting a day prior to infection.

3. *Standard bacterial cultures*: Prepare LB broth and LB agar plates according to standard protocols (e.g., Maniatis *et al*., 1982).

4. *Preactivating culture of EPEC*: DMEM, low glucose for culturing EPEC prior to infection of cell monolayers.

5. *Preactivating culture of EHEC*: DMEM, low glucose, supplemented with 100 m*M* HEPES, pH 7.4, for culturing EHEC prior to infection of cell monolayers.

6. *Phosphate-buffered saline (PBS)*: 140 m*M* NaCl, 2.7 m*M* KCl, 10 m*M* Na_2HPO_4, 1.8 m*M* KH_2PO_4, pH 7.4

7. *Fixative*: Prepare a 4% solution of PFA in PBS, pH 7.4. Paraformaldehyde is very toxic, work in fumehood when preparing stock, do not inhale, and wear gloves. To prepare 100 ml, add 4 g PFA to 90 ml PBS. In order for the PFA to dissolve, heat the solution to 60–65°C with continuous stirring. If necessary, adjust the pH to 7.4 by adding NaOH (be patient!). Do not heat solution above 70°C, as PFA will degrade. Let cool to room temperature, check the pH, and adjust with PBS to full volume. Filter through paper filter to remove insoluble aggregates and store in aliquots (e.g., 15 and 50 ml) at –20°C.

8. *Cell permeabilization*: Fixative supplemented with 0.1% Triton X-100 just prior to use. Make up a 10% stock solution of Triton X-100 in PBS and store at 4°C.

9. *Antibody diluent*: 1% BSA in PBS. Prepare and store in suitable aliquots (1–2 ml) at –20°C.

10. *Blocking solution*: 10% normal goat serum in PBS. Prepare from frozen aliquots of serum just prior to use.

11. *Antibody Mixtures*: Dilute antibodies just prior to use to appropriate working concentration in 1% BSA in PBS. The ideal concentration will result in a strong signal with no or little background staining and has to be established experimentally for each new antibody. To start, follow instructions given by the supplier. When using a concentrated primary antibody, a 1:100 dilution resulting in about 10 µg/ml should be a good starting point for immunofluorescence microscopy. Secondary antibodies conjugated to fluorophores are available from numerous suppliers. In our hands, secondary reagents coupled to Alexa Fluor dyes from Molecular Probes have worked very well. Note, however, that most polyclonal antisera will exhibit unspecific cross-reaction with EPEC and EHEC bacteria. A way to avoid problems associated with unspe-

cific labelling of bacteria is to use monoclonal reagents (see general comment in Section IV). We store our antibodies in the dark at 4°C in a refrigerator. For long-term storage, antibodies may be stored at –20 or –80°C. Follow the recommendations given by the supplier.

12. *Mounting medium*: Weigh out 6 g glycerol and add 2.4 g Mowiol 4-88. Stir thoroughly. Add 6 ml aqua dest and mix for several hours at room temperature. Add 0.2 ml 0.2 *M* Tris–Cl, pH 8.5, and heat to 60°C for 10 min. Remove insoluble material by centrifugation at 6000 g for 30 min. Store in aliquots at –20°C. In order to reduce photobleaching during fluorescence microscopy, add 2.5–5 mg/ml *n*-propyl gallate prior to use (Giloh and Sedat, 1982).

A. Basic Protocol: Infection of Cell Monolayers with EPEC or EHEC

EPEC and EHEC pose a significant threat to human health, especially EHEC with its low infectious dose of ~10–100 cfu. When working with EPEC and EHEC, always wear protective clothing and work under an appropriate clean bench in accordance with national safety regulations. Decontaminate all materials that have been in contact with the pathogen.

Steps

1. Pretreat 12-mm round glass coverslips as follows: wash coverslips in a mixture of 60% absolute ethanol and 40% concentrated HCl for 30 min and rinse extensively with aqua dest (heating in a microwave oven is helpful). To dry coverslips, spread on lint-free absorptive paper. Sterilize for tissue culture either by autoclaving on the dry cycle at 220°C or by exposing to ultraviolet light for 45 min in a culture dish.

2. On day 1, streak EPEC and EHEC from frozen glycerol stocks onto fresh LB agar plates and incubate overnight at 37°C. Keep plates in the refrigerator until liquid overnight cultures are started.

3. On day 2, seed cells onto 12-mm pretreated coverslips in a 24-well tissue culture plate in cell culture growth media without antibiotics. Incubate overnight in a tissue culture incubator supplemented with CO_2 to allow the cells to adhere to the coverslips. For MEFs, we find microscopic analysis of actin pedestal formation easiest if cells have reached about 80% confluency at the time of analysis; the number of cells seeded should be adjusted accordingly. To reduce detachment of MEFs infected with EHEC, use fibronectin coated coverslips.

4. Start an overnight liquid culture of EPEC or EHEC in 5 ml LB medium with bacteria from the streaked plate. In our experience, small inoculation loads result in a higher infection efficiency. Grow overnight with aeration at 37°C on a rotary shaker at 180 rpm.

5. On day 3, collect bacteria from the 0.5-ml overnight culture by centrifugation for 3 min at 4500 rpm in a tabletop centrifuge. Wash bacterial pellet twice in DMEM and inoculate 25 ml DMEM (EPEC) or 25 ml DMEM supplemented with 100 m*M* HEPES, pH 7.4 (EHEC). Grow at 37°C at 180 rpm for 3 h.

Environmental cues such as temperature, pH, and osmolarity, as well as growth phase, have been described to influence the transcriptional regulation of expression of virulence factors, e.g., of the type III secretion system. Media conditions that appear to stimulate virulence are those considered to mimic the gastrointestinal tract (e.g., Beltrametti *et al*., 1999; Kenny *et al*., 1997). In our experience, preactivation of EPEC and EHEC by growth for 3 h in DMEM for EPEC or DMEM supplemented with 100 m*M* HEPES, pH 7.4, for EHEC is sufficient for reproducible efficient bacterial infection of cultured cell monolayers. In our hands, the morphological appearance of preactivated bacterial cultures correlates with their infectious capability: After 3 h, EPEC should be found aggregated to small clumps of bacteria but should not grow in long rows. Aggregation likely reflects the expression of type IV bundle-forming pili, rope-like appendages that represent an important additional virulence factor found to enhance initial adherence and virulence of EPEC (Bieber *et al*., 1998). EHEC, which lack bundle-forming pili, should be present as single bacteria in preactivation cultures, but again should not grow in long rows.

6. In the meantime, exchange cell culture medium of cell monolayers with 1 ml per well of fresh cell culture medium without antibiotics.

7. Add 10 µl of the bacterial 3-h preactivation culture into each well. Initiate infection by brief centrifugation for 5 min at 650 g in a centrifuge prewarmed to at least room temperature, allowing bacteria and cells to make contact with each other.

8. Place in an incubator supplemented with 7.5% CO_2 at 37°C for 1 h. Incubation at lower temperatures results in a reduced infection efficiency.

9. Remove media containing nonattached bacteria by aspiration and gently replace with 1 ml of fresh prewarmed culture medium without antibiotics per well. Be careful not to let the cells dry out when exchanging the medium.

10. Repeat medium changes every hour until a total infection time of 4.5 to 5 h has been reached.

In our hands, longer infection times generally result in pedestals of increased length, facilitating analysis of

pedestal composition. In addition, after short incubation times, EPEC bacteria are found mostly adhered in aggregates, which may confound analysis. Later during infection, EPEC bacteria will distribute from aggregates, making it easier to distinguish single pedestals. However, too long incubation results in increased cell death and detachment of cells, especially when working with EHEC.

11. After the incubation period, remove the medium by aspiration and gently wash the coverslips twice with PBS prewarmed to 37°C to remove unattached bacteria.
12. For fixation, immerse each coverslip with 500 µl of fixative prewarmed to 37°C and incubate at room temperature for 20 min.
13. After fixation, gently wash twice with PBS and store in PBS at 4°C until proceeding to cell permeabilization and immunostaining.

B. Alternative Protocol: EPEC and EHEC Infections of Transiently Transfected Cell Monolayers

For experiments involving ectopic expression of host cell molecules, e.g., tagged with GFP, designed to analyse their role in actin pedestal formation induced by EPEC or EHEC (see general comments, Section IV), follow the basic protocol with the exceptions that cells are already seeded on day 1, and day 2 will be required for transfection of host cell monolayers with plasmid DNA in addition to starting bacterial overnight cultures.

Steps

1. On day 1, seed cells in regular cell culture growth media on coverslips as described in the basic protocol with the modification that the number of cells seeded should be reduced to allow for the additional day needed for transfection. Again, about 80% confluency of MEFs should be reached at the time of bacterial infection.
2. On day 2, prior to transfection, exchange the cell culture growth medium for 0.5 ml growth medium without antibiotics. Transfect cells growing on coverslips in 24-well plate 12–24 h overnight according to standard protocols, e.g., using FuGENE 6 transfection reagent. We use 0.2 µg of DNA per well of a 24-well plate with a ratio of FuGENE 6 to DNA of 3:1. In our hands, plasmid DNA prepared with MaxiPrep kits, e.g., from Qiagen or Invitrogen Corp. is sufficiently pure for cell transfection.

Good transfection efficiency is a prerequisite for analyses involving bacterial infections, as the number of cells that are both transfected and infected may be too low. You may want to consider testing different lots of fetal bovine serum, as we have detected great variability in transfection rates using different sera. Alternatively, you may have to resort to fluorescence-assisted cell sorting to enrich for the population expressing the GFP-tagged protein of interest. In this case, transfect cells in regular cell culture plates and seed onto coverslips after sorting.

C. Immunofluorescence Microscopy

See general comments about immunofluorescence microscopy analysis of EPEC- and EHEC-infected cells.

Steps

1. Permeablize cells in 0.1% Triton X-100 in PBS for 1 min.
2. Gently wash twice with PBS.
3. Prepare a humid chamber: Lay out a large square plastic dish (e.g., 24.5 × 24.5-cm polystyrene dish with lid) with a moistened piece of absorptive filter paper and coat with a layer of Parafilm M.

Perform all blocking and immunolabelling steps as follows: Using forceps, place coverslips with the cell side facing downward onto a drop of about 20 µl of blocking or antibody mixture spotted onto parafilm in the humid chamber. This helps minimize the amount of antibody needed without letting the cells dry out. In order to minimize the loss of cells when moving the coverslips after each incubation step, pipette a small amount of PBS right next to the edge of each coverslip after each incubation step. This will cause the coverslips to float on top of the PBS and will allow easy removal of the coverslips using forceps. Wash coverslips by carefully submerging them successively into three small beakers filled with PBS. In between individual washing steps, drain residual PBS by carefully streaking the edge of the coverslips across thin absorptive filter paper without allowing the cells to dry out.

4. Block with 10% normal goat serum in PBS for 20 min in humid chamber.
5. Stain with primary antibody mixture for 1 h at room temperature in humid chamber.
6. Wash three times with PBS. For polyclonal primary antibodies, include 0.1% Triton-X100 during first two washing steps.
7. Stain with secondary antibody mixture for 1 h at room temperature in humid chamber in the dark. To specifically label F-actin, use fluorescent dye-coupled

phalloidin, e.g., Alexa Fluor 594 phalloidin (red fluorescence), added at a concentration of 1–2.5 U/ml. To detect Leatuis by staining bacterial DNA, blue fluorescent DAPI may be added.

8. Wash three times with PBS. For polyclonal primary antibodies, include 0.1% Triton-X100 during first two washing steps.

9. To mount coverslips onto microscope glass slides, place drops of about 5 µl mounting medium on ethanol-wiped slides. Avoid air bubbles. Using forceps, gently place coverslips on mounting medium with the cell side facing downward. Once in contact with the mounting medium, avoid moving the coverslips as this will cause cells to be ripped off. Carefully remove access mounting media or residual PBS by placing a piece of absorptive filter paper onto the glass slides without moving the coverslips.

10. Dry mount coverslips for 3–4 h at room temperature in the dark or overnight prior to microscopic observation when using oil immersion lenses.

11. Store samples in the dark at 4°C. It is advisable to complete photography of samples within 1–2 weeks, as background fluorescence increases over time.

12. Using epifluorescence and appropriate emission filters, infected cells are detected readily by fluorescence actin staining (FAS) of actin pedestals. Search for interesting cells (e.g., both transfected and infected) using low magnification (e.g., 40×). To resolve subcellular structures such as pedestals, switch to higher magnification (100×) with or without optovar magnification. Always use minimal exposure time required to get a good signal-to-noise ratio.

IV. GENERAL COMMENTS ON IMMUNOFLUORESCENT ANALYSIS OF EPEC- AND EHEC-INFECTED CELLS

It is important to consider that polyclonal antibodies are likely to exhibit cross-reactivity against *E. coli*, which will lead to unspecific labeling of EPEC or EHEC bacteria and may confound the analysis of the role of a specific protein in actin pedestal formation by immunofluorescence microscopy. Thus, it may be difficult to discern between recruitment of a protein to the very tips of pedestals or bacterial attachment sites and unspecific labeling of bacteria, especially when using low magnification. Always test secondary reagents for unspecific labeling of bacteria. Consider using affinity-purified reagents. For polyclonal primary reagents, try addition of 0.1% Triton-X100 to PBS during washing steps. Cross-reaction of polyclonal reagents is no problem when immunolabelling is only performed to detect bacteria, as is the case in the examples shown in Fig. 2, in which EPEC bacteria were detected with monoclonal antibodies against bacterial EspE (Deibel *et al*., 1998) and Alexa Fluor 350 fluorescent-labelled goat antimouse secondary antibodies, whereas F-actin was stained with fluorescent Alexa Fluor 594 phalloidin, and the host cell protein Nck was visualized with the help of an EGFP tag. There are reports in the literature about preabsorption of antibodies against fixed bacteria prior to immunolabelling, which when tried in our laboratory was of little success. Another possible solution to overcome the problem may be the use of monoclonal secondary reagents (e.g., rat antimouse), which are available from various suppliers (e.g., Zymed Laboratories), although so far not as conjugates with AlexaFluor dyes.

An alternative approach to detect the subcellular localisation of a given protein during EPEC- or EHEC-induced pedestal formation is the use of the enhanced green fluorescent protein (EGFP) as a tag (see Fig. 2). It is important to keep in mind that tagging may significantly alter folding, activity, and proper subcellular localisation of the protein of interest. Thus, we recommend testing N- and C-terminal fusions and confirming that the localization pattern of an EGFP fusion protein equals the localization pattern of the untagged protein as detected by immunofluorescence microscopy. In addition, with the increasing availability and use of knockout cell lines, testing an EGFP-tagged protein for its ability to complement a null mutation may become a feasible possibility to ensure proper function of the EGFP-tagged protein.

Acknowledgments

We thank Florian Gunzer for the transmission electron micrograph of EHEC-infected piglet colon for Fig. 1, Klemens Rottner and Theresia Stradal for support and helpful discussions, and Brigitte Denker for excellent technical assistance. Listeria monocytogenes: Techniques to Analyze Bacterial Infection *in vitro*

Javier Pizarro-Cerdá and Pascale Cossart

I. INTRODUCTION

Listeria monocytogenes is a gram-positive food-borne pathogen responsible for listeriosis, a human infection with an overall 30% mortality rate, ranging from a clinically nonapparent fecal carriage to sever gastroenteritis, mother-to-child infections, and central nervous system infections (Dussurget *et al*., 2004; Lecuit and Cossart, 2002; Vazquez-Boland *et al*., 2001). At the individual level, *Listeria* has the capability to cross three internal barriers: the intestinal barrier, the blood–brain barrier, and the feto–placental barrier. At the cellular level, *Listeria* is able to enter macrophages, as well as nonprofessional phagocytes, such as epithelial cells. Within infected cells, *Listeria* disrupts its internalisation vacuole and escapes the phagocytic cascade by proliferating in the cytoplasm. In this environment, *Listeria* promotes actin polymerisation in order to move inside infected cells and induces its translocation to neighbouring cells, where the intracellular infectious cycle starts again (Fig. 1). *Listeria* has become a paradigm of bacterial pathogenesis at both cellular and individual levels due to the extensive study of the bacterial virulence factors and of the cellular machinery necessary for the infectious process (Gaillard *et al*., 1991; Kocks *et al*., 1992; Dramsi *et al*., 1995; Ireton *et al*., 1996; Mengaud *et al*., 1996; Lecuit *et al*., 1999; Braun *et al*., 2000; Shen *et al*., 2000). This article describes some basic methods in cellular microbiology that have been used routinely to study the infection process of *Listeria in vitro* that can be adapted to study the pathogenesis of other intracellular bacteria.

II. MATERIALS AND INSTRUMENTATION

Listeria monocytogenes wild-type strain EGD (serovar 1/2a) comes from the bacterial collection in our laboratory at the Pasteur Institute. Lovo cells (Cat. No. CCL-229) are from the American Type Culture Collection. F-12K nutrient mixture (Kaighn's modification, Cat. No. 21127-022), L-glutamine (200 m*M*, 100×, Cat. No. 25030-024), fetal calf serum (Cat. No. 16000-044), trypsin/EDTA (1×, Cat. No. 25300-054), trypan blue (0.4% solution, Cat. No. 15250-061), and phosphate-buffered saline (PBS, pH 7.4, 10×, Cat. No. 70011-036) are from Gibco. Gentamicin (10 mg/ml, Cat. No. G-1272), bovine serum albumin (BSA, Cat. No. A-7030), saponin (Cat. No. S-7900), $CaCl_2$ (Cat. No. C-4901), $MgCl_2$ (Cat. No. M-8266), NaOH (Cat. No. 930-65), Tris (Cat. No. T-6066), paraformaldehyde (Cat. No. P-6148), and NH_4Cl (Cat. No. A-5666) are from Sigma. Malassez cell counting chamber (Cat. No. 99501.01), glass slides (Cat. No. 79703.01), coverslips (Cat. No. 79720.02), plastic boxes (Cat. No. 96496.02), curved forceps (Cat. No. 24434.01), Whatmann 3 mm chromatography paper (Cat. No. 10343.01), absorbant paper (Cat. No. 62908.01), Parafilm (Cat. No. 97949.01), orbital shaker (Cat. No. 08242.107), beakers (Cat. No. 11362.01), and

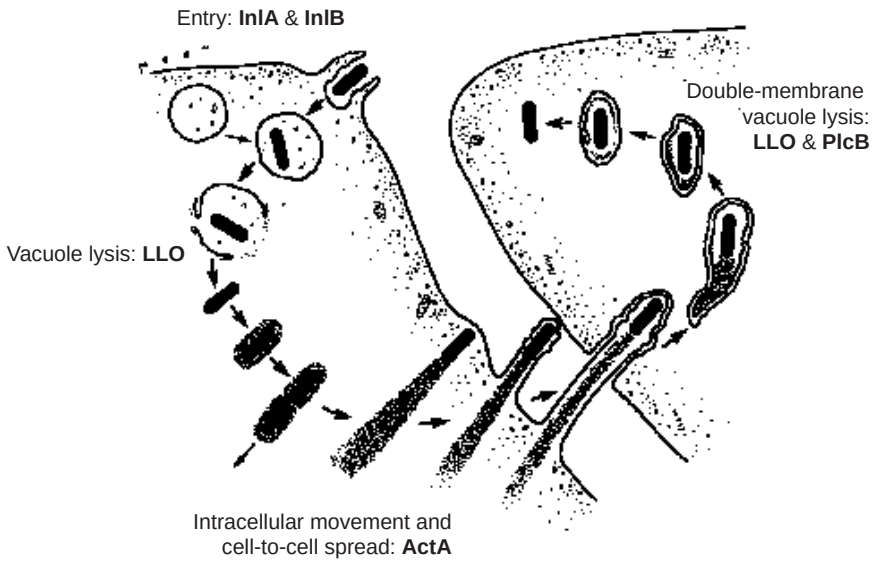

FIGURE 1 Intracellular cycle of *Listeria monocytogenes*. *Listeria* induces its own internalisation in non-phagocytic cells through interaction of the bacterial invasion proteins InlA and InlB with their cellular receptors E-cadherin and c-Met, respectively. Bacteria are initially located in a phagocytic vacuole that is disrupted by the lytic enzyme listeriolysin O (LL0), enabling *Listeria* to reach the cytoplasm and to proliferate in this environment. Intracellular actin-based movement is then induced due to the expression of the bacterial product ActA, which recruits several key players involved in actin polymerisation. Those *Listeria* that have reached the plasma membrane can form protrusions that extend to neighbouring cells. Bacteria are contained in a double-membrane phagosome that is lysed through the action of listeriolysin O and the phosphatidylcholine phospholipase C PlcB, allowing the infectious cycle to start again.

pH meter (Cat. No. 71519.01) are from Merck-Eurolab. Twenty-four-well plates (Cat. No. 351157), 15-ml polystyrene conical tubes (Cat. No. 352099), petri dishes (Cat. No. 343633), 75-cm^2 vented cell culture flasks (Cat. No. 353110), brain–heart infusion agar (Cat. No. 241830), and brain–heart infusion broth (Cat. No. 299070) are from Becton-Dickinson Biosciences. Anti-*Listeria* rabbit polyclonal serum was developed in our laboratory at the Pasteur Institute (clone R69). The mouse monoclonal anti-E cadherin BTA-1 antibody is from R&D Systems. Rabbit polyclonal antihuman c-Met (Cat. No. C-28) is from Santa Cruz Biotechnology. Goat antirabbit antibodies coupled with Alexa Fluor 488 (Cat. No. A-11008) or Alexa Fluor 546 (Cat. No. A-11010) and goat antimouse antibodies coupled with Alexa Fluor 488 (Cat. No. A-11001) and Alexa Fluor 488 phalloidin (Cat. No. A-12379) are from Molecular Probes. Mowiol 4-88 (Cat. No. 475904) is from Calbiochem. The tabletop 5415D centrifuge is from Eppendorf. Spectrophotometer Ultrospec 3000 Pro is from Amersham Pharmacia Biotech. The axiovert 135 microscope is from Zeiss. Image acquisition is performed with a RTE/CDD-1300 camera by Princeton Scientific Instruments. Image analysis and processing are done with Metamorph software from Universal Imaging Corporation.

III. PROCEDURES

A. Measurement of Bacterial Invasion: The Gentamicin Survival Assay

This procedure is a classical method that can be adapted to study the intracellular survival kinetics of different intracellular pathogens.

Solutions

1. *Cell culture medium*: F-12K nutrient mixture (Kaighn's modification) without supplements. Store at 4°C. Warm at 37°C just before use.

2. *Complete cell culture medium*: F-12K nutrient mixture (Kaighn's modification) supplemented with 2 m*M* L-glutamine and 10% fetal bovine serum. To make 500 ml, add 5 ml of a 200 m*M* L-glutamine stock solution and 50 ml of fetal bovine serum to 445 ml of F-12K nutrient mixture (Kaighn's modification). Store at 4°C and use within 7 to 8 weeks. Warm at 37°C just before use.

3. *Complete cell culture medium supplemented with gentamicin*: Complete cell culture medium supplemented with 10 µg/ml gentamicin. To make 50 ml, add 50 µl of the gentamicin stock solution (at

10 mg/ml) to 50 ml of F-12K nutrient mixture. Prepare fresh and warm at 37°C just before use.

4. *1× PBS*: To make 500 ml, add 50 ml of the PBS, pH 7.4, 10× solution to 450 ml of sterile distilled water. Store at room temperature. Warm at 37°C just before use.

5. *Trypsin/EDTA*: Aliquot in 5-ml portions in sterile 15-ml tubes. Keep at –20°C. Warm at 37°C just before use.

6. *Trypan blue solution*: Keep at room temperature.

7. *Brain–heart infusion agar*: Suspend 52 g of the powder in 1 liter of water and dissolve by frequent agitation. Autoclave at 121°C for 15 min, cool down at 50°C, and distribute in petri dishes. Keep at 4°C.

8. *Brain–heart infusion broth*: Suspend 37 g of the powder in 1 liter of water and dissolve by frequent agitation. Autoclave at 121°C for 15 min. Cool down and keep at room temperature.

Steps

1. Two days before the invasion assay, wash the LoVo cells (grown to 90% confluence in a 75-cm^2 flask) by removing the cell culture medium and adding 10 ml of PBS. Remove the PBS, add 1 ml of trypsin/EDTA, and incubate the cells for 5 min at 37°C in a 10% CO_2 atmosphere. After this incubation, carefully hit the flask to release the cells and dilute them in 10 ml of fresh complete cell culture medium. Take 10 µl of this solution and mix with 90 µl of a 0.4% trypan blue solution. With a visible light microscope, count viable cells (the ones not stained by the dye) on a Malassez cell counting chamber (100 squares = 1 µl) and dilute them to a final concentration of 10^5 cells/ml with complete cell culture medium. Add 500 µl of this solution to each of three wells of a 24-well plate and incubate for 48 h at 37°C in a 10% CO_2 atmosphere.

2. The evening before the invasion assay, take a colony of *L. monocytogenes* from a brain–heart infusion agar plate and inoculate in 5 ml of brain–heart infusion broth contained in a 15-ml tube. Incubate overnight on a rocking platform at 37°C.

3. The day of the assay, dilute 400 µl of the bacterial overnight culture in 5 ml of fresh brain–heart infusion broth contained in a 15-ml tube and incubate it on a rocking platform at 37°C to an OD_{600} of 0.8 (approximately 8×10^8 bacteria/ml).

4. Centrifuge 1 ml of the bacterial culture for 2 min at 6000 rpm and resuspend the pellet in 1 ml of PBS. Repeat this step twice; the second time resuspend the bacterial pellet in 1 ml of cell culture medium. Measure the OD and dilute bacteria to a final solution of 10^7 bacteria/ml with cell culture medium.

5. Wash LoVo cells in each well once with 1 ml of cell culture medium and add 500 µl of the bacterial dilution (MOI of 50, as we assume that cells have grown to a final density of 10^5 cells/well). Incubate for 1 h at 37°C in a 10% CO_2 atmosphere.

6. Make a 10-fold dilution of the initial bacterial solution by adding 100 µl of this preparation to 900 µl of sterile distilled water contained in an Eppendorf tube. Make another 10-fold dilution by adding 100 µl of the first 10-fold dilution to 900 µl of sterile distilled water contained in a different Eppendorf tube. Repeat this operation twice. Take a brain–heart infusion agar plate, divide the surface into four equal parts (by tracing a cross on the bottom of the plate), and plate 50 µl of each 10-fold dilution on each part. Incubate the plate overnight at 37°C in order to have an exact record of the precise number of bacteria that were inoculated on LoVo cells.

7. After 1 h of bacterial inoculation, wash LoVo cells carefully three times with 1 ml of PBS and then add 1 ml of the cell culture medium supplemented with gentamicin. Incubate the cells for another hour at 37°C in a 10% CO_2 atmosphere.

8. Wash the cells twice with 1 ml of PBS and add 1 ml of sterile distilled water to each well. Disrupt the cells by pipetting up and down water several times. Make a 10-fold dilution by adding 100 µl of the disrupted cell solution contained in each well to a different Eppendorf containing 900 µl of steriled distilled water. Make another 10-fold dilution for each tube by adding 100 µl of the first 10-fold dilution to 900 µl of sterile distilled water contained in a different Eppendorf tube. Repeat this operation once for each individual series of tubes. Take three brain–heart infusion agar plates, divide their surface in four equal parts (by tracing a cross on the bottom of the plate), and for each series of tubes, plate 50 µl of each 10-fold dilution on a different part of the agar plate (also plate 50 µl of the initial disrupted cell solution contained on the wells). Incubate the plate overnight at 37°C.

9. The day after the invasion assay, count the colony-forming units (CFU) on the agar plates at a dilution that allows a clear discrimination of individual bacterial colonies. The percentage of *Listeria* that were able to invade the LoVo cells (and which survived the gentamicin treatment) is evaluated as the ratio of bacteria recovered from the disrupted cell solution divided by the total number of bacteria added to the monolayers (results are expressed as the mean of bacterial counts obtained from the three different wells ± standard deviation).

Comments

1. Cells are grown preferentially without antibiotics.

2. *Listeria* are P2 microorganisms and should be manipulated in a microbiological hood.

3. The replication of bacteria inside cells can be analysed over time if different subsets of cells are infected initially at the same time and then each subset of cells is lysed at different time points after inoculation. This procedure is helpful in order to track the proliferation or killing of bacteria in the intracellular environment.

B. Measurement of Bacterial Invasion: Differential Immunofluorescence Labeling of Intracellular versus Extracellular Bacteria

Visualisation of bacteria allows evaluation of several parameters, such as the proportion of cells in the inoculated monolayer to which bacteria attach, as well as the proportion of adherent versus invasive bacteria.

Solutions

1. *Cell culture medium, complete cell culture medium, 1× PBS, trypsin/EDTA, trypan blue solution, brain–heart infusion agar, and brain–heart infusion broth*: Prepare as described in the Section III,A.

2. *Fixation solution*: 3% paraformaldehyde in PBS. To prepare 100 ml, heat 80 ml of PBS to 80°C and then add 3 g of paraformaldehyde while stirring. Mix until clear (add a few drops of 1 *N* NaOH to help dissolution if the liquid does not become clear after several minutes of stirring). Add 100 µl of 100 m*M* $CaCl_2$ and 100 µl of 100 m*M* $MgCl_2$, cool down at room temperature, add PBS up to 100 ml, and check pH (should be about 7.4). Aliquot in 5-ml portions and store at –20°C. Use only freshly thawed solution.

3. *Quenching solution*: 50 m*M* NH_4Cl in PBS. Prepare 100 ml of a stock solution of 1 *M* NH_4Cl in PBS by adding 5.35 g of NH_4Cl to 80 ml of PBS. Mix until clear and add PBS up to 100 ml. Keep at room temperature. The quenching solution used in the experiment will be prepared freshly by diluting 500 µl of the 1 *M* NH_4Cl stock solution in 9.5 ml of PBS.

4. *Blocking solution*: 1% BSA in PBS. To prepare 200 ml, add 2 g of BSA to 200 ml of PBS. Mix until clear. Prepare fresh just before performing the experiment.

5. *Permeabilising/blocking solution*: 0.05% saponin in blocking solution (1% BSA in PBS). To prepare 100 ml, add 50 µg of saponin to 100 ml of blocking solution. Prepare fresh just before performing the experiment.

6. *First primary antibody solution*: 1/500 dilution of R11 anti-*Listeria* rabbit polyclonal serum in blocking solution. To prepare 500 µl, add 1 µl of the R11 serum in 499 µl of blocking solution (1% BSA in PBS). Prepare fresh before performing the experiment.

7. *First secondary antibody solution*: 1/500 dilution of Alexa 546 antirabbit serum in blocking solution. Prepare as in step 6.

8. *Second primary antibody solution*: 1/500 dilution of R11 anti-*Listeria* rabbit polyclonal serum in permeabilising solution. Prepare as in step 6, using permeabilising/blocking solution instead of blocking solution.

9. *Second secondary antibody solution*: 1/500 dilution of Alexa 488 antirabbit serum in permeabilising solution. Prepare as in step 7, using permeabilising/blocking solution instead of blocking solution.

10. *Mounting solution*: 2.4% Mowiol/6% glycerol in 20 m*M* Tris buffer. To prepare 100 ml, add 2.4 g of Mowiol and 6 g of glycerol to 6 ml of distilled water. Keep at room temperature overnight. Add 90 ml of 0.2 *M* Tris, pH 8.5, warm in a water bath at 50°C, and mix regularly until total dissolution. Spin 15 min at 4000 rpm and aliquot supernatant in 1-ml portions at –20°C. Once an aliquot is thawed, keep at 4°C.

Steps

1. Infect LoVo cells following steps 1 to 5 described in Section III,A, adding 12-mm-diameter glass coverslips to the wells before seeding the cells (step 1).

2. After 1 h of bacterial inoculation, wash LoVo cells carefully three times with 1 ml of PBS and then add 500 µl of the fixation solution. Incubate for 15 min (all steps are now performed at room temperature).

3. Wash LoVo cells carefully once with 1 ml of PBS and add 500 µl of the quenching solution in order to block free aldehyde groups. Incubate for 10 min.

4. Prepare a wet incubation chamber by humidifying a 10 × 10-cm piece of Whatman 3 mm chromatographic paper. Add a sheet of Parafilm over the Whatman paper and, for each coverslip that is going to be labelled, add a drop of 30 µl of the first primary antibody solution to the Parafilm sheet.

5. Take carefully each coverslip from the wells with the forceps, carefully remove the excess of liquid from the coverslip by touching gently the tip of the coverslip with absorbant paper, and label extracellular bacteria by putting the coverslip (cells downwards) over the drop of the first primary antibody solution. Cover with a plastic lid and incubate for 30 min.

6. Prepare a second wet incubation chamber as described in step 4 and add a drop of 30 µl of the first secondary antibody solution to the Parafilm sheet for each coverslip that is going to be labeled.

7. Take carefully each coverslip with the forceps and, in order to wash the first primary antibody solution, dip it gently 10 times in a 50-ml beaker containing 40 ml of the blocking solution. Remove excess

liquid as described in step 5 and label the first primary antibody by putting the coverslip (cells downwards) over the drop of the first secondary antibody solution. Cover with the plastic lid and incubate for 25 min.

8. Prepare a third wet incubation chamber as described in step 4 and, for each coverslip that is going to be labelled, add a drop of 30 µl of the second primary antibody solution to the Parafilm sheet.

9. Take carefully each coverslip with the forceps and wash the first secondary antibody solution by dipping the coverslip 10 times in a 50-ml beaker containing 40 ml of the blocking solution and then dipping it again 10 times in a 50-ml beaker containing 40 ml of the permeabilising/blocking solution. Remove excess liquid from the coverslip as described in step 5 and label intracellular and extracellular bacteria by putting the coverslip (cells downwards) over the drop of the second primary antibody solution. Cover with the plastic lid and incubate for 30 min.

10. Prepare a fourth wet incubation chamber as described in step 5 and add a drop of 30 µl of the second secondary antibody solution to the Parafilm sheet for every coverslip that is going to be labelled.

11. Take carefully each coverslip with the forceps and wash the second primary antibody solution by dipping the coverslip 10 times in a 50-ml beaker containing 40 ml of the permeabilising/blocking solution. Remove excess liquid as described in step 5 and label the second primary antibody by putting the coverslip (cells downwards) over the drop of the second secondary antibody solution. Cover with the plastic lid and incubate for 25 min.

12. Take carefully each coverslip and wash the second secondary antibody solution by dipping it 10 times in a 50-ml beaker containing 40 ml of the permeabilising/blocking solution, 10 times in a different 50-ml beaker containing 40 ml of PBS, and 10 times in a third 50-ml beaker containing 40 ml of distilled water. Remove excess water and put the coverslip carefully over a 10-µl drop of mounting medium on top of a glass slide.

13. Visualise the preparation with a fluorescence microscope (Fig. 2). Extracellular bacteria, labelled with the first and second primary antibodies and, accordingly, also labelled with the first and second secondary antibodies, will appear yellow (due to the superposition of the green signal of the Alexa 488 fluorochrome and of the red signal of the Alexa 546 fluorochrome). Intracellular bacteria, however, labelled only with the second primary antibody and, consequently, labelled only with the second secondary antibody, will appear green. Count extracellular and intracellular *Listeria* in at least 100 LoVo cells and express the results in a histogram standardising the

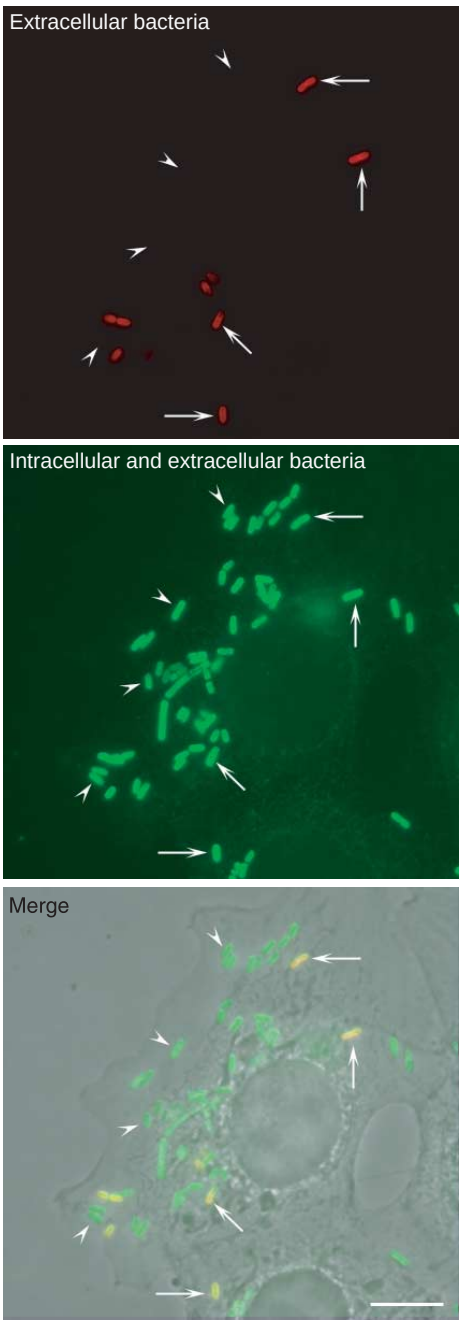

FIGURE 2 Differential immunolabeling of intracellular versus extracellular bacteria. LoVo cells were infected with *L. monocytogenes* as described in the text, and extracellular bacteria were distinguished from intracellular microorganisms by differential immunolabeling. (Top) Extracellular bacteria were labeled with an anti-*Listeria* serum without permeabilising LoVo cells. (Middle) The total population of bacteria (both extracellular and intracellular) was labeled with the same anti-*Listeria* serum after permeabilising LoVo cells. Intracellular bacteria are identified as those bacteria that are labeled only after the permeabilisation treatment. (Bottom) Phase image of LoVo cells and *Listeria*. Bar: 5 µm. Arrowheads, intracellular bacteria; arrows; extracellular bacteria.

total number of bacteria to 100% and expressing accordingly the corresponding proportions of extracellular and intracellular *Listeria*.

Comments

1. Never allow cells to dry.
2. As fluorochromes are sensitive to light, perform incubations in the dark by covering with a plastic lid enveloped in aluminum foil.
3. Antibody dilutions are suggested accordingly to their use in our own laboratory. They could need finer adjustment depending on the batch used.

C. Visualisation of the Interaction of *Listeria* with Its Receptors E-Cadherin and c-Met

Two bacterial proteins, InlA (internalin) and InlB, are known to mediate the internalisation process of *Listeria* into target cells (Gaillard *et al*., 1991; Dramsi *et al*., 1995; Cossart *et al*., 2003). InlA promotes entry into a subset of epithelial cells that express its cellular receptor, the adhesion molecule E-cadherin (Mengaud *et al*., 1996; Lecuit *et al*., 1999), a transmembrane protein that is normally involved in homophilic cell/cell interactions. Two different cellular receptors have been identified for InlB: the receptor for the globular part of the complement component C1q (gC1q-R) (Braun *et al*., 2000) and c-Met, the receptor for the hepatocyte growth factor (Shen *et al*., 2000). Interaction of InlA and InlB with their respective cellular receptors induces the recruitment to the site of bacterial entry of intracellular molecules that mediate cytoskeletal rearrangements necessary to induce bacterial invasion (Ireton *et al*., 1996, 1999; Lecuit *et al*., 2000; Bierne *et al*., 2001). By immunofluorescence it is possible to visualise the recruitment of E-cadherin and c-Met at the site of bacterial invasion.

Solutions

1. *Cell culture medium, complete cell culture medium, 1× PBS, trypsin/EDTA, trypan blue solution, brain–heart infusion agar, and brain–heart infusion broth*: Prepare as described in Section III,A.

2. *Fixation solution, quenching solution, permeabilising/blocking solution, and mounting medium*: Prepare as described in Section III,B.

3. *Primary antibody solution*: 1/100 dilution of both the anti-E-cadherin mouse monoclonal serum BTA-1 and the anti-C-Met polyclonal serum C-28. To prepare 500 µl, add 5 µl of the anti-E-cadherin BTA-1 serum and 5 µl of the anti-C-Met C-28 serum to 490 µl of permeabilising/blocking solution. Prepare fresh before performing the experiment.

4. *Secondary antibody solution*: 1/500 dilution of both Alexa 488 antimouse serum and Alexa 546 antirabbit serum in permeabilising/blocking solution. To prepare 500 µl, add 1 µl of each secondary antibody to 498 µl of permeabilising/blocking solution freshly before use.

Steps

1. Infect LoVo cells following step 1 in Section III,B.
2. Fix and quench LoVo cells following steps 2 and 3 in Section III,B.
3. Label LoVo cells following steps 4 to 7 in Section III,B, taking into account that in the present experiment there is only one primary antibody solution (containing actually a mix of two different primary antibodies) and only one secondary antibody solution (containing a mix of two different secondary antibodies).
4. Wash and mount the cells following step 12 in Section III,B.
5. Visualise the preparation with a fluorescence microscope (Fig. 3). c-Met will be recognised by the red signal (from the Alexa 546 fluorochrome) and will be observed at different locations of the plasma membrane of LoVo cells. E-cadherin will be detected by the green signal (from the Alexa 488 fluorochrome) and will be found essentially at adherens junctions located in the borderline region between two different adjacent cells. *Listeria* can be visualised by light microscopy (phase contrast). Both receptors can also be detected at the site of entry of invading *Listeria*.

D. Visualisation of *Listeria*-Induced Actin Comet Tails and Protrusions

A hallmark of *Listeria* infection is the polymerisation of cellular actin: bacteria that have escaped their internalisation vacuoles take advantage of this actin-based motility mechanism to reach and infect neighbouring cells without leaving the intracellular environment. A single bacterial product, the protein ActA, is responsible for this phenomenon by recruiting to the bacterial rear end two cellular key players of the actin nucleation process: VASP and the Arp2/3 complex (Cossart, 2000). Polymerised actin can be visualised as a structure that extends from the rear end of the moving *Listeria* to the cell cytoplasm, which has been named the actin comet tail. Bacteria that have reached the plasma membrane of a primary infected cell form protrusions that extend into the cytoplasm of neighbouring cells (or that extend simply to the extracellular space in the case of cells that do not have adjacent neighbours). These structures can be visualised by labelling the cel-

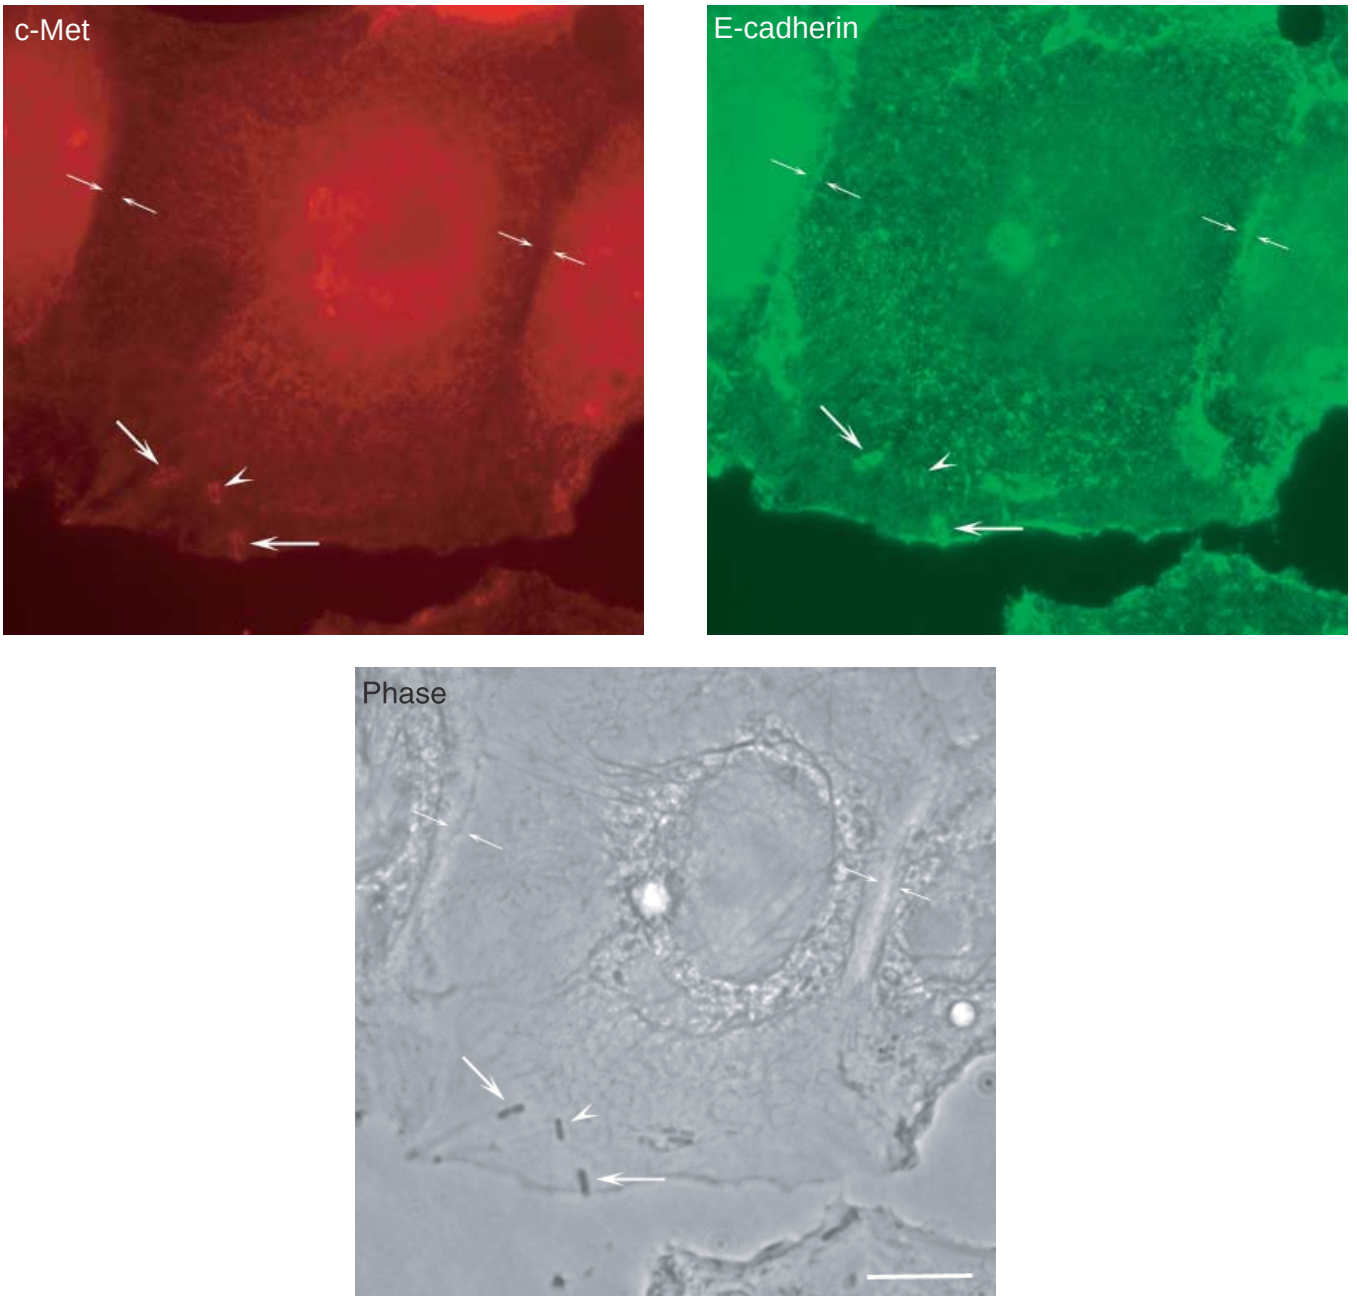

FIGURE 3 Interaction of *Listeria* with its receptors E-cadherin and c-Met. LoVo cells were infected with *L. monocytogenes* as described in the text, and its receptors E-cadherin and c-Met were immunolabelled. (Top left) c-Met shows a diffuse distribution in LoVo cells and is clearly absent at sites of adherens junctions formation, but is clearly recruited at sites of bacterial invasion. While some of the invading *Listeria* colocalise with both E-cadherin and c-Met, one bacterium is shown that only colocalises with c-Met and not with E-cadherin (arrowhead), suggesting that the interaction of *Listeria* with each one of their receptors can be uncoupled, as observed in cells lines such as Caco-2 (in which invasion is mediated mainly by the InlA/E-cadherin interaction) or Vero (in which invasion is driven exclusively by the InlB/c-Met interaction). (Top right) E-cadherin distribution at the plasma membrane of LoVo cells can be clearly seen at sites of adherens junction formation as well as at sites of bacterial entry. (Bottom) Phase image of LoVo cells and *Listeria*. Bar: 5µm. Opposing arrows, adherens junction; large arrows, bacteria that recruit E-cadherin and c-Met at their site of entry; arrowheads, bacterium that only recruits c-Met at its site of entry.

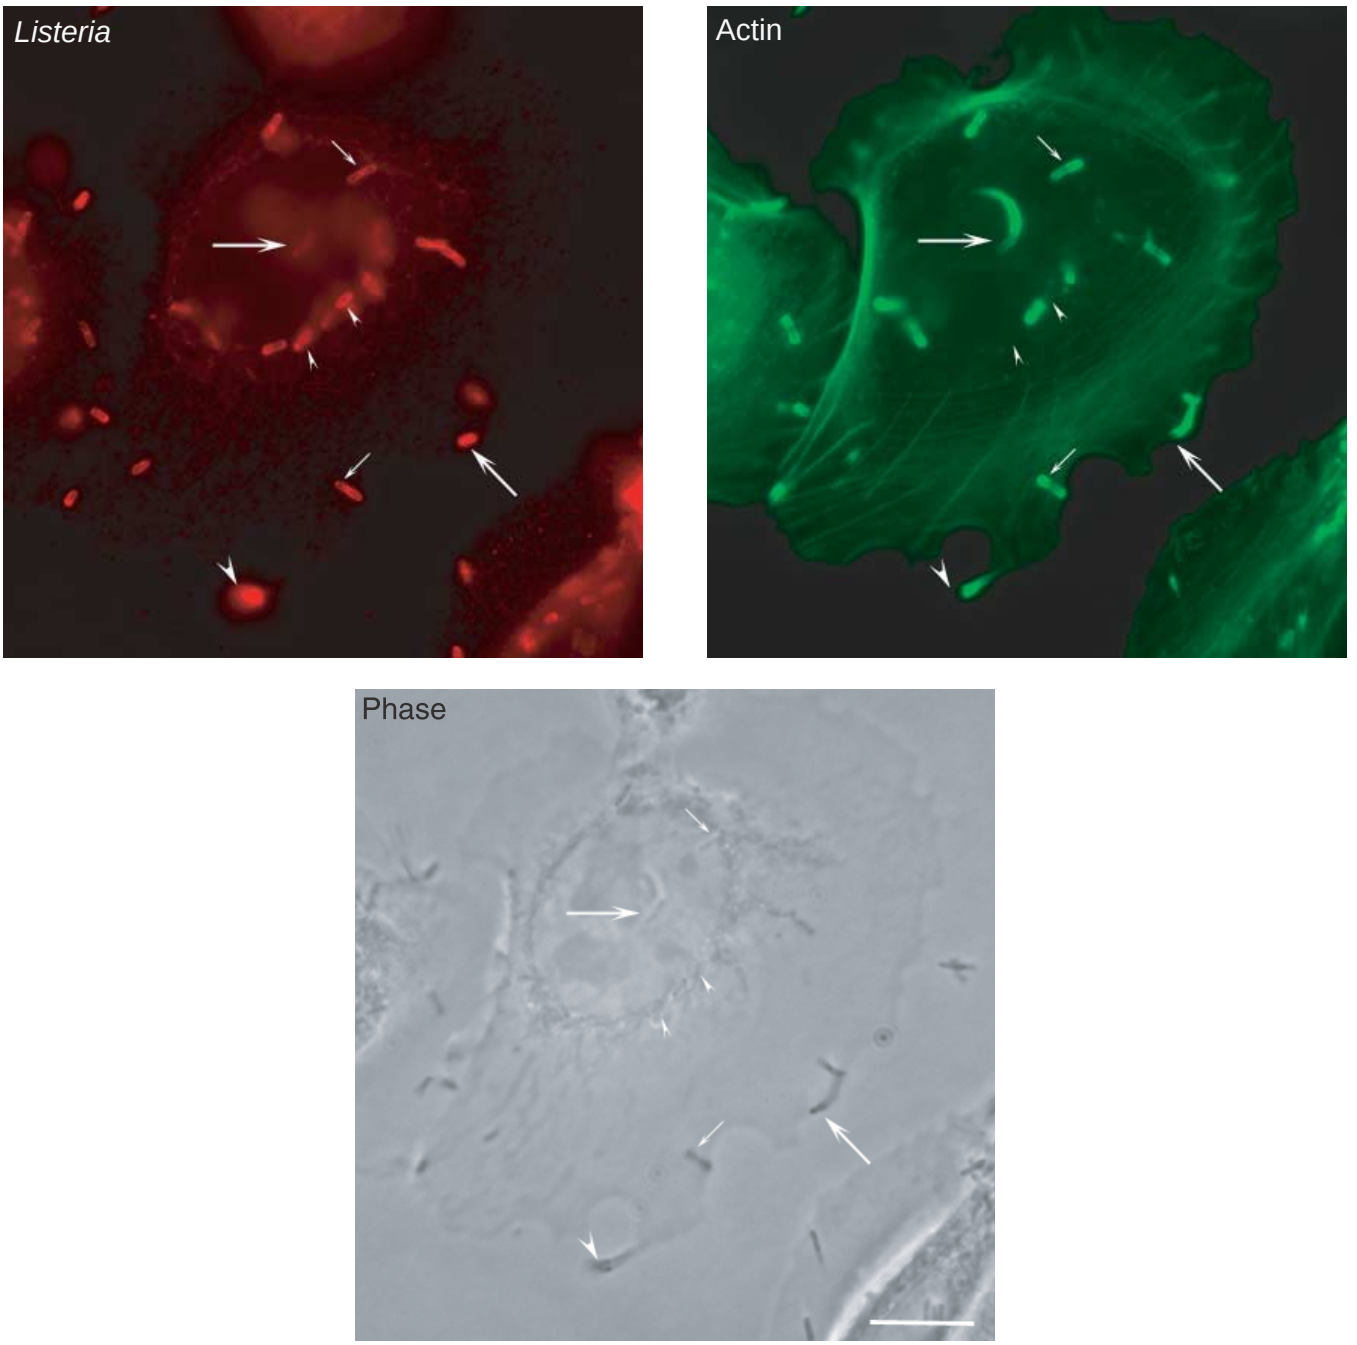

FIGURE 4 Actin polymerisation and protrusion formation by *Listeria*. LoVo cells were infected with *Listeria* as described in the text. Both bacteria and the actin cytoskeleton were labelled for immunofluorescence analysis. (Top left) Labelling of the total population of bacteria associated to LoVo cells. (Top right) Actin labelling with the fungal drug phalloidin. While some bacteria are not associated with actin (small arrowheads), other bacteria are detected at early phases of actin polymerisation (small arrows). Bacteria at later stages of their intracellular cycle can be observed at the tip of actin comet tails (big arrows). *Listeria* that have reached the plasma membrane can form protrusions that extend beyond the infected cell (big arrowhead). (Bottom) Phase image of LoVo cells and *Listeria*. Bar: 5µm.

lular actin with the fungal drug phalloidin in cells that have been infected with *Listeria* for at least 5 h.

Solutions

1. *Cell culture medium, complete cell culture medium, 1× PBS, trypsin/EDTA, trypan blue solution, brain–heart infusion agar, and brain–heart infusion broth*: Prepare as described in Section III,A.

2. *Fixation solution, quenching solution, permeabilising/blocking solution, and mounting medium*: Prepare as described in Section III,B.

3. *Primary antibody solution*: 1/500 dilution of R11 anti-*Listeria* rabbit polyclonal serum in permeabilising/blocking solution. To prepare 500 µl, add 1 µl of the R11 serum in 499 µl of permeabilising/blocking solution. Prepare fresh before performing the experiment.

4. *Secondary antibody and probe solution*: 1/500 dilution of Alexa 546 antirabbit serum in permeabilising/blocking solution and 1/100 dilution of phalloidin Alexa 488. To prepare 500 µl, add 1 µl of the Alexa 546 serum and 5 µl of the phalloidin Alexa 488 probe to 496 µl of permeabilising/blocking solution. Prepare freshly before use.

Steps

1. Infect LoVo cells following steps 1 to 5 and step 7 in Section III,A, adding 12-mm-diameter glass coverslips to the wells before seeding the cells (step 1) and incubating the LoVo cells in the presence of cell culture medium supplemented with gentamicin for 5 h insted of 1 h (step 7).

2. Fix and quench LoVo cells following steps 2 and 3 in Section III,B.

3. Label LoVo cells following steps 4 to 7 in Section III,B, taking into account that in the present experiment there is only one primary antibody solution (containing one primary antibody) and only one secondary antibody solution (containing a mix of one secondary antibody and one cytoskeletal probe).

4. Wash and mount the cells following step 12 in Section III,B.

5. Visualise the preparation using a fluorescence microscope (Fig. 4). Actin will be detected by the green signal (from the Alexa 488 fluorochrome) and will be observed at different cellular locations, such as stress fibres or cortical filaments near the plasma membrane. *Listeria* will appear as red (due to the signal of the Alexa 546 fluorochrome). Bacteria that have just lysed their phagosomal membrane and that have already started to polymerise actin will also be surrounded uniformly with the Alexa 488 fluorochrome. Those *Listeria* that broke their vacuole early will be associated with comet tails, which can be visualised starting at the rear pole of red bacteria and projecting into the cell cytoplasm. In the case of those *Listeria* that have reached the plasma membrane of an infected cell, a protrusion can be seen as a protruding structure that contains a red bacteria at its tip and a green actin comet tail following behind.

Mechanical Stress in Single Cells

CHAPTER

53

Measurement of Cellular Contractile Forces Using Patterned Elastomer

Nathalie Q. Balaban, Ulrich S. Schwarz, and Benjamin Geiger

1. INTRODUCTION

The adhesive interaction of cells with their neighbors and with the extracellular matrix is a characteristic feature of all metazoan organisms. Cell adhesion is essential for cell migration, tissue assembly, and the direct communication of cells with their immediate environment. These interactions are mediated via specific cell surface receptors that specifically interact with the external surface, and link it, across the membrane, with the actin cytoskeleton (Geiger *et al.*, 2001). These multimolecular complexes are subjected to constant mechanical perturbation, generated either by the cellular contractile system or by changes in the neighborhood of the cell. To list just a few examples, in the course of cell migration, focal adhesions (FA) are formed, where contractile microfilament bundles, consisting of actin and myosin, are anchored. Their pulling on the substrate is involved in regulating the adhesion itself, as well as in coordinating the persistent forward movement of the cell. Mechanical perturbations are generated by diverse external factors, such as muscle contraction, blood flow, gravitational forces, and acoustic waves. Both internal and external forces apparently act at adhesion sites and modulate their organization and signaling activity (Geiger and Bershadsky, 2001; Riveline *et al.*, 2001; Galbraith *et al.*, 2002). In view of the major physiological significance of these cellular forces, it appears important to develop approaches for the accurate measurement of cellular forces with an appropriate sensitivity and spatial resolution (Beningo and Wang, 2002; Roy *et al.*, 2002). This article describes an approach for measuring such forces using the patterned polydimethylsiloxane (PDMS) elastomer as an adhesive substrate and cells expressing fluorescent focal adhesion molecules (Balaban *et al.*, 2001). These experiments demonstrated that cells maintain a constant stress at focal adhesion sites, of the order of ~5 n$N/\mu m^2$, and that changes in cellular contractility lead rapidly to changes in FA organization. This article describes the technique used for the preparation of the patterned elastomeric substrate and for measuring the cellular forces.

II. MATERIALS AND EXPERIMENTATION

A. Lithography

Silicone wafer
Photoresist: Microposit S1805 (Shipley, Marlborough, MA)
Developer: Microposit MF-319 (Shipley)
HMDS or tridecafluorooctyltrichlorosilane (UCT, Bristol, PA)
Acetone, methanol
Spinner (Headway Research, Inc., Garland TX)
Mask aligner (Karl Suss, MJB3, Germany)
Chrome mask with desired pattern, or transparency
Digital hot plates
Oven
Scriber

B. Elastomer

PDMS: Sylgard 184, Dow Corning
No. 1 glass coverslips (diameter 25 mm)
Oven

Copyright 2006, Elsevier Science (USA).
All rights reserved.

C. Microscopy

The DeltaVision microscopy system (Applied Precision Inc., Issaquah, WA) is used in these experiments. Similar microscopy systems could be used for such purpose, provided that they are capable of accurately acquiring high-resolution images (512 × 512 pixels or better) at a high sensitivity (allowing for low-dose recording) and high dynamic range (12 bit or better).

D. Calibration

Bulk calibration: weights, clamps

Calibrated micropipettes with elastic constants 10–50 n$N\,\mu m^{-1}$

E. Image Analysis

Image analysis software: Priism (Applied Precision Inc.)

Data analysis software: Matlab (The Mathworks, Natick, MA) (This software can be purchase with image analysis toolbox and used to perform the image analysis as well)

F. Calculation of Forces

A detailed description of this calculation is provided in a web site established by Dr. Ulrich Schwartz (see later).

III. PROCEDURES

A. Lithography

This step provides molds consisting of a pattern of photoresist on silicon wafer that will be used for the patterning of elastomer substrates, a technique termed "soft lithography" (Whitesides *et al.*, 2001). It relies on access to a clean room with basic optical lithography. It also assumes the availability of the chrome mask with the pattern of interest. For high-resolution patterns (features below 1 µm), such masks are produced by electron beam lithography (also available in many clean room facilities). For low-resolution patterns (5 µm features and more), transparencies with appropriate resolution (5080 dpi) can be used.

1. Clean silicon wafer in acetone and then immediately wash with methanol and blow dry.
2. (Optional) Bake for 20 min in a 120°C oven.
3. Dispense HMDS in the middle of the wafer until full coverage and spin at 6000 rpm for 1 min.
4. Dispense S1805 photoresist in the middle of the wafer covering approximately one-third of the wafer and spin at 5000 rpm for 30 s.
5. Soft bake on hot plate at 80°C for 5 min.
6. Make sure the wafer and the mask are in contact in the mask aligner.
7. Expose for 10 s. This number is only an estimate; exposure and development times have to be adjusted for the specific exposure system. Typically an exposure of 100–140 mJ/cm^2 is recommended.
8. Develop for 10 s (see aforementioned comment).
9. Hard bake for 5 min in a 120°C oven.
10. In order to prevent sticking between the mold and the PDMS, an additional spin of HMDS can be performed at this stage. Alternatively, overnight exposure to vapors of tridecafluorooctyltrichlorosilane can be done.
11. Dice the wafer with a scriber in small pieces of about 5 × 5 mm. Each of these pieces can be reused as a mold many times for patterning of the PDMS substrates.

B. Elastomer Substrates

1. Pour about 30 ml of part A of the Sylgard 184 kit. Add 1 part of B (cross-linker) for 50 parts of A (in weight). Mix thoroughly.

2. Cover and let stand on bench until bubbles are scarce (typically 30 min).

3. Coat glass coverslips with the PDMS mixture. For large patterns that can be seen with low-resolution, long working distance objectives, put a few drops of the mixture in the middle of the coverslip on a flat surface covered with aluminium foil and let flow until the whole coverslip is covered. For short working distance objectives, a thinner layer is needed. This can be achieved by spinning No.1 coverslips at 1000 rpm on a spinner equipped with a 0.05-in. rotating head or "chuck." Alternatively, coverslips coated with PDMS can be put vertically to allow the flow of excess PDMS and attain a thinner thickness (typically 0.05 mm).

4. Place the coated coverslips on aluminium foil and bake in an oven at 65°C for 25 min until the top layer of the PDMS has started to solidify.

5. Place the rest of the PDMS mixture in the oven for bulk calibration purposes (see Section III,D).

6. Place a piece of the mold in the center of each coverslip (the patterned side of the mold should be in contact with the PDMS) and put back in oven overnight.

7. Delicately separate the mold from the patterned coverslip.

8. Glue each patterned coverslip to the botton of a 35-mm tissue culture plate with a 15-mm hole. This step can be done with melted paraffin.

9. Wash the coverslip and dish extensively with phosphate-buffered saline (PBS).

10. Incubate at 4°C overnight with a solution of 10 µg/ml of fibronectin in PBS.

11. Before plating the cells, wash the fibronectin solution with fresh plating medium twice and incubate the substrates with medium at 37°C for 1 h.

12. Plate cells at appropriate dilution and incubate immediately until observation.

C. Microscopy

Images are recorded, using phase-contrast or fluorescence optical mode, with a DeltaVision system digital microscopy system. This system is based on a Zeiss inverted microscope equipped with filter sets for multiple color microscopy and a high-resolution, scientific-grade CCD camera. Images are acquired using high numerical aperture oil objectives for the high-resolution pattern and focal adhesion detection (Fig. 3); long distance objectives are used for semiquantitative estimates of force using large patterns (Fig. 2). Image processing is conducted primarily using the Prism software of the DeltaVision system.

D. Calibration of Elastic Properties of the Elastomer

The aim of this step is to determine whether the cured PDMS is an elastomer and to obtain the two parameters that characterize its elasticity, namely the Young modulus (Y) and the Poisson ratio (σ) (Feynman, 1964).

1. *Bulk Calibration*

Cut strips of cured elastomer (see Section III,B, step 5). Typically a strip of 100 × 30 × 5 mm can be used. Hold each side with clamps wider than the strip. With a marker, draw two lines on the elastomer, away from the clips, separated by about 50 mm. The distance between the lines is marked as L in Fig. 1. Add increasing masses, m, to the lower clamp and measure the total increase in length, dL, until $dl > L$. Plot the relation $\frac{dl}{L}(m)$ with m expressed in kilograms. Verify that the relation is linear and extract the linear coefficient, α. The Young modulus (in Pa) is given by

$$Y = \frac{g}{A\alpha}$$

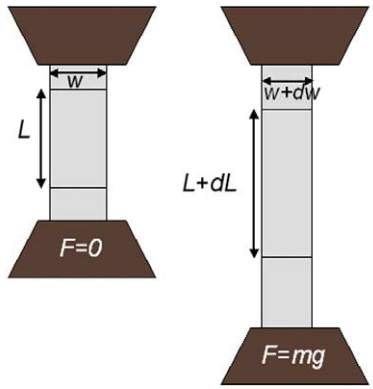

FIGURE 1 **Bulk calibration of the elastomer.** A stripe of PDMS prepared in parallel to preparation of elastomer substrates is checked for its elastic properties. The procedure consists of subjecting the stripe to increasing masses while measuring the force–extension response.

with $A = w*h$, the cross section of the strip (in m^2), and $g = 9.8\,m\,s^{-2}$.

The Poisson ration, σ, is given by measuring the contraction in w and h:

$$\frac{dw}{w} = \frac{dh}{h} = -\sigma\frac{dl}{L}$$

The strips should be stretched overnight to verify that they relax to their original length, L, once the weights are removed.

2. In Situ *Calibration*

In order to verify that the plating of cells does not modify the elastic characteristics of the surface, *in situ* calibration of the elasticity of the patterned substrate is performed under a microscope.

Mount the calibrated micropipette on a micromanipulator. Approach the surface slowly, keeping the micropipette parallel to the patterned elastomer surface. Once the tip of the micropipette is in contact with the surface, acquire an image of the patterned elastomer and of the tip of the pipette. Slowly move the stage by 2–3 µm in order to create a stress between the micropipette and the surface. Acquire a new image of the deformed pattern and of the micropipette bending. Usually, images at different magnifications are necessary in order to visualize the distortions of the pattern and of the micropipette. The force exerted by the micropipette is measured directly by quantifying the deflection of the pipette in the image. Verify that the calculation of force using the bulk Young modulus agrees with the known force exerted by the calibrated micropipette.

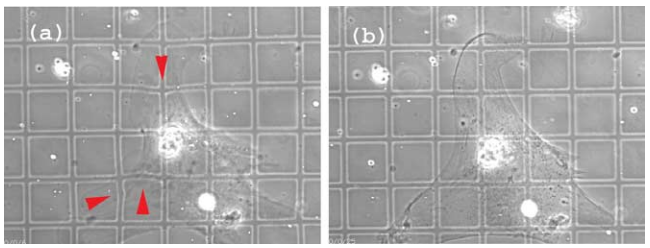

FIGURE 2 **Rapid semiquantitative estimate of forces (Balaban *et al.*, 2001).** A large grid-patterned elastomer is used for the easy visualization of distortions. (a) A rat cardiac fibroblast exerts forces on the elastomer substrates, which result in deformations of the grid (marked by arrows). (b) Once the forces are relaxed by adding an inhibitor of contractility, the grid returns to its original regular shape. Grid size: 30 μm.

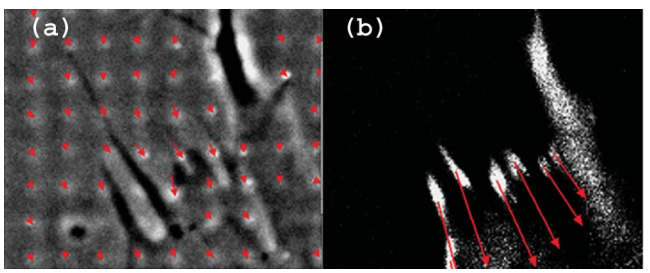

FIGURE 3 **From displacements to forces (Balaban *et al.*, 2001).** (a) Phase-contrast image of a small part of a fibroblast on the high-resolution dot pattern. Arrows denote displacements of the center of mass of the dots relative to the relaxed image. Pitch size: 2 μm. (b) Fluorescence image of the same field of view showing locations of the focal adhesions. The length of the arrows here indicates the forces at each focal adhesion, calculated from displacement data.

E. Image Analysis

Substrates with low resolution patterns such as the 30-μm grid shown in Fig. 2 can provide semiquantitative estimates of the mechanical perturbation due to cells and is useful for the rapid comparison between different cell types or conditions. However, for the quantitative measurement of the forces at single adhesion sites, high-resolution patterns of dots (Fig. 3a), as well as fluorescence tagging of adhesion sites, are needed (Fig. 3b). In this section, it is assumed that the following images are available for the same field of view.

a. Phase contrast of cells on a high-resolution pattern of dots ("dot_force.tif").

b. Phase contrast of the high-resolution pattern of dots, after forces have been relaxed ("dot_relaxed.tif"), namely after treatment with acto-myosin inhibitors or trypsinization. Alternatively, locations of the dots in the relaxed pattern can be generated directly as ("center_relaxed.dat") by assuming the regularity of the pattern.

c. Fluorescence image of adhesion sites ("focals.tif").

Registration of Images

In order to correct for eventual shifts during image acquisitions, all three images should be aligned using fixed reference points. Typically, corrections of a few pixels shift in x or y might be needed; angular shift are infrequent.

The step is performed using the registration option of the image analysis software.

Detection of the Pattern

This step automatically detects the dots in the two phase-contrast images and outputs their center-of-mass coordinates to an ASCII file. It is important to use the same parameters for both images.

a. Filter "dot_force.tif " and dot_relaxed.tif" with a large kernel in order to correct for background unevenness.

b. Depending on the image quality, use a high pass filter with a small kernel to enhance the dots contrast on both images.

c. Perform segmentation for the detection of the dots. Verify that the segmentation detected the dots properly. Correct manually for eventual defects.

d. Save the center of mass coordinates of the dots in each picture in two separate ASCII files ("center_relaxed.dat" and "center_force.dat").

e. Using Matlab, load the two ASCII files and arrange in pairs nearest neighbors according to their center of mass coordinates to identify equivalent dots between the two files. This will work for most of the image where there are no displacements. In areas where displacements are larger than the distance between dots, manual corrections might be needed (see Section III,F). Save data as an ASCII file ("lines.dat") whose first two columns are the x and y coordinates of the dots in "center_relaxed.dat" and the last two columns are the x and y coordinates of the equivalent dots from "center_force.dat".

f. Visualization of the displacements: load "lines.dat" using a procedure for drawing arrows in the image analysis software (DrawArrows in Prism) on top of the phase-contrast images. Correct for wrong or missing arrows. Save corrections.

3. Detection of Focal Adhesions

This step automatically detects focal adhesions in the fluorescence image of cells with GFP-tagged focal adhesion protein (Zamir *et al.*, 1999). ("focals.tif") and

outputs their center-of-mass coordinates to an ASCII file ("focals.dat"). The segmentation procedure is analogous to the detection of dots in the pattern.

F. Calculation of Forces

The main advantage of flat elastic substrates is that they interfere little with cell adhesion as traditionally studied on glass or plastic surfaces. In particular, by using transparent elastomers such as PDMS, one can use the normal setups for light microscopy. The main disadvantage of flat elastic substrates is that a computational technique has to be implemented to calculate force from displacement. For the procedure described here, a package with Matlab routines can be downloaded from http://www.mpikggolm.mpg.de/th/people/schwarz/ElasticSubstrates/. For well-spread cells, one can assume that forces are applied to the top side of the elastic film mainly in a tangential fashion. Because the PDMS film is much thicker than typical displacements on its top side, one can moreover assume that displacements follow from forces as in the case of an elastic half-space. Because we focus on forces from single focal adhesions, where force is localized to a small region of space (namely the focal adhesion), we finally assume that each focal adhesion corresponds to one point force. Then displacement follows from force as described by the well-known Boussinesq solution for the Green function (Landau and Lifshitz, 1970). Since we only consider the case of small deformations (i.e., magnitude of strain tensor $|u_{ij}| < 1$), we deal with linear elasticity theory, and deformations resulting from different force centers can be simply added up to give overall deformation at a given point. However, because the Green function of a point force diverges for small distance r as $1/r$, we first use the Matlab program "data.m" to clear the file "lines.dat" from all displacement data points, which are closer to the positions of the focal adhesions in "focals.dat" than a distance of the order of the size of focal adhesions [this procedure can be justified with the concept of a force multipolar expansion (Schwarz *et al.*, 2002)]. This gives a new file "newlines.dat", which together with "focals.dat" is used by our main Matlab program, "inverse.m". Since we are interested in force as a function of displacement, but the Boussinesq solution from linear elasticity theory describes deformation as a function of force, we now have to solve an inverse problem. Because the elastic kernel effectively acts as a smoothing operation that removes high-frequency data, this inversion is ill posed in presence of noise in displacement data: small differences in displacement data can result in large differences in the force pattern. Due to the noise problem, we only can estimate force through a χ^2 minimization. Moreover, the target function has to be extended by a so-called regularization term, which prevents the program from reproducing every detail of displacement data through a force estimate with unrealistically large forces. Therefore, we add a quadratic term in force to the target function, which guarantees that forces do not become exceedingly large. The regularization procedure introduces an additional variable, the regularization parameter λ, whose value is fixed by the program "inverse.m" with the help of the so-called discrepancy principle, which states that the difference between measured displacement and displacement following from the force estimate should attain a certain nonvanishing value. Because the target function remains quadratic for the simple regularization term used, it can be inverted easily by singular value decomposition. For this purpose, the Matlab program "inverse.m" uses the freely available package of Matlab routines *Regularization Tools* by P. C. Hansen. Finally the force estimate is saved in a new ASCII file "forces.dat", which for each entry in "focals.dat" gives the corresponding force estimate. Force calibration assumes the value $\sigma = 0.5$ for the Poisson ratio and requires values for Young modulus Y and microscope resolution. The resolution of this procedure depends on the details of the force pattern under consideration, but can be estimated by data simulation. Even under the most favorable conditions, which can be achieved experimentally in regard to quality of displacement data, the original force cannot be reproduced completely and regularization is required to arrive at a reasonable estimate. Spatial and force resolutions have been found to be better than $4\,\mu m$ and $4\,nN$, respectively. Therefore the calculated point force should be correlated with other properties of a focal adhesion only when no other focal adhesions are closer than the spatial resolution of our method.

IV. PITFALLS

1. The mixing of the PDMS should be done in many strokes (typically for a few minutes) and preferably in plastic dishes with lids.

2. Because of variations between batches, the 50:1 ratio of the Sylgard kit might need adjustment.

3. The first bake of the PDMS layer should be fine tuned: too much baking before putting the mold will result in a poor pattern, whereas insufficient baking will result in difficulties separating the mold from the PDMS. Baking times can be reduced by increasing the temperature.

4. Before dicing the patterned wafer, make sure the scriber is good by practicing on a similar unpatterned wafer.

5. The choice of the cells to use is important: immortalized cell lines often exert forces that are below the force resolution of this method.

6. Focal adhesions formed on PDMS may differ, at the molecular level, from those formed on other substrates and their composition (e.g., type of integrin) should be examined.

Acknowledgments

BG is the E. Neter Prof. for cell and tumor biology.

NQB is supported by the Bikura program of the Israel Science foundation and is a fellow of the Center for Complexity; The Horowitz Foundation.

APPENDIX

CHAPTER

54

Resources

José M.A. Moreira and Emmanuel Vignal

I. INTRODUCTION

In the past decade, researchers have witnessed an explosive growth in the amount of information available to them at internet-based sites. In this day and age, researchers requiring supplementary information to a particular aspect of a research technique can do so by using a search engine or browsing through the internet, but this is more often than not a time-consuming and frustrating endeavour where one ends up having to deal with thousands of hits that are not relevant to the initial query.

This section lists outstanding resources for cell and molecular biology research that complement and extend the usefulness of the research protocols described in the previous sections. We have found the sites listed here to be comprehensible, useful, and generally well run and consequently we recommend them as good starting points for any researcher rummaging around for information. Nonetheless, this compilation is intended solely as a valuable aid to the research techniques described throughout this book rather than a stand-alone guide of laboratory procedures or an exhaustive listing of Web resources.

II. INTERNET RESOURCES FOR CELL BIOLOGISTS

A. Cells and Tissue Culture

1. The World Federation for Culture Collections (WFCC)

http://wdcm.nig.ac.jp/wfcc

The WFCC is a federation concerned with the collection, authentication, maintenance, and distribution of cultures of microorganisms and cultured cells. The WFCC, through the World Data Center for Microorganisms (WDCM), developed an international database on culture resources worldwide. This data resource is now maintained at the National Institute of Genetics (NIG, Japan) and has records of nearly 469 culture collections from 62 countries (http://wdcm.nig.ac.jp/hpcc.html). The records contain data on the organisation, management, services, and scientific interests of the collections. Each of these records is linked to a second record containing the list of species held.

2. European Collection of Cell Cultures (ECACC)

http://ecacc.org.uk

In addition to being a bank of cell lines and hybridomas, ECACC also provides an EBV immortalisation service to establish lymphoblastoid cell lines from patients and their families with genetic and chromosomal abnormalities. This site boasts a full 25,000 cell lines and approximately 420 hybridomas.

3. RIKEN Cell Bank

http://www.rtc.riken.go.jp

The RIKEN cell bank has been organized as a unique, nonprofit public collection for deposit, isolation, preservation, and distribution of cultured animal cell lines produced by the life science research community. It houses a large number of cell lines as well as hybridomas established by its staff.

4. American Type Culture Collection (ATCC)

http://www.atcc.org

The ATCC Cell Biology Collection (http://www.atcc.org/SearchCatalogs/CellBiology.cfm) includes a very comprehensive and diverse cell bank, consisting of 4000 cell lines from more than 150 different species.

Copyright 2006, Elsevier Science (USA).
All rights reserved.

It holds 950 cancer cell lines (including 700 human cancer cell lines) and over 1200 hybridomas for the production of monoclonal antibodies, as well as a variety of special collections.

5. The Mammalian Genetics Unit at Harwell (MGU)

http://www.mgu.har.mrc.ac.uk

Home page of an integrated campus for mouse genetics research with facilities for molecular genetics, genomics, mutagenesis, transgenesis, and bioinformatics. The MGU has a large collection of mouse stocks containing over 200 mutant, chromosome abnormality, and inbred lines. The stocks are maintained for experimental and breeding purposes and are available to investigators on request.

6. Stem Cell Information at NIH

http://escr.nih.gov

A Web site provided by the National Institutes of Health (NIH) hosting information and links on stem cells.

7. The Stem Cell Database (SCD)

http://stemcell.princeton.edu/index.html

A joint project of the laboratories of Ihor R. Lemischka (Princeton University) and G. Christian Overton (University of Pennsylvania), the SCD contains data on the molecular phenotype of hematopoietic stem cells.

B. Viruses

1. All the Virology on the WWW

http://www.tulane.edu/~dmsander/garryfavweb.html

A site that collects many virology-related Web sites of interest for virologists and others interested in learning more about viruses.

2. The Universal Virus Database (ICTVdB)

http://ictvdb.bio2.edu/index.htm

The directory of ICTVdB is an index of viruses, a list of approved virus names linked to virus descriptions coded from information in "Virus Taxonomy: The Seventh Report of the International Committee on Taxonomy of Viruses" by van Regenmortel *et al.* (eds.), Academic Press (2000), and includes updates subsequently approved by ICTV. It also incorporates the plant virus database VIDEdB and is illustrated with EM pictures, diagrams, and images of symptoms contributed by virologists around the world.

C. Antibodies

1. The Antibody Resource Page

http://www.antibodyresource.com

A site that provides a broad collection of links to companies that sell antibodies or antibody-related products on the internet. Furthermore, it also presents sections containing links to online educational resources about antibodies and databases and software with immunological relevance.

2. AbCam

http://www.abcam.com

AbCam features an extensive compilation of antibody information and advice for locating specific antibodies with a large selection of antibodies available online and a search engine to other antibody companies. In addition, AbCam provides a conference calendar, a database of conferences that have been submitted by research scientists.

3. KabatMan

http://www.bioinf.org.uk/abs

A site that provides information on antibody structure and sequence as well as other useful links.

4. Information Resources for Adjuvants and Antibody Production

http://www.nal.usda.gov/awic/pubs/antibody

A very useful Web page for any researcher interested in antibody production. A rather comprehensive set of references is an added value.

5. Developmental Studies Hybridoma Bank (DSHB), at the University of Iowa

http://www.uiowa.edu/~dshbwww

The DSHB supplies investigators with low-cost monoclonal antibodies useful for studies in developmental and cell biology. They may be ordered as tissue culture supernatants, ascites, or partially purified immunoglobulins. Certain selected hybridomas are also available as frozen or growing cells.

6. IMGT, the International ImMunoGeneTics Information System

http://imgt.cines.fr

An integrated information system specializing in immunoglobulins, T-cell receptors, major histocompatibility complex, and related proteins of the immune system of human and other vertebrate species. This

site contains standardized and annotated data on proteins of the immune system, which include databases of nucleotide and protein sequences, gene maps, genetic polymorphisms, specificities, 2D and 3D structures, and a collection of interactive tools.

D. Flow Cytometry

1. Flow Cytometry Core Laboratory at the University of Florida

http://www.biotech.ufl.edu/FlowCytometry

One of the core laboratories that compose the Interdisciplinary Center for Biotechnology Research at the University of Florida in Gainesville, Florida. This Web page provides a wealth of information and links related to flow cytometry. Included is the database for antibody cross-reactivity (http://www.keithbahjat.com/abcxr/), a repository for flow cytometry software, and protocols for FACS-based analysis.

2. Flow Cytometry on the Web

http://flowcyt.salk.edu/sitelink.html

A collection of links for those interested in flow cytometry. A good starting point if one is looking for software, protocols, instrumentation, protocols, or any flow cytometry-related subject.

E. Immunohistochemistry

1. ImmunoQuery

http://www.immunoquery.com

An immunohistochemistry database query system to help determine the best panel of immune stains that will aid in the differential diagnosis of tumors. It lists antibodies that can differentiate between tumors entered by the user (e.g., lung adenocarcinoma vs breast carcinoma), ranks the antibodies in terms of their ability to differentiate between tumors, and provides instant references to journal articles describing the reactivity of these antibodies.

2. IHC World

http://www.ihcworld.com

A Web site dedicated to everything related to immunohistochemistry. Provides comprehensive and updated information regarding tissue processing, antigen retrieval, antibody selections, antibody protocol database, image analysis, protocol links, books, and journals.

3. DAKOCytomation's Immunochemical Staining Methods Online Handbook (3rd Ed.)

http://ca.us.dakocytomation.com/ihcbook/hbcontent.htm

This site features a pdf-based online version of DAKO's IHC handbook. A very useful book, with detailed information on basic immunohistochemistry techniques including protocols and reviews of alternative methods.

4. PathBase: The European Mutant Mouse Pathology Database

http://eulep.anat.cam.ac.uk

Pathbase is a database of histopathology photomicrographs and macroscopic images derived from mutant or genetically manipulated mice. This site containes a searchable database of histopathological images mainly from transgenic and knockout mice with effects on cell proliferation and cancer, and the response of adult and fetal animals to environmental insults such as radiation at high and low doses relevant to accidental, environmental, and medical irradiation of humans.

5. Histosearch

http://www.histosearch.com

A site comprising a histology search engine for searches over 20,000 Web pages from histology-related sites on the internet, hyperlinks to other histology sites, and to relevant newsgroups and archives.

F. Transgenes and Gene Knockout and -down Technology

1. C. elegans Gene Knockout Consortium

http://www.celeganskoconsortium.omrf.org

This consortium aims at facilitating genetic research of this important model system through the production of deletion alleles at specified gene targets. Targets are chosen based on investigator requests. Strains produced by the consortium are freely available with no restrictions to any investigator.

2. BioMedNet's Mouse Knockout and Mutation Database

http://research.bmn.com/mkmd

A comprehensive database of phenotypic and genotypic information on mouse knockouts and classical mutations with more than 8000 database entries covering over 3000 unique genes.

3. The Nagy Laboratory Cre Transgenic Database

http://www.mshri.on.ca/nagy/cre.htm

This Web site contains a database of published as well as unpublished and in the making Cre transgenic lines. Also some mouse genetics protocols and links. All in all, a good site for those researchers with an interest in ES cell-mediated rodent genome alterations.

4. Database of Gene Knockout

http://www.bioscience.org/knockout/knochome.htm

A mouse gene knockout database with strains classified alphabetically or according to the viability of the knockout: viable mice, or resulting in prenatal, postnatal, or perinatal mortality.

5. Gene Targeting Protocols

http://www.biowww.net/index.php/article/articleview/125/1/16/

A set of 23 gene targeting protocols from Practical Approach Online (in pdf format).

6. Antisense Gene Targeting

http://www.gene-tools.com

GeneTools produces antisense morpholino oligosnucleotides to shut down selected RNA sequences. Provides a very good alternative to phosphorothioates. Microinjection or electroporation of Morpholino oligosnucleotides into the embryos of frogs, zebrafish, chicks, and sea urchins has been shown to successfully and specifically shuts down the expression of desired mRNAs. Another alternative is locked nucleic acid oligosnucleotides that can be obtained through http://www.exiqon.com.

7. RNA Interference Resources

http://www.ambion.com/techlib/resources/RNAi

A resource containing a wealth of information on siRNA-mediated gene silencing, with many useful reviews, references, and links to other sites of interest. An additional site of interest is McManus home page (http://web.mit.edu/mmcmanus/www/RNAi.html), a very good Web site for researchers interested in the process of RNA interference.

G. Organelle Systems

1. Cell Biology Topics: Organelles

http://cellbio.utmb.edu/cellbio

A collection of links to Web pages providing basic information on organelle systems. Most of the topics focus on structure/function correlations.

2. The Virtual Cell Web Page

http://personal.tmlp.com/Jimr57/textbook/chapter3/chapter3.htm

A nice presentation on cell organization and function/structure relations. A similar resource can be found at http://www.life.uiuc.edu/plantbio/cell.

H. Genomics

1. DNA Microarray Web Site

http://www.gene-chips.com/GeneChips.html#proteinchip

A Web page boasting a collection of links to academic and industrial sites of interest for researchers with an interest in microarrays (DNA as well as protein chips).

2. Grid It

http://www.bsi.vt.edu/ralscher/gridit

A useful resource for researchers interested in microarray technology. Includes an introduction to microarray technology and links to sources of equipment, analysis software, and other microarray sites.

3. LGM Microarray Links

http://www.biologie.ens.fr/en/genetiqu/puces/links.html

A collection of links to microarray resources.

4. Genomics: A Global Resource

http://www.biopad.org

A gateway to a plethora of genomic resources.

I. Proteomics

1. Meta-Database Catalog of Two-Dimensional Gel Images Found in Web Databases (2DWG)

http://www-lmmb.ncifcrf.gov/2dwgDB/2DWG.html

A catalog of some of the 2D gel images that can be found in 2D gel databases on the Web.

2. Two-Dimensional Gel Electrophoresis Tutorial

http://www.aber.ac.uk/parasitology/Proteome/Tut_2D.html

A tutorial written by Dr James R. Jefferies. Sections covering this topic include 2D gel electrophoresis, immobilized pH gradients, 2D procedure, sample preparation, sample solubilisation, chaotrophe, reductants, detergents–surfactants, ampholytes, interfering substances, protein estimation, gel electrophoresis, IEF

run, strip equilibration, SDS–PAGE run, staining, general considerations, and references.

3. The Danish Centre for Human Genome Research's 2D PAGE Databases

http://proteomics.cancer.dk

A site containing proteomic databases developed for the study of global cell regulation in health and disease, focusing on skin biology and bladder cancer. Procedures are illustrated with still images and videos. The site also features a gallery of 2D gels of cells, tissues, and fluids, as well as 2D gel immunoblots.

4. EXPASy World 2DPAGE Index

http://www.expasy.ch/ch2d/2d-index.html

A site containing references to known 2D PAGE database servers, as well as to 2D PAGE-related servers and services.

J. Spectroscopy

1. Spectroscopy Now

http://www.spectroscopynow.com/Spy/basehtml/SpyH

A gateway to various spectroscopy resources, including mass spectrometry, RAMAN, and NMR.

2. Protein Prospector

http://prospector.ucsf.edu

A collection of proteomics tools for mining sequence databases in conjunction with mass spectrometry experiments.

K. Cell Signaling

1. The Alliance for Cell Signaling

http://www.signaling-gateway.org

The AfCS-Nature Signaling Gateway is a comprehensive and up-to-the-minute resource for anyone interested in cell signaling. The AfCS is an initiative with the aim of performing comprehensive experimental analyses of selected signaling systems, providing these data freely to the research community. Several tools of interest to investigators within the signalling community are also available here.

2. Phosphobase

http://www.cbs.dtu.dk/databases/PhosphoBase

A database of phosphorylation sites, including two implementations of algorithms for prediction of potential phosphorylation sites.

3. List of Apoptosis Regulators

http://www-personal.umich.edu/~ino/List/AList.html

A Web site providing general and specific information of apoptosis regulators and signalling pathways, as well as quick access to relevant papers and sequences.

4. Science's Signal Transduction Knowledge Environment

http://stke.sciencemag.org

A global resource useful to scientists who specialize in signal transduction, as well as the many scientists who need to follow and apply the current findings of this field even though their primary interest may not be in signal transduction mechanisms themselves.

5. Inositols.com

http://www.inositols.com

A Web-based resource for inositols, phosphoinositides, phosphatidylinositols, and other essential cell-signaling molecules.

6. BioCarta's Pathways

http://www.biocarta.com/genes/index.asp

A Web site containing interactive graphic models of molecular and cellular pathways.

L. Databases of Molecular Interactions and Pathways

1. Biomolecular Interaction Network Database (BIND)

http://www.bind.ca

This site consists of a search engine, PreBIND, that allows the user to mine the biomedical literature for protein–protein interactions and a database, BIND, that stores descriptions of interactions, molecular complexes, and pathway records.

2. General Repository of Interaction Databases (GRID)

http://biodata.mshri.on.ca/grid/servlet/Index

A database of genetic and physical interactions containing interaction data from many different sources. This site is also home to the Osprey Network Visualization System (http://biodata.mshri.on.ca/osprey/servlet/Index), a powerful application for graphically representing physical and genetic biological interactions that is coupled to the GRID database.

3. Database of Interacting Proteins (DIP)

http://dip.doe-mbi.ucla.edu

A database of experimentally determined interactions between proteins. It combines information from a variety of sources to create a single, consistent set of protein–protein interactions.

4. Molecular Interactions Database (MINT)

http://cbm.bio.uniroma2.it/mint

A database of functional interactions between biological molecules (proteins, RNA, DNA). Beyond cataloguing the formation of binary complexes, MINT also stores other type of functional interactions, namely enzymatic modifications of one of the partners.

5. Curagen's PathCalling Yeast Interaction Database

http://portal.curagen.com/extpc/com.curagen.portal.servlet.Yeast

PathCalling is a proteomic technology designed to identify protein–protein interactions on a genome-wide scale.

6. Biomolecular Relations in Information Transmission and Expression (BRITE)

http://www.genome.ad.jp/brite

BRITE is a database of binary relations for computation and comparison of graphs involving genes and proteins. It contains diverse sets of binary relations, including the generalized protein interactions that underlie the KEGG pathway diagrams, systematic experimental data on protein–protein interactions by yeast two-hybrid systems, sequence similarity relations by SSEARCH, expression similarity relations by microarray gene expression profiles, and cross-reference links between database entries.

7. KEGG Pathway Database

http://www.genome.ad.jp/kegg/kegg2.html#pathway

A part of the Kyoto Encyclopedia of Genes and Genomes, this graphical interface for pathway diagrams is very user friendly and a boon of information for any researcher looking for relational information for a given protein. Two diagrammatical databases are available, a metabolic pathway database (http://www.genome.ad.jp/kegg/metabolism.html) and a regulatory pathway database (http://www.genome.ad.jp/kegg/regulation.html); each one of these divided in subsections. In addition to the possibility to perform searches on particular objects or sequences in the various pathways, one can also generate possible reaction pathways.

8. Yeast Interacting Proteins Database

http://genome.c.kanazawa-u.ac.jp/Y2H

A companion site to a publication reporting on the comprehensive two-hybrid analysis of the budding yeast proteome. One can download the complete datasets or analyse them as well as previously reported protein–protein interactions using a graphical system for viewing gene regulatory networks.

M. Gateways to Scientific Resources

1. The DEAMBULUM–BIONETosphere Thematic Exploration

http://www.infobiogen.fr/services/deambulum/english

A gateway to useful online resources for molecular biology, biocomputing, medicine, and biology. It includes hyperlinks to databases (sequence, bibliographic, organisms, etc.), sequence analysis tools, software, and many others.

2. The WWW Virtual Library of Cell Biology

http://vlib.org/Science/Cell_Biology/index.shtml

A very large repository of cell biology information. It includes numerous sections with hyperlinks to various cell biology laboratories, databases, journals, methods, organizations, and meetings, among others.

3. Pedro's Biomolecular Research Tools

http://www.public.iastate.edu/~pedro/research_tools.html

An extensive and quite comprehensive collection of links to resources useful to molecular and cell biologists.

4. The Canadian Bioinformatics Resource

http://cbr-rbc.nrc-cnrc.gc.ca/index_e.php

A Web site providing convenient, effective access to widely used bioinformatic tools and databases.

5. Atelier BioInformatique, aBi Online Analysis Tools

http://www.up.univ-mrs.fr/~wabim/english/logligne.html

An extensive collection of hyperlinks to various bioinformatics tools available online. A similar but complementary Web site is the home page of Dr. Andrew Kropinski (http://molbiol-tools.ca/).

6. bioWWW a Resource for Life Science Researchers

http://www.biowww.net/index.php

A forum for life science researchers containing information and links to protocols, news groups, and many other resources.

7. Molecular Biology Gateway

http://www.horizonpress.com/gateway

A gateway to Web resources for molecular biology, genetics, microbiology, and biochemistry.

N. Sequence Databases and Analysis Tools

This is arguably the largest single group of scientific Web sites in existence. The number of sites featuring sequence analysis tools (of proteins as well as nucleic acids), database queries, and prediction algorithms, among others, is overwhelming and many times the hardest task is to choose which one to use. Listing of even just the most interesting and relevant sites would exceed by far the scope of this resource section. We have chosen instead to provide a few select Web pages of major biology servers containing a large and well-curated collection of databases and tools that allow them be used as entry points for broader searches.

1. The European Bioinformatics Institute (EBI)

http://www.ebi.ac.uk/services

The European Bioinformatics Institute is a nonprofit academic organisation that forms part of the European Molecular Biology Laboratory (EMBL). The EBI manages databases of biological data and provides a comprehensive range of very useful bioinformatics tools.

2. The Catalog of Databases (DBCAT)

http://www.infobiogen.fr/services/dbcat

A near-exhaustive list of existent databases for various application fields, such as DNA, RNA, and proteins.

3. The National Center for Biotechnology Information (NCBI)

http://www.ncbi.nlm.nih.gov

One of the major bioinformatics servers, NCBI creates public databases, conducts research in computational biology, develops software tools for analyzing genome data, and disseminates biomedical information. It provides an extensive collection of tools and resources, including, but not limited to, molecular databases such as GenBank, Entrez, and dbEST; literature databases such as PubMed and OMIM; and tools such as BLAST, Cn3D, and LinkOut.

4. Genome Net

http://www.genome.ad.jp

A Japanese network of database and computational services for genome research and related research areas in molecular and cellular biology. A gateway providing entry points to resources, including, but not limited to, DBGET (Integrated Database Retrieval System), KEGG (Kyoto Encyclopedia of Genes and Genomes), and SSDB (Sequence Similarity Database) (http://www.genome.ad.jp/dbget/dbget.links.html).

5. The Protein DataBank at Brookhaven (PDB)

http://www.rcsb.org/pdb

PDB is the repository for the processing and distribution of 3D biological macromolecular structure data. In addition to containing structural data deposited by crystallographers and spectroscopists (NMR), worldwide PDB also presents a large collection of software for structural work and educational resources.

6. Center for Biological Sequence Analysis Server (CBS)

http://www.cbs.dtu.dk/services

The server at CBS provides a set of very useful tools for sequence analysis, such as *TMHMM* for the identification of transmembrane helices in proteins; *TargetP* for the determination of subcellular location of proteins; and *NetNGlyc* for the identification of N-linked glycosylation sites in human proteins, as well as a very nice collection of links to other sites of interest.

7. The Expert Protein Analysis System (ExPASy) Molecular Biology Server

http://www.expasy.org

The ExPASy proteomics server of the Swiss Institute of Bioinformatics (SIB) is dedicated to protein analysis and contains a large number of tools as well as links to biology servers. The Amos Bairoch's WWW links page within the ExPASy server (http://www.expasy.org/alinks.html) contains pointers to information sources for life scientists with an interest in biological macromolecules. Additionally, this site is also home to Biohunt (http://www.expasy.org/BioHunt), a molecular biology search engine.

8. The Institute for Genomic Research (TIGR)

http://www.tigr.org

A not-for-profit research institute whose primary research interests are in structural, functional, and

comparative analysis of genomes and gene products from a wide variety of organisms. This site contains a collection of curated databases containing DNA and protein sequence, gene expression, cellular role, protein family, and taxonomic data for microbes, plants, and humans. Particularly interesting is the TIGR microarray resources page, where one can find many software tools available for free download.

9. GeneCards

http://discover.nci.nih.gov/textmining/filters.html

A database of human genes, their products, and their involvement in diseases. A search engine useful for people who wish to find information about genes of interest.

O. Educational and General Information Resources

1. Cell and Molecular Biology Online

http://www.cellbio.com

A site containing general information and links for cell and molecular biologists. It features several hyperlinks to many resources such as online journals, methods, protocols, and laboratories.

2. The Glossarist

http://www.glossarist.com/glossaries/science/life-sciences

A searchable glossary directory. Looking for the definition of a term in a particular subject can be difficult and time-consuming. That is where the Glossarist can help you look. This Web page contains links to several online dictionaries and glossaries, including, but not limited to, the online version of the book published by Lackie and Dow (1999) (http://on.to/dictionary) and BioABACUS (http://www.nmsu.edu/~molbio/bioABACUShome.htm), a searchable database of abbreviations and acronyms in biotechnology.

3. Kimball's Biology Pages

http://biology-pages.info

A Web site containing an online biology textbook. Even though some of the information in this Web site has been taken from the sixth edition of the author's general biology text "Biology" published in 1994 by Wm. C. Brown, frequent updates make this site well worth a visit.

4. Online Biology Book

http://www.emc.maricopa.edu/faculty/farabee/BIOBK/BioBookTOC.html

A college-level introduction biology text with an interesting set of lectures with many illustrations.

5. The Biology Project

http://www.biology.arizona.edu

An online interactive resource for biology. This site consists of student-oriented, highly interactive learning materials that can be used to support lectures for laboratory meetings, and discussion sessions of general education courses.

6. Biotech's Scientific Dictionary

http://biotech.icmb.utexas.edu/search/dict-search.html

A dictionary on general terminology of biochemistry, biotechnology, botany, cell biology, and genetics, as well as more specific brief definitions of the cell constituents.

7. Biology Online

http://www.biology-online.org

A source of basic biological information, with tutorials and a dictionary of biology, as well as links to hundreds of related biology sites.

8. The Visible Mouse

http://ccm.ucdavis.edu/tvmouse/index.html

A Web site providing a very nice introduction to the anatomy, physiology, histology, and pathology of the laboratory mouse with emphasis on genetically engineered mice.

9. Lee M. Silver's Mouse Genetics

http://www.informatics.jax.org/silver

The electronic version of Silver's book.

10. The Zebrafish Book

http://zfin.org/zf_info/zfbook/zfbk.html

A guide for the laboratory use of zebrafish (*Danio rerio*).

11. Mark Blaxter's Home Page

http://nema.cap.ed.ac.uk/Caenorhabditis/C_elegans_genome/Celegansgenome.html

It contains "The Genetics of *Caenorhabditis elegans*, an Introduction," a very well-written introduction to the biology of *C. elegans*.

12. BioResearch

http://bioresearch.ac.uk

A gateway to evaluated internet resources in the basic biological and biomedical sciences, aimed at students, researchers, academics, and practitioners in biological or biomedical science.

P. Safety, Ethical Issues, Legislation, and Patents

1. International Centre for Genetic Engineering and Biotechnology–Biosafety

http://www.icgeb.org/~bsafesrv

The ICGEB Biosafety Web pages, containing information on biosafety, international biosafety regulations (USA, Europe and others), handling of GMOs, and links to other related sites.

2. European Agency for Safety and Health at Work (OSHA)

http://agency.osha.eu.int

This is the corporate Web site of the OSHA. It provides useful information and access to full-text versions of all OSHA's publications.

3. European Chemical Bureau (ECB)

http://ecb.jrc.it

The ECB is the focal point in Europe for data and the assessment procedure on dangerous chemicals. This site provides information on the classification and labelling of substances, import/export of dangerous chemicals, legislation, and a collection of links to other related sites.

4. Material Safety Data Sheet (MSDS) Databases Search

http://www.msdssearch.com/DBLinksN.htm

A search engine for MSDS libraries. MSDSSEARCH is a reliable starting point for obtaining the most updated MSDS documents from the manufacturer and provides a single, international, database with all MSDSs available in text format at no cost to users.

5. EUROPA Steering Committee on Bioethics

http://www.coe.int/T/E/Legal_Affairs/Legal_co-operation/Bioethics/CDBI

This Web site contains information concerning meetings and documentation produced by the CDBI as well as links to other relevant sites.

6. The International Bioethics Committee (IBC)

http://portal.unesco.org/shs/en/ev.php@URL_ID=1372&URL_DO=DO_TOPIC&URL_SECTION=201.html)

The Bioethics Programme is part of UNESCO's Division of the Ethics of Science and Technology in the Social and Human Sciences Sector and, through its committees, produces advice, recommendations, and proposals to submit to the Director-General for consideration by UNESCO's governing bodies. In addition to providing access to IBC's documents, this Web site has various links to legislative institutions, databases of bioethics institutions, and other related websites.

7. Institutional Animal Care and Use Committee at University of Iowa

http://research.uiowa.edu/animal

This Web site has a very descriptive collection of basic biomethodology for mouse, rat, rabbit, and guinea pig animal husbandry, as well as a large number of established guidelines/regimens for various animal uses (e.g., recommendations for the production of ascitic fluid; regimens for anesthesia and analgesia of laboratory animals).

8. Animal Care at Johns Hopkins

http://www.jhu.edu/animalcare/committee1.html

A lot of useful information on regulations and polices on animal care and use.

9. UCAR Manual on the Responsible Care and Use of Laboratory Animals

http://www.urmc.rochester.edu/ucar/manual/index.htm

A resource from the University of Rochester Medical Center. It includes a manual on care and use of laboratory animals and links to other resources, such as the dosage calculator (http://www.fda.gov/cder/cancer/animalframe.htm).

10. OECD Principles of Good Laboratory Practices

http://www.oecd.org/EN/home/0,,EN-home-526-14-no-no-no-no,00.html

A Web site containing information on OECD guidelines for GLP, and principles of GLP, as well as links to national GLP sites.

11. U.S. Environmental Protection Agency (EPA)

http://www.epa.gov/Compliance/monitoring/programs/glp/index.html

EPA's home page to the Good Laboratory Practice Standards (GLPs) compliance monitoring program.

12. *Esp@cenet*

http://gb.espacenet.com

Europe's network of patent databases. Search published worldwide patent applications with an English abstract and title as well as published patent applications in their original language from various European countries. A real trove of information, reagents, and sequences is sometimes buried in patent applications.

Q. Literature Datasets

1. *BioMed Central*

http://www.biomedcentral.com

An open access, independent publishing house committed to providing immediate free access to peer-reviewed biomedical research.

2. *PubMed*

http://www.ncbi.nlm.nih.gov/PubMed

PubMed is a service of the National Library of Medicine providing access to over 12 million MEDLINE citations back to the mid-1960s and additional life science journals. PubMed also includes links to many sites providing full text articles and other related resources. A similar service is provided by *HighWire* (http://highwire.stanford.edu).

3. *Online Mendalian Inheritance in Man (OMIM)*

http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM

A resource provided by NCBI containing curated reviews on human genes of interest with many references and embedded hyperlinks to other resources.

4. *The Cochrane Library*

http://www.update-software.com/cochrane

This site consists of a regularly updated collection of evidence-based medicine databases, including The Cochrane Database of Systematic Reviews, which provide high-quality information to people providing and receiving care and those responsible for research, teaching, funding, and administration at all levels. The Cochrane Library is available on a subscription basis, but there are several countries that have arranged national provisions and thus allow all residents to access The Cochrane Library for free (e.g., Australia, England, Norway, Finland).

5. *The Wellcome Library*

http://library.wellcome.ac.uk

One of the world's greatest collections of books, manuscripts, pictures, and films around the meaning and history of medicine.

6. *LOCATORplus*

http://locatorplus.gov

A catalog of books, journals, and audiovisuals in the National Library of Medicine collections.

7. *MedBioWorld*

http://www.sciencekomm.at/index.html

A large medical reference site including an exhaustive list of medical journals and medical associations and similar resources in the biological sciences. Other research tools include medical glossaries, disease databases, clinical trials and guidelines, and medical journals offering full-text article.

8. *BioMail Service*

http://www.biomail.org

Biomail is an automatic service that regularly (weekly by default) searches for articles, that have recently appeared in the PubMed Medline database using customized search terms. Then it emails lists of the found articles to the user.

R. General Protocols

1. *bioProtocol*

http://www.bio.com/protocolstools

This Web site features a collection of protocols contributed by scientists from over 125 academic laboratories covering a variety of life science disciplines. A large site with a plethora of links and many useful protocols.

2. *iProtocol*

http://iprotocol.mit.edu

An initiative by a team of MIT-affiliated researchers and local software engineers to develop a free Web site containing research protocols used in biological sciences.

3. *BioVisa.net*

http://www.biovisa.net

A specialized Web site containing a collection of links to more than 2000 online protocols. You can discuss these protocols with researchers that share a

similar interest. The protocols are indexed into eight categories: anatomy and histology, biochemistry and molecular biology, biotechnology, cell biology, developmental biology, genetics, immunology, and neuroscience.

4. Protocol Online

http://www.protocol-online.org

A database of research protocols in a variety of life science fields. It features user-submitted protocols as well as links to other Web sites.

S. General Reagents and Techniques

1. The Biocurrents Research Center—Database of Pharmocological Compounds

http://zeus.mbl.edu/public/BRC

A NIH-funded database providing its user with a useful forum on the use of pharmacological compounds in cellular research. It lists over 500 compounds with details on their mode of action and employ, including references.

2. Biocompare

http://www.biocompare.com

A buying guide for life sciences. Even though this site is commercially oriented it allows one to search a wide range of product-related technical information for the life science researcher in a rather comprehensive manner. If you need something and do not know where to buy it and whom to buy it from, this site may be just what you need. Included is Biocompare's Antibody Search, which allows you to search over 60,000 antibodies from various antibody suppliers. A similar service provider is BioSupplyNet (http://www.biosupplynet.com/) where you can browse and search for suppliers in a variety of areas of life science research.

3. Bioresearch Online

http://www.bioresearchonline.com/content/homepage

A sourcing site for bioresearch. In addition to it belong a buyer's guide and a free newsletter, it contains a search engine for product information.

4. LabVelocity's Biowire

http://home.labvelocity.com/scientists/index.jhtml?subSection=biowire

A Web site containing user-written laboratory product reviews pertaining to the life sciences community. It holds a very large number (ca. 25,000) of product reviews, which are a good aid not only when deciding on purchasing a particular item, but also if you are searching for a specific product. A complementary site is SciQuest (http://www.sciquest.com/commerce/CommerceRouter/Index), a site providing search possibilities for scientific products.

5. MedWebPlus

http://medwebplus.com

A search engine for finding health sciences information.

T. Model Organisms

1. The Mouse Genome Resources

http://www.ncbi.nlm.nih.gov/genome/guide/mouse

A gateway to mouse resources. This site is an entry point to access information pertaining to the NCBI mouse genome sequence as well as other extramural mouse resources.

2. Whole Mouse Catalog

http://www.rodentia.com/wmc/index.html

A collection of links to internet resources of particular interest to scientific researchers using mice or rats in their work.

3. The Jackson Laboratory Home Page

http://www.jax.org

JAX online consists of a series of resources of interest for mouse researchers, including databases (http://www.jax.org/resources/search_databases.html) and a mouse strain repository (http://jaxmice.jax.org/index.html) for the collection and distribution of genetically engineered mice, as well as a Mouse Genome Informatics (MGI) site that provides integrated access to data on the genetics, genomics, and biology of the laboratory mouse.

4. The Mouse Phenome Database

http://aretha.jax.org/pub-cgi/phenome/mpdcgi?rtn=docs/home

A collection of comprehensive phenotypic and genotypic data on inbred laboratory mouse strains.

5. The Edinburgh Mouse Atlas Project (EMAP)

http://genex.hgu.mrc.ac.uk/intro.html

This Web site is the home page of a collaborative project within the University of Edinburgh aiming at the creation of a digital atlas of mouse embryonic development. It consists of a series of interactive three-dimensional computer models of mouse embryos at

successive stages of development with defined anatomical domains linked to a stage-by-stage ontology of anatomical names. Additionally, the EMAP atlas underlies an image-mapped gene-expression database (EMAGE; http://genex.hgu.mrc.ac.uk/Emage/database/intro.html). These two databases are interoperable.

6. ARKdb

http://www.thearkdb.org

This database system provides access to comprehensive public repositories for genome mapping data from farmed and other animal species (e.g., cat, chicken, cow, deer, horse, pig, salmon, sheep, tilapia, turkey). Data stored include details of loci and markers, references/papers, authors, genetic linkage map assignments, cytogenetic map assignments, experimental techniques, PCR primers and conditions, and any other data pertaining to genome mapping.

7. Rat Genome Database (RGD)

http://rgd.mcw.edu

A Web site providing a large amount of rat genetic and genomic resources. It includes curated data on rat genes, quantitative trait loci (QTL), microsatellite markers, and rat strains used in genetic and genomic research. In addition, RGD provides a large number of tools for gene prediction, radiation hybrid mapping, polymorphic marker selection, and more.

8. FlyBase

http://flybase.bio.indiana.edu

A database of genetic and molecular data for *Drosophila*. FlyBase includes data on all species from the family Drosophilidae, but the primary species represented is *Drosophila melanogaster*. This site also contains several links to resources of interest for *Drosophila* researchers.

9. The Zebrafish Information Network (ZFIN)

http://zfin.org

ZFIN is a database resource for the laboratory use of zebrafish. It provides integrated zebrafish genetic, genomic, and developmental information, together with links to corresponding data in other model organism and human databases.

10. The HGMP-RC Fugu Genome Project

http://fugu.hgmp.mrc.ac.uk

In addition to containing the publicly available draft sequence of the Fugu genome, this site also provides a collection of protocols, publications, and much data for the scientific community with an interest in *Fugu rubripes* (the Japanese puffer fish).

11. Caenorhabditis elegans WWW Server

http://elegans.swmed.edu

A Web site aimed at the community of *C. elegans* researchers. This site boasts a large number of resources, including literature search, methods, a list of meetings, labs, and researchers, links to Bionet.celegans, etc. A companion site is WormBase (http://www.wormbase.org/). A Web site displaying a large amount of relevant information and hyperlinks for the *C. elegans* scientific community.

12. WWW Virtual Library for Xenopus

http://www.xenbase.org/xmmr/frog.html

A site dedicated to *Xenopus laevis*, a commonly used model system for studying vertebrate early development. One of the main uses of this site is as a reference for researchers looking for molecular probes. It also contains a collection of whole mount staining patterns using both antibody and nucleic acid probes, a methods book, supplier listing, Xenopus scientific community white pages, and more.

13. dictyBase

http://dictybase.org

An informatics resource for *Dictyostelium discoideum*, it consists of a comprehensive genomic *Dictyostelium* database, lab protocols and strain availability, and a list of researchers, among many other links.

14. The Arabidopsis *Information Resource (TAIR)*

http://www.arabidopsis.org

A comprehensive resource for the scientific community working with *Arabidopsis thaliana*, a widely used model plant. TAIR consists of a searchable relational database, which includes many different data types. In addition, pages on news, information on the Arabidopsis Genome Initiative (AGI), Arabidopsis lab protocols, and useful links are provided.

Additional sites and nonlisted model organisms can be found at the following sites:

The WWW Virtual Library: Model Organisms (http://ceolas.org/VL/mo/)

The Sanger Institute's Model Organisms Resources Links (http://www.sanger.ac.uk/Info/Links/modelorgs.shtml)

Infobiogen's list of genomes and organisms (http://www.infobiogen.fr/services/deambulum/english/genomes1.html)
NIH's Model Organisms for Biomedical Research website (http://www.nih.gov/science/models/).

III. IMAGING TECHNIQUES IN CELL BIOLOGY

One of the paramount interests of cell biologists is to observe cellular themes, temporally as well as spatially resolved. No longer just structures, but also proteins and their cellular localisation, dynamics, and interaction(s). The field of cellular imaging is currently one of the cornerstones of cell biology and microscopy constitutes arguably its single most important technique. For this reason, we have chosen to list and highlight Web sites dealing with the subject of microscopy in a more comprehensive manner then hitherto. This part of the resources section is thus devoted to microscopy techniques and covers the subject in a broad manner with sites that should be of great use to the novice and experienced user alike.

A. Light Microscopy

1. A Brief History of Optics

http://members.aol.com/WSRNet/D1/hist.htm

A part of the laser-optics UK Web site giving a historical summary of the important discoveries in the field of optics.

2. Properties of Light and Introductory Optics

http://micro.magnet.fsu.edu/primer/lightandcolor/index.html

The Molecular Expressions Microscopy Primer is an excellent microscopy Web site from Florida State University (principal authors: Michael W. Davidson, FSU and Mortimer Abramowitz—http://micro.magnet.fsu.edu/). An extensive series of tutorials on light and colours can be found on this Web site: nature of light (electromagnetic radiation, duality of light, definition of colours), physical properties (reflection, refraction, diffraction, polarisation, interference), and fundamental tools to generate and direct light (lenses, filters, sources of light, laser). A good introduction about light microscopy written by these authors can be downloaded at: http://screensavers.magnet.fsu.edu/pdfs/microscopy.pdf.

3. Anatomy of a Light Microscope and Basic Concepts in Optical Microscopy

http://micro.magnet.fsu.edu/primer/anatomy/components.html

http://micro.magnet.fsu.edu/primer/anatomy/anatomy.html

The complete description of the different parts of a microscope can be found within this link: microscope components configuration, optical train components, perfect lens characteristics, objectives, and other important parts of the microscope.

4. Concepts and Formulas in Microscopy

http://www.microscopyu.com/articles/formulas/formulasindex.html

A part of the Nikon's MicroscopyU Web site (http://www.microscopyu.com/). This Web site was originally designed to provide an educational forum for all aspects of optical microscopy, digital imaging, and photomicrography and complements the Molecular Expressions Microscopy Primer microscopy Web site (http://micro.magnet.fsu.edu/). This Web site part covers concepts and formulas in microscopy and includes definitions on some very important and often not well-understood parameters (numerical aperture, depth of field, resolution, and many others).

5. Sources of Visible Light

http://micro.magnet.fsu.edu/optics/lightandcolor/sources.html

Description of various sources of light used for fluorescence microscopy.

6. Köhler Illumination

http://micro.magnet.fsu.edu/primer/anatomy/kohler.html

Köhler illumination is a basic requirement of all modern light microscopy. The purpose is to obtain an evenly lit field of view and as wide a cone of radiation as possible in order to achieve maximum resolution. This Web page explains clearly what the Köhler illumination is and how to set it up.

7. Specialised Microscopy Techniques

http://micro.magnet.fsu.edu/primer/techniques/index.html

Microscopic techniques can be separated into two categories: microscopy using polychromatic light (basic light microscopy) and microscopy using specific wavelength (fluorescence microscopy) that need specific filters. Here you will find a description of

different nonfluorescent microscopy techniques: bright-field and dark-field microscopy, Nomarski (or DIC), phase contrast, and so on.

B. Fluorescence Microscopy

1. What Is Fluorescence? The Stokes Law

http://micro.magnet.fsu.edu/primer/techniques/fluorescence/introduction.html

Cell biologists want to observe the localisation, dynamics, and relocalisation of proteins. Unfortunately, proteins are not directly visible; in order to monitor their localisation they need to be tagged with fluorescent probes. This site gives the necessary background about how fluorescence is generated.

http://micro.magnet.fsu.edu/optics/timeline/people/stokes.html

A link about George Gabriel Stokes.

2. Fluorescence Microscopy Tutorials

http://micro.magnet.fsu.edu/primer/techniques/fluorescence/fluorhome.html

Fluorescence microscopy is the most common technique today in medical and biological sciences. This link focuses on excitation and emission fundamentals, light sources, lasers, and filter cubes. The section interactive Java tutorials give very useful information about fluorochrome data tables, excitation/emission wavelengths, and filter cube suggestions listed by applications.

3. Laser and Fluorescence Microscopy

http://www.olympusmicro.com/primer/lightandcolor/laserhome.html

Section about laser fundamentals from the Olympus Web site. Lasers can be found in CD players and various other commonly used objects. In the field of microscopy, lasers are used for their monochromatic properties, light coherence, and power. This link gives useful and accessible information about laser physics. Many Java tutorials are also available.

C. Image Acquisition

1. Cameras and CCD Detectors

http://www.olympusmicro.com/primer/digitalimaging/index.html

Originally, mechanisms of image capture were restricted to photomicrography on film. Currently, the development of sensitive and low noise cameras gives the possibility to acquire digitally images from the microscope. These cameras with high sensitivity are at the core of the development of video microscopy. Digitalized images, as an ordered matrix of integers rather than a series of analog variations in colour and intensity, give the interesting possibility to post process images in order to enhance features and extract information. This section addresses a variety of current topics in image acquisition and processing.

http://www.roperscientific.com/library_encyclopedia.shtml

A part of the Roper scientific Web site (http://www.roperscientific.com) called encyclopedia and describing many camera concepts, such as binning, gain, and dynamic range, among others. A very useful reference to understand basic principles of cameras and CCD detectors.

http://helios.mol.uj.edu.pl/camera.html

Comparison of technical characteristics of several cameras.

D. Filter Sets and Fluorescence Filter Cubes

http://micro.magnet.fsu.edu/primer/techniques/fluorescence/filters.html

Filter sets are designed to select a specific wavelength for specimen illumination with polychromatic light sources and are essential for selectively collecting fluorescent light coming from the sample. Proper selection of filters is the key to successful fluorescence microscopy. This section describes characteristics of excitation and emission filters used in combination with dichroic mirrors to design filter cubes.

http://www.omegafilters.com/front/curvomatic/spectra.php

The Curvomatic application from the Omega Web site (http://www.omegafilters.com) is a tool helping microscopists to choose their filters set according to fluorophores used. A very useful application.

E. Fluorescence Tables

http://micro.magnet.fsu.edu/primer/techniques/fluorescence/fluorotable2.html

This link provides a table that summarizes several peak excitation and emission wavelengths of commonly used fluorochromes. These different fluorescence tags can be coupled with proteins or drugs (e.g., phalloidin or taxol) to monitor localisation of proteins in cells.

http://fluorescence.nexus-solutions.net/frames6.htm

The Bio-Rad fluorescence database has been designed to allow the user to superimpose graphical fluorochrome data from various fluorochromes onto a normalised axis. Both emission and excitation spectra can be plotted from any fluorochrome in the database. These can subsequently be overlaid with filter data curves and laser lines, which aids the microscopist in selection of the correct fluorochrome for use with their samples and microscope.

http://www.bdbiosciences.com/spectra/

The fluorescence spectrum viewer from bdbiosciences. This can be used as an alternative to Bio-Rad fluorescent database and the curvomatic application from Omega.

F. Fluorescent Probes for Light Microscopy

1. Fluorophores and Fluorescents Reagents

http://www.probes.com/handbook/

An electronic version of the Molecular Probes Handbook. Molecular Probes is one of the most interesting providers of fluorescent probes for cell biology. This Web edition of the handbook is an updated version of the 9th edition and is presented in two formats. Very useful information can be found in this Web handbook, such as cross-linking techniques, photoreactives reagents, probes for cytoskeletal proteins, membranes, organelles, and endocytosis, as well as pH indicators, and ions indicators.

http://www.probes.com/servlets/spectra/

This link points to the complete list of fluorescent Probes available from Molecular Probes. For each probe a sheet summarizes some characteristic of the probe (emission and excitation spectra, physical properties, etc . . .). Spectra are also available for download.

http://www.probes.com/resources/calc/basedyeratio.html

A base/dye ratio calculator from molecular probes. This applet allows the possibility to calculate fluorescence characteristics (maximum wavelength, extinction coefficient) of a nucleotide coupled to a fluorescent dye.

2. Secondary Antibodies for Immunohistochemistry

http://www.aecom.yu.edu/aif/instructions/immunofluor/controls/abodies.htm

A part of the analytical imaging facility Web site from Albert Einstein college of medicine (New York, http://www.aecom.yu.edu/aif/). This link points to a troubleshooting guide on immunofluorescence nonspecific labelling; very useful for understanding staining problems in immunofluorescence experiments.

http://www.jacksonimmuno.com/, http://www.zymed.com/pindex/index64.html and http://www.probes.com/

Jackon immunoresearch and Zymed are providers (although not unique) of secondary antibodies used in fluorescence microscopy. Secondary antibodies are classical tools used in cell biology to reveal localisation of proteins by fluorescence microscopy. Molecular Probes also provides some secondary antibodies.

3. GFP. Background and Properties of GFP and Related Tags

http://www.biochemtech.uni-halle.de/PPS2/projects/jonda/index.htm

These Web pages about green fluorescent protein (GFP) have been developed as a dissertation project for the principles of protein structure using the internet course (http://www.cryst.bbk.ac.uk/PPS2/top.html). You will find the *in vivo* role of the GFP and some basic properties. Biosynthesis, chemical structure of the fluorophore, and spectrum characteristics of this protein are also available.

4. Commercial Web site of Fluorescent Proteins

http://www.clontech.com/gfp/index.shtml

This link points to the Clontech Web site, with emphasis on GFP vectors. Clontech is historically the first provider of GFP-expressing vectors.

G. Immunohistochemistry and Immunofluorescence Protocols

1. Protocols Database

http://www.ihcworld.com/protocols.htm

Protocol Links Web page of IHC world Web site (http://www.ihcworld.com/; online information center for immunohistochemistry). An extensive list of Web sites, pdf files, and protocols covering fields of general histology, immunohistochemistry, immunofluorescence, *in situ* hybridisation, and electron microscopy protocols.

http://www.ihcworld.com/protocol_database.htm

Link to the protocols database of the IHC Web site. You can query the protocol database for a specific antibody-staining protocol.

2. Immunohistochemistry and in situ *Hybridization*

http://home.no.net/immuno

Link to a Web site explaining theory and techniques of immunolabelling. Some protocols are available and many Powerpoint presentations are downloadable. Useful teaching resource.

3. Other Immunofluorescence Protocols

http://www.itg.uiuc.edu/publications/techreports/99-006/

Web site of the imaging technology group from the Beckman Institute for Advanced Science and Technology (http://www.itg.uiuc.edu/). Link includes technical bulletin providing an introduction to fluorescent microscopy and a collection of various protocols for specific applications of fluorescence.

H. Other Microscopy Techniques

1. Three-Dimensional Laser Confocal Microscopy

http://www.cs.ubc.ca/spider/ladic/overview.html

Web site from Lance Ladic, Department of Physiology, University British Columbia, giving a basic introduction to 3D laser-scanning microscopy.

http://www.mih.unibas.ch/Booklet/Booklet96/Chapter1/Chapter1.html

Link to the course "Looking inside cells and tissues by optical sectioning with a confocal laser scanning microscope" prepared by M. Dürrenberger and R. Sütterlin. Also some basics about confocal microscopy.

http://www.science.uwaterloo.ca/physics/research/confocal/intro.html

Home page of the scanning laser microscopy lab (also known as the confocal microscopy group) of the physics department at the University of Waterloo. This site is designed for researchers who use (or might like to use) confocal microscopes. This Web site describes optical design, problems of lateral and axial resolution, and problems of confocal slicing in confocal microscopy. Some formulae can also be found.

http://micro.magnet.fsu.edu/primer/techniques/confocal/index.html

A complete section about confocal microscopy from the Molecular Expressions Microscopy Primer Web site. Basic concepts, imaging modes, specimen preparation and imaging, laser systems for confocal microscopy, etc . . . A very nice interactive java tutorial showing how a confocal microscope is working. This tutorial also shows effects of pinhole aperture on the quality of the confocal image.

2. Spinning Disk Confocal Microscopy

http://www.atto.com/Carv/confocaldesc.htm

A short Web page that describes differences between confocal scanning microscopy and the new technique of spinning disk confocal microscopy.

3. Multiphoton Fluorescence Microscopy and Two Photon Theory

http://microscopy.fsu.edu/primer/techniques/fluorescence/multiphoton/multiphotonhome.html

Multiphoton fluorescence microscopy is a powerful research tool that combines the advanced optical techniques of laser-scanning microscopy with long wavelength multiphoton fluorescence excitation. Multiphoton microscopy is generally used to specifically excitate fluorophores in a specific Z location. This link gives much information about this technique complementary to confocal microscopy.

4. Fluorescence Resonance Energy Transfer (FRET) Microscopy

http://www.anatomy.usyd.edu.au/mru/fret/abot.html

FRET microscopy uses the same physical principle as FRET spectroscopy. FRET is a technique used to determine the interaction (or proximity) of two fluorescent labelled molecules. This site gives the mathematical background necessary to explain FRET spectroscopy. Observations and equations described here are applicable to FRET microscopy.

http://www.probes.com/handbook/boxes/0422.html

Molecular Probes Web page about fluorescence resonance energy transfer microscopy. Information about primary conditions of FRET, Förster radius, and fluorophore pairs used for FRET can be found.

5. Fluorescent Lifetime Imaging Microscopy (FLIM)

http://www.cci.virginia.edu/flim/

Time-resolved fluorescence emission spectroscopy of a photoexcited sample is a powerful tool for the study of living cells in both space and time of their internal biochemistry. The Web page of the W.M. Reck Center for Cellular Imaging (University of Virginia) provides theory, images, and references about FLIM.

6. Fluorescent Recovery after Photobleaching (FRAP) Microscopy

http://www.bio.davidson.edu/courses/Molbio/FRAPx/FRAP.html

Link about FRAP to the Department of Biology, Davidson College, US. FRAP is used to measure the ability of a molecule to move around over time. This link provides information about this technique.

7. Fluorescence Correlation Microscopy

http://imd-www.es.hokudai.ac.jp/~gnishi/fcs/fcs.html

Web page of fluorescence correlation spectroscopy and its application, maintained by Goro Nishimura from Hokkaido University. The principle of fluorescence correlation spectroscopy is described in this Web page.

8. Fluorescence Speckle Microscopy

http://www.scripps.edu/cb/waterman/Flurorescent_speckle_categories.htm

Part of Clare Waterman-Storer Web site (http://www.scripps.edu/cb/waterman/) related to speckle microscopy. Everything needed to perform speckle microscopy is described: introduction to this technique, design and building of a fluorescent speckle microscope system, theory of fluorescent speckle microscopy image formation, preparation of living cell for speckle microscopy, and analysis of time-lapse FSM image series. A very informative Web site.

I. Electron Microscopy

1. Electron Microscopy for Dummies

http://cryoem.berkeley.edu/~nieder/em_for_dummies/

These pages have been designed and written by Hanspeter Niederstrasser of the laboratory of Dr. Eva Nogales, University of California, Berkeley. As the title implies, this Web site gives a good overview of electron microscopy techniques (transmission and scanning electron microscopy). A brief description of basic methods of preparation of samples can also be found.

2. What Are Electron Microscopes?

http://www.unl.edu/CMRAcfem/em.htm

This Web site from the Center for Materials Research and Analysis University of Nebraska–Lincoln gives more information about how electron microscopes work: descriptions of electron source, magnetic lenses, apertures, and interaction with the specimen leading to EM "image" formation.

3. Transmission Electron Microscope (TEM)

http://em-outreach.sdsc.edu/web-course/toc.html

A very complete Web course on TEM from the Electron Microscopy Outreach Program (http://em-outreach.sdsc.edu/). Principle of TEM, microscope design, microscope operation, specimen preparation, and so on are described in this Web course. Essential as a teaching resource.

4. Transmission Electron Microscope Sample Preparation

http://bama.ua.edu/~hsmithso/class/bsc_656/websites/sample_tem.html

A Web site about TEM sample preparation maintained by H.E. Smith Somerville (http://bama.ua.edu/~hsmithso/index.shtml) from the University of Alabama. Fixation and processing protocols, embedding, and immunocytochemistry are described.

5. Scanning Electron Microscopy

http://www.jeol.com/sem_gde/tbcontd.html

A guide to scanning microscope observation, part of the Jeol Web site (a company manufacturing electron microscopes). Good overview about scanning electron microscopy.

6. Electron Microscopy Protocols

http://biousa.hypermart.net/cellbio/microscopy/electron_microscopy.htm

This site was originally created and is maintained by Dr. Longcheng Li while doing postdoctoral research at UCSF. Some electron microscopy protocols can be found.

J. Miscellaneous

1. Image Galleries

http://www.cellsalive.com/toc.htm

Cell Alive Web site is a virtual museum of microscopic images (light microscopy and electron microscopy) of various organisms (eukaryotic, prokaryotic cells, plants, etc . . .).

http://www.microscopyu.com/galleries/index.html

Microscopy image gallery from Nikon microscopy Web site. Different sections showing images obtained using different techniques (wide field, confocal, etc . . .).

2. An Archive of Electron Micrographs

http://www.biochem.wisc.edu/inman/empics/

A collection of electron micrography images from the Institute for Molecular Virology, University of Wisconsin–Madison.

3. Atlas of Microscopy Anatomy

http://www.vh.org/adult/provider/anatomy/MicroscopicAnatomy/MicroscopicAnatomy.html

Electronic version of the Atlas of Microscopic Anatomy: A Functional Approach: Companion to Histology and Neuroanatomy, second edition.

4. A Video Tour of Cell Motility

http://cellix.imolbio.oeaw.ac.at/Videotour/video_tour.html

Contribution to the EAMNET network (http://www.embl.de/eamnet) from the John Victor Small laboratory. An original gallery of video microscopies describing the phenomenon of cell motility.

5. Free Software for Microscopy

http://www.cs.ubc.ca/spider/ladic/software.html

A part from Lance Ladic Web site (Department of Physiology, University British Columbia) giving many links for microscopy and image processing softwares.

6. ImageJ–Freeware Java Image Processing Software

http://rsb.info.nih.gov/ij/

ImageJ is a very good image processing software, written in Java and available for all types of platforms (Linux/UNIX, Windows and Mac-based computer).

7. Power Point Presentations on Microscopy

http://www.cyto.purdue.edu/flowcyt/educate/pptslide.htm

General teaching resource about light microscopy available as powerpoint presentations.

8. The European Advanced Light Microscopy Network (EAMNET) Network

http://www.embl.de/eamnet

EAMNET is a EU-funded network of eight European laboratories and two industrial partners working in the field of light microscopy. The aim of EAMNET is to assist scientists in exploiting the power of imaging by organizing practical teaching courses, creating online teaching modules, and offering software packages for microscopy.

9. Cell Migration Consortium

http://www.cellmigration.org/sciMovies.html

Movies and photo from the cell migration consortium (http://www.cellmigration.org/).

Contents of Volume 3

Contents of other Volumes

VOLUME 1

PART A. CELL AND TISSUE CULTURE: ASSOCIATED TECHNIQUES

Section 1. General Techniques

Section 2. Culture of Specific Cell Types: Stem Cells

Section 3. Culture of Specific Cell Types: Haemopoietic, Mesenchymal, and Epithelial

Section 5. Membranes

Section 6. Mitochondria

Section 7. Nuclear Transport

Section 8. Chromatin Assembly

Section 9. Signal Transduction Assays

Section 7. Sample Fractionation for Proteomics

Section 8. Gel Electrophoresis

Section 9. Detection of Proteins in Gels

Section 10. Gel Profiling of Posttranslationally Modified Proteins

Section 11. Protein/Protein and Protein/Small Molecule Interactions

Preface

Scientific progress often takes place when new technologies are developed, or when old procedures are improved. Today, more than ever, we are in need of complementary technology platforms to tackle complex biological problems, as we are rapidly moving from the analysis of single molecules to the study of multifaceted biological problems. The third edition of *Cell Biology: A Laboratory Handbook* brings together 236 articles covering novel techniques and procedures in cell and molecular biology, proteomics, genomics, and functional genomics. It contains 165 new articles, many of which were commissioned in response to the extraordinary feedback we received from the scientific community at large.

As in the case of the second edition, the *Handbook* has been divided in four volumes. The first volume covers tissue culture and associated techniques, viruses, antibodies, and immunohistochemistry. Volume 2 covers organelles and cellular structures as well as assays in cell biology. Volume 3 includes imaging techniques, electron microscopy, scanning probe and scanning electron microscopy, microdissection, tissue arrays, cytogenetics and in situ hybridization, genomics, transgenic, knockouts, and knockdown methods. The last volume includes transfer of macromolecules, expression systems, and gene expression profiling in addition to various proteomic technologies. Appendices include representative cultured cell lines and their characteristics, Internet resources in cell biology, and bioinformatic resources for in silico proteome analysis. The Handbook provides in a single source most of the classical and emerging technologies that are essential for research in the life sciences. Short of having an expert at your side, the protocols enable researchers at all stages of their career to embark on the study of biological problems using a variety of technologies and model systems. Techniques are presented in a friendly, step-by-step fashion, and gives useful tips as to potential pitfalls of the methodology.

I would like to extend my gratitude to the Associate Editors for their hard work, support, and vision in selecting new techniques. I would also like to thank the staff at Elsevier for their constant support and dedication to the project. Many people participated in the realization of the *Handbook* and I would like to thank in particular Lisa Tickner, Karen Dempsey, Angela Dooley, Carl Soares, and Tari Paschall for coordinating and organizing the preparation of the volumes. My gratitude is also extended to all the authors for the time and energy they dedicated to the project.

Julio E. Celis
Editor

Light Microscopy

CHAPTER

1

Fluorescence Microscopy

Werner Baschong and Lukas Landmann

I. ABOUT FLUORESCENCE

A. Luminescence, Fluorescence, and Phosphorescence

Luminescent substances emit light when irradiated, in contrast to most other light-absorbing substances, which merely heat up. Luminescence is usually induced by light, but can also be initiated by other electromagnetic radiation or by chemical reactions. In any case, bound or free electrons or atoms or molecules are temporarily excited to a higher energy state. When falling back to a lower state they emit part of the energy in the form of light. Since this excitation/relaxation process itself consumes energy, the wavelength of the emitted light is always longer than that required for excitation (Stoke's law). Fluorescence is emitted within nanoseconds after irradiation, i.e., in biological terms immediately. Phosphorescence manifests rather as an afterglow lasting between fractions of a second and several months.

B. Primary Fluorescence

A number of substances such as oils, optical brighteners, and plastic material but also many tissue components such as chlorophyll or bone intrinsically emit fluorescent light when irradiated with shortwave radiation. This kind of fluorescence is called primary fluorescence (1°-fluorescence) or inherent autofluorescence.

C. Secondary Fluorescence

Most of the objects to be investigated with a light microscope, i.e., cells, tissues, and bacteria, do not show an inherent fluorescence. These objects or specific details of these objects are rendered fluorescent either by fluorescent dyes or by tissue processing, e.g., fixation. Light emission caused by fluorochromes added to the specimen is called secondary fluorescence (2°-fluorescence) or just fluorescence. Processing-induced 2°-fluorescence is also called processing-related autofluorescence or, often and also together with inherent autofluorescence, simply autofluorescence.

D. Fluorophores (Fluorochromes)

Fluorophores are, in analogy to chromophores, the chemical groups responsible for the colour of a molecule, the groups responsible for a molecule's fluorescence. Fluorochromes are fluorescent molecules, often dyes. The expressions "fluorophore" and "fluorochrome" are often used equivalently. Each fluorophore has a specific (often overlapping) excitation and emission spectrum with distinct maxima.

Calcein, fluorescein, and, in the wider sense, tetracyclines, which accumulate in bone and teeth, are typical fluorochromes. Site-specific fluorescent dyes include the widely used DNA probes 4,6-diamino-2-phenylindole (DAPI), ethidium iodide, Hoechst 33342, and acridine orange, but also include fluorescent analogues of specific membrane lipids (e.g., www/probes.com/site-specific).

E. Direct and Indirect Immunofluorescence

Immunofluorescence (IF) is used to reveal the presence of specific antigens in body fluid, cells, or tissue by means of the corresponding fluorophore-conjugated antibodies and illumination with an

appropriate light source. The technique relies on the strong binding between antibodies and corresponding antigens, which allows for washing off nonbound label, thus displaying fluorescent objects against a dark background.

The principle of IF has found wide application in diagnostics, directly for the detection of antigens or indirectly for that of antibodies. In the former case, the presence of an antigen is directly visualized via the corresponding fluorescence-labeled (F-) antibody. Antigens may be viruses, bacteria fungi, etc. In the latter case, a specific—often immobilized—antigen is incubated, e.g., with a patient's serum, and in a second step, a F-labeled antihuman immunoglobulin antibody is used to detect the presence of antigen-specific antibodies. The indirect test reveals the presence of antibodies directed against a specific virus or a marker-protein typical for a specific disease.

Chem.* (1980)) were grown as monolayer on glass coverslips. *Prefixation*: 2% octyl-POE (*n*-octylpolyethoxyethylene)/0.125% glutaraldehyde, 5 min in MHB (Hanks buffer, Ca-free, containing 2 m*M* EGTA and 5 m*M* MES, pH 7. *Postfixation*: 1% glutaraldehyde in MHB (20 min) at ~20°C. Removal of background fluorescence with 0.5 mg/ml $NaBH_4$ (2 × 10 min at 0°C). *Labeling:* Filamentous actin (green): phalloidin Alexa-488 (www.probes.com); vimentin (blue): mouse anti-vimentin-Cy3 (monoclonal, www.sigma-aldrich.com); and tubulin (red): 1°-antibody, mouse anti-β-tubulin (monoclonal, www.sigma-aldrich.com) and 2°-antibody, goat antimouse IgG-Cy5. Composite image by triple exposure. Scale bar: 25 µm.

II. PRINCIPLES OF EPIFLUORESCENCE MICROSCOPY

A. Fluorescence Microscopy (FM)

Conventional bright-field microscopy visualizes structures of cells and tissues via the absorption and diffraction of light. In contrast, in FM, fluorochromes become independent light sources when irradiated with the appropriate exciting wavelengths, while the nonfluorescent surroundings remain dark. FM takes advantage of (i) Stoke's law, i.e., the difference of wavelength between exciting and emitted light, and (ii) the high visibility of fluorescent objects in the dark.

The fluorescence microscope is designed to induce the strongest possible fluorescence in the fluorescent object and the least interference from light of other wavelengths. This is achieved by (i) physically filtering the irradiating light so that it matches the exciting wavelength of the fluorophore and (ii) filtering the light emitted by the specimen in a fashion that only the fluorescent light emitted by the excited fluorophore will enter the optical path. Light of other wavelengths, including the exciting light, is barred off, thus generating a dark background, i.e., "good" image contrast.

The F-labeled object compares to a torch at night: The light is well visible, whereas the structure of the torch itself not. This manifests in the virtual resolution of FM. (i) Even cytoskeletal elements, e.g., microfilaments (6 nm), intermediate filaments (8–10 nm), and microtubules (25 nm), become well discernible when F-labeled, despite the theoretical resolution of ~200 nm of the microscopes (Fig. 1; cf. Baschong *et al*., 1999). (ii) However, it is difficult to decide whether two different fluorescent labels observed at the same spot really colocalize or whether they only appear to overlap because they cross over in space.

1. Fluorescence Microscopes for Transmitted Light Excitation

Initially, in fluorescence microscopes the beam of the exciting light was transmitted to the object through a bright-field condenser. This type of fluorescence microscope is practically no longer used in biology because the transmitted light causes considerable brightening of the specimen background and, consequently, low image contrast.

2. Fluorescence Microscopes for Incident Light Excitation (Epifluorescence)

Today's fluorescence microscopes work as epifluorescence microscopes and illuminate the object from

above, comparable to illumination in reflection microscopy (Fig. 2). Typically, the light source is placed perpendicular to the optical path. The light then passes through an "excitation" filter and hits at an angle of 45° a reflection short pass filter (dichroic beam-splitting mirror) placed in the optical path. As a mirror it deflects the excitation light to the objective (which also functions as a condenser) and ultimately to the specimen. Fluorescent light emitted by the irradiated specimen is collected by the objective lens and transmitted to the reflection long-pass filter (dichroic beam-splitting mirror) again. As a long-pass filter the latter now blocks any reflected excitation light and is translucent only for the longer-waved light emitted by the specimen. This emitted light is further filtered through a barrier or suppression filter before reaching the eyepiece.

Epifluorescence imaging can be complemented with visualization by transmitted light bright-field, dark-field, phase contrast, interference contrast, or by polarized light. Most conventional bright-field microscopes, including inverted microscopes or ster-eomicroscopes, can be adapted to FM (fore details, see, e.g., www.leica.com; www.nikon.com; www.olympusbiosystems.com; www.zeiss.com).

B. Components of the Fluorescence Microscope

1. Light Sources

Fluorescence microscopes require a light source, which illuminates the field of view (i) evenly and uniformly (ii) at the exciting wavelength dictated by the fluorochrome and (iii) with high intensity, as the fluorescence yield amounts only to a few percent of the excitation energy. High-pressure gas discharge lamps such as mercury (HBO) or xenon (XBO) arcs are most suitable. HBO burners emit a spectrum of a background continuum with the typical high-intensity mercury lines (Fig. 3). The XBO spectrum is also continuous. It is more intense in the red and far-red and comes closer to the spectrum of daylight (Fig. 4). HBO are usually preferred for conventional FM because of the higher radiation output in the ultraviolet to green region.

For even and uniform illumination, proper alignment of the arc is prerequisite. Since gas discharge lamps (50–400 W) operate at 10–15 bars and generate a substantial amount of heat, manufacturers instructions on alignment, installation, and safety are compulsory. (For light sources and spectra, see, e.g., www.esrf.fr, www.heraeusnoblelight.com; www.osram.com; www.olympusbiosystems.com.)

2. Optical Filters and Dichroic Mirrors

Filters for FM are designed to selectively transmit light matching the excitation wavelength of a given fluorochrome (exciter, excitation filter), to transmit only the light emitted by fluorochrome fluorescence (emitter, emitter barrier filter), or to separate the exciting and emitted light (dichroic mirror).

The three elements are usually mounted in blocks (Fig. 2) and are inserted into sliders or filter wheels. This allows for rapid switching of filter sets and facilitates operation at multiple channels. Exciter and emitter filter have to be oriented exactly at 45° to the dichroic mirror and the emitter filter perpendicular to the optical axis. Moreover, precision of the sliding mechanism is prerequisite (shift free), as the images of different filter sets will be displaced laterally, a phenomenon typically manifested when recording multi-fluorescence images via supraexposure.

Filters are characterized by their transmission and absorption or reflection properties: Short-pass (KP, SP) filters transmit light up to a certain cut-off wavelength and absorb longer wavelength light. Absorption of short wavelength and transmission of long wavelength light are provided by long-pass (LP) or barrier filters. Today, band-pass (BP) filters (Fig. 2) or multiple band-pass filters, which are translucent for one or several specific bands of wavelength, are most widely used. Dichroic mirrors (dichroic beam-splitting mirrors, color dividers, or reflection long-pass filters) also display LP characteristics. Multiple dichroic mirrors are translucent for several specific bands of wavelengths.

KP and LP filters and dichroic mirrors are characterized by their cut-off wavelength in nanometers, BP filters by the wavelength at maximal transmission, and the bandwidth at 50% transmission in nanometers. The smaller the overlap (crosstalk; Fig. 2) of the transmission curves of exciter and barrier filters, the better the image contrast. Occasionally, standard filter sets are offered where spectral separation may have been traded in for brightness of the fluorescent image: Brightness appeals to the naked eye but not to the charge-coupled device (CCD) camera, which discloses deficient channel separation rigorously.

3. Objective Lenses

The numerical aperture of the objective is the single most important factor for the brightness of the fluorescent image: Objectives with larger apertures concentrate more of the exciting light (illumination) on the specimen and collect more of the emitted light forming the fluorescence image. Because both the intensity of excitation and that of the emitted image

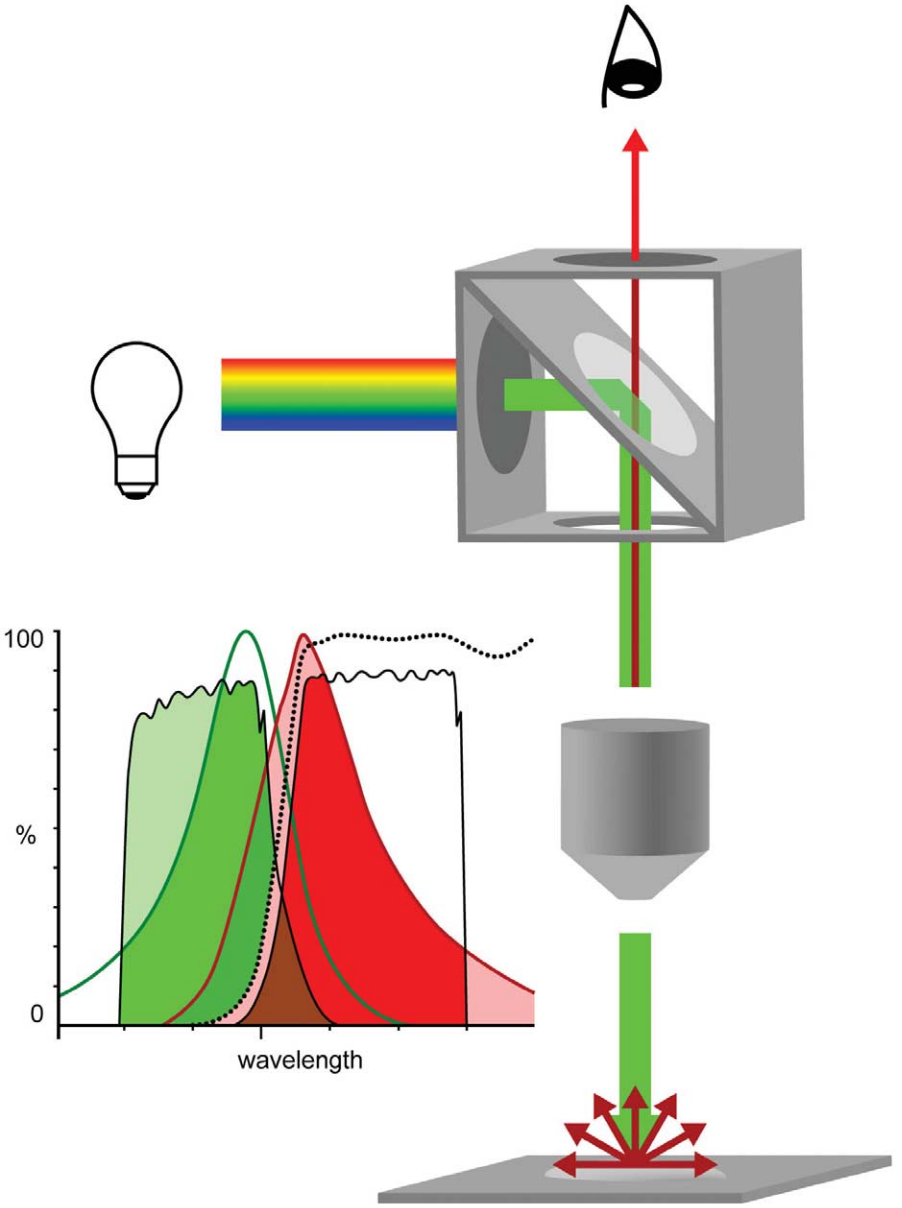

FIGURE 2 The epifluorescence microscope. Light source, positioned perpendicular to the optical axis of the fluorescence microscope, irradiates a cube that is placed in the axis and that comprises an exciter filter (ExF), a dichroic mirror (DM), and an emitter filter (EmF). Only light corresponding to the exciting wavelengths (green) passes ExF and reaches the DM placed at an angle of 45°, where light is deflected along the optical axis to be condensed by the objective (Oj) and focused onto the specimen. Corresponding fluorophores are excited and emit longer-waved fluorescent light (red). The Oj collects the emitted light (red) together with reflected exciting light (green). The DM is transparent for the longer-waved light, but not for the reflected exciting light, i.e., it functions as a long-pass filter. The EmF band pass filter is transparent only for light corresponding to the bandwidth of the emitted light (EmF filters off interfering shorter and longer-waved frequencies) and reaches the eye or the registration device, respectively.

Spectral separation by band-pass filters (Exm, EmF) and DM (dotted line) of exciting (green line) light and emitted (red line) fluorescence light, and cross talk.

The DM reflects most of the light passing the ExF (light green). This light corresponds mainly to the exciting spectrum of the fluorophore (green). Most of the emitted light (light red and red) passes the DM. The EmF further restrains this light (red) and filters off interfering light of lower or higher wavelength. However, because the transparence of ExF and EmF and the spectra of exciting and emission spectra are rarely separated but overlap to some extent, separation is not complete. Part of the higher wavelength light confined by the ExF passes the DM and also the EmF, where it adds as cross talk to the emitted signal (brown). Comparably, a part of the emitted light passes in the exciter channel.

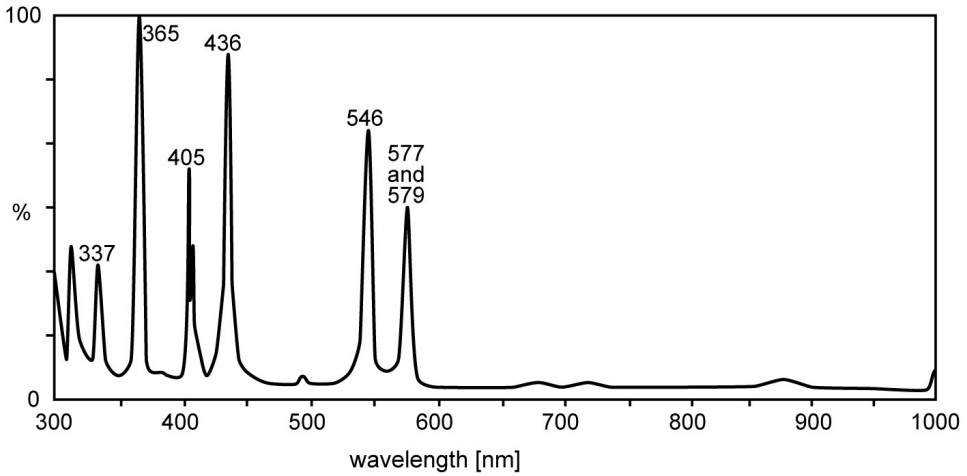

FIGURE 3 Relative spectral radiation of a high-pressure mercury lamp (HBO). Note the typical mercury lines of intense radiance. Courtesy of www.osram.com.

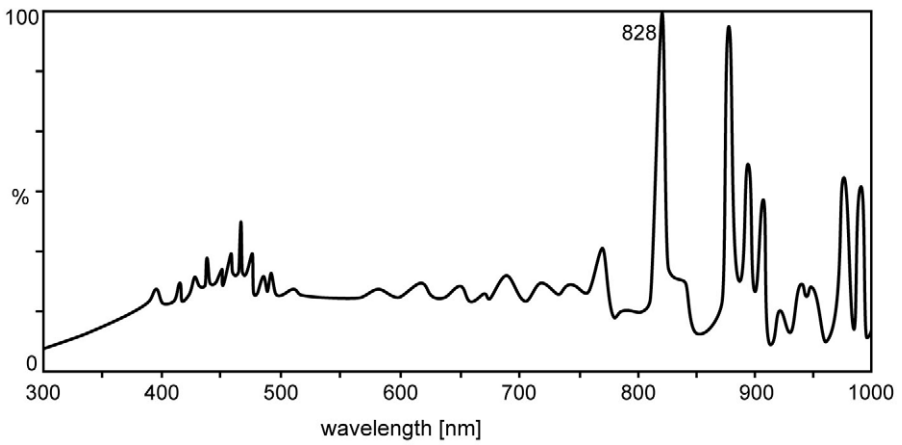

FIGURE 4 Relative spectral radiation of a high-pressure xenon lamp (XBO).

are proportional to the square of the numerical aperture (NA) of the objective lens and inverse proportional to the overall magnification (Mag_{tot}), the brightness (B) of the image increases with the fourth power of the NA,

$$B = \frac{(NA_{obj})^4}{(Mag_{tot})^2}$$

i.e., the higher the NA of an objective and the lower its magnification, the brighter the resulting image. Consequently, immersion objectives with their high numerical aperture are preferred even for low magnifications and they are combined with an eyepiece or with intermediary optics of the lowest magnification needed to detect the details of interest.

For excitation in the visible most of the objective lenses have good transmission properties and lack fluorescent components, including cements. For near UV excitation down to 360 nm, plan-fluorite objectives specifically coated against internal reflection and designed for use with oil, glycerol, or water immersion, with and without coverslips, are available from all major manufacturers. Typically, oil immersion objectives have numerical apertures of up to 1.4 and water immersion objectives up to 1.2. The latter have longer working distances, which make them well suitable for the observation of living cells in culture. Plan-apochromat lenses (63/1.4 and 100/1.4) suitable for UV excitation are also available.

When working with tissue, where overview images are essential, low magnification objectives (0.5–4×) should be accessible. Note that phase rings in an objective lens will reduce light throughput by up to 25%.

4. Recording Systems

a. Photomicrography. High-quality photographic recording of fluorescent images is not trivial. Because the emitted light is of low intensity, fast, i.e., highly sensitive, and therefore grainy, films have to be used. Nonetheless, exposure times will be long, which requires correction of the automatic exposure measurements by a film-specific reciprocity factor. Automatic illumination measurements are deceived by the nature of the fluorescent image, which is made up of a small bright signal against a large dark background, thus rendering integrated and spot measurements equally ineffective.

b. Charge-Coupled Device Imaging. With CCD imaging by solid state or video cameras, image quality and settings can be monitored on screen and adjusted accordingly. The single most important factor is sensitivity, defined by quantum efficiency, which is a measure of the efficiency of the detector to generate electric charge from incident photons. For weak fluorescence it is crucial that the imaging device is able to integrate and add up several frames.

Image resolution depends directly on the number of pixels registered per frame. For most applications, 1 megapixel, which yields images with a resolution roughly equivalent to 35-mm photographic film, is sufficient. Because CCD cameras are most sensitive in the red and far-red parts of the spectrum, auto gain control (AGC) should be switched off except when an infrared blocking filter is used.

Digital registration facilitates image processing and analysis. However, image files are of considerable size and require appropriate space for storage.

III. PRACTICAL CONSIDERATIONS

A. Choice of Filters

The selection of filters is dictated by the fluorophores intended to use (or vice versa). The latter have been roughly divided into four classes: (i) ultraviolet dyes, which are excited by UV light (~350 nm) and emit in the blue spectrum (~450 nm), (ii) fluorophores of the fluorescein isothiocyanate (FITC) class excited in the blue (~490 nm) and emitting in the green (~520 nm), (iii) rhodamine class dyes excited in the green (~560 nm) and emitting in the red (~580 nm), and (iv) fluorochromes such as Cy5 excited by red light (~630 nm) and emitting in the far red (~660 nm). For each class of fluorochromes, specific exciter/emitter filter blocks are available. Lists of fluorochromes, their spectral characteristics, and the appropriate filter sets are displayed by all major manufactures (e.g. www.chroma.com; www.seojinft.co.kr; www.omegafilters, www.schott.com).

Combinations of multiband-pass filters for the simultaneous observation and recording of two to three fluorochromes are also available. The latter are excellent for the observation of moving live specimens, but are generally more prone to cross talk than single channel filters. Alternatively, multiple fluorescence imaging can be performed by single channel imaging in conjunction with multiple photographic supraexposure.

B. Plasticware, Immersion Media, Embedding Resins, Mounting

For FM of cultured cells, culture medium and plasticware should not contain fluorescent compounds. Immersion oils, embedding resins, and mounting media should not fluoresce. Manufacturers often specify products as "safe to use for FM." Nonetheless, a quick check under the FM possibly together with the fluorochrome intended for use is never a waste of time.

For mounting of the specimen, various permanent water-soluble and water-insoluble resins (Kagayama and Sasano, 1999) containing an antifading compound are in use (Berrios *et al.*, 1999). Mounting media prepared on the basis of glycerol are very common because they are quick and simple to prepare. Sealing the coverslip after glycerol mounting with nail polish onto the slide provides mechanical stability and excludes oxygen.

Polymerizing mounting media such as Mowiol (Hoechst 1188, www.sigma-aldrich.com) generate stable mounts and exclude oxygen better than glycerol. In both cases, specimens should be stored in the dark, preferentially at 4°C.

C. Fading

In chemical terms, fading is caused by light-induced oxidation and decay of the fluorochrome, i.e., fluorescence underlies continuously progressing and irreversible destruction (Berrios *et al.*, 1999). Fluorochromes vary considerably with respect to fading; whereas FITC and green fluorescent protein (GFP) are highly sensitive, more recently introduced fluorochromes, such as indol-cyanine-based Cy dyes (www.amersham.com) and coumarin- or rhodamin-derived Alexa dyes (www.probes.com), are extremely stable toward light and oxygen. Nonetheless, exposition of a F-labeled specimen to light and oxygen should

be minimized and radical scavengers, e.g., *n*-propylgallate (www.sigma-aldrich.com), added to the mounting medium. The shutter at the light source should be used as often as possible. In addition, excitation intensity should be adjusted to the lowest possible level. Samples should be stored in the dark at 4°C.

D. Autofluorescent Compounds in Cells and Tissue

Inherent 1°-autofluorescence in cells often relates to the presence of NADH, riboflavin, or lysosomal residual material (lipofuscin) that are excited by near UV and blue light. If fluorescence labeling is expected to be weak, using fluorochromes emitting in the red or far-red may thus be advantageous. Furthermore, specific cell and tissue constituents such as chlorophyll in plants, hemoglobin in red blood cells, and elastic fibers, mast cell granules, bone, and so on in tissue typically exhibit 1°-autofluorescence.

2°-processing-related autofluorescence is essentially caused by fluorescent contaminants either due to unspecific adsorption of fluorescent molecules, e.g., fluorescent probes during processing, or generated by fixation, e.g., due to binding of fluorescent probes by nondeactivated aldehydes or by generation of glutaraldehyde or acrolein-derived polymers.

E. Poor Fluorescence Contrast

Poor contrast in a fluorescent image can be the effect of various causes: (i) autofluorescent contaminants in the immersion oil or (mounting) medium and (ii) inadequate filter combination with cross talk between excitation and emission wavelengths. (iii) If spectral properties seem to be adequate, poor contrast may be due to "minidefects" in the exciting filter. (iv) In thicker specimens, fluorescence generated above and below the focal plane may obscure the image. Those specimens need deconvolution and/or examination by confocal microscopy.

IV. IMMUNOFLUORESCENCE MICROSCOPY

A. Principle

Immunofluorescence microscopy (IMF) takes advantage of both fluorescence microscopy, as initiated about hundred years ago by Köhler and others for the documentation of autofluorescent or fluorescence-stained structures, and detection of fluorophore-conjugated antibodies, as introduced by Coons and Kaplan (1950). Specific cell and tissue constituents are visualized by IF either (i) directly (direct IF, primary fluorescence, 1°-IF) by fluorophore-conjugated antibodies (F-antibody) raised against the antigen of interest or (ii) indirectly (indirect IF, secondary IF, 2°-IF) via incubating a specimen, e.g., with a serum containing specific antibodies and revealing their presence by means of F-antibodies against the class and species of the first antibody (Fig. 5). Indirect IF is usually preferred because the 2° F-antibodies can be used against any primary antibodies of the appropriate class. Moreover, 2°-IF seems to provide brighter signals, as a 1°-antibody can bind more than one 2°-F-antibody. For multiple labeling 1°-IF, 2°-IF and site-specific fluorescent stains such as DAPI and F-phalloidin, are frequently combined.

B. Specimen Preparation

1. Objective Slides

Sample processing for IFM involves several steps of extensive washing and may be preceded by deparaffination. Specimen sections may not adhere enough to withstand such manipulations and get lost during washing. Adhesion of sections can be improved by using silanized or polylysine-treated slides (e.g., www.emsdiasum.com/ems/histology/slides.html) (see also article by Osborn and Brandfass).

2. Permeabilization

In specimens involving whole cell preparations or thicker tissue sections (e.g., cryostat sections), cytosolic proteins may be hardly accessible for antibodies because of the cell membrane (Fig. 6). In order to preserve the three-dimensional architecture of intracellular elements, e.g., of the cytoskeleton, the membrane lipids should be removed without interfering with the intracellular architecture. This is achieved either by chilled alcohol or acetone or by detergents used together with aldehydes. The principal steps are the same: During extraction of the membrane lipids by the solvent, e.g., ethanol, the detergent solution, or even the aldehyde solution itself, the solvent penetrates into the cell interior and immediately stabilizes the interior elements either by alcohol precipitation or by aldehyde cross-linking, respectively.

Permeabilization has to be adapted to the specific requirements of the cells and tissue in question and to the specific elements to be visualized; e.g., for cytoskeletal labeling permeabilization of cells with buffered solutions of 0.5–2% Octyl-POE (*n*-octylpolyethoxyethylene, www.alexis-corp-com) or of 1–2% Triton X-100 (e.g., www.sigma-aldrich-com) both

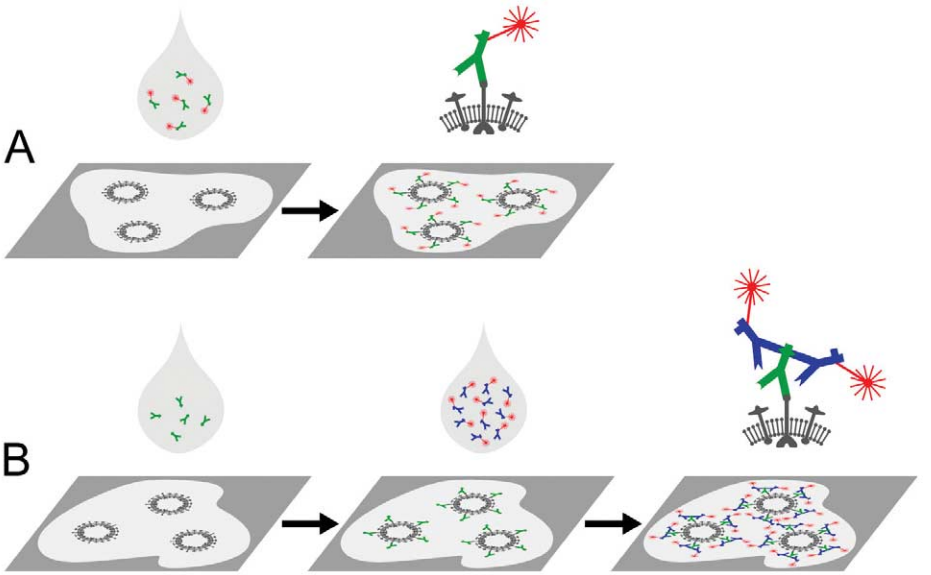

FIGURE 5 Primary and secondary immunofluorescence labeling. Primary immunofluorescence (A): A specimen with the antigen to be visualized (e.g., a viral surface protein) is incubated with the specific antibody conjugated to a fluorophore. Excess antibodies are washed off. Fluorescence microscopy reveals the presence of the antigen (e.g., the virus) directly as fluorescent signals. Secondary immunofluorescence (B): The same specimen is first incubated with antigen-specific antibodies (e.g., a rabbit serum) and excess is washed off. The specimen is then incubated with fluorophore-conjugated antibodies directed against the species and type of the primary antibody (e.g., antirabbit IgG antibodies raised in goat) and excess is washed off. The presence of the antigen manifests in the fluorescence microscope as a fluorescent signal. Since more than one secondary antibody may bind to each primary antibody, the signal may be stonger than obtained by primary immunolabeling.

containing 0.125–0.25% glutaraldehyde, and subsequent post-fixation with 1% glutaraldehyde or 1% formaldehyde proved efficient between pH 5.5 and 9.5 (Baschong *et al*., 1999).

3. *Physical Fixation*

While cryofixation and cryosectioning have become state of the art, microwave fixation, i.e., heat-related denaturation and stabilization of tissue and cells, comparable to boiling an egg, has not yet reached general applicability. In connection with FM it is used preferentially in a clinical environment. Preservation of morphology and antigenicity by microwave fixation is apparently comparable to cryopreservation or to chemical fixation, yet it can be achieved within several orders of magnitude faster and in tissue probes as large as 1 cm^3. However, extensive calibration and preferably specific microwave devices are prerequisites for proper performance. Employing common large-cavity microwave devices (e.g., household) will lead to irreproducible results if not calibrated properly (for details, see Login and Dvorak, 1994; Giberson and Demaree, 1995).

4. *Chemical Fixation*

a. Fixation by Solvents. Fixation by solvents is common in immunohistochemistry. These organic solvents—most often methanol or acetone chilled to –20°C—disrupt the membrane and simultaneously precipitate the proteins in the cytosol. Protein precipitation of intracellular elements might displace intracellular structures and induce cytoskeletal elements to coalesce. However, especially when using cryo sections, solvent fixation may dissolve lipophilic surface layers that interfere with antibody access or may denature proteins and make them more accessible for antibodies prepared from denatured antigens. For processing plant and yeast material and also for certain endoparasites (W. Baschong, personal communication), solvent fixation has proven advantageous.

b. Fixation by Aldehydes. Formaldehyde and, to a lesser extent, glutaraldehyde and acrolein are used routinely for the stabilization of supramolecular assemblies, e.g., of cytoskeletal and cytoskeleton-associated elements, i.e., for preserving the three-

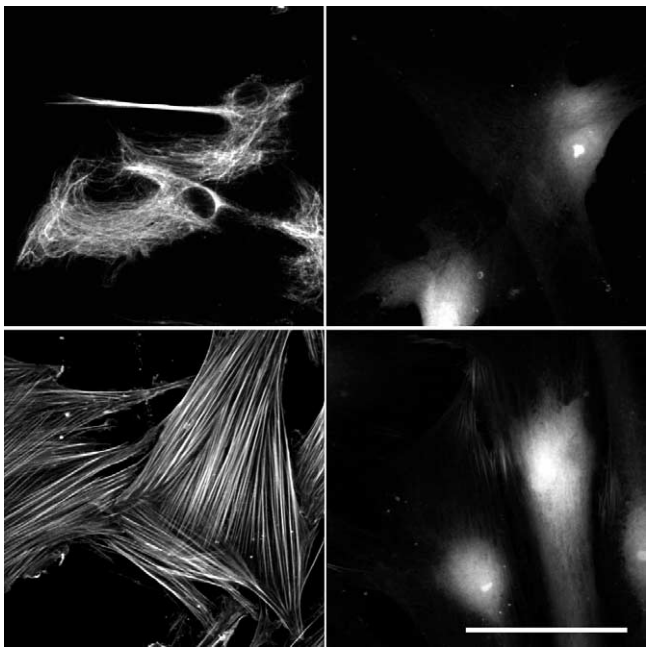

FIGURE 6 Effect of permeabilization/prefixation on cytoskeletal labeling. Human dental ligament cells on glass coverslips. Top, bottom (left) with and top, bottom (right) without permeabilization/prefixation as described in Fig. 1. *Labeling*: vimentin (top): Cy3 antivimentin (monoclonal mouse, www.amershambiosciences.com). F-actin (bottom): TRITC-phalloidin (www.sigma-aldrich.com). Cytoskeletal labeling only in permeabilized cells. In non-permeabilized cells actin is partially accessible for small phalloidin (1250 Da) but not for large anti-vimentin IgG (~150,000 Da). Scale bar: 25 µm. From Baschong *et al*. (1999).

dimensional (3D) architecture of cell and tissue constituents. Formaldehyde is usually diluted to a final concentration of 4–5%, either from a concentrated 37% stock or from freshly dissolved paraformaldehyde (so far we have not experienced differences in performance of one or the other), acrolein, or glutaraldehyde to a final concentration of 1%. Indeed, at the electron microscopic level, structural preservation of pure protein assemblies by either solution proved comparable (Baschong *et al*., 1984). Glutaraldehyde seems to react faster and to polymerize in the presence of oxygen to a large network, whereas formaldehyde seems to react slower and via oligomeric HCHO chains (Baschong *et al*., 1983). In fact, this is also reflected in the depth of antibody penetration: While immunolabeling of liver tissue fixed with 0.1% glutaraldehyde tissue was confined to a surface zone of about 1 µm, labeling of the same tissue fixed with 4% paraformaldehyde proved to be regular and intense down to 5 µm (L. Landmann personal communication). In our hands, 4–5% HCHO for routine microscopy or 1% glutaraldehyde postfixation in conjunction with permeabilization provided acceptable results in most cells and tissue. Nonetheless, it should be kept in mind that the mode of fixation can affect the antigenicity (see Section IV,B,4), i.e., optimal fixation conditions for immunolabeling an antigen in a specific tissue have to be established by trial and error. Tris buffers should not be used. They react with aldehydes under liberation of HCl, which may destroy the specimen.

4. Antigen Preservation

Preservation of antigenicity is of major concern in IFM. However, tissue preservation and embedding involves denaturation (microwave and solvent fixation) or chemical cross-linking of proteins, i.e., processes that may, and often do, affect the epitopes an antibody had been raised against. Moreover, in cryopreserved specimens, where denaturation is least, epitopes may become degraded by nondeactivated proteases. In short, there are no rules indicating how to minimize loss of antigenicity other than trial and error. At least, most suppliers of antibodies now indicate at which conditions successful labeling had been achieved with their products, thus providing the first step toward optimal labeling.

5. Managing Autofluorescence

Secondary preparation-related autofluorescence mostly relates to chemical fixation: Nonreacted aldehyde groups [e.g., of glutaraldehyde or (paraformaldehyde)] bind fluorescence markers either directly or via binding antigens or primary antibodies, thus creating substantial background fluorescence. Binding can be prevented by blocking aldehyde groups with amines such as glycine and ethanolamine, or by reducing them to OH-groups by sodium borohydride. The latter also considerably reduces the fluorescence of glutaraldehyde-derived polymers (Fig. 7).

For controlling autofluorescene in more complex tissue, e.g., bone marrow, multiple strategies such as NH_3 and $NaBH_4$ treatment before and Sudan black B counterstaining after labeling may be required (Baschong *et al*., 2001). In any case, an unlabeled specimen should be examined at the start of any study.

C. Antibody Conjugates

1. Preparation of Fluorescent Antibody Conjugates

Historically, fluorochromes, e.g., carboxyfluorescein, were coupled directly to the antibody of interest. Nowadays, not only antibodies coupled to a variety of fluorochromes and against practically all types of primary antibodies, but also a lot of fluorophore-tagged primary antibodies against many structural and pathological markers are available from a multi-

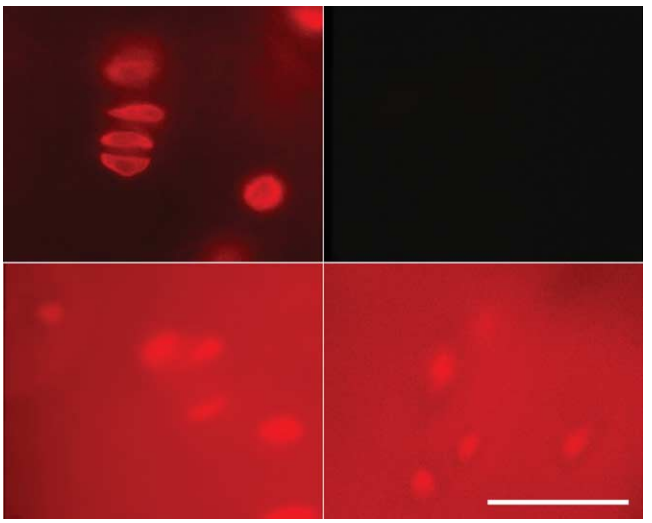

FIGURE 7 Control of background fluorescence by $NaBH_4$. Bovine articular cartilage (100-µm-thick sections). Fixation as described in Fig. 1, but prefixation 40 min and postfixation 60 min. Top (left and right): Treatment with 5 mg/ml $NaBH_4$, 2 × 30 min. Bottom (left and right): Control without NaBH4-treatment. *Labeling*: Left (top and bottom): Cy3 antivimentin; right (top and bottom): nonlabeled control. tude of suppliers. For specific fluorescence labeling of antibodies, e.g., in conjunction with primary IFM, specific labeling kits comprising a variety of fluorochromes are on the market (e.g., www.amersham.com).

2. *Antibody Titration*

For FM, the antibody titer is defined as the highest dilution, which results in optimal specific staining with the lowest possible background. This dilution has to be determined empirically for each antibody. Typically, titers vary from 1:5 to 1:100 for monoclonals in cell culture supernatant, from 1:100 to 1:2000 for polyclonal antisera, and up to 1:100,000 for monoclonals in ascites fluid. Manufacturers occasionally indicate a dilution range that may serve as a starting point for titration. Typically, checkerboard titrations (Table I) are used to determine the optimal dilutions of more than one reagent simultaneously, e.g., of a primary and the corresponding secondary antibody.

One slide is prepared for each pairing, i.e., nine (3^2) slides if three dilutions of the 1° and the 2° antibody have to be tested. Test slides are judged visually for both specific staining/labeling (ss) and background fluorescence (bg). If different dilutions show identical or similar results (indicated by oblique line in Table I), antibody costs can become a criterion for selection.

TABLE I

I AB/II Ab	1:50	1:100	1:200
1:250	ss:	ss:	ss:
	bg:	bg:	bg:
1:500	ss:	ss:	ss:
	bg:	bg:	bg:
1:1000	ss:	ss:	ss:
	bg:	bg:	bg:

Negative controls carried out in parallel, i.e., performing the labeling protocol without the 1° antibody or without 2° antibody, indicate unspecific binding of the 2° antibody or autofluorescence, respectively.

3. *Labeling with Primary or Secondary Fluorescence Antibodies*

Incubation time and incubation temperature are interdependent with the antibody titer, although with less influence on the quality of labeling than the latter. Generally, incubation times between 30 and 120 min at ambient temperature are sufficient. When labeling intracellular elements, e.g., cytoskeletal structures, in permeabilized 3D-cell cultures or tissue, 3–4 h of incubation with the 1° antibody at 20°C followed by three to four washes for 10 min each and subsequent incubation with the 2°F-antibody and four to five washes for 10–20 min is adequate (Baschong *et al*., 1999). Antibodies with lower affinity may perform better if incubated overnight at 4°C.

To avoid drying out of the specimen, incubations should always be performed in a moist chamber.

Occasionally, incubation at an elevated temperature (e.g., 37°C) in combination with microwave treatment is reported. Such conditions may be optimal for the specific antibody and tissue described, yet difficult to transform to other experiments without extensive calibration (see also microwave fixation).

Unspecific binding of 1° or 2° antibodies or both results in background labeling. Underlying mechanisms are manifold and difficult to elucidate. Nonetheless, some general precautions will reduce the risk. Unspecific binding of polyclonal antisera can be reduced by employing only its immunoglobulin G fraction isolated via affinity chromatography, e.g., over a protein A column (e.g. www. amersham.com; www. bio-rad.com). Unspecific binding can be reduced further by cross-absorption of antibodies against preimmune serum from the species providing the antibody and—in case of multiple labeling—against the antibodies used for labeling in other channels.

Unspecific binding due to hydrophobic interactions can be reduced by incubation with a 1% solution of a blocking protein such as albumin, ovalbumin, or gelatin, either prior to the primary antibody step and/or together with the antibody solution.

4. Commercial Antibodies

As indicated previously, antibodies are available from a multitude of suppliers, be it nonlabeled as antisera, as affinity-purified immunoglobulines, as monoclonal antibody preparations, or as F-labeled 1° and 2° antibodies (e.g., www.amersham.com; www.jacksonimmuno.com; www.probes.com; www.sigma-aldrich.com; www.dianova.de). Such preparations may be supplied in buffer as concentrated or diluted solutions, as frozen or freeze-dried preparations, etc. There are no standard conditions for supplying antibody preparations. The form in which they are supplied is at least in part dictated by the environment wherein they best maintain their activity. Antibody preparations may be sensitive to high salt or low salt concentrations and to high or low pH. They may contain traces of proteases, limiting their shelf life. Other preparations may be sensitive to freezing and should definitively be stored above 0°C. Some freeze-dried preparations may already contain the amount of salts required for yielding the appropriate buffer solution upon reconstitution; then reconstitution with phosphate-buffered saline (PBS) instead of the indicated water may turn out detrimental. In consequence, keeping antibodies at other conditions than indicated by the provider may interfere with their activity. Fluorescent probes should always be kept in the dark. Antibody solutions should be protected against microorganisms (e.g., by 0.1–0.05% sodium azide).

V. MISCELLANEOUS

A. Green Fluorescent Protein and Analogues

The discovery of GFP of the jellyfish *Aequorea victoria* less than 10 years ago has added a new dimension to the study of cells and their molecular organization (Miswender *et al*, 1995; Wouters *et al*., 2001). Directly engineering the GFP sequence into the protein of interest not only reveals its topology, but also allows for the visualization of dynamic processes, such as polymerization/depolymerization reactions, intracellular transport, and ligand binding and in living cells and by time-lapse FM.

A GFP fusion protein is characterized by its brilliant green fluorescence (excitation 484 nm, emission 510 nm). More photostable genetic variants such as EGFP (enhanced GFP, 10–35 × brighter signal) and with different spectral properties such as cyan fluorescent protein (CFP; excitation 439 nm, emission 476 nm) and yellow fluorescent protein (YFP; excitation 512 nm, emission 529 nm) have been introduced consecutively. For the visualization of these markers, specific filter sets are available. However, because of the closeness of exciting and emitting wavelengths, cross talk is difficult to avoid.

CFP and YFP are the most widely used pairs for multifluorescence imaging. Corresponding multipass filters for simultaneous imaging are available. Because of the cross talk, weak signals are best visualized by the consecutive application of single channel filters or, more accurately, by "spectral fingerprinting" using confocal microscopy.

The recent introduction of reef coral fluorescent proteins (RCFPs), which include variants with emissions in the cyan, green, yellow, red, and far-red part of the spectrum, has increased experimental flexibility greatly. RCFPs make powerful tools for monitoring promoter activity, labeling whole cells, and, in some cases, visualizing organelles. The RCFP "DsRed" has been combined with GFP or with YFP and CFP, respectively (www.bdbiosciences.com) (see also article by Rottner *et al*.).

B. Multiparameter Strategies

1. Double Labeling–Multiple Labeling

Several antigens or specific sites in a specimen can be labeled as long as the fluorescent probes comprise fluorophores of different classes. For multifluorescence labeling it is advisable to use the more stable fluorochromes of the Cy (www.amersham.com) or Alexa (www.probes.com) series. The sequence of labeling may be crucial in limiting cross-reactions and weak labeling due to steric hindrance. As a rule of thumb, indirect labeling using 2°-F-antibodies should precede direct labeling with 1°-F-antibodies, F-phalloidin, DAPI, etc., and polyclonal antibodies should be used prior to monoclonal antibodies.

Double labeling can also be performed using a solution of a monoclonal antibody (raised in mouse) in a polyclonal antiserum (raised in rabbit) followed by incubation with a mixture of the corresponding 2°-F-antibodies carrying fluorophores of different classes. If two antibodies raised in the same species—normally mouse monoclonal antibodies—have to be used, at least one antibody should be applied directly as 1°-F-antibody (see Section IV,C,1). Alternatively, two different monoclonal antibodies can be visualized by the sequential addition of fluorescence-labeled antimouse

Fab-fragments carrying fluorophores of different classes (F_1 and F_2). The first mouse monoclonal antibody is visualized by F_1-antimouse Fab fragments and after thorough washing, the second mouse monoclonal is applied and visualized by a F_2-antimouse antibody or by F2-antimouse Fab-fragments (e.g., www.dianova.de) (see also article by Prast *et al*.).

2. *Multipass Filters Versus Sequential Recording*

Multichannel fluorescence (e.g., double or triple label IF) can be monitored with specific filter sets that are designed to visualize up to four fluorochromes simultaneously. Multichannel imaging is ideal for imaging dynamic processes and for live cell imaging, as the time-consuming switching of channels is obsolete. In general, multipass filters are more prone to cross talk and less sensitive than single channel filter sets.

Subsequent recording of each fluorochrome with its appropriate filter set yields better separation of channels and higher sensitivity. It permits also to manually balance brightness of the different channels. However, the perfect x/y register (shift free) of the different images is crucial. In case of need, the filter alignment can be tested with special fluorescent beads (alignment beads, e.g., www.probes.com; www.bio-rad.com).

Appendix

Immunofluorescence labeling of cytoskeletal elements in cultured cells (cf. Fig. 1). Cells [rat SM2 fibroblasts (Leavitt and Kakunaga, (1980)] were seeded onto glass coverslips (ca. 12 mm diameter) placed in 24-well culture plates and grown in culture medium for 24 h.

Solutions

1. *PBS* (*without magnesium and calcium*):

NaCl	140 m*M*	8.19 g
KCl	14 m*M*	1.05 g
$Na_2HPO_4 \cdot 12H_2O$	11 m*M*	4.8 g
KH_2PO_4	4 m*M*	0.6 g

Make up to 1 liter with double-distilled water and adjust with 1 *N* HCl to pH 7.2–7.4; alternatively, purchase (e.g., www.sigma-aldrich). Pass through a 0.22-µm filter and store at 4°C. If not used for living cells, preserve buffers with 0.05% NaN_3.

2. *MHB buffer (modified Hank's buffer according to Small and Celis, 1978)*:

NaCl	137 m*M*	8 g
KCl	5 m*M*	0.4 g
$Na_2HPO_4 \cdot 12H_2O$	1.1 m*M*	0.48 g
KH_2PO_4	0.4 m*M*	0.06 g
$NaHCO_3$	4 m*M*	0.35 g
Glucose	5.5 m*M*	1 g
$MgCl_2$	2 m*M*	2 ml from 1 M stock
EGTA	2 m*M*	8 g
MES (e.g., www.sigma-aldrich.com)	5 m*M*	1.065 g

Make up to 1 liter with double-distilled water and adjust with 1 *N* HCl to pH 7. Pass through a 0.22-µm filter and store at 4°C. If not used for living cells, preserve buffer with 0.05% NaN_3.

3. *Permeabilization/prefixation solution*: 2% *n*-octylpolyethoxyethylene (www.alexis-corp-com) and 0.125% glutaraldehyde in MHB.

4. *Fixation solution*: 1% glutaraldehyde in MHB.

5. *$NaBH_4$ solution (for aldedhyde reduction and removal of autofluorescence)*: 0.5% (w/v) of $NaBH_4$ dissolved in cold PBS. Prepare freshly before use. Keep on ice.

6. *Incubation buffer*: 0.5% (w/v) bovine serum albumin (BSA, e.g., fraction V, www.sigma-aldrich.com) in MHB.

Mounting Solutions

1. *Glycerol*: Dissolve 0.75% *n*-propyl gallate (www.sigma-aldrich.com) or 2.5% MHB DABCO (diazabicyclo[2.2.2.] octane, www.sigma-aldrich.com) in 10 ml PBS and stir vigorously at room temperature. Add 90 ml glycerol and stir until homogeneous.

2. *Mowiol*: Dissolve 20 g of Mowiol (Hoechst 1188, www.aventis.com) at roomtemperature in 80 ml PBS (pH 7.2) or MHB [pH. 6.5 (Small and Celis 1978)]. Add while stirring 40 ml glycerol and stir for another 8–24 h. Remove insoluble particles by centrifugation (20,000 *g*, 15 min). Then dissolve 0.75% *n*-propyl gallate or 2.5% DABCO by stirring for another 4 h in the dark. Divide the solution in aliquots and store airtight and at 4°C in the dark.

3. *Mowiol for fluorescence staining of DNA*: Supplement 100 *ml* Mowiol solution with 5 µl of a DAPI (4,6-diamino-2-phenylindole, e.g., www.sigma-aldrich.com) stock solution (1 mg/ml in distilled water). Use this solution when mounting the specimen instead of the conventional Mowiol solution in order to stain nuclear and possibly also mitochondrial DNA.

Labeling Protocol

Permeablization, fixation, and blocking of free aldehyde groups can be performed in a 24-well culture dish.

1. Rinse coverslips with cells shortly with PBS.
2. Replace with permeabilization solution and incubate for 5 min at room temperature.
3. Rinse with MHB (1 × 3 min).
4. Incubate with fixation solution for 20 min at room temperature.

5. Rinse with PBS or MHB (3 × 3 min).
6. Place dish on ice and add precooled $NaBH_4$ for 10 min.
7. Change $NaBH_4$ and incubate again for 10 min on ice.
8. Replace solution with PBS or MHB solution (3 × 10 min) while agitating dish at room temperature using a shaker.

The following fluorescence markers and antibodies are used for immunolabeling.

Antigen	Marker	Dilution	Source
Actin filaments	Phalloidin Alexa-488	1:400	www.probes.com
Vimentin	Mouse antivimentin-Cy3 (IgG_1)	1:1000	www.sigma-aldrich.com
Tubulin	1°antibody Mouse anti-β-tubulin (IgG_1)	1:50	www.sigma-aldrich.com
Mouse IgG_1	2°antibody Goat antimouse IgG-Cy5	1:500	www.amersham-biosciences-com

Dilute all antibodies in incubation buffer.

All steps involving fluorochromes should be carried out in the dark (e.g., keep dishes in a black box).

1. Rinse with incubation buffer for 10 min at room temperature.
2. Incubate with normal goat serum (i.e., species in which the 2° antibodies were raised) diluted 1:20 in incubation buffer for 30 min at room temperature.
3. Incubate with primary antibody (i.e., mouse anti-β-tubulin) for 60 min at room temperature.
4. Wash with PBS (3 × 5 min).
5. Incubate with a mixture of the secondary antibody (i.e., goat antimouse IgG-Cy5) and phalloidin Alexa-488 for 60 min at room temperature.
6. Wash with PBS (3 × 5 min).
7. Incubate with antivimentin-Cy3 for 60 min at room temperature.
8. Wash with PBS (3 × 5 min).

Mount coverslips with Mowiol on slides. Cells must not be allowed to dry out. Certain antibodies may require incubation overnight at 4°C to yield better results. Specimens can be stored for several weeks at 4°C.

CHAPTER

2

Total Internal Reflection Fluorescent Microscopy

Derek Toomre and Daniel Axelrod

I. INTRODUCTION

A. Overview and Applications

Total internal reflection fluorescent microscopy (TIRFM), also called evanescent wave microscopy, selectively excites fluorophores in a very thin (<100 nm) optical plane near the cell/coverslip interphase; the intensity of this evanescent field drops off exponentially away from the coverslip (Axelrod, 2003). The net effect is that there is virtually no out-of-focus background fluorescence and the vertical resolution and signal-to-noise are excellent, unmatched by any other light microscopy technique. These attributes make TIRFM ideal for sensitive and quantitative imaging of processes near the ventral (or basal) cell surface. The advent of a multicolor pallet of green fluorescent proteins tags (e.g., CFP, GFP, YFP, and dsRed) and other fluorophores (e.g., FlAsH), new very high numerical aperture (NA) lens, and "turn-key" commercial TIRFM systems has made TIRFM increasingly popular with cell biologists.

Its applications include studies of exocytosis (Steyer and Almers, 2001; Toomre and Manstein, 2001; Zenisek *et al*., 2000; John *et al*., 2001), endocytosis (Merrifield *et al*., 2002), cytoskeleton dynamics (Merrifield *et al*., 2002; Vale *et al*., 1996), and *in vivo* and *in vitro* single molecule studies (Ishijima and Yanagida, 2001; Pierce, 1999; Sako and Uyemura, 2002). For example, exocytic fusion of single vesicles can be observed directly by TIRFM as a fluorescent "flash" and cytoskeleton elements near the "footprint" of the cell are selectively illuminated (Fig. 1). Moreover, it can be combined with other microscopy techniques, including bright-field and epifluorescence microscopy (Toomre and Manstein, 2001), fluorescent resonance energy transfer (FRET) (Sako and Uyemura, 2002), fluorescent recovery after photobleaching (FRAP) (Sund and Axelrod, 2000), fluorescence correlation spectroscopy (FCS) (Starr and Thompson, 2001), and atomic force microscopy (AFM) (Nishida *et al*., 2002). In-depth reviews of TIRFM theory (Axelrod, 2003), implementation (Axelrod, 2003; Oheim, 2001), and applications (Axelrod, 2001; Ishijima and Yanagida, 2001; Steyer and Almers, 2001; Toomre and Manstein, 2001) are available, and excellent interactive tutorials can be found at http://www.olympusmicro.com/primer/techniques/fluorescence/tirf/tirfhome.html.

B. Theoretical Principles

The following is a condensed summary of total internal reflection (TIR) theory; for brevity, specialized properties of TIR illumination, such as the effects of polarized light and the use of metal films for creating surface plasmon resonance effects, can be found elsewhere (Axelrod, 2003; Sund *et al*., 1999).

TIRFM is based on how light behaves at an interface of two mediums of different refractive index (see Fig. 2). Specifically, if a beam of light traveling in a medium of high refractive index, such as glass (n_3 ~1.51), enters a lower refractive index medium, such as water (n_1~1.33) or the cytosol of a cell (n_1 ~1.36–1.38), beyond a certain critical angle, θ_c (measured from the normal), it is totally internally reflected, rather than simply refracted. For TIR to occur, two conditions must be met: $n_3 > n_1$ *and* the incidence angle of the light, θ, must be greater than the critical angle, θ_c. This critical angle can be derived from Snell's law of

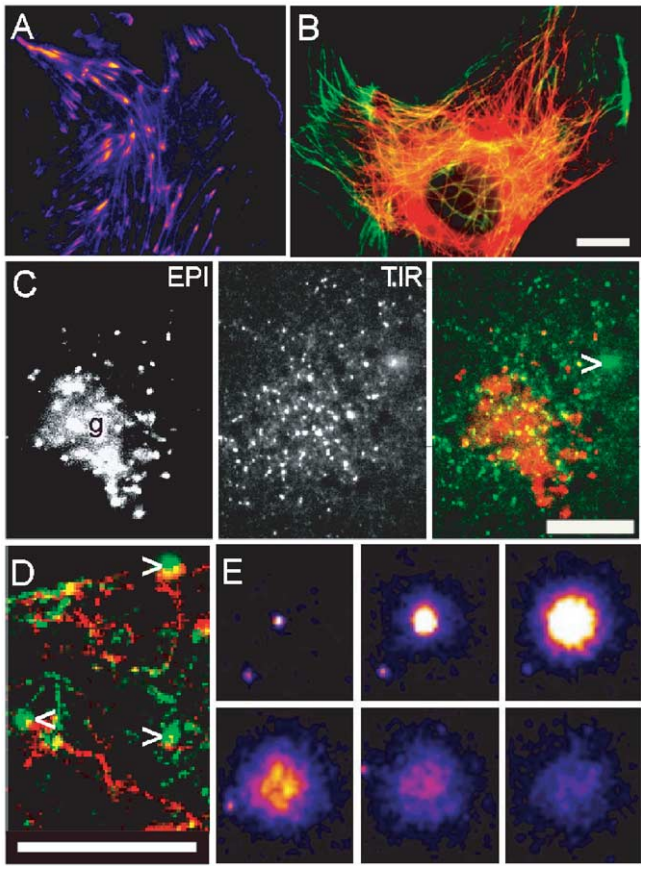

FIGURE 1 Images of cell cytoskeleton and membrane traffic with TIRFM. (**A** and **E**) Images of the TIR fluorescent signal that have been false colored; bright to dimmest signal is white > yellow > red > purple. (**B–D**) The normal epifluorescent signal (EPI) is colored red and the TIR fluorescent signal (TIR) is shown in green. All images are from PtK_2 epithelial-like cells labeled with various YFP constructs. (**A**) Actin-YFP. Note that the ends of stress fibers (likely focal adhesions) are particularly bright. (**B**) Tubulin-YFP. Tubulin near the coverslip is yellowish-green. Note that single microtubules can be observed clearly by TIRFM (green) even under dense areas of microtubules (red). (**C**) Different views of membrane cargo. VSVG-YFP, a membrane protein, was accumulated in the Golgi (g) and then released. The cursor indicates a vesicle that has just fused with the plasma membrane (PM). Note that EPI and TIR images of the cell are very different (even though the focal plane was not changed). In EPI the Golgi area is stained brightly, whereas in TIR vesicles near the membrane are brightest; there is weak PM staining due to VSVG-YFP that has already fused. (**D**) Tracking trafficking and fusion. A series of ~200 frames were back subtracted and the difference image was projected. Vesicles that moved out gave a red EPI "track," turned yellow/green as they approached the membrane, and fusion itself gave a green circular "flash," indicated by the cursors. (**E**) Collage of a vesicle undergoing fusion. Starting in the top left, 1 sec intervals are shown from left to right. The fading of the signal in frames 4–6 is due to lateral diffusion of protein in the membrane. All images were taken with a TIRFM microscope similar to that in Fig. 4A, but with a hemicylinder prism. Scale bars: 5 μm (B–D) and 2 μm width of Box in (E). Reprinted from Toomre and Manstein (2001).

refraction ($n_3 \sin\theta_3 = n_1 \sin\theta_1$). By definition, at the critical angle $\theta_1 = 90°$, giving $n_3 \sin\theta_c = n_1(1)$, θ_c is thus expressed as

$$\theta_c = \sin^{-1}(n_1/n_3)$$

where n_1 and n_3 are the refractive indices of the liquid and solid, respectively. In the example with cells attached to glass, $\theta_c = 64.2°$ (if n_1~1.36). In reality, there is often a thin intermediate layer(s) such as the cellular plasma membrane (n_2), but for many purposes these can be disregarded as the effects are often nominal (Axelrod, 2003).

Although the TIR beam does not propagate into and through the low density medium (e.g., the cell interior), it does create an electromagnetic field in a thin zone in that region near the solid surface. This "evanescent field" decays exponentially in intensity with distance from the surface (z axis) and only fluorophores in the aqueous medium near the glass are excited, as illustrated in Fig. 2; this assumes that the coherent light beam acts as an "infinitely" extended plane wave, which is a fair approximation in most TIRFM setups. The intensity of the evanescent field, I, at various distances, z, from the coverslip and its penetration depth, d (defined as a decay of I_z to 1/e or ~37% intensity), can be expressed by the following equations:

$$I(z) = I(0)e^{-z/d} \quad \text{where} \quad d = \frac{\lambda_o}{4\pi}\left(n_3^2 \sin^2\theta_3 - n_1^2\right)^{-1/2}$$

Shallower penetration depths occur with large differences in refractive index of the two mediums, short wavelength light (λ_o), and steep angles of incident light. Practically, d can be as low as ~20 nm with exotic high refractive index materials, but ~50–200 nm is typical with common materials, wavelengths, and setups. It is worth noting that the emitted light can also experience near field effects, causing significant anisotropic deviations from a simple exponential curve; this deviation will vary depending on the NA of the objective lens and its location. For "objective-type" TIRFM setups, the field decays quicker, whereas it is slower in "prism-type" setups (these setups are described in detail later) (Axelrod, 2003; Steyer and Almers, 2001).

C. Advantages of TIRFM over Confocal Microscopes

A principal advantage of TIRFM is excellent signal to noise, achieved by limiting the illumination to a thin focal plane. High-contrast images can be imaged quickly with minimal photobleaching. In contrast, confocal laser scanning microscopes are slower and

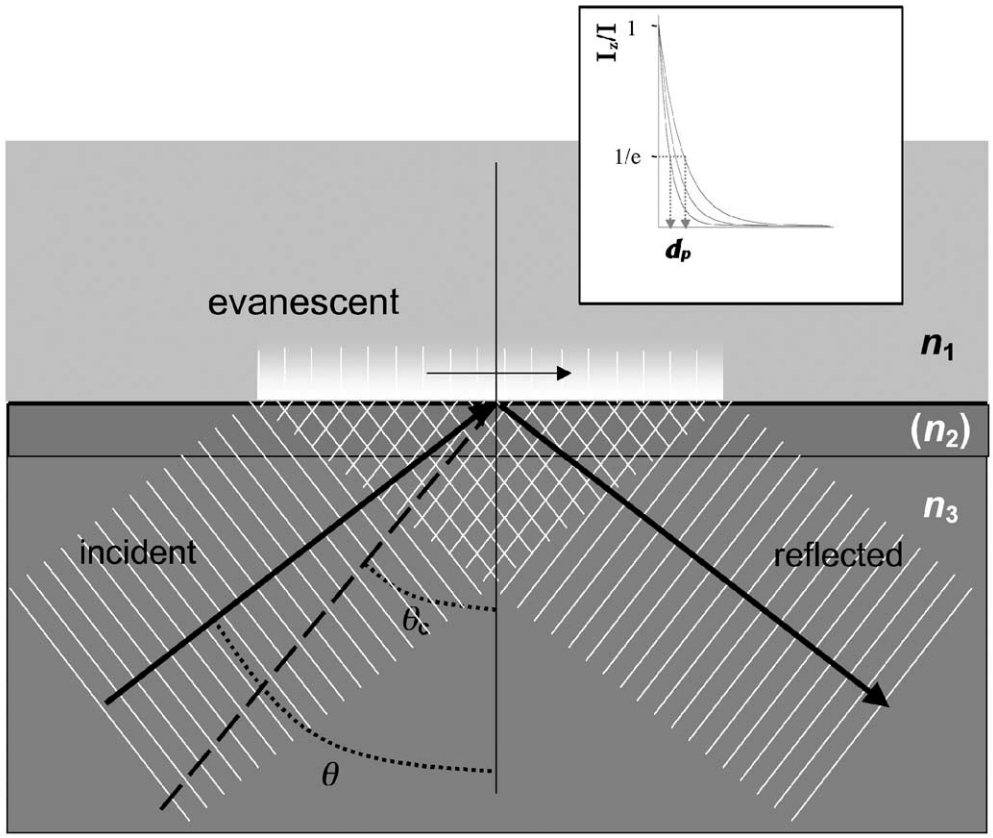

FIGURE 2 Geometrical scheme of TIR. Refractive index n_3 must be greater than n_1. The intermediate layer (consisting of metal or a dielectric material of refractive index n_2) is not necessary for TIR to occur, but can introduce useful optical properties. Most applications of TIRFM do not use an intermediate layer. The incidence angle θ must be larger than the critical angle θ_c for TIR to occur. The exponentially decaying evanescent field in the n_1 material is used to excite fluorophores. The inserted box shows examples of exponential decay curves of the intensity of the evanescence field at various penetration depths (d). Adapted from Axelrod (2003).

less sensitive, but can image the entire depth of the cell, one slice at a time (Table I).

II. MATERIALS AND INSTRUMENTATION

A. Illumination

In practice, most TIRFM systems employ lasers, which allow for an intense colliminated beam of light. Typically lasers that provide 10 s to 100 s of milliwatts per line(s) of interest are used. For imaging GFP proteins, an air-cooled argon laser (e.g., 100 mW, 488 nm, Melles Griot) or, alternatively, an optically pumped-diode laser (e.g., "Sapphire", 20–200 mW, 488 nm, Coherent) can be used; multicolor samples generally require stronger lasers to "pick" a weaker line or multiple lasers coupled with dichroic filters. In some configurations, mentioned later, an arc lamp may be feasible.

B. Light Path to the Microscope

The beam of laser light must be redirected to the microscope (prism or objective) and focused. Traditionally, an optical chain of mirrors and lens are employed, requiring an "optical table." An alternative is to couple the light into a single mode fiber optic, providing a more flexible configuration (the laser need not be on the optical table and the fiber can be positioned easily). The fiber is generally coupled to a focusing lens or TIR condenser. A set of XY[1] and possibly Z micro-

[1] For convention here, the Z axis is parallel to the laser and optical axis and XY is perpendicular to it.

TABLE I A Comparison of TIRFM and Confocal Microscopes

	TIRFM	Confocal microscope (laser scanning)
Illumination depth (*z* axis)	~50- to 100-nm penetration depth (1/e)	~500 nm
Detector	Cooled CCD or intensified camera	Photomultiplier tube
Quantum Efficiency of detector	~40–90%	~10–20%
Acquisition speed	Fast; can capture the image in milliseconds, depending on the camera and signal to noise	Slow; scanning a frame typically takes seconds
Contrast	Excellent: signal to noise is ~10–100× better than confocal or ~1000× better than wide-field microscopes	Moderate to good
Sensitivity	Single molecule capable	Hundreds of molecules
Bleaching	Low	Considerable
Cellular imaging	Cell surface only	Entire cell
Approximant cost	~$1–50 K+ for conversion of a wide-field fluorescent microscope, depending on the method used	~$300–500 K

TABLE II Comparison of Objective-Type and Prism-Type TIRFM Setups

	Objective type	Prism type
Illumination angle	Fixed or limited range	Variable
Access to top of sample?	Yes (inverted scope)	Limited (upright scope) None (inverted scope)
Objective lens	Oil immersion (1.4 NA, 1.45 NA, 1.65 NA[a])	Water immersion (~1.0–1.2 NA)
Light path for excitation and emission light	Same (coupled)	Separate (uncoupled)
Signal to noise	Very good; but some noise due to internal reflections of excitation light in the objective lens	Better; less background light
Commercial system?	Yes	No
Object brightness	Collected light varies approximately monotonically with distance[b]	Collected light varies nonmonotonic with distance[b]
XY resolution	Excellent (higher NA lens)	Good to very good

[a] Requires expensive coverslips and special immersion oil.
[b] See Axelrod (2003) and Steyer and Almers (2001).

manipulaters are used to control the angle and position of the beam (e.g., where it strikes the prism or the back focal plane of the objective).

C. TIRFM Optical Configurations

There are basically two kinds of TIRFM setups: an "objective type" (also called "prismless") and a "prism type." Both can be mounted in numerous configurations; for simplicity, a few common configurations are shown in Figs. 3 and 4. Both setups have advantages and disadvantages as outlined in Table II.

1. Objective-Type TIRFM

Principle

The recent development of very high NA objectives has made objective-type TIRFM feasible. The microscope can be configured in several variations by use of commercial accessories or straightforward modifications (e.g., Fig. 3). To achieve TIR, a beam of light, usually from a laser, is focused off-axis at the back focal plane (BFP) of the objective. The greater the off-axis radial position of the focus, the greater the angle of incidence θ_3 of the beam in the glass. The maximal angle of incidence, θ_m ($\geq\theta_3$), depends on the NA of the

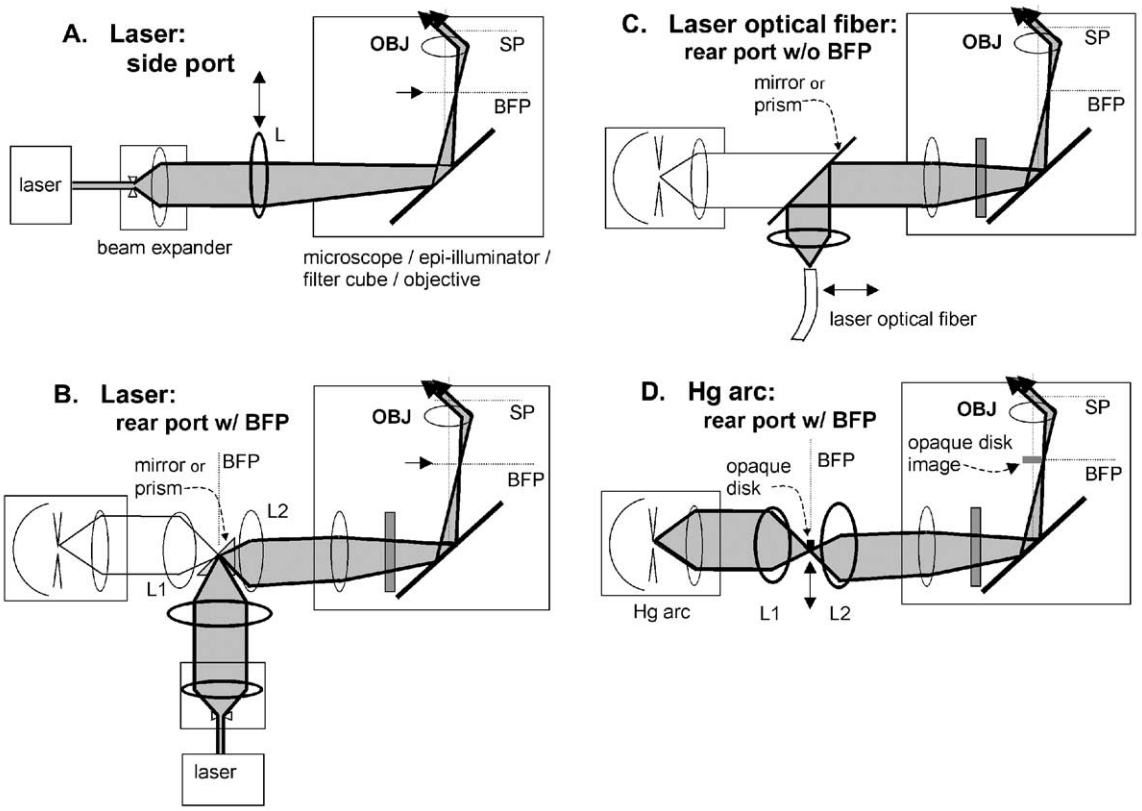

FIGURE 3 Four arrangements for objective-type (prismless) TIRFM in an inverted microscope. In all these configuration, OBJ refers to the objective, SP refers to sample plane, and BFP refers to the objective's back focal plane or its equivalent or "aperture" planes. Components drawn with heavier lines need to be installed; components in lighter lines possibly preexist in the standard microscope. (**A**) Laser illumination through a side port (requires a special dichroic mirror cube facing the side, available for the Olympus IX-70 microscope). The beam is focused at the back focal plane at a radial position sufficient to lead to supercritical angle propagation into the coverslip. Moving the focusing lens L transversely changes the angle of incidence at the sample and allows switching between subcritical (EPI) and supercritical (TIR) illumination. (**B**) Laser illumination in microscope systems containing an equivalent BFP in the rear path normally used by an arc lamp. The laser beam is focused at the BFP where the arc lamp would normally be imaged. The Zeiss Axiovert 200 provides this BFP, marked as an "aperture plane." If (as in the Olympus IX-70) an aperture plane does not exist in the indicated position, it can be created with the pair of lens L1 and L2. (**C**) Laser illumination introduced by an optical fiber through the rear port normally used by the arc lamp. This scheme is employed in the commercial Olympus TIR device. (**D**) Arc lamp TIR illumination with no laser at all. The goal is to produce a sharp-edged shadow image of an opaque circular disk at the objective back focal plane such that only supercritical light passes through the objective. The actual physical opaque disk (made ideally of aluminized coating on glass) must be positioned at an equivalent upbeam BFP, which, in Kohler illumination, also contains a real image of the arc. The Zeiss Axiovert 200 provides this BFP, marked as an "aperture plane." If (as in the Olympus IX-70) an aperture plane does not exist in the indicated position, it can be created with the pair of lens L1 and L2. Illumination at the back focal plane is a circular annulus; it is shown as a point on one side of the optical axis for pictorial clarity only. Adapted from Axelrod (2003).

objective (by definition NA = $n_{oil} \sin \theta_m$). Snell's law ($n_3 \sin \theta_3 = n_1 \sin \theta_1$) leads NA $\geq n_1 \sin \theta_1$. At the critical angle, θ_c, $\theta_1 = 90°$ and thus NA $\geq n_1$. In the cellular context, for TIR to occur, we must have NA $> n_{cytosol}$. For a 1.4 NA oil lens and $n_{cytosol} = 1.38$, only a very thin cone at the outer edge of the back focal plane of the objective barely (<3% of the aperture) allows TIR excitation. (Of course, the whole aperture is still used to gather emitted light.) Practically, TIR is easier to obtain with 1.45 and 1.65 NA objectives that allow θ_c to be surpassed more easily and TIR can occur in ~10 and 25% of the aperture, respectively.

An arc-lamp illumination system can also be configured for TIRFM illumination by use of an opaque

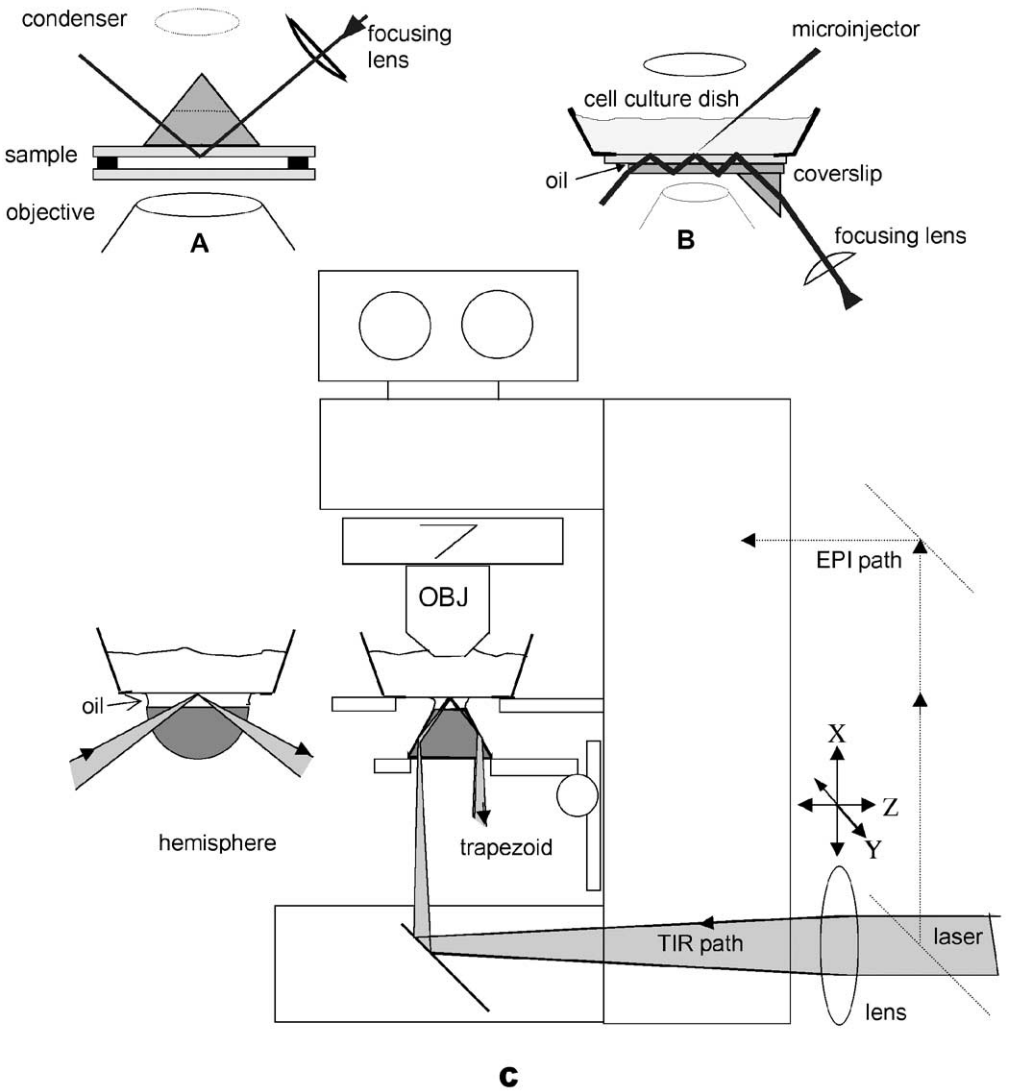

FIGURE 4 Schematic drawings for prism-based TIRFM using a laser as a light source. The vertical distances are exaggerated for clarity. (**A**) This configurations uses a TIR prism above the sample. The buffer-filled sample chamber sandwich consists of a lower bare glass coverslip, a spacer ring (made of 60 μm-thick Teflon or double-stick cellophane tape), and the cell coverslip inverted so the cells face down. The upper surface of the cell coverslip is put in optical contact with the prism lowered from above by a layer of immersion oil or glycerol. The lateral position of the prism is fixed but the sample can be translated while still maintaining optical contact. The lower coverslip can be oversized and the spacer can be cut with gaps so that solutions can be changed by capillary action with entrance and exit ports. (**B**) This configuration places the prism below the sample and depends on multiple internal reflections in the substrate, thus allowing complete access to the sample from above for solution changing and/or electrophysiology studies. However, only air or water immersion objectives may be used because oil at the lower surface of the substrate will thwart the internal reflections. (**C**) TIRFM on an upright microscope utilizing the integral optics in the microscope base and a trapezoidal prism on the vertically movable condenser mount. The position of the beam is adjustable by moving the external lens. An alternative hemispherical prism configuration for variable incidence angle is also indicated to the left. Vertical distances are exaggerated for clarity. An extra set of mirrors can be installed to deflect the beam into an epi-illumination light path (shown with dashed lines). Adapted from Axelrod (2003).

disk of the correct diameter inserted in an "upbeam" plane equivalent of the BFP of the objective (Fig. 3D). It is less expensive, gives freedom in the choice of excitation wavelengths, and avoids interference fringes, but it is considerably dimmer as much of the excitation light is necessarily blocked; this can be improved somewhat by employing a conical prism in the arc-lamp light path (Axelrod, 2003).

Materials

1. Microscope: usually inverted (this allows complete access to the cells). Objectives: high NA "TIRFM" objective(s), typically 1.45–1.65 NA, 60–100× magnification: currently available from Olympus, Zeiss, and Nikon (1.65 NA only from Olympus).
   a. 1.45 NA objectives use regular #1.5 coverslips (n = 1.52), possibly premounted in a 30-mm petri dish (e.g., Mattek, Ashland, MA).
   b. 1.65 NA objective requires "special" high refractive index oil (n = 1.78), really iodomethane, that is volatile and potentially toxic (Cargille, USA). Similarly, high refractive index coverslips are needed, e.g. n = 1.78 coverslips made of LAFN21 glass (Olympus) or SF11 glass (custom cut by VA Optical Co, San Anselmo, CA). Unfortunately, such coverslips are expensive (>$20/coverslip), fragile, and practically are only reusable a few times. It is, however, a good choice when a thin d is needed.
2. Filters: dichroic filters and emission filters appropriate for the laser line(s): These must block scattered light from the laser and generally require high band-pass filters (e.g., Chroma Corp., USA).
3. *Optional*: commercial objective-type TIRFM condensers are available from Till Photonics, Olympus, Zeiss, and Nikon for mounting to their respective microscopes. Generally lasers are coupled into them via a fiber optic.

Configuration

1. Focus the laser beam (using an external focusing lens) to a point on the BFP of a high NA objective (1.45–1.65 NA) so that it emerges from the objective as a collimated "beam" of light, (*Caution: Use safety glasses*.)
2. Using XY micromanipulators adjust the point of focus radially off-axis in the BFP so as to achieve TIR (see protocol later). There is a one-to-one correspondence between the off-axis radial distance ρ and the angle θ. At a sufficiently high ρ, the critical angle for TIR can be exceeded; further increases in ρ reduce the penetration depth, d.

2. Prism-Type TIRFM

Principle

Some typical TIRFM setups are shown in Fig. 4. Note that TIR illumination of cells is achieved on the coverslip side with the aid of an optically coupled prism, whereas emitted light is detected with a conventional water-immersion lens on the opposite side. This restricts access to the sample, but allows for TIR to be achieved over a greater range of angles and hence greater flexibility in d.

Materials

1. Microscope (upright will provide some access to sample)
2. ~1.0–1.25 NA water immersion objective (~20×–60×). If access to the sample is desired, a long working distance "dip-in" objective may be best.
3. Prism: triangular, trapezoidal, or hemispherical, depending on the setup. Equilateral prisms made from flint glass (n = 1.648) are available commercially (Rolyn Optics, USA) and will provide a sufficiently high n for TIR to occur at the aqueous interface. A hemispherical prism (e.g., quartz) allows for variable incidence angles over a continuous range but requires external optical elements (vertical optical rail with XYZ translators).
4. A mount for holding and positioning (XY) the prism (see Fig. 4)
5. Dichroic filters and emission filters appropriate for the laser line(s): These must block the scattered or propagating laser light (usually less than in "objective-type" setups)
6. Cells are usually grown on disposable glass coverslips/slides, but more exotic high n_3 materials such as sapphire, titanium dioxide, and strontium titanate (with n as high as 2.4) can yield exponential decay depths d as low as $\lambda_o/20$.
7. Optical coupling of prism to coverslip/slide: This may be optically coupled with glycerol, cyclohexanol, or microscope immersion oil, among other liquids, and need not exactly match in refractive index.

Configuration

Figures 4A and 4B show representative schematic drawings for setting up prism-based TIR in an inverted microscope. Figure 4C shows a convenient low-cost prism-based TIRFM setup for an upright microscope. Specifically, the laser beam is introduced in the same port in the microscope base as intended for the transmitted light illuminator (which should be removed), thereby utilizing the microscope's own in-

base optics to direct the beam vertically upward. The prism, in the shape of a trapezoid, is mounted on the microscope's condenser mount, in optical contact (through a layer of immersion oil) with the underside of the glass coverslip. An extra lens, just upbeam from the microscope base, allows the incident beam to be adjusted to totally reflect off one of the sloping sides of the prism, from which the beam continues up at an angle toward the cells grown on the coverslip where it is weakly focused.

In all the prism-based methods, the TIRF spot should be focused to a width no larger than the field of view and θ should exceed θ_c by at least a couple of degrees. At incidence angles very near θ_c, the cells cast a noticeable "shadow" along the surface.

C. Camera

A good cooled CCD camera should be adequate for most TIRFM imaging of cells. For instance, current "extended range" (ER) front-illuminated CCD cameras have quantum efficiencies up to ~65% (available from Hamamatsu, PCO, Roper, etc.). Back-thinned cameras are more sensitive but generally slower and more expensive. Intensified or electron multiplying (EM) CCD cameras are typically used for rapid single molecule imaging (Pierce, 1999).

D. Accessories

Cells grown on coverslips are placed in cell imaging chamber (e.g., Mattek dishes with glued in coverslip). Focus drift along the *z* axis can be problematic, especially when heating cells to 37°C, as even minor drifts are very noticeable in TIRFM. To minimize drift, an environmental chamber or heated "plexiglass" box is helpful. A number of commercial based ones are available; however, this can also be homebuilt for much less using a "Air-therm" (World Precision Instruments; England) or similar hot-air blower and a self-built box. Another solution is to use an active autofocusing device connected to a piezoelectric device.

III. PROCEDURES

Caution! *The use of lasers should be considered potentially hazardous to the eyes and proper laser safety should be followed. Precautions include (but not limited to) using appropriate laser safety glasses/goggles, attenuating the laser power while making adjustments, never looking directly into the beam or its reflections, and not looking into the eyepiece unless adequate dichroic and emission filters are in place (and even then use extreme caution). Indirect imaging of the beam and sample image can be accomplished with CCD cameras and is much safer.*

A. Objective-Type TIRFM Setup: A Practical Protocol

This description is for the setup in Figs. 3A–3C, but is similar for other configurations.

1. Prepare a test sample consisting of a film of fluorescent lipid adsorbed to the coverslip. Dissolve dioctadecylindocarbocyanine ("diI"; Molecular Probes) in ethanol at ~0.5 mg/ml, place a droplet on the coverslip, and rinse with distilled water before it dries and a diI monolayer will remain on the coverslip. When excited at 488 nm and observed with a fluorescein dichroic and "long-pass" emission filter, the diI will appear orange. Add an aqueous dilute fluorescein solution (faint yellow) to the sample chamber, which will emit in green. Alternatively, add an aqueous suspension of fluorescent microbeads (~100 nm diameter, 488 nm, Molecular Probes, USA). Some of the beads will adhere to the surface, whereas bulk suspended beads will jitter with Brownian motion.

2. Carefully place a drop of immersion oil on the objective lens, set the sample on the microscope stage, and slowly raise the objective to establish optical contact.

3. Remove the excitation filter from the filter cube if it were present for arc illumination, leaving only the appropriate dichroic and emission filters, or instead use a laser "clean-up" excitation filter (e.g., laser line wavelength ± ~10 nm; Chroma).

4. Remove all obstructions between the test sample and the ceiling. Allow a collimated "raw" laser beam to enter the side or rear epi-illumination port along the optical axis. A large area of laser illumination should be seen on the ceiling, roughly straight up. *(Make sure to keep your eyes out of the laser beam path! Ideally use laser safety glasses.)*

5. Place a focusing lens (~100 mm focal length plano- or double-convex lens mounted on a XY microtranslator) at a position ~about 20 cm "upbeam" from where the beam enters the microscope illumination port. The illuminated region on the ceiling will now be a different size, probably smaller.

6. Move the focusing lens longitudinally (along the *z* axis) to minimize the illuminated region on the ceiling. This will occur where the converging lens focal point falls exactly at the objective's back focal plane. At this position, the beam is thereby also focused at the

objective's actual back focal plane and emerges from the objective in a roughly collimated form.

7. Fine tune the lateral position of the focusing lens so that (as you face the microscope) the beam spot on the ceiling moves down a wall to the right or left. The inclined path of the beam through the fluorescent aqueous medium in the sample will be obvious to the eye. Continue to adjust the focusing lens lateral position until the beam traverses almost horizontally through the fluorescent medium and then farther, past where it just disappears. The beam is now totally reflecting at the substrate/aqueous interface.

8. Carefully view the sample through the microscope eyepieces (or with a color CCD camera). The diI/fluorescein sample should appear orange, not green, as only the surface is being excited; the beads should look like high contrast immobilized dots, occasionally some will "blink" as they diffuse into and out of the evanescent field. Back off the focusing lens to where the beam reappears in the sample (i.e., subcritical incidence). When viewed through the eyepieces, the diI/fluorescein sample should now appear very bright green or beads will have lots of background as they jiggle through multiple focal planes and emit out-of-focus light.

9. If the illuminated region in the field of view is not centered, adjust the lateral position of the "raw" laser beam before it enters the focusing lens and repeat Steps 7 and 8. If the illuminated region thereby approaches the center, continue to readjust the raw beam in the same direction and repeat the steps until centering is achieved. If the illuminated region moves even farther to the side, then adjust the raw beam in the opposite direction and repeat the steps. The final position will be a laser beam entering the focusing lens parallel to its optical axis but somewhat off center.

10. If the illuminated region is too small, increase the width of the beam before it enters the focusing lens with a beam expander or long focal length diverging lens. At best, about two-thirds of the whole field of view can be illuminated by TIR (which includes the entire central region typically viewed by a CCD camera).

11. Replace the test sample with the sample of interest and focus the microscope. As the lateral position of the external focusing lens is adjusted through the critical angle position, the onset of TIR fluoresence should be obvious as a sudden darkening of the background and a flat two-dimensional look to the features near the surface. Importantly the entire field of view has only one plane of focus. A good control is to take one image by TIR and then, without adjusting the focus, take another fluorescent image by conventional epi-illumination (see Fig. 1). For most cellular objects, these two images, when overlaid, should look very different. As one's experience increases, the test sample can be skipped and all the adjustments made directly on the actual sample of interest (although this can be tricky if, say, there are only a few transfected GFP cells that one must "hunt" down).

B. Prism-Type TIRFM Practical Protocol

This description is for the setup in Fig. 4C, but is basically similar for other configurations.

1. Mount the prism on the condenser mount carrier, if possible. Alternatively, the prism holder can be fixed directly to the optical table or microscope.

2. Depending on the configuration, a system of mirrors with adjustable angle mounts fixed to the table must be used to direct the beam toward the prism.

3. Place a test sample (e.g., a diI-coated coverslip and fluorescein or bead solution; see earlier) in the same kind of sample holder as to be used for real cell-based experiments.

4. With the test sample on the stage, focus on the fluorescent surface with bright-field or fluorescent epi-illumination. Usually, dust and defects can be seen well enough to find the focal plane by the coverslip/medium interface.

5. Place a small droplet of immersion oil directly on the prism and carefully translate the prism vertically so it touches and spreads the oil, but does not inhibit lateral sliding; too much oil may interfere with the illumination path.

6. Rough adjustments: Using safety goggles to attenuate errant reflections and without the focusing lens in place, adjust the "raw" collimated laser beam position with the mirrors so that TIR occurs directly in line with the objective's optical axis, as seen from the scatter of the laser light as it traverses through the prism, oil, and TIR surface.

7. Insert the focusing lens so that the focus is roughly at the TIR area under observation. By eye, using XY translators on the focusing lens, adjust its lateral position so that the TIR region occurs directly in line with the objective. Look for three closely aligned spots of scattered light, corresponding to where the focused beam first crosses the immersion oil layer, where it totally reflects off the sample surface, and where it exits and recrosses the oil.

8. Fine adjustments: The yellow-orange TIR elliptical region should now be in view but not centered. Make final adjustments with the focusing lens (XY) to center this area and move it along the z axis to achieve the desired size. TIR can be distinguished from two out-of-focus blurs past either end of the ellipse. The

TIR spot contains sharply focused images of defects in the diI coating or sharp dots of adsorbed beads and flashes as diffusing beads drift into the evanescent wave; as a negative control the green-emitting fluorescein is hardly seen.

9. With the optics now aligned correctly for TIR, lower the prism vertically to remove the diI sample and replace it with the actual cell sample. Raise the prism to make optical contact. Although the TIR region will be slightly off, it will be close enough to make final adjustments while observing fluorescent cells.

IV. COMMENTS

1. A "homebuilt" TIRFM system can be ideal in terms of flexibility and cost; however, commercial "turn-key" systems may be quicker or easier to implement.

2. Even "thick cells" can be imaged by TIRFM, but one will only "see" where the cell contacts the coverslip. In theory, it is sometimes possible to image deeper in the cell if there is a big refractive index difference of organelles/membranes, but in practice this is rarely implemented. Also, if the penetration is too deep (e.g., past 150 nm), higher refractive index organelles such as granules can scatter the TIR light, producing artifacts.

3. TIRFM is different from the nonfluorescent technique called "reflection internal microscopy" (RIM or also IRM) that uses bright-field illumination to visualise cell–substrate contacts.

V. PITFALLS

A common problem is adjusting the system so that a homogeneous evanescent field is achieved. If alignment on a single mode fiber is off, output light may give a speckled appearance from hitting the cladding and will require realignment. Laser illumination can produce interference fringes, manifested as intensity variations over the sample area. In this case, it may be advisable to scramble the light (e.g., in a commercially optical fiber phase scrambler).

CHAPTER

3

Band Limit and Appropriate Sampling in Microscopy

Rainer Heintzmann

I. INTRODUCTION

A. What Is "Sampling?"

In microscope images obtained with the help of electronic devices (e.g., CCD camera) or in a scanning microscope system, data are usually obtained (sampled) at equidistant coordinates in object space. The distance between these measurement positions is usually denoted as the "sampling distance." Current technology samples on orthogonal coordinates (rectilinear sampling) with appropriate sampling distances along the in-plane coordinates X, Y and the axial coordinate Z (for three-dimensional imaging).

For a deeper understanding of how to choose these distances correctly, it is useful to assume the intensity distribution near the detector (translated back to sample coordinates) to be a continuous function (Fig. 1). The equidistant sampling coordinates, at which the values of the image function are recorded, are depicted as dashed lines in Fig. 1. The fact that pixels have a discrete physical size is not considered here to keep the discussion simple. This pixel-size effect is described by a convolution and can be considered as a multiplicative modification of the optical transfer function (Sheppard *et al.*, 1995). In the considerations given in this article, noise resulting from photons and/or the detector system is neglected.

B. Spatial Frequencies

Any physical function (e.g., as shown in Fig. 1) can be decomposed into a sum of sine waves, each with a different frequency, amplitude, and zero position (so-called phase). To exactly represent a function, this sum generally contains an infinite amount of components. Such decomposition is useful especially in optics, as images of (linear) optical systems have the interesting property of only transmitting sine waves of the sample up to a fixed limiting frequency. A periodic fluorescence distribution with a count of maxima per µm above this limit frequency will appear as a uniform constant in the image. Such systems are often called "band-limited" systems, as only a compact, limited band of frequencies (from zero to the maximal transmittable frequency) is transferred. How well a defined frequency is transferred is depicted in the "optical transfer function (OTF)" as outlined in Fig. 2 for in-plane imaging in a fluorescence wide-field microscope.

The "spatial frequency" given on the X axis of this graph denotes the number of maxima per meter for each sine wave. The sum of all sine waves yields the perfect image. The transfer strength of the OTF (Y axis) denotes how well a sample consisting of only one spatial frequency (one such sine wave) would be transferred to the detector.

C. Band Limit of Optical Systems

1. Fluorescence Microscopy

When considering the sampling properties of microscopic imaging, a physical model (Young, 1985) of the microscope system has to be constructed. Due to the laws of physics, this OTF is zero beyond a well-defined limiting frequency (see Appendix or Sheppard *et al.*, 1994). In the case of wide-field fluorescence microscopy, the limiting frequency is as follows:

$$k_{xy,\max} = \frac{2NA}{\lambda_{\mathrm{em}}},$$

with $k_{xy,\max}$ denoting the maximal in-plane spatial frequency, λ_{em} the shortest detected vacuum wavelength

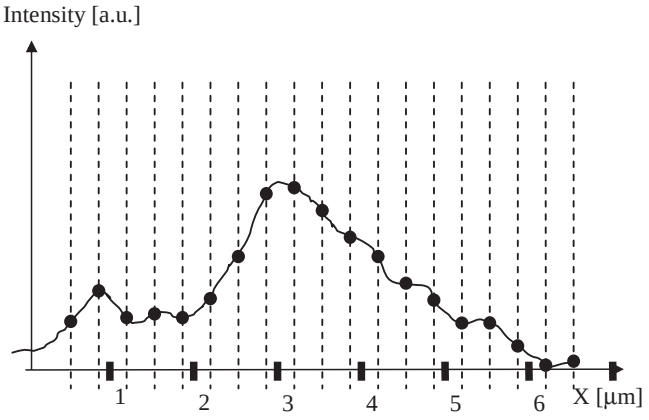

FIGURE 1 Diagram of a microscope image as a continuous function over space (here indicated as the *X* coordinate). Dashed lines indicate the points at which the function is sampled (its value is recorded).

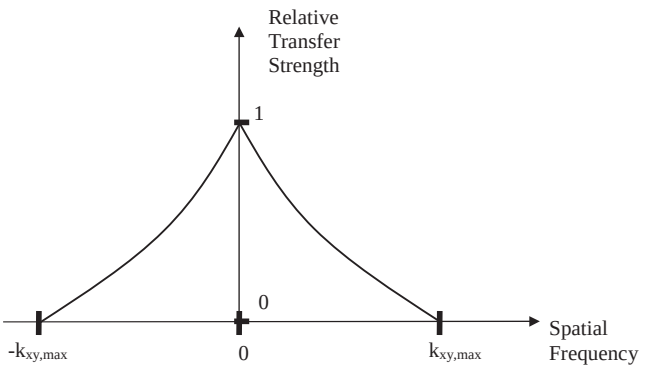

FIGURE 2 The approximate shape of the in-plane optical transfer function of a fluorescence wide-field microscope. For spatial frequencies above the limiting frequency ($k_{xy,max}$), no information can be transferred from the object to the microscope image.

of the fluorescence emission light, and $NA = n\sin(\alpha)$ the numerical aperture defined by the refractive index n of the medium immersing the sample and the objective detecting light at an aperture half-angle of α.

Similarly, a limiting maximal transmittable axial spatial frequency $k_{z,max}$ can be given for sine waves with Z components as:

$$k_{z,\max} = \frac{NA}{\lambda_{em}} \frac{[1-\cos(\alpha)]}{\sin(\alpha)}.$$

In confocal fluorescence microscopy, the illumination is confined to a diffraction-limited spot. At very small pinhole size, detection is also diffraction limited. A fluorophore needs to be excited and detected by the system, leading to a multiplicative process of excitation and detection. As a result, the aforementioned

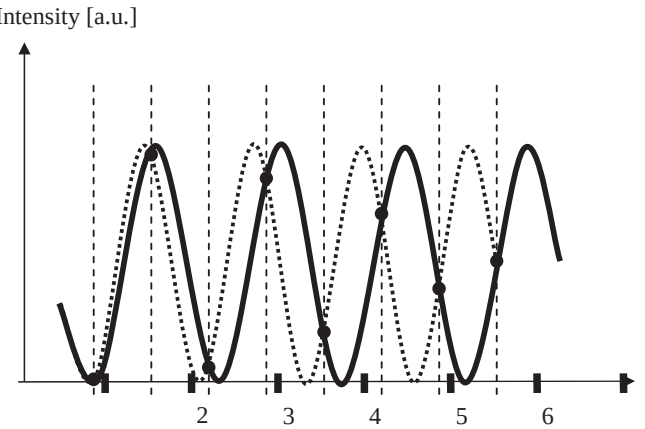

FIGURE 3 Aliasing. Two sine waves with different spatial frequencies yield identical sampled values. A distinction based on the measured values is only possible when the dashed alternative wave can be excluded, as its frequency lies above the transfer limit. This gives rise to the Nyquist theorem stating that the maximal possible frequency in the image has to be sampled with more than two positions per wavelength.

frequency limits have to be extended for the case of confocal fluorescence microscopy (see Appendix for details).

It should be noted that for larger pinhole sizes (>0.3 Airy discs, definition see Section III,B), the in-plane transfer function reaches values very close to zero above the spatial frequency stated by the wide-field limit. This explains why the in-plane resolution of confocal images achievable in practice is rarely substantially superior to wide-field images.

2. *Aliasing*

Because the images can be decomposed into the sine waves, it is useful to consider how an individual sine wave is sampled by the equidistant measurements. Figure 3 shows such a sine wave (solid black line) along with its values marked at equidistant sampling positions. Does such a measurement determine the frequency of the measured sine wave uniquely? As evident from Fig. 3 (dotted line), this is not the case, as multiple sine waves (these are called aliases) could possibly give the same measured values. However, if it is known that a maximal transmittable frequency exists, frequencies of sine waves in the image beyond that limit can be excluded as possible sources for this measurement. To guarantee a unique interpretation of a given measurement, all that needs to be done is to ensure all aliasing frequencies lie beyond the *a priori* known transmittable frequency limit.

In an acquired image, multiple frequencies are measured simultaneously, and the aforementioned

should be true for all spatial frequencies possibly present in the image. The highest frequencies in the image (just below the frequency limit, e.g., $k_{img} < k_{max} = 5\,\mu m^{-1}$) turn out to be most critical, as their lowest frequency alias ($k_{alias} = k_s - k_{img}$, e.g., at $k_s = 11\,\mu m^{-1}$, k_{alias} is $6\,\mu m^{-1}$) appears at lower frequencies than aliases of other lower frequency image contributions. If the image is sampled at least at twice its highest contained spatial frequency ($k_s > 2k_{img}$), aliasing can be avoided, as interpretation of the sampled values is unique because k_{alias} is above the limiting frequency k_{max}. In other words, the sampling frequency ($k_s = 1/D$), as defined by the sampling distance D, has to exceed the maximal transmittable frequency by a factor of two ($k_s > k_{Nq} = 2k_{max}$). This limiting sampling frequency k_{Nq} is called the Nyquist frequency.

This means that all values of the continuous band-limited function in between the sampled values can theoretically be predicted solely based on the knowledge of the band limit of the system and the sampled values (assuming an infinite amount of them and not considering noise). Sampling denser than this requirement stated earlier is termed oversampling; sampling sparser than the limit is termed undersampling.

II. INSTRUMENTATION

Selection of the appropriate sampling distances is crucial for almost all optical systems with computerized image acquisition. In the field of optical microscopy, one has to discriminate among *fluorescence-*, *transmission-*, and *reflection-based* systems.

III. PROCEDURES

In the procedures suggested here, equations are stated for different microscopy arrangements. They are derived from Fourier theory in the Appendix.

A. CCD-Based Imaging Systems (in Plane)

Many imaging systems do not allow for any direct control over the size of the detector bins. CCD camera-based systems and digitizing micrographs on a scanner fall in this category. To select the appropriate sampling distance:

1. Obtain the pixel pitch (P) of your CCD camera from the manufacturer/supplier. The pixel pitch is the distance in X and Y directions between successive pixels. Usually this is in the range of 5 to 20 µm. When binning is used during image acquisition, the pixel pitch has to be multiplied with the binning factor (e.g., with 2×2 binning: multiply the pixel pitch by 2). When digitizing micrographs, a corresponding value is given by either the pixel-to-pixel distance after scanning or the resolution of the micrograph, whichever value is bigger. When a micrograph is scanned, care has to be taken to account for all magnification factors to finally obtain a pixel size corresponding to the image plane.

2. Make a list of available objectives. Note magnification (e.g., 40 or 63×) and numerical aperture (e.g., 0.9 or 1.3) for each of them. These values are usually engraved on the side of the objectives. If any post-magnification system (e.g., Zeiss Optovar) is available on your microscope, multiply the objective magnification with the appropriate factor. The obtained total magnification is called M.

3. Calculate the in-plane sampling distance (D_{xy}) as dictated by the detector pixel pitch in the object plane for each objective, dividing the pixel pitch by the magnification:

$$D_{xy} = \frac{P}{M}$$

4. Calculate the maximum sampling distance (d_{max}) in the object plane from the numerical aperture of the objective and the vacuum wavelength of light used for imaging:

Wide-field fluorescence: $$d_{xy,\max} = \frac{\lambda_{em}}{4NA_{obj}}$$

Transmission or phase microscopy:

$$d_{xy,\max} = \frac{\lambda}{2\left(NA_{obj} + NA_{cond}\right)}$$

In wide-field illumination microscopy systems, λ_{em} should be the shortest detected emission wavelength (e.g., FITC $\lambda_{em} = 500$ nm); in transmission microscopy, the shortest transmitted wavelength should be used (e.g., blue at $\lambda = 400$ nm). Note that the numerical aperture of the condensor (NA_{cond}) contributes equally as the objective numerical aperture to the final resolution, although the contrast may suffer in transmission microscopy with a high condensor numerical aperture. Also note that the value NA_{cond} is taken for a fully open condensor aperture; a closed condensor aperture enhances the contrast but reduces NA_{cond} and thus the resolution.

5. Ensure that $D_{xy} < d_{xy,max}$ by selecting the appropriate objective and/or postmagnification optics from the list.

CCD Example

Let's say the pixel pitch of your camera is 7 µm and you are using no binning. The question is whether using a 100×, 1.3 NA oil ($n = 1.516$) immersion objective with the standard microscope tube lens (i.e., $M = 100$), the sampling distance in the focal plane corresponding to $D_{xy} = \frac{7\mu m}{100} = 70\ nm$ satisfies the Nyquist limit. The maximum sampling distance for wide-field fluorescence microscopy (e.g., detecting FITC at 500 nm shortest detection wavelength) is $d_{xy,\max} = \frac{500\ nm}{4 \cdot 1.3} \approx 96.15\ nm > 70\ nm$, thus your system respects the Nyquist limit. A 2 × 2 binning on the CCD, however, would undersample the image.

B. Confocal Systems (in Plane)

Confocal microscopy usually allows for free control over the sampling distance in the object plane by selecting an appropriate magnification ("zoom") and image size in pixels. A notable exception to this is a Nipkov-type disc-scanning system employing a CCD camera. For such systems, the maximum sampling distances ($d_{xy,\max}$ and $d_{z,\max}$) corresponding to a confocal system have to be selected, although the protocol for the CCD camera should be followed.

1. Calculate the maximum sampling distance (Sheppard, 1989; Wilson, 1990; Sheppard *et al*., 1994) from the parameters of the objective (see CCD procedure for definitions):

Confocal fluorescence (small pinhole):

$$d_{xy,\max} = \frac{\lambda_{eff}}{4NA_{obj}},\ \lambda_{eff} = \frac{1}{\frac{1}{\lambda_{ex}} + \frac{1}{\lambda_{em}}}$$

Confocal fluorescence (large pinhole):

$$d_{xy,\max} = \frac{\lambda_{eff}}{4NA_{obj}}$$

Confocal two-photon fluorescence (no pinhole):

$$d_{xy,\max} = \frac{\lambda_{ex}}{8NA_{obj}},$$

with λ_{ex} being the irradiating wavelength (usually in the infrared).

Confocal reflection: $d_{xy,\max} = \frac{\lambda}{4NA_{obj}}$

The strict theoretical limit even for large pinholes is the value given for small pinhole size. However, because the lateral high-frequency content for larger pinholes is negligible and usually lies well below the noise level, the "wide-field fluorescence" in-plane equation (as given earlier) can be applied, replacing the emission wavelength with the excitation wavelength. As a rule of thumb, consider pinhole sizes below 0.5 Airy discs in the pinhole plane as being small and sizes above 1.5 Airy discs as being large. In object space coordinates one Airy disc diameter (the first dark ring of a diffraction limited spot, assuming low *NA*) is

$$1.22\frac{\lambda_{em}}{NA_{obj}}.$$

To compare with actual pinhole sizes, the pinhole has to be translated to the object space coordinates by the appropriate demagnification factor, if the pinhole size is not stated in Airy disc units in the microscope operating software.

2. For beam-scanning or object-scanning confocal systems, the in-plane sampling distance (D_{xy}) is usually stated somewhere on the screen. It can also be calculated from the image size in the object plane (S_{img}) and the number of pixels (N_{pix}) along *X* or *Y*: $D_{xy} = \frac{S_{img}}{N_{pix} - 1}$.

This distance should be selected to be below the $d_{xy,\max}$ calculated earlier.

Confocal Example

With the microscope parameters as stated in the wide-field example in Section III,A, confocal microscope illuminating at 488 nm

$$\left(\lambda_{eff} = \frac{1}{\frac{1}{488\ nm} + \frac{1}{500\ nm}} \approx 247.0\ nm \right),$$

with a small detection pinhole setting, would allow a maximum in-plane sampling distance of

$$d_{xy,\max} \approx \frac{247\ nm}{4 \cdot 1.3} = 47.5\ nm$$

and the pixel-to-pixel spacing D_{xy} should be adjusted to a smaller value. For large pinholes, the following sampling distance should be acceptable:

$$d_{xy,\max} = \frac{488\ nm}{4 \cdot 1.3} \approx 93.8\ nm.$$

C. Focus Series

For the acquisition of focus series (Z stacks), an additional sampling limit along the axial direction also needs to be obeyed by choosing an appropriate distance between neighboring image planes. To calculate the corresponding maximum plane-to-plane distance ($d_{z,\max}$), the aperture half-angle of the objective (α_{obj}) has to be known. Because this value is often not stated, it has to be calculated from the numerical aperture and the refractive index (n) of the immersion medium:

1. Calculate the aperture half-angle of the objective as

$$\alpha_{obj} = \arcsin\left(\frac{NA}{n}\right).$$

   Approximate values for the refractive index are stated in Table I.
2. Once the aperture half-angle is known, the maximum plane-to-plane distance is calculated as

Wide-field fluorescence:

$$d_{z,\max} = \frac{\lambda_{em}}{2NA_{obj}} \frac{\sin(\alpha_{obj})}{(1-\cos(\alpha_{obj}))}$$

Transmission or phase microscopy:

$$d_{z,\max} = \frac{\lambda}{2NA_{\max}} \frac{\sin(\alpha_{\max})}{(1-\cos(\alpha_{\max}))}$$

Confocal fluorescence:

$$d_{z,\max} = \frac{\lambda_{eff}}{2NA_{obj}} \frac{\sin(\alpha_{obj})}{(1-\cos(\alpha_{obj}))}, \lambda_{eff} = \frac{1}{\frac{1}{\lambda_{ex}} + \frac{1}{\lambda_{em}}}$$

Confocal two-photon fluorescence:

$$d_{z,\max} = \frac{\lambda_{ex}}{4NA_{obj}} \frac{\sin(\alpha_{obj})}{(1-\cos(\alpha_{obj}))},$$

   with λ_{ex} being the irradiating wavelength (usually in the infrared).

Reflection confocal: $d_{z,\max} = \frac{\lambda}{4n}$

TABLE I List of Refractive Indices

Medium	Refractive index n
Air or vacuum	1
Water	1.33
Oil	1.516
Glycerin (100%)	1.47

   For transmission or phase microscopy, $NA_{\max}$ and $\alpha_{\max}$ denote the corresponding values of the greater of the condensor and objective numerical aperture.
3. Ensure that the distance between successive image planes (D_z) in object coordinates is below $d_{z,\max}$.

Focus Series Examples

For the parameters of the wide-field fluorescence example just given, the appropriate spacing between successive image planes should be chosen to be below

$$d_{z,\max} \approx \frac{500\,nm}{2 \cdot 1.3} \frac{\sin(59°)}{(1-\cos(59°))} \approx 339.6\,nm$$

with the aperture half angle being estimated from the NA (1.3) and the refraction index of oil (n = 1.516):

$$\alpha_{obj} = \arcsin\left(\frac{1.3}{1.516}\right) \approx 59.0°$$

Accordingly, the maximum spacing for confocal fluorescence microscopy (parameters as given in Section III,B) is calculated as

$$d_{z,\max} \approx \frac{247\,nm}{2 \cdot 1.3} \frac{\sin(59°)}{(1-\cos(59°))} \approx 167.8\,nm$$

IV. PITFALLS: CONTRAST AND SAMPLING

Suppose the object and its image consist of a sine wave with a single spatial frequency (e.g., 200 nm distance between two maxima). The sampling limit requires sampling at more than the double frequency (i.e., D_{xy} < 100 nm). If this image is sampled too close to the limiting frequency, there may be a problem. Depending on the exact position of the object, one may be fortunate enough to sample a maximum, then a minimum, a maximum again, and so on or, if unlucky, always sample half the maximum (see example in Fig. 4). In the latter case, the result would be indistinguishable from an object with zero frequency. Even when sampling at distances slightly below the required minimum distance, a very low contrast can result for images of small size. Therefore, one should oversample, such that at least one full period of the resulting envelope amplitude modulation is captured. In other words, with M pixels along a spatial direction, the stated maximum sampling distance should be lowered by multiplication with the factor $M/(M+1)$. For common image sizes (e.g., 512×512), this factor is negligible, but it can be substantial when acquiring only few Z sections (in which case M is the number of sections).

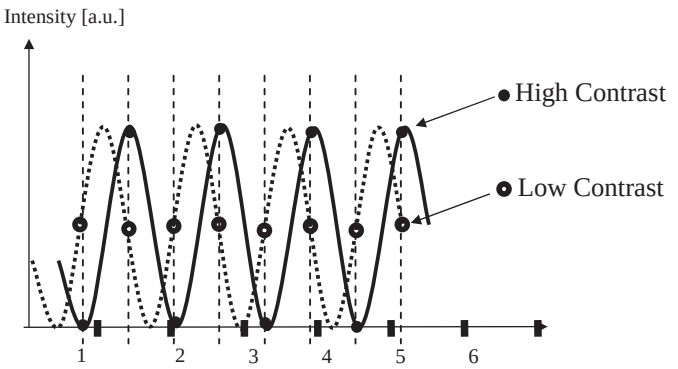

FIGURE 4 For images containing only a few measured values, the measured contrast can be dependent on the exact phase of the sine wave to perform measurements even when the Nyquist limit frequency is obeyed (compare the contrast of closed and open circles). To ensure that at least one full variation of contrast is recorded, oversampling is recommended, as it leads to a required sampling frequency enhanced by a factor of $(M + 1)/M$ with M measured sampled points.

A. When to Use Undersampling

For some applications the sampling limit does not need to be obeyed. If, for example, the task is to count homogeneously filled cells with a fluorescent dye using a 20×, 0.9 NA objective, it makes a lot of sense to seriously undersample the data. For a cell to be identified it might suffice to detect two adjacent bright pixels. Thus the required sampling can, in some cases, depend on the size of the object structure to image. Undersampling (e.g., by binning) can reduce the amount of acquired data (important in screening applications), reduce the readout noise, dark current, and sometimes enlarge the field of view. In the mentioned application the introduced aliasing effects should be tolerable.

In other applications (e.g., neuronal imaging of dendrites) it may be very tempting to undersample the data. However, thin structures (such as dendrites) may occasionally be lost in some pixels because they happen to lie between two sample points. Such missing gaps can then render a computer-based analysis difficult, as the structures appear ruptured and will also cause serious problems when successive computerized deconvolution is applied to data. In these cases it can even be better to reduce the numerical aperture of the objective than to seriously undersample at high *NA*.

B. When to Use Oversampling

For some gray value-based image processing tasks, oversampling is recommendable (Young, 1996, 1988; Verbeek, 1985; Verbeek and vanVliet, 1993); e.g., if the aim is the precise determination of object positions, one should oversample data by a factor of at least 1.5 (sample at a 1.5 times smaller pixel pitch as compared to the limits given earlier). Simulations revealed (Heintzmann, 1999) that determination of the center of mass can result in a significant systematical error even when sampled according to the stated sampling limits. Furthermore, a smaller sampling distance determines more precisely where each photon hits the detector, thus leading to a slightly more precise estimate of the particle position (Heintzmann, 1999). Oversampling can also be useful when successive deconvolution of data is planned (see below). Note that with oversampling, the photon dose delivered to the sample can still be kept constant. Acquired images may look inferior at a first glance, but they still contain all the necessary information. Such data always allow for successive binning, resampling, and/or smoothing to enhance the visual appearance.

C. Deconvolution: Out-of-Band Reconstruction Possibilities

When the computerized deconvolution is applied to data, it is often useful to oversample data during data acquisition. The reason is that constrained deconvolution is capable of "guessing" high-frequency components in the object structure that have not been acquired. This is enabled by the use of prior knowledge about the object, e.g., its positivity or smoothness (Sementilli *et al.*, 1993). In principle, acquired data can be resampled, but this always involves loss of information about the photon statistics, or even interpolation errors can result. Although software might be able to reconstruct on a denser grid than raw data, there may be (depending on the algorithm) some resampling involved, which in turn can skew the statistics of the deconvolution procedure, thus leading to inferior results. As a rule of thumb, a two-fold oversampling (two times smaller sampling distances as compared to the given limits) should suffice even for advanced deconvolution software.

Appendix: Derivation of Cut-Off Frequencies

To obtain the equations given in the text, an expression for the cut-off spatial frequency was derived and the Nyquist theorem applied, calculating the maximum sampling distance as half the distance corresponding to this cut-off spatial frequency. Note that this derivation is valid for high NA vector theory.

Electric field components of a plane wave can be described by a single point in Fourier space. Its dis-

tance to the origin is proportional to the inverse wavelength. A lens forms its image by the constructive interference of converging parallel beams. It can thus be described by a "cap" (Gustafsson *et al*. 1995) in Fourier space (Fig. 5a).

For incoherent **fluorescence wide-field** imaging, the intensity in focus describing the point spread function (PSF) is obtained as the square of the absolute magnitude of the electric field distribution. Because the optical transfer function (OTF) is the Fourier transformation of the PSF, it can be obtained as an autocorrelation of Fig. 5a, which is identical to the convolution with itself mirrored at the origin in Fourier space. The resulting region of support is depicted in Fig. 5b. The corresponding distances are the reciprocal values, which have to be halved, yielding the respective maximum sampling distance in *XY* and *Z* directions.

In the case of confocal microscopy, photons have to be excited and detected. This leads to a multiplication of the probabilities of excitation PSF (corresponding to the OTF in Fig. 5b, but for λ_{ex}) and the emission PSF (corresponding to the OTF in Fig. 5b). In Fourier space, this translates to a convolution of Fig. 5b as depicted in Fig. 6, yielding the appropriate equations for the confocal closed pinhole case. The size and shape of the pinhole is described by a multiplicative modification of the detection OTF with the Fourier transformed pinhole. The two-photon (no detector pinhole) derivation follows in a similar fashion, as its PSF is the square of the excitation PSF, which can be described by autocorrelation of Fig. 5b for λ_{ex}.

When dealing with wide-field transmission, the situation is different. The image can no longer strictly be described as a convolution of the object with a point spread function. However, for incoherent imaging in transmission, such approximation still holds. Nevertheless it is preferable to think of this as a scattering problem. Neglecting multiple scattering, one can look for the scattering object vectors in Fourier space, which should be imaged by the system. Scattering theory states that the incoming wave vector plus the object vector yields the outgoing wave vector. Incoming and outgoing vectors are restricted by the Ewald sphere and the numerical aperture of the condensor and objective, respectively. As depicted in Fig. 7a the range of possible scattering vectors depends on both, the incoming light as defined by the numerical aperture of the condensor and the outgoing light as restricted by the objective.

The equation for confocal reflection microscopy is obtained by considering the possible scattering vectors when illuminating and detecting through the same objective (Fig. 7b).

Acknowledgments

B. Rieger, S. Höppner, E. Lemke, I. T. Young, and T. M. Jovin are thanked for their help in revising this manuscript and C. J. R. Sheppard for fruitful discussions on sampling.

CHAPTER

4

Optical Tweezers: Application to the Study of Motor Proteins

Walter Steffen, Alexandre Lewalle, and John Sleep

I. INTRODUCTION

Optical tweezers allow the study of interactions of single molecules of motor proteins with the track, actin or microtubules, on which they run. The mechanical properties of cellular motors can only be studied at the single molecule level, and for those that act in organised structures, notably muscle, study at this level avoids the complexity of interpreting the effect of large numbers of motors acting in parallel and asynchronously. This article concentrates primarily on the use of the "bead–actin–bead dumbbell" method (Finer *et al.*, 1994, Fig. 1) for studying actomyosin interactions, which necessitates the use of a dual-beam trap. This approach is particularly useful for nonprocessive actin-based motors, but many of the principles are equally applicable to processive actin and microtubule-based motors. Sheetz (1998) has edited a useful volume of articles on laser tweezers in biology.

II. MATERIALS AND INSTRUMENTATION

1. Optical table (~4 × 3 ft).
2. Research-quality inverted microscope with provision for epi-illumination, a xenon light source for bright-field imaging, and an objective >60× and ≥1.25 NA with good transmission properties at 1064 nm.
3. A high-quality piezo-controlled stage (e.g., Physik Instrumente P-528) and a piezo-controlled focussing device (e.g., Physik Instrumente P-723 or with superior capacitative position sensor P-725).
4. Nd : YAG laser ≥ 1 W.
5. Two 2-mm aperture electro-optic deflectors (EOD) (Leysop) with associated high-voltage amplifiers (Apex sells inexpensive high-voltage hybrid amplifiers).
6. Two CCD cameras and one intensified camera for fluorescence.
7. Dual-photodiode quadrant detector (QD) and associated electronics with a frequency response >10 kHz.
8. One computer with DAQ board for primary data acquisition and one with frame grabber for servo-controlled stage feedback. (A single computer might suffice for these two applications.) We use National Instruments DAQ boards and frame grabbers in association with Labview software.

III. OVERVIEW OF OPTICAL TWEEZERS

The standard single-beam gradient setup is capable of trapping small particles, e.g., 1-μm latex beads, of higher refractive index than the surrounding medium. The mode of operation has been explained in varying degrees of detail in many review articles, including the compilation by Sheetz (1998). Most modern microscopes use infinity-corrected optics and we will assume this to be the case in this article. To form a trap, a parallel beam must fill the back focal plane of the objective, i.e., be ~5 mm in diameter. Most of the common lasers used for trapping emit narrower beams than this, which necessitates the use of a beam-expanding telescope. This could be a proprietary item but in order to place all the optical components in their

Copyright 2006, Elsevier Science (USA).
All rights reserved.

correct positions, it is more convenient to use two separate lenses for this purpose (Figs. 2 and 4). Outside the beam-expanding telescope, it is the angle of the laser beam that controls the position of the trap, whereas within the beam-expanding telescope, i.e., between **L1** and **L2**, it is the lateral displacement of the beam. The mirror in Fig. 2 is in a plane that is conjugate to the back focal plane of the microscope so that the amount of light entering the objective is independent of the angle of the mirror. This mirror allows initial positioning of the trap at the beginning of the experiment. An electro-optic or acousto-optic deflector at or near this position allows rapid control of trap position.

IV. PRACTICAL DESIGN

An optical trap setup has to fulfill several other functions besides trapping. For actomyosin experiments, a bright-field image is required to visualise the beads for trapping and a video-rate fluorescence image is required for attaching the actin filaments to the beads, which necessitates an intensified CCD camera. The positions of the two beads of the dumbbell must be measured with a precision of ≤1 nm with a frequency of >10 kHz, which is achieved most readily by projecting a bright-field image of the beads onto two QDs. A xenon arc is a favourable light source for this purpose. If the position of the stage is to be servo controlled to overcome drift, a CCD camera with a field width of about 10 µm is also required. Figure 3 shows the various light paths.

An inverting microscope is generally preferred because it allows the majority of optical components to be close to the optical table and is generally more stable. Furthermore, beads floating in solution tend to fall towards the coverslip, the region useful for exploring myosin interactions. The trapping beam is introduced into the optical system via a dichroic mirror (**d1** in Figs. 3 and 4). The best location for this dichroic is

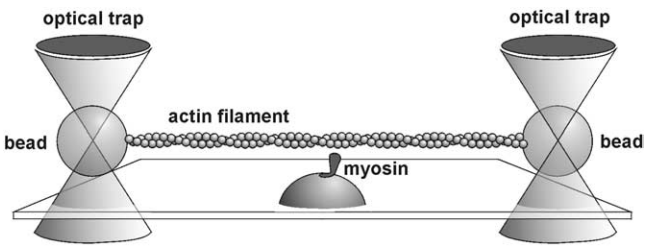

FIGURE 1 The dumbbell setup.

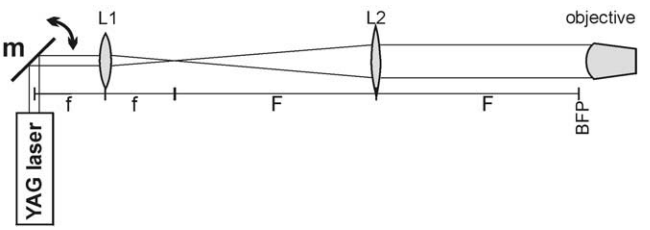

FIGURE 2 Basic optics of the trapping beam (**m** = **m3** in Fig. 3). Focal lengths are f and F and BFP is the back focal plane of the objective.

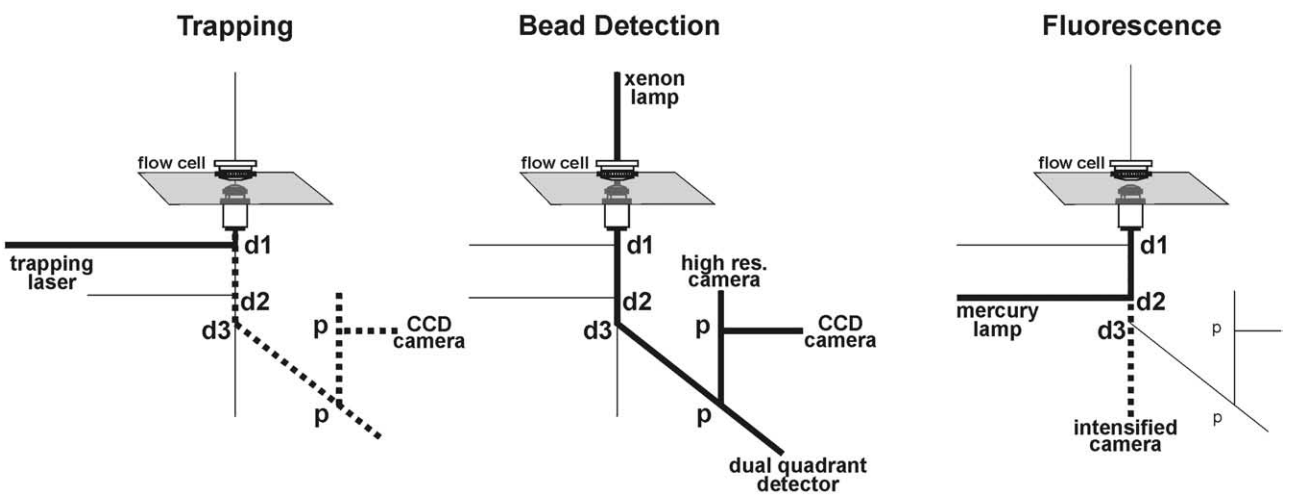

FIGURE 3 The main light paths. Dotted lines in the trapping panel correspond to the reflected light, which is useful for alignment and in the fluorescence panel to the emitted fluorescence. d are dichroic mirrors and p are beam splitting prisms.

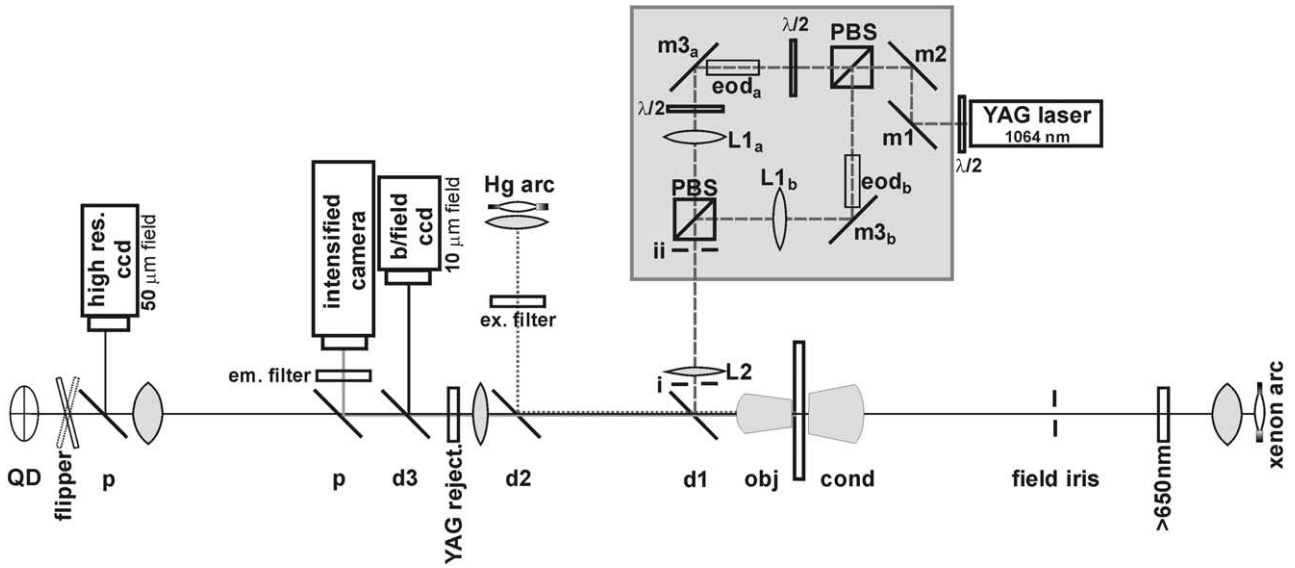

FIGURE 4 Diagram of the trap setup.

immediately below the objective (Lang *et al*., 2002), but can be combined with the fluorescence excitation beam or before the dichroic of the fluorescence cube. The dumbbell assay requires two traps that can be created either by temporal sharing of a single beam (Visscher *et al*., 1993) or by using polarising beam splitters. We will describe the simplest possible version of the latter approach (Fig. 4). The wavelength of Nd:YAG lasers (1064 nm) is suitably distant from the absorption of most biological materials, yet near enough to the visible spectrum for the performance of standard microscope objectives to be adequate. The first $\lambda/2$ waveplate controls the relative intensities of the two beams. Mirrors **m1** and **m2** control the position and angle of the laser beam. Mirrors **m3** are at a distance f away from lenses **L1** and are thus conjugate with the back focal plane of the objective. They allow positioning of the two traps at the beginning of the experiment to tension the dumbbell to the desired level. Because the angular deviation from the EODs is small, the entry of the beam into the back focal plane of the microscope is affected negligibly, provided that they are positioned close to the mirrors **m3**. Path **a** needs a $\lambda/2$ wave plate on both sides of the EOD to rotate the plane of polarisation by 90° and back again as the EODs have a preferred polarisation direction. The dichroic **d1** reflects wavelengths above 900 nm. The YAG rejection filter avoids reflected trapping laser light, contributing to the bright-field QD signal. The dichroic **d2** reflects below 550 nm for the exciting Hg lamp. Pellicle beam splitters **p** provide light for the low and high magnification bright-field cameras. The dichroic **d3** reflects light >555 nm to pick out the emitted fluorescence, which then passes through the emission filter. The light path of the trapping laser must be enclosed to avoid movement of the laser beam due to air currents in the room. This is done most easily by a combination of tubes and a box around the square of the beam splitting prisms (grey box in Fig. 4).

V. ALIGNMENT

On the first occasion, alignment of the two trapping beam can cause frustration, but the following protocol works even if the trap is being constructed from scratch rather than being based on a microscope. It is based on the principle of sending a HeNe or similar visible laser beam backwards through the microscope to define the optical axes of the various light paths. Laser safety glasses are required during the alignment procedure.

1. Check that the microscope stage is horizontal with a spirit level.
2. Establish a rough vertical optical axis by dropping a plumb line from the ceiling to the centre of the objective holder.
3. To refine the line of the beam, attach a tiltable mirror at the ceiling so that the HeNe beam can be reflected back to the objective. Place a mirror on the stage and adjust the position of the HeNe beam on the ceiling mirror and the angle of that mirror so that

the beam is hitting the centre of the objective and is being reflected back along itself.

4. Before extension of the optic axis to the trapping laser, remove lenses **L1** and **L2** and the EODs from their provisional positions. Replace the microscope objective with a ~4-mm aperture (readily made from an old objective) to let the reference beam through. This defines the back aperture of the objective.

5. Centre two apertures on the HeNe beam, as widely spaced as possible between the microscope and the recombining prism (positions i and ii in Fig. 4).

6. Switch on the trapping laser and make the two paths collinear with the HeNe laser beam. For path **a**, orientation of **m1** allows the trapping beam to be made coincident with the reference beam at **m2**, and the orientation of **m2** allows it to be made collinear with the reference beam. For path **b**, a small rotation of the first polarising beam splitter together with orientation of its prism table allows the trapping beam of path **b** to be made concident with the reference beam at **m3b**, and orientation of **m3b** allows the beams in path **b** to be made collinear. Any CCD cameras attached to microscope ports now show the beam in the centre and those not on microscope ports should be centred at this time. The focus of the cameras should be adjusted to correspond to that of the microscope eyepiece.

7. Replace the objective aperture with the objective, place a dry flow cell (construction described later) on the stage and focus on the inner surface of the cover slip. The alignment should be adequate to see the reflected laser beam with a low-magnification, infrared-sensitive CCD camera. Fine-tune the alignment of the trapping beams to make the diffraction pattern around the reflected image symmetrical.

8. Lens **L2** can now be inserted at its focal length F (~300 mm) from the back focal plane of the objective and positioned laterally so that the reversed beam still impinges on the trapping laser and the reflected image remains symmetrical. Note that **L2** focusses the trapping beam at the back focal place of the objective. The laser beam should be turned down to minimum intensity to avoid damage.

9. Insert the two lenses **L1** at a distance (f + F) further back from **L2** so that **L1** and **L2** form beam-expanding telescopes (Fig. 2). Adjust their lateral position so that the reflected image is again symmetrical. If the objective is replaced by the aperture, the parallel beam should hit the ceiling mirror at the same point as the HeNe laser.

10. The apparatus should now be able to trap 1-μm beads. A small adjustment of axial position of lenses **L1** can be used to fine control the z position of each trap.

11. Adjust the orientation of the mirrors **m3** to position the two traps for the dumbbell experiment ~6 μm apart.

12. Position the electro-optic deflectors (EOD) as near as possible to the mirrors **m3**. EODs are convenient because, in the absence of an applied voltage, the beam is not deflected. If an AOD is used rather than an EOD, typically the angle of the beam will change at this point, which will need some realignment. Some AODs are more convenient in that they have the far face cut so that refraction compensates for the diffraction and at the centre frequency the first-order beam remains parallel to the input beam.

13. The relative intensities of the two beams can be monitored using an adequately large (~1 cm) photodiode mounted above the field stop of the condenser and equalised by rotation of the $\lambda/2$ plate positioned prior to the first beam splitter. The stiffness of the two traps should now be roughly equal.

14. Equalise the height at which the two beads are trapped by final positioning of the lenses **L1**. Move the lenses **L1** closer to the microscope to move the trapped bead further from the surface of the coverslip.

VI. CALIBRATION

1. Transimpedance amplifiers are used to convert the currents from the individual quadrants of the photodetector to voltages. A signal that is almost linearly proportional to, for example, the horizontal bead displacement for movements up to about one-third of a bead diameter is gained by summing the two left-hand and the two right-hand quadrants and taking the difference signal between these values. This signal needs to be converted from volts into bead movement in nanometers. First, it is necessary to convert volts to micrometers movement of the bead image at the quadrant detector by moving the QD to a series of positions with a micrometer-driven slide. Magnification of the microscope from the stage to the quadrant detector then allows conversion of QD volts to bead movement in nanometers. As an accurate calibration using the micrometer is time-consuming, we apply a 2-Hz square wave to a stepper motor to rotate a thin (~0.5 mm) microscope slide ± 7.5° so as to give a constant lateral displacement of the bead image (see Fig. 5), which can be measured.

2. A variety of methods have been described for measuring the trapping strength, but probably the most robust one for routine use is to apply a square wave to the traps. The bead position record is then averaged over a sufficient number of cycles to give a

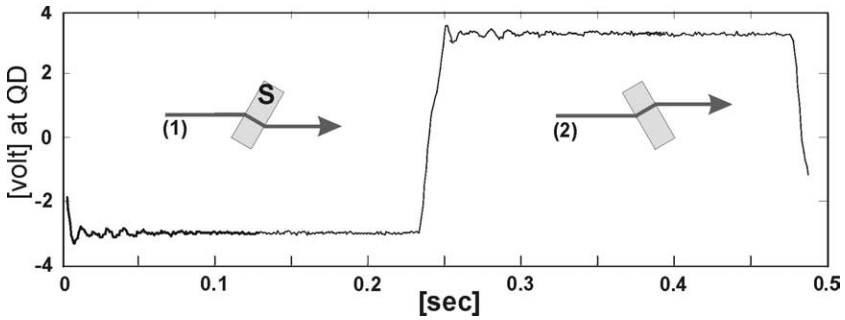

FIGURE 5 Calibration using the "flipper" to provide known lateral movement of the bead image.

smooth trace and a rate λ fitted to the exponential decay. The trap stiffness is then $6\pi r\eta\lambda$ (r being the radius of bead and η the viscosity). It should be noted that η is quite temperature dependent and also that the bulk value is only applicable if the trapped bead is a few bead diameters away from the coverslip. Other methods of measuring trap stiffness have been described by Svoboda and Block (1994).

VII. THE DUMBBELL EXPERIMENT

A. Assembling the Dumbbell

Preparation of the components is described in Section X. The first step is to trap two beads: if one can be found that has already stuck near to the end of a 5- to 8-mm-long actin filament, so much the better. In the absence of such good fortune, the piezo stage is moved in order to catch a suitable filament near its end. The spacing of the beads is then adjusted to match the filament prior to attaching the loose end by aligning the actin filament using movement of the stage to induce flow past the stationary beads. If the beads and actin filaments have been prepared properly, attachment to the second bead should occur almost instantly because of the constraining influence of the flow. It soon becomes apparent that the correct concentration of beads and actin filaments is critical for successful assembly and use of dumbbells. If there is an inadequate supply of either, too much time is spent searching for beads or actin, if the concentration of one of these is too high, the perfect dumbbell is liable to be spoilt by the capture of extra beads or actin filaments. Due to the effect of radiation pressure, beads enter the trap from the objective side (beads about to be caught look blacker than in their trapped position), which has the fortunate repercussion that the required beads are normally caught ~10 µm deep, whereas in the operating position, 1.5 µm above the surface of the coverslip, uninvited beads rarely enter the trap. However, actin filaments can float past and become attached. The traps naturally accumulate all forms of small particles that can seriously increase the noise when measuring bead position. All solutions should be filtered and/or centrifuged prior to use.

B. Tensioning the Dumbbell

The success of an experiment is dependent upon the movement of the actin filament being transmitted to the trapped beads, which requires that the compliance between the segment of actin interacting with the myosin and the bead be low compared to that of the myosin head. The compliance of actin itself is low, and the limiting feature is the link between the actin and the bead. The compliance of this link is very nonlinear, and to achieve the required value (>1 pN/nm), a significant pretension (>5 pN) is necessary. One way of doing this is to align the quadrant detectors, apply a triangular wave to one of the traps, and monitor whether the other bead faithfully follows the first. If not, the dumbbell tension is increased using one of the mirrors **m3**. One problem is that for a weak trap (0.02 pN/nm) and a 1-µm bead this is quite close to the maximum force. Moreover, the stiffness along the beam (z) axis is several times weaker than the x,y stiffness and is reduced further when the bead is at the edge of the trap. The overall result is that the beads become rather unstable, particularly in the z direction, and the quality of the results is degraded. The application of positive feedback, outlined later, significantly helps limit this problem.

A myosin, suitably positioned near the top of a fixed 1.5-µm glass bead, now needs to be found to allow interaction with the actin. The initial search can be done with a mouse-driven stage but it is very convenient to be able to move the actin ±300 nm along the y

axis (regarding the axis of the actin filament as x) using a potentiometer so that the filament can be placed exactly above the myosin to get the maximum rate of interaction. At realistic values of dumbbell tension, thermal motion results in the standard deviation of the position of the middle of the actin filament being about 40 nm, so the actin needs to be positioned in the y and z axes to within ~20 nm of its optimal position. At this point it is desirable to servo control the position of the stage relative to the traps so that the rate of interaction becomes reasonably constant. Typically 100 second data files are recorded (normally at 10 kHz with a 5-kHz antialias filter).

VIII. IMPROVEMENT OF PERFORMANCE

A. Positive Feedback of Bead Position to Trap Position

For a simple trap the maximum force provided by a trap is directly related to its stiffness, with the width of the energy well being controlled by the size of the trapped bead and of the diffraction limited spot. It is advantageous to carry out actomyosin experiments with traps that are considerably more compliant than the myosin head to provide a good contrast in the variance of bead position between periods of actin attachment and detachment, which limits the extent that the dumbbell can be pretensioned to a somewhat suboptimal level. One way to get around this problem is to feedback a fraction α of the bead position to the trap position ($X_t = \alpha X_b$) (Steffen *et al.*, 2001). Such positive feedback broadens the energy well and reduces the stiffness by a factor of α, which allows the intensity of the trapping beam to be increased by this factor to restore the stiffness to its original value. Both the maximum force and the stiffness in the y and, more importantly, the z directions are increased due to this increase in beam intensity. This procedure works well for modest values of α (~2), but considerable care needs to be taken if larger values are used because noise other than that arising from the thermal motion of the bead is also amplified.

B. Stage Feedback

The stability of optical microscopes is comparable to the resolution, i.e., slightly submicrometer. The monomer periodicity of actin is 5.5 nm and this will not be resolved unless the stability of the position of the stage with respect to the objective is around the 1-nm level during the period of data collection. This is only possible by servo-controlling the stage position. We have used a combination of piezo-positioned stage and objective, but piezo stages, which have adequate movement in the z as well as the x,y directions, are now available (e.g., Physik Instrumente: P-562.3CD) and are probably the most convenient solution. It is advantageous to bolt the objective directly below the stage so as to minimise thermal drift. Positioning in all three directions can be controlled on the basis of video images, but the noise level is probably slightly lower if an image of the fixed, myosin-bearing bead is projected onto a third quadrant detector to control the x,y position. For most applications, speed of the feedback loop is not the issue. A simple Labview program is available for download from traps.rai.kcl.ac.uk.

IX. ANALYSIS OF DATA

The activity of nonprocessive motors is usually detected on the basis of the reduction of variance of bead position during periods of attachment (Molloy *et al.*, 1995). If both the compliance of at least one of the actin bead links and of the myosin is more than five times the combined stiffness of the traps, at least the longer events will be readily visible on an oscilloscope trace. In these circumstances, detection of events on the basis of reduction of the variance of the bead position is relatively straightforward. We use a program developed by Smith *et al.* (2001), which carries out a maximum-likelihood analysis of the whole trace and assigns the rates of attachment, f, and detachment, g, as well as the periods of attachment. By comparison of the covariance and autovariance of the bead positions during periods of attachment and detachment, the program also deduces the compliance of the two actin bead links and of the myosin link and corrects the observed working stroke for the effect of these compliances. The core Fortran program and a Matlab program that calls them and analyses batches of files and plots out the most useful aspects of the analysis is available from traps.rai.kcl.ac.uk.

Two parts of the standard output are shown in Fig. 6 (obtained from separate experiments). Figure 6a shows a histogram of the positions of interactions for a dumbbell that is kept stationary with respect to the myosin for the duration of the 100-s record. In general, it is necessary to servo control the stage position to be able to associate each interaction as being with a specific actin monomer. Patlak (1993) proposed a method of analysis of ion channel data based on mean-variance histograms and he has adapted the method for acto-

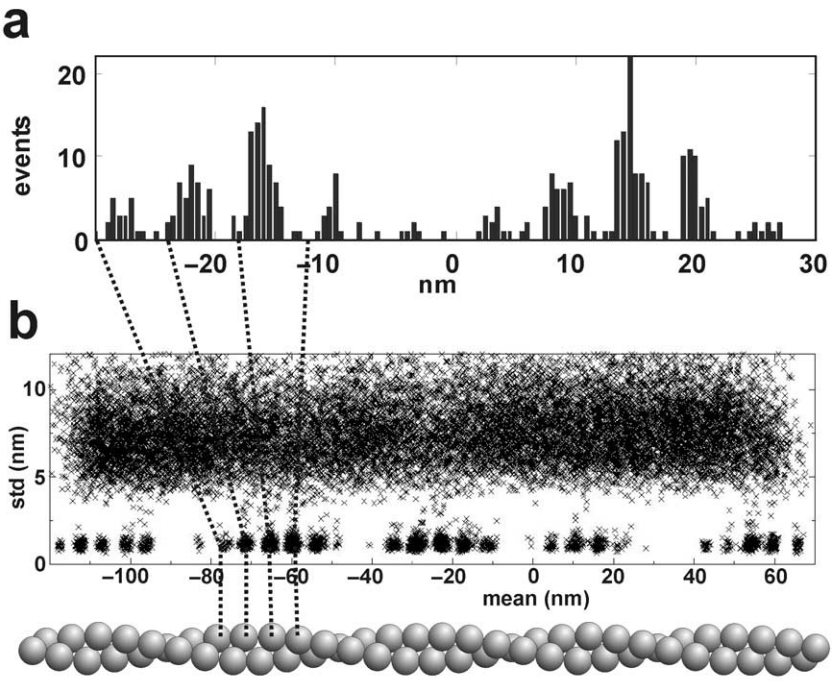

FIGURE 6 (a) Histogram of the position of interactions with a stationary dumbbell and a relatively weak trap so that two target zones are accessed. The myosin is halfway between the two target zones. (b) A plot of the standard deviation versus the mean position of 5-ms time slices of a data record in which the dumbbell is moved past five target zones during the 100 s of data collection.

myosin data (Guilford *et al.*, 1997). We have not used the method for final analysis of data but find that plotting the standard deviation against the mean for time slices of bead position data provides a very valuable initial check on data quality. Such a plot is shown in Fig. 6b. In this record the dumbbell has been moved past five target zones of the actin filament (a target zone is a region in which monomers are suitably oriented to interact with actin). The plot readily identifies both the target zones and the underlying actin monomers. Such plots reveal inhomogeneities among target zoned and monomers. Analysis methods have been reviewed by Knight *et al.* (2001).

X. PROCEDURES

A. Preparation of Latex Beads

The preparation of neutravidin-coated latex beads is a straightforward procedure and, in our hands, appears to be superior to commercial products. By first generating latex beads covalently cross-linked to biotin, one can generate a stock of beads that can be stored for many months. Once coated with neutravidin the beads are used for a period of 2–3 weeks.

Buffer, Solutions, and Materials

Carboxylated latex beads (Sigma, L3905, 1 µm in diameter, 2.5% solids)
Eppendorf reaction vials, screw top
1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDAC) (Sigma, E1769)
50 m*M* phosphate buffer, pH 7.0
2 mg/ml biotin-x-cadaverine (Molecular Probe, A1594) in dimethyl sulfoxide, aliquots stored at –80°C
10% NaN_3
1 *M* glycine
5 mg/ml neutravidin (Molecular Probe, A-2666, aliquots stored at –80°C)

Biotinylated Latex Beads

1. Centrifuge 250-µl latex beads in a 1.5-ml Eppendorf reaction vial at 6000 *g* preferably in a swing-out rotor (e.g., Sorvall RSA) for 10 min.
2. Aspirate supernatant without disturbing the pellet.
3. Resuspend beads in 500 µl of 50 m*M* phosphate buffer, pH 7.0, place in sonicating bath for 10 seconds, and centrifuge as in step 1.
4. Repeat washing step.
5. Resuspend beads in 250 µl of phosphate buffer, pH 7.0.

6. Add 25 µl of 2 mg/ml biotin-x-cadaverine and vortex.
7. Add ~2 mg of EDAC cross-linker, mix, and incubate at room temperature for 30 min.
8. Add 500 µl of phosphate buffer and centrifuge as in step 1.
9. For the washing step, resuspend beads in 500 µl phosphate buffer, sonicate in a bath for 10 s, and centrifuge as in step 1.
10. Repeat washing step at least five-times.
11. After final wash, resuspend beads in 500 µl phosphate buffer containing 0.02% NaN_3 and store in a refrigerator.

Neutravidin – Biotin Latex Beads

1. Resuspend 25 µl of biotinylated 1-µm latex beads (see earlier discussion) in 175 µl phosphate buffer.
2. Centrifuge at 6000 *g* for 10 min.
3. Aspirate supernatant.
4. Resuspend beads in 100 µl of phosphate buffer containing 0.1 *M* glycine.
5. Add 15 µl of 5 mg/ml neutravidin and incubate at room temperature for 20 min (mix intermittently).
6. Add 100 µl phosphate buffer and centrifuge as in step 2.
7. For the washing step, resuspend beads in 500 ml phosphate buffer, sonicate in a bath for 10 s, and centrifuge as in step 2.
8. Repeat washing step at least five-times.
9. After final wash, resuspend beads in 200 ml phosphate buffer containing 0.02% NaN_3 and store in a refrigerator.
10. Test beads in a binding assay (fluorescence microscopy) by mixing beads with 1–4 µg/ml biotinylated F-actin at a ratio of 1:50.

B. Preparation of Biotin-Tetramethyl Rhodamine-Actin

F-actin (~50 µ*M*) is modified with a 0.5–1 molar ratio of biotin–$PEAC_5$–maleimide (Dojindo) in a buffer consisting of 10 m*M* $NaHCO_3$, basically as described by Ishijima *et al*. (1998). It is taken through two depolymerisation cycles before adding 2 mg/ml trehalose and flash freezing 10-µl aliquots. An aliquot is polymerised with a small molar excess of tetramethyl rhodamine phalloidin overnight. The next morning, excess dye and any monomeric actin are removed by spinning through 200 µl of 10% sucrose (29,000 *g*, 30 min: 30,000 rpm in Beckman TLA 100.1 rotor) to remove monomeric actin, and the filamentous actin is resuspended with 0.1 mole rhodamine phalloidin per mole of actin.

C. Preparation of Fixed-Bead Microscope Slides (Flow Cell)

To allow myosin to access the actin of the dumbbell, it must be raised above the surface of the cover slip. This is achieved most simply by applying a suspension of 1.5-µm glass beads in a nitrocellulose solution to the coverslip surface.

Steps

1. Apply 2 µl of glass microspheres (1.5 µm) suspended in 0.05% nitrocellulose in amyl acetate to coverslips (#1.5: 22 × 22 mm). Spread the suspension evenly using the edge of a second coverslip mounted on a cocktail stick. Allow to dry.
2. On a microscope slide lay down two thin strips of vaseline (spacing ~8 mm) using a syringe (~22-gauge needle).
3. Place nitrocellulose-coated coverslips on top of the slide and press down lightly to produce a gap of about 30 µm. (Thick aluminium foil can be used as a spacer.)
4. Secure the four corners of the coverslip with Superglue.

D. Sample Preparation

Buffers and Solutions

Deoxygenation system (Harada *et al*., 1990):
1 mg/ml catalase (Sigma, C-100) and
5 mg/ml glucose oxidase (Sigma, G7141)
1 m*M* phalloidin (Sigma, P2141) in methanol, store at –20°C
100 m*M* Na-ATP
Buffer A: 25 m*M* K–HEPES, pH 7.6, 25 m*M* KCl, 4 m*M* $MgCl_2$, 0.02% NaN_3
Reaction mix (RM) freshly prepared before every experiment: 1 ml buffer A, 20 µl of 5 mg/ml glucose oxidase, 20 µl of 1 mg/ml catalase, 20 µl of 100 mg/ml glucose, 1 µl β-mercaptoethanol (BME), 0.5 µl of 1 µ*M* phalloidin, and 1 µ*M* ATP or other nucleotides at concentration of choice
Blocking solution: 1 ml buffer A and 20 µl of 50 mg/ml bovine serum albumin
Buffer B (make fresh every day):
1 ml buffer A,
1 µl of 1 m*M* phalloidin, and
2 µl BME
Actin freshly diluted 1:200 in buffer B
10× actin polymerisation buffer: 50 m*M* phosphate, pH 7.5, 500 m*M* K–acetate, 20 m*M* Mg-acetate, and 20 m*M* NaN_3

Procedure

1. Add 1–5 µg/ml of myosin in buffer B to flow cells and incubate for 1 min.
2. Wash out excess myosin with 30 µl of buffer B followed by 30 µl of blocking solution. Incubate with blocking solution for 1 min.
3. Wash with 30 ml of buffer B.
4. Apply 30 µl of final reaction mix containing 1-µl neutravidin-coated latex beads, 1–2 n*M* biotinylated actin, and the chosen concentration of ATP. If the ATP concentration is less than 10 µ*M*, addition of a regenerating system (1 m*M* phosphocreatine, 20 µg/ml creatine phosphokinase) is advisable.

CHAPTER

5

An Introduction to Electronic Image Acquisition during Light Microscopic Observation of Biological Specimens

Jennifer C. Waters

I. INTRODUCTION

This article introduces the reader to the choices and considerations that need to be made when designing an image acquisition system. It focuses on the use of electronic cameras to record images of biological specimens generated with light microscopy techniques. There is no one image acquisition system that will work for every light microscopy application. To make the best choices for your application, you should understand your needs, as well as the strengths and limitations of the equipment available.

II. UNDERSTANDING YOUR NEEDS

The ideal image acquisition system would be sensitive enough to acquire beautiful images of very dim fluorescence specimens, fast enough to record the most dynamic processes, have high resolution to capture the finest detail, and have enough useful dynamic range to accurately measure minute differences in intensity. However, optimizing any one of these criteria can only be accomplished by limiting one or more of the others (Shotton, 1993; Spring, 2000). It is therefore impossible to design one image acquisition system that will be ideal for the wide range of light microscopy applications in cell biology. Instead, one should determine how best to meet the needs of the majority of system users, with an understanding that some compromises will probably need to be made.

To begin, it is useful to recognize the demands that the mode of microscopy used to generate the images imposes on the image acquisition system. In their research, cell biologists most commonly use fluorescence microscopy and various forms of transmitted light microscopy. Fluorescence microscopy techniques include standard wide-field epifluorescence (i.e., where the fluorescence excitation light reaches the specimen through the same objective lens that is used to image the fluorescence emission) (Herman, 1998), laser-scanning confocal (Inoué, 1995), and Nipkow spinning disk confocal (see article by Waterman-Storer and Gupton; Maddox, 2003). Laser-scanning confocal systems use photomultiplier tubes, not electronic cameras, to collect photons sequentially from the pixels that are used to generate images. Transmitted light techniques include standard bright-field microscopy (Murphy, 2001) and contrast generation methods such as phase contrast and differential interference contrast (DIC, Nomarski) (Inoué and Spring, 1997; Murphy, 2001).

A. Fluorescence Microscopy

In fluorescence microscopy, cellular components are labeled with molecules that emit photons when illuminated with excitatory light of the appropriate wavelength (Berland, 2001; Herman, 1998). Its high level of molecular specificity and relative ease of use have made fluorescence microscopy the most commonly used mode of light microscopy in cell biology research today. The use of fluorescence microscopy to visualize the dynamics of specific molecules in live cells over

time has increased greatly since the discovery and cloning of green fluorescent protein (GFP) (Tsien, 1998).

Acquiring fluorescence images presents a special challenge because of the relatively low number of photons emitted by the specimen that must be collected by the microscope optics and detected by the camera (Herman, 1998; Spring, 2001). The number of photons emitted by the specimen is limited by the concentration of fluorophore and the efficiency with which the fluorophore emits photons when exposed to excitation wavelengths of light. Fluorescence image acquisition is further complicated by the gradual decrease in fluorescence known as photobleaching. When fluorophores are exposed to excitation photons, they can and do undergo chemical modifications that irreversibly inhibit further emission of light (Herman, 1998). Therefore, when choosing microscope optics and a camera for a fluorescence microscopy image acquisition system, attention should be paid to light efficiency: achieving the highest image quality with the smallest number of excitation photons (Salmon and Waters, 1996). Light efficiency is particularly critical when the acquisition system will be used for imaging fluorescence in live cells over time, where the rate of photobleaching imposes limits on the length of an experiment, and where overexposure to excitation light can also induce phototoxicity in the illuminated cells.

B. Bright-Field-Transmitted Light Microscopy

There are several different types of transmitted light microscopy that are routinely used by cell biologists (Murphy, 2001). Most of the thin specimens that cell biologists examine with transmitted light microscopy absorb very little light and are therefore essentially transparent. Standard bright-field microscopy is consequently used primarily in conjunction with histology stains that bind with some specificity to cellular components and absorb particular wavelengths of light. When illuminated with white light, these stains result in a bright high-contrast color image. A camera capable of recording color images (Spring, 2000) is usually preferred when working with such histology-stained slides in bright-field mode.

Even though thin biological specimens usually absorb little light, they do cause changes in the optical path of the light rays that pass through them because of refractive index changes; these changes, however, are invisible to our eyes and to electronic cameras. A variety of optical contrast generation methods use additional components in the transmitted light path that translate changes in refractive index into contrast that our eyes and electronic cameras can detect (Murphy, 2001; Inoué and Spring, 1997). The contrast generation methods used most commonly by cell biologists are phase contrast and differential interference contrast. These methods have the benefit of generating contrast in transparent specimens in a noninvasive manner that allows them to be used with living cells and tissues without the need for chemical treatments or the application of stains.

The light efficiency of the image acquisition system that is of such concern to the fluorescence microscopist matters less for the various transmitted light-imaging techniques, which are usually not photon limited. In transmitted bright-field microscopy, briefly increasing the intensity of illumination light will increase the brightness of the image without inducing specimen damage, allowing the user to meet the requirements of a less sensitive and less expensive camera, although it should be noted that prolonged exposure to intense light below 500 nm in wavelength (i.e., blue and ultraviolet) is phototoxic to cells. Cameras optimized for fast acquisition can be used to record transmitted light images of dynamic processes, such as cell motility, or changes in cell or organelle morphology with the high temporal resolution (Shotton, 1993; see article by Weiss).

III. THE IMAGE ACQUISITION SYSTEM

An image acquisition system minimally consists of a microscope and a camera, but may also include a computer, imaging software, and a variety of motorized components for automated acquisition (Salmon and Waters, 1996). Selection of the appropriate equipment for your application requires a basic knowledge of the parameters used to evaluate the equipment and how they affect performance.

A. Electronic Cameras

There are many different electronic cameras available for acquiring images from light microscopes. The basics of choosing the appropriate camera for your application will be introduced here, while subsequent articles will discuss the details of video-enhanced light microscopy (see article by Weiss) and cooled charge-coupled device (CCD) camera technology.

1. Analog Video Cameras versus Digital CCD Cameras

The majority of video and digital cameras produced today use a charge-coupled device, comprising a two-

dimensional array of on-chip single pixel photodiodes to sense incident photons (Spring, 2000; Hiraoka *et al*., 1987). However, video and digital cameras differ in their final signal output; a video camera has an analog output corresponding to one of the video standards (PAL, SECAM, or NTSC) while a digital camera has digital output. The analog signal from a video camera can be viewed in real time on a conventional video monitor and is usually recorded onto analog videotape, which is a very inexpensive medium. A CCD camera is referred to as a digital camera when the analog signal is digitized prior to output from the camera or camera controller. In a 12-bit camera, for example, the analog signal is converted into gray scale values ranging from 0 (equivalent to black) to 4095 (equivalent to white), giving a total of 2^{12} gray levels. The digital image information can be recorded on digital videotape in DV format or can be output to a computer RAM or hard drive and archived onto other digital media, such as the hard drives of network servers, CD-ROMs, and DVDs.

Digital imaging has now become the norm in many research laboratories. Digital images can be viewed and inspected immediately, processed and analyzed using specialized software packages, and inserted easily into digital documents or shared via the Internet. Significant advances in camera technology, software capabilities, computer speed, and storage capacity have made digital imaging favorable and affordable for a wide range of light microscopy applications (Spring, 2001; Salmon and Waters, 1996; Mason, 1999).

2. *Video-Enhanced Microscopy*

Analog video microscopy has some unique advantages over digital imaging that make it preferable for select applications, particularly video-enhanced contrast microscopy where electronic adjustment of the contrast and background "black level" are required during real-time recording (Inoué and Spring, 1997; Murphy, 2001; Shotton, 1993; see article by Weiss). Video cameras are also useful and economical for bright-field applications that require continuous monitoring over long periods of time, without worrying about the memory limitations of computer RAM and hard disk space. Video cameras have high temporal resolution, with their images being recorded onto videotape at 25 frames per second (PAL and SECAM) or 30 frames per second (NTSC). Alternatively, time-lapse VCRs can be used to slow the rate at which the video signal is sampled and recorded. However, videotape fails to capture the full resolution of the video signal. Full resolution digital images can be recorded directly from a video camera to disk using a specialized frame-grabber board containing an analog-to-digital converter installed in a computer (Inoué and Spring, 1997; Shotton, 1993).

Video cameras are commonly used to record movement and changes in specimen shape, including processes such as cell motility, chromosome movement during mitosis, cytokinesis, early embryonic development, chemotaxis, and wound healing. In the early 1980s, Shinya Inoué, Robert Allen, and others demonstrated that using video camera controls to manipulate the analog signal electronically can increase the dynamic range and contrast of very low contrast images that would otherwise be invisible to the eye (Inoué and Spring, 1997). Digital image processors can be used in conjunction with video camera controls to reduce noise and further improve image contrast by real-time digital subtraction of a background image. For example, high-resolution video-enhanced DIC microscopy can be used to image the dynamics of individual microtubules in real time: individual microtubules, which at a diameter of 25 nm are about 10 times below the resolution limit of the light microscope, can be visualized clearly (Inoué and Spring, 1997; see article by Weiss).

3. *Digital-Cooled CCD Cameras*

Slow scan-cooled CCD cameras record full size images at a slower rate (1–10 frames per second) than video cameras, but have superior light sensitivity, low noise, large dynamic range, linear response, and high spatial resolution (Spring, 2000; Inoué and Spring, 1997; Murphy, 2001). These properties make cooled CCDs the detector of choice for acquisition of fluorescence microscopy images (Spring, 2001; Hiraoka *et al*., 1987) and are used routinely to collect images of fixed specimens labeled with fluorescent antibodies and dyes. Cooled CCDs are also used to record the dynamics of live fluorescent cells, including cells loaded with calcium indicators (Mason, 1999) and cells expressing GFP-tagged proteins (Tsien, 1998), and to collect images from Nipkow spinning disk confocals. The Yokogawa CSU-10 dual Nipkow spinning disk confocal (Maddox *et al*., 2003; Mason, 1999) can be used to collect high-resolution confocal images of weakly fluorescent specimens with greater speed and signal to noise than traditional laser-scanning confocals. This is probably due in part to the use of a low noise-cooled CCD as a detector instead of the photomultiplier tube used by laser-scanning confocals. There are many different cooled CCD cameras available that can be used for these types of fluorescence applications, with a wide range in price and performance. Comparison shopping for a cooled CCD camera requires a basic

understanding of the properties used to describe performance (Spring, 2000).

Quantum efficiency is a measure of the percentage of incident photons that are recorded by a CCD camera (Spring, 2000; Inoué and Spring, 1997; Murphy, 2001). The higher the quantum efficiency, the more sensitive the camera will be to photons emitted from the specimen, which translates into shorter exposure times and better temporal resolution. Quantum efficiency of a CCD chip varies with the wavelength of light. Back-thinned CCD chips can have a maximum quantum efficiency as high as 90%, but are relatively delicate and expensive detectors. The more commonly used CCD chips have a maximum quantum efficiency in the range of 50–70%. The camera manufacturers provide graphs of the quantum efficiency of the CCD chips used in their camera at different wavelengths of light. For very low-light applications, image intensifiers can be used in conjunction with the CCD chip to increase the intensity of the signal (Inoué and Spring, 1997), while limiting spatial resolution and dynamic range. Dynamic range is a measure of the range of intensities that can be detected by the CCD chip and is defined by the full well capacity of a single pixel on-chip photodiode divided by the mean camera pixel noise (Spring, 2000; Inoué and Spring, 1997; Murphy, 2001). A new class of back-thinned CCD chip, called an electron multiplying charge-coupled device (EMCCD), which has built-in amplification of the signal from each pixel before readout, gives a sensitivity that exceeds even that of avalanche photodiodes, while retaining the benefits of fast CCD array readout, and promises to bring additional benefits to low-light imaging applications.

All CCD cameras contribute some amount of noise to the images they create (Inoué and Spring, 1997; Spring, 2000). Excessive noise can drown out the signal coming from a specimen, effectively decreasing the sensitivity and dynamic range of the camera. For fluorescence microscopy, in which the level of signal is inherently low, it is important to choose a camera that has been designed to minimize noise. The two main types of CCD camera noise are thermal noise and readout noise (Spring, 2000). Thermal noise (also known as dark noise) is reduced greatly by cooling the CCD chip below ambient temperature, making cooled CCD cameras optimal for fluorescence applications. Readout noise is generated as the signal is read from the CCD chip and is proportional to the readout speed: the faster the CCD chip is read, the greater the probability of error in the A-to-D converter and thus the higher the readout noise. Slow scan-cooled CCD cameras are preferable for low-light level fluorescence microscopy applications (Spring, 2001), as long as the speed of acquisition can be sacrificed.

The spatial resolution of a CCD camera is determined by the size of the photon-sensitive photodiodes that make up the CCD chip relative to the optical magnification of the microscopic image focused upon it (Shotton, 1993, 1997; Inoué and Spring, 1997; Spring, 2000). Cooled CCD cameras usually have at least 1024^2 light-sensing photodiodes (i.e., pixels), which range in size on CCDs from different manufacturers from $5 \times 5\,\mu m$ to $25 \times 25\,\mu m$ each. (The pixels on some CCDs, particularly those on three-color CCD chips, are oblong rather than square, but these should be avoided for scientific imaging applications because of the potential problems caused in subsequent image processing.) The optical resolution of the microscope will be adequately preserved by the camera only if each resolvable point in the magnified image is sampled by at least two photodiodes (the Nyquist criterion) (Shotton, 1993; Inoué and Spring, 1997; Shotton, 1997; Stelzer, 1998). For example, the Abbe diffraction resolution limit (Inoué, 1995; Inoué and Spring, 1997) of an objective lens with a numerical aperture of 1.4 at 510 nm (the peak emission wavelength of GFP) is 0.22 µm. With 60× magnification by the objective lens and no secondary magnification between this lens and the CCD camera, this would be projected to 13.2 µm at the CCD chip. Therefore, a photodiode size of 6.5 µm or smaller would be necessary to match the resolution of the objective lens and prevent loss of specimen detail by digital undersampling of the optical image.

For live cell fluorescence applications, in which greater temporal resolution is needed, some cooled CCD cameras allow the user to increase the acquisition rate by binning adjacent photodiodes together and/or reading only a subarray of the chip (Inoué and Spring, 1997; Shotton, 1997; Spring, 2000; Salmon and Waters, 1996). Binning photodiodes 2×2, for example, results in a fourfold increase in image intensity, allowing for shorter exposure times. Binning also decreases the number of pixels in the output image, using less computer memory and allowing for faster image transfer. The increase in image intensity and acquisition times does come at a price: such 2×2 binning of adjacent pixels results in a twofold loss in spatial resolution. For many fluorescence applications, however, where the critical parameter is usually the ability to detect faint fluorescent objects rather than to resolve them spatially, the increase in image intensity and speed of acquisition are well worth the decrease in spatial resolution (Salmon and Waters, 1996). Some cameras allow the user to increase the image transfer time by reading only a subarray, or region-of-interest, of the full CCD chip. When the interesting area of the specimen does not fill the entire camera field of view, this

is an easy way to increase image acquisition speed and decrease the image file size.

4. Color Cameras

Because CCD chips cannot differentiate between different wavelengths of light, color CCD cameras must use wavelength selection components within the camera itself to produce red, green, and blue images of the specimen from subarrays of pixels, which are then combined into the resulting color image (Spring, 2000). Color CCD cameras are significantly less sensitive and have lower spatial resolution than monochromatic cameras because of the additional filters and beam splitters used for wavelength selection and because of the division of the pixels to image the three primary colors. Color CCD cameras are useful for recording bright-field colored specimens and may be necessary for fluorescence imaging in the rare case that the color of light emitted by the fluorophore is diagnostic. However, for the majority of fluorescence microscopists, the best solution is a monochromatic CCD camera used in conjunction with appropriate wavelength-specific filters within the microscope and with image processing software to pseudo-color and merge the wavelength-specific monochrome images subsequent to acquisition.

B. Computers and Software for Digital Imaging

Digital cameras output the signal in a format that can be interfaced directly to the computer (IEEE-1394 "FireWire," RS-422, and SCSI interfaces are commonly used; Inoué and Spring, 1997). The necessary computer boards are usually purchased from the manufacturer of the camera or the image acquisition software. The software manufacturer may recommend purchasing the computer as well as necessary boards for image acquisition directly from them; this is usually preferable because the software manufacturer will install the boards into the computer and make sure that all of the components are compatible before they arrive in your laboratory. A computer dedicated to image acquisition will need a fast processor and a significant amount of RAM and hard drive space, as a single full frame image from a high-resolution 12-bit monochrome CCD camera can easily exceed 2 MB. At least 512 MB of computer RAM will be needed for most live cell applications. A CD-ROM or DVD writer is also useful.

Image acquisition software is used to manipulate camera settings such as gain, exposure time, and binning. An image acquisition and processing software package should minimally provide such useful features as pseudo-coloring, image merging/overlay, and manipulation of image brightness, contrast, and gamma for optimal display. Advanced software packages will also drive additional hardware, such as shutters and filter wheels, necessary for automated imaging (see Section IIID), and will provide tools for postacquisition image analysis. For a live cell image acquisition system, a software package that allows full customization will provide the most flexibility in designing experiments. For example, the software package MetaMorph (Universal Imaging Corp., a subsidiary of Molecular Devices) allows customized control of the parameters, sequence, and timing of image acquisition via "journals," a sequence of instructions to the software that are easily generated by recording selections from the program menus (Salmon and Waters, 1996). When choosing a software package, it is important to consider the long-term imaging and analysis goals of the user group. A software package that can meet the growing needs of the users may cost more up front, but will be well worth the investment in the long run. The long-term benefits that accrue from use of a digital asset management system for the organization of all image data within a laboratory, such as the freely available Open Microscopy Environment (www.openmicroscopy.org), which permits recording of descriptive metadata and image analysis results in a database together with raw and processed image files (Swedlow *et al*., 2003), should not be underestimated.

C. Microscope and Optics

To prevent vibration from degrading images, a stable, high-quality microscope stand is needed, preferably mounted on a vibration isolation table. Microscope optics should be kept clean, and every effort should be made to keep the environment dust free (for instructions on how to clean optics, see Inoué and Spring, 1997). The microscope illumination pathway should be aligned using the principles of Koehler illumination (Murphy, 2001; Inoué and Spring, 1997; http://www.microscopyu.com). All of the modern advances in image processing cannot compensate for dirty, misaligned optics.

Electronic cameras can be mounted on either an upright or an inverted microscope stand. An inverted microscope is usually preferable for live cell work, as the design allows easy access to the specimen during image acquisition for microinjection or perfusion and accommodates most heated incubation chambers. Inverted stands also have the added benefit of being particularly stable and resistant to focus drift.

Electronic cameras are usually mounted onto light microscopes via a camera port. An additional adapter, available from the microscope manufacturer, is used to couple the camera to the port. Research grade light microscopes can be equipped with multiple camera ports for attaching more than one camera. This is particularly useful on microscopes that are used for different modes of light microscopy so that cameras optimally suited for each mode can be mounted on the microscope simultaneously. For example, a microscope used for both bright-field histology-stained slides and fluorescence microscopy would be best outfitted with a color CCD camera as well as a cooled CCD camera. While cameras can be taken on and off of microscopes with relative ease, it is preferable to leave cameras mounted on the microscope to prevent dust from entering the body of the microscope and from adhering to the camera faceplate. Microscopes with camera ports come with a set of mirrors and/or prisms that are used to reflect to the camera image-forming light that would otherwise go to the eyepieces. Any light sent to the eyepieces during image acquisition is done so at the expense of light sent to the camera. Therefore, it is preferable to use a 100% reflecting mirror to send all of the light to the camera when acquiring photon-limited fluorescence microscopy images.

Provided that the optical image is adequately sampled by the camera, the spatial resolution of an image acquisition system is determined primarily by the microscope optics (Inoué and Spring, 1997; Shotton, 1997; Murphy, 2001). For transmitted light microscopy techniques, the spatial resolution limit is defined as the minimum distance two objects must be separated in order from them to be distinguished as separate and, according to Rayleigh's criterion, is equal to 1.22λ divided by the condenser NA plus the objective NA, where λ is the wavelength of the light source and NA is the numerical aperture (Inoué, 1995). For fluorescence microscopy, the optical resolution limit is defined as the radius of an image of an infinitely small point source of light and is equal to 0.61λ divided by the NA of the objective lens, where λ is the fluorescence emission wavelength (Inoué, 1995). However, for two-photon confocal microscopy, the resolution is limited by the longer infrared excitation wavelength. To ensure that spatial resolution is limited by the optics and not by the pixel size in the CCD chip, the minimum total magnification used from specimen to image plane should be equal to twice the photodiode width divided by the optical resolution limit (Shotton, 1997; Spring, 2000, 2001), as explained earlier. For low-light (and therefore low-contrast) specimens, it is ideal to oversample the image by using a magnification equal to three times the photodiode width divided by the optical resolution limit (Maddox *et al*., 2003; Stelzer, 1998), although, as explained earlier, it may alternatively be necessary to sacrifice spatial resolution in order to capture enough photons per pixel to render the objects under study visible at all. Microscopes can be equipped with relay lenses that increase the magnification of the image to the camera in order to meet these requirements.

For some applications, spatial resolution is less important than capturing a large field of view. The rectangular CCD chip in a camera does not capture the entire round field of view seen through the microscope eyepiece—usually only 50–70% of the field of view is collected by the camera. If a larger field of view is required, magnification-reducing lenses can be placed in front of the camera. A 0.6× relay lens will usually come close to matching the camera field of view with the eyepiece field of view, while sacrificing image resolution. Alternatively, to maintain high resolution, multiple images of adjacent fields of view can be collected at high magnification, ideally using a scanning specimen stage on the microscope, and then "stitched" together into a larger image using image processing software.
